Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

Sir John V. Dacie, MD, FRCPath, FRS (1912–2005).

S. Mitchell Lewis, BSc, MD, DCP(London), FRCPath, FIBMS (*b*. 1924).

This 12th edition celebrates the 66th year of *Practical Haematology*, a notable achievement. The first edition by JV (later Professor Sir John) Dacie was published in 1950. This work, and subsequent editions with Mitchell Lewis as co-author, were based on the haematology course for the University of London Diploma of Clinical Pathology and subsequently the MSc in Haematology at the then Royal Postgraduate Medical School.

In the last 66 years the techniques and instrumentation available to the laboratory haematologist have expanded at a rate once undreamed of. What has not changed is that laboratory haematology continues to provide the bedrock that supports the equally astonishing developments in clinical haematology. Haematology as a discipline remains strongest when it is an integrated discipline with a very close relationship between the laboratory and the clinical service. Reflecting this ideal state, the authors of this edition include laboratory scientists and clinical and laboratory haematologists.

The 12th edition, like its predecessors, incorporates the latest advances in laboratory haematology while continuing to describe traditional techniques that remain applicable, particularly, but not only, in under-resourced laboratories in low- and middle-income countries.

It is with sadness that we record the death of one of the authors, Ms Carol Briggs, BSc FIBMS, during the preparation of this edition.

We are honoured to have taken over the editorship of *Practical Haematology* from our distinguished predecessors, Sir John Dacie and Dr Mitchell Lewis. We hope that our efforts have done them justice.

Barbara J. Bain
Michael A. Laffan
Imelda Bates

Contributors

The editor would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible.

Collection and Handling of Blood

Christopher McNamara

CHAPTER OUTLINE

Following an informed decision to analyse a blood sample, a specimen must be safely and correctly procured. It is essential to be aware that variation in this pre-analytical phase of the testing process can lead to errors in the analytical phase (see Box 1-1).

Venous blood is used for most examinations. Capillary blood samples may be satisfactory for some purposes but in general the use of capillary blood should be restricted to children and to some point-of-care screening tests.

BIOHAZARD PRECAUTIONS

Laboratory policies must be in place to ensure that staff who collect blood samples and transfer them to the laboratory minimise the risk of infection from various pathogens during all aspects of specimen handling (see Chapter 24). Additional precautions should be taken when handling high-risk specimens (e.g. those from patients suspected of having a viral haemorrhagic fever).[1] In this circumstance, the collection policy should stipulate the use of personal protective equipment, such as disposable gloves, body apron and protective eyewear. Care must be taken to prevent injuries, especially when handling and disposing of needles and lancets. Recommendations for standardising blood collection have been published.[2,3]

PROCUREMENT OF VENOUS BLOOD

Equipment

It is important to assemble a tray or prepare a workspace that has all the requirements for blood collection (Box 1-2). The selection of needle diameter is a compromise between achieving adequate flow with minimal turbulence and minimising patient discomfort. A 19-gauge (19G) or 21G* needle is suitable for most adults. A 23G needle is often selected for children. The shaft of the needle should be short (about 15 mm). It may be helpful to collect the blood by means of a winged needle (often referred to as a *'butterfly'*) connected to a length of plastic tubing that can be attached to the nozzle of the syringe or to a needle for entering the cap of an evacuated container (see Specimen Containers).

Specimen containers

Containers for testing whole blood are available commercially with dipotassium, tripotassium or disodium

*The International Organisation for Standardisation has established a standard (ISO 7864), which relates the following diameters for the different gauges: 19G = 1.1 mm; 21G = 0.8 mm; 23G = 0.6 mm.

BOX 1-1 Causes of misleading results related to specimen collection

PRE-COLLECTION

- Urination within 30 min; food or water intake within 2 h
- Smoking
- Physical activity (including fast walking) within 20 min
- Stress
- Drugs or dietary supplement administration within 8 h

DURING COLLECTION

- Different times (diurnal variance)
- Posture: lying, standing or sitting
- Haemoconcentration from prolonged tourniquet pressure
- Excessive negative pressure when drawing blood into syringe
- Incorrect type of tube
- Capillary versus venous blood

HANDLING OF SPECIMEN

- Insufficient or excess anticoagulant
- Inadequate mixing of blood with anticoagulant
- Error in patient and/or specimen identification
- Inadequate specimen storage conditions
- Delay in transit to laboratory

BOX 1-2 Items to be included in a phlebotomy tray

- Syringes and needles
- Tourniquet
- Specimen containers (tubes or evacuated tube system) – plain and with various anticoagulants
- Request form
- 70% isopropanol swabs or 0.5% chlorhexidine
- Sterile gauze swabs
- Adhesive dressings
- Self-sealing plastic bags with a separate compartment for the request form
- Rack to hold specimens upright during process of filling (except when an evacuated tube system is used)
- Puncture-resistant disposal container

ethylenediaminetetra-acetic acid (EDTA) anticoagulant, and often have a mark to indicate the correct amount of blood to be added.[4] Containers are also available containing trisodium citrate, heparin or acid–citrate–dextrose, as well as containers with no additive which are used when serum is required. Design requirements and other specifications for specimen collection containers have been described in a number of national and international standards (e.g., that of the International Council for Standardisation in Haematology[5]) and the European standard (EN 14820). There is no universal agreement regarding the colours used for identifying containers with different additives so phlebotomists should familiarise themselves with the colours used by their local suppliers.

Evacuated tube systems in common use consist of a glass or plastic tube under a defined vacuum, a needle and a needle holder, which secures the needle to the tube. The main advantage is that the cap can be pierced so that it is not necessary to remove it either to fill the tube or subsequently to withdraw samples for analysis, thus minimising the risk of aerosol discharge of the contents. An evacuated system is useful when multiple samples in different anticoagulants are required. The vacuum controls the amount of blood that enters the tube, ensuring an adequate volume for testing with the correct proportion of any anticoagulant.

Phlebotomy procedure

Staff undertaking this procedure should be adequately trained. The phlebotomist must check that the patient's identity corresponds to the details on the request form and also ensure that the phlebotomy tray contains all the required specimen containers and other equipment necessary for the procedure.

A tourniquet should be applied just above the intended venepuncture site. Blood is best withdrawn from an antecubital vein or other visible veins of the forearm by means of either an evacuated tube or a syringe. It is recommended that the skin be cleaned with 70% alcohol (e.g., isopropanol) and allowed to dry spontaneously before being punctured. The tourniquet should be released as soon as the vein is punctured and blood begins to flow into the syringe or evacuated tube – delay in releasing the tourniquet leads to fluid shift and haemoconcentration as a result of venous blood stagnation.[6] After the vein has been successfully punctured, the piston of the syringe should be withdrawn slowly with no attempt being made to withdraw blood faster than the vein is filling. Anticoagulated specimens must be mixed by inverting the container several times. The risk of unwanted haemolysis of the specimen can be minimised by using minimal tourniquet time, withdrawing blood carefully, using an appropriately sized needle, delivering the blood slowly into the receptacle and avoiding unnecessary agitation when mixing with the anticoagulant. Note that if blood is drawn too slowly or is inadequately mixed with the anticoagulant some coagulation may occur, rendering the sample unsuitable. After collection, containers must be firmly capped to minimise the risk of leakage.

If blood collection fails, it is important to remain calm, communicate with the patient and consider the possible causes. These include poor technique (e.g., passing the needle through the vein, or poor selection of veins), scarring of tissues and haematoma formation.

After obtaining the necessary specimens, remove the needle and press a sterile swab over the puncture site.

Gentle pressure should be applied to the swab with the arm slightly elevated for a minute before checking that bleeding has completely ceased. Finally, the puncture site should be covered with a small adhesive dressing.

Obtaining blood from an indwelling line or catheter is an important potential source of error. It is common practice to flush indwelling lines with heparin, so they must be flushed free from heparin and the first 5 ml of blood must be discarded before any blood is collected for laboratory testing. If intravenous fluids are being transfused into an arm, blood should generally not be collected from that arm; however, if this is essential, the specimen should be obtained from below the intravenous infusion with the tourniquet being placed below the site of infusion.

Postphlebotomy procedure

It is essential that every specimen is labelled with adequate patient identification immediately after the samples have been obtained and at the patient's bedside. The information should include, as a minimum, surname and forename or initials, hospital number or other unique identifying number, date of birth and date and time of specimen collection. Many centres have adopted automated patient identification using a bar code printed on a wrist or ankle band worn by the patient. If this type of system is used both the specimen label and the request form should be barcoded with identical data, unless the sample is to be used for blood transfusion tests, in which case the label should be handwritten (see Chapter 22).

Specimens should be sent in individual plastic bags separated from the request forms to prevent contamination of the forms in the event of leakage. Samples and form should remain together until the request is registered in the laboratory reception area.

CAPILLARY BLOOD

Collection of capillary blood

Skin puncture is carried out with a needle or lancet. In adults and older children, blood can be obtained from a finger; the recommended site is the distal digit of the third or fourth finger on its palmar surface, lateral to the nail bed. In infants, satisfactory samples can be obtained by a deep puncture of the plantar surface of the heel in the area shown in Figure 1-1. The central plantar area and the posterior curvature should not be punctured in small infants, especially newborns, to avoid the risk of injury and possible infection to the underlying tarsal bones.

The area selected for capillary puncture should be cleaned with an antiseptic and allowed to dry. The skin is punctured to a depth of 2–3 mm with a sterile, disposable lancet. After wiping away the first drop of blood with dry sterile gauze the finger (or heel in infants) is squeezed gently to encourage a free flow of blood for collection. Free flow of blood is essential and only very gentle squeezing is permissible; ideally, large drops of blood should exude slowly but spontaneously.

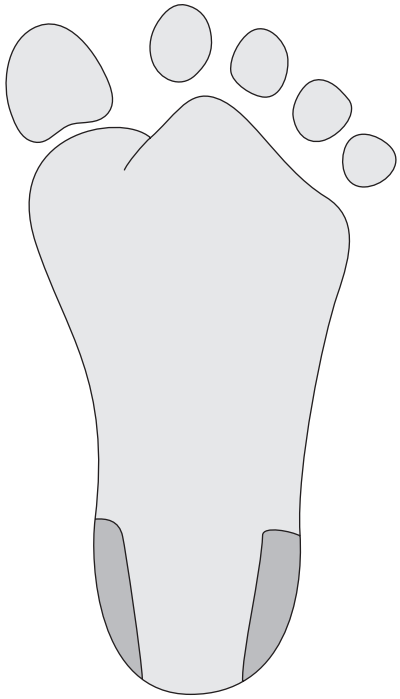

FIGURE 1-1 Skin puncture in infants. Puncture must be restricted to the outer medial and lateral portions of the plantar surface of the foot indicated by the shaded area.

After use, lancets should be placed in a puncture-resistant container for subsequent waste disposal. They must never be re-used on another individual.

BLOOD FILM PREPARATION

Ideally, blood films should be made immediately after the blood has been collected. However, in practice, blood samples are usually sent to the laboratory after a variable delay. Automated methods for making films are available and often employed in large centres. When films are not made on site they should be made in the laboratory soon after arrival as blood film morphology will deteriorate with any delay beyond a few hours.

DIFFERENCES BETWEEN CAPILLARY AND VENOUS BLOOD

Venous blood and capillary blood are not equivalent. Blood from a skin puncture is a mixture of blood from arterioles, veins and capillaries and it contains some interstitial and intracellular fluid.[7] The packed cell volume/haematocrit (PCV/Hct), red blood cell count (RBC) and

haemoglobin concentration (Hb) of capillary blood may be slightly higher than those of venous blood. The total leucocyte and neutrophil counts may also be higher. Conversely, the platelet count appears to be higher in venous than in capillary blood; this may be due to adhesion of platelets to the site of the skin puncture. All of these differences are minimised when a free flow of blood has been obtained after skin puncture.

SAMPLE HOMOGENEITY

To ensure even dispersal of the blood cells it is essential that specimens are mixed effectively in the laboratory, immediately before being tested. The specimen tube can be placed on a mechanical rotating mixer for 2 min or the tube can be inverted 8–10 times by hand. If the specimen has been stored at 4 °C, it will be viscous and the blood should be allowed to warm to room temperature before being mixed.

SERUM

The difference between plasma and serum is that the latter lacks fibrinogen and some coagulation factors. Blood collected in order to obtain serum should be delivered into sterile tubes with caps or into commercially available plain (no anticoagulant) evacuated collection tubes and allowed to clot undisturbed for about 1 h at room temperature before centrifugation.[†] Some containers have silica particles and an inert polymer gel, which floats between the serum and the red cells when centrifuged, facilitating separation of serum and making the specimen suitable for use on some automated analysers. This eliminates the need to decant the serum and preserves the integrity of the specimen.

The tubes, whether with or without a serum separator, are then centrifuged for 5 minutes at 3000 revolutions per minute (rpm). Some tests require a further centrifugation to remove any remaining particulate material. Supernatant serum may be transferred to tubes for further tests or stored. For most tests, serum should be kept at 4 °C until used, but if testing is delayed, serum can be stored at −20 °C for up to 3 months and at −40 °C or below for long-term storage. Validation of storage conditions and sample viability should be undertaken for all tests performed. Frozen specimens should be thawed in a water bath or in a 37 °C incubator, and then inverted several times to ensure homogeneity before being used for a test.

COLD AGGLUTININS

If cold agglutinins are suspected the blood must be kept at 37 °C from the point of collection until the sample has been processed. If cold agglutinins are suspected, it is best to bring the patient to a suitable location close to the laboratory and to collect blood into a previously warmed syringe and then to deliver the blood into containers that have been kept warm at 37 °C. When filled, the containers should be promptly replaced in the 37 °C water bath. In this way, it is possible to assess the effect of any putative antibodies acting, *in vivo,* at body temperature. When this is not feasible, specimens can be tightly capped and placed in a thermos at 37 °C.

ANTICOAGULANTS

Ethylenediaminetetra-acetic acid (EDTA)

EDTA and sodium citrate remove calcium, which is essential for coagulation. Calcium is either precipitated as insoluble oxalate (crystals of which may be seen in oxalated blood) or bound in a non-ionised form. Heparin binds to antithrombin, thus inhibiting the interaction of several clotting factors.

EDTA anticoagulation is used for blood counts; sodium citrate is used for coagulation testing and for the erythrocyte sedimentation rate. For better long-term preservation of red cells for certain tests and for transfusion purposes, citrate is used in combination with dextrose in the form of acid–citrate–dextrose (ACD) or citrate–phosphate–dextrose (CPD).

An excess of EDTA affects both red cells and leucocytes, causing shrinkage and degenerative changes. EDTA in excess of 2 mg/ml of blood may result in a significant decrease in PCV assessed by centrifugation and an increase in mean cell haemoglobin concentration (MCHC).[8] The platelets may also be affected; an excess of EDTA causes them to swell and then disintegrate, causing an artificially high platelet count, as the fragments are large enough to be counted as platelets. Care must therefore be taken to ensure that the correct amount of blood is added, and that by repeated inversions of the container the anticoagulant is thoroughly mixed with the blood specimen. EDTA is responsible for the activity of a naturally occurring antiplatelet autoantibody, which sometimes causes platelet aggregation of platelet adherence to neutrophils in blood films. All patients with apparent thrombocytopenia therefore require a blood film to identify this *in vitro* phenomenon. Repeat estimation of the platelet count in an alternative anticoagulant will resolve this problem, as the aforementioned antibody is inactive in the absence of EDTA.[9]

Trisodium citrate

For coagulation studies, 9 volumes of blood are added to 1 volume of 109 mmol/l sodium citrate solution (32 g/l of $Na_3C_6H_5O_7 \bullet 2H_2O$[‡]).[10] This ratio of anticoagulant to blood is critical as osmotic effects and changes in free calcium

[†]Room temperature is usually considered 18–25 °C.

[‡]38 g/l of $2Na_3C_6H_5O_7 \bullet 11H_2O$.

ion concentration affect coagulation test results. This ratio of citrate to blood may need to be adjusted when samples with a high haematocrit require coagulation studies (see Chapter 18).

Heparin

Lithium or sodium salt of heparin at a concentration of 10–20 iu/ml of blood is a commonly used anticoagulant for chemistry, gas analysis and emergency tests. It does not alter the size of the red cells and it is recommended when it is important to reduce to a minimum the chance of lysis occurring after blood has been withdrawn. When red cells are required for testing, as in the investigation of certain types of haemolytic anaemia, the sample can be defibrinated (see previous editions for details) although heparinised blood is now more often used for such tests.

Heparin is not suitable for blood counts and films as it often induces platelet and leucocyte clumping[11] and gives a faint blue colouration to the background when films are stained by Romanowsky dyes (especially, but not only, in the presence of abnormal proteins). Heparin inhibits enzyme activity and it should not be used when a polymerase chain reaction with restriction enzymes is to be performed.[12]

EFFECTS OF STORAGE ON THE BLOOD COUNT

Various changes take place in anticoagulated blood when it is stored at room temperature, and these changes occur more rapidly at higher ambient temperatures. These occur regardless of the anticoagulant. The RBC, white blood cell count (WBC), platelet count and red cell indices are usually stable for up to 8 h after blood collection, although as the red cells start to swell the PCV/Hct and mean cell volume (MCV) start to increase, osmotic fragility increases and the erythrocyte sedimentation rate decreases. When the blood is kept at 4 °C the effects on the blood count are not usually significant for up to 24 h. Thus, for many purposes blood can safely be allowed to stand overnight in the refrigerator if precautions against freezing are taken. Nevertheless, it is best to count leucocytes and especially platelets within 2 h and it should be noted that the decrease in the leucocyte count and a progressive decrease in the absolute lymphocyte count may become marked within a few hours, especially if there is an excessive amount of EDTA (>4.5 mg/ml).[13] Storage beyond 24 h at 4 °C results in erroneous data for automated white cell differential counts. One study using an aperture impedance analyser on blood left at room temperature showed WBC and neutrophil counts to be stable for 2–3 days but other leucocyte counts were stable for only a few hours.[14]

Reticulocyte counts are unchanged when the blood is kept in either EDTA or ACD anticoagulant for 24 h at 4 °C, but at room temperature the count begins to fall within 6 h. Nucleated red cells disappear in the blood specimen within 1–2 days at room temperature.

Haemoglobin concentration remains unchanged for days. However, within 2–3 days, and especially at high ambient temperatures, the red cells begin to lyse, resulting in a decrease in the RBC and PCV/Hct, with an increase in the calculated MCH and MCHC.

Coagulation test stability is critical for diagnosis and treatment of coagulopathies; it is recommended that tests be carried out within 2 h when the blood or plasma is stored at 22–24 °C, within 4 h when stored at 4 °C, within 2 weeks when stored at −20 °C, and within 6 months when stored at −70 °C.[3]

For a serum or plasma test, blood should be centrifuged within 5 h of collection. For vitamin B_{12} and folate assays, the serum or plasma should be kept at 4 °C or at −20 °C if storage for more than 2–3 weeks is required. For long-term storage, specimens should be divided into several aliquots to avoid repeated freezing and thawing.

Inappropriate handling of blood specimens during transfer to the laboratory (e.g. excess shaking or being exposed to temperature extremes) may cause haemolysis, partial coagulation and cell disintegration. Shipping of specimens requires special packaging and should reach certain minimum specifications.[14]

EFFECTS OF STORAGE ON BLOOD CELL MORPHOLOGY

Changes in blood cell morphology of stored samples occur within a few hours of blood collection. Irrespective of anticoagulant, films made from blood that has been standing for <1 h at room temperature are not easily distinguished from films made immediately after collection of the blood. By 3 h, changes may be discernible and by 12–18 h these become striking. Some but not all neutrophils are affected; their nuclei may stain more homogeneously than in fresh blood, the nuclear lobes may become separated and the cytoplasmic margin may appear ragged or less well-defined; small vacuoles appear in the cytoplasm (Fig. 1-2, *A, B*). Some or many of the large monocytes develop marked changes; small vacuoles appear in the cytoplasm and the nucleus undergoes irregular lobulation, which may almost amount to disintegration (Fig. 1-2, *C*). Lymphocytes undergo similar changes: a few vacuoles may be seen in the cytoplasm, nuclei stain more homogeneously than usual and in some the nucleus undergoes budding, giving rise to nuclei with two or three lobes (Fig. 1-2, *D–F*). Normal red cells are little affected by standing for up to 6 h at room temperature. Longer periods lead to progressive crenation (Fig. 1-2, *B, E, F*). With an excess of EDTA, a marked degree of red cell crenation occurs within a few hours. All the aforementioned changes are retarded but not abolished in blood stored at 4 °C. Their occurrence underlines the

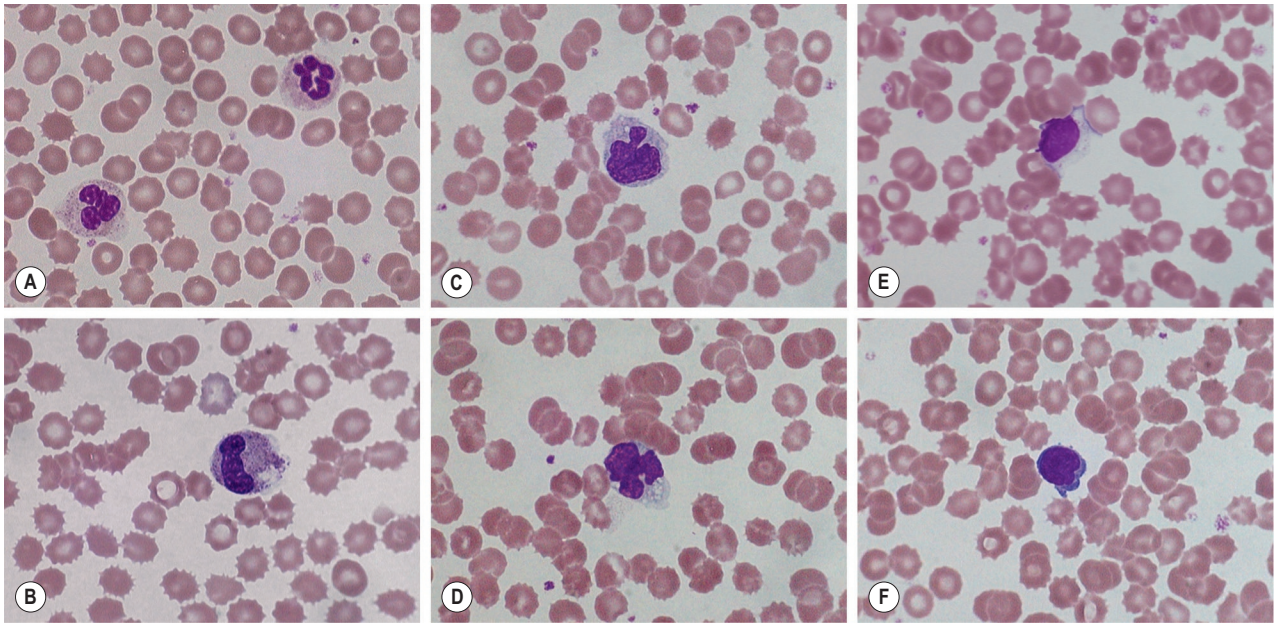

FIGURE 1-2 Effect of storage on blood cell morphology. Photomicrographs from films made from ethylenediaminetetra-acetic acid (EDTA) blood after 24 h at 20 °C. **(A, B)** Polymorphonuclear neutrophils; **(C, D)** monocytes; **(E, F)** lymphocytes. Red cell crenation is prominent in all images.

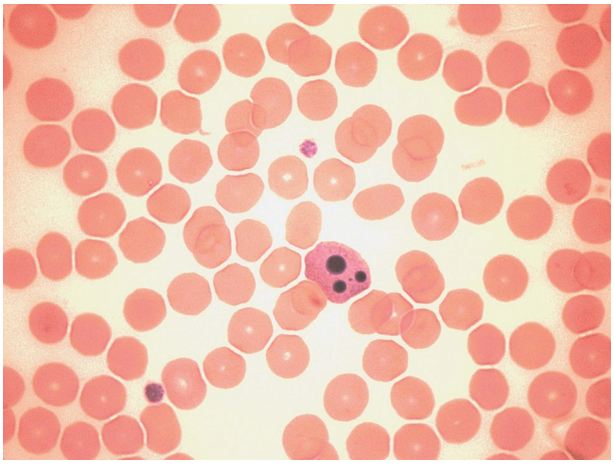

FIGURE 1-3 Morphological features of apoptosis.

importance of making films as soon as possible after the blood has been collected.

These artefactual changes must be distinguished from apoptosis, which can be seen in high-grade haematological neoplasms. Apoptosis is characterised, morphologically (Fig. 1-3), by cell shrinkage, a homogeneously glassy appearance of the nucleus, cytoplasmic condensation around the nuclear membrane and indentations in the nucleus, followed by its fragmentation. Apoptotic neutrophils with a single apoptotic body may be confused with nucleated red cells if the cytoplasmic features are not appreciated.

ACKNOWLEDGEMENT

The author wishes to acknowledge the contribution of previous authors of this chapter – the late Corrine Jury, Yutaka Nagai and the late Noriyuki Tatsumi – and of Gareth Ellis, who reviewed the content of this chapter.

2

Reference Ranges and Normal Values

Imelda Bates

CHAPTER OUTLINE

A number of factors affect haematological values in apparently healthy individuals. As described in Chapter 1, these include the technique and timing of blood collection, the transport and storage of specimens, the posture of the subject when the sample is taken, the prior physical activity and the degree of ambulation (e.g. whether the subject is confined to bed or not). Variation in the analytical methods used may also affect the measurements. These can all be standardised.

More problematic are the inherent variables as a result of gender, age, occupation, body build, genetic background and adaptation to diet and to environment (especially altitude). These factors must be recognised when establishing physiologically normal values. It is also difficult to be certain that the 'normal' subjects used for constructing normal ranges are completely healthy and do not have nutritional deficiencies, mild chronic infections, parasitic infestations or the effects of smoking.

Haematological values for the normal and abnormal will overlap and a value within the recognised normal range may be definitely pathological in a particular subject. For these reasons the concept of 'normal values' and 'normal ranges' has been replaced by *reference values* and the *reference range,* which is defined by *reference limits* and obtained from measurements on the *reference population* for a particular test. Unless a reference range is derived in this manner, the term should not be used. The reference range is also termed the *reference interval.*[1,2] Ideally, each laboratory should establish a databank of reference values that takes account of the variables mentioned earlier and the test method, so that an individual's result can be expressed and interpreted relative to a comparable apparently normal population, insofar as normal can be defined.

New haematological parameters such as the number of immature cells or the number of red cell fragments are often initially developed for research purposes but can be used for clinical decision making once internal quality control and external quality assessment processes are in place.[3]

REFERENCE RANGES

A reference range for a specified population can be established from measurements on a relatively small number of subjects (discussed later) if they are assumed to be representative of the population as a whole.[2] The conditions for obtaining samples from the individuals and the analytical procedures must be standardised, whereas data should be analysed separately for different variables relating to individuals – recumbent or ambulant, smokers or nonsmokers and so on. One approach is that specimens are collected at about the same time of day, preferably in the morning before breakfast; the last meal should have been eaten no later than 9 p.m. on the previous evening, and at that time alcohol should have been restricted to one bottle of beer or an equivalent amount of another

alcoholic drink.[4] An alternative approach is that, unless a test is usually done on a fasting patient, specimens are collected throughout the day on subjects who are not fasting or resting, as this will produce a reference range that is more relevant to results from patients. It is sometimes appropriate that the reference population is defined as having normal results for specific laboratory tests. For example, if determining a reference range for blood count components it may be necessary, in some populations, to exclude iron deficiency, β thalassaemia heterozygosity and, when relevant, α thalassaemia.

STATISTICAL PROCEDURES

In biological measurements, it is usually assumed that the data will fit a specified type of pattern, either symmetric (Gaussian) or asymmetric with a skewed distribution (non-Gaussian). With a Gaussian distribution, the *arithmetic mean* ($\bar{x}$) can be obtained by dividing the sum of all measurements by the number of observations. The *mode* is the value that occurs most frequently and the *median* (*m*) is the point at which there are an equal number of observations above and below it. In a true Gaussian distribution they should all be the same. The standard deviation (SD) can be calculated as described on page 565.

If the data fit a Gaussian distribution, when plotted as a frequency histogram the pattern shown in Figure 2-1 is obtained. Taking the mode and the calculated SD as reference points, a Gaussian curve is superimposed on the histogram. From this curve, practical reference limits can be determined even if the original histogram included outlying results from some subjects not belonging to the normal population. Limits representing the 95% reference range are calculated from the arithmetic mean ±2SD (or more accurately ±1.96SD).

When there is a log normal (skewed) distribution of measurements, the range to −2SD may even extend to zero (Fig. 2-2, *A*). To avoid this anomaly, the data should be plotted on semilogarithmic graph paper to obtain a normal distribution histogram (Fig. 2-2, *B*). To calculate the mean and SD the data should be converted to their logarithms. The log–mean value is obtained by adding the logs of all the measurements and dividing by the number of observations. The log SD is calculated by the formula on page 566 and the results are then converted to their antilogs to express the data in the arithmetic scale. This process is now generally carried out using an appropriate statistical computer program.

When it is not possible to make an assumption about the type of distribution, a nonparametric procedure may be used instead to obtain the median and SD. To obtain an approximation of the SD, the range that comprises the middle 50% spread (i.e. between 25 and 75% of results) is read and divided by 1.35. This represents 1SD.

Confidence limits

In any of the methods of analysis, a reasonably reliable estimate can be obtained with 40 values, although a larger number (≥120) is preferable (Fig. 2-3).[5] When a large set of reference values is unattainable and precise estimation is impossible, a smaller number of values may still serve as a useful clinical guide. Confidence limits define the reliability (e.g. 95% or 99%) of the established reference values

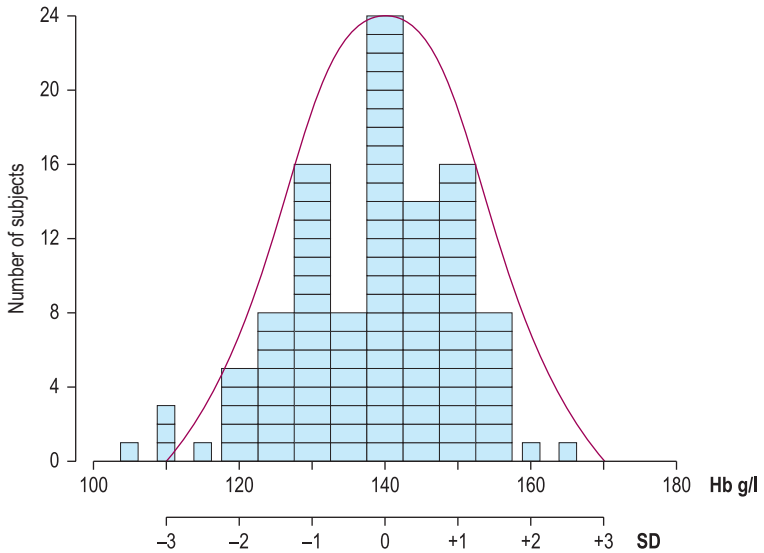

FIGURE 2-1 Example of establishing a reference range. Histogram of data of Hb measurements in a population, with Gaussian curve superimposed. The ordinate shows the number that occurred at each reference point. The mean was 140 g/l; the reference ranges at 1SD, 2SD and 3SD are indicated.

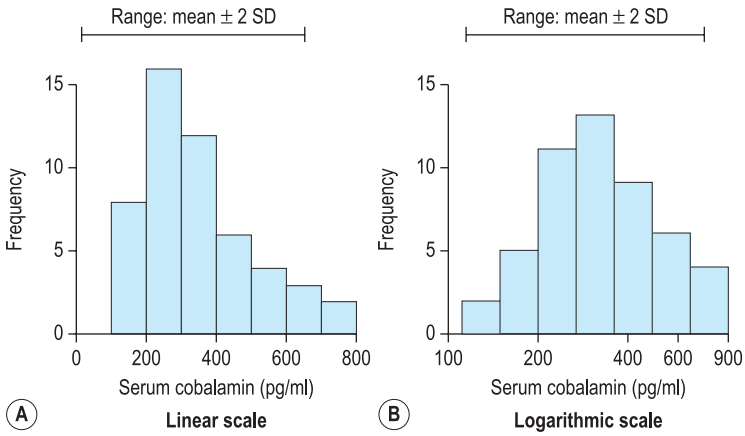

FIGURE 2-2 Example of conversion to a log normal distribution. Data of serum cobalamin (vitamin B_{12}) measurements in a population. **(A)** Arithmetic scale: mean 340 pg/ml; 2SD range calculated as 10–665. **(B)** Geometric scale: mean 308 pg/ml; 2SD range calculated as 120–780.

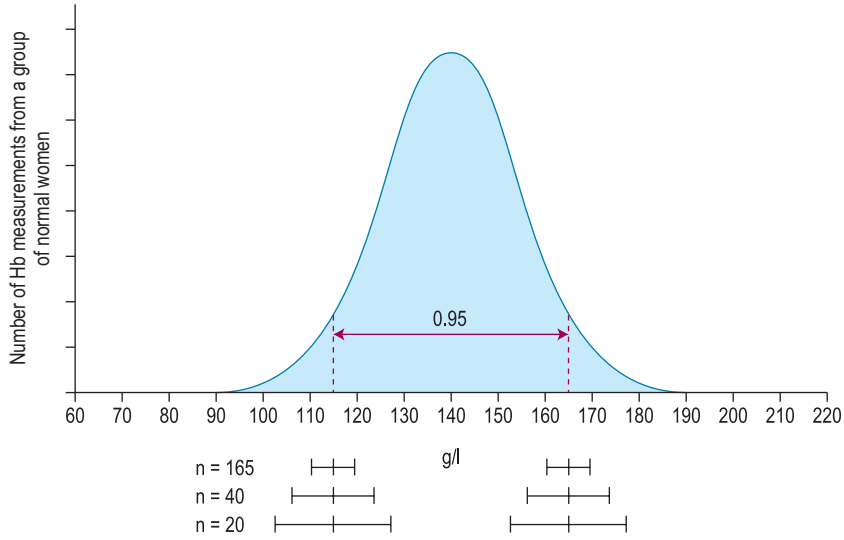

FIGURE 2-3 Effect of sample size on reference values. A smoothed distribution graph was obtained for Hb measurements from a group of normal women; the ordinate shows the frequency distribution. The 95% reference range is defined by the lower and higher reference limits, which are 115 and 165 g/l, respectively. The confidence levels for these values are shown for three sample sizes of 20, 40 and 165, respectively.

when assessing the significance of a test result, especially when it is on the borderline between normal and abnormal. Calculation of confidence limits is described on page 566. Another important measurement is the coefficient of variation (CV) of the test because a wide CV is likely to influence its clinical utility (see p. 566).

NORMAL REFERENCE VALUES

The data given in Tables 2-1, 2-2 and 2-3 provide general guidance to normal reference values that are applicable to most healthy adults and children in high-income countries. However, slightly different ranges may be found in individual laboratories where different analysers and methods are used. The reference interval, which comprises a range of ±2SD from the mean, indicates the limits that should cover 95% of normal subjects; 99% of normal subjects will be included in a range of ±3SD. Age and gender differences have been taken into account for some values. Even so, the wide ranges that are shown for some tests reflect the influence of various factors, as described below. Narrower ranges would be expected under standardised conditions. Because modern analysers provide a high level of technical precision, even small differences in successive measurements may be significant. It is thus important to establish and understand the limits of physiological variation for various tests. The blood count data and other test results can

TABLE 2-1

HAEMATOLOGICAL VALUES FOR NORMAL ADULTS (PREDOMINANTLY FROM EUROPE AND NORTH AMERICA) EXPRESSED AS A MEAN ± 2SD OR AS A 95% RANGE

Red blood cell count	
Men	$5.0 \pm 0.5 \times 10^{12}$/l
Women	$4.3 \pm 0.5 \times 10^{12}$/l
Haemoglobin concentration*	
Men	150 ± 20 g/l
Women	135 ± 15 g/l
Packed cell volume (PCV) or haematocrit (Hct)	
Men	0.45 ± 0.05 l/l
Women	0.41 ± 0.05 l/l
Mean cell volume (MCV)	
Men and women	92 ± 9 fl
Mean cell haemoglobin (MCH)	
Men and women	29.5 ± 2.5 pg
Mean cell haemoglobin concentration (MCHC)	
Men and women	330 ± 15 g/l
Red cell distribution width (RDW)	
As coefficient of variation (CV)	12.8% ± 1.2%
Red cell diameter (mean values)	
Dry films	6.7–7.7 µm
Red cell density	1092–1100 g/l
Reticulocyte count	$50–100 \times 10^9$/l (0.5–2.5%)
White blood cell count	$4.0–10.0 \times 10^9$/l
Differential white cell count	
Neutrophils	$2.0–7.0 \times 10^9$/l (40–80%)
Lymphocytes	$1.0–3.0 \times 10^9$/l (20–40%)
Monocytes	$0.2–1.0 \times 10^9$/l (2–10%)
Eosinophils	$0.02–0.5 \times 10^9$/l (1–6%)
Basophils	$0.02–0.1 \times 10^9$/l (<1–2%)
Lymphocyte subsets (approximations from ranges in published data)	
CD3	$0.6–2.5 \times 10^9$/l (60–85%)
CD4	$0.4–1.5 \times 10^9$/l (30–50%)
CD8	$0.2–1.1 \times 10^9$/l (10–35%)
CD4/CD8 ratio	0.7–3.5
Platelet count	$280 \pm 130 \times 10^9$/l
Bleeding time†	
Ivy method	2–7 min
Template method	2.5–9.5 min
Thrombin time	15–19 s
Plasma fibrinogen concentration	1.8–3.6 g/l
Plasminogen concentration‡	0.75–1.60 u/ml
Antithrombin concentration‡	0.75–1.25 u/ml
Protein C concentration‡	
Functional	0.70–1.40 u/ml
Antigen	0.61–1.32 u/ml
Protein S concentration‡	
Total antigen	0.78–1.37 u/ml
Free antigen	0.68–1.52 u/ml
Premenopausal women§	0.55–1.55 u/ml
Functional	0.60–1.35 u/ml
Premenopausal women	0.55–1.35 u/ml
Heparin cofactor II concentration‡	0.55–1.45 u/ml
Median red cell fragility (MCF) (g/l NaCl)	
Fresh blood	4.0–4.45 g/l NaCl
After 24 h at 37 °C	4.65–5.9 g/l NaCl
Cold agglutinin titre (4 °C)	<64
Blood volume (normalised to 'ideal weight')	
Red cell volume	
Men	30 ± 5 ml/kg
Women	25 ± 5 ml/kg
Plasma volume	45 ± 5 ml/kg
Total blood volume	70 ± 10 ml/kg
Red cell lifespan	120 ± 30 days
Serum iron	
Men and women	10–30 µmol/l (0.6–1.7 mg/l)
Total iron-binding capacity	47–70 µmol/l (2.5–4.0 mg/l)
Transferrin saturation	16–50%
Serum ferritin concentration	
Men	15–300 µg/l (median 100 µg/l)
Women	15–200 µg/l (median 40 µg/l)
Serum vitamin B_{12} concentration	180–640 ng/l
Serum folate concentration	3–20 µg/l (6.8–45 nmol/l)
Red cell folate concentration	160–640 µg/l (0.36–1.45 µmol/l)
Plasma haemoglobin concentration	10–40 mg/l
Serum haptoglobin concentration	
Radial immunodiffusion	0.8–2.7 g/l
Haemoglobin binding capacity	0.3–2.0 g/l
Haemoglobin A_2	2.2–3.5%
Haemoglobin F	<1.0%
Methaemoglobin	<2.0%
Erythrocyte sedimentation rate (mm in 1 h at 20 ± 3 °C)	
Men	
17–50 years	≤10
51–60 years	≤12
61–70 years	≤14
>70 years	≤30
Women	
17–50 years	≤12
51–60 years	≤19
61–70 years	≤20
>70 years	≤35
Plasma viscosity	
25 °C	1.50–1.72 mPa/s
37 °C	1.16–1.33 mPa/s

*Haemoglobin concentration may sometimes be reported as g/dl.
† Bleeding time is no longer recommended for routine assessment of haemostasis but may be useful in suspected collagen disorders.
‡ These ranges are for general guidance only because each laboratory should establish its own normal range.

Platelets ($\times 10^9$/l)	200–550	200–490	170–450

*Approximations because wide variations have been reported in different studies.

then provide sensitive indications of minor abnormalities that may be important in clinical interpretation and health screening.

It should be noted that in Table 2-1 the differential white cell count is shown as percentages and in absolute numbers. Automated analysers provide absolute counts for each type of leucocyte and, because proportional (percentage) counting is less likely to indicate correctly their absolute increase or decrease, the International Council for Standardisation in Haematology has recommended that the differential leucocyte count should always be given as the absolute number of each cell type per unit volume of blood.[6] The neutrophil:lymphocyte ratio obtained from a differential leucocyte count should be regarded only as an approximation. There are variations in the ability of different automated blood cell analysers to characterise, quantify and flag different types of cells. Most analysers show good correlation for neutrophils and eosinophils but counts and flags for basophils, blasts and immature granulocytes may not be reliable enough for clinical use.[7]

PHYSIOLOGICAL VARIATIONS IN THE BLOOD COUNT

Red cell components

Age and gender

There is considerable variation in the red blood cell count (RBC) and Hb at different periods of life and there are also transient fluctuations, the significance of which is often difficult to assess. At birth the Hb is higher than at any period subsequently (Table 2-2). The RBC is high immediately after birth,[8] and values for Hb above 200 g/l, RBC higher than 6.0×10^{12}/l and a haematocrit (Hct) over 0.65 are encountered frequently when cord clamping is delayed and blood from the placenta and umbilical artery re-enters the infant's circulation. There are rapid fluctuations in the blood count of newborn babies, infants and older children. Reference ranges for preterm infants vary with gestational age. For example, in preterm infants in the United States between 22 and 41 weeks' gestation, the packed cell volume increases from 0.40 to 0.52 l/l, the Hb from 140 to 170 g/l and the platelet count from 200 to 250×10^9/l, whereas the mean cell volume (MCV) and mean cell haemoglobin (MCH) gradually decrease from 121 to 105 fl and from 40.5 to 35.5 pg, respectively.[9]

After the immediate postnatal period, the Hb falls fairly steeply to a minimum by about the second month (Fig. 2-4). The RBC and Hct also fall, although less steeply, and the cells may become microcytic with the development of iron deficiency. The changes in the MCH, mean cell haemoglobin concentration (MCHC) and MCV from the neonate through infancy to early childhood are shown in Tables 2-2 and 2-3.

The Hb and RBC increase gradually through childhood to reach almost adult levels by puberty. The lower normal limits for Hb (i.e. 2SD below the mean) are usually taken as 130 g/l for men and 120 g/l for women. The levels in women tend to be significantly lower than those in men[10] partly due to a hormonal influence on haemopoiesis, and

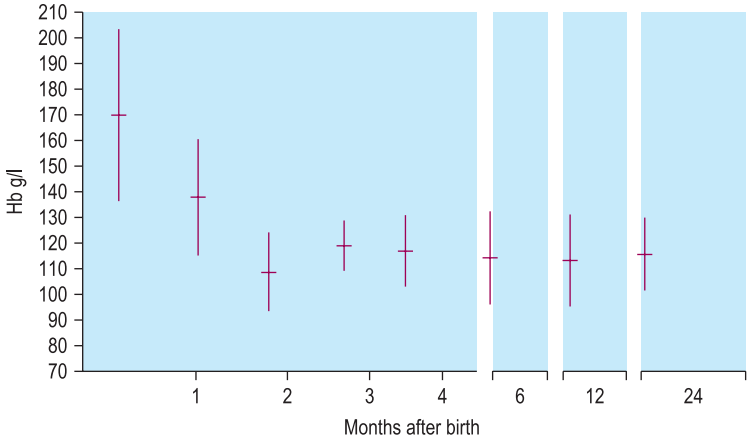

FIGURE 2-4 Changes in Hb values in the first 2 years after birth. The horizontal lines show the means and the perpendicular lines the 2SD ranges.

possibly subclinical iron deficiency in women. The extent to which menstrual blood loss is a significant factor is not clear because a loss of up to 100 ml of blood with each period may lead to iron depletion without causing anaemia. There may also be ethnic differences in Hb (e.g. the Hb is 5–10 g/l lower in black Americans than in socially comparable white counterparts). In older adults the threshold Hb level at which mortality increases is lower.[11]

Pregnancy

In normal pregnancy, there is an increase in erythropoietic activity and a simultaneous increase in plasma volume occurs, which overall results in a progressive decrease in Hb, Hct and RBC (Table 2-4). There is a slight increase in MCV during the second trimester. Serum ferritin decreases in early pregnancy and usually remains low throughout pregnancy, even when supplementary iron is given.[12] The haematological parameters return to normal about a week after delivery.

The elderly

In healthy men and women, Hb, RBC, Hct and other red cell indices remain remarkably constant until the sixth decade. Anaemia becomes more common in those older than 70–75 years[13] and is associated with poor clinical outcomes due to reduced cognition, increased frailty and an elevated risk of hospitalisation and of complications during hospitalisation. In the elderly, the difference in Hb between men and women is 10 g/l or less compared with a difference of 20 g/l in younger age groups. Serum iron increases as women age although serum ferritin levels remain higher in elderly men than in women. Factors that contribute to the lower Hb in the elderly include renal insufficiency, inflammation, testosterone deficiency, diminished erythropoiesis, stem cell proliferative decline and myelodysplasia.

TABLE 2-4

HAEMOGLOBIN CONCENTRATION VALUES IN PREGNANCY

First trimester	124–135 g/l
Second trimester	110–117 g/l
Third trimester	106–109 g/l*
Mean values postpartum	
Day 2	104 g/l
Week 1	107 g/l
Week 3	116 g/l
Month 2	119 g/l

*Higher values (120 g/l or higher) may be found when supplementary iron is being given.

Moderate or severe anaemia should never be attributed to ageing *per se* until underlying disease has been excluded; however, a significant number of elderly subjects with anaemia have no identifiable clinical or nutritional causes.

Exercise

Optimal athletic performance depends on proper function of many organs, including the blood. Several haematological parameters can affect or be influenced by physical activity, including blood cell counts and coagulation mechanisms.[14] For example, endurance athletes may develop so-called 'sports anaemia', which is thought to be the result of increased plasma volume. Increasing oxygen delivery by raising the Hct is a simple acute method to improve athletic performance. Legal means of raising the Hct include altitude training and use of hypoxic tents. Illegal means include blood doping and the administration of erythropoietin (EPO) (see Chapter 6).[15] Endurance athletes may also have decreased levels of serum iron and

ferritin, possibly associated with loss of iron in sweat. Conversely, in sprinters who require a short burst of very strenuous muscular activity, there is a transient increase in RBC by 0.5×10^{12}/l and in Hb by 15 g/l, largely because of a reduction in plasma volume and to a lesser extent the re-entry into the circulation of cells previously sequestered in the spleen. The effects of exercise must be distinguished from a form of haemolysis known as 'runner's anaemia' or 'march haemoglobinuria', which occurs as a result of pounding of the feet on the ground.[16] A similar phenomenon has been reported in djembe drummers from repeated hand trauma.

Posture

There is a small but significant alteration in the plasma volume with an increase in Hb and Hct as the posture changes from lying to sitting, especially in women;[17] conversely, changing from walking to lying results in a 5–10% decrease in the Hb and Hct. The difference in position of the arm during venous sampling, whether dependent or held at atrial level, can also affect the Hct.

These aspects highlight the relevance of using a standardised method for blood collection, although this is not necessarily practicable in routine practice. This is discussed in Chapter 1 and the differences between venous and capillary blood are described on page 3.

Diurnal and seasonal variation

Changes in Hb and RBC during the course of the day are usually slight, about 3%, with negligible changes in the MCV and MCH. However, variation of 20% occurs with reticulocyte counts.[18] Studies of diurnal variation of serum erythropoietin have shown conflicting results. Pronounced, but variable, diurnal variations are seen in serum iron and ferritin and in patients taking iron-containing supplements.[19] It has been suggested that minor seasonal variations also occur, but the evidence for this is conflicting.

Altitude

The effect of altitude is to reduce the plasma volume, increase the Hb and Hct and raise the number of circulating red cells with a lower MCV.[20] The magnitude of the polycythaemia depends on the degree of hypoxaemia. At an altitude of 2000 m, Hb is ≈ 8–10 g/l and Hct is 0.025 higher than at sea level; at 3000 m, Hb is ≈ 20 g/l and Hct is 0.060 higher; and at 4000 m, Hb is 35 g/l and Hct is 0.110 higher. Corresponding increases occur at intermediate and at higher altitudes.[20] These increases appear to be the result of enhanced erythropoiesis secondary to the hypoxic stimulus, and the decrease in plasma volume that occurs at high altitudes.

Smoking

Cigarette smoking affects Hb, RBC, Hct and MCV (see p. 16).

Leucocyte count

At birth, the total leucocyte count is high; neutrophils predominate, reaching a peak of $\approx 13.0 \times 10^9$/l within 6–8 h for neonates of >28 weeks' gestation and 24 h for those delivered at <28 weeks.[9] The count then falls to $\approx 4.0 \times 10^9$/l over the next few weeks and then stabilises (Tables 2-1, 2-2 and 2-3). The lymphocytes decrease during the first 3 days of life, often to a low level of $\approx 2.0–2.5 \times 10^9$/l, and then rise up to the tenth day; after this time, they are the predominant cell (up to about 60%) until the fifth to seventh year, when neutrophils predominate. From that age onwards, the levels are the same as those of adults. There are also slight sex differences; the total leucocyte count (WBC) and the neutrophil count may be slightly higher in girls than in boys, and in women than in men.[21] After the menopause, the counts fall in women so that they tend to become lower than in men of similar age.

People differ considerably in their leucocyte counts. Some tend to maintain a relatively constant level over long periods; others have counts that may vary by as much as 100% at different times. In some subjects, there appears to be a rhythm, occurring in cycles of 14–28 days, and in women this may be related to the menstrual cycle or to the use of oral contraception. There is no clear-cut diurnal variation, but minimum counts are found in the morning with the subject at rest and during the course of a day there may be differences of 14% for the WBC, 10% for neutrophils, 14% for lymphocytes and 20% for eosinophils;[18] in some cases this may result in a reversed neutrophil:lymphocyte ratio. Random activity may raise the count slightly; strenuous exercise causes increases of up to 30×10^9/l, partly because of mobilization of marginated neutrophils and changes in cortisol levels.[22] Large numbers of lymphocytes and monocytes also enter the bloodstream during strenuous exercise. However, there have also been reports of neutropenia and lymphopenia in athletes undergoing strenuous exercise.[23]

Epinephrine (adrenaline) injection causes an increase in the numbers of all types of leucocytes (and platelets), possibly reflecting the extent of the reservoir of mature blood cells present not only in the bone marrow and spleen but also in other tissues and organs of the body. Emotion may possibly cause an increase in the leucocyte count in a similar way. A transient lymphocytosis with a reversed neutrophil:lymphocyte ratio occurs in adults with physical stress or trauma. The effect of ingestion of food is uncertain. Cigarette smoking has an effect on the leucocyte count (see p. 16).

A moderate increase in the WBC, of up to 15×10^9/l, is common during pregnancy, owing to an increase in the neutrophil count, with the peak in the second trimester. The count returns to non-pregnancy levels about a week after delivery.[24]

In individuals of African ancestry there is a tendency for the neutrophil:lymphocyte ratio to be reversed primarily due to a reduction in neutrophil count. This is due to genetic rather than environmental factors. Significantly lower WBC and neutrophil counts have also been observed in Africans and Afro-Caribbeans living in Britain as well as in many African countries. 'Benign ethnic neutropenia' occurs in up to 5% of African Americans and is defined as a neutrophil count $<1.5 \times 10^9$/l without overt cause or complications.[25] A Duffy null polymorphism is associated with the difference in WBC and neutrophil counts between African Americans and European Americans.[26] Elderly people receiving influenza vaccination show a lower total leucocyte count owing to a decrease in lymphocytes.[27]

Platelet count

There is a slight diurnal variation in the platelet count of about 5%;[18] this occurs during the course of a day as well as from day-to-day. Within the wide normal reference range, there are some ethnic differences, and in healthy Afro-Caribbeans and Africans platelet counts may on average be 10–20% lower than those in Europeans living in the same environment.[28] There is also a gender difference; thus, in women, the platelet count is about 20% higher than in men.[29] A decrease in the platelet count may occur in women at about the time of menstruation. In the first year after birth the reference range for the platelet count is higher than the adult reference range. Strenuous exercise causes a 30–40% increase in platelet count;[22] the mechanism is similar to that for leucocytes.

Further information. Detailed ranges related to age, gender, ethnic origin and pregnancy status are given in reference 30.

Other blood constituents

As with the blood count, variations from usual values occur in relation to gender, age, exercise, stress, diurnal fluctuation and so on. These are described in the relevant chapters.

EFFECTS OF SMOKING ON HAEMATOLOGICAL NORMAL REFERENCE VALUES

Both active and passive cigarette smoking have a significant effect on many haematological normal reference values (Table 2-5).[31,32] Some effects may be transient and their severity varies between individuals as well as by the number of cigarettes smoked. Smoking ≥10 cigarettes a day results in a slight increase in Hb, Hct and MCV. This is probably partly due to the accumulation of carboxyhaemoglobin in the blood together with a decrease in plasma volume. After a single cigarette, the carboxyhaemoglobin level increases by about 1%, and in heavy smokers the carboxyhaemoglobin may constitute ≈4–5% of the total haemoglobin. The WBC increases, largely as a result of an increase in the neutrophils; neutrophil function may also be affected. Smoking can cause an increase in CD4-positive lymphocytes and total lymphocyte count. Smokers tend to have higher platelet counts than non-smokers, but the counts decrease rapidly on cessation of smoking. Studies of platelet aggregation and adhesiveness have given equivocal results, but there appears to be a consistent increase in platelet turnover with decreased platelet survival and increased plasma β thromboglobulin. Elevated fibrinogen concentration (with increased plasma viscosity) and reduced protein S have been reported, but smoking does not seem to have any consistent effects on the fibrinolytic system.

TABLE 2-5

EFFECTS OF CIGARETTE SMOKING*

Increased	Decreased
Haemoglobin concentration (Hb)	Plasma volume
Red blood cell count (RBC)	Protein S
Haematocrit (Hct)	
Mean cell volume (MCV)	
Mean cell haemoglobin (MCH)	
White blood cell count (WBC)	
Neutrophil count	
Lymphocyte count	
T cells (CD4-positive)	
Monocyte count	
Carboxyhaemoglobin (>2%)	
Platelet count (transient)	
Mean platelet volume	
Fibrinogen concentration	
β thromboglobulin concentration	
von Willebrand factor	
Red cell mass	
Haptoglobin concentration	
Plasma viscosity	
Whole blood viscosity	
Erythrocyte sedimentation rate (ESR)	

*Extent of change from normal reference values varies with individuals and the amount smoked. Some effects may be transient or occur only during and immediately after smoking.

Basic Haematological Techniques

Carol Briggs • Barbara J. Bain

CHAPTER OUTLINE

It is possible to use manual, semiautomated or automated techniques to determine the various components of the full blood count (FBC). Manual techniques are generally low cost with regard to equipment and reagents but are labour intensive; automated techniques entail high capital costs but permit rapid performance of a large number of blood counts by a smaller number of laboratory workers. Automated techniques are more precise, but their accuracy depends on correct calibration and the use of reagents that are usually specific for the particular analyser. Many laboratories now use automated techniques almost exclusively, but certain manual techniques are necessary as reference methods for standardisation. Manual methods may also be needed to deal with samples that have unusual characteristics that give discrepant results with automated analysers.

All the tests discussed in this chapter can be performed on venous or free-flowing capillary blood that has been anticoagulated with ethylenediaminetetra-acetic acid (EDTA) (see p. 4). Thorough mixing of the blood specimen before sampling is essential for accurate test results. Ideally, tests should be performed within 6 h of obtaining the blood specimen because some test results are altered by longer periods of storage. However, results that are sufficiently reliable for clinical purposes can usually be obtained on blood stored for up to 24 h at 4°C.

HAEMOGLOBINOMETRY

The haemoglobin concentration (Hb) of a solution may be estimated by measurement of its colour, by determination of its power of combining with oxygen or carbon monoxide or by analysis of its iron content. The methods to be described are all colour or light-intensity matching techniques, which also measure, to a varying extent, any methaemoglobin (Hi) or sulphaemoglobin (SHb) that may be present. The oxygen-combining capacity of blood is 1.34 ml of O_2 per g of haemoglobin. Ideally, for assessing the clinical consequences of anaemia, a functional estimation of Hb should be carried out by measurement of oxygen capacity, but this is hardly practical in the routine haematology laboratory. It gives results that are at least 2% lower than those given by the other methods, probably because a small proportion of inert pigment is always present. The iron content of haemoglobin can be estimated accurately,[1] but again the method is impractical for routine purposes. Estimations based on iron content are generally taken as authentic, but iron bound to inactive pigment is included. Iron content is converted into haemoglobin by assuming the following relationship: 0.347 g of iron = 100 g of haemoglobin.[2]

MEASUREMENT OF HAEMOGLOBIN CONCENTRATION USING A SPECTROMETER (SPECTROPHOTOMETER) OR PHOTOELECTRIC COLORIMETER

Only the haemiglobincyanide (HiCN; cyanmethaemoglobin) method is now in common use. It has the advantage over the oxyhaemoglobin (HbO_2) method of there being a stable and reliable reference preparation available. With the exception of several point-of-care instruments, the HbO_2 method is now rarely used. The method is given in the previous edition of this book.

Although the HiCN reagent contains cyanide, there is only 50 mg of potassium cyanide per litre and 600–1000 ml would have to be swallowed to produce serious effects. However, the use of potassium cyanide has been viewed as a potential hazard; alternative less hazardous reagents that have been introduced are sodium azide[3] and sodium lauryl sulphate,[4,5] which convert haemoglobin to haemiglobinazide and haemiglobinsulphate, respectively. They are used in some automated systems, but no stable standards are available and they, too, are toxic substances that must be handled with care.

Other methods that have been used include Sahli's acid–haematin method, which is less accurate because the colour develops slowly, is unstable and begins to fade almost immediately after it reaches its peak. The alkaline–haematin method gives a true estimate of total haemoglobin concentration even if carboxyhaemoglobin (HbCO), Hi or SHb is present; plasma proteins and lipids have little effect on the development of colour, although they cause turbidity. The original method was more cumbersome and less accurate than the HiCN or HbO_2 methods, but a modified method has been developed in which blood is diluted in an alkaline solution with nonionic detergent and read in a spectrometer at an absorbance of 575 nm against a standard solution of chlorohaemin.[6,7] One evaluation gave encouraging results,[8] although another study showed a bias of 2.6% compared with the reference method, with nonlinearity in the relationship between haemoglobin concentration and absorbance at high and low haemoglobin concentrations.[9]

HAEMIGLOBINCYANIDE (CYANMETHAEMOGLOBIN) METHOD

The haemiglobincyanide (cyanmethaemoglobin) method is the internationally recommended method[2] for determining the haemoglobin concentration of blood. In some countries cyanide reagents are no longer available. The basis of the method is dilution of blood in a solution containing potassium cyanide and potassium ferricyanide. Haemoglobin, Hi and HbCO, but not SHb, are converted to HiCN. The absorbance of the solution is then measured in a spectrometer at a wavelength of 540 nm or in a photoelectric colorimeter with a yellow-green filter, such as Ilford 625, Wratten 74 (may be available on www.ebay.co.uk) or Horiba XF3415, 530QM30 (www.horiba.com).

Diluent

The original (Drabkin) reagent had a pH of 8.6. The following modified solution listed in Table 3-1, Drabkin-type reagent, as recommended by the International Committee (now Council) for Standardisation in Haematology (ICSH),[2] has a pH of 7.0–7.4. It is less likely to cause turbidity from precipitation of plasma proteins and requires a shorter conversion time (3–5 min) than the original Drabkin solution, but it has the disadvantage that the detergent causes some frothing.

The pH must be checked with a pH meter at least once a month. The diluent should be clear and pale yellow. When measured against water as a blank in a spectrometer at a wavelength of 540 nm, the absorbance must be zero. If stored at room temperature in a brown borosilicate glass bottle, the solution keeps for several months. If the ambient temperature is higher than 30°C, the solution should be stored in the refrigerator but brought to room temperature before use. It must not be allowed to freeze. The reagent must be discarded if it becomes turbid, if the pH is found to be outside the 7.0–7.4 range or if it has an absorbance other than zero at 540 nm against a water blank.

TABLE 3-1

DRABKIN-TYPE REAGENT

Reagent	Amount
Potassium ferricyanide (0.607 mmol/l)	200 mg
Potassium cyanide (0.768 mmol/l)	50 mg
Potassium dihydrogen phosphate (1.029 mmol/l)	140 mg
Nonionic detergent*	1 ml
Distilled or deionised water	To 1 litre

*Suitable nonionic detergents include Nonidet P40 substitute (Sigma–Aldrich; www.sigmaaldrich.com, Roche Diagnostics; http://lifescience.roche.com and other suppliers) or Triton X-100 (Sigma–Aldrich).

Haemiglobincyanide reference standard

With the advent of HiCN solution, which is stable for many years, other standards have become outmoded.[10] The ICSH[2] has defined specifications on the basis of a relative molecular mass (molecular weight) of human haemoglobin of 64 458 (i.e. 16 114 as the monomer) and a millimolar area absorbance (extinction coefficient) of 11.0 (that is, the absorbance at 540 nm of a solution containing 55.8 mg of haemoglobin iron per litre).

Some standards are prepared from ox blood, which has the same extinction coefficient but a molecular weight of 64 532 (16 133 as the monomer). These specifications have been widely adopted; a World Health Organisation (WHO) International Standard has been established and a comparable reference material is available from the ICSH (www.eurotrol.com). A new lot of the haemoglobincyanide or haemoglobin standard was released in 2008.[11] This replaces the previous lot and was produced using the same methodology previously specified by ICSH.[2] The current standard has an assigned concentration value of 574.2 (±5.1) mg/l or 35.63 (±0.32) µmol/l; the exact concentration is indicated on the label. The stability expectation of this standard is 15 years[11] but it will continue to be monitored on a twice-yearly basis over the lifetime of the lot. The haemoglobin standard provides a reference material from which both laboratory-based cell counters and point-of-care instruments calibrate their haemoglobin methods.[2]

The HiCN solution is dispensed in 10 ml sealed ampoules and is regarded as a dilution of whole blood. The original Hb that it represents is obtained by multiplying the figure stated on the label by the dilution to be applied to the blood sample. Thus, if the standard solution contains 800 mg (0.8 g) of haemoglobin per litre, it will have the same optical density as a blood sample containing

160 g/l of haemoglobin if diluted 1 to 200 or as one containing 200 g/l of haemoglobin if diluted 1 to 250. Within the Système International d'Unités (SI), Hb may be expressed as mass concentration as g/l (or g/dl) or in terms of substance concentration as μmol/l = g/l × 0.062. For clinical purposes, there are practical advantages in expressing Hb in mass concentration per litre or per decilitre (dl) and this is our recommendation.

The HiCN reference preparation is intended primarily for direct comparison with blood that is converted to HiCN.

Method

Make a 1 in 201 dilution of blood by adding 20 μl of blood to 4 ml of diluent. Stopper the tube containing the solution and invert it several times. Let the test sample stand at room temperature for at least 5 min (to ensure the complete conversion of haemoglobin to haemiglobincyanide) and then pour it into a cuvette and read the absorbance in a spectrometer at 540 nm or in a photoelectric colorimeter with a suitable filter (see above) against a reagent blank. The absorbance of the test sample must be measured within 6 h of its initial dilution. The absorbance of a commercially available HiCN standard (brought to room temperature if previously stored in a refrigerator) should also be compared with that of a reagent blank in the same spectrometer or photoelectric colorimeter as was used for the patient sample. The standard should be kept in the dark and, to ensure that contamination is avoided, any unused solution should be discarded at the end of the day on which the ampoule is opened.

Calculation of haemoglobin concentration

$$\text{Hb}(\text{g/l}) = \frac{{}^{*}\text{A}^{540}\text{ of test sample}}{\text{A}^{540}\text{ of standard}} \times \text{Conc. of standard} \times \frac{\text{Dilution factor}\,(201)^{\dagger}}{1000}$$

Preparation of standard graph and standard table

When many blood samples are to be tested, it is convenient to read the results from a standard graph or table relating absorbance readings to Hb in g/l for the specific instrument. This graph should be prepared each time a new photometer is put into use or when a bulb or other component is replaced. It can be prepared as follows.

Prepare five dilutions of the HiCN reference standard (or equivalent preparation) (brought to room temperature) with the cyanide–ferricyanide reagent according to Table 3-2. Because the graph will be used to determine the haemoglobin measurements, it is essential that the dilutions are performed accurately.

TABLE 3-2

DILUTIONS OF HAEMIGLOBINCYANIDE (HiCN) REFERENCE SOLUTION FOR PREPARATION OF STANDARD GRAPH

Tube	Haemoglobin* (%)	HiCN Volume (ml)	Reagent Volume (ml)
1	100 (full strength)	4.0 (neat)	None
2	75	3.0	1.0
3	50	2.0	2.0
4	25	1.0	3.0
5	0	None	4.0 (neat)

*As a percentage of haemoglobin in reference solution.

The haemoglobin concentration of the reference preparation in each tube should be plotted against the absorbance measurement. For example, if the label on the reference preparation states that it contains 800 mg/l (i.e. 0.8 g/l) and the method for haemoglobin measurement uses a dilution of 1:201, the respective haemoglobin concentrations of tubes 1–5 would be 160, 120, 80, 40 and 0 g/l.

Using linear graph paper, plot the absorbance values (formerly called optical density) on the vertical axis and the haemoglobin values on the horizontal axis. In some instruments, measurements are read as percentage transmittance; in this case, use semilogarithmic paper with the transmittance recorded on the vertical or log scale. The points should fit a straight line that passes through the origin. Providing that the standard has been correctly diluted, this provides a check that the calibration of the photometer is linear. From the graph, it is possible to construct a table of readings and corresponding haemoglobin concentration values. This is more convenient than reading values from a graph when large numbers of measurements are made. It is important that the performance of the instrument does not vary and that its calibration remains constant in relation to haemoglobin measurements. To ensure this, the reference preparation should be measured at frequent intervals, preferably with each batch of blood samples.

The main advantages of the HiCN method for haemoglobin determination are that it allows direct comparison with the reference standard and that the readings need not be made immediately after dilution so batching of samples is possible. It also has the advantage that all forms of haemoglobin, except SHb, are readily converted to HiCN.

The rate of conversion of blood containing HbCO is markedly slow. This difficulty can be overcome by prolonging the reaction time to 30 min before reading the results.[12] The difference between the 5 and 30 min readings can be used as a semiquantitative method for estimating the percentage of HbCO in the blood.

*Absorbance of a solution containing 5.8 mg of haemoglobin iron per litre at 540 nm.

†Or 251 if initial dilution is 250 (i.e. 20 μl of blood to 5 ml of reagent).

As referred to earlier, lauryl sulphate[5] or sodium azide[3] can be used as nonhazardous substitutes for potassium cyanide. However, no stable standards are available for these methods so a sample of blood that has first had a haemoglobin value assigned by the HiCN method needs to be used as a secondary standard.

Abnormal plasma proteins or a high leucocyte count may result in turbidity when the blood is diluted in the Drabkin-type reagent. The turbidity can be avoided by centrifuging the diluted sample or by increasing the concentration of potassium dihydrogen phosphate to 33 mmol/l (4.0 g/l).[13]

DIRECT SPECTROMETRY

The haemoglobin concentration of a diluted blood sample can be determined by spectrometry without the need for a standard, provided that the spectrometer has been correctly calibrated. The blood is diluted 1:201 (or 1:251) with cyanide–ferricyanide reagent (see p. 20) and the absorbance is measured at 540 nm. Haemoglobin concentration is calculated as follows:

$$\mathrm{Hb}(\mathrm{g/l}) = \frac{A^{540}\,\mathrm{HiCN} \times 16\,114 \times \text{Dilution factor}}{11.0 \times d \times 1000}$$

$$\text{or } \mathrm{Hb}(\mu\mathrm{mol/l}) = \frac{A^{540}\,\mathrm{HiCN} \times \text{Dilution factor}}{110 \times d \times 1000}$$

where A^{540} = absorbance of solution at 540 nm; 16 114 = monomeric molecular weight of haemoglobin; dilution = 201 when 20 ml of blood are diluted in 4 ml of reagent; 11.0 = millimolar extinction coefficient; d = layer thickness in cm; and 1000 = conversion of mg to g.

When assigning a value to a haemoglobin solution that may be used as a reference preparation, it is necessary first to calibrate the spectrometer. This requires checking wavelength with a holmium oxide filter, absorbance with a set of calibrated neutral density filters and stray light with a neutral density filter at 220 nm (National Physical Laboratory, Teddington, UK, www.npl.co.uk). Matched optical or quartz glass cuvettes with a transmission difference of <1% at 200 nm should be used. Subsequently, the calibration of the spectrophotometer can be checked by verifying that it gives an accurate reading of the HiCN standard. Slight deviations from the expected A^{540} HiCN value for the standard may be used to correct the results of test samples for a bias in measurement.[2]

DIRECT READING PORTABLE HAEMOGLOBINOMETERS

Colour comparators

These are simple clinical devices that compare the colour of blood against a range of colours representing haemoglobin concentrations. They are intended for anaemia screening in the absence of laboratory facilities and are described in Chapter 26.

Portable haemoglobinometers

Portable haemoglobinometers have a built-in filter and a scale calibrated for direct reading of Hb in g/l or g/dl. They are generally based on the HbO_2 method. A number of instruments are now available that use a light-emitting diode of appropriate wavelength; they are standardised to give the same results as with the HiCN method.

The HemoCue system (www.radiometer.co.uk/en-gb/products/hemocue) is a well-established method for haemoglobinometry. It consists of a precalibrated, portable, battery-operated spectrometer; no dilution is necessary because blood is run by capillary action directly into a cuvette containing sodium nitrite and sodium azide, which convert the haemoglobin to azidemethaemoglobin. The absorbance is measured at wavelengths of 565 and 880 nm. Measurements are not affected by high levels of bilirubin, lipids or white cells and the HemoCue system is sufficiently reliable for use as a laboratory instrument; it is easy for nontechnical personnel to operate and is thus also suitable for use at point-of-care sites. The cuvettes must be stored in a container with a drying agent and kept within the temperature range of 15 to 30°C. Some devices are now available that use reagent-free cuvettes that will not deteriorate in adverse climatic conditions.[14] The manufacturers of HemoCue have also released a portable system that measures both Hb and the white blood cell count (WBC), the HemoCue WBC.[15]

Chempaq (Chempaq A/s, Farum, Denmark; http://chempaq-dk.business1.com/) produces two different portable multiplatform haematology analysers that use impedance cell counting and measurement of Hb by a spectrophotometric method on 20 µl of blood. The Chempaq XBC uses a disposable cartridge to measure three different test profiles, Hb alone or WBC, with three-part differential, plus Hb or Hb with red blood cell count (RBC), haematocrit (Hct), mean cell volume (MCV), mean cell haemoglobin (MCH) and mean cell haemoglobin concentration (MCHC). The Chempaq XDM701 uses the same principles but also reports a platelet count.

The DiaSpect Haemoglobinometry system (www.diaspect.eu) measures Hb in unaltered whole blood in a special plastic cuvette that also serves as the sampling device.[16] The instrument is a portable spectrophotometer powered by 3.6 V integrated lithium-ion rechargeable batteries or by a 100–240 V adaptor. Because the cuvettes do not contain any reagents, they are not affected by temperature or humidity and no special storage conditions are required. They have a shelf life of at least 2 years. Haemoglobin fractions are measured from absorbance wavelengths between 400 and 800 nm. A patented method eliminates the impact of scattering from

the blood cells while possible background turbidity from interfering substances is measured and compensated for at high wavelength. The results are displayed in <5 s. An accuracy within ±3 g/l for measurements between 10 and 200 g/l has been shown.

Noninvasive screening tests

Methods have been developed for using near-infrared spectroscopy at body sites, mainly a finger, to identify the spectral pattern of haemoglobin in an underlying blood vessel and derive a measurement of Hb. Several studies have shown an approximate correlation with blood haemoglobinometry.[17,18]

RANGE OF HAEMOGLOBIN CONCENTRATION IN HEALTH

See Chapter 2, Tables 2-1, 2-2 and 2-3, for ranges for Hb in health. It should be noted that there are gender differences, diurnal variations and environmental and physiological factors that must also be taken into account.

PACKED CELL VOLUME OR MICROHAEMATOCRIT

The packed cell volume (PCV) can be used as a simple screening test for anaemia, as a reference method for calibrating automated blood count systems and as a rough guide to the accuracy of Hb measurements. The PCV × 1000 is about three times the Hb expressed in g/l (e.g. 0.36 × 1000 is approximately 120 × 3). In conjunction with estimations of Hb and RBC, PCV can be used in the calculation of red cell indices. However, its use in under-resourced laboratories may be limited by the need for a specialised centrifuge and a reliable supply of capillary tubes.

The microhaematocrit method for determining the PCV[19] is carried out on blood contained in capillary tubes 75 mm in length and having an internal diameter of about 1 mm. The tubes may be plain for use with anticoagulated blood samples or coated inside with 1 international unit (iu) of heparin for the direct collection of capillary blood. The centrifuge used for the capillary tubes provides a centrifugal force of circa (*c.*) 12 000 *g* and 5 min centrifugation results in a constant PCV. When the PCV is >0.5, it may be necessary to centrifuge for a further 5 min.

Allow blood from a well-mixed specimen, or from a free flow of blood by skin puncture, to enter the tube by capillarity, leaving at least 15 mm unfilled. Then seal the tube by a plastic seal (e.g. Cristaseal, Hawksley, Lancing, Sussex; www.hawksley.co.uk). Sealing the tube by heating is not recommended because the seals tend to be tapered and there is the likelihood of lysis. After centrifugation for 5 min, measure the proportion of cells to the whole column (i.e. the PCV) using a reading device.

Accuracy of microhaematocrit

The microhaematocrit method has an adequate level of accuracy and precision for clinical utility.[20] However, attention must be paid to a number of factors that may produce an inaccurate result.

Anticoagulant

K_2-EDTA is recommended, because K_3-EDTA causes shrinking of the red cells, reducing the PCV by about 2%. Anticoagulant concentration in excess of 2.2 mg/ml may also cause a falsely low PCV as a result of cell shrinkage.

Blood sample

Because the PCV gradually increases with storage, the test should be performed within 6 h of collecting the blood sample, but a delay of up to 24 h is acceptable if the blood is kept at 4°C.

Failure to mix the blood sample adequately will produce an inaccurate result. The degree of oxygenation of the blood also affects the result because the PCV of venous blood is ≈2% higher than that of fully aerated blood (which has lost CO_2 and taken up O_2).[21] To ensure adequate oxygenation and sample mixing, the free air space above the sample should be >20% of the container volume.

Capillary tubes

Variation of the bore of the tubes may cause serious errors if they are not within the narrow limits of defined specifications that should be met by manufacturers: length 75 ± 0.5 mm; internal diameter 1.07–1.25 mm; wall thickness 0.18–0.23 mm; and bore taper not exceeding 2% of the internal diameter over the entire length of the tube.[20]

Centrifuge

Centrifuges should be checked at intervals (at least annually) by a tachometer for speed and by a stopwatch for timer accuracy. Efficiency of packing should also be tested by centrifuging samples of normal and polycythaemic blood for varying times from 5 to 10 min to determine the minimum time for complete packing of the red cells.

Reading

The test should be read as soon as possible after centrifugation because the red cells begin to swell and the interface becomes progressively more indistinct. To avoid errors in reading with the special reading device, a magnifying glass should be used. White cells and platelets (the buffy coat) must be excluded as far as possible from the reading of the PCV. If a special reading device is not available, the ratio of red cell column to whole column can be calculated from measurements obtained by placing the tube against arithmetic graph paper or against a ruler.

Plasma trapping

The amount of plasma trapped between red cells, especially in the lower end of the red cell column, and red cell dehydration during centrifugation generally counterbalance each other and the error caused by trapped plasma is usually not more than 0.01 PCV units. Thus, in routine practice, it is unnecessary to correct for trapped plasma, but if the PCV is required for calibrating a blood cell analyser or for calculating blood volume, the observed PCV should be reduced by a 2% correction factor after it has been centrifuged for 5 min or for 10 min with polycythaemic blood.[22] It is, however, preferable to use the surrogate reference method.[23] Plasma trapping is increased in macrocytic anaemias,[24] spherocytosis, thalassaemia, hypochromic anaemias and sickle cell anaemia;[25] it may be as high as 20% in sickle cell anaemia if all the cells are sickled.[24]

International Council for Standardisation in Haematology reference method

Haemoglobin concentration is measured by the routine method on blood specimens with a range of Hb samples. Samples of the same specimens are then taken into special borosilicate glass capillary tubes, which are centrifuged for 5 min or longer to achieve full red cell packing. The tubes are then broken at the midpoint of the packed red cells, blood is extracted with a micropipette and its haemoglobin concentration is measured. PCV is calculated as the ratio of the Hb of whole blood to that of the packed cells. This method[26] is appropriate for instrument and reagent manufacturers, but it is time-consuming, is potentially unsafe and requires significant expertise, which makes it impractical for occasional use in routine laboratories. Accordingly, the International Council for Standardisation in Haematology has developed a 'surrogate reference method'.[23]

Surrogate reference method

Equipment

- Standard microhaematocrit centrifuge
- Borosilicate glass capillary tubes with the following specifications: length 75 ± 0.5 mm; inner diameter 1.55 ± 0.085 mm; outer diameter 1.9 ± 0.085 mm (Drummond Scientific, Broomall, PA 19008: Catalogue #1–000–751C; www.drummondsci.com)
- Capillary tube holder consisting of a 75 × 25 mm glass slide mounted on a 75 × 50 mm slide
- Microscope fitted with a vernier scale and ocular crossbar

Method

1. Take up duplicate samples of well-mixed blood into the specified capillary tubes and centrifuge as described on page 23.
2. Promptly remove the tubes from the centrifuge, position each in turn against the edge of the 25 mm slide and place this on the stage of the microscope.
3. Ensure that the capillary tube is aligned in a true horizontal position relative to the field of view and, using low power, note on the vernier scale the lengths of the tube at the interfaces of (a) red cells and seal, (b) red cells and leucocytes and (c) plasma and air.
4. Calculate the spun PCV = $(b - a)/(c - a)$. Determine the acceptability of paired measurements – duplicates must agree within 0.007 units; if they do not, the paired tests must be repeated.
5. Calculate the surrogate reference PCV from the formula:

$$\frac{\text{Spun PCV} - 0.011.9}{0.9736}$$

This formula applies only to the specified capillary tubes; other tubes require specific validation by the ICSH reference method[22] so that an appropriate formula can be derived. If the surrogate reference measurements are to be used to validate equipment or methods, a minimum of six different blood samples are required, at least two in each of the ranges of PCV 0.20–0.25, 0.40–0.45 and 0.60–0.65. If necessary, the PCV of normal samples may be adjusted by the appropriate addition or removal of autologous plasma.

Range of packed cell volume in health

See Chapter 2, Tables 2-1, 2-2 and 2-3.

MANUAL CELL COUNTS AND RED CELL INDICES

The principles of manual cell counts, the use of the haemocytometer counting chamber for manually counting white cells and platelets and the limitations of these measurements are described in Chapter 26.

An accurate RBC enables the MCV and MCH to be calculated. In most laboratories, where these indices are provided by an automated system (see p. 35), they are of considerable clinical importance and are widely used in the classification of anaemia. Where automated analysers are not used, manual RBCs (and consequently, calculations of these red cell indices) are so imprecise and time-consuming that they have become obsolete.

The only measurement that can be obtained with reasonable accuracy by manual methods is MCHC because this is derived from Hb and PCV from the following formula:

$$\text{MCHC}(\text{g/l}) = \text{Hb}(\text{g/l}) \div \text{PCV}(\text{l/l}).$$

Range of MCHC in health

See Chapter 2, Tables 2-1, 2-2 and 2-3.

MANUAL DIFFERENTIAL LEUCOCYTE COUNT

Differential leucocyte counts are now usually performed, at least on essentially normal samples, by automated instruments. They can also be performed by visual examination of blood films that are prepared on slides by the spread or 'wedge' technique. Unfortunately, even in well-spread films, the distribution of the various cell types is not totally random (see below).

For a reliable differential count on films spread on slides, the film must not be too thin and the tail of the film should be smooth. To achieve this, the film should be made with a rapid movement using a smooth glass spreader. This should result in a film in which there is some overlap of the red cells, diminishing to separation near the tail, and in which the white cells in the body of the film are not too badly shrunken. If the film is too thin or if a rough-edged spreader is used, many of the white cells, perhaps even 50% of them, accumulate at the edges and in the tail (Fig. 3-1). Moreover, a gross qualitative irregularity in distribution is the rule: polymorphonuclear neutrophils and monocytes predominate at the margins and the tail; lymphocytes predominate in the middle of the film (Fig. 3-2). This separation probably depends on differences in stickiness, size and specific gravity of the different types of cell.

Differences in distribution of the various types of cell are probably always present to a small extent even in well-made films. Various systems for performing the differential count have been advocated, but none can compensate for the gross irregularities in distribution in a badly made film. On well-made films, the following technique of counting is recommended.

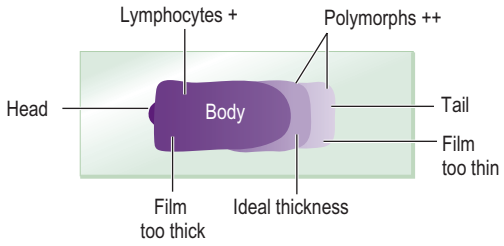

FIGURE 3-2 Schematic drawing of a blood film made on a slide. The film has been spread from left to right. An indication is given of the way the white blood cells are distributed.

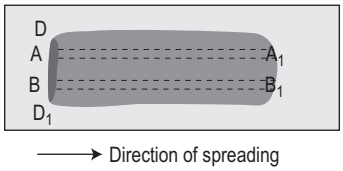

FIGURE 3-3 Schematic drawing illustrating the longitudinal method of performing differential leucocyte counts. The original drop of blood spreads out between spreader and slide ($D - D_1$). The film is made in such a way that representative strips of films, such as $A - A_1$ and $B - B_1$, are formed from blood originally at A and B, respectively. To perform an accurate differential count, all the leucocytes in one or more strips, such as $A - A_1$ and $B - B_1$, should be inspected and classified.

Method

Count the cells using a ×40 objective in a strip running the whole length of the film. Avoid the lateral edges of the film. Inspect the film from the head to the tail and if fewer than 100 cells are encountered in a single narrow strip, examine one or more additional strips until at least 100 cells have been counted. Each longitudinal strip represents the blood drawn out from a small part of the original drop of blood when it has spread out

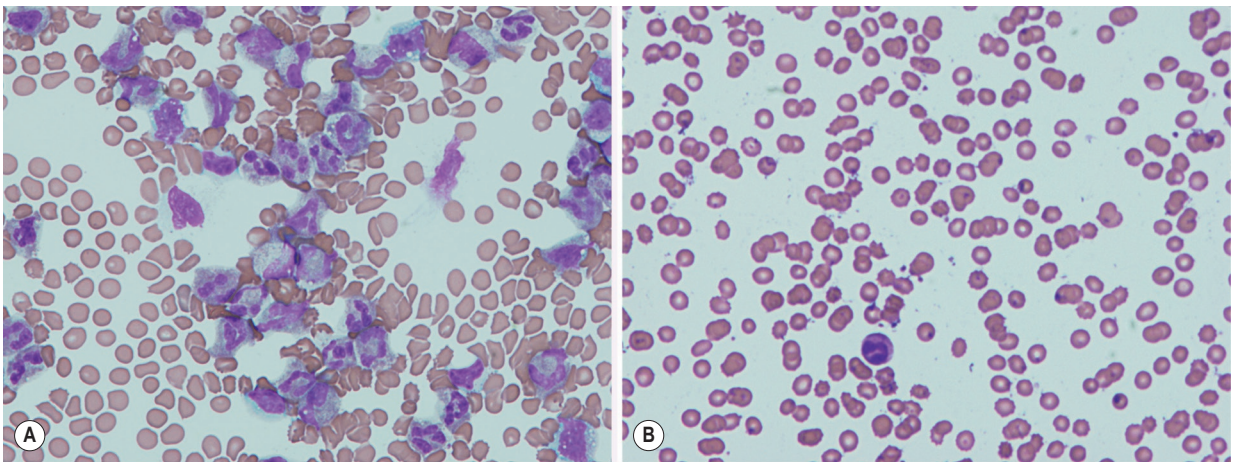

FIGURE 3-1 Badly spread film. Two areas of a badly spread film from a patient with a white blood cell count of 20×10^9/l showing **(A)** many leucocytes in the tail and **(B)** very few leucocytes in body of film.

between the slide and spreader (Fig. 3-3). If all the cells are counted in such a strip, the differential totals will closely approximate the true differential count. This technique is liable to error if cells in the thick part of the film cannot be identified; also, it does not allow for any excess of neutrophils and monocytes at the edges of the film, but this preponderance is slight in a well-made film and in practice makes little difference to the result.

This technique is easy to carry out; with high counts ($10–30 \times 10^9$/l), a short, 2–3 cm film is desirable. In patients with very high counts (as in leukaemia), the method has to be abandoned and the cells should be counted in any well-spread area where the cell types are easy to identify. Other systems of counting, such as the 'battlement' count, are more elaborate but may minimise error owing to variation of distribution of cells between the centre and the edge of the film. The results of the differential count can be recorded using a multiple manual register or they can be directly entered onto a computer.

The variance of the differential count depends not only on artefactual differences in distribution owing to the process of spreading but also on 'random' distribution; together they are by far the most important causes of unreliable differential counts. The random distribution means that, if a total of 100 cells are counted, with a true neutrophil proportion of 50%, the range (±2SD) within which 95% of the counts will fall is of the order of ±14% (i.e. 36%–64%) neutrophils. A 200-cell count can provide a more accurate estimate; in the previous example, the ±2SD range will be about 40% to 60%. In a 500-cell count, the range would be reduced to 44%–56% neutrophils. In practice, a 100-cell count is recommended as a routine procedure. However, if abnormal cells are present in small numbers, they are more likely to be detected when 200–500-cell counts are performed than with a 100-cell count. When quantifying the proportion of blast cells when a myelodysplastic syndrome or acute myeloid leukaemia is suspected, a minimum of 200 cells must be counted.

BASOPHIL AND EOSINOPHIL COUNTS

A manual basophil or eosinophil count may be necessary to validate an automated count or when abnormal characteristics of the cells render an automated count unreliable (e.g. with degranulated eosinophils). Count the percentage of eosinophils or basophils in a differential count of all the leucocytes on a stained blood film. If the cells of interest are infrequent, a 500-cell differential count should be performed. If fewer than 500 cells are seen in the film, continue the count on a second film. However, if the eosinophil count is markedly elevated a conventional 100-cell count will suffice for most purposes. Calculate the eosinophil or basophil count per litre from the total leucocyte count. It is essential to have thin, preferably short, films with the leucocytes evenly distributed throughout the film and readily identified (see p. 25).

Range of eosinophil count in health

See Chapter 2, Tables 2-1, 2-2 and 2-3.

There is normally considerable diurnal variation in the eosinophil count and differences amounting to as much as 100% have been recorded. The lowest counts are found in the morning (10 AM to noon) and the highest at night (midnight to 4 AM).[27,28] For a review of the causes of eosinophilia, see Bain.[29]

Range of basophil count in health

See Chapter 2, Table 2-1.

Gilbert and Ornstein[30] reported a 95% distribution in normal subjects of $0.01–0.08 \times 10^9$/l. There are no age or gender differences, although serial counts have shown lower levels during ovulation.[31]

REPORTING THE DIFFERENTIAL LEUCOCYTE COUNT

The differential count, expressed as the percentage of each type of cell, should be related to the total leucocyte count and the results should be reported in absolute numbers ($\times 10^9$/l). The only time that the percentage of a cell type is required is in the diagnosis and classification of acute myeloid leukaemia, the myelodysplastic syndromes and the overlap myelodysplastic/myeloproliferative neoplasms. Myelocytes and metamyelocytes, if present, are recorded separately from neutrophils. Band (stab) cells are generally included in the neutrophil count. They normally constitute <6% of the neutrophils; an increase may point to an inflammatory process even in the absence of an absolute leucocytosis.[32] However, the band cell count is imprecise and, although it is sometimes recommended in infants, it has been found to be unhelpful in predicting occult bacteraemia even in this group.[33]

Correcting the count for nucleated red blood cells

When nucleated red blood cells (NRBCs) are present, they may be included in the total WBC, which is then actually a 'total nucleated cell count' (TNCC). In this instance they should also be included in the differential count, as a percentage of the TNCC and reported in absolute numbers ($\times 10^9$/l) in the same way as the different types of leucocyte. If they are present in significant numbers, the TNCC should be corrected to obtain the true total WBC. Thus, for example, if total WBC is 8.0×10^9/l and the percentage of NRBCs on the differential count is 25%, then

$$\text{Corrected WBC} = 8 - (8 \times 25/100) = 6 \times 10^9/1.$$

In other instances an automated instrument produces a true WBC that does not include any NRBCs; NRBCs are enumerated and expressed as an absolute count. The absolute counts of different leucocyte types can then be calculated from the manual differential count and the true WBC.

Care should be taken to differentiate small lymphocytes from nucleated red blood cells (e.g. Chapter 5, Fig. 5-64).

Reference differential white cell count

A reference method is required to validate the accuracy of automated systems[34] (described later). The method that has been used widely for this purpose is essentially similar to the routine manual procedure on stained blood films, but to ensure adequate precision a 200-cell count is carried out by two independent observers, each on two films prepared from the same sample. However, this is still too imprecise for cells with a low frequency; attempts have been made to establish a reference method using flow cytometry with specific monoclonal-antibody labelling of the specific cell types including immature leucocytes.[35,36] More recent flow cytometric protocols also include counting of blast cells and reactive lymphocytes, differentiation between B and T lymphocytes and counting of NRBCs.[37,38]

Range of differential white cells in health

See Chapter 2, Tables 2-1, 2-2 and 2-3.

PLATELET COUNT

The method for manual counting of platelets using a counting chamber is described on page 554. If an RBC by a semiautomated counter is available, it is possible to obtain an approximation of the platelet count by counting the proportion of platelets to red cells in a thin part of a film made from an EDTA-anticoagulated blood sample, using the ×100 oil-immersion objective and, if possible, eyepieces provided with an adjustable diaphragm, as for a reticulocyte count.

Range of platelet count in health

See Chapter 2, Tables 2-1, 2-2 and 2-3.

RETICULOCYTE COUNT

Reticulocytes are juvenile red cells; they contain remnants of the ribosomal ribonucleic acid (rRNA) that was present in larger amounts in the cytoplasm of the nucleated precursors from which they were derived. Ribosomes have the property of reacting with certain basic dyes such as azure B, brilliant cresyl blue or New methylene blue (see below) to form a blue or purple precipitate of granules or filaments.

This reaction takes place only in vitally stained unfixed preparations. Stages of maturation can be identified by their morphological features. The most immature reticulocytes are those with the largest amount of precipitable material; in the least immature, only a few dots or short strands are seen. Reticulocytes can be classified into four groups, ranging from the most immature reticulocytes, with a large clump of reticulin (group I), to the most mature, with a few granules of reticulin (group IV) (Fig. 3-4).

If a blood film is allowed to dry and is afterwards fixed with methanol, reticulocytes appear as polychromatic red cells, being diffusely basophilic if the film is stained with one of the basic dyes.

Complete loss of basophilic material probably occurs in the bloodstream and, particularly, in the spleen after the cells have left the bone marrow.[39] This maturation is thought to take 2–3 days, of which about 24 h are spent in the circulation.

The number of reticulocytes in the peripheral blood is a fairly accurate reflection of erythropoietic activity, assuming that the reticulocytes are released normally from the bone marrow and that they remain in circulation for the normal time period. These assumptions are not always valid because an increased erythropoietic stimulus leads to premature release into the circulation. The average maturation time of these so-called 'stress' or stimulated reticulocytes may be as long as 3 days. In such cases, a higher than normal proportion of immature reticulocytes will be found in the circulation. A more precise assessment of reticulocyte maturation is possible by quantitative flow cytometry of their RNA content. Nevertheless, adequate information is usually obtained from a simple reticulocyte count recorded either as a percentage of the red cells or, preferably, when the RBC is known, as an absolute number per litre. When there is severe anaemia, the reticulocyte count can be corrected for the anaemia and expressed as a reticulocyte index.[40]

$$\text{Reticulocyte index} = \text{Observed reticulocyte\%} \times \frac{\text{Measured Hb or PCV}}{\text{Appropriate normal Hb or PCV}}$$

Reticulocyte stains and count

Better and more reliable results are obtained with New methylene blue than with brilliant cresyl blue. New methylene blue is chemically different from methylene blue, which is a poor reticulocyte stain. New methylene blue stains the reticulofilamentous material in reticulocytes more deeply and more uniformly than does brilliant cresyl blue, which varies from sample to sample in its staining ability. Azure B is a satisfactory substitute for New methylene blue; it has the advantage that the dye does not precipitate and it is available in pure form.[41] It is used in the same concentration and the staining procedure is the same as with New methylene blue.

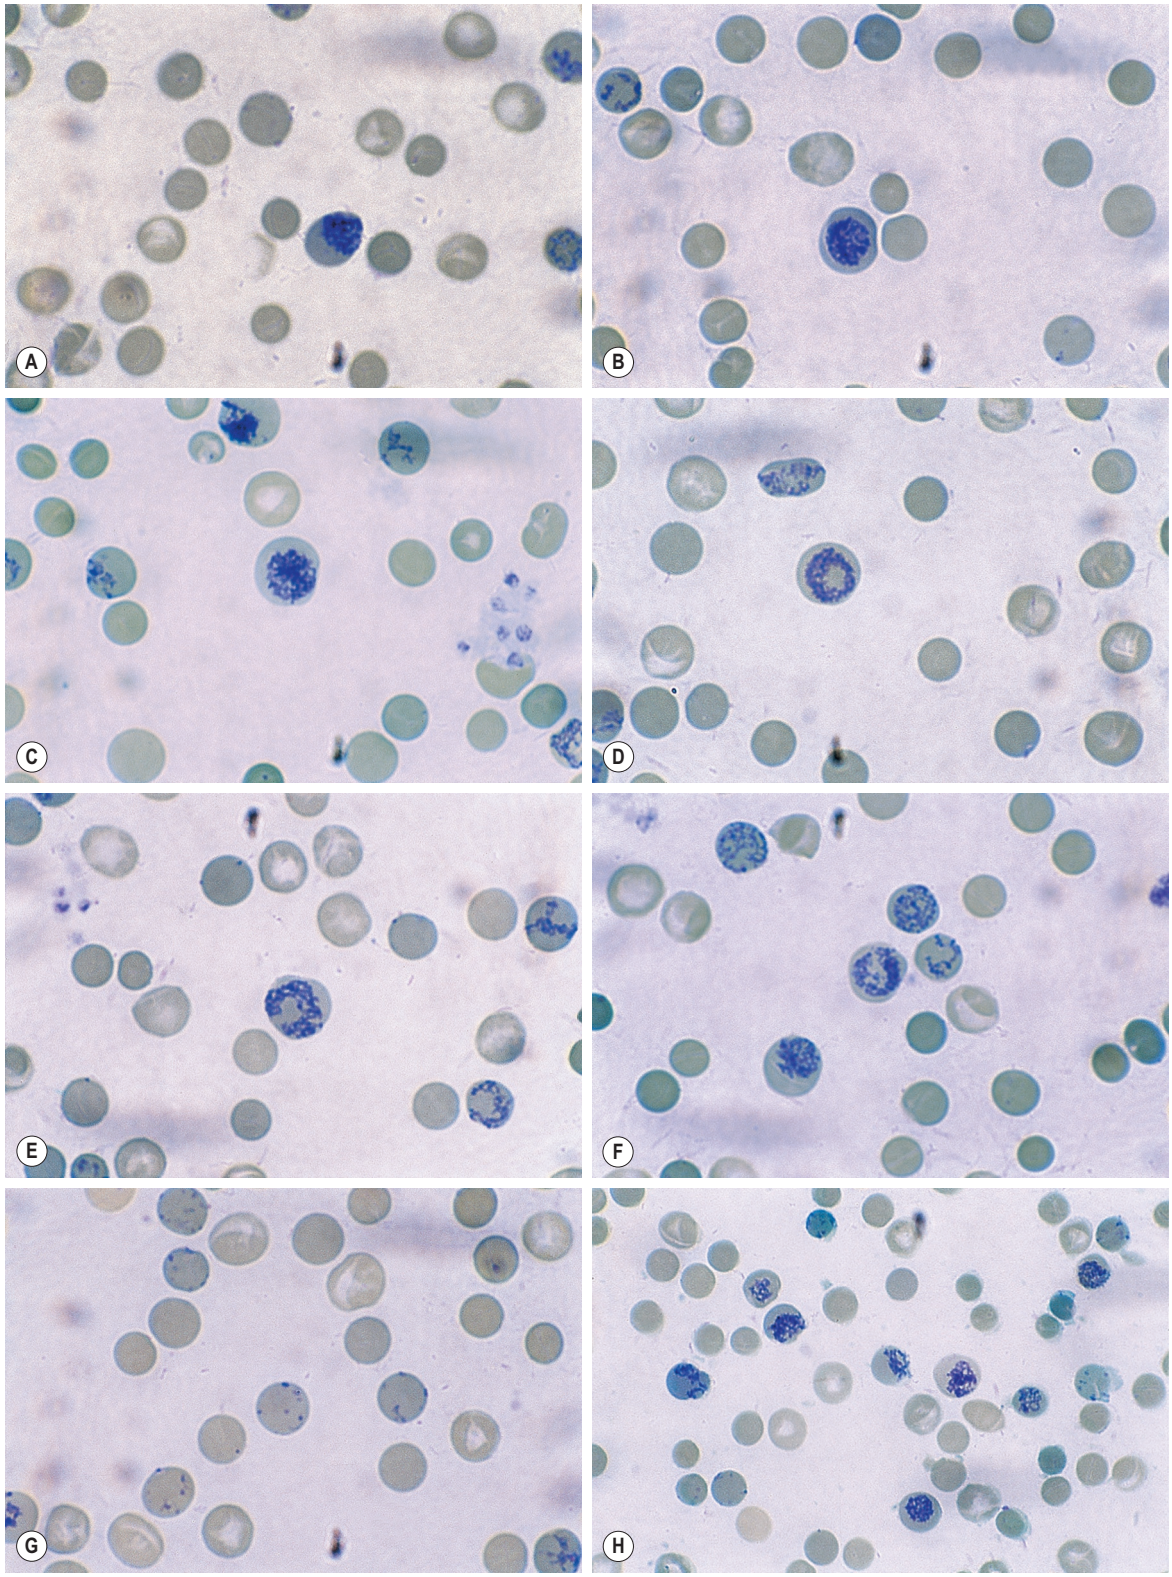

FIGURE 3-4 Photomicrographs of reticulocytes showing stages of maturation. (A, B) Most immature (group I); **(C, D)** intermediate (group II); **(E, F)** later-stage intermediate (group III); **(G)** most mature (group IV); and **(H)** haemolytic anaemia, stained supravitally by New methylene blue.

Staining Solution

Dissolve 1.0 g of New methylene blue (CI 52030) (www.sigmaaldrich.com) or azure B (CI 52010) (www.sigma-aldrich.com) in 100 ml of 3% trisodium citrate–saline solution (30 g of sodium citrate in 1 l of saline). Filter once the dye has been dissolved.

Method

Deliver 2 or 3 drops of the dye solution into a 75 × 10 mm plastic tube by means of a plastic Pasteur pipette. Add 2–4 volumes of the patient's EDTA-anticoagulated blood to the dye solution and mix. Keep the mixture at 37°C for 15–20 min. Resuspend the red cells by gentle mixing and make films on glass slides in the usual way. When dry, examine the films without fixing or counterstaining.

The exact volume of blood to be added to the dye solution for optimal staining depends on the Hb. A larger proportion of anaemic blood, and a smaller proportion of polycythaemic blood, should be added than of normal blood. In a successful preparation, the reticulofilamentous material should be stained deep blue and the nonreticulated cells should be stained diffuse shades of pale greenish blue. Films should not be counterstained. The reticulofilamentous material is not better defined after counterstaining and precipitated stain overlying cells may cause confusion. Moreover, Heinz bodies will not be visible in fixed and counterstained preparations. If the stained preparation is examined under phase contrast, both the mature red cells and the reticulocytes are well defined. By this technique, late reticulocytes characterised by the presence of remnants of filaments or threads are readily distinguished from cells containing inclusion bodies. Satisfactory counts may be made on blood that has been allowed to stand (unstained) for as long as 24 h, although the count will tend to decrease after 6–8 h unless the blood is kept at 4°C.

Counting reticulocytes

An area of film should be chosen for the count where the cells are undistorted and where the staining is good. A common fault is to make the film too thin; however, the cells should not overlap. To count the cells, use the ×100 oil-immersion objective and, if possible, eyepieces provided with an adjustable diaphragm. If eyepieces with an adjustable diaphragm are not available, a paper or cardboard diaphragm, in the centre of which has been cut a small square with sides about 4 mm in length, can be inserted into an eyepiece and used as a less convenient substitute.

The counting procedure should be appropriate to the number of reticulocytes present. Very large numbers of cells have to be surveyed if a reasonably precise count is to be obtained when only small numbers of reticulocytes are present. When the count is <10%, a convenient method is to survey successive fields until at least 100 reticulocytes have been counted and to count the total red cells in at least 10 fields to determine the average number of red cells per field.

Calculation

Number of reticulocytes in n fields = x
Average number of red cells per field = y
Total number of red cells in n fields = $n \times y$
Reticulocyte percentage = $[x \div (n \times y)] \times 100$
Absolute reticulocyte count = % × RBC

Thus, when the reticulocyte percentage is 3.3 and the RBC is 5×10^{12}/l, the absolute reticulocyte count per litre is as follows: $(3.3/100) \times 5 \times 10^{12} = 165 \times 10^{9}$.

It is essential that the reticulocyte preparation be well spread to ensure an even distribution of cells in successive fields.

When the reticulocyte count exceeds 10%, only a relatively small number of cells will have to be surveyed to obtain a standard error of 10%.

An alternative method is based on the principle of balanced sampling, using a Miller ocular (Graticules Ltd, Tonbridge, UK; www.pyser-sgi.com). This is an eyepiece giving a square field, in the corner of which is a smaller ruled square, one-ninth the area of the total square (Fig. 3-5). Reticulocytes are counted in the large square and the total number of red cells is counted in the small square.

The number of fields that should be surveyed to obtain a desired degree of precision depends on the proportion of reticulocytes (Table 3-3).

It is essential that the reticulocyte preparation be well spread and well stained. Other important factors that affect the accuracy of the count are the visual acuity and patience of the observer and the quality and resolving power of the microscope. The most accurate counts are carried out by a conscientious observer who has no knowledge of the supposed reticulocyte level, thus eliminating the effect of conscious or unconscious bias.

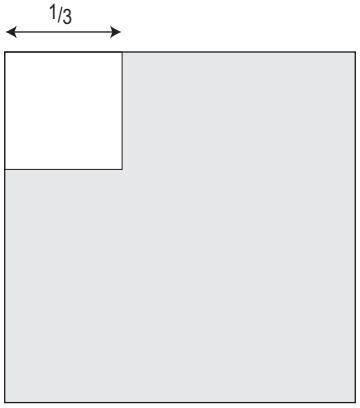

FIGURE 3-5 Miller ocular.

TABLE 3-3

PRECISION OF RETICULOCYTE COUNTS WITH MILLER OCULAR

Reticulocytes		Standard Error (σ)*		
Percentage	**Proportion *(p)***	**2%**	**5%**	**10%**
1	0.01	27 500	4400	1100
2	0.02	13 600	2180	550
5	0.05	5280	845	210
10	0.10	2500	400	100
25	0.25	835	135	35

*Columns 3 to 5 indicate the total number of red cells to be counted *in the small squares* so as to give the required standard error at different reticulocyte levels. It is derived from the following equation: $\sigma = \sqrt{p(1-p)/\lambda}$, where p = the number of reticulocytes in n large squares ÷ (the number of red cells in n small squares × f); f = the ratio of large to small squares (i.e. 9); and λ = the approximate total number of cells in n large squares.

Differentiating between reticulocytes and other red cell inclusions

The decision as to what is and what is not a reticulocyte may be difficult because the most mature reticulocytes contain only a few dots or threads of reticulofilamentous material. Fortunately, in well-stained preparations viewed under the light microscope, the Pappenheimer (iron-containing) type of granular material – usually present as a single small dot, less commonly as multiple dots – stains a darker shade of blue than does the reticulofilamentous material of the reticulocyte. As described earlier, phase contrast will help to distinguish them. If there is any doubt, Pappenheimer bodies can be identified by overstaining the film for iron by Perls reaction.

Haemoglobin H undergoes denaturation in the presence of New methylene blue, resulting in round inclusion bodies that stain greenish blue (see Fig. 14-4). These can be easily differentiated from reticulofilamentous material (Fig. 3-4).

Heinz bodies are also stained by New methylene blue, but they stain a lighter shade of blue than the reticulofilamentous material of reticulocytes and stain well with methyl violet (Fig. 15-5).

Fluorescence methods for performing a reticulocyte count

Reticulocytes can be counted manually by fluorescence microscopy on appropriately stained films.[42] Add 1 volume of acridine orange solution (50 mg/100 ml of 9 g/l NaCl) to 1 volume of blood. Mix gently for 2 min; make films on glass slides, dry rapidly and examine with a fluorescence microscope. RNA gives an orange–red fluorescence, whereas nuclear material (deoxyribonucleic acid, DNA) fluoresces yellow. Although the amount of fluorescence is proportional to the amount of RNA, the brightness and colour of the fluorescence fluctuate and the preparation quickly fades when exposed to light; also, it requires a special fluorescence microscope. It is thus not suitable for routine use for reticulocyte counting.

Fluorescent staining combined with flow cytometry has been developed as a method for automated reticulocyte counting (see p. 42).

Manual reference method

The manual reference method[43,44] is essentially the same procedure as for the routine method, the supravitally stained films being examined by bright field or phase contrast microscopy. Reticulocytes are identified as nonnucleated red cells that contain at least two blue staining particles or one particle linked to a filamentous thread; every nonnucleated cell in each field must be classified as a red cell or a reticulocyte. Three suitable blood films must be selected for each sample and counting is performed by moving from field to field in a battlement pattern until sufficient red cells have been counted to satisfy precision requirement (Table 3-3). The objective is a variance of 2%, but this is impractical when the reticulocyte proportion is in the range 0.01 to 0.02.

Range of reticulocyte count in health

The range of reticulocyte counts in adults and children is 50 to 100 × 10^9/l (0.5% to 2.5%). At birth or in cord blood, it is 120 to 400 × 10^9/l (2% to 5%).

AUTOMATED BLOOD COUNT TECHNIQUES

A variety of automated instruments for performing blood counts are in widespread use. Semiautomated instruments require some steps (e.g. dilution of a blood sample) to be carried out by the operator. Fully automated instruments require only that an appropriate blood sample is presented to the instrument. Semiautomated instruments often measure a small number of components (e.g. WBC and Hb). Fully automated multichannel instruments usually measure from 8 to 20 components for the basic FBC and white blood cell differential, including some variables that have no equivalent in manual techniques. Automated

instruments usually have a high level of precision, which, for cell-counting and cell-sizing techniques, is greatly superior to that achievable with manual techniques. If instruments are carefully calibrated and their correct operation is ensured by quality control procedures, they produce test results that are generally accurate. When blood has abnormal characteristics, the results for one or more parameters may be aberrant; instruments are designed so that such inconsistent results are 'flagged' for subsequent review. The abnormal characteristics that lead to inaccurate counts vary between instruments, so it is important for instrument operators to be familiar with the types of factitious results to which their instruments are prone.

Blood cell counters may have automated procedures for sample recognition (e.g. by bar-coding), for ensuring that adequate sample mixing occurs, for taking up the test sample automatically and for detection of clots or inadequately sized samples. Ideally, blood sampling is carried out by piercing the cap of a closed tube so that samples that carry an infection hazard can be handled with maximum safety.

Laboratories performing large numbers of blood counts each day require fully automated blood counters capable of the rapid production of accurate and precise blood counts, including platelet counts and differential counts, either three-part or five- to seven-part. The sample throughput required varies with the workload and the timing of arrival of blood specimens in the laboratory, but for most large laboratories, a throughput of 100 or more samples per hour is required. Sample size and the availability of a 'predilute' mode are particularly relevant if the laboratory receives many paediatric specimens.

Choice of an instrument for an individual laboratory, as well as for point-of-care sites outside the laboratory (see p. 522), should take account of capital expenditure and running costs, including maintenance and reagents; size of instrument; requirements of services such as water, compressed air, drainage and an electricity supply with stable voltage; environmental disturbance by generation of heat, vibration and noise; any influence on performance by the ambient temperature and humidity; storage requirements for the often bulky reagents; ease of operation; and the likely level of support that can be expected from the manufacturer.

A practical guide on the principles of the various systems has been published,[45] and there are guidelines to help in the choice of an instrument suitable for the needs of an individual laboratory and also to assess its performance, compared with the claims of the manufacturer, when it has been installed and is being used in routine practice.[46] Choice of instrument may be aided by reference to published reports of instrument evaluations and related monographs.[45,47,48] Some semiautomated instruments aspirate a sample of accurately determined volume and so can perform absolute cell counts and accurate estimations of Hb. Most automated instruments, however, count for a specified period of time rather than measuring an exact volume of blood; they therefore require calibration by means of the direct counts derived from instruments counting cells in a defined volume of diluted blood. For some variables, instruments are calibrated by the manufacturer, but others require calibration in the laboratory. Performance characteristics of an instrument vary over time, so periodic recalibration is needed: both when quality control procedures indicate the necessity and when certain components are replaced.

HAEMOGLOBIN CONCENTRATION

Some automated counters still measure Hb by a modification of the manual HiCN method with cyanide reagent; however, manufacturers have changed their methods to allow the use of a nonhazardous chemical, such as sodium lauryl sulphate, imidazole, sodium dodecyl sulphate or dimethyl laurylamine oxide, which avoids possible environmental hazards from disposal of large volumes of cyanide-containing waste. Modifications include alterations in the concentration of reagents and in the temperature and pH of the reaction. A nonionic detergent is included to ensure rapid cell lysis and to reduce turbidity caused by cell membranes and plasma lipids. Measurements of absorbance are made at various wavelengths depending on the final stable haemochromogen, cyanmethaemoglobin, oxyhaemoglobin, methaemoglobin or monohydroxyferriporphyrin and at a set time interval after mixing of blood and the active reagents but before the reaction is completed.

RED BLOOD CELL COUNT

Red cells and other blood cells can be counted in systems based on either aperture impedance or light-scattering technology. Because large numbers of cells can be counted rapidly, there is a high level of precision. Consequently, electronic counts have rendered the RBC and the red cell indices derived from it (the MCV and the MCH) of much greater clinical relevance than was possible when only a slow and imprecise manual RBC was available.

COUNTING SYSTEMS

Impedance counting

Impedance counting, first described by Wallace Coulter in 1956,[49] depends on the fact that red cells are poor conductors of electricity, whereas certain diluents are good conductors; this difference forms the basis of the counting systems used in Beckman Coulter, Sysmex, Abbott, Horiba Medical and a number of other instruments.

For a cell count, blood is highly diluted in a buffered electrolyte solution. The flow rate of this diluted sample is controlled by a mercury siphon (as in the original Coulter system) or by displacement of a tightly fitting piston. This results in a measured volume of the sample passing through an aperture tube of specific dimensions (e.g. 100 mm in diameter and 70 mm in length). By means of a constant source of electricity, a direct current is maintained between two electrodes, one in the sample beaker or the chamber surrounding the aperture tube and another inside the aperture tube. As a blood cell is carried through the aperture, it displaces some of the conducting fluid and increases the electrical resistance. This produces a corresponding change in potential between the electrodes, which lasts as long as the red cell takes to pass though the aperture; the height of the pulses produced indicates the volume of the cells passing through the aperture. The pulses can be displayed on an oscillograph screen. The pulses are led to a threshold circuit provided with an amplitude discriminator for selecting the minimal pulse height, which will be counted (Fig. 3-6). The height of the pulses is used to determine the volume of the red cells.

Light scattering

Red cells and other blood cells may be counted by means of electro-optical detectors.[50] A diluted cell suspension flows through an aperture so that the cells pass, in single file, in front of a light source; light is scattered by the cells passing through the light beam. The scattered light is detected by a photomultiplier or photodiode, which converts it into electrical impulses that are accumulated and counted. The amount of light scattered is proportional to the surface area and therefore the volume of the cell so that the height of the electrical pulses can be used to estimate the cell volume. The high-intensity coherent laser beams used in current instruments have superior optical qualities to the noncoherent tungsten light of earlier instruments. Sheathed flow allows cells to flow in an axial stream with a diameter not much greater than that of a red cell; light can be precisely focused on this stream of cells. Electro-optical detectors are used for red cell sizing and counting in Siemens (previously Bayer-Technicon) systems and for white cell differential counting in a number of other instruments.

RELIABILITY OF ELECTRONIC COUNTERS

Electronic counts are precise, but care needs to be taken so that they are also accurate. The recorded count on the same sample may vary from instrument to instrument and even between different models of instrument from the same manufacturer. Inaccuracy may be introduced by coincidence (i.e. by two cells passing through an orifice simultaneously and being counted as one cell or by a pulse being generated during the electronic dead time of the circuit); by recirculation of cells that have already been counted; by red cell agglutination (which causes a clump of cells to be counted as one cell); and by the counting of bubbles, lipid droplets, microorganisms or extraneous particles as cells. Faulty maintenance may lead to variation in the volume aspirated or the flow rate. Single-channel instruments may have their thresholds set incorrectly and multichannel instruments may be incorrectly calibrated.

A statistical correction may be applied for coincidence (coincidence correction); in some instruments, this is done automatically by electronic editing. Errors of coincidence can be detected by carrying out a series of measurements at various dilutions of the same specimen, plotting the data on graph paper and then extrapolating the graph to the baseline for the true value. Alternatively, the need for coincidence correction can be avoided by having the dimensions and flow characteristics of the aperture through which the cells pass such that cells can only pass in single

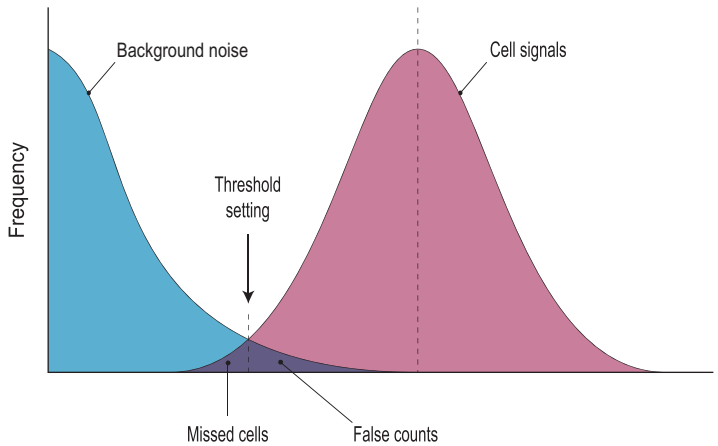

FIGURE 3-6 Effect of threshold discrimination (horizontal axis) in separating cell signals from background noise.

file; this may be achieved by sheathed flow or hydrodynamic focusing in which diluted blood is injected into a sheath of fluid as it flows into the sensing zone. This induces the cells to pass through the centre of the sensing zone in single file and free of distortion. Coincidence can be more effectively reduced with sheathed flow and precisely focused light in an electro-optical detector than in an impedance counter so that less dilution of the blood sample is needed.[46] Electrical impulses generated by recirculation of cells can be eliminated by electronic editing; alternatively, recirculation of cells in the region of the aperture can be prevented by 'sweep flow' in which a directed stream of diluent sweeps cells and debris away from the aperture, thus preventing cells from being recounted and debris from being counted as cells.

Inaccurate counts consequent on red cell agglutination are usually the result of cold agglutinins. They are recognised as erroneous because of an associated marked factitious elevation of the MCV. A correct count can be achieved by prewarming the blood sample and, if necessary, also prewarming the diluent.

A correct RBC and, particularly, a correct measurement of the MCV are dependent on the use of an appropriate diluent. For impedance counters, pH, temperature and rate of ionisation have to be standardised and remain constant because changes alter the electrical field and may lead to artefactual alterations in the size, shape and stability of the blood cells in the diluent. Diluents must be free of particles and give a background count of <50 particles in the measured volume. The correct diluent for each individual instrument must be used; other diluents, even those made by the same manufacturer, may not be interchangeable. Any laboratories using diluents other than those recommended by the manufacturer of the instrument must satisfy themselves that no error is being introduced.

For red cell counting in simple single-channel counters a suitable diluent requires a pH of 7.0–7.5 and an osmolality of 340 ± 10 mmol. Physiological saline (9 g/l NaCl) or phosphate-buffered saline, both of which have the advantages of simplicity and ready availability, can be used as a red cell diluent, provided that the counts are performed immediately after dilution to avoid errors caused by sphering. Commercial solutions of saline (for intravenous use) are usually particle-free. Other solutions may require filtration through a 0.22 or 0.45 mm Micropore filter to remove dust.

Setting discrimination thresholds

An accurate RBC requires that thresholds be set so that all red cells, but a minimum of other cells, are included in the count. Some counters have a lower threshold but no upper threshold so that white cells are included in the 'RBC'. Because the WBC is usually very low in relation to the RBC, this is not usually of practical importance; however, an appreciable error can be introduced if the WBC is greatly elevated, particularly if the patient is also anaemic. The setting of the lower threshold is of considerable importance because it is necessary to ensure that microcytic red cells are included in the count without also counting large platelets.

Current multichannel instruments, both impedance counters and counters using light-scattering technology, have thresholds that are either precalibrated by the manufacturer or are automatically adjusted, depending on the characteristics of individual blood samples. Single-channel impedance instruments capable of performing a direct RBC require setting of thresholds so as to separate pulses generated by red cells from background noise and from pulses generated by platelets. This is done by adjusting the aperture current and the pulse amplification. A simple method is to dilute a fresh blood sample and carry out successive counts on the suspension, while the lower threshold control is moved incrementally from its maximum to its minimum position. At the maximum position, the count should be zero or close to zero and the counts will increase as the amplitude is reduced. The counts at each setting are plotted on arithmetic graph paper (Fig. 3-7). The correct threshold setting is at the left of the horizontal part of the graph before the line begins to slope. It is important to check that the setting selected is valid for microcytic cells. The threshold can be defined more precisely for an individual sample by means of a pulse height analyser linked to the counting system. The lower threshold is correctly set if beyond this point there are $<0.5\%$ of the counts at the peak (mode) of the pulse size distribution curve (Fig. 3-6).

PACKED CELL VOLUME AND MEAN CELL VOLUME

Modern automated blood cell counters estimate PCV/haematocrit by technology that has little connection with packing red cells by centrifugation. It is convenient to use different terms to distinguish the manual and automated tests and for this reason the ICSH has suggested that the term 'haematocrit' (Hct) rather than packed cell volume (PCV) should be used for the automated measurement. However, it should be noted that, in the past, these two terms have been used interchangeably for the manual procedure.

With automated instruments, the derivations of the RBC, Hct and MCV are closely interrelated. The passage of a cell through the aperture of an impedance counter or through the beam of light of a light-scattering instrument leads to the generation of an electrical pulse, the height of which is proportional to cell volume. The number of pulses generated allows the RBC to be determined, as discussed earlier. Pulse height analysis allows either the MCV or the Hct to be determined. If the average pulse height is computed, this is indicative of the MCV and the Hct can be derived by multiplying the estimated MCV by the RBC.

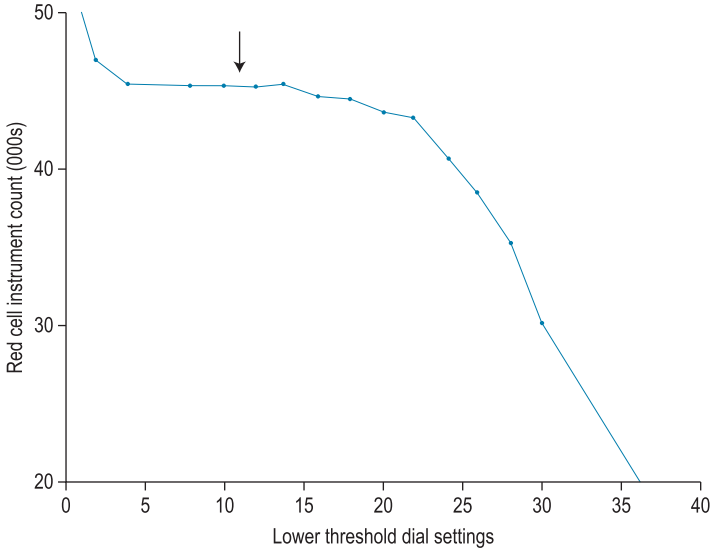

FIGURE 3-7 Method to establish working conditions of cell counters. The correct setting of the threshold (at *arrow*) is intended to exclude noise pulses without loss of the signal pulses produced by the blood cells.

Similarly, if the pulse heights are summated, this figure is indicative of the Hct and the MCV can, in turn, be derived by dividing the Hct by the RBC.

Automated instruments require calibration before the Hct or MCV can be determined. Calibration of the Hct can be based on manual PCV determinations. Alternatively, the MCV can be calibrated by means of the pulse heights generated by latex beads, stabilised cells or some other calibrant containing particles of known size; however, unfixed human red cells that are biconcave and flexible will not necessarily show the same characteristics in a cell counter as latex particles or some other artificial calibrant. BCR (Bureau Communautaire de Référence) certified preparations are available from the Institute for Reference Materials and Measurements (IRMM) (https://ec.europa.eu/jrc/en/institutes/irmm). Aperture-impedance systems measure an apparent volume that is greater than the true volume, being influenced by a 'shape factor';[52] this factor is less than 1.1 for young, flexible red cells; between 1.1 and 1.2 for fixed biconcave cells; and about 1.5 for spheres, whether they be fixed cells or latex spheres.[50,51]

The MCV, and therefore the Hct, as determined by an automated counter, will vary with certain cell characteristics other than volume. As indicated earlier, such characteristics include shape, which in turn is partly determined by flexibility. With impedance counters, the normal disc-shaped red cell becomes elongated into a cigar shape as it passes through the aperture; this is caused by deformation in response to shear force, which occurs in cells of normal flexibility. Cells with a reduced haemoglobin concentration undergo more elongation than normal cells; this leads to a reduced 'shape factor', a reduced pulse height in relation to the true size of the cell and underestimation of the MCV. Conversely, cells with abnormally rigid membranes and cells such as spherocytes with a high haemoglobin concentration will undergo less deformation than normal and the MCV will be overestimated. Earlier light-scattering instruments also underestimated the volume of red cells with a reduced haemoglobin concentration because light scattering was affected by the haemoglobin concentration.[52] These artefacts are seen even with normal red cells of varying haemoglobin concentration but are more apparent with red cells from patients with defects in haemoglobin synthesis such as those from patients with iron deficiency. Light-scattering instruments have been developed to avoid artefacts of this type. Cells are isovolumetrically sphered; light-scattering characteristics of sphered red cells are predictable and permit the computation of both individual cell volume and intracellular haemoglobin concentration using a calibrated Mie map that describes the scatter and refraction characteristics of spherical particles in a monochromatic light source.[53] Light scattering by each individual cell is measured at two angles: low-angle scatter at 2–3° and high-angle scatter at 5–15 degrees, which permits computation of both cell volume and haemoglobin concentration.[52] The measure of cellular haemoglobin is designated as the cellular haemoglobin concentration mean (CHCM) to distinguish it from the traditional MCHC derived from the Hb and the PCV. If all measurements are accurate, the CHCM and the MCHC should give the same results, thus providing an internal quality control mechanism.

The automated MCV and Hct are prone to certain errors that do not occur or are less of a problem with manual methods. These include those resulting from microclots or partial clotting of the specimen, extreme

microcytosis and the presence of cryoglobulins or cold agglutinins; the last is a relatively common cause of factitious elevation of the MCV because clumps of cells are sized as if they were single cells. Because the RBC is underestimated, the Hct is less affected, although it is also inaccurate. It is rare for warm agglutinins to cause a similar problem. Sickling may cause a factitious increase in MCV and Hct, whereas alterations in plasma osmolarity occurring, for example, in severe hyperglycaemia, also cause factitious elevation of the MCV and Hct.[48,54,55]

RED CELL INDICES

Red cell indices traditionally have been the derived parameters of MCV, MCH and MCHC; more recently, red cell distribution width (RDW) has also been included and, for some instruments, haemoglobin distribution width (HDW). These indices can provide a basis for classifying anaemias and in various combinations they have been used to aid in the distinction between iron deficiency and thalassaemias.[56–58] It is important to note, however, that these formulae may not be consistent between different instruments and their use provides only a guide to the most likely diagnosis. When diagnosis is important, as in preconceptual or antenatal screening for thalassaemia, definitive tests are required, even in patients whose red cell indices are more suggestive of iron deficiency.

Mean cell volume

As described earlier, in most automated systems, MCV is measured directly, but in semiautomated counters MCV is calculated by dividing the Hct by the RBC.

Thus, for example, if the Hct is 0.45 (i.e. 0.45 l of red cells per litre of blood) and the RBC is 5×10^{12} per litre:

$$\text{Volume of 1 cell} = 0.45 \div 5 \times 10^{12}$$
$$= 90 \text{ femtolitres (fl)}$$

Mean cell haemoglobin and mean cell haemoglobin concentration

MCH is derived from the Hb divided by RBC.

Thus, for example, if there are 150 g of haemoglobin and 5×10^{12} red cells per litre:

$$\text{MCH} = 150 \div 5 \times 10^{12} = 3 \div 10^{11} \text{ g}$$
$$= 30 \text{ picograms (pg)}$$

The MCHC is derived in the traditional manner (see p. 24) from the Hb and the Hct with instruments that measure the Hct and calculate the MCV, whereas when the MCV is measured directly and the Hct is calculated, the MCHC is derived from the Hb, MCV and RBC according to the following formula:

$$\text{MCHC (g/l)} = \frac{\text{Hb (g/l)} \times 1000}{\text{MCV (fl)} \times \text{RBC} \times 10^{-12}/\text{l}}$$

For example, if the Hb is 150 g/l, the MCV is 90 fl and the RBC is 5×10^{12}/l:

$$\text{MCH} = 150 \times \frac{1000}{90 \times 5}$$
$$= 333 \text{ g/l}$$

When automated counters were introduced, it was noted that a reduced MCHC, which with manual methods had been a useful indicator of hypochromia in early iron deficiency, was a less sensitive indicator of developing iron deficiency. The explanation of this is complex. In iron deficiency, there is not only true hypochromia but also increased plasma trapping within the column of red cells in a microhaematocrit tube that increases the PCV and exaggerates the decrease in the MCHC. The lowered MCHC is thus partly a true reflection of hypochromia and partly an artefact. When the MCHC is derived by automated counters, the artefact of increased plasma trapping is no longer present, but the instruments are also less sensitive to a true reduction of the MCHC because of the underestimation of the size of hypochromic red cells described earlier. Because the MCHC is calculated from the formula given earlier, the underestimation of the MCV leads to an overestimation of the MCHC. The MCHC thus shows little alteration as cells become hypochromic. Where CHCM is available, it is a more directly measured equivalent of the MCHC. This provides improved sensitivity to iron deficiency because true MCHC and the CHCM decrease as hypochromia develops.[59]

VARIATIONS IN RED CELL VOLUMES: RED CELL DISTRIBUTION WIDTH

Automated instruments produce volume distribution histograms that reflect the degree of variation in cell size and allow the presence of more than one population of cells to be identified. Instruments may also assess the percentage of cells falling above and below given MCV thresholds and 'flag' the presence of an increased number of microcytes or macrocytes. Such measurements may indicate the presence of a small but significant increase in the percentage of either microcytes or macrocytes before there has been any change in the MCV.

Most instruments also produce a quantitative measurement of the variation in cell volume, an equivalent of the microscopic assessment of the degree of anisocytosis. This parameter has been named the 'red cell distribution

width'. The RDW is derived from pulse height analysis and can be expressed either as the standard deviation (SD) in fl or as the coefficient of variation (CV) (as a percentage) of the measurements of the red cell volume. The RDW SD is measured by calculating the width in fl at the 20% height level of the red cell size distribution histogram, and the RDW CV is calculated mathematically as the coefficient of variation; that is, RDW (CV) % = (1SD/MCV) × 100.

Most instruments express the RDW as the SD, but Sysmex instruments and the Beckman Coulter DxH express it as both SD and CV. The normal reference range is in the order of 12.8% ± 1.2% as CV and 42.5 ± 3.5 fl as SD. However, widely different ranges have been reported; therefore it is important for laboratories to determine their own reference ranges. The RDW expressed as the CV has been found of some value in distinguishing between iron deficiency (RDW usually increased) and thalassaemia trait (RDW usually normal) and between megaloblastic anaemia (RDW often increased) and other causes of macrocytosis (RDW more often normal).

PERCENTAGE HYPOCHROMIC RED CELLS AND VARIATION IN RED CELL HAEMOGLOBINISATION: HAEMOGLOBIN DISTRIBUTION WIDTH

Instruments that determine the haemoglobin concentration of individual red cells provide the percentage of hypochromic red cells, with distribution curves of the haemoglobin concentration, and are able to flag the presence of increased numbers of hypochromic or hyperchromic cells. The percentage of hypochromic red cells depends on the concentration of haemoglobin in individual cells rather than being a mean, such as MCH or MCHC. It is a more sensitive marker of the availability of iron for erythropoiesis because small changes in the number of red cells with inadequate haemoglobin can be measured before there is any appreciable change in the MCHC. Hypochromic red cells are defined as cells with a haemoglobin concentration of less than 280 g/l (28 g/dl).[60] In the healthy population the percentage of hypochromic red cells does not exceed 2.5% and values greater than this are indicative of iron deficient erythropoiesis.[61] It has been reported to be a useful indicator of functional iron deficiency (where reticuloendothelial iron stores are normal or even high, but the iron is not delivered to erythroblasts and is therefore unavailable for erythropoiesis) in haemodialysis patients. Other manufacturers' instruments have different parameters reported to be equivalent to percentage hypochromic red cells, such as low haemoglobin density (LHD%) on some Beckman Coulter instruments.[62] LHD% is derived from a sigmoid transformation of the MCHC and has been proposed as a parameter to assess the available iron stores for erythropoiesis.

The degree of variation in red cell haemoglobinisation is quantified as the HDW; this is the CV of the measurements of haemoglobin concentration of individual cells. The normal 95% range is 1.82 to 2.64. Because the volume of individual red cells is determined, it is possible to distinguish between hypochromic microcytes, which are indicative of a defect in haemoglobin synthesis, and hypochromic macrocytes, which often represent reticulocytes.[63] An increased percentage of hyperchromic cells may result from the presence of spherocytes, irregularly contracted cells or sickled cells.

WHITE BLOOD CELL COUNT

The WBC is determined in whole blood in which red cells have been lysed. The lytic agent is required to destroy the red cells and reduce the red cell stroma to a residue that causes no detectable response in the counting system without affecting leucocytes in such a manner that the ability of the system to count them is altered. Various manufacturers recommend specific reagents, and for multichannel instruments that also perform an automated differential count, use of the recommended reagent is essential. For a simple single-channel impedance counter, the following fluid is satisfactory:

Cetrimide 20 g
10% formaldehyde (in 9 g/l NaCl) 2 ml
Glacial acetic acid 16 ml
NaCl 6 g
Water to 1 litre

Relatively simple instruments are also available that determine the Hb and the WBC by consecutive measurements on a single blood sample. The diluent contains a reagent to lyse the red cells and another to convert haemoglobin to haemiglobincyanide. Hb is measured by a modified HiCN method and white cells are counted by impedance technology. Apart from the reagents specified by the manufacturers, a diluent containing potassium cyanide and potassium ferricyanide together with ethylhexadecyldimethylammonium bromide can be used.[64,65]

Fully automated multichannel instruments perform WBCs by impedance or light-scattering technology, or both. Residual particles in a diluted blood sample are counted after red cell lysis or, in the case of some light-scattering instruments, after the red cells have been rendered transparent. Thresholds are set to exclude normal platelets from the count, although giant platelets are included. Some or all of any NRBCs present are usually included, so that when such cells are present the count approximates more to the TNCC than to the WBC.

Factitiously low automated WBCs occasionally occur as a consequence of leucocyte agglutination, prolonged sample storage or abnormally fragile cells (e.g. in leukaemia).

Factitiously high counts are more common and usually result from failure of lysis of red cells. With certain instruments this may occur with the cells of neonates or be consequent on uraemia or on the presence of an abnormal haemoglobin such as haemoglobin S or haemoglobin C; high counts may also be the result of microclots, platelet clumping or the presence of a cryoglobulin.

AUTOMATED DIFFERENTIAL COUNT

Most automated differential counters that are now available use flow cytometry incorporated into a full blood counter rather than being stand-alone differential counters. Increasingly, automated blood cell counters have a differential counting capacity, providing either a three-part or a five- to seven-part differential count. Counts are performed on diluted whole blood in which red cells are either lysed or are rendered transparent. A three-part differential count assigns cells to categories usually designated (1) 'granulocytes' or 'large cells'; (2) 'lymphocytes' or 'small cells'; and (3) 'monocytes', 'mononuclear cells', or 'middle cells'. In theory, the granulocyte category includes eosinophils and basophils, but in practice it is common for an appreciable proportion of cells of these types to be excluded from the granulocyte category and to be counted instead in the monocyte category.[66] Some other three-part differentials categorise leucocytes as WBC-small cell ratio (equivalent to lymphocytes), WBC-middle cell ratio (equivalent to monocytes, eosinophils and basophils) and WBC-large cell ratio (equivalent to neutrophils).[67]

Five- to seven-part differential counts classify cells as neutrophils, eosinophils, basophils, lymphocytes and monocytes and in an extended differential count may also include immature granulocytes or large immature cells (composed of blasts and immature granulocytes) and atypical lymphocytes (including small blasts). Automated instruments performing differential counts (that do not enumerate immature granulocytes or NRBC separately) are able to flag or reject counts from the majority of samples with NRBC, myelocytes, promyelocytes, blasts or atypical lymphocytes. To a lesser extent, instruments incorporating a three-part differential count, although not capable of enumerating eosinophils or basophils as individual categories of cell, are able to flag a significant proportion of samples that have an increased number of one of these cell types.

Both impedance counters and light-scattering instruments are capable of producing three-part differential counts from a single channel; the categorisation is based on the different volume of various types of cell following partial lysis and cytoplasmic shrinkage. Most five- to seven-part differential counts require two or more channels in which cell volume and other characteristics are analysed by various modalities (Table 3-4). Analysis may be dependent only on volume and other physical characteristics of the cell or also on binding of certain dyes to granules or activity of cellular enzymes such as peroxidase. Technologies used to study cell characteristics include light scattering and absorbance and impedance measurements with low- and high-frequency electromagnetic current or radiofrequency current. Cells may have been exposed to lytic agents or a cytochemical reaction may have occurred before cell characteristics are studied. Two-parameter analysis or more complex discriminant functions divide cells into clusters that can be matched with the position of the various white cell clusters in normal blood. Thresholds, some fixed and some variable, divide clusters from one another, permitting cells in each cluster to be counted.

TABLE 3-4

AUTOMATED FULL BLOOD COUNTERS WITH A FIVE-PART OR MORE DIFFERENTIAL COUNTING CAPACITY*

Instrument and Manufacturer	Technology Used for Differential Count
Beckman Coulter GEN-S, LH series, DxH	Impedance with low-frequency electromagnetic current Impedance with high-frequency electromagnetic current Laser light scattering
Sysmex SE, X-series (XE, XT, XN)	Impedance with low-frequency direct current Impedance with radiofrequency current Fluorescence flow cytometry
Siemens Advia series	Light scattering and absorbance following peroxidase reaction Two-angle light scatter following differential cytoplasmic stripping
Abbott Cell-Dyn 3500, 4000, Sapphire	Four light-scattering parameters: forward light scatter, orthogonal light scatter, narrow-angle light scatter and depolarised orthogonal light scatter
Horiba Medical Pentra series	Electrical impedance with intact cells and following differential cytoplasmic stripping Light absorbance
Mindray BC series	Impedance with low-frequency direct current Fluorescence flow cytometry
Nihon–Kohden MEK series	Impedance with low-frequency direct current Fluorescence flow cytometry

*In addition to the blood counters listed here, there are an increasing number of instruments on the market, some of which are small bench-top analysers while others are designed for point-of-care testing, which are capable of providing full differential or partial differential counts using various technologies.

Automated differential counters using flow cytometry count a far greater number of cells than is possible with a manual differential count. Automated counts are consequently much more precise than manual counts. The accuracy of automated counters is less impressive than their precision. With all types of counters, unusual cell characteristics or ageing of a blood specimen can lead to misclassification of cells. Although the majority of samples containing abnormal cells are flagged, this is not invariably so; the presence of NRBCs, immature granulocytes, atypical lymphocytes and blasts (even occasionally quite large numbers of blasts) may not give rise to a flag. However, human observers performing a 100-cell manual differential count also miss significant abnormalities. In general, automated counts have compared favourably with routine manual counts, especially if the instruments are assigned only two functions, performing differential counts on normal samples and flagging abnormal samples. If morphological abnormalities are flagged, microscopic examination of a stained blood film should always be undertaken.

The Sysmex XN has some different stains and algorithms to improve flagging, compared with the earlier XE and XT series. The WBC differential channel has better separation of the lymphocytes and monocytes, reducing the number of false positives for the atypical lymphocyte flag. In the WBC nucleated red cell channel, an NRBC count is performed on all samples without the necessity to rerun the sample. In the WBC precursor channel, if the combined flag for abnormal lymphocytes/blasts is positive there is further reflex analysis to distinguish abnormal lymphocytes from blast cells and to remove the flag if it is falsely positive. There are automatic extended counts for low WBC and platelets for better accuracy and precision.[68] The WBC precursor channel has been shown to be useful in neonates and children since there are far fewer abnormal lymphocytes and blast flags without loss of sensitivity or specificity.[69]

THE AUTOMATED IMMATURE GRANULOCYTE COUNT

Most fully automated analysers now report an immature granulocyte count. Promyelocytes, myelocytes and metamyelocytes are all included in the automated immature granulocyte count but are not identified as separate classes of cells. The presence of low numbers of immature granulocytes is more reliably detected on automated haematology analysers than by manual microscopy, due to the higher number of cells counted. Often low numbers of immature granulocytes, particularly in leucopenic samples or when small percentages are present, are missed in a 100-cell differential count or film review. Immature granulocytes may be identified either by a combination of light absorbance (after staining of the cells) and impedance or by flow cytometry to detect side-scattered light and fluorescence of cells stained with a fluorescent dye. Measurement of immature granulocytes may be clinically relevant. The percentage of immature granulocytes as measured by the Sysmex XE-2100 has, for example, been found to be predictive of infection, although it should be noted that it is no more predictive than the absolute neutrophil count.[70]

Some instruments do not quantitate immature granulocytes and still rely on an abnormal white cell flag generated by the analyser to indicate their possible presence in the blood sample.

For instruments that do not report an NRBC count, automated differential counts often include some, but not all, NRBC in the total 'WBC'; thus, in the presence of a significant number of NRBC, the total count is neither a true 'WBC' nor a true 'TNCC' and the absolute WBC counts calculated from the total will necessarily be somewhat erroneous. This differs from the situation with earlier instruments that included any NRBC in the 'WBC'. It may be possible to make some assessment of the proportion of the NRBCs included in the total count by studying the graphic output of the instrument; otherwise, if accurate absolute counts of different leucocyte types are needed, it is necessary to revert to earlier instruments to provide the TNCC and to correct it to a WBC by means of a differential count.

THE AUTOMATED NUCLEATED RED BLOOD CELL COUNT

The ability of haematology instruments to perform precise and accurate automated NRBC counts over the entire concentration range in peripheral blood offers advantages to the diagnostic laboratory. Enumeration of NRBC is important because their presence can have a direct effect on the accuracy of the WBC on some blood cell counters. The correct WBC was previously only obtained by examination of a peripheral blood film. The NRBCs are reported as the number per 100 white blood cells and subtraction of the number of NRBCs from the total nucleated count gives the correct WBC. The morphological correction of the WBC can be inaccurate since if the nuclear size of an NRBC falls below the white blood cell threshold of the instrument, these cells are not included in the automated WBC in the first place. Instruments currently in use that automatically count NRBCs and correct the WBC for NRBC interference include the Abbott Sapphire; the Sysmex XE-2100, XE-500 and XN; the Beckman Coulter LH750 and DxH; the Horiba Medical Pentra DX120 and the Siemens Advia 2120.

Instruments determine NRBCs by staining them with a nuclear dye and using either fluorescence laser light scatter or flow cytometry to separate them from WBC or a combination of impedance and cell volume. Beckman Coulter instruments use cell volume conductivity and scatter measurements. The Siemens Advia 2120 utilises nuclear density and degree of peroxidase staining. The WBC and differential are corrected for the presence of NRBC where necessary.

The NRBC counting method on some instruments is not a direct measure of the cells and there is the possibility of other interfering substances in blood occupying the NRBC signature position and producing false-positive results.

AUTOMATED DIGITAL IMAGING ANALYSIS OF BLOOD CELLS

Over the last 20 years automated imaging processes have started to be introduced where stained blood films are scanned by a computer-driven microscope and leucocytes are classified; early methods were slow and had difficulty in classifying abnormal cells and, as only a small number of cells were counted in a reasonable time, the precision of the automated count was no better than that of a manual count.[71] However, with improved computing technology and with the use of artificial neural networks, such instruments (e.g. CellaVision DM96 AB, Lund, Sweden, www.cellavision.com and HemoFAXS, Tissuegnostics GmbH, Wein, Austria, www.tissuegnostics.com) are now capable of providing a useful differential count on blood samples, even those containing abnormal cells.[72] The DM96 is composed of a slide scanning unit and a computer. The scanning unit consists of a motorised microscope and a digital charge-coupled device (CCD) camera. The instrument scans the stained blood film, identifies potential white cells, takes digital images of them and uses artificial neural network-based software to analyse the cells. Up to 30 films an hour can be processed. Digital images of preclassified cells are presented to the operator on a computer screen for conformation or reclassification. The operator of the instrument needs to be skilled in blood cell morphology in order to accept or reclassify accurately the cells presented.[73]

NEW WHITE CELL PARAMETERS

Many instruments are able to flag the presence of abnormal leucocytes by features such as an alteration in cell size, nuclear size or cell granularity that causes changes in impedance or light-scattering characteristics. Automated white cell counters can also analyse cell characteristics by novel technologies and identify cell types by features that differ greatly from those used when a blood film is examined visually. It is possible, for example, to identify eosinophils by the ability of their granules to polarise light[74] or to detect a left shift or the presence of blasts by the reduced light scattering of the nuclei of more immature granulocytes. There is also the potential to produce information that is not directly analogous with that available from a manual differential count. Recently white blood cell differential parameters have been reported to demonstrate clinical utility in the diagnosis of some diseases. Abnormal cell populations that have previously only triggered a flag, on some instruments, can now be quantitated.

Numerical data (coordinates) generated by Beckman Coulter analysers that use volume, conductivity and scatter (VCS) are now available. These coordinates, indicating the position and size of the cell cluster in the VCS differential plot, are available for neutrophils, lymphocytes, monocytes and eosinophils, and cells of each cell type have normal values. Any deviations from normal are thought to reflect differences in cell size and complexity and may be indicative of a potential disease process or specific to a morphological characteristic. These parameters are still for laboratory use only but it may be possible to use them as advanced flags for specific diseases or conditions in certain clinical circumstances. Lymphocyte positional parameters can be used to distinguish between different lymphoproliferative disorders and viral infections.[75] Neutrophil conductivity and neutrophil scatter can be used in the detection of dysplastic neutrophils,[76] with low values for these parameters correlating with neutrophil hypogranularity.

Sepsis-associated neutrophil left shift can be identified by a change from normal values of neutrophil volume and may be used as an indicator of acute bacterial infections.[77]

It has been suggested that VCS and other instrument parameters used for defining leucocyte types might also allow detection of the presence of malaria pigment in white blood cells or larger than normal monocytes and may be used as a screening test for malaria.[78,79]

In a similar way for other instruments, using forward scattered light and fluorescence, new parameters have been developed on the basis of abnormal leucocyte positions in the differential scattergram. Plasma cells appear in a high fluorescence area of the lymphocyte cluster in the differential channel of the Sysmex XE-2100 and are flagged as atypical lymphocytes; they can now be quantitated.[80] On the same instrument, NEUT-X is the mean value for side scatter diffraction of the neutrophil population; it represents the internal structure of the neutrophils. It correlates with hypogranularity of neutrophils and when taken into consideration with anaemia is suggestive of a myelodysplastic syndrome.[81] Instruments such as Siemens Advia analysers that incorporate a cytochemical reaction give information on enzyme activity expressed as the mean peroxidase activity index (MPXI). An increased MPXI has been observed in infections, in some myelodysplastic syndromes and leukaemias, in the acquired immune deficiency syndrome (AIDS) and in megaloblastic anaemia, whereas a reduced MPXI occurs in inherited and acquired neutrophil peroxidase deficiency.[59,82,83] These new parameters provide numerical values for the changes that can be seen in the instruments' scatter plots by an experienced operator. Such measurements have the potential for clinical usefulness and may allow the development of specific disease flags and new indicators of abnormality.

AUTOMATED INSTRUMENT GRAPHICS

Fully automated instruments produce a graphic display of much of the data produced. This is displayed on a colour monitor and can be printed, either in black and white or in colour. Inspection of the graphic display can give further information beyond that which is available from assessment of the numerical data. Displays usually include histograms of red cell, white cell and platelet size and sometimes histograms of red cell haemoglobin concentration and scatter plots of size versus haemoglobin concentration. Differential counts are graphically represented as scatter plots of two variables or scatter plots of discriminant functions derived from more than two variables.

Typical printouts of histograms or scatter plots of current automated instruments are shown in Figure 3-8.

PLATELET COUNT

Platelets can be counted in whole blood using the same techniques of electrical or electro-optical detection as are used for counting red cells. An upper threshold is needed to separate platelets from red cells and a lower threshold is needed to separate platelets from debris and electronic noise. Recirculation of red cells near the aperture should be prevented, because the pulses produced may simulate those generated by platelets. Three techniques for setting thresholds have been used: (1) platelets can be counted between two fixed thresholds (e.g. between 2 and 20 fl); (2) pulses between fixed thresholds can be counted with subsequent fitting of a curve and extrapolation so that platelets falling outside the fixed thresholds are included in the computed count; and (3) thresholds can vary automatically, depending on the characteristics of individual blood samples, to make allowance for microcytic or fragmented red cells or for giant platelets. Factitiously low impedance platelet counts may be the result of giant platelets being identified as red cells or of EDTA-induced platelet clumping or satellitism (see p. 91). Misleadingly, high platelet counts may be due to markedly microcytic or fragmented red cells, to white cell fragments in leukaemia[84] or to bacteria or fungi.

An optical fluorescence platelet count has been introduced on some Sysmex analysers, in addition to the traditional impedance count.[85] A dye is used to stain the RNA of reticulocytes and platelet membranes and granules. The fluorescent staining of the platelets allows the exclusion of nonplatelet particles from the count and also allows the inclusion of large or giant platelets. However, for samples from patients undergoing cytotoxic chemotherapy, the impedance count is sometimes more accurate. This is probably due to the erroneous staining of white cell fragments following apoptosis.[84] A switching algorithm has been designed on the instrument to report the most accurate platelet count, either optical or impedance.

An immunofluorescence method for platelet counting by flow cytometry has also been developed.[86] Platelets in a blood sample are labelled fluorescently with a specific monoclonal antibody or combination of antibodies, and by measuring the RBC:platelet ratio the platelet count can be calculated. Suitable antibodies to platelet antigens are CD41, CD42 and CD61. This method using CD41 and CD61 has been adopted by the ICSH as the reference method.[87] The Abbott Cell-Dyn and Sapphire instruments provide an automated immunological platelet count for diagnostic use. Although instruments can count platelets down to levels of 10×10^9/l or less, it should be noted that precision at these levels is often poor with CVs of 22–66% being observed[88] and with counts below 10×10^9/l differing appreciably between instruments and from the ICSH reference method.[89]

Platelet count in health

In health, there are approximately 150 to 400×10^9 platelets per litre of blood. The counts are somewhat higher in women than in men,[90] and there is cycling, with slightly lower counts at about the time of menstruation.[91] Lower platelet counts are observed in apparently healthy Afro-Caribbeans and Africans than in Caucasians.[92]

Mean platelet volume

The same techniques that are used to size red cells can be applied to platelets. The mean platelet volume (MPV) is derived from the impedance platelet size distribution curve. The MPV is very dependent on the technique of measurement and on the length and conditions of storage before the blood is tested. When MPV is measured by impedance technology, it has been found to vary inversely with the platelet count in normal subjects. If this curve is extrapolated, it has been found that data fit the extrapolated curve when thrombocytopenia is caused by peripheral platelet destruction; however, the MPV is lower than predicted when thrombocytopenia is caused by megaloblastic anaemia or bone marrow failure.[93,94] Large platelets are haemostatically more active than smaller platelets and may be more important functionally than smaller platelets. An increase in MPV has been observed in patients at risk of and following myocardial infarction[95] and cerebral infarction.[96] A high MPV can provide important evidence of an inherited macrothrombocytopenia. The MPV is generally greater than normal in myeloproliferative neoplasms, but differentiating essential thrombocythaemia from reactive thrombocytosis on this basis has not been very successful.

Other platelet parameters that can be computed by automated counters include the platelet distribution width (PDW), which is a measure of platelet anisocytosis, and the 'plateletcrit', which is the product of the MPV and platelet count and, by analogy with the haematocrit, may

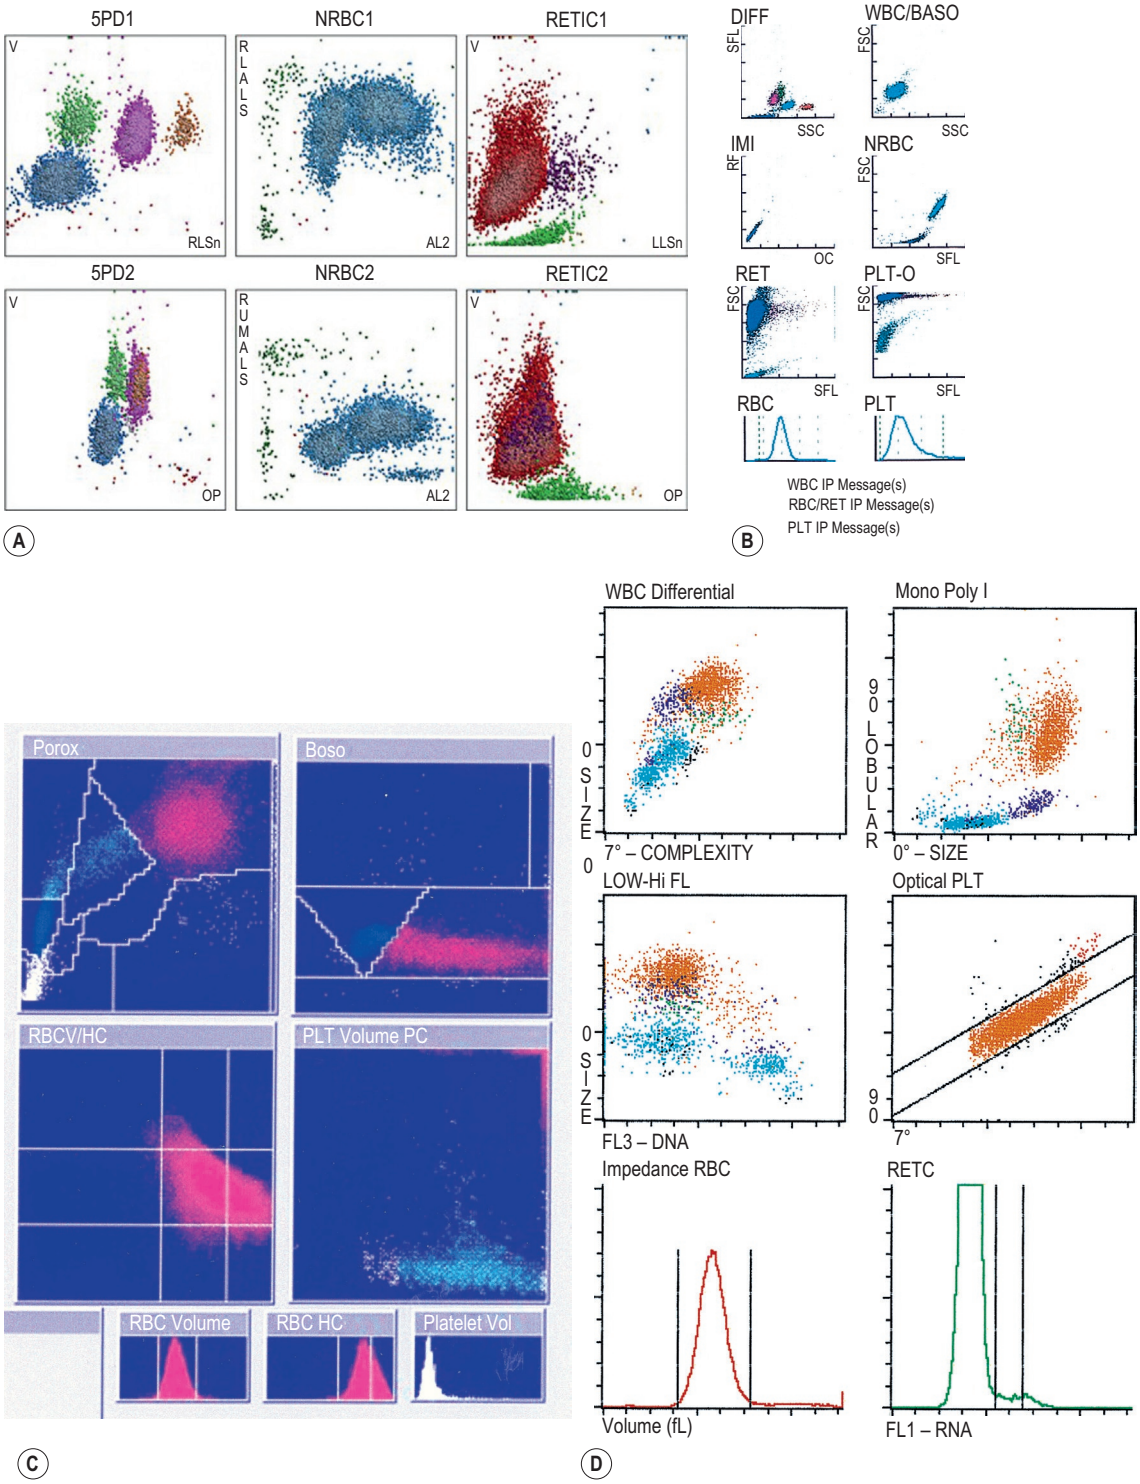

FIGURE 3-8 Patterns of blood count printout of some automated systems. (A) Beckman Coulter DxH; **(B)** Sysmex XE-2100; **(C)** Siemens Advia; **(D)** Abbot Cell-Dyn 4000.

be seen as indicative of the volume of circulating platelets in a unit volume of blood. The platelet large cell ratio (P-LCR), reported by some instruments, is the number of platelets falling above the 12 fl threshold on the platelet size histogram divided by the total number of platelets. A high P-LCR or PDW may indicate peripheral immune destruction of platelets.[97] The PDW has been found to be of some use in distinguishing essential thrombocythaemia (PDW increased) from reactive thrombocytosis (PDW normal). The plateletcrit does not appear to provide any information of clinical value. All derived platelet parameters are highly specific to the individual technologies, with different analysers having different normal ranges.

Reticulated platelets and immature platelet fraction

After labelling with specific immunological markers and a fluorescent dye that binds RNA, it is possible to identify young platelets with a higher RNA content by flow cytometry.[87,98–100] By analogy with the reticulocyte count, these have been called 'reticulated platelets', and it has been suggested that an increased number in the circulation is a sensitive and early indication of recovery of thrombopoiesis in aplastic anaemia. However, because there is a constant exchange of platelets between the circulation and the spleen, it is not clear whether their presence in the blood has the same significance as reticulocytes.

A new automated method to quantitate reticulated platelets, expressed as the immature platelet fraction (IPF), has been developed on some Sysmex instruments. The measurement of the IPF uses a fluorescent dye containing polymethine and oxazine. These two dyes penetrate the cell membrane, staining any RNA in red cells and platelets, and the stained cells are then passed through a semiconductor diode laser beam. The resulting forward light scatter (cell volume) and fluorescence intensity (RNA content) are measured and reticulocytes and reticulated platelets are identified. The IPF is raised in patients with peripheral consumption/destruction of platelets (autoimmune thrombocytopenic purpura and thrombotic thrombocytopenia purpura) and is normal or low in patients with marrow failure.[101] Following a peripheral blood stem cell transplant, the IPF has been reported to increase 1–2 days prior to the platelet count increasing.[102,103]

RETICULOCYTE COUNT

Automated reticulocyte counts have been developed by using the fact that various dyes and fluorochromes combine with the RNA of reticulocytes.[40,104] Following binding of the dye, fluorescent cells can be enumerated using a flow cytometer. Most fully automated blood counters now incorporate a reticulocyte counting capacity so that use of a stand-alone reticulocyte counter is no longer necessary and use of a general purpose flow cytometer is no longer appropriate. An international standard for this method has been published by the Clinical and Laboratory Standards Institute (CLSI) in collaboration with ICSH.[44] The dyes used in the different systems include auramine O or polymethine with oxazine (Sysmex), thiazole orange (ABX), CD4K 530 (Abbott), as well as nonfluorescent dyes such as oxazine 750 (Siemens) and the traditional New methylene blue (Beckman Coulter, Abbott).

After staining, it is necessary to separate the reticulocytes from unstained red cells and, because the dyes also combine with DNA of nucleated cells, these cells must also be excluded. The threshold for this exclusion is determined by the intensity of fluorescence and particle sizing. Although the separation of reticulocytes from mature red cells is not always clear-cut, automated reticulocyte counts correlate well with manual reticulocyte counts; however, absolute counts may differ because automated counts are dependent on the conditions of incubation and the method of calibrating the instrument.[104] Precision is much superior to that of the manual count because many more cells are counted, which has allowed reliable flagging of reticulocytopenia and the subjective element inherent in recognising late reticulocytes is eliminated. Potential sources of inaccuracy are the inclusion of some leucocytes and platelets and, less often, Howell-Jolly bodies or malarial parasites in the 'reticulocyte' count.

Automated reticulocyte counts are fairly stable in blood that has been stored for 1–2 days at room temperature or up to 3–5 days at 4°C.

Immature reticulocyte fraction

Fully automated instruments provide a measure of the various degrees of reticulocyte maturation because the most immature reticulocytes, produced when erythropoietin levels are high, have more RNA and fluoresce more strongly than the mature reticulocytes normally present in the peripheral blood. An assessment of reticulocyte maturation can be important for diagnosing the cause of anaemia and assessing the degree of effective erythropoiesis.

For example, an increase in mean fluorescence intensity indicative of the presence of immature reticulocytes has been noted as an early sign of engraftment following bone marrow transplantation.

The characteristics of reticulocyte output in different types of anaemias can be especially appreciated from an output bivariate graph relating fluorescent intensity to reticulocyte count.[40] As described earlier, low total count with a relatively high immature reticulocyte fraction (IRF) is indicative of a regenerating marrow, whereas a reticulocytopenia with low IRF is typical of severe aplastic anaemia or renal failure. A high total count with high IRF occurs in acute haemolysis and blood loss, whereas a low to normal total count with a high IRF occurs in dyserythropoiesis and during the early response to haematinics.[105–107] The appearance of reticulocytes with high fluorescence also heralds

response when severe aplastic anaemia is being treated with immunosuppressive therapy,[105] and is a reliable indication of haemopoietic regeneration after marrow ablative chemotherapy. A high IRF has also been found to be useful in predicting the optimal time for stem cell harvests in some but not all studies.[108] A normal total count with an unexpectedly high IRF in athletes has been suggested as a method to detect 'doping' with erythropoietin.[109] It may also be useful in deciding whether a macrocytic anaemia is megaloblastic or nonmegaloblastic.[110] It should be noted that normal ranges for the IRF are very instrument dependent.

Reticulocyte counts in health

Reference ranges reported for automated reticulocyte counts vary considerably between different automated methods and may differ significantly from the 50 to 100 × 10^9/l (0.5% to 2.5%) observed by microscopy. It is therefore important to use instrument-specific normal ranges and for laboratories to establish their own ranges.

Measurement of reticulocyte haemoglobin

The reticulocyte count provides a quantitative measure of erythropoiesis but no information on the quality of erythropoiesis. With the development of flow cell haematology analysers it is now possible to measure the volume and haemoglobin content of reticulocytes. The parameter from Siemens is termed CHr (i.e. mean reticulocyte haemoglobin content) and that from Sysmex, the Ret-H_e (i.e. the reticulocyte haemoglobin concentration). CHr is measured in the stained reticulocytes using two-angle light scatter and Ret-H_e is a measure of the forward scatter of stained reticulocytes and has a curvilinear relationship with CHr.[111] The reticulocyte haemoglobin content provides an indirect measure of the functional iron available for new red blood cell production over the previous 3–4 days. More recently, other instruments have developed parameters that may give information equivalent to reticulocyte haemoglobin; these are based on a measure of mean reticulocyte volume (MRV). Reticulocyte haemoglobin and reticulocyte volume may have similar clinical utility, but the MRV produced by different instruments lacks standardisation, which means numerical results from different manufacturers are not comparable. Red blood cell size factor (RSf) is a new parameter provided by Beckman Coulter, which relates to the volume of erythrocytes and reticulocytes. Good correlation between CHr and RSf has been reported.[112]

POINT-OF-CARE INSTRUMENTS

There are two types of technology to support point-of-care testing (POCT) (see p. 522) – small bench-top analysers and hand-held devices. The bench-top systems are often smaller versions of laboratory analysers, providing an FBC with red cell indices and either a five-part white cell differential or a three-part differential. Bench-top analysers are equipped with automated calibration and quality control; however, they are too large for use at the patient's bedside and are designed for use in clinics or small laboratories. It is recommended that instruments that employ primary sampling are used, rather than instruments that involve dilution of whole blood in the preanalytical phase.[113] The most widely used test with a hand-held device is the measurement of Hb, but one device, the HemoCue WBC DIFF system, using a disposable cartridge, also counts leucocytes and platelets and performs a three-part differential on capillary blood. The range of equipment available will inevitably expand as more POCT is implemented. POCT devices should generate results that are comparable to those of the local reference laboratory. Internal quality control (IQC) must be available for all POCT instruments to detect significant deviations from acceptable performance. The analysis of control material before analysing patient samples can provide reassurance that the system is working correctly. POCT should be overseen by a named laboratory and at regular intervals parallel testing of a patient sample should be carried out at the POCT site and in the central laboratory to ensure comparable results.

Ideally, there should also be an objective external method of quality assurance, external quality control (EQA). EQA involves the analysis of samples received from an accredited external source with undisclosed values; this could be from a manufacturer or from an accredited national scheme. Results are subject to peer group assessment and statistical analysis to compare results across different sites.

Local haematologists/pathologists should encourage POCT users to participate in the supervising laboratory's EQA.[113]

Haematologists should be aware of the potential for error if point-of-care blood gas analysers are used for estimation of Hb or Hct. Use of instruments that are based on conductivity measurements is not recommended since discrepancies of 20 g/l in the Hb and 0.04 l/l in the Hct can occur when the plasma protein concentration is low (e.g. if crystalloid has been used for blood replacement) and there is also a downward bias when the Hct is less than 0.30 l/l.[113] Furthermore, the reproducibility of Hct measurements can be poor. As long as there is adequate quality control, instruments based on spectrophotometry/co-oximetry agree more closely with laboratory measurements of Hb.[113]

CALIBRATION OF AUTOMATED BLOOD CELL COUNTERS

The following methods are recommended for calibrating an automated blood cell counter:[114,115]

1. Use of fresh normal blood specimens to which values have been assigned for Hb, PCV, RBC, WBC and platelet count by standardised reference methods.

2. Use of a stable calibrant (either preserved blood or a substitute) to which values appropriate for the instrument in question have been assigned by comparison with fresh normal blood.
3. Use of a commercial calibrant with assigned values suitable for the instrument in question.

For reasons of convenience and economy, control materials are commonly used as calibrants; however, this practice is not recommended. Such materials are not sufficiently stable to serve as calibrants and their stated values are often approximations that are not assigned by reference methods. They are designed to give test results within a stated range over a stated period rather than a specific result.

The procedure for assigning values to fresh blood samples and indirectly to a stable calibrant is as follows:

1. Blood specimens (4 ml) are obtained from three haematologically normal volunteers and are anticoagulated with K_2-EDTA.
2. The Hb value is assigned by using the haemiglobincyanide method and the mean of two measurements.
3. The Hct is assigned by the microhaematocrit method, taking the mean of measurements in four microhaematocrit tubes.
4. The RBC is assigned by performing counts on a single-channel aperture-impedance counter capable of performing a direct cell count; the mean of two dilutions, each counted twice, is used.
5. The MCV is assigned by calculation from the RBC and PCV.
6. The WBC is assigned by performing counts on a single-channel aperture-impedance instrument capable of performing direct cell counts; the mean of two dilutions, each counted twice, is used.
7. The platelet count is assigned by using a flow cytometer capable of measuring the ratio of platelets to red cells; the platelet count is calculated from the ratio and an independently measured RBC. Where fluorescent monoclonal antibody labelling is available, the ICSH/International Society for Laboratory Haematology (ISLH) reference method[89] should be used. In preparations intended as a differential leucocyte count or a reticulocyte count calibrant, assign the values by the reference manual methods,[34,43] as described on pages 27 and 30, respectively.

To calibrate the automated counter directly from the three fresh blood samples, perform two counts with each sample and take the means. If the measured counts differ from those assigned, recalibrate the counter appropriately.

To calibrate a stable calibrant, perform two counts on the calibrant and on each fresh sample using the automated instrument, *A*, and take the means. From the ratio of the test results on fresh blood to those on the calibrator, assign corrected values to the calibrator by using the following calculations:

$$\text{Corrected calibrator value} = A_C \times \sqrt[3]{\frac{D_{F1}}{A_{F1}} \times \frac{D_{F2}}{A_{F2}} \times \frac{D_{F3}}{A_{F3}}}$$

where

A_C = measurement of calibrator by automated counter
A_F = measurement of the fresh blood samples (1, 2 and 3) by automated counter
D_F = direct measurement of the fresh blood samples (1, 2 and 3)

Considerable care is required to ensure that the initial measurements on the fresh blood are as accurate as possible. Dilutions should be made with individually calibrated pipettes and grade A volumetric flasks. The cell counter should be calibrated as described on page 32, with a signal-to-noise ratio of >100:1 and the count corrected for coincidence. Details of procedures to be used are described by the ICSH.[116] Procedures for verification of the performance of multichannel analysers by the users have also been published by the ICSH[46] and, in the United States of America, by the National Committee for Clinical Laboratory Standards.[117]

FLAGGING OF AUTOMATED BLOOD COUNTS

Flagging[118,119] refers to a signal indicating that the specimen being analysed may have a significant abnormality because one or more of the blood count variables are outside specified limits (usually 2SD) or there is a qualitative abnormality that requires a quality control check and/or additional investigation. Abnormal cells have differing characteristics, such as nuclear size and granule content, from normal cells. The instrument detects a cell population as having an abnormal size or shape by cluster analysis. Under these circumstances, abnormal cell flags are generated to alert the user to the possibility of inaccurate results. Abnormal cells or interfering substances may render the automated differential inaccurate or unreportable. A blood film will need to be examined microscopically to verify the automated count and confirm the presence of abnormal cells. Most point-of-care bench-top analysers have the ability to generate flags in the presence of abnormal cells or interfering substances; however, the range of alert flags available on these instruments is limited and their sensitivity and specificity may not be as good as those on more sophisticated laboratory haematology analysers. Although it is theoretically desirable for every blood count to include examination of a stained film, this has become impossible as a result of increasing workloads; time- and cost-effective rationalisation has therefore been required. This has been helped by the availability of automated analysers that report differential leucocyte counts on every specimen. Consequently, significantly fewer blood films

BOX 3-1

Blood count request: Is it a first-time count or a repeat count?
First-time count: Is it a routine screening test or special category?
If routine: What is the analyser report for the blood count alone?
Film is required if any flags are signalled.
Special category film required:
1. Diagnosed blood disease patients
2. Patients receiving radiotherapy and/or chemotherapy but not on a daily basis, only if changes are noted on delta check
3. Recent onset of renal disease
4. Neonates
5. Intensive care unit patients
6. If special tests have also been requested for infectious mononucleosis, haemolytic anaemia, enzymopathy, haemoglobinopathies
7. If the clinical details on the request form indicate lymphadenopathy, splenomegaly or jaundice or suggest the possibility of leukaemia or lymphoma
8. Specific requests by clinician

Repeat count film required:
1. Delta check positive compared with previous record
2. Any unexpected flag in present count
3. On each occasion for patients with known blood diseases, for neonates and when specifically requested by clinicians

are now examined microscopically. Thus a decision of when a blood film should be made, stained and examined should take account of flagging and the need to ensure analytic reliability. This includes a check of any significant changes from a recent previous count (delta check), as well as consideration of any specific clinical circumstances. There are previously published guidelines that describe blood film review criteria following FBC and differential analysis,[120] which may be adapted to the individual laboratory's needs. Box 3-1 is a guide to this selection.

MICROSCOPY

Microscope components

The main components of most routine microscopes are illustrated in Figure 3-9. The objectives are marked with their magnifying power. The working distance of the objective is the distance between the objective and the object to be visualised. The greater the magnifying power of the objective, the smaller the working distance (Table 3-5).

These specifications mean that when a coverslip is used, if it is too thick it will not be possible to focus at high magnification. Thus the coverslip should be no more than 0.15 mm thick for examination of covered preparations by the ×100 oil-immersion objective. Furthermore, if the glass slide is too thick, this may prevent correct focus of the light path through the condenser to the object, as described later.

TABLE 3-5

OBJECTIVE MAGNIFYING POWER AND THE ASSOCIATED WORKING DISTANCE

Objective	Working Distance
×10	5–6 mm
×40	0.5–1.5 mm
×100	0.15–0.20 mm

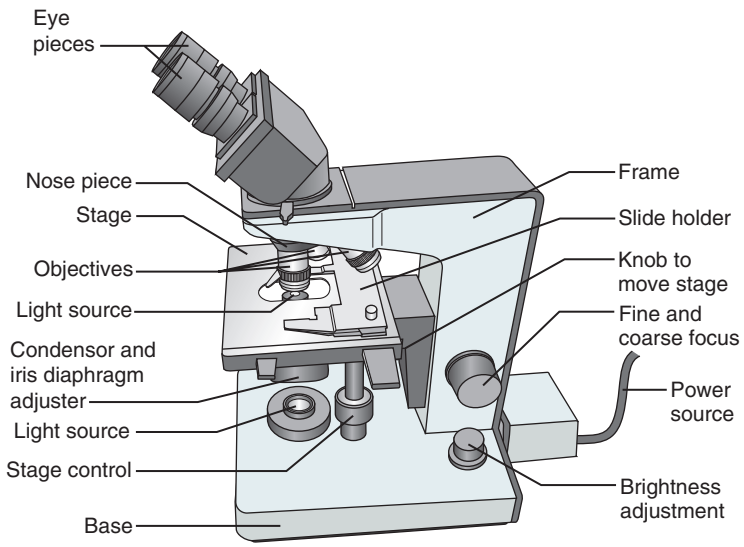

FIGURE 3-9 Diagram of a microscope, showing its component parts.

Setting up the microscope illumination

1. If the microscope requires an external light source, using the mirror at the base, direct the light into the condenser. If the illumination is built in, make sure that the lamp voltage is turned down before switching on the microscope; then turn up the lamp until it is at *c.* 70% of maximum power.
2. Place a slide of a blood film with a coverslip on the stage.
3. Lower the condenser, open the iris diaphragm fully and bring the preparation on the slide into focus with the ×10 objective.
4. Check that the eyepieces are adjusted to the operator's interpupillary width and that the specimen is in focus for each eye by rotating the focusing mechanism on the adjustable eyepiece.
5. Close the diaphragm and raise the condenser slowly until the edge of the circle of light comes into sharp focus and there is a faint blue tinge at the edge of the diaphragm.
6. Using the condenser centring screws, adjust its position so that the circle of light is in the centre of the field.
7. Open the diaphragm completely so that light fills the whole field of view.
8. Remove the eyepieces, so that the upper lens of the objective is seen to be filled with a circle of light. Close the diaphragm slowly until the circle of light occupies about two-thirds of the surface.
9. Replace the eyepieces, refocus the specimen and if necessary readjust the condenser aperture and lamp brightness to obtain the sharpest possible image.

Examination of slides

Low power (×10). Start with the objective just above the slide preparation. Then raise the objective with the coarse adjustment screw until a clear image is seen in the eyepiece. If there is insufficient illumination, rack up the condenser slightly.

Medium power (×40). Rack the condenser halfway down; lower the objective until it is just above the slide preparation. Use the coarse adjustment to raise the objective very slowly until a blurred image appears. Then bring the image into focus using the fine adjustment. If necessary, raise the condenser to obtain sufficient illumination.

High power – oil immersion (×100). Place a small drop of immersion oil on the part to be examined. Rack up the condenser as far as possible. Lower the objective until it is in contact with the oil. Bring it as close as possible to the slide, but avoid pressing on the preparation. Look through the eyepiece and turn the fine adjustment very slowly until the image is in focus.

After using the oil-immersion objective, to avoid scratching the lens or coating the ×40 lens with oil, first swing the ×10 objective (or an empty lens space on the nosepiece) into place before removing the slide. As far as possible, use oil only when essential (e.g. for determining malaria species) and examine blood films for morphology or differential leucocyte count with the ×40 lens without oil (or with a ×50 or ×60 lens when observation of finer detail is needed).

If you cannot focus using the oil-immersion lens, consider that:

The coverslip may be too thick.
Two coverslips may have been accidentally applied.
You may have inverted the slide.

Routine maintenance of the microscope

The microscope is a delicate instrument that must be handled gently. It must be installed in a clean environment away from chemicals, direct sunlight, heating sources or moisture. If the stage is contaminated with saline, it must be cleaned immediately to avoid corrosion. Even in a temperate climate, humidity and high temperatures cause growth of fungus, which can damage optical surfaces. Because storage in a closed compartment encourages fungal growth, do not store the microscope in its wooden box, but keep it standing on the bench protected by a light plastic cover.

After use of the microscope, wipe the oil-immersion objective with lens tissue, absorbent paper, soft cloth or medical cotton wool. If other lenses are smeared with oil, wipe them with a small amount of toluene or a solution of 40% petroleum ether, 40% ethanol and 20% ether.

Lenses must never be soaked in alcohol because this may dissolve the cement.

Clean nonoptical parts with mild detergent and remove grease or oil with petroleum ether, followed by 45% ethanol in water. Remove dust from the inside and outside of the eyepieces with a blower or soft camel-hair brush.

Clean the condenser in the same way as the lenses with a soft cloth or tissue moistened with toluene and clean the mirror (if present) with a soft cloth moistened with 5% alcohol. The iris diaphragm is very delicate and if damaged or badly corroded it is usually beyond repair.

Never force the controls. If movement of the focusing screws or mechanical stage becomes difficult, lubricate them with a small drop of machine oil. All accessible moving parts should be cleaned occasionally and given a touch of oil to protect against corrosion. Do not use vegetable oils because they become dry and hard. Always keep the surface of the fixed stage dry because moving wet slides requires increased force, which may damage the mechanical stage.

For care of microscopes in hot humid and hot dry climates, see page 549.

Preparation and Staining Methods for Blood and Bone Marrow Films

Barbara J. Bain

CHAPTER OUTLINE

PREPARATION OF BLOOD FILMS ON SLIDES

Blood films should be made on clean glass slides. Films made on coverglasses have negligible advantages and are unsuitable for modern laboratory practice. Films may be spread by hand or by means of an automated slide spreader, the latter being either a stand-alone instrument or a component of an automated blood cell counter.

Manual method

Blood films can be prepared from fresh blood with no anticoagulant added or from ethylenediaminetetra-acetic acid (EDTA)-anticoagulated blood. Heparinised blood should not generally be used because its staining characteristics differ from those of EDTA-anticoagulated blood. Good films can be made in the following manner using clean slides, if necessary wiped free from dust immediately before use. Slides should measure 75 × 25 mm and

be approximately 1 mm thick; ideally, they should be frosted at one end to facilitate labelling, but these are more expensive.

First, make a spreader from a glass slide that has a smooth end. Using a glass cutter, break off one corner of the slide, leaving a width of about 18 mm as the spreader. A spreader can be used repeatedly unless the edge becomes chipped, but it must be thoroughly cleaned and dried between films.

Place a small drop of blood in the centre line of a slide about 1 cm from one end. Then, without delay, place a spreader in front of the drop at an angle of about 30 degrees to the slide and move it back to make contact with the drop. The drop should spread quickly along the line of contact. With a steady movement of the hand, spread the drop of blood along the slide. The spreader must not be lifted off until the last trace of blood has been spread out; with a correctly sized drop, the film should be about 3 cm in length. It is important that the film of blood finishes at least 1 cm before the end of the slide (Fig. 4-1).

The thickness of the film can be regulated by varying the pressure and speed of spreading and by changing the angle at which the spreader is held. With anaemic blood, the correct thickness is achieved by using a wider angle, and, conversely, with polycythaemic blood, the angle should be narrower.

The ideal thickness is such that on microscopy there is some overlap of red cells throughout much of the film's length (see p. 25). The leucocytes should be easily recognisable throughout most of the film. With poorly made films the leucocytes will be unevenly distributed, with monocytes and other large leucocytes being pushed to the end and the sides of the film. An irregular streaky film will occur if the slide is greasy, and dust on the surface will cause patchy spots (Fig. 4-1).

The films should be allowed to dry in the air. In humid conditions the films may be exposed to a current of warm air (e.g. from a hairdryer), but this should be in a microbiological safety hood.

Automated methods

The manufacturer's instructions should be followed unless local experience has demonstrated that variation of the recommended technique achieves better results.

Labelling blood films

The film should be labelled immediately after being spread. Write in pencil either a laboratory reference number or the name of the patient and the date on the frosted end of the slide or on the film itself (writing on the thickest part, which is least suitable for microscopic examination). A label written in pencil will not be removed by staining. A paper label should be affixed to the slide later. If blood films are to be stored for future reference, apply the paper label in such a manner that it is easily read when the slides are filed.

In a computerised laboratory, bar-coded specimen identification labels are convenient and preferable. These should have the patient's name, the date and the laboratory number as well as the bar code.

Fixing blood films

To preserve the morphology of the cells, films must be fixed as described on page 53. This must be done without delay, and the films should never be left unfixed for more than a few hours. If films are sent to the laboratory by post, it is essential that, when possible, they are thoroughly dried and fixed before dispatch.

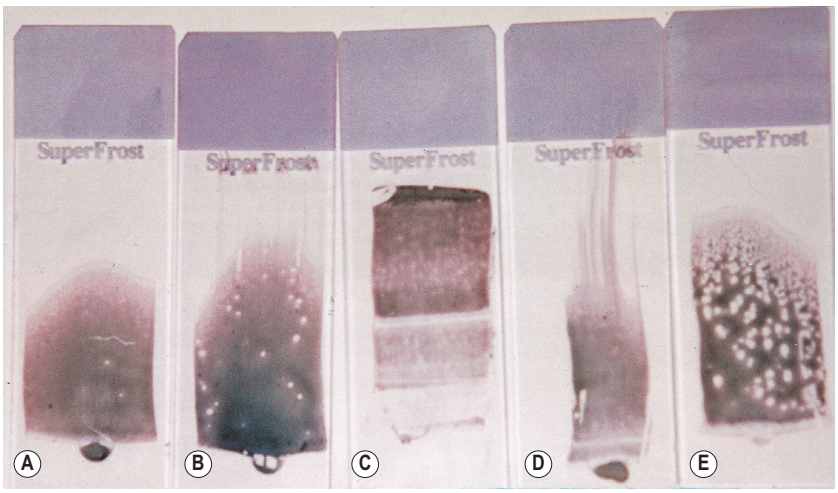

FIGURE 4-1 Blood films made on slides. (A) A well-made film. **(B)** An irregular patchy film on a dusty slide. **(C)** A film that is too thick. **(D)** A film that has been spread with inconsistent pressure and using an irregularly edged spreader, resulting in long tails. **(E)** A film made on a very greasy slide.

Bone marrow films

The method for preparation of films of aspirated bone marrow is described on page 116. They should be made without delay. Films must be thoroughly dry before they are fixed or artefactual changes will occur. At least one film should be fixed for a Perls stain on the initial bone marrow aspirate of each patient, and, if necessary, films should be fixed in the appropriate fixatives for special staining (Chapter 15); others should be fixed and stained with a Romanowsky stain as described later. Crushed bone marrow particles and touch preparations from trephine biopsy specimens can be stained in the same manner.

STAINING BLOOD AND BONE MARROW FILMS

Romanowsky stains are used universally for routine staining of blood films. The remarkable property of the Romanowsky dyes of making subtle distinctions in shades of staining, and of staining granules differentially, depends on two components: azure B (trimethylthionine) and eosin Y (tetrabromofluorescein).[1,2]

The original Romanowsky combination was polychrome methylene blue and eosin. Several of the stains now used routinely that are based on azure B also include methylene blue, but the need for this is debatable. The presence of methylene blue in the stain is considered by some authors to enhance the staining of nucleoli and polychromatic red cells; in its absence, normal neutrophil granules tend to stain heavily and may resemble 'toxic granules' in conventionally stained films.[3]

There are a number of causes of variation in staining. One of the main factors is the presence of contaminants in the commercial dyes, and a simple combination of pure azure B and eosin Y might be considered preferable to the more complex stains because this ensures consistent results from batch to batch.[1,4,5] However, in practice, absolutely pure dyes are expensive, and it is sufficient to ensure that the stains contain at least 80% of the appropriate dye.[6] Among the Romanowsky stains now in use, Jenner is the simplest and Giemsa is the most complex. Leishman stain, which occupies an intermediate position, is still widely used in the routine staining of blood films, although the results are inferior to those obtained by the combined May–Grünwald–Giemsa, Jenner–Giemsa, and azure B–eosin Y methods. Wright stain, which is widely used in North America, gives results that are similar to those obtained with Leishman stain, whereas Wright–Giemsa gives results that are similar to those obtained with May–Grünwald–Giemsa. A pH to the alkaline side of neutrality accentuates the azure component at the expense of the eosin and vice versa. A pH of 6.8 is usually recommended for general use, but to some extent this depends on personal preference. (When looking for malaria parasites, a pH of 7.2 is recommended to see Schüffner dots.) To achieve a uniform pH, 50 ml of 66 mmol/l Sörensen phosphate buffer (see p. 563) may be added to each litre of the water used in diluting the stains and washing the films.

The mechanism by which certain components of a cell's structure stain with particular dyes while other components fail to do so depends on complex differences in binding of the dyes to chemical structures and interactions between the dye molecules.[7] Azure B is bound to anionic molecules, and eosin Y is bound to cationic sites on proteins.

Thus the acidic groupings of the nucleic acids and proteins of the cell nuclei and cytoplasm of primitive cells determine their uptake of the basic dye azure B, and, conversely, the presence of basic groupings on the haemoglobin molecule results in its affinity for acidic dyes and its staining by eosin. The granules in the cytoplasm of neutrophil leucocytes are weakly stained by the azure complexes. Eosinophilic granules contain a spermine derivative with an alkaline grouping that stains strongly with the acidic component of the dye, whereas basophilic granules contain heparin, which has an affinity for the basic component of the dye. These effects depend on the molar equilibrium between the two dyes in time-dependent reactions.[2] Deoxyribonucleic acid (DNA) binds rapidly, ribonucleic acid (RNA) more slowly, and haemoglobin more slowly still; hence the need to have the correct azure B to eosin ratio to avoid contamination of the dyes and to stain for the right time. Standardised stains and staining methods have been proposed (see p. 55).

The colour reactions of the Romanowsky effect are shown in Table 4-1; causes of variation in staining are given in Table 4-2.

Preparation of solutions of Romanowsky dyes

May–Grünwald stain

Weigh out 0.3 g of the powdered dye and transfer it to a conical flask of 200–250-ml capacity. Add 100 ml of methanol and warm the mixture to 50 °C. Allow the flask to cool to *c.* 20 °C and shake several times during the day. After letting it stand for 24 h, filter the solution. It is then ready for use, no 'ripening' being required.

Jenner stain

Prepare a 5 g/l solution in methanol in exactly the same way as described earlier for the May–Grünwald stain.

Giemsa stain

Weigh 1 g of the powdered dye and transfer it to a conical flask of 200–250-ml capacity. Add 100 ml of methanol and warm the mixture to 50 °C; keep at this temperature for 15 min with occasional shaking, then filter the solution. It is then ready for use, but it will improve on standing for a few hours.

TABLE 4-1

COLOUR RESPONSES OF BLOOD CELLS TO ROMANOWSKY STAINING

Cellular Component	Colour
Nuclei	
Chromatin	Purple
Nucleoli	Light blue
Cytoplasm	
Erythroblast	Dark blue
Erythrocyte	Dark pink
Reticulocyte	Grey-blue
Lymphocyte	Blue
Metamyelocyte	Pink
Monocyte	Grey-blue
Myelocyte	Pink
Neutrophil	Pink/orange
Promyelocyte	Blue
Basophil	Blue
Granules	
Promyelocyte (primary granules)	Red or purple
Basophil	Purple-black
Eosinophil	Red-orange
Neutrophil	Purple
Toxic granules	Dark purple
Platelet	Purple
Other Inclusions	
Auer body	Purple
Cabot ring	Purple
Howell–Jolly body	Purple
Döhle body	Light blue

TABLE 4-2

FACTORS CAUSING VARIATION IN STAINING

Appearances	Causes
Too blue	Incorrect preparation of stock, eosin concentration too low
	Stock stain exposed to bright daylight
	Batch of stain solution overused
	Impure dyes
	Staining time too short
	Staining solution too acidic
	Film too thick
	Inadequate time in buffer solution
Too pink	Incorrect azure B:eosin Y ratio
	Impure dyes
	Buffer pH too low
	Excessive washing in buffer solution
Pale staining	Old staining solution
	Overused staining solution
	Incorrect preparation of stock
	Impure dyes, especially azure A and/or C
	High ambient temperature
Neutrophil granules not stained	Insufficient azure B
Neutrophil granules dark blue/black (pseudotoxic)	Excess azure B
Other stain anomalies	Various contaminating dyes and metal salts
Stain deposit on film	Stain solution left in uncovered jar
	Stain solution not filtered
Blue background	Inadequate fixation or prolonged storage before fixation
	Blood collected into heparin as anticoagulant

Azure B–Eosin Y stock solution

The stock solution includes azure B, tetrafluoroborate or thiocyanate (Colour Index 52010), >80% pure, and eosin Y (Colour Index 45380), >80% pure.

Dissolve 0.6 g of azure B in 60 ml of dimethyl sulphoxide (DMSO) and 0.2 g of eosin Y in 50 ml of DMSO; preheat the DMSO to 37 °C before adding the dyes. Allow the solution to stand at 37 °C, shaking vigorously for 30 s at 5-min intervals until both dyes are completely dissolved. Add the eosin Y solution to the azure B solution and stir well. This stock solution should remain stable for several months if kept at room temperature in the dark. DMSO will crystallize below 18 °C; if necessary, allow it to redissolve before use.

Leishman stain

Weigh out 0.2 g of the powdered dye, and transfer it to a conical flask of 200–250-ml capacity. Add 100 ml of methanol and warm the mixture to 50 °C for 15 min, occasionally shaking it. Allow the flask to cool and filter the solution. It is then ready for use, but it will improve on standing.

Buffered water

Make up 50 ml of 66 mmol/l Sörensen phosphate buffer of the required pH to 1 litre with water at a pH of 6.8 (see p. 563). An alternative buffer may be prepared from buffer tablets, which are available commercially. Solutions of the required pH are obtained by dissolving the tablets in water.

STAINING METHODS

May–Grünwald–Giemsa stain

Dry the films in the air, then fix by immersing in a jar of methanol for 5–10 min. For bone marrow films, allow a longer time to ensure thorough drying and then leave it for 15–20 min in the methanol. Films should be fixed as soon as possible after they have dried. If they are left unfixed at room temperature it may be found that the background of dried plasma stains a pale blue that is impossible to

remove without spoiling the staining of the blood cells. It is important to prevent any contact with water before fixation is complete. Methyl alcohol (methanol) is the fixative of choice, although ethyl alcohol ('absolute alcohol') can also be used. To prevent the alcohol from becoming contaminated with absorbed water, it must be stored in a bottle with a tightly-fitting stopper and not left exposed to the atmosphere, especially in humid climates (see Chapter 26). As little as 1% water may affect the appearance of the films, and a greater water content causes gross changes (Fig. 4-2). Methylated spirits must not be used because it contains water.

Transfer the fixed films to a staining jar containing May–Grünwald stain freshly diluted with an equal volume of buffered water. After the films have been allowed to stain for about 15 min, transfer them without washing to a jar containing Giemsa stain freshly diluted with 9 volumes of buffered water, pH 6.8.

After staining for 10–15 min, transfer the slides to a jar containing buffered water, pH 6.8, rapidly wash in three or four changes of water, and finally allow slides to stand undisturbed in water for a short time (usually 2–5 min) for differentiation to take place. This may be controlled by inspection of the wet slide under the low power of the microscope; with experience, the naked-eye colour of the film is often a good guide. The slides should be transferred from one staining solution to the other without being allowed to dry. Because the intensity of the staining is affected by any variation in the thickness of a film, it is not easy to obtain uniform staining throughout a film's length.

When differentiation is complete, stand the slides upright to dry. This method is designed for staining a number of films at the same time. Single slides may be stained by flooding the slide with a combined fixative and staining solution (e.g. Leishman stain, p. 55). The red cells will

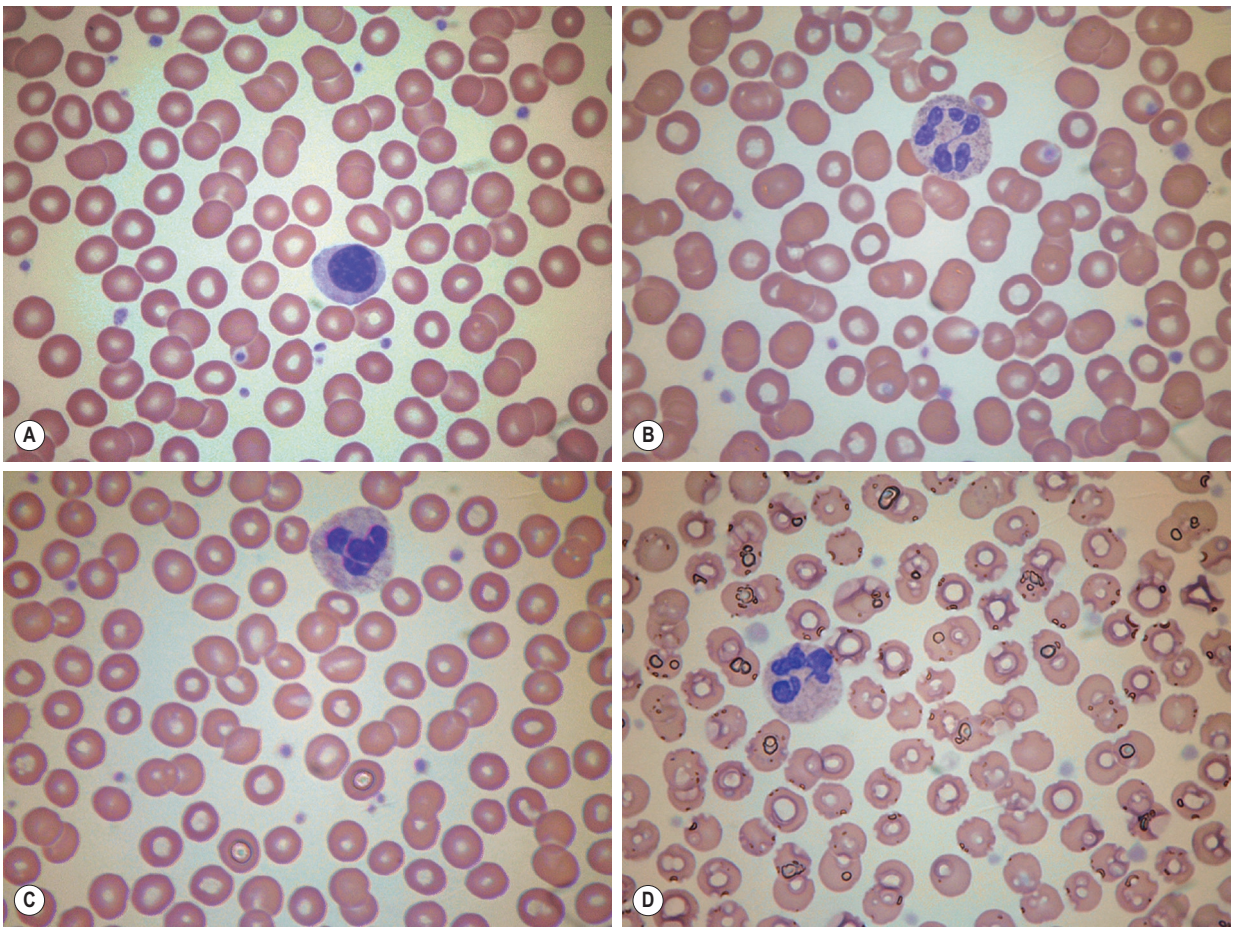

FIGURE 4-2 Blood film appearances following methanol fixation. Photomicrographs of Romanowsky-stained blood films that have been fixed in methanol containing **(A)** 1% water; **(B)** 3% water; **(C)** 4% water; and **(D)** 10% water. The red cells and leucocytes are well fixed in **(A)** and reasonably well fixed in **(B)**, but badly fixed in **(C)** and **(D)**.

be affected not only by water in the methanol but also by traces of detergent on inadequately washed slides (see Fig. 26-5, p. 556).

The diluted stains usually retain their staining powers sufficiently well for several batches of slides to be stained in them. They must be made up freshly each day, and it may be convenient to stain the day's films in two batches, morning and afternoon. There is no need to filter the stains before use unless a deposit is present.

Standardised Romanowsky stain

A standardised Romanowsky stain[2,5] based on a method with pure dyes was proposed by the International Committee (now Council) for Standardisation in Haematology (ICSH). It is useful for checking the performance of routine stains. The method is described fully in previous editions.

Jenner–Giemsa stain

Jenner stain may be substituted for May–Grünwald stain in the technique described above. The results are a little less satisfactory. The stain is used with 4 volumes of buffered water and the films, after being fixed in methanol, are immersed in the Jenner stain for approximately 4 min before being transferred to the Giemsa stain. They should be allowed to stain in the latter solution for 7–10 min. Differentiation is carried out as described earlier.

Leishman stain

Air-dry the film and flood the slide with the stain. After 2 min, add double the volume of water and stain the film for 5–7 min. Then wash it in a stream of buffered water until it has acquired a pinkish tinge (up to 2 min). After the back of the slide has been wiped clean, set it upright to dry.

Automated staining

Automated staining machines are available that enable large batches of slides to be handled. They may be either stand-alone staining machines or a part of a large automated blood counting instrument. In many instances, the instrument spreads, fixes and stains blood films. Some automated instruments incorporating staining can only be programmed to prepare and stain a single film per sample. Others can prepare and stain multiple films from a single blood sample; this is useful for preparing slides for teaching and for quality control purposes. Some systems apply staining solutions to slides lying horizontally (flat-bed staining), whereas others either immerse a slide or slides in a bath of staining solution ('dip-and-dunk' technique) or spray stain onto slides in a cytocentrifuge. Problems include increased background staining, inadequate staining of neutrophil granules, degranulation of basophils and blue or green rather than pink staining of erythrocytes. These problems are usually related to the specific stains and staining protocols used rather than to the type of instrument, although flat-bed stainers are more likely to cause problems with stain deposit. However, as a rule, staining is satisfactory provided that reliable stains are used and there is careful control of the cycle time and other variables.[8] Flat-bed stainers may not stain an entire film (e.g. a bone marrow film) if the film exceeds the standard length.

Rapid staining method

The Field method[9,10] was introduced to provide a quick method for staining thick films for malaria parasites (see p. 59). With some modifications, it can be used fairly satisfactorily for the rapid staining of thin films. The stains are available commercially ready for use, or they can be prepared as follows.

Stains

Stain A (Polychromed methylene blue)

Methylene blue	1.3 g
Disodium hydrogen phosphate ($Na_2HPO_4 \cdot 12H_2O$)	12.6 g
Potassium dihydrogen phosphate (KH_2PO_4)	6.25 g
Water	500 ml

Dissolve the methylene blue and the disodium hydrogen phosphate in 50 ml of water. Then boil the solution in a water bath almost to dryness to 'polychrome' the dye. Add the potassium dihydrogen phosphate and 500 ml of freshly boiled water. After stirring to dissolve the stain, set aside the solution for 24 h before filtering. Filter again before use. The pH is 6.6–6.8.

Alternatively, azure B may be added to the methylene blue in the proportion of 0.5 g of azure B to 0.8 g of methylene blue, and the combined dyes are then dissolved directly in the phosphate buffer solution.

Stain B (Eosin)

Eosin	1.3 g
Disodium hydrogen phosphate ($Na_2HPO_4 \cdot 12H_2O$)	12.6 g
Potassium dihydrogen phosphate (KH_2PO_4)	6.25 g
Water	500 ml

Dissolve the phosphates in warm freshly boiled water and then add the dye. Filter the solution after letting it stand for 24 h.

Method

Fix the film for 10–15 s in methanol. Pour off the methanol and drop on the slide 12 drops of diluted Stain B (1 volume of stain to 4 volumes of water). Immediately add 12 drops of Stain A. Agitate the slide to mix the stains. After 1 min, rinse the slide in water, then differentiate the film for 5 s in phosphate buffer at pH 6.6, wash the slide in water and then place it on end to drain and dry. Two-stage stains of this type are also available commercially.

MOUNTING OF COVERSLIP

When thoroughly dry, cover the blood film with a rectangular No. 1 coverslip (also known as a coverglass), using for this purpose a mountant that is miscible with xylol (e.g. DPX Mountant, Merck) (www.sigmaaldrich.com). For a temporary mount, cedarwood oil may be used.

The coverslip should be large enough to overlie the whole film, so that the edges and the tail of the film can be examined. If a neutral mounting medium is used, the staining should be preserved for many years if kept in the dark. Although it is probable that stained films keep best unmounted, there are disadvantages: it is almost impossible to keep the slides free from dust and from being scratched and, in the absence of a coverslip, the observer is tempted to examine the film solely with the oil-immersion objective, a practice that is to be deprecated because it is important to have a general overview of the film before studying specific cells.

EXAMINATION OF WET BLOOD FILM PREPARATIONS

The examination of a drop of blood sealed between a slide and coverslip is sometimes of considerable value. The preparation may be examined in several ways: by ordinary illumination, by dark-ground illumination or by Nomarski (interference) illumination. Chemically clean slides and coverslips (see p. 564) should be used,* and the blood should be allowed to spread thinly between them. If the glass surfaces are free from dust, the blood will spread spontaneously and pressure, which is undesirable, should not be necessary. The edges of the preparation may be sealed with a melted mixture of equal parts of petroleum jelly and paraffin wax or with nail varnish.

Red cells

Rouleaux formation is typically seen in varying degrees in wet preparations of whole blood and must be distinguished from autoagglutination. The distinction is sometimes a matter of considerable difficulty, particularly when, as not infrequently happens, rouleaux formation is superimposed on agglutination. The rouleaux, too, may be notably irregular in haemolytic anaemias characterised by spherocytosis, whereas the clumping caused by massive rouleaux formation of normal type may closely simulate true agglutination. This pseudoagglutination owing to massive rouleaux formation may be distinguished from true agglutination in two ways:

1. By noting that the red cells, although forming parts of larger clumps, are mostly arranged side by side as in typical rouleaux.
2. By adding 3–4 volumes of 9 g/l NaCl to the preparation. Pseudoagglutination owing to massive rouleaux formation should either disperse completely or transform itself into typical rouleaux. The addition of saline to blood that has undergone true agglutination may cause the agglutinates to break up somewhat, but a major degree of it is likely to persist and typical rouleaux will not be seen.

Anisocytosis and *poikilocytosis* can be recognised in 'wet' preparations of blood, but the tendency to crenation and the formation of rouleaux tend to make observations on shape changes rather difficult. Such changes can best be studied in a wet preparation after fixation. For this, dilute a sample of freshly collected heparinised or EDTA-anticoagulated blood in 10 volumes of iso-osmotic phosphate buffer, pH 7.4 (see p. 563), and immediately fix with an equal volume of 0.3% glutaraldehyde in iso-osmotic phosphate buffer, pH 7.4. After standing for 5 min, add 1 drop of this suspension to 4 drops of glycerol and place 1–2 drops on a glass slide that is then sealed.[11]

Pitting occurs normally in less than 2% of the red cells; an increase of more than 4% is an indication of splenic dysfunction. The pits are readily identified by Nomarski illumination or electron microscopy when they have the appearance of small crater-like indentations on the cell surface.[12]

Sickling of red cells in 'wet' preparations of blood is described in Chapter 14.

Crystals of haemoglobin C can be demonstrated by incubating a sample of blood with an equal volume of 30 g/l sodium chloride for 4 h at 37 °C.[13] In blood from patients with haemoglobin C disease this induces formation of intracellular haemoglobin C crystals: large, clear structures that are well shown when the preparation is then stained by any Romanowsky stain.[13] They can also be demonstrated in red cells from patients with compound heterozygosity for haemoglobins S and C.

Cryoglobulinaemia

To identify cryoglobulinaemia, put a drop of blood from an EDTA-anticoagulated sample that has been kept at room temperature onto a glass slide, cover it with a glass coverslip, and examine it by phase contrast microscopy. The cryoglobulin will be seen as large clear deposits of amorphous material or as refringent precipitates that disappear when the slide is warmed to 37 °C.

*Precleaned slides and coverslips are available commercially.

This is a useful test when an automated blood count gives anomalous results with spuriously elevated white blood cell and platelet counts.[14]

Leucocytes

The motility of leucocytes can be readily studied in heparinised blood if the microscope stage can be warmed to about 37 °C. Usually, only the granulocytes show significant progressive movements. However, the examination of living neutrophils in plasma is not useful in day-to-day routine haematological practice. Specialised microscopy techniques applicable to leucocytes are discussed in the 8th edition of this book.

SEPARATION AND CONCENTRATION OF BLOOD CELLS

A number of methods are available for the concentration of leucocytes or abnormal cells when they are present in only small numbers in the peripheral blood. Concentrates are most simply prepared from the buffy coat of centrifuged blood. However, most methods affect to some extent subsequent staining properties, chemical reactions and viability of the separated cells.

Making a buffy coat preparation

Centrifuge an EDTA-anticoagulated blood sample in a plastic tube for 5–10 min at 1200–1500 *g*. Then remove the supernatant plasma carefully with a fine plastic pipette and with the same pipette, deposit the platelet and underlying leucocyte layers onto one or two slides. Mix the buffy coat in a drop of the patient's plasma and then spread the films. Allow them to dry in the air and then fix and stain in the usual way.

When leucocytes are scanty or if many slides are to be made, it is worthwhile centrifuging the blood twice; first, about 5 ml are centrifuged and a second tube is then filled from the upper cell layers of this sample.

As an alternative to centrifugation, the blood may be allowed to sediment by placing the tube vertically on the bench without disturbance, with or without the help of sedimentation-enhancing agents such as fibrinogen, dextran, gum acacia, Ficoll (www.gelifesciences.com) or methylcellulose.[15] Bøyum reagent[16] (methylcellulose and sodium metrizoate) is particularly suitable for obtaining leucocyte preparations with minimal red cell contamination.

Utility of the buffy coat

It is well-known that atypical or primitive blood cells circulate in small numbers in the peripheral blood in health. Thus atypical mononuclear cells, metamyelocytes and megakaryocytes may be found. Even promyelocytes, blasts and nucleated red cells may occasionally be seen but only in very small numbers. Efrati and Rozenszajn[17] described a method for the quantitative assessment of the numbers of atypical cells in normal blood and gave figures for the incidence of megakaryocyte fragments (e.g. mean 21.8 per 1 ml of blood) and of atypical mononuclear cells, metamyelocytes and myelocytes. In cord blood, the incidence of all types of primitive cells is considerably greater.[18]

In disease, abnormal cells may be seen in buffy coat preparations in much larger numbers than in films of whole blood (Fig. 4-3). For example, megakaryocytes and immature cells of the granulocyte series are found in relatively large numbers in disseminated carcinoma.[19] Megaloblasts, if present, may help in the diagnosis of a megaloblastic anaemia. Ring sideroblasts may be seen in patients with sideroblastic anaemia; their presence can be confirmed with a Perls stain. Haemophagocytosis, which is more often observed in the bone marrow, may also sometimes be demonstrated in buffy coat preparations.[20] Erythrophagocytosis may be conspicuous in cases of autoimmune haemolytic anaemia. In systemic lupus erythematosus (SLE) a few LE cells may be found, but this is not the best way to demonstrate LE cells; moreover, the detection of LE cells for the diagnosis of SLE has been supplanted by immunological tests for the detection of antibodies to double-stranded deoxyribonucleic acid (DNA).

Buffy coat films can be useful for the detection of bacteria, fungi or parasites within neutrophils, monocytes or circulating macrophages; they also can help find cells that may be present in very small numbers (e.g. hairy cells in hairy cell leukaemia). With the availability of monoclonal antibodies reactive with epithelial and other tumour cells, immunocytochemical techniques can now be applied for the identification of infrequent neoplastic cells.

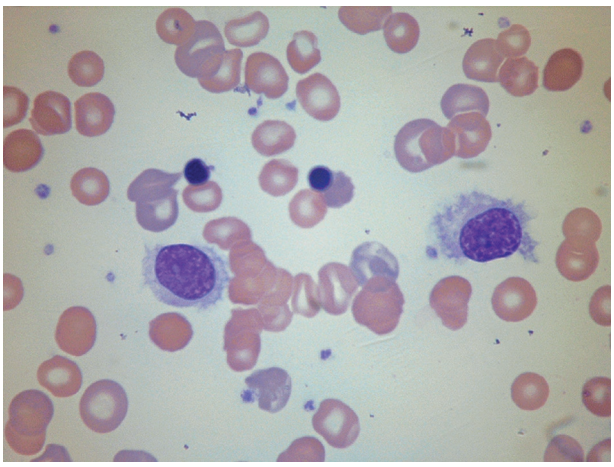

FIGURE 4-3 Buffy coat film. From blood of a patient with pancytopenia showing two hairy cells, an erythroblast and a bare nucleus. Only rare cells resembling hairy cells were seen in the conventional film, whereas the buffy coat film showed many such cells.

TABLE 4-3

MEDIAN DENSITY OF BLOOD CELLS AND THEIR PRECURSORS

Erythrocytes	1100
Eosinophils	1090
Neutrophils	1085
Myelocytes	1075
Lymphocytes	1070
Monocytes	1064
Myeloblasts	1062
Platelets	1035

Separation of specific cell populations

It is now possible to identify specific cell populations by flow cytometric immunophenotyping, and the need for separation of mononuclear cells from blood has diminished. However, differences in density of cells can also be used to separate individual cell types, using gradient solutions of selected specific gravity.[16,21] This is also a useful method for use in leucocyte imaging with radioisotope-labelled neutrophils (see p. 363). A simple convenient technique has been described for layering the blood or bone marrow over the density preparations.[22] The median density values for the main haemopoietic cells and their progeny are shown in Table 4-3.

BACTERIA AND FUNGI DETECTABLE IN BLOOD FILMS

Ehrlichiosis is a tick-borne fever in which clusters of small organisms may be seen in Romanowsky-stained blood films. The detection of organisms within neutrophils or monocytes is important for its speedy diagnosis. Other bacteria and fungi are occasionally detected within neutrophils or monocytes or extracellularly.

PARASITES DETECTABLE IN BLOOD, BONE MARROW OR SPLENIC ASPIRATES

There are now a number of screening tests for diagnosing malaria based on the detection of malarial antigens (see Chapter 6). However, the essential method for a definitive diagnosis remains the finding of parasites in a blood film and the identification of the species by morphology.[23,24] In addition to the plasmodia that give rise to malaria, the other important parasites to be found in the blood are leishmaniae, babesiae, trypanosomes and microfilariae.

In addition to standard thin films, thick films are extremely useful when parasites are scanty. These should be prepared and examined as a routine, although identification of the species is less easy than in thin films and mixed infections may be missed. If 5 min are spent examining a thick film, this is equivalent to about 1 h spent in traversing a thin film. Once the presence of parasites has been confirmed, a thin film should be used for determining the species and, in the case of *Plasmodium falciparum* and *Plasmodium knowlesi,* for assessing the severity of the infection by counting the percentage of parasitised cells (excluding cells containing only gametocytes).

Low levels of parasitaemia detected by immunological tests may be missed by microscopy, and proficiency testing studies have demonstrated the need for all laboratories, and especially those lacking expertise, to take part in external quality control programmes and to refer problematic cases to more experienced centres.[25,26]

Thick blood films are also useful for the detection of microfilariae. When they are used for this purpose, it is important to scan the entire film using a low-power objective, or parasites may be missed. Examination of wet preparations of blood can be used for identification of microfilariae and has the advantage that the parasites are easily detected because they are moving. A stained film is necessary for confirmation of species. Wet preparations are also useful for the detection of trypanosomes and the spirochaetes of relapsing fever. The presence of small numbers of trypanosomes or spirochaetes is revealed by occasional slight agitation of groups of red cells. Examination of a stained film confirms the nature of the cells.

EXAMINATION OF BLOOD FILMS FOR PARASITES

Making thick films

Make a thick film by placing a small drop of blood in the centre of a slide and spreading it out with a corner of another slide to cover an area about four times its original area. The correct thickness for a satisfactory film will have been achieved if, with the slide placed on a piece of newspaper, small print is just visible.

Allow the film to dry thoroughly for at least 30 min at 37 °C. If it is necessary to hurry the procedure, the slide can be left near, but not touching, a light bulb where the temperature is 50–60 °C, for about 7 min; the quality of the film may deteriorate if it is overheated. Films that are not completely dry may wash off in the stain.

Staining thick films for parasites

The Field method of staining[9,10] is quick and usually satisfactory for thick films, but the method is not practical for staining large numbers of films; for this purpose the Giemsa, Leishman or azure B–eosin Y methods are more suitable. Careful attention to pH is critical for satisfactory staining of parasites.

Field staining

The preparation of the stains is described on p. 55.

1. Dip the slide with the dried film on it into Stain A for 3 s.
2. Dip into a jar of tap water for 3 s with gentle agitation.
3. Dip into Stain B for 3 s.
4. Wash gently in tap water for a few seconds until all excess stain is removed.
5. Drain the slide vertically and leave to dry. Do not blot.

Giemsa staining

1. Dry the films thoroughly, as explained previously.
2. Immerse the slides for 20–30 min in a staining jar containing Giemsa stain freshly diluted with 20 volumes of buffered water (pH 7.2).
3. Wash in buffered water, pH 7.2, for 3 min.
4. Stand the slides upright to dry. Do not blot.

Azure B–Eosin Y staining

1. Prepare a staining solution from the stock stain, as described on p. 53, but using HEPES buffer (Sigma–Aldrich, www.sigmaaldrich.com) at pH 7.2.
2. After the films have been dried and treated as described earlier, stain for 10 min in the staining solution.
3. Rinse for 1 min in buffered water, pH 7.2.
4. Stand the slides upright to dry. Do not blot.

Sometimes when thick films are stained, they become overlaid by a residue of stain or spoilt by the envelopes of the lysed red cells. These defects can be minimised by adding 0.1% Triton X-100 to the buffer before diluting the stock stain.[27] An alternative, but more laborious, method is to lyse 1 volume of blood with 3 volumes of 1% saponin in saline for 10 min, then centrifuge for 5 min, decant the supernatant and make films from the residual pellet.[28]

Staining thin films for parasites

Thin films should be stained with a Giemsa stain or a Leishman stain at pH 7.2, not with a standard May–Grünwald–Giemsa stain.

Leishman stain

Use commercially available stain or prepare stain as follows:

1. Add glass beads to 500 ml of methanol.
2. Add 1.5 g of Leishman powder.
3. Shake well, leave on a rotary shaker during the day and then incubate at 37 °C overnight.

There is no need to filter.

Method

1. Make a thin film and air-dry rapidly.
2. Place the film on a staining rack, flood with Leishman stain and leave for 30 s to 1 min to fix.
3. Add twice as much buffered distilled water (preferably from a plastic wash bottle because this permits better mixing of the solution), pH 7.2.
4. Leave to stain for 10 min.
5. Wash off stain with tap water.

Blood Cell Morphology in Health and Disease

Barbara J. Bain

CHAPTER OUTLINE

Examination of a fixed and stained blood film is an essential part of a haematological investigation, and it cannot be emphasised too strongly that, to obtain maximum information from the examination, the films must be well spread, well stained and examined systematically. Details of the recommended procedure for examination are given later in this chapter.

The most important red cell abnormalities, as seen in fixed and stained films, are described and illustrated, and some notes on their significance and diagnostic importance are added. Leucocyte and platelet abnormalities are also described and, where appropriate, are illustrated. The slides were stained with May–Grünwald–Giemsa. Variations in the colours are due not only to minor variations in the stains but also to whether a daylight blue filter was used in the microscope and to variations in photographic processing.

EXAMINATION OF BLOOD FILMS

Blood films should be examined systematically, starting with macroscopic observation of the stained film and then progressing from low-power to high-power microscopic examination. It is useless to place a drop of immersion oil randomly on the film and then to examine it using the high-power ×100 objective.

First, the film should be examined macroscopically to assess whether the spreading technique was satisfactory and to judge its staining characteristics and whether there are any abnormal particles present that may represent large platelet aggregates, cryoglobulin deposits or clumps of tumour cells. Either before or after macroscopic assessment, the film should be covered with a coverslip using a neutral medium as mountant. Next the film should be inspected under a low magnification (with a ×10 or ×20 objective) to (a) get an idea of the quality of the preparation; (b) assess whether red cell agglutination, excessive rouleaux formation or platelet aggregation is present; (c) assess the number, distribution and staining of the leucocytes; and (d) find an area where the red cells are evenly distributed and are not distorted. A large part of the film should be scanned to detect scanty abnormal cells such as occasional granulocyte precursors or nucleated red blood cells.

Having selected a suitable area, a ×40 or ×50 objective or ×60 oil-immersion objective should then be used. A much better appreciation of variation in red cell size, shape and staining can be obtained with one of these objectives rather than with the ×100 oil-immersion lens. It should be possible to detect features such as toxic granulation or the presence of Howell–Jolly bodies or Pappenheimer bodies. The major part of the assessment of a blood film is usually done at this power. The ×100 objective in combination with ×10 eyepieces should be used only for the final examination of unusual cells and for looking at fine details such as basophilic stippling (punctate basophilia) or Auer rods. Whether it is necessary to examine a film with a ×100 objective depends on the clinical features, the blood count and the nature of any morphological abnormality detected at lower power.

Because the diagnosis of the type of anaemia or other abnormality present usually depends on comprehension of the whole picture the film presents, the red cells, leucocytes and platelets should all be systematically examined. The film examination also serves to validate the automated blood count, distinguishing, for example, between true macrocytosis and factitious macrocytosis caused by the presence of a cold agglutinin and, similarly, between true thrombocytopenia and factitious thrombocytopenia caused by platelet aggregation or satellitism.

RED CELL MORPHOLOGY

In health, the red blood cells vary relatively little in size and shape (Fig. 5-1). In well-spread, dried and stained films the great majority of cells have round, smooth contours and diameters within the comparatively narrow range of 6.0–8.5 μm. As a rough guide, normal red cell size appears to be about the same as that of the nucleus of a small lymphocyte on the dried film (Fig. 5-1). The red cells stain quite deeply with the eosin component of Romanowsky dyes, particularly at the periphery of the cell as a result of the cell's normal biconcavity. A small but variable proportion of cells in well-made films (usually <10%) are definitely oval rather than round, and a very small percentage may be contracted and have an irregular contour or appear to have lost part of their substance as the result of fragmentation (schistocytes). According to Marsh, the percentage of 'pyknocytes' (irregularly contracted cells) and schistocytes in blood from healthy adults does not exceed 0.1% and the proportion is usually considerably less than this, whereas in normal, full-term infants the proportion is higher, 0.3–1.9%, and in premature infants it is still higher, up to 5.6%.[1]

Normal and pathological red cells are subject to considerable distortion in the spreading of a film and, as already mentioned, it is imperative to scan films carefully to

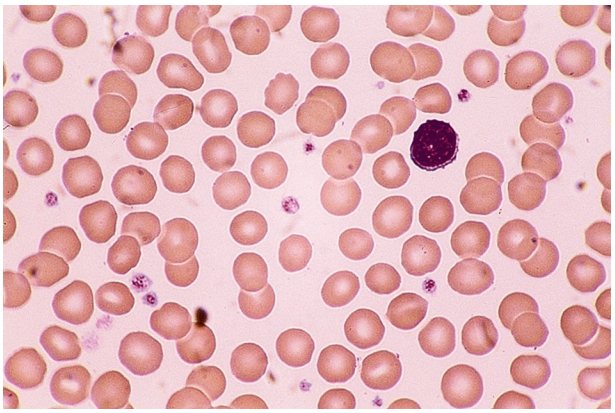

FIGURE 5-1 Photomicrograph of a blood film from a healthy adult.

find an area where the red cells are least distorted before attempting to examine the cells in detail. Such an area can usually be found toward the tail of the film, although not actually at the tail. Rouleaux often form rapidly in blood after withdrawal from the body and may be conspicuous even in films made at a patient's bedside. They are particularly noticeable in the thicker parts of a film that have dried more slowly. Ideally, red cells should be examined in an area in which there are no rouleaux and the red cells are touching but with little overlap. The film in the chosen area must not be so thin as to cause red cell distortion; if the tail of the film is examined, a false impression of spherocytosis may be gained. The varying appearances of different areas of the same blood film are illustrated in Figures 5-2 to 5-4. The area illustrated in Figure 5-2 would clearly be the best for looking at red cells critically.

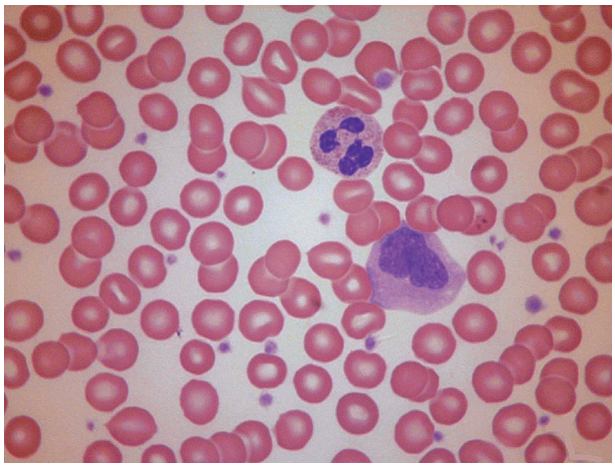

FIGURE 5-2 Photomicrograph of a blood film. Ideal thickness for examination.

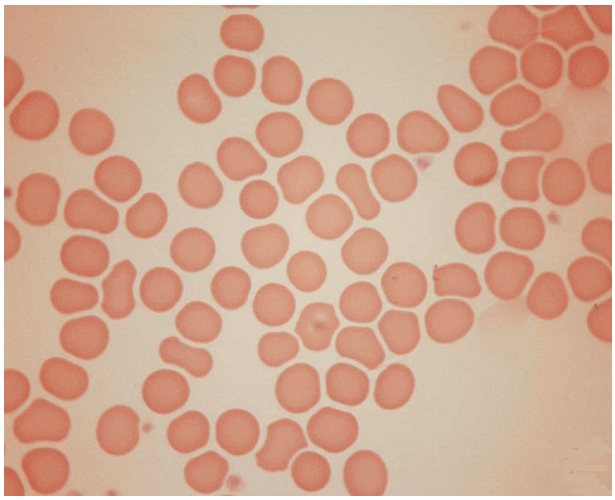

FIGURE 5-3 Photomicrograph of a blood film showing an area that is too thin for examination. The loss of central pallor can give a false impression of spherocytosis (same film as Fig. 5-2).

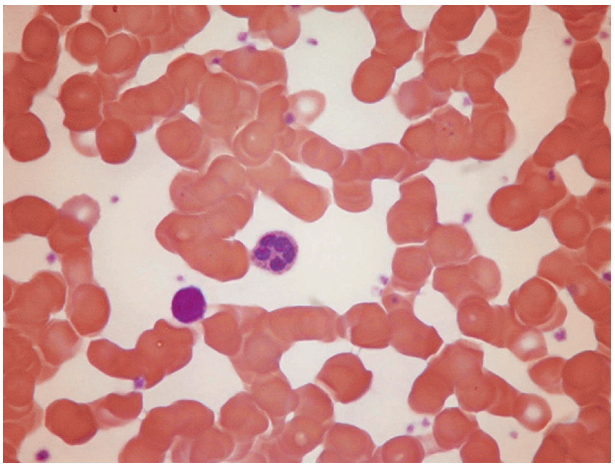

FIGURE 5-4 Photomicrograph of a blood film showing an area that is too thick for examination. No cellular detail can be discerned (same film as Fig. 5-2).

The advantages and disadvantages of examining red cells suspended in plasma have been referred to briefly in Chapter 4 (see p. 56). By this means, red cells can be seen in the absence of artefacts produced by drying, and abnormalities in size and shape can be better and more reliably appreciated than in films of blood dried on slides. However, the ease and rapidity with which dried films can be made, and their permanence, give them an overwhelming advantage in routine studies.

In disease, abnormality in the red cell picture stems from four main causes, which lead to characteristic cytological abnormalities (Table 5-1).

ABNORMAL ERYTHROPOIESIS

Anisocytosis (*ανισοξ*, unequal) and poikilocytosis (*ποικιλοξ*, varied)

Anisocytosis and poikilocytosis are nonspecific features of almost any blood disorder. The terms imply more variation in size or shape than is normally present (Figs. 5-5 and 5-6). Anisocytosis may be a result of the presence of cells larger than normal (macrocytosis), cells smaller than normal (microcytosis) or both; frequently both macrocytes and microcytes are present (Fig. 5-5).

Poikilocytes are produced in many types of abnormal erythropoiesis, for example, megaloblastic anaemia (Fig. 5-7), iron deficiency anaemia, thalassaemia, myelofibrosis (both primary and secondary) (Fig. 5-8), congenital dyserythropoietic anaemia (Fig. 5-9) and the myelodysplastic syndromes. Elliptocytes and ovalocytes are among the poikilocytes that may be present when there is dyserythropoiesis; they are often present in megaloblastic anaemia (macro-ovalocytes) and in iron deficiency anaemia ('pencil cells'), but they may also be seen in myelodysplastic

TABLE 5-1

MECHANISMS OF RED CELL ABNORMALITIES AND RESULTANT CYTOLOGICAL FEATURES

Cause	Resultant Abnormality
Attempts by the bone marrow to compensate for anaemia by increased erythropoiesis	Signs of less mature cells in the peripheral blood (polychromasia and erythroblastaemia)
Inadequate synthesis of haemoglobin	Reduced or unequal haemoglobin content and concentration (hypochromia, anisochromasia or dimorphism)
Abnormal erythropoiesis, which may be effective or ineffective	Increased variation in size (anisocytosis) and shape (poikilocytosis), basophilic stippling, sometimes dimorphism
Damage to, or changes affecting, the red cells after leaving the bone marrow, including the effects of reduced or absent splenic function	Spherocytosis, elliptocytosis, ovalocytosis or fragmentation (schistocytosis); the presence of Pappenheimer bodies, Howell–Jolly bodies and variable numbers of certain specific poikilocytes (target cells, acanthocytes, echinocytes and irregularly contracted cells)

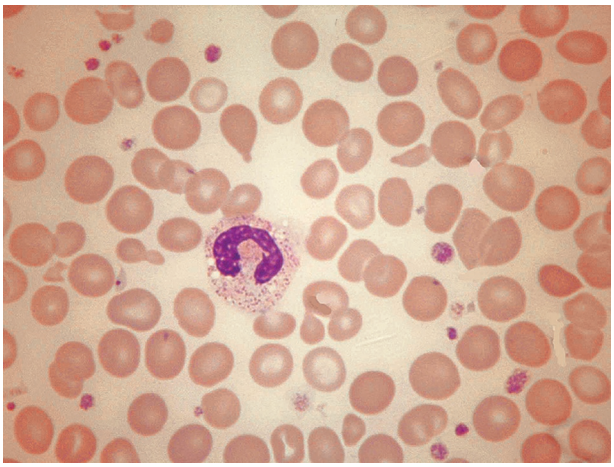

FIGURE 5-5 Photomicrograph of a blood film from a patient with a myelodysplastic/myeloproliferative neoplasm, unclassified. Shows moderate anisocytosis, anisochromasia and poikilocytosis. There are several hypochromic microcytes and one neutrophil band form, which is vacuolated.

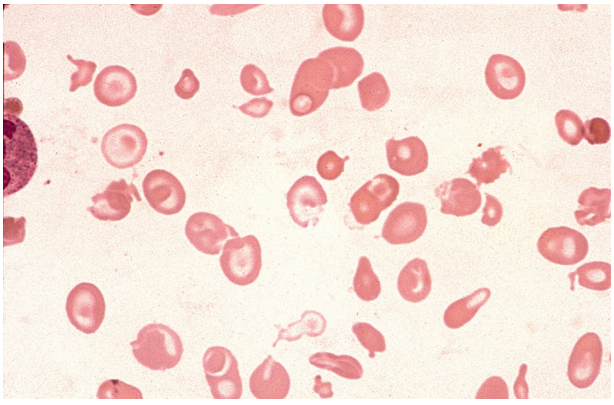

FIGURE 5-6 Photomicrograph of a blood film from a patient with compound heterozygosity for haemoglobin E and β^0 thalassaemia. Shows marked anisocytosis and poikilocytosis.

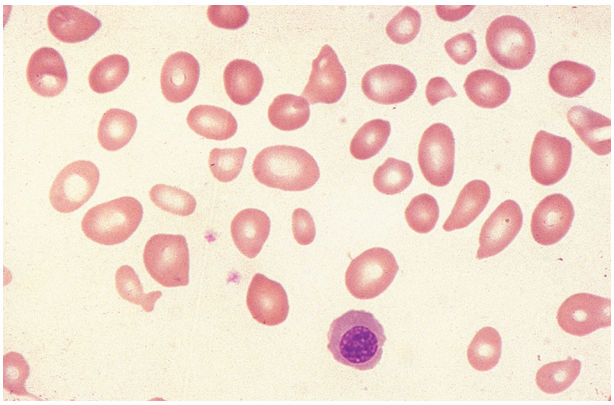

FIGURE 5-7 Photomicrograph of a blood film. Pernicious anaemia. Shows marked anisocytosis, moderate poikilocytosis (including oval macrocytes and teardrop cells) and a megaloblast.

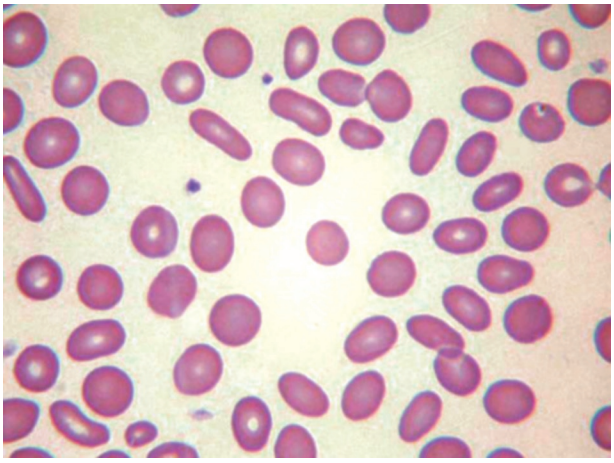

FIGURE 5-8 Photomicrograph of a blood film. Primary myelofibrosis. Many of the erythrocytes are elliptical or oval.

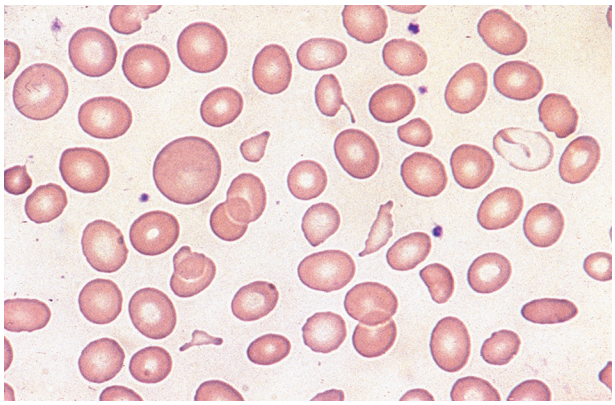

FIGURE 5-9 Photomicrograph of a blood film. Congenital dyserythropoietic anaemia type II. Shows marked anisocytosis, marked poikilocytosis, one unusually large macrocyte and one severely hypochromic cell.

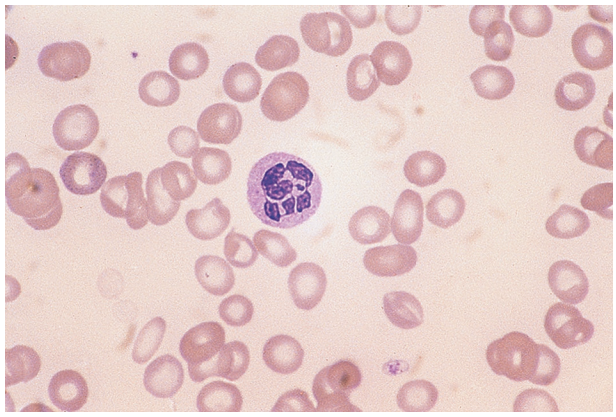

FIGURE 5-10 Photomicrograph of a blood film. Megaloblastic anaemia. Shows macrocytes, oval macrocytes and a hypersegmented neutrophil. There are also hypochromic cells and a mixed vitamin B_{12} and iron deficiency might be suspected.

syndromes and in primary myelofibrosis (Fig. 5-8). The number of elliptocytes and teardrop poikilocytes has been observed to correlate with the severity of iron deficiency anaemia.[2] Poikilocytes are not only characteristic of disordered erythropoiesis but are also seen in various congenital haemolytic anaemias caused by membrane defects and in acquired conditions such as microangiopathic haemolytic anaemia and oxidant damage; in these disorders, the abnormality of shape results from damage to cells after formation and is described later in this chapter.

Macrocytes

Classically found in megaloblastic anaemias (Fig. 5-10), macrocytes are also present in some cases of aplastic anaemia, myelodysplastic syndromes and other dyserythropoietic states. In patients being treated with hydroxycarbamide (previously known as hydroxyurea) the red cells are often macrocytic. A common cause of macrocytosis is excess alcohol intake, and it occurs in alcoholic and other types of chronic liver disease. In these conditions, the red cells tend to be fairly uniform in size and shape and there may also be stomatocytes (Fig. 5-11). In the rare type III form of congenital dyserythropoietic anaemia, some of the macrocytes are exceptionally large. Another rare cause of macrocytosis is benign familial macrocytosis.[3] Macrocytosis also occurs whenever there is an increased rate of erythropoiesis, because of the presence of reticulocytes. Their presence is suspected in routinely stained films because of the slight basophilia, giving rise to polychromasia (see p. 78), and is easily confirmed by special stains (e.g. New methylene blue, see p. 27). These polychromatic macrocytes should be distinguished from other macrocytes because the diagnostic significance is quite different.

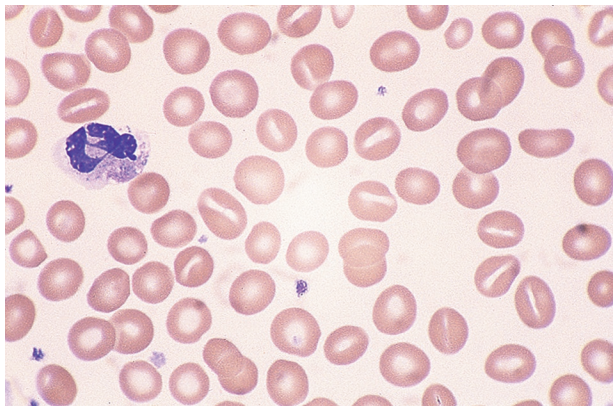

FIGURE 5-11 Photomicrograph of a blood film. Liver disease. Shows macrocytosis and stomatocytosis.

Microcytes

The presence of microcytes usually results from a defect in haemoglobin formation. Microcytosis is characteristic of iron deficiency anaemia (Fig. 5-12), various types of thalassaemia (Fig. 5-13), and severe cases of anaemia of chronic disease. Causes that are rarer include congenital and acquired sideroblastic anaemias. Microcytosis related to a defect in haemoglobin synthesis should be distinguished from red cell fragmentation or schistocytosis (see p. 72). Both abnormalities can lead to a reduction of the mean cell volume (MCV). However, it should be noted that a low MCV is common in association with a defect in haemoglobin synthesis, whereas it is uncommon in fragmentation syndromes because the fragments usually comprise only a small percentage of erythrocytes.

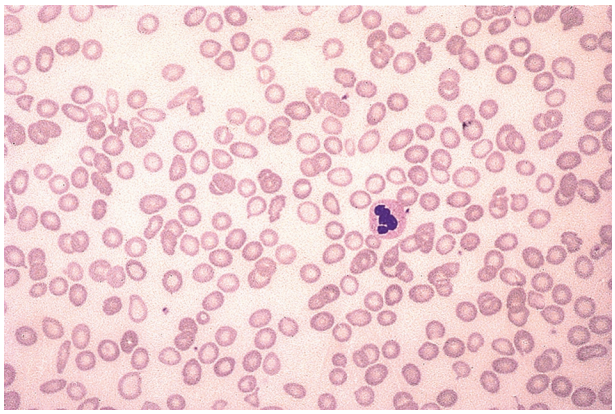

FIGURE 5-12 Photomicrograph of a blood film. Iron deficiency anaemia. Shows hypochromia, microcytosis and poikilocytosis.

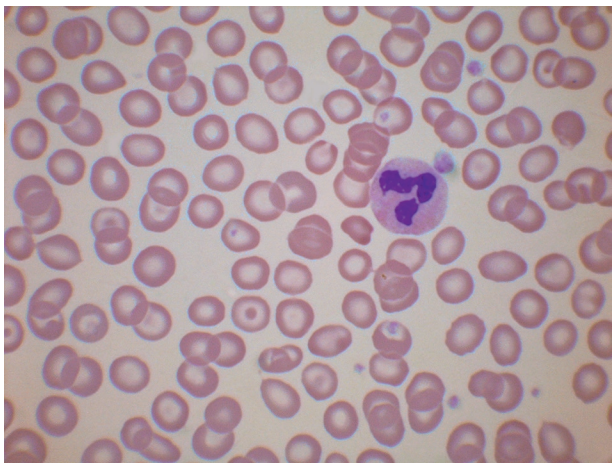

FIGURE 5-13 Photomicrograph of a blood film. β thalassaemia heterozygosity. Shows hypochromia, microcytosis and several target cells.

Basophilic stippling

Basophilic stippling or punctate basophilia means the presence of numerous basophilic granules distributed throughout the cell (Fig. 5-14); in contrast to Pappenheimer bodies (see below), they do not give a positive Perls reaction for ionised iron. Punctate basophilia has quite a different significance from diffuse cytoplasmic basophilia. It is indicative of disturbed rather than increased erythropoiesis. It occurs in many blood diseases: thalassaemia, megaloblastic anaemias, infections, liver disease, poisoning by lead and other heavy metals, unstable haemoglobins and pyrimidine-5′-nucleotidase deficiency.[4]

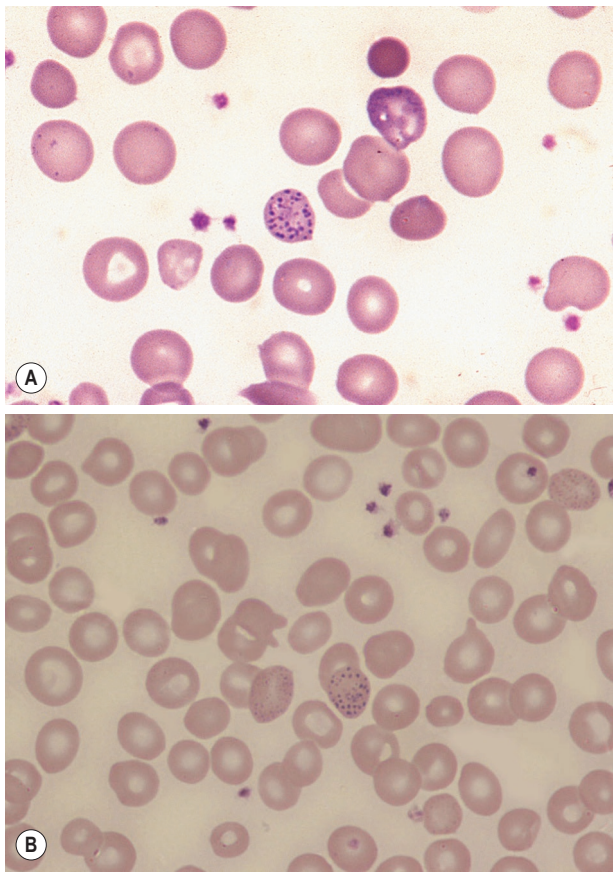

FIGURE 5-14 Photomicrographs of blood films. (A) β thalassaemia trait shows hypochromia, microcytosis and basophilic stippling. **(B)** Lead poisoning. One erythrocyte shows coarse basophilic stippling, while several others show fine basophilic stippling.

INADEQUATE HAEMOGLOBIN FORMATION

Hypochromia (Hypochromasia) (*υπορ,* under)

The term *hypochromia* (previously often designated *hypochromasia*), refers to the presence of red cells that stain unusually palely. (In doubtful cases, it is wise to compare the staining of the suspect film with that of a normal film stained at the same time.) There are two possible causes: a lowered haemoglobin concentration and abnormal thinness of the red cells. A lowered haemoglobin concentration results from impaired haemoglobin synthesis. This may stem from failure of haem synthesis – iron deficiency is a very common cause (Fig. 5-15) and sideroblastic anaemia (Fig. 5-16) is a rare cause – or from failure of globin

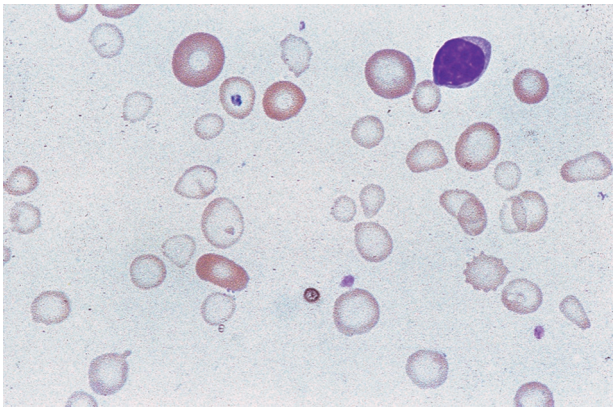

FIGURE 5-15 Photomicrograph of a blood film. Severe iron deficiency anaemia. Shows a marked degree of hypochromia, microcytosis, marked anisocytosis and mild poikilocytosis; there are some normally haemoglobinised cells.

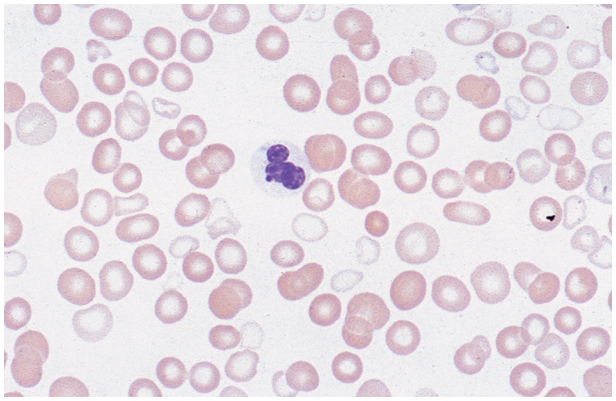

FIGURE 5-16 Photomicrograph of a blood film. Acquired sideroblastic anaemia (refractory anaemia with ring sideroblasts). Shows a dimorphic blood film with a mixture of normochromic normocytic cells and hypochromic microcytes; there are also several polychromatic macrocytes.

synthesis as in the thalassaemias (Fig. 5-17). Haemoglobin synthesis may also be impaired in chronic infections and other inflammatory conditions. Abnormally thin red cells (leptocytes) (see p. 74) can be the result of a defect in haemoglobin synthesis (e.g. in thalassaemias and iron deficiency) but they also occur in liver disease. It cannot be too strongly stressed that a hypochromic blood picture does not necessarily mean iron deficiency, although this is the most common cause. In iron deficiency, the red cells are characteristically hypochromic and microcytic, but the extent of these abnormalities depends on the severity; hypochromia may be minor and may be overlooked if the haemoglobin concentration (Hb) exceeds 100 g/l. In heterozygous or homozygous α^+ thalassaemia, heterozygous α^0 thalassaemia or heterozygous β thalassaemia,

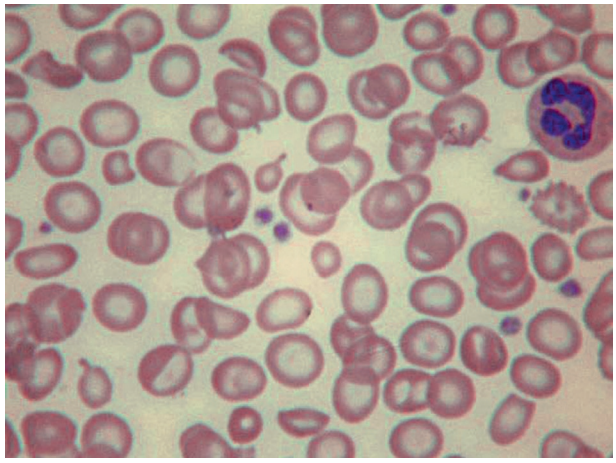

FIGURE 5-17 Photomicrograph of a blood film. Haemoglobin H disease. Shows microcytosis, moderate hypochromia, moderate anisocytosis and some poikilocytes (including teardrop poikilocytes and red cell fragments).

hypochromia is often less marked, in relation to the degree of microcytosis, than in iron deficiency. The presence of target cells or basophilic stippling also favours a diagnosis of thalassaemia trait rather than iron deficiency. In homozygous or compound heterozygous β thalassaemia (β thalassaemia intermedia or major), the abnormalities are greater than in iron deficiency at the same Hb and nucleated red cells are present, whereas they are not a feature of iron deficiency. If the patient is being transfused regularly, normal donor cells will also be present, producing a dimorphic blood film (Fig. 5-18).

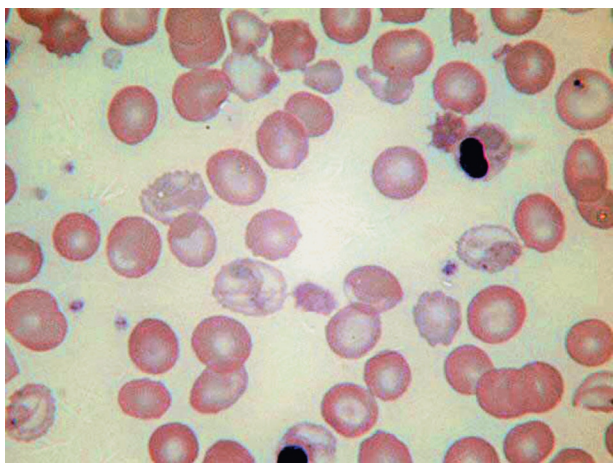

FIGURE 5-18 Photomicrograph of a blood film. β thalassaemia major. Shows a dimorphic blood film. The normal cells are transfused cells. The patient's own cells show severe hypochromia. There are two nucleated red blood cells.

Anisochromasia (*ανισοζ,* unequal) and dimorphic red cell population

A distinction should be made between anisochromasia, in which there is abnormal variability in staining of red cells, and a dimorphic picture, in which there are two distinct populations. Anisochromasia, in which some but not all of the red cells stain palely, is characteristic of a changing situation. It can occur during the development or resolution of iron deficiency anaemia (Fig. 5-19) or the anaemia of chronic disease. In thalassaemia trait, in contrast, anisochromasia is much less common. A dimorphic blood film can be seen in several circumstances. It can occur when an iron deficiency anaemia responds to iron therapy, when a patient being treated for megaloblastic anaemia develops iron deficiency,[5] after the transfusion of normal blood to a patient with a hypochromic anaemia and in sideroblastic anaemia (Fig. 5-20). In acquired sideroblastic anaemia as a feature of a myelodysplastic syndrome, the two populations of cells are usually hypochromic microcytic and normochromic macrocytic, respectively.

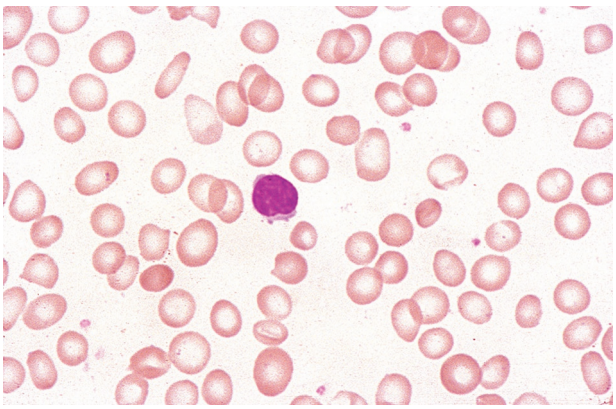

FIGURE 5-19 Photomicrograph of a blood film. Iron deficiency anaemia. Shows a constant gradation of haemoglobinisation of cells (i.e. anisochromasia). There is one elliptocyte.

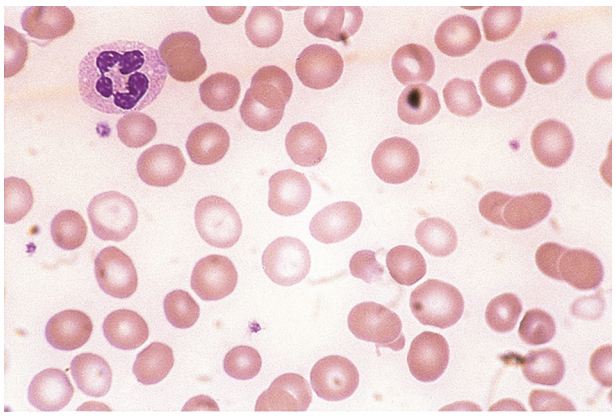

FIGURE 5-20 Photomicrograph of a blood film. Acquired sideroblastic anaemia. Shows two distinct populations of cells: hypochromic cells, which also tend to be microcytic, and normocytic normochromic cells.

DAMAGE TO RED CELLS AFTER FORMATION

Poikilocytosis can result not only from abnormal erythropoiesis but also from damage to red cells after their formation. The damage may be consequent on an intrinsic abnormality of the red cell such as a haemoglobinopathy, a membrane defect or an enzyme defect that renders the cell prone to shape alteration. Poikilocytosis can also result from extrinsic causes, as when a red cell is damaged by drugs, chemicals or toxins; by heat; or by abnormal mechanical forces. Poikilocytes of specific shapes suggest different aetiological factors.

Hyperchromia (Hyperchromasia) (*υπερ,* over)

Unusually deep staining of the red cells with a lack of central pallor may be seen in two circumstances: first, in the presence of macrocytes; and second, when cells are abnormally rounded. In macrocytosis, as in neonatal blood and megaloblastic anaemias, it is the increased red cell thickness that causes the hyperchromia, and the mean cell haemoglobin concentration is normal. When hyperchromia results from cells being of abnormal shape, the red cell thickness is greater than normal and the MCHC is increased. Abnormally rounded cells may be either spherocytes or irregularly contracted cells. The distinction between these two cell types is of diagnostic importance.

Spherocytosis (*σφαιρα,* sphere)

Spherocytes are cells that are more spheroidal (i.e. less disc-like) than normal red cells but maintain a regular outline. Their diameter is less and their thickness is greater than normal. Only in extreme instances are they almost spherical in shape. It is useful to draw a distinction between spherocytes of normal size and microspherocytes; the latter result from red cell fragmentation or from removal of a considerable proportion of the red cell membrane by splenic or other macrophages. Spherocytes may result from genetic defects of the red cell membrane as in hereditary spherocytosis (Fig. 5-21); from the interaction between immunoglobulin- or complement-coated red cells and phagocytic cells, as in delayed transfusion reactions, ABO haemolytic disease of the newborn (Fig. 5-22) and autoimmune haemolytic anaemia (Fig. 5-23); and from the action of bacterial toxins (e.g. *Clostridium perfringens* lecithinase; Fig. 5-24) or snake venoms.

Spherocytes usually appear perfectly round in contour in stained films; they have to be carefully distinguished

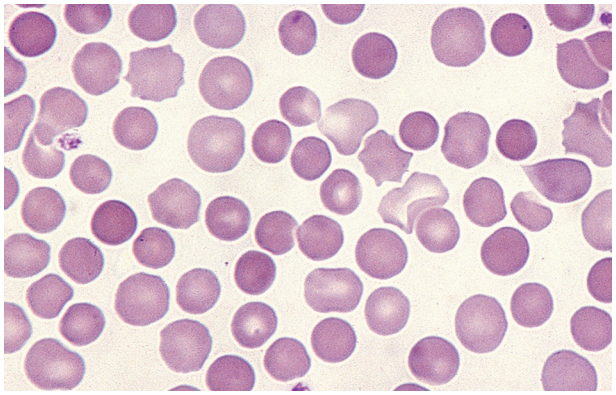

FIGURE 5-21 Photomicrograph of a blood film. Hereditary spherocytosis. Shows marked spherocytosis and some anisocytosis. Note the round contour of the spherocytes. The larger cells have a faint blue tinge, indicating that the reticulocyte count is increased.

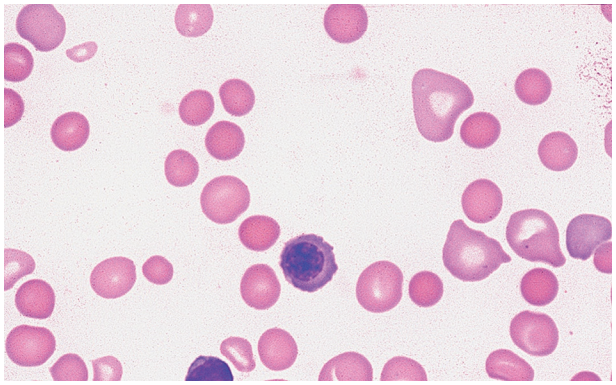

FIGURE 5-22 Photomicrograph of a blood film. ABO haemolytic disease of the newborn. Spherocytosis is intense, and there are several polychromatic macrocytes.

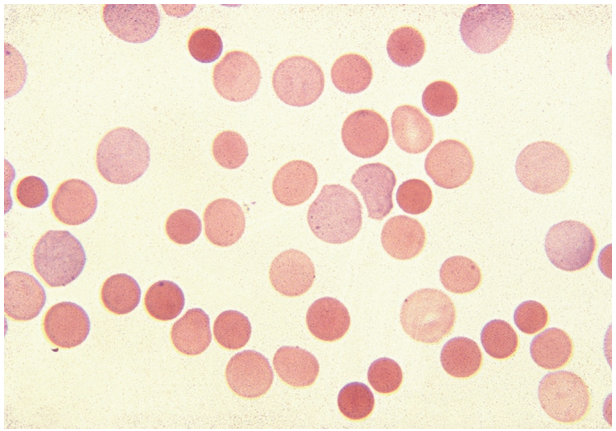

FIGURE 5-23 Photomicrograph of a blood film. Autoimmune haemolytic anaemia. Shows marked spherocytosis and anisocytosis. There are numerous polychromatic macrocytes.

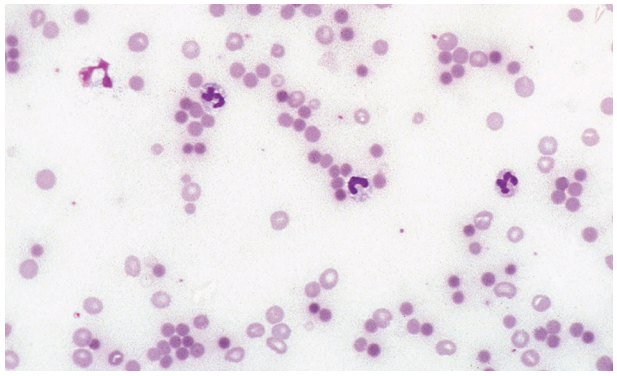

FIGURE 5-24 Photomicrograph of a blood film. *Clostridium perfringens* septicaemia. Shows an extreme degree of spherocytosis; note the round contour of the spherocytes. A markedly dimorphic picture.

from both irregularly contracted cells and 'crenated spheres' or sphero-echinocytes (Fig. 5-25), which are the end result of crenation (see p. 74). Sphero-echinocytes develop as artefacts, especially in blood that has been allowed to stand before films are spread (Fig. 5-26). The blood film of a patient who has been transfused with stored blood may show a proportion of sphero-echinocytes (Fig. 5-27).

Irregularly contracted red cells

There are a number of causes of irregularly contracted cells. In oxidant drug- or chemical-induced haemolytic anaemias, a proportion of the red cells are smaller than normal and unusually densely stained (i.e. they appear contracted) and their margins are slightly or moderately irregular and may be partly concave (Fig. 5-28). Similar cells may be seen in films of some unstable haemoglobinopathies before splenectomy (e.g. that caused by the presence of haemoglobin Köln or haemoglobin St Mary's; Fig. 5-29), in

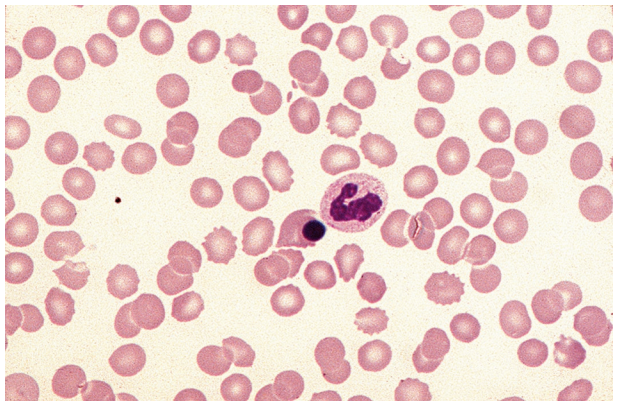

FIGURE 5-25 Photomicrograph of a blood film. Sodium chlorate poisoning. Shows sphero-echinocytes, one keratocyte, one nucleated red cell and several crenated cells (echinocytes).

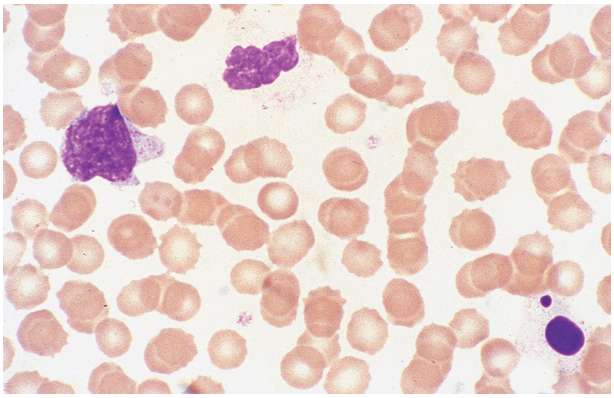

FIGURE 5-26 Photomicrograph of a blood film. Normal blood after 24 h at 20 °C. Shows a marked degree of crenation; also degenerative changes in white cells.

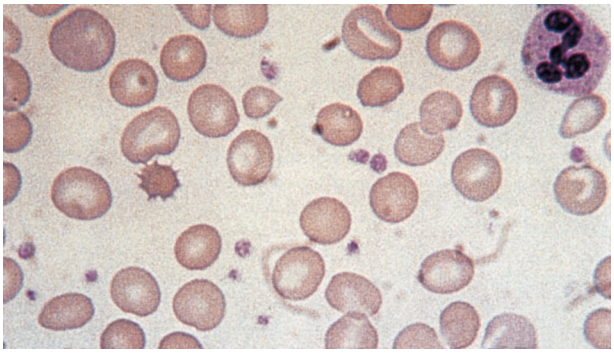

FIGURE 5-27 Photomicrograph of a blood film. Post-transfusion, showing one sphero-echinocyte.

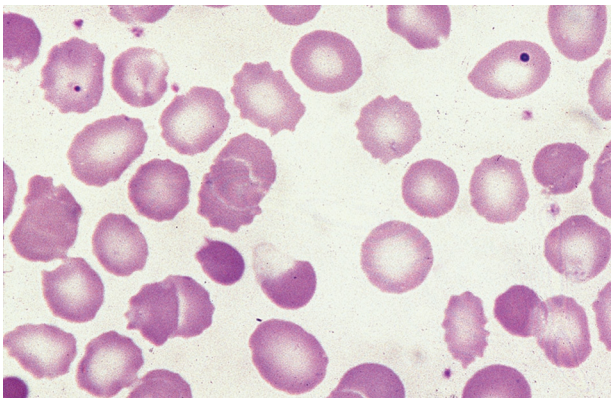

FIGURE 5-28 Photomicrograph of a blood film. Haemolytic anaemia caused by an overdose of phenacetin. Shows four irregularly contracted cells; one of these is a 'hemi-ghost'. There is also crenation and there are two Howell–Jolly bodies, likely to be indicative of functional hyposplenism.

haemoglobin E homozygosity (Fig. 5-30) and, to a lesser extent, haemoglobin E heterozygosity. They can result from oxidant damage due to release of copper from liver cells in Wilson disease.[6] An extreme degree of irregular contraction is characteristic of severe favism or any other very acute haemolytic episode in individuals who are glucose-6-phosphate (G6PD) deficient. It is typical to see cells in which the haemoglobin appears to have contracted away from the cell membrane, an appearance sometimes referred to as a blister cell or a hemi-ghost (Fig. 5-28); there may also be ghost cells – cells with almost empty membranes containing negligible haemoglobin (Fig. 5-31). Irregularly contracted cells can be seen in small numbers in β thalassaemia trait and in heterozygosity for haemoglo-

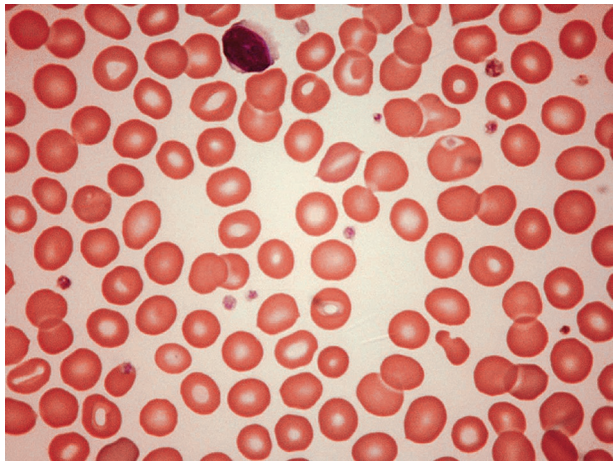

FIGURE 5-29 Photomicrograph of a blood film. An unstable haemoglobin haemolytic anaemia (haemoglobin St Mary's). Shows several irregularly contracted cells.

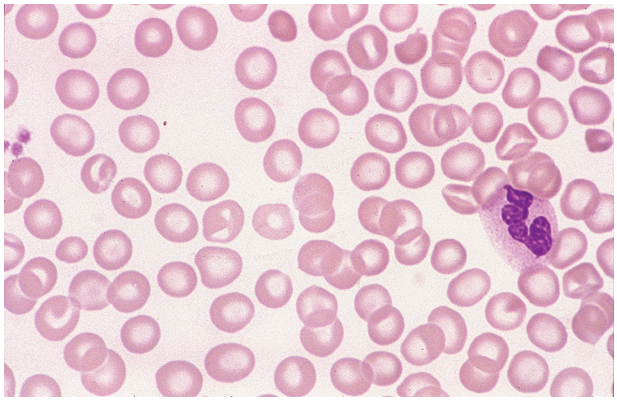

FIGURE 5-30 Photomicrograph of a blood film. Haemoglobin E homozygosity showing four irregularly contracted cells and target cells.

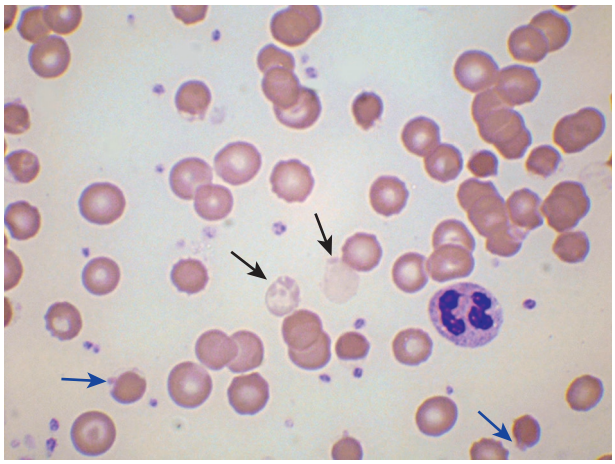

FIGURE 5-31 Photomicrograph of a blood film. Acute drug-induced haemolysis in a patient with glucose-6-phosphate dehydrogenase (G6PD) deficiency. There are irregularly contracted cells and ghost cells *(black arrows)*. Heinz bodies can be seen protruding from erythrocytes *(blue arrows)*.

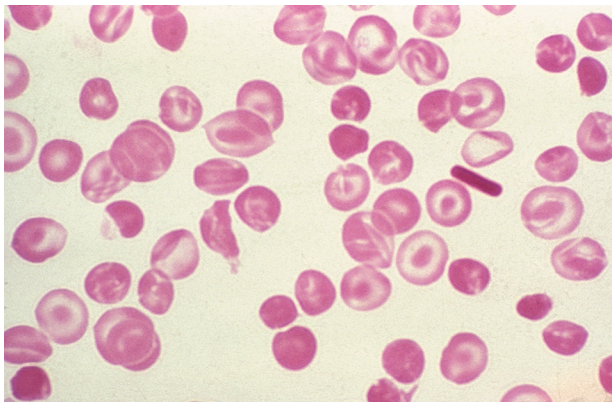

FIGURE 5-32 Photomicrograph of a blood film. Haemoglobin C disease (homozygosity for haemoglobin C). Shows many target cells, irregularly contracted cells and a crystal of haemoglobin C. Sometimes it is apparent that haemoglobin C crystals are within otherwise empty red cell membranes.

bin C. There may be a considerable number in haemoglobin C homozygosity, and in this condition haemoglobin C crystals may also be seen (Fig. 5-32).

Heinz bodies are not normally readily visible in Romanowsky-stained blood films, although they are sometimes seen in such films as pale pinkish-brown–staining bodies at the cell margin or even protruding from the erythrocytes. This observation may be made in severe unstable haemoglobin haemolytic anaemias after splenectomy and in acute oxidant-induced haemolytic anaemia, including that occurring in deficiency of G6PD.

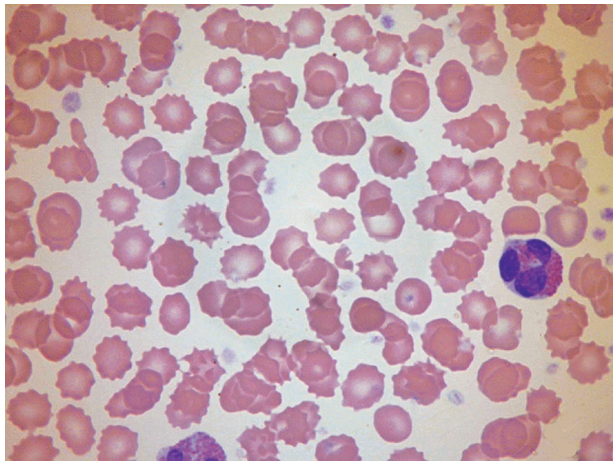

FIGURE 5-33 Photomicrograph of a blood film. Infantile pyknocytosis. Shows irregularly contracted spiculated cells.

A type of irregular contraction of unknown origin has been described by the term 'pyknocytosis'.[7] The pyknocytes closely resemble chemically damaged red cells but in addition are spiculated. As already mentioned (see p. 62), a small number of pyknocytes may be found in the blood of infants in the first few weeks of life, especially in premature infants. The term 'infantile pyknocytosis' refers to a transient haemolytic anaemia, related to glutathione peroxidase and selenium deficiency, affecting infants in whom many pyknocytes are present (Fig. 5-33).[7,8]

Elliptocytosis and ovalocytosis

Elliptocytes are often present in large numbers in hereditary elliptocytosis (Fig. 5-34). In hereditary pyropoikilocytosis, elliptocytes are only one of the many types of

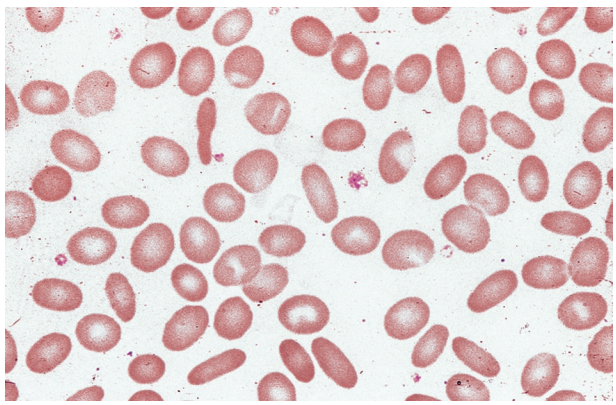

FIGURE 5-34 Photomicrograph of a blood film. Hereditary elliptocytosis. Many of the cells are elliptical, and others are oval.

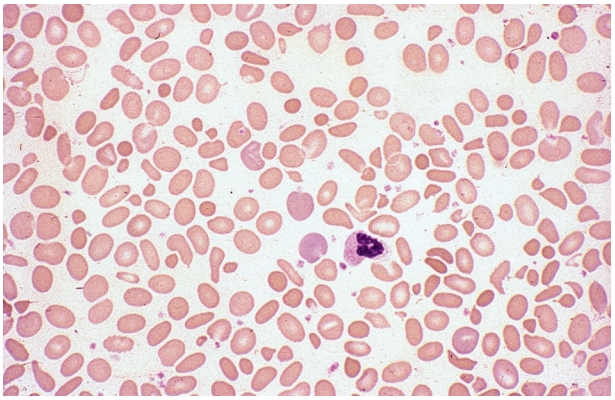

FIGURE 5-35 Photomicrograph of a blood film from a child with hereditary pyropoikilocytosis. Shows spherocytes, elliptocytes, ovalocytes, red cell fragments and polychromatic macrocytes.

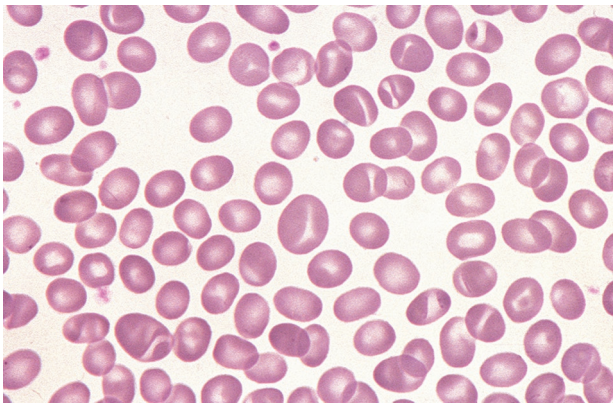

FIGURE 5-36 Photomicrograph of a blood film. Southeast Asian ovalocytosis. Shows stomatocytes, macrostomatocytes and macro-ovalocytes.

poikilocyte present (Fig. 5-35). Southeast Asian ovalocytosis is characterised by the presence of a variable number of elliptocytes, ovalocytes, macro-ovalocytes and stomatocytes (Fig. 5-36). In all these conditions, the reticulocytes are round in contour (i.e. the cell assumes an abnormal shape only in the late stages of maturation). Although the causative condition is inherited, the abnormalities of red cell shape only become apparent as the cells reach maturity.

SPICULATED CELLS AND RED CELL FRAGMENTATION

The terminology applied to spiculated cells has been confusing because the same terms have been used to designate different types of cells. For this reason the term 'burr cell' should be discarded and the terms recommended by Bessis[9] should be adopted. On the basis of scanning electron microscopy (discussed later), he distinguished four types of spiculated cell – schistocyte, keratocyte, acanthocyte and echinocyte. The term 'echinocyte' is used for the crenated cell. It is differentiated from the acanthocyte on the basis of the number, shape and disposition of the spicules.

Schistocytosis (Fragmentation) (*σχιστοζ*, cleft)

Schistocytes or erythrocyte fragments are found in many blood diseases. They are smaller than normal red cells and of varying shape. Sometimes they have sharp angles or spines (spurs), and sometimes they are round in contour, usually staining deeply but occasionally palely as the result of loss of haemoglobin at the time of fragmentation. If they are both round and densely staining, they may be referred to as microspherocytes. They occur in the following situations:

1. In certain genetically determined disorders (e.g. thalassaemias, congenital dyserythropoietic anaemia and hereditary pyropoikilocytosis)
2. In acquired disorders of red cell formation when erythropoiesis is megaloblastic or dyserythropoietic
3. As the consequence of mechanical stresses (e.g. in the microangiopathic haemolytic anaemias [Figs. 5-37 to 5-39] and in mechanical haemolytic anaemias such as those caused by a perivalvular leak accompanied by turbulence of left ventricular flow in a patient with a prosthetic cardiac valve [Fig. 5-40])
4. As the result of direct thermal injury, as in severe burns (Fig. 5-41)

It is important to be aware of schistocytes as a feature of megaloblastic[10] and dyserythropoietic anaemias so that misattribution to a thrombotic microangiopathy is avoided. In burns, schistocytes are often rounded, being either microspherocytes or very small disc-shaped fragments. In addition, erythrocytes may be seen to be budding off small rounded blebs of cytoplasm. Not infrequently,

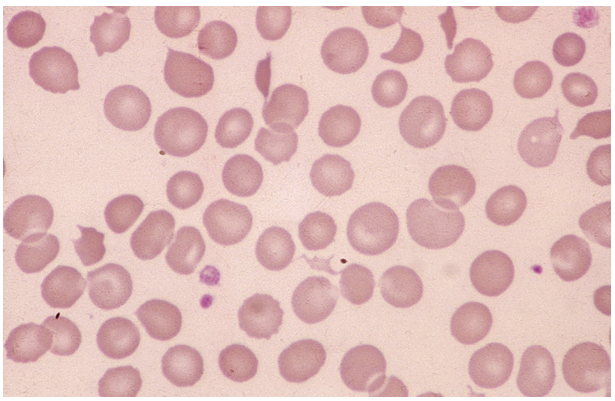

FIGURE 5-37 Photomicrograph of a blood film. Microangiopathic haemolytic anaemia. Shows angular red cell fragments.

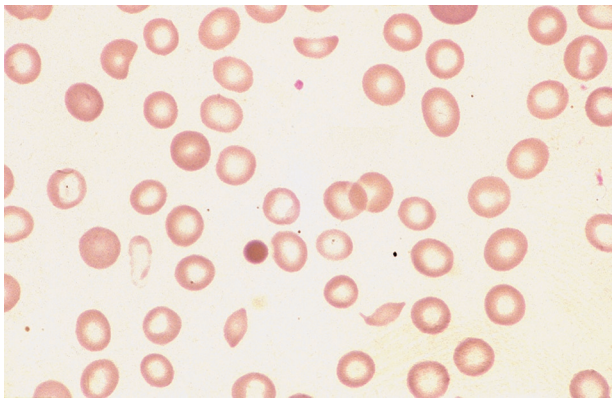

FIGURE 5-38 Photomicrograph of a blood film. Microangiopathic haemolytic anaemia in systemic lupus erythematosus. Shows one very dense microspherocyte and other red cell fragments.

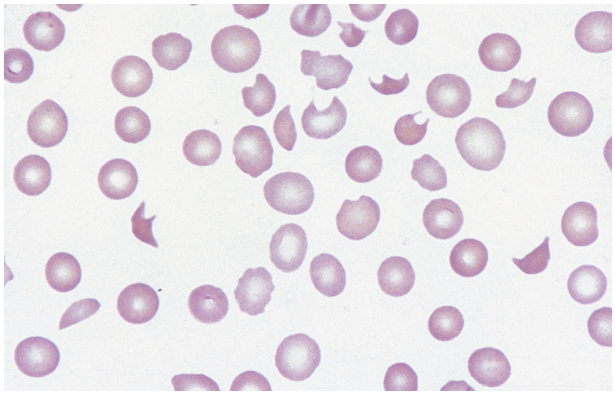

FIGURE 5-39 Photomicrograph of a blood film. Microangiopathic haemolytic anaemia. Shows numerous bizarrely shaped red cell fragments.

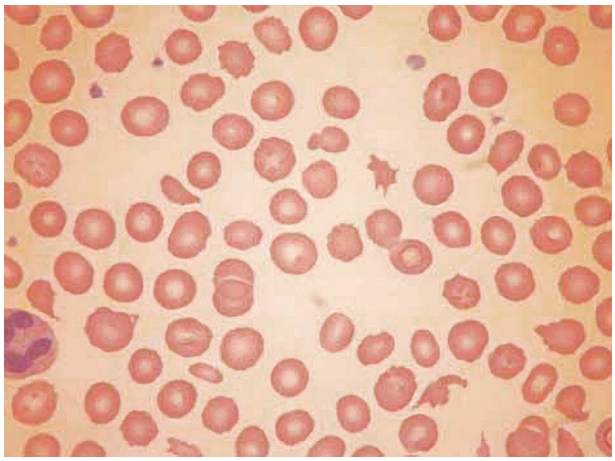

FIGURE 5-40 Photomicrograph of a blood film. Haemolytic anaemia after previous cardiac surgery. Shows numerous irregularly shaped cell fragments.

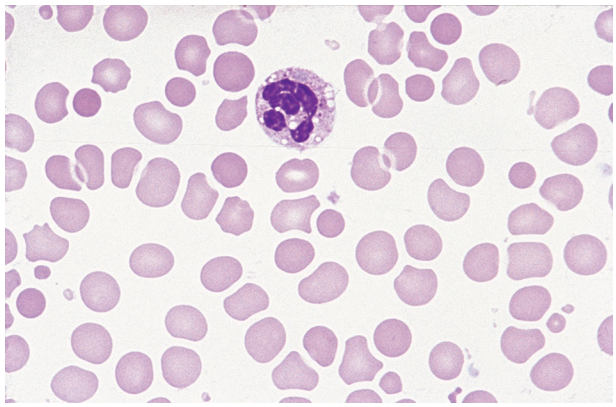

FIGURE 5-41 Photomicrograph of a blood film. Severe burns. Shows many very small, rounded red cell fragments (microspherocytes), a 'microdiscocyte' (bottom right), another characteristic feature of burns, and one vacuolated neutrophil.

as, for instance in the haemolytic uraemic syndrome in children, the blood picture is made more bizarre by the superimposition of varying degrees of echinocytic change. Schistocytes are also a feature of thrombotic thrombocytopenia purpura. International Council for Standardisation in Haematology (ICSH) guidelines are available for the recognition and enumeration of schistocytes in suspected thrombotic thrombocytopenic purpura.[11]

Keratocytes (*κεραζ*, horn)

Keratocytes have pairs of spicules, usually either one pair or two pairs. They may result from removal of a Heinz body (by the pitting action of the spleen) (Fig. 5-42) or from mechanical damage (Figs. 5-43 and 5-44). The terms 'helmet cell' and 'bite cell' have sometimes been used to describe keratocytes.

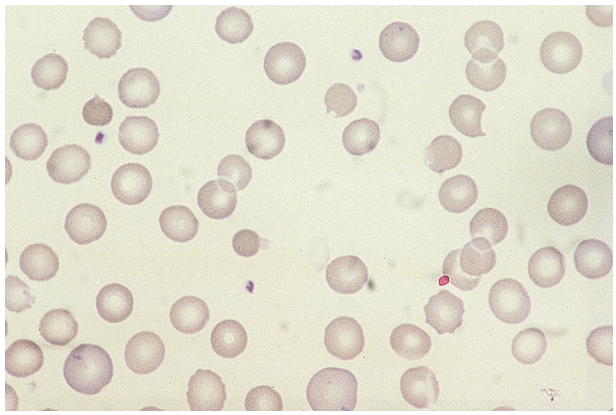

FIGURE 5-42 Photomicrograph of a blood film. Keratocytes and irregularly contracted cells in a patient with haemolysis caused by G6PD deficiency.

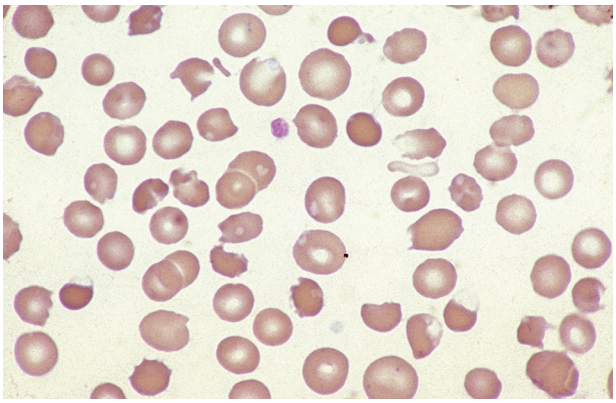

FIGURE 5-43 Photomicrograph of a blood film. Haemolytic anaemia caused by dapsone. Shows many irregularly contracted cells, three cells with haemoglobin retracted from the red cell membrane and one keratocyte.

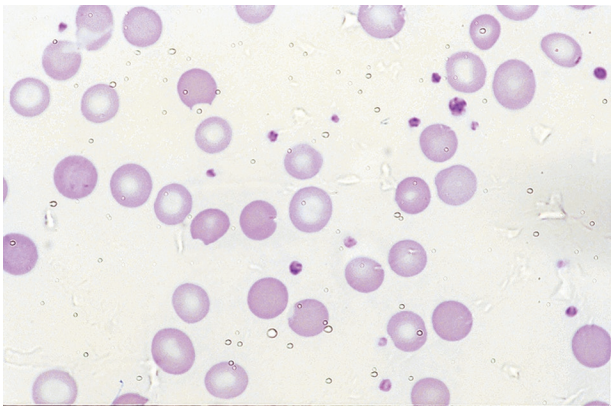

FIGURE 5-44 Photomicrograph of a blood film. Two keratocytes in a patient with microangiopathic haemolytic anaemia.

Acanthocytosis (*ακανθα,* spine)

The term 'acanthocytosis' was introduced to describe an abnormality of the red cell in which there are a small number of spicules of inconstant length, thickness and shape, irregularly disposed over the surface of the cell (Fig. 5-45). They are often associated with abnormal phospholipid metabolism[12–14] or with inherited abnormalities of red cell membrane proteins, as in the McLeod phenotype, caused by lack of the Kell precursor (Kx).[15] They are present in varying numbers following splenectomy and in hyposplenism. A similar cell occurs in severe liver disease ('spur cell' anaemia).[16]

Echinocytosis (*εχινοζ,* sea-urchin or hedgehog)

Echinocytosis or crenation describes the process by which red cells develop numerous short, regular projections from their surface (Figs. 5-25 and 5-26). First described by Ponder[17] as disc-sphere transformation, crenation has

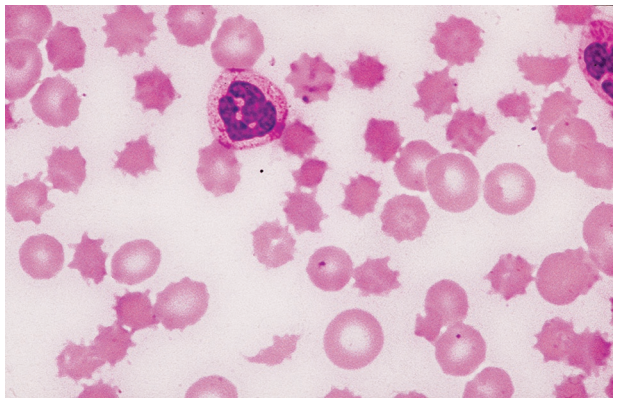

FIGURE 5-45 Photomicrograph of a blood film. Liver failure. Acanthocytes are conspicuous.

many causes. A few crenated cells may be seen in many blood films, even in those from healthy subjects. Crenation regularly develops if blood is allowed to stand overnight at 20°C before films are made (Fig. 5-26). It may be a marked feature, for obscure and probably diverse reasons, in freshly made blood films of patients suffering from a variety of illnesses, especially uraemia. Marked echinocytosis has been reported in premature infants after exchange transfusion or transfusion of normal red cells.[18] When crenation is superimposed on an underlying abnormality, the red cells may appear bizarre in the extreme.

Crenation also occurs as an artefact if red cells are washed free from plasma and suspended in 9 g/l NaCl between glass surfaces, particularly at a raised pH; it also occurs in the presence of traces of fatty substances on the slides on which films are made and in the presence of traces of chemicals that at higher concentrations cause lysis.

The end stages of crenation are the 'finely crenated sphere' and the 'spherical form', which closely resemble spherocytes. The disc-sphere transformation may be reversible (e.g. that produced by washing cells free from plasma), and in this respect the contracted 'spherical form' (which has not lost surface) is quite distinct from the 'spherocyte' (which has lost surface), although they may closely resemble one another in stained films.

If echinocytosis is observed in a film, it usually represents a storage artefact caused by delay in making the film. It is a warning that morphological features in the blood film cannot be assessed reliably. If present in films made from fresh blood, it is a clinically significant observation.

MISCELLANEOUS ERYTHROCYTE ABNORMALITIES

Leptocytosis (*λεπτοζ,* thin)

The term 'leptocytosis' has been used to describe unusually thin red cells, as in severe iron deficiency or thalassaemia in which the cells may stain as rings of membrane with a

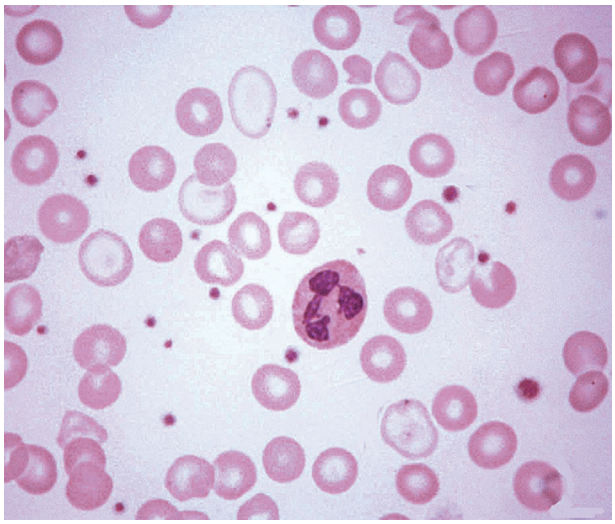

FIGURE 5-46 Photomicrograph of a blood film. β thalassaemia major, after splenectomy. Shows one target cell and cells grossly deficient in haemoglobin, which are leptocytes. There are some transfused cells.

little attached haemoglobin with large, almost unstained, central areas (Fig. 5-46). They can also occur when there is an excess of membrane in relation to cytoplasm, as can occur in liver disease.

Target cells

The term 'target cell' refers to a cell in which there is a central round stained area and a peripheral rim of haemoglobinised cytoplasm separated by nonstaining or more lightly staining cytoplasm. Target cells result from cells having a surface that is disproportionately large compared with their volume. They may be normal in size, microcytic or macrocytic. They are seen in films in chronic liver diseases in which the cell membrane may be loaded with cholesterol (Fig. 5-47), in hereditary hypobetalipoproteinaemia,[19] and in varying numbers in iron deficiency anaemia and in thalassaemia. They are often conspicuous in certain haemoglobinopathies (e.g. haemoglobin C/β^0 thalassaemia [Fig. 5-48]), haemoglobin C disease (Fig. 5-49), haemoglobin H disease (Fig. 5-50), sickle cell anaemia, sickle cell/haemoglobin C disease (Fig. 5-51), sickle cell/β thalassaemia and haemoglobin E disease. Smaller numbers are usual in haemoglobin C trait, haemoglobin E trait and postsplenectomy. Splenectomy in thalassaemia may result in an extreme degree of leptocytosis and target cell formation.

Stomatocytosis (*στομα,* mouth)

Stomatocytes are red cells in which the central biconcave area appears slit-like in dried films. In 'wet' preparations, the stomatocyte is a cup-shaped red cell. The slit-like appearance of the cell's concavity, as seen in dried films, is thus to some extent an artefact. The term was first used

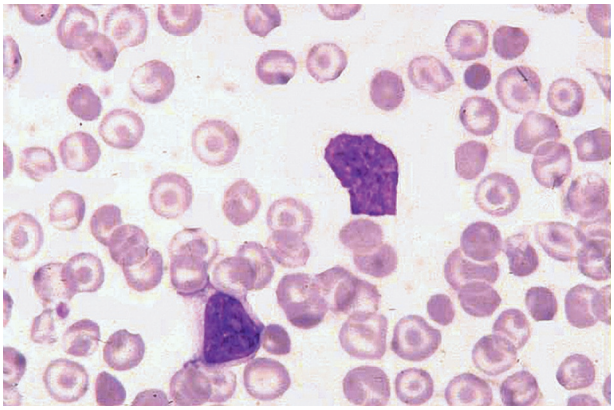

FIGURE 5-48 Photomicrograph of a blood film. Haemoglobin C/β^0 thalassaemia compound heterozygosity showing target cells, irregularly contracted cells and one spherocyte.

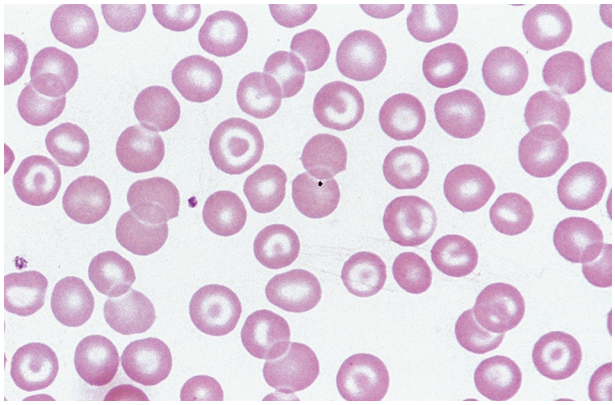

FIGURE 5-47 Photomicrograph of a blood film. Alcoholic liver disease. Shows many target cells.

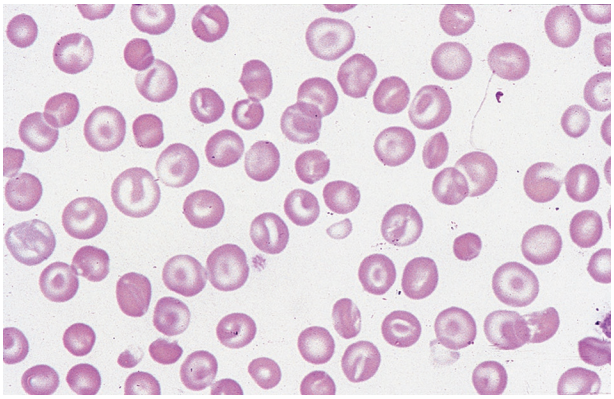

FIGURE 5-49 Photomicrograph of a blood film. Haemoglobin C homozygosity. Shows numerous target cells and irregularly contracted cells.

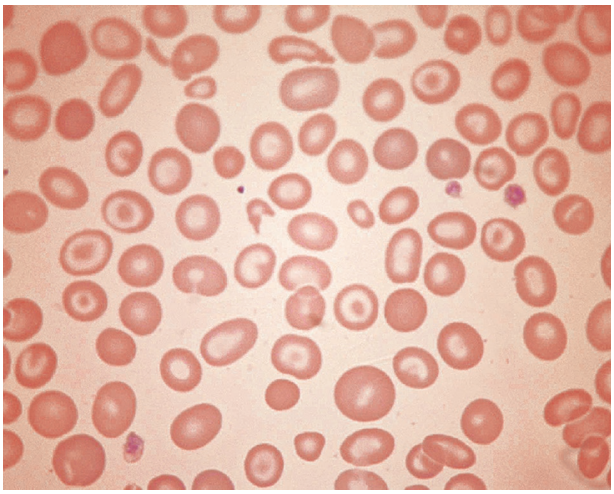

FIGURE 5-50 Photomicrograph of a blood film. Haemoglobin H disease. Shows target cells, hypochromic cells and poikilocytes.

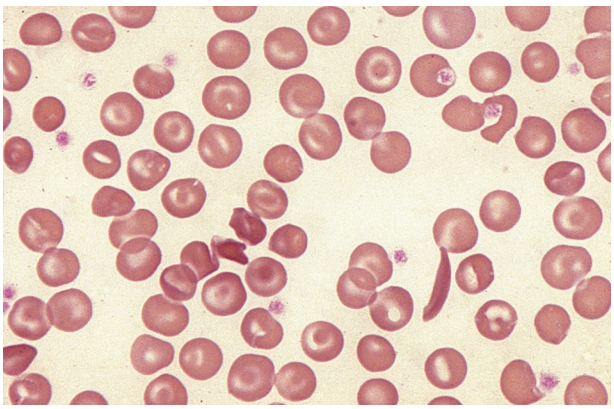

FIGURE 5-51 Photomicrograph of a blood film. Sickle cell/haemoglobin C disease. Shows a sickle cell, target cells and two SC poikilocytes.

to describe the appearance of some of the cells in a rare type of haemolytic anaemia, hereditary stomatocytosis.[20] They are also a feature of Southeast Asian ovalocytosis. They were once described as being particularly frequent in films of Australians of Mediterranean origin,[21] with at least some of these cases now known to represent hereditary phytosterolaemia.[22] Subsequently, stomatocytes were recognised in acquired conditions and occasionally they are prominent (Fig. 5-52). They are observed in liver disease, in alcoholism[23] and occasionally in the myelodysplastic syndromes. There is a suspicion that in some films the occurrence of stomatocytosis is an *in vitro* artefact because it is known that the change can be produced by decreased pH and as the result of exposure to cationic detergent-like compounds and nonpenetrating anions.[24]

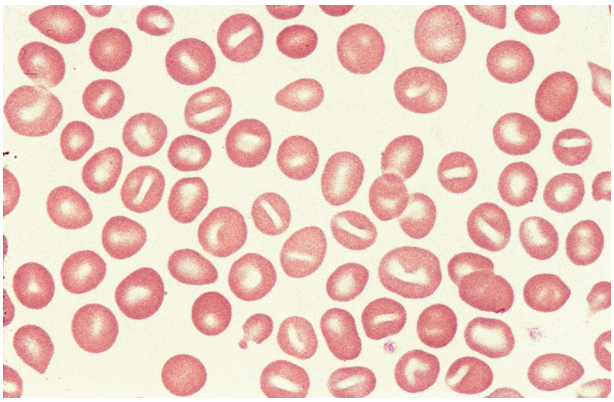

FIGURE 5-52 Photomicrograph of a blood film. Patient with chronic myelogenous leukaemia taking hydroxycarbamide. Shows stomatocytosis. Many of the cells have a slit-like central unstained area.

Sickle cells

The varied film appearances in sickle cell anaemia are illustrated in Figures 5-53 to 5-55. Sickle cells are almost always present in films of freshly withdrawn blood of adults with homozygosity for haemoglobin S. However, sickle cells are usually absent in neonates and are rare in adult patients with a high haemoglobin F percentage. Sometimes, many irreversibly sickled cells are present, and in all cases massive sickling takes place when the blood is subjected to anoxia (see p. 297). In films of fresh blood, the sickled cells vary in shape between boat-shaped forms and sickles. Target cells are also often a feature of blood films from patients with sickle cell anaemia, and Howell–Jolly bodies are found when there is splenic atrophy.

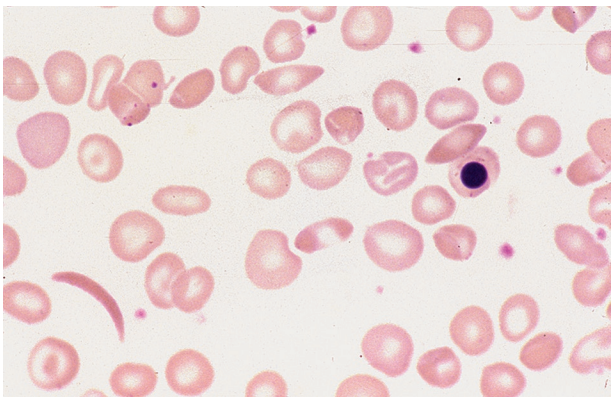

FIGURE 5-53 Photomicrograph of a blood film. Sickle cell anaemia (homozygosity for haemoglobin S). Shows a sickled cell, boat-shaped cells, a nucleated red cell and target cells.

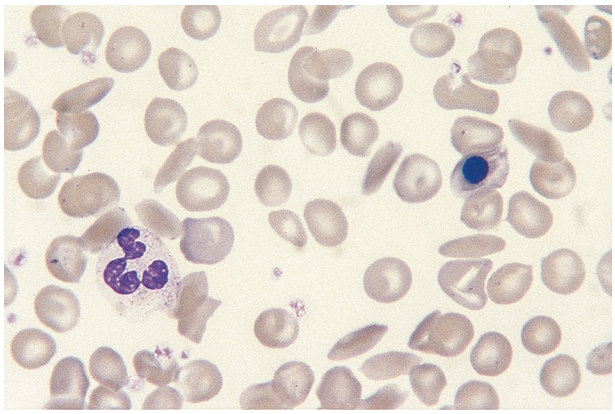

FIGURE 5-54 Photomicrograph of a blood film. Sickle cell anaemia (homozygosity for haemoglobin S). Shows boat-shaped cells and a nucleated red blood cell.

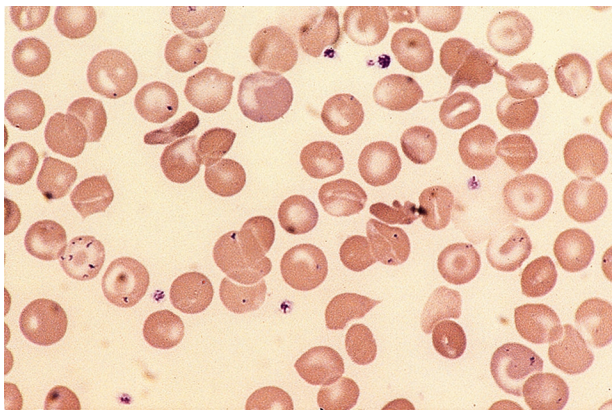

FIGURE 5-55 Photomicrograph of a blood film. Sickle cell anaemia (homozygosity for haemoglobin S). Shows elliptical sickle cells, target cells and Pappenheimer bodies.

Haemoglobin C crystals and SC poikilocytes

In patients with homozygosity for haemoglobin C, target cells and irregularly contracted cells are usually numerous and there may be occasional straight-edged haemoglobin C crystals, either apparently extracellularly (Fig. 5-32) or within the ghost of a red cell. In patients who are compound heterozygotes for haemoglobin S and haemoglobin C, the film sometimes resembles that of haemoglobin C disease (Fig. 5-32). In other patients, there are elliptical cells, rare sickle cells and sometimes distinctive SC poikilocytes (Fig. 5-56).

Erythrocyte inclusions

The possibility of sometimes suspecting the presence of Heinz bodies on a routinely stained film and the detection of haemoglobin crystals within red cells has already been

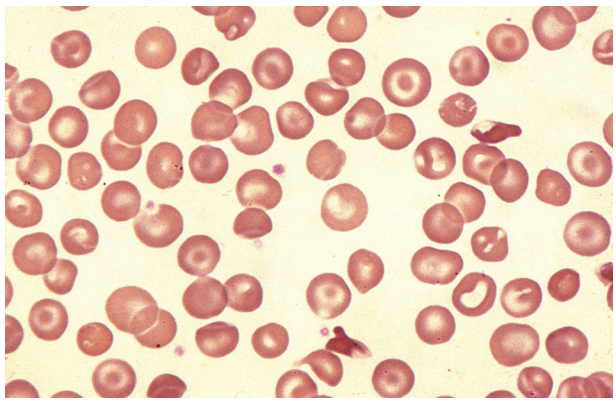

FIGURE 5-56 Photomicrograph of a blood film. Sickle cell/haemoglobin C disease showing SC poikilocytes and target cells.

mentioned. Alpha chain inclusions can also sometimes be seen (e.g. in β thalassaemia major or intermedia) following splenectomy.[25] Other red cell inclusions include Howell–Jolly bodies and Pappenheimer bodies.

Howell–Jolly bodies

Howell–Jolly bodies are nuclear remnants. They are small, round cytoplasmic inclusions that stain purple on a Romanowsky stain. They are regularly present after splenectomy and when there is splenic atrophy (Fig. 5-57). They may be seen in a small percentage of red cells in pernicious anaemia. Usually only a few such inclusions are present, but they may be numerous in cases of coeliac disease and in other conditions in which there is splenic atrophy and megaloblastosis.

Pappenheimer bodies

Pappenheimer bodies are small peripherally sited basophilic (almost black) erythrocyte inclusions. They are smaller than Howell–Jolly bodies. Usually only a small number are

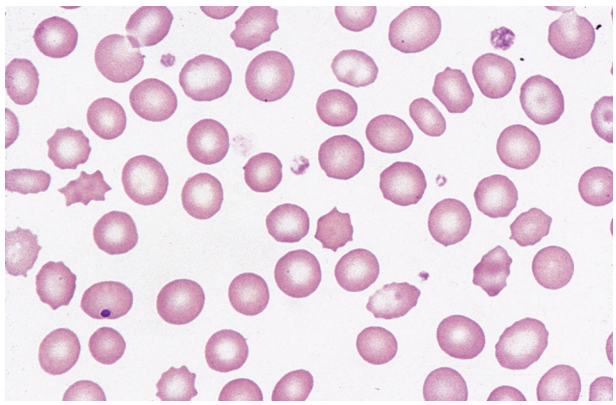

FIGURE 5-57 Photomicrograph of a blood film. Postsplenectomy. Shows acanthocytes, a target cell and a Howell–Jolly body.

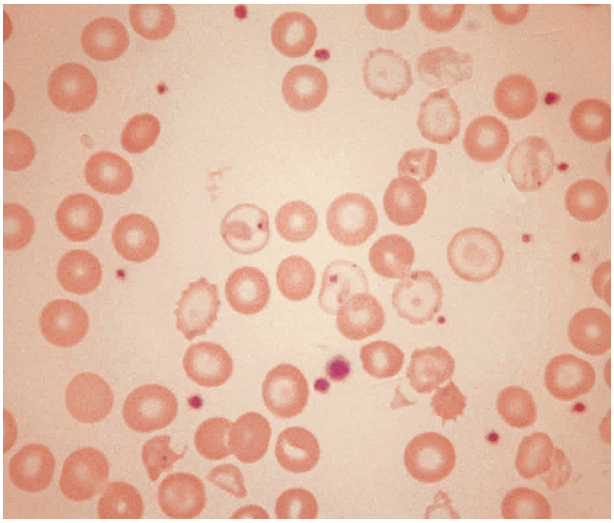

FIGURE 5-58 Photomicrograph of a blood film. β thalassaemia major, patient on regular blood transfusions, showing Pappenheimer bodies in several poorly haemoglobinised cells.

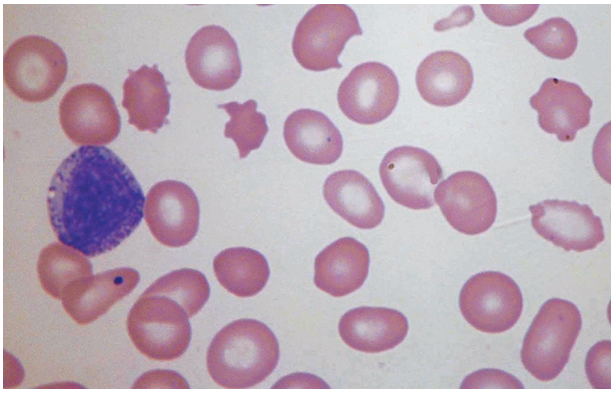

FIGURE 5-59 Photomicrograph of a blood film. Autoimmune thrombocytopenic purpura, postsplenectomy, showing a Pappenheimer body and a Howell–Jolly body.

present in a cell. They are composed of haemosiderin and their presence is related to sideroblastic erythropoiesis and hyposplenism (Figs. 5-58 and 5-59). Sometimes they are found in the majority of circulating red cells. Their nature can be confirmed by means of a Perls stain. They correspond to the siderotic granules of siderocytes and are not distributed in large numbers throughout the cells as in classic punctate basophilia. However, a single cell may show both punctate basophilia and Pappenheimer bodies. With Perls stain, the former granules are pink, whereas the latter are blue.

Rouleaux and autoagglutination

Rouleaux occur to some extent in all films but increased rouleaux formation is significant. The differences between rouleaux and autoagglutination are described on page 56,

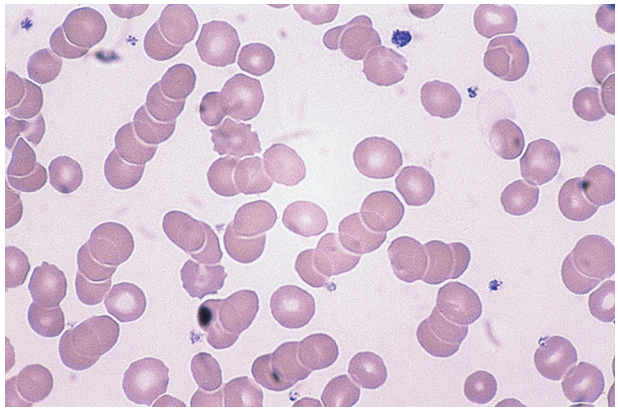

FIGURE 5-60 Photomicrograph of a blood film. Increased rouleaux formation in a patient with bacterial infection.

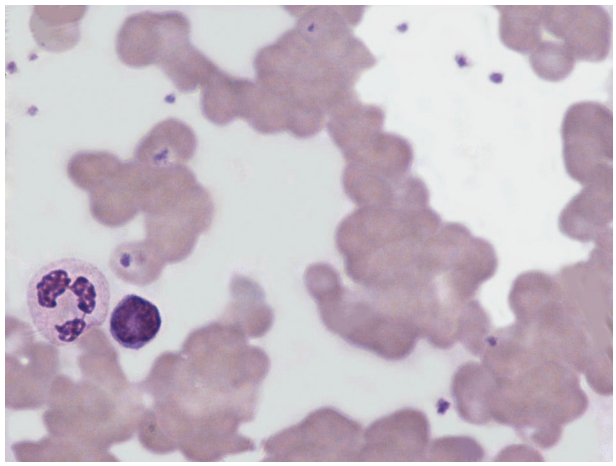

FIGURE 5-61 Photomicrograph of a blood film. Shows agglutination in a patient with chronic cold haemagglutinin disease (compare with Fig. 5-60).

and there is usually no difficulty in differentiating between them in stained films (Figs. 5-60 and 5-61). However, in myelomatosis and in other conditions in which there is intense rouleaux formation, the rouleaux may simulate autoagglutination. Even so, if the film, apparently showing autoagglutination, is carefully scanned, an area in which rouleaux can be clearly seen will almost certainly be found, emphasizing the importance of careful selection of the area of film to be examined.

CHANGES ASSOCIATED WITH A COMPENSATORY INCREASE IN ERYTHROPOIESIS

Polychromasia (*πολθζ*, many)

The term 'polychromasia' suggests that the red cells are being stained many colours. In practice, it means that some of the red cells stain shades of bluish grey (Fig. 5-62) –

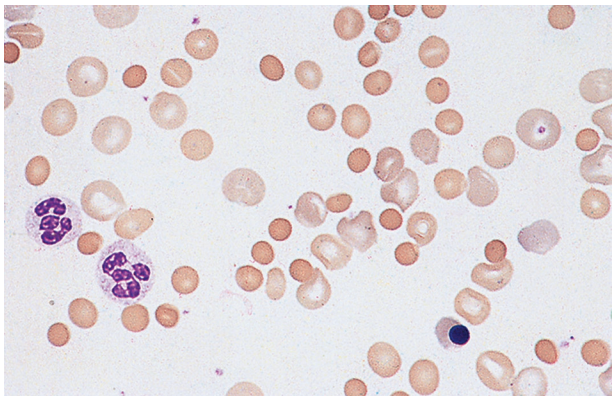

FIGURE 5-62 Photomicrograph of a blood film. Polychromasia. Some red cells stain shades of bluish grey. There are also spherocytes and one nucleated red blood cell.

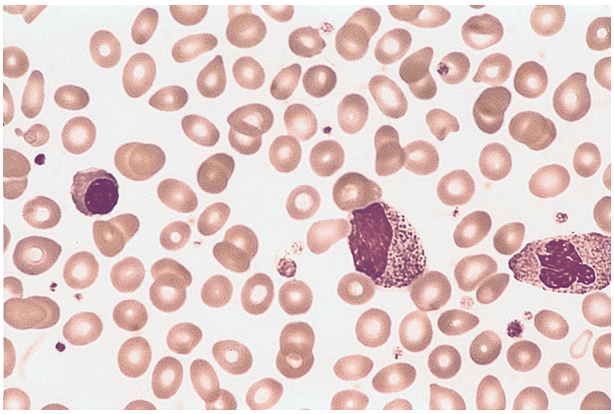

FIGURE 5-63 Photomicrograph of a blood film. Primary myelofibrosis. Shows a leucoerythroblastic blood film, teardrop poikilocytes and ovalocytes.

these are the reticulocytes. Cells staining shades of blue, 'blue polychromasia', are unusually young reticulocytes. 'Blue polychromasia' is most often seen when there is either an intense erythropoietic drive or when there is extramedullary erythropoiesis, as, for instance, in primary myelofibrosis or carcinomatosis. It should be noted that in certain circumstances the **absence** of polychromasia is significant; in a patient with severe anaemia it indicates that the bone marrow response is inadequate (e.g. in aplastic anaemia and pure red cell aplasia).

Erythroblastaemia

Erythroblasts may be found in the blood films of almost any patient with a severe anaemia; they are, however, very unusual in aplastic anaemia, and their presence should lead to this diagnosis being doubted. They are more common in children than in adults, and large numbers are a very characteristic finding in haemolytic disease of the newborn. Small numbers can be found in the cord blood of normal infants, whereas quite large numbers are found in that of premature infants.

When large numbers of erythroblasts are present, many of them may be derived from extramedullary foci of erythropoiesis (e.g. in the liver and spleen). This is likely, for instance, in haemolytic disease of the newborn and primary myelofibrosis. In myelofibrosis and carcinomatosis, the number of erythroblasts is often disproportionately high for the degree of anaemia, and a few granulocyte precursors are usually also present (designated leucoerythroblastic anaemia) (Fig. 5-63).

Erythroblasts can usually be found in the peripheral blood after splenectomy, and many may be present in severe anaemia and in the presence of extramedullary erythropoiesis (Fig. 5-64). Large numbers are frequently seen in the blood films of patients with sickle cell anaemia in painful crises. Small numbers of erythroblasts are not uncommon in blood from patients suffering from cyanotic heart failure or septicaemia.

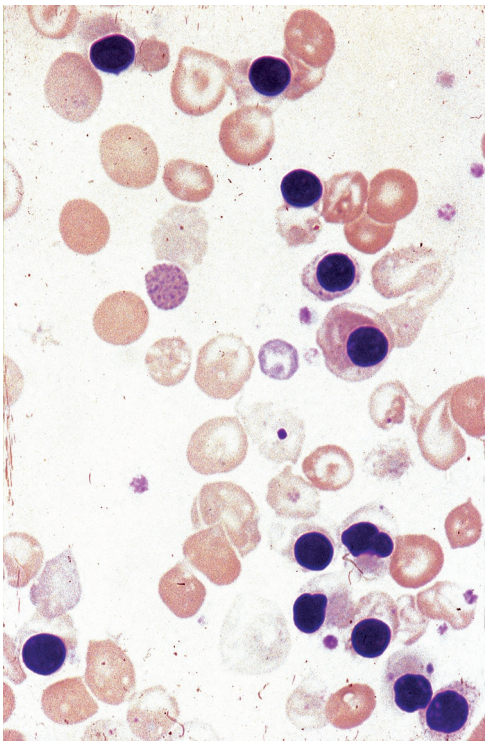

FIGURE 5-64 Photomicrograph of a blood film. β thalassaemia major with inadequate blood transfusion support. There are numerous erythroblasts; there are also hypochromic cells, target cells and a cell containing a Howell–Jolly body.

It should be noted that when the term 'normoblast' is used, it implies that erythroid maturation is normoblastic. 'Erythroblast' is a more general term that also includes megaloblasts.

EFFECTS OF SPLENECTOMY AND HYPOSPLENISM

Some of the effects of splenectomy and hyposplenism have already been mentioned – namely, the occurrence of target cells, acanthocytes, Howell–Jolly bodies and Pappenheimer bodies (Fig. 5-57). In addition, there may be neutrophilia (early after splenectomy), lymphocytosis, thrombocytosis and giant platelets. In people who are haematologically normal, the blood film features of hyposplenism are variable – sometimes striking and sometimes very minor.

SCANNING ELECTRON MICROSCOPY

The morphology of red cells, as illustrated in this chapter, may be distorted by spreading and drying films in the traditional way. A more authentic portrayal of red cell shape *in vivo* can be seen by scanning electron microscopy. This provided the means for a critical re-examination of red cell morphology. Bessis and his co-workers published excellent photographs of pathological red cells and, from their appearances, proposed a terminology[9,24,26] that has generally been adopted in this chapter. They also discussed the difficult question of the *in vivo* significance of crenation (echinocytic change) observed *in vitro*. It seems that neither echinocytosis nor acanthocytosis is necessarily associated with increased haemolysis. It cannot be concluded, either, that crenation is occurring *in vivo,* when the phenomenon is markedly evident in films made on glass slides. To ensure that cells are crenated in any blood sample as it is withdrawn, Brecher and Bessis recommended that the blood be examined immediately between plastic, instead of glass coverslips or slides, to avoid the known 'echinocytogenic' effect of glass surfaces, probably caused by alkalinity.[26] Nevertheless, for practical purposes, if a blood film of a freshly drawn blood specimen shows echinocytosis and films from other patients prepared using the same glass slides do not, the abnormality can be accepted as genuine.

The specialised procedure of scanning electron microscopy is not practical as a routine but helps in understanding the nature of cells observed in stained blood films. Morphological changes in red cells may be very complex. Echinocytic and stomatocytic change can be superimposed on other pathological forms, giving rise to 'sickle-stomatocytes' and 'stomato-acanthocytes'. Acanthocytes can undergo crenation, the product being termed an 'acantho-echinocyte'. Following splenectomy in patients with hereditary spherocytosis, sphero-acanthocytes may be observed.

The appearance of various cells by scanning electron microscopy is illustrated in Figures 5-65 to 5-72.

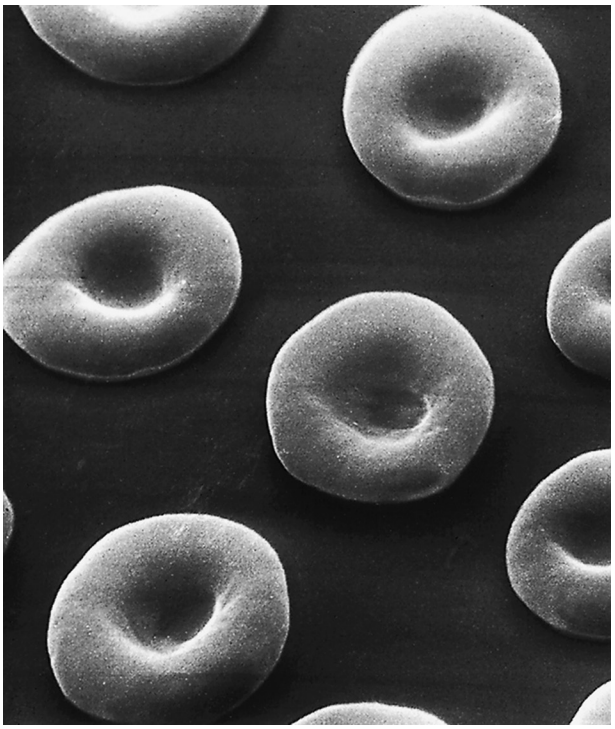

FIGURE 5-65 Scanning electron microscope photograph. Normal red cells.

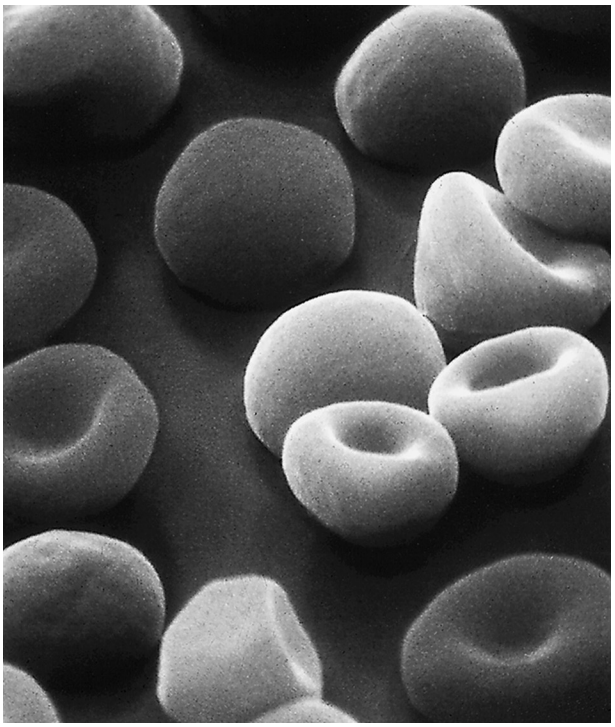

FIGURE 5-66 Scanning electron microscope photograph. Hereditary spherocytosis. Note the roundness of spherocytes but also that there are cells intermediate in form between spherocytes and normal discocytes. (Compare with Fig. 5-65; also see blood film appearances as shown in Fig. 5-21.)

MORPHOLOGY OF LEUCOCYTES

This section will include a description of the normal leucocytes, some congenital anomalies and reactive changes that are commonly encountered. To describe adequately the various changes found in malignant conditions would require a lengthy text and many illustrations that are beyond the scope of this book. They will be referred to briefly here, but for detailed reference readers should consult a specialist text[27] or an atlas on blood cells. For classification of the acute leukaemias, see the original description by the FAB (French–American–British) group[28] and the subsequent revision.[29] There is also a World Health Organisation classification,[30] which supersedes the FAB classifications when facilities are available for fully characterising leukaemia and is now in widespread use. However, the FAB classification remains useful as a widely accepted scheme for the initial morphological description of leukaemias.

It should be noted that the terms 'polymorph' and 'granulocyte' refer to neutrophils, eosinophils and basophils and should not be used as synonyms for neutrophils.

POLYMORPHONUCLEAR NEUTROPHILS

In normal adults, neutrophils account for more than half the circulating leucocytes. They are the main defence of the body against pyogenic bacterial infections. Normal neutrophils are uniform in size, with an apparent diameter of about 13 μm in a film. They have a segmented nucleus and, when stained, pink/orange cytoplasm that is due to the presence of fine granulation, below the level of resolution of the light microscope (Fig. 5-73). The majority of neutrophils have three nuclear segments (lobes) connected by tapering chromatin strands. The chromatin shows clumping and is usually condensed at the nuclear periphery. A small percentage have four lobes, and occasionally five lobes may be seen. Up to 8% of circulating neutrophils are unsegmented ('band' forms) (discussed later).

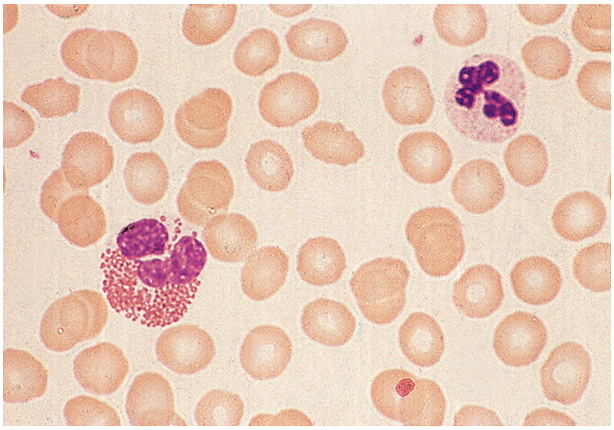

FIGURE 5-73 Photomicrograph of a blood film. Normal polymorphonuclear neutrophil and normal eosinophil.

In women, 2–3% of the neutrophils show an appendage at a terminal nuclear segment. This 'drumstick' is about 1.5 μm in diameter and is connected to the nucleus by a short stalk. It represents the inactive X chromosome and corresponds to the Barr body of buccal cells.

Occasionally, red cells adhere to neutrophils, forming rosettes. The mechanism is unknown, but it is likely to be immune; usually it appears to be of no clinical significance but occasionally it is seen in an immune haemolytic anaemia. Leucoagglutination also occurs as an *in vitro* artefact.[31] Occasionally neutrophils (and/or monocytes) have phagocytosed erythrocytes (Fig. 5-74). This is particularly common in paroxysmal cold haemoglobinuria.[32]

It is extremely important to ensure the consistency of staining of the blood films using a standardised Romanowsky method (see Chapter 4) because changes in the staining intensity, colour and appearance of cytoplasmic granulation, if not artefactual, may have diagnostic significance. Common neutrophil abnormalities are described later in this chapter.

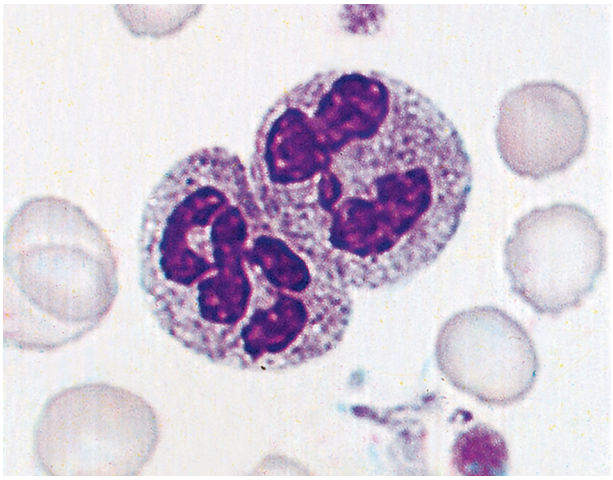

FIGURE 5-75 Photomicrograph of a blood film. Severe infection. Neutrophils show toxic granulation.

Granules

'Toxic granulation' is the term used to describe an increase in staining density and possibly the number of granules that occurs regularly with bacterial infection and often with other causes of inflammation (Fig. 5-75). It can also be a feature of administration of granulocyte colony-stimulating factor (G-CSF),[33] acute liver failure,[34] neutrophilic leukaemoid reactions (e.g. in plasma cell neoplasms)[35] and aplastic anaemia. Poorly staining (hypogranular) and agranular neutrophils occur in the myelodysplastic syndromes (Fig. 5-76) and in some forms of myeloid leukaemia.

There are rare inherited disorders that are manifest by abnormal neutrophils. In the Alder–Reilly anomaly, the granules are very large, are discrete, stain deep red and may obscure the nucleus (Fig. 5-77). Other leucocytes, including some lymphocytes, also show the abnormal granules. In the Chédiak–Higashi syndrome there are giant but scanty azurophilic granules (Fig. 5-78), and the other leucocyte types may also be affected; the colour of the granules is abnormal. Alder–Reilly neutrophils function normally, but in Chédiak–Higashi syndrome there is a functional defect that is manifested by susceptibility to severe infection.

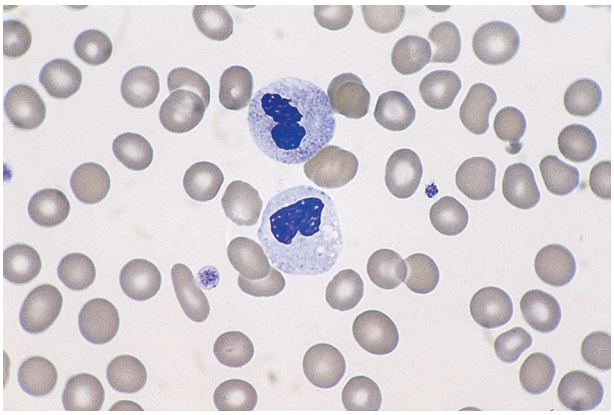

FIGURE 5-76 Photomicrograph of a blood film. Myelodysplastic syndrome. Shows a hypogranular neutrophil and another that is more normally granulated. Both neutrophils have nuclei of abnormal shapes.

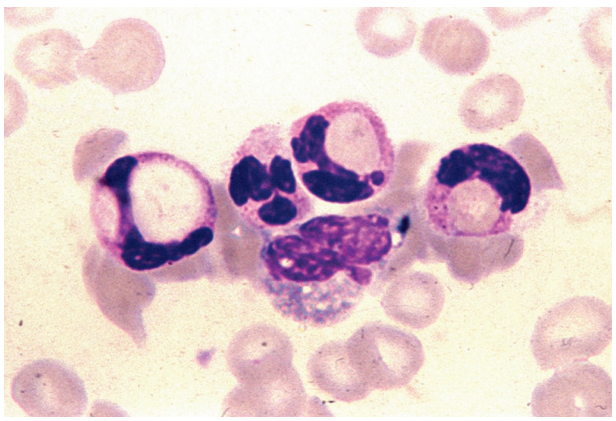

FIGURE 5-74 Photomicrograph of a blood film. Erythrophagocytosis in a patient with a positive direct antiglobulin test.

Vacuoles

In blood films spread without delay, the presence of vacuoles in the neutrophils is usually indicative of severe sepsis, when toxic granulation is usually also present. They can be due to alcohol toxicity[36] or acute liver failure.[34] Vacuoles will develop as an artefact with prolonged standing of the blood before films are made (see Chapter 1, Fig. 1-3, see p. 6).

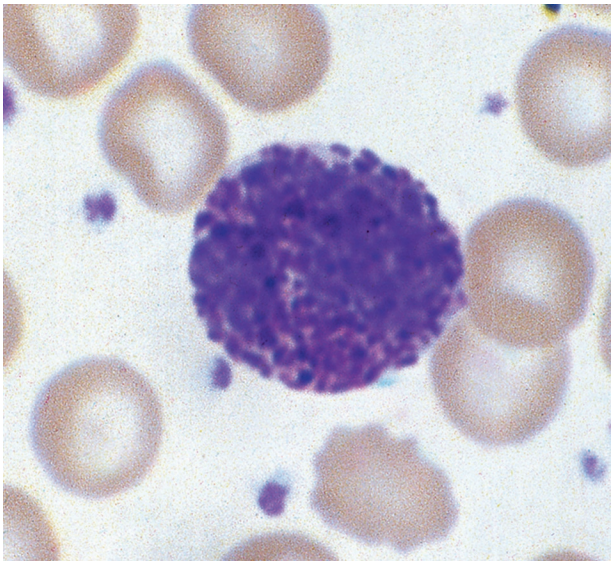

FIGURE 5-77 Photomicrograph of a blood film. Alder–Reilly anomaly. The nucleus is obscured by the cytoplasmic granules.

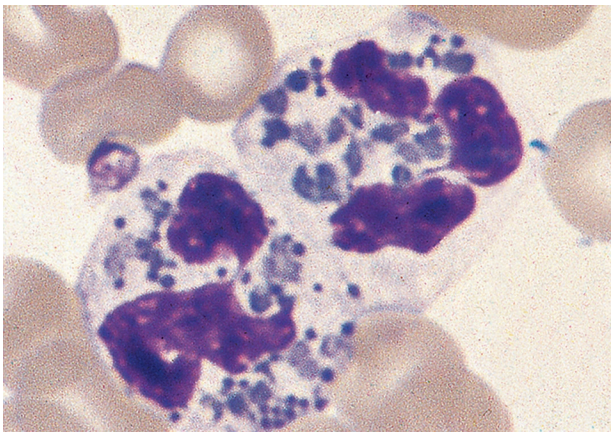

FIGURE 5-78 Photomicrograph of a blood film. Chédiak–Higashi syndrome. Neutrophils show abnormal granules.

Bacteria and fungi

Very rarely, in the presence of overwhelming septicaemia (e.g. meningococcal or pneumococcal), bacteria are seen within vacuoles or apparently lying free in the cytoplasm of neutrophils. When blood is taken from an infected central line, clumps of bacteria or fungi may be seen scattered in the film as well as being present in neutrophils within phagocytic vacuoles (Fig. 5-79). In premature infants with staphylococcal septicaemia, the detection of bacteria in neutrophils helps in early diagnosis.[37] In endemic areas, detection of bacteria within neutrophils is important in the diagnosis of ehrlichiosis and anaplasmosis.

Other neutrophil inclusions

Other neutrophil inclusions include cryoglobulin, bilirubin crystals, erythrocytes (see above) and malaria pigment.[38]

Döhle bodies

Döhle bodies are small, round or oval, pale blue–grey structures usually found at the periphery of the neutrophil. They consist of ribosomes and endoplasmic reticulum. They are seen in bacterial infections but also following tissue damage including burns, in inflammation, following administration of G-CSF, in neutrophilic leukaemoid reactions[35] and during pregnancy. There is also a benign inherited condition known as May–Hegglin anomaly with a similar but not identical morphological structure; in this condition, the inclusions tend to be larger and angular and occur in all types of leucocyte except lymphocytes. Similar inclusions are seen in related conditions, referred to collectively as *MYH9*-related disorders.[39]

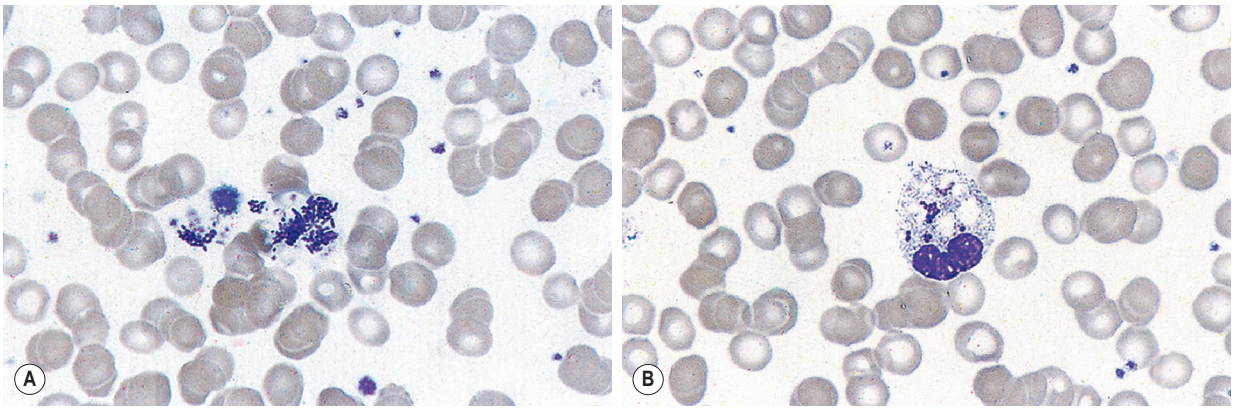

FIGURE 5-79 Photomicrograph of a blood film. Blood collected from infected site, showing bacteria **(A)** in scattered clumps and in a neutrophil **(B).**

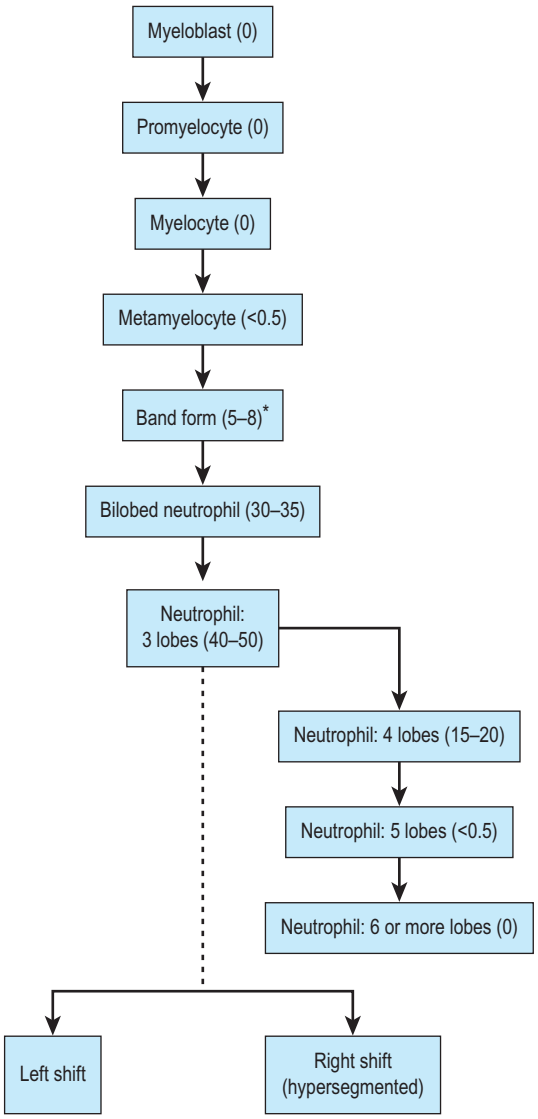
Nuclei

Segmentation of the nucleus of the neutrophil is a normal event as the cell matures from the myelocyte. With the three-lobed neutrophil as a marker, a shift to the left (less mature) or to the right (hypermature) can be recognised (Fig. 5-80). A left shift with band forms, metamyelocytes and perhaps occasional myelocytes, is common in sepsis (Fig. 5-81), when it is usually accompanied by toxic granulation. If promyelocytes and myeloblasts are also present, it is likely to be a feature of a leucoerythroblastic anaemia or leukaemia (Fig. 5-82); occasionally this extreme picture is seen in very severe infections, when it is called a 'leukaemoid reaction'. A left shift, with a significant number of band forms, occurs normally in pregnancy.



The figures in brackets give an approximate indication of the number per 100 neutrophils in a normal film. They are intended only as a rough guide.
*However, according to the United States Health and Nutrition Examination surveys, the normal band (non-segmented neutrophil) count is lower – about 0.5% of the neutrophils.[41]

FIGURE 5-80 Stages of granulocyte maturation.

Hypersegmentation

The presence of hypersegmented neutrophils is an important diagnostic feature of megaloblastic anaemias. Neutrophil hypersegmentation can be defined as the presence of neutrophils with six or more lobes or the presence of more than 3% of neutrophils with at least five lobes. In florid megaloblastic states, neutrophils are often enlarged and their nuclei may have six or more segments connected by particularly fine chromatin bridges (Fig. 5-10). A right shift with moderately hypersegmented neutrophils may

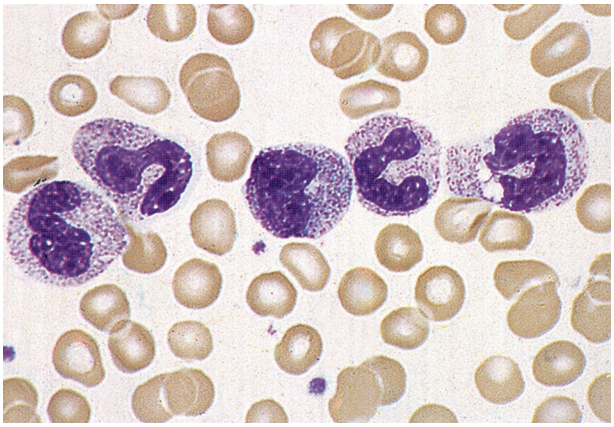


FIGURE 5-81 Photomicrograph of a blood film. Infection. Shows left shift of the neutrophils with toxic granulation.

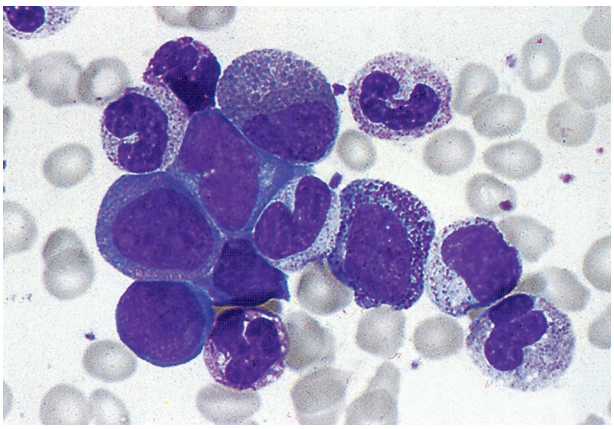

FIGURE 5-82 Photomicrograph of a blood film. Chronic myelogenous leukaemia. There is a left shift with band forms, metamyelocytes, myelocytes and one myeloblast.

also be seen in uraemia and not infrequently in iron deficiency.[40] Hypersegmentation can be seen after cytotoxic and antimetabolite treatment, especially with methotrexate, hydroxycarbamide and other drugs that induce megaloblastosis.[41]

Pelger–Huët cells

The Pelger–Huët anomaly is an autosomal dominant inherited condition which is benign in heterozygotes; there is a failure of normal granulocyte segmentation. The majority of circulating neutrophils have only two discrete equal-sized lobes connected by a thin chromatin bridge (Fig. 5-83). Eosinophils and basophils are also hyposegmented. The chromatin is coarsely clumped, and granule content is normal.

A similar acquired morphological anomaly, known as a pseudo-Pelger or acquired Pelger–Huët anomaly, can be seen in myelodysplastic syndromes, acute myeloid leukaemia with dysplastic maturation, and occasionally in chronic myelogenous leukaemia (during the accelerated phase) (Fig. 5-84). In these conditions, the neutrophils are often also hypogranular and they tend to have a markedly irregular nuclear pattern.

Detached nuclear fragments

Detached nuclear fragments, similar in appearance to Howell–Jolly bodies in red cells, can be seen in HIV infection[42] and following cytotoxic chemotherapy or treatment with G-CSF.[33]

Pyknotic neutrophils (Apoptosis)

Small numbers of dead or dying cells may normally be found in the blood, especially when there is an infection. They may also develop in normal blood *in vitro* after standing for 12–18 h, even if kept at 4 °C. These cells have round, dense, featureless nuclei and their cytoplasm tends to be dark pink (see p. 4 and Fig. 1-3). It is important not to confuse these cells with erythroblasts.

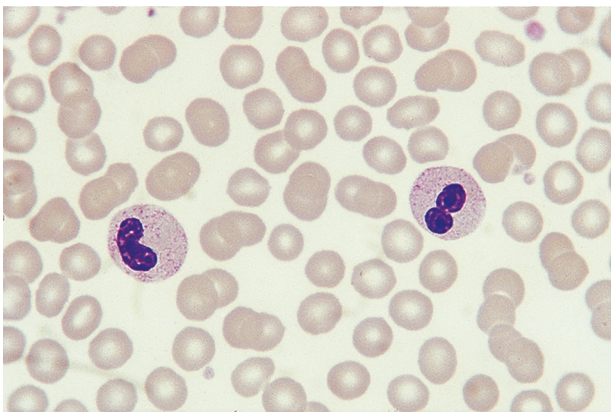

FIGURE 5-83 Photomicrograph of a blood film. Pelger–Huët anomaly. Shows hypolobated neutrophils.

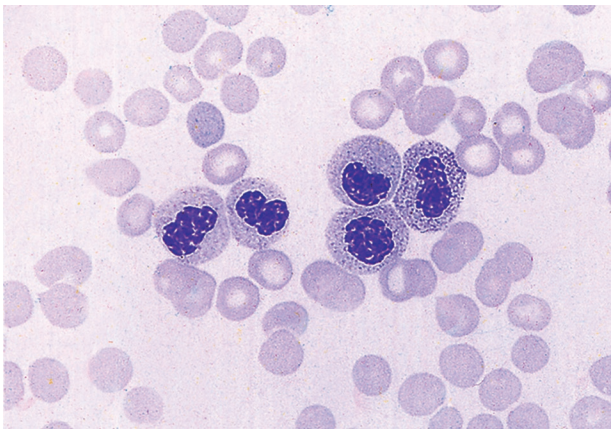

FIGURE 5-84 Photomicrograph of a blood film. Chronic myelogenous leukaemia. There are five 'pseudo-Pelger' cells; this abnormality is not a feature of the chronic phase of this disease and indicates that there has already been disease evolution.

EOSINOPHILS

Eosinophils are a little larger than neutrophils, 12–17 μm in diameter. They usually have two nuclear lobes or segments, and the cytoplasm is packed with distinctive spherical gold/orange (eosinophilic) granules (Figs. 5-73 and 5-85). The underlying cytoplasm, which is usually obscured by the granules, is pale blue. Prolonged steroid administration causes eosinopenia. Moderate eosinophilia occurs in allergic conditions; more severe eosinophilia ($20–50 \times 10^9$/l) may be seen in parasitic infections and even greater numbers may be seen in other reactive eosinophilias, eosinophilic leukaemia and the idiopathic hypereosinophilic syndrome. Reactive eosinophilia with very high counts may be seen in T-cell lymphoma, B-cell

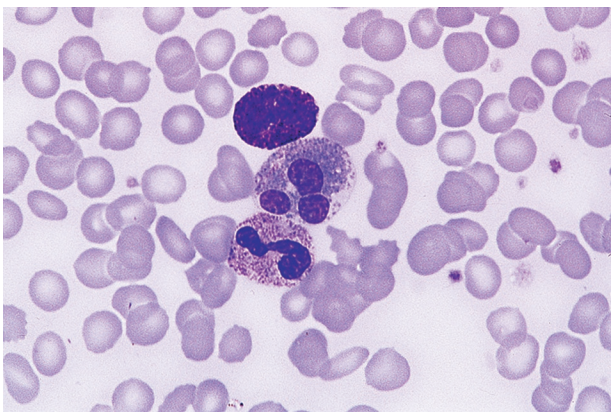

FIGURE 5-85 Photomicrograph of a blood film. Normal adult. Shows a basophil, an eosinophil and a neutrophil.

lymphoma, Hodgkin lymphoma and acute lymphoblastic leukaemia. Eosinophils are part of the leukaemic population in chronic myelogenous leukaemia, in haematological neoplasms associated with rearrangement of *PDGFRA*, *PDGFRB* or *FGFR1* and in some cases of acute myeloid leukaemia. Neither eosinophil numbers nor cytological abnormalities in eosinophils is very useful in distinguishing between neoplastic and reactive eosinophils.

BASOPHILS

Basophils are the rarest (<1%) of the circulating leucocytes. Their nuclear segments tend to fold up on each other, resulting in a compact irregular dense nucleus resembling a closed lotus flower. The distinctive, large, variably sized purple granules of the cytoplasm (Fig. 5-84) often obscure the nucleus; they are rich in histamine, serotonin and heparin. Basophils tend to degranulate, leaving cytoplasmic vacuoles.

Basophils are present in increased numbers in myeloproliferative neoplasms and are especially prominent in chronic myelogenous leukaemia; in the latter condition, basophils constituting more than 10% of leucocytes may be a sign of accelerated phase or impending blast crisis.

MONOCYTES

Monocytes are the largest of the circulating leucocytes, 15–18 μm in diameter. They have bluish grey cytoplasm that contains variable numbers of fine purplish red granules. The nucleus is large and curved, often in the shape of a horseshoe, but it may be folded or curled (Figs. 5-86 and 5-87). It does not undergo segmentation. The chromatin is finer and more evenly distributed than that in neutrophil nuclei. An increased number of monocytes occur in some chronic infections and inflammatory conditions such as tuberculosis and Crohn disease, in chronic myeloid leukaemias (particularly atypical chronic myeloid leukaemia and chronic myelomonocytic leukaemia) and in acute leukaemias with a monocytic component. In chronic myelomonocytic leukaemia, the mature monocyte count may reach as high as 100×10^9/l. It is occasionally difficult to distinguish abnormal monocytes from the large activated T lymphocytes produced in infectious mononucleosis or from circulating high-grade lymphoma cells.

LYMPHOCYTES

The majority of circulating lymphocytes are small cells with a thin rim of cytoplasm, occasionally containing scanty azurophilic granules (Figs. 5-1 and 5-88). Nuclei are remarkably uniform in size (about 9 μm in diameter). This provides a useful guide for estimating red cell size (normally about 7–8 μm) from the blood film. Some 10% of circulating lymphocytes are larger, with more abundant pale blue cytoplasm containing azurophilic granules

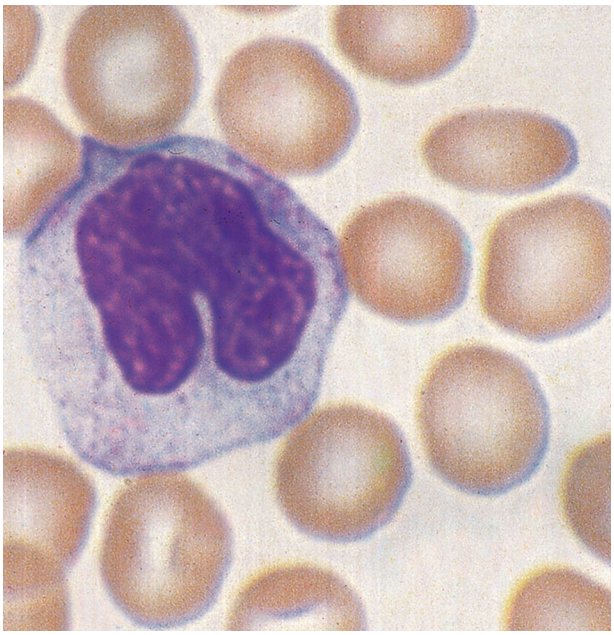

FIGURE 5-86 Photomicrograph of a blood film. Healthy adult. Monocyte.

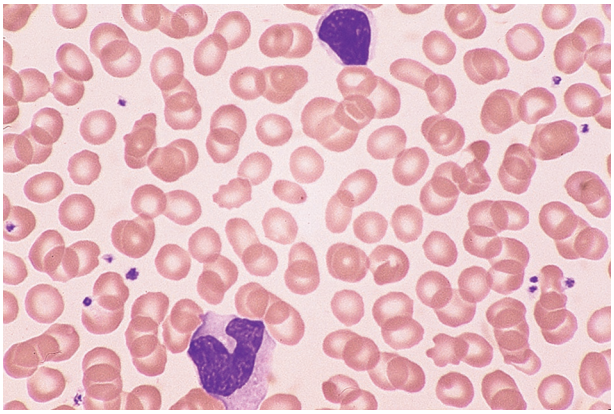

FIGURE 5-87 Photomicrograph of a blood film. Healthy adult. Shows a monocyte and a lymphocyte.

(Fig. 5-88). The nuclei of lymphocytes have homogeneous chromatin with some clumping at the nuclear periphery. About 85% of the circulating lymphocytes are T cells or natural killer (NK) cells.

In infections, both bacterial and viral, transformed lymphocytes may be present. These immunoblasts or 'Türk' cells are 10–15 μm in diameter, with a round nucleus, often with a large nucleolus, and abundant, deeply basophilic cytoplasm (Fig. 5-89). They may develop into plasmacytoid lymphocytes and plasma cells, and these are occasionally seen in the blood in severe infections. In the absence of infection, multiple myeloma must be excluded. In viral infection, other types of 'reactive lymphocyte'

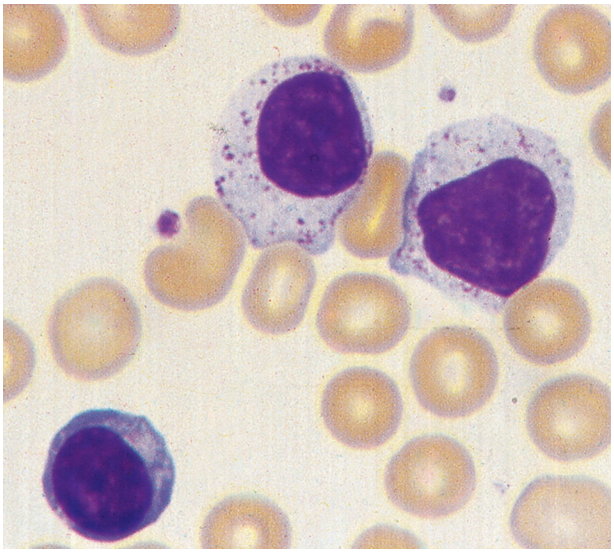

FIGURE 5-88 Photomicrograph of a blood film. Shows a small lymphocyte and two large granular lymphocytes with azurophilic granules.

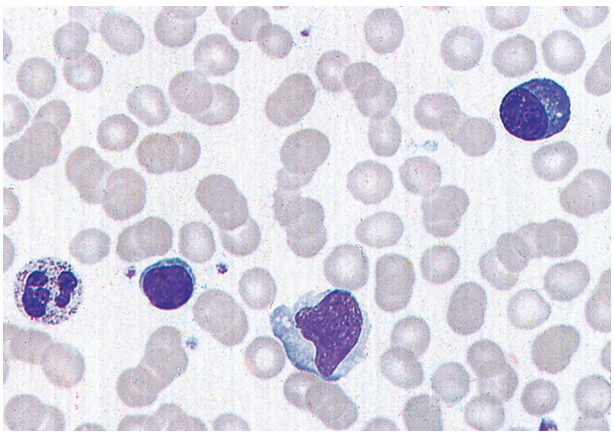

FIGURE 5-89 Photomicrograph of a blood film. Viral infection. Shows a Türk cell, another reactive lymphocyte, which is plasmacytoid, and a small lymphocyte.

appear in the blood. These have slightly larger nuclei with more open chromatin and abundant cytoplasm that may be irregular. The most extreme examples of these cells are usually found in infectious mononucleosis (Fig. 5-90). These 'glandular fever' cells have irregular nuclei and abundant cytoplasm that is often basophilic at the periphery; they have a tendency to appear, on a blood film, to have flowed around adjacent erythrocytes, but this feature is not specific for a reactive cell. Increased lymphocyte apoptosis may be seen in association with viral infections such as infectious mononucleosis.

Neoplastic lymphoid cells vary enormously in their morphology. The commonest malignancy is chronic lymphocytic

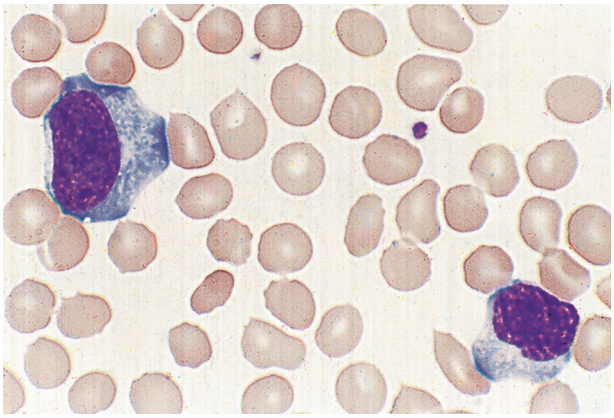

FIGURE 5-90 Photomicrograph of a blood film. Infectious mononucleosis. There are two activated lymphocytes ('atypical mononuclear cells').

leukaemia, the leukaemic population being composed almost exclusively of small lymphocytes (Fig. 5-91), sometimes with a few larger nucleolated cells. In prolymphocytic leukaemia, the majority of cells are a little larger than small lymphocytes with more cytoplasm and usually one large distinct nucleolus (Fig. 5-92). Lymphoblasts of acute lymphoblastic leukaemia (Figs. 5-93 and 5-94) vary in size from only slightly larger than lymphocytes to cells

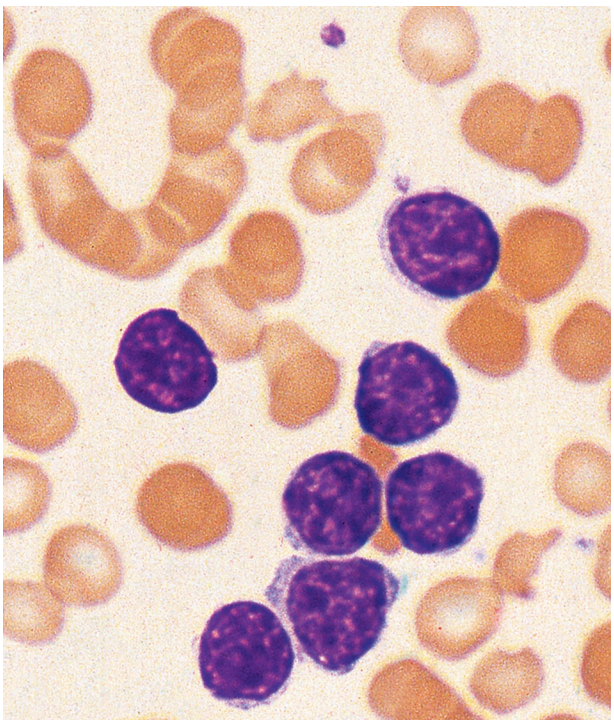

FIGURE 5-91 Photomicrograph of a blood film. Chronic lymphocytic leukaemia. The cells are small lymphocytes; note that rouleaux formation is increased.

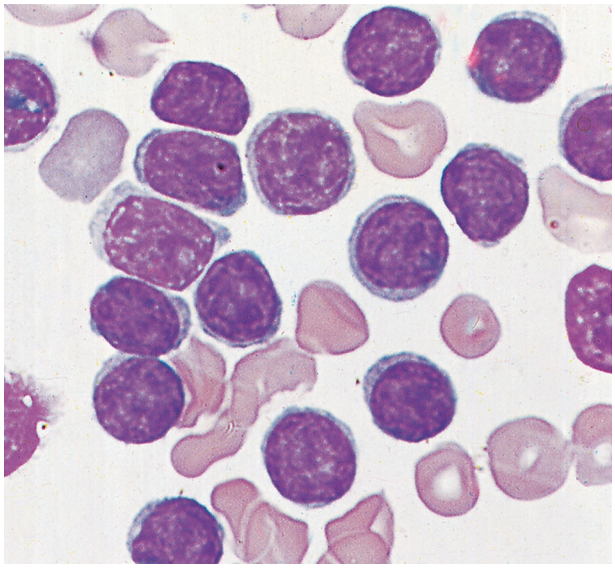

FIGURE 5-92 Photomicrograph of a blood film. Prolymphocytic leukaemia. There is a uniform population of prolymphocytes.

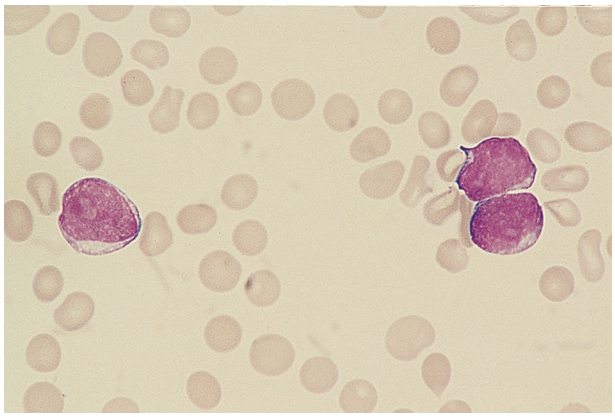

FIGURE 5-93 Photomicrograph of a blood film. Philadelphia-positive acute lymphoblastic leukaemia (FAB L1 category). Shows three lymphoblasts with a high nucleocytoplasmic ratio, very delicate chromatin and visible nucleoli.

of 15–17 μm in diameter. The nuclei generally have diffuse chromatin, but there may be some chromatin condensation in the smaller blasts. Nucleoli may be apparent. The cytoplasm varies from weakly to strongly basophilic.

Circulating lymphoma cells vary markedly in size and other characteristics, depending on the type of lymphoma. When there is a lymphocytosis, the lymphocytes are usually far less uniform than those seen in chronic lymphocytic leukaemia, and the lymphoma cells frequently have irregular lobed, indented or cleaved nuclei (particularly in follicular lymphoma) and relatively scanty agranular cytoplasm that varies in its degree of basophilia. Mantle cell lymphoma can have quite pleomorphic lymphocytes that can sometimes be

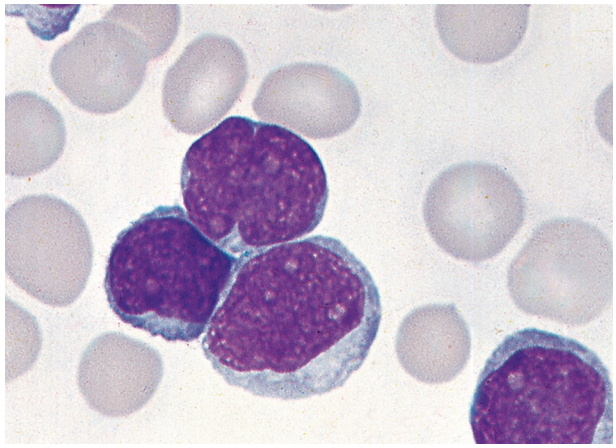

FIGURE 5-94 Photomicrograph of a blood film. Acute lymphoblastic leukaemia (FAB L1 type). Shows lymphoblasts with some chromatin condensation and small nucleoli.

confused with the atypical lymphocytes of infectious mononucleosis. Lobulated lymphocytes are a feature of HTLV-1 (human T-lymphotropic virus type 1) infection and of adult T-cell leukaemia/lymphoma. However, lymphocytes with definite lobulation are also a common storage artefact in blood kept for 18–24 h at room temperature (see p. 6).

Lymphocytes predominate in the blood films of infants and young children. In this age range, large lymphocytes and reactive lymphocytes tend to be conspicuous, and a small number of lymphoblasts may also be present.

There is no uniform approach to the terminology used to refer to cytologically abnormal lymphocytes, a problem compounded by the fact that sometimes it is difficult to distinguish reactive lymphocytes from neoplastic. The term 'variant lymphocyte' is sometimes used but it is not a term that is known to many clinicians. It is not prudent to describe lymphocytes as 'reactive'; it is better to refer to 'atypical lymphocytes, appear reactive' or, in other circumstances, 'abnormal lymphocytes, suspect lymphoma'. In this way an opinion, which may be wrong, is differentiated from a factual morphological description.

PLATELET MORPHOLOGY

Normal platelets are 1–3 μm in diameter. They are irregular in outline with fine red granules that may be scattered or centralised. A small number of larger platelets, up to 5 μm in diameter, may be seen in normal films. Larger platelets may be seen in the blood when platelet production is increased (Fig. 5-95) and in hyposplenism (Fig. 5-96). Thus, for example, in severe immune thrombocytopenia, some large platelets will be seen on the film. Very high platelet counts as a feature of a myeloproliferative neoplasm may be associated with extreme platelet anisocytosis, with some platelets being as large as red cells and often with some agranular or hypogranular platelets

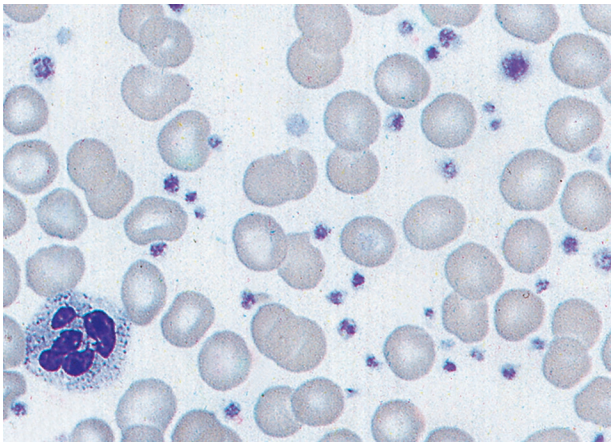

FIGURE 5-95 Photomicrograph of a blood film. Essential thrombocythaemia. Shows platelet anisocytosis and increased numbers of platelets.

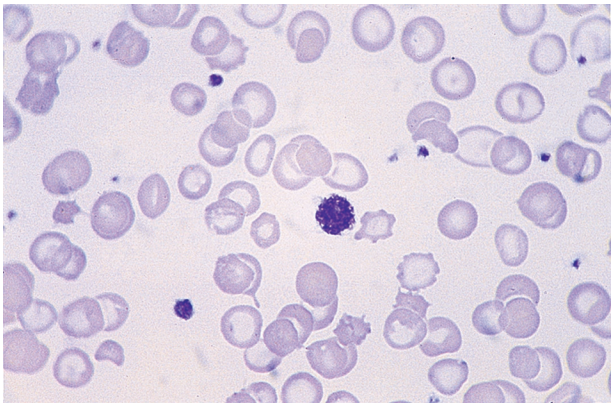

FIGURE 5-96 Photomicrograph of a blood film. Hyposplenism in coeliac disease. Shows giant platelet. There is also marked hypochromia, indicative of associated iron deficiency.

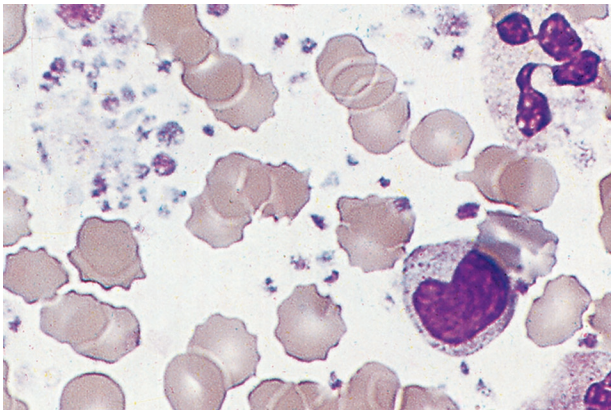

FIGURE 5-97 Photomicrograph of a blood film. Myeloproliferative neoplasm. Shows platelet anisocytosis with some giant platelets and some poorly granulated platelets.

(Fig. 5-97). The platelet count frequently increases with acute inflammatory stress or bleeding but seldom to more than 1000×10^9/l. More than this, unless the patient is critically ill or hyposplenic, makes a myeloproliferative neoplasm a definite possibility.

Characteristic morphological features are seen in various uncommon inherited platelet disorders associated with bleeding. These include the Bernard–Soulier syndrome, in which there are giant platelets (with a defective ristocetin response), and the grey platelet syndrome, in which the platelets have decreased granules and have a ghost-like appearance on the stained blood film (Fig. 5-98). Thrombocytopenia with large platelets is also a feature of the May–Hegglin anomaly (see p. 84).

In about 1% of individuals, ethylenediaminetetraacetic acid (EDTA) anticoagulant causes platelet clumping, resulting in pseudothrombocytopenia.[43] This is much less likely to occur when the blood is collected into any other anticoagulant.[44] This phenomenon may be detected when it gives rise to a 'flag' on an automated blood cell counter; it is identifiable on the blood film. It is not associated with any coagulation disturbance and platelet function is normal. When this abnormality is detected it is important that the erroneous platelet count is deleted from the report. If the blood film shows that the platelet count is clearly normal, the statement 'Platelet count normal' is sufficient, rather than a repeat sample in an alternative anticoagulant being requested. Occasionally, EDTA inhibits the staining of platelets.[45] Occasionally, platelets may be seen adhering to neutrophils, known as platelet satellitism (Fig. 5-99).[46–49] This has been reported in patients who have demonstrable antiplatelet autoantibodies,[50] but it is more commonly seen in apparently healthy individuals. It is not seen in films made directly from blood that has not

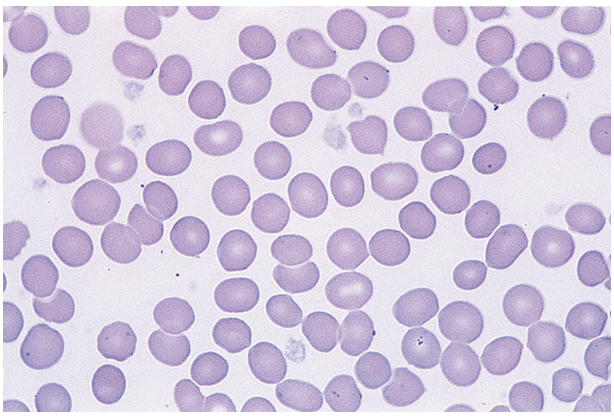

FIGURE 5-98 Photomicrograph of a blood film. Grey platelet syndrome. Shows severely hypogranular platelets.

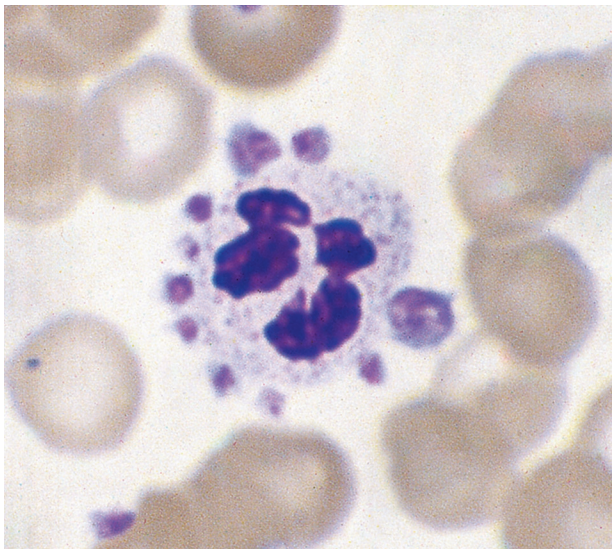

FIGURE 5-99 Photomicrograph of a blood film. Shows adhesion of platelets to a neutrophil (platelet satellitism).

been anticoagulated. Sometimes the platelets are ingested by neutrophils.[51] If a blood film in a patient with platelet satellitism or phagocytosis shows that the automated count is erroneous and the platelet count is in fact normal, the erroneous count should be deleted from the report and an explanation given.

Supplementary Techniques Including Blood Parasite Diagnosis

Andrew Osei-Bimpong • John Burthem

CHAPTER OUTLINE

TESTS FOR THE ACUTE-PHASE RESPONSE

Inflammatory response to tissue injury (i.e. the acute-phase response) includes alteration in serum protein concentration, especially increases in fibrinogen, haptoglobin, caeruloplasmin, immunoglobulins (Ig) and C-reactive protein (CRP), and a decrease in albumin. The changes occur in acute infection, during active phases of chronic inflammation, with malignancy, in acute tissue damage (e.g. following acute myocardial infarction) and with physical injury. Measurement of the acute-phase response

is a helpful indicator of the presence and extent of inflammation or tissue damage, and of the response to treatment. The usual tests for detecting an acute-phase response are estimation of CRP and measurement of the erythrocyte sedimentation rate (ESR); some studies have suggested that plasma viscosity is also a useful indicator, but there is debate about the relative value of these tests.[1,2]

Kits that are sensitive and precise are available for CRP assay; small increases in serum levels of CRP can often be detected before any clinical features become apparent, whereas as a tissue-damaging process resolves, the serum level rapidly decreases to within the normal range (<5 mg/l). The ESR is slower to respond to changes in acute disease activity and it is insensitive to small changes in disease activity. It is less specific than CRP because it is also influenced by immunoglobulins (which are not acute-phase reactants) and by anaemia. Moreover, because the rate of change of ESR is slower than that of CRP, it rarely reflects the current disease activity and clinical state of the patient as closely as the CRP concentration. The ESR is a useful screening test, and the conventional manual ESR method is simple, cheap and independent of a power supply, thus making it suitable for point-of-care (near-patient) testing. It is recommended that, in clinical practice, the two tests should be carried out in tandem.[3] Because a CRP assay is a biochemical test usually performed in the clinical chemistry laboratory, it will not be discussed further here.

Erythrocyte sedimentation rate

The method for measuring the ESR recommended by the International Council for Standardisation in Haematology (ICSH)[4] and also by various national authorities[5] is based on that of Westergren, who developed the test in 1921 for studying patients with pulmonary tuberculosis. The ESR is the measurement of the sedimentation of red cells in diluted blood after standing for 1 h in an open-ended glass tube of 30 cm length mounted vertically on a stand.

Conventional Westergren method

The recommended tube is a straight glass or rigid transparent plastic tube 30 cm in length and no less than 2.55 mm in diameter. The bore must be uniform to within 5% throughout. A scale graduated in mm extends over the lower 20 cm. The tube must be clean and dry and kept free from dust. If reusable, before being reused it should be thoroughly washed in tap water and then rinsed with deionised or distilled water and allowed to dry. Specially made racks with adjustable levelling screws are available for holding the sedimentation tubes firmly in an exactly vertical position. The rack must be constructed so that there will be no leakage of the blood from the tube. It is conventional to set up sedimentation rate tests at room temperature (18–25 °C). Sedimentation is normally accelerated as the temperature increases, and if the test is to be carried out at a higher ambient temperature, a normal range should be established for that temperature. Exceptionally, when high thermal amplitude cold agglutinins are present, sedimentation becomes noticeably less rapid as the temperature is increased toward 37 °C.

Method. The method described below, originally described by the ICSH[4] and now adopted by the Clinical and Laboratory Standards Institute (CLSI) as its approved method,[5] is intended to provide a reference method for verifying the reliability of any modification of the test.

Either collect venous blood in ethylenediaminetetra-acetic acid (EDTA) and dilute a sample accurately in the proportion of 1 volume of citrate to 4 volumes of blood, or collect the blood directly into citrate diluent. For the diluent, prepare a solution of 109 mmol/l trisodium citrate (32 g/l $Na_3C_6H_5O_7 \cdot 2H_2O$). Filter through a Micropore filter (0.22 mm) into a sterile bottle. It can be stored for several months at 4 °C but must be discarded if it becomes turbid through the growth of mould.

The test should be carried out on the diluted sample within 4 h of collecting the blood, although a delay of up to 6 h is permissible provided that the blood is kept at 4 °C. EDTA-anticoagulated blood can be used up to 24 h if the specimen is kept at 4 °C, provided that 1 volume of 109 mmol/l (32 g/l) trisodium citrate is added to 4 volumes of blood immediately before the test is performed.

Mix the blood sample thoroughly and draw it up into the Westergren tube to the 200 mm mark by means of a teat or a mechanical device; mouth suction should never be used. Place the tube exactly vertical and leave undisturbed for exactly 60 min, free from vibrations and draughts and not exposed to direct sunlight. Read the height of the clear plasma above the upper limit of the column of sedimenting cells to the nearest 1 mm. The result is expressed as ESR = *X* mm in 1 h. A poor delineation of the upper layer of red cells sometimes occurs, especially when there is a high reticulocyte count.

Range in health. The mean values and the upper limit for 95% of normal adults are given in Table 6-1. There is a progressive increase with age, but it is difficult to define a strictly healthy population for determining normal values in individuals older than 70 years.[6] In the newborn, the ESR is usually low. In childhood and adolescence, it is the same as for normal men with no differences between boys and girls. It is increased in pregnancy, especially in the later stages, and can be independent of anaemia;[7] this is due to the physiological effect of an increase in the plasma volume causing haemodilution.

In the newborn, the ESR has been reported to be 0–2 mm in 1 h, increasing to 4 mm in 1 h at 1 week, up to 17 mm in 1 h by day 14, and then to 10–20 mm in 1 h for both girls and boys, until puberty.[8] However, as the samples in infants were obtained by the capillary method, results are not directly comparable to the Westergren method.

TABLE 6-1

ERYTHROCYTE SEDIMENTATION RATE RANGES IN HEALTH

Age Range (Years)	ESR Mean (mm in 1 h)
10–19	8
20–29	10.8
30–39	10.4
40–49	13.6
50–59	14.2
60–69	16
70–79	16.5
80–91	15.8
Pregnancy	
Early gestation	48 (62 if anaemic)
Later gestation	70 (95 if anaemic)

Modified methods.

Length of tube. The overall length of the tube is not a critical dimension for the test provided that it fits firmly in an appropriate holding device. The tube must, however, be long enough to ensure that packing of the cells does not start before the test has been completed.

Plastic tubes. A number of plastic materials (e.g. polypropylene and polycarbonate) are recommended as substitutes for glass in Westergren tubes. However, not all plastics have similar properties, and it must be demonstrated that the ESR with the chosen tubes is reproducible and not affected by the plastic.

Disposable glass tubes. Disposable glass tubes should be supplied clean and dry and ready for use. It is necessary to show that neither the tube material nor the manufacturer's cleaning process affects the ESR.

Capillary method. Short tubes of narrower bore than that of the standard tube are available, mainly for tests on infants. These are, however, no longer in general use, and it is necessary to establish normal ranges or a correction factor to convert results to an approximation of ESR by the Westergren method.

Test duration. Sedimentation is measured after aggregation has occurred and before the cells start to pack, usually at 18–24 min. From the rate during this time period the sedimentation that would have occurred at 60 min is derived and converted to the conventional ESR equivalent by an algorithm.[9]

Sloping tube. Red cells sediment more quickly when streaming down the wall of a sloped tube. This phenomenon has been incorporated into automated systems in which the end-point is read after 20 min with the tube held at an angle of 18° from the vertical.[10] Incorporating a low-speed centrifugation step (approximately 800 rpm) in this automated method reduces the end-point time further.[11] These methods have been shown to give results comparable to the conventional method.

Anticoagulant. EDTA-anticoagulated blood can be used without citrate dilution, at least if packed cell volume (PCV) is below 0.36 l/l or haemoglobin concentration (Hb) is below 110 g/l; less precise results are obtained when the PCV is higher. Because of the biohazard risk of blood contamination inherent in using open-ended tubes, it is now recommended that, where possible, a closed system be used in routine practice. Manual methods are available that avoid transfer of the blood into the sedimentation tube. Automated closed systems use blood collected in special evacuated tubes containing blood anticoagulated with either citrate or EDTA. A sample is taken up through a pierceable cap and then automatically diluted in the system if this is required.

Whenever a different method or tube is planned, a preliminary test should be carried out to check precision and to compare results with those obtained by the CLSI standardised method described earlier.

Evaluation of a new routine method

For the evaluation of a new ESR method the test should be carried out on at least 60 samples. These samples could be collected separately from the same subjects in accordance with specified requirements (e.g. undiluted EDTA samples or directly into tubes containing citrate). The samples should come from patients with a wide variety of diseases (as well as from normal subjects) to cover the range of ESR from 15 to 105 mm, with approximately the same number of samples in each quartile. If any test fails to give a clear-cut plasma erythrocyte interface in either the test system or the standardised test, the pair of values should be eliminated from the data.

Any new method may be considered to be satisfactory if 95% of results differ consistently by no more than 5%. However, because the ESR may be affected by several uncontrolled variables, the reference method cannot be used to adjust the measurements that are obtained. Thus if the new method gives disparate readings, it will be necessary to establish a normal range specifically for the method.

Quality control

The standardised method can be used as a quality-control procedure for routine tests or, alternatively, stabilised whole blood preparations can be used for the daily control of automated systems (e.g. ESR-Chex, www.streck.com).[12] Three or four specimens of EDTA blood kept at 4 °C will also serve as a control on the following day.

Another control procedure is to calculate the daily cumulative mean, which is relatively stable when at least 100 specimens are tested each day in a consistent setting (see Chapter 25). A coefficient of variation of <15% between daily sets appears to be a satisfactory index for monitoring instrument performance.[13]

Semiquantitative slide method

Enhanced red cell adhesion/aggregation can be demonstrated by allowing a drop of citrated blood to dry on a

slide. An estimate of the amount of cell aggregation on the film by image analysis provides a semiquantitative measure of the acute-phase response that appears to correlate with the ESR.[14] Based on this principle, serial microscopic images of red cells aggregating on a glass slide taken every 30 s for 5 min can distinguish a normal ESR from a high value (Figs. 6-1 and 6-2). The images demonstrate greater spacing of cells in blood with higher ESR values compared with blood with lower ESR values.

Mechanism of erythrocyte sedimentation

The rate of fall of the red cells is influenced by a number of interacting factors. It depends on the difference in specific gravity between red cells and plasma, but it is influenced very greatly by the extent to which the red cells form rouleaux, since these sediment more rapidly than single cells. Other factors that affect sedimentation include the ratio of red cells to plasma (i.e. the PCV), the plasma viscosity, the verticality (or otherwise) of the sedimentation tube, the bore of the tube and the dilution (if any) of the blood.

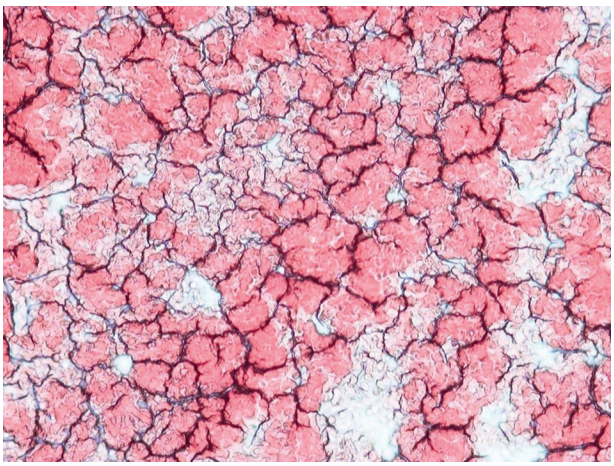

FIGURE 6-1 ESR of 9 mm in 1 h after 2 min.

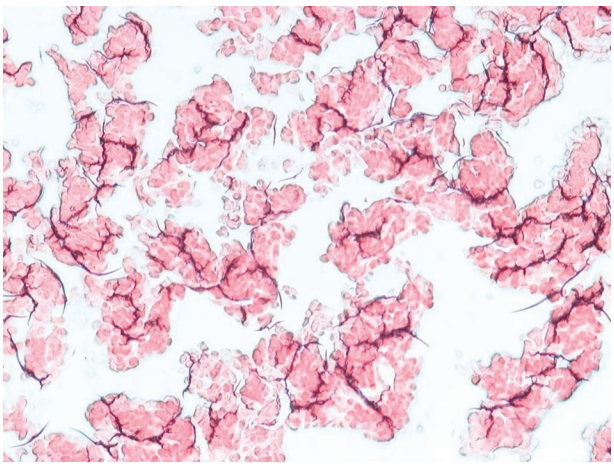

FIGURE 6-2 ESR of 69 mm in 1 h after 2 min.

The rouleaux formation and the red cell clumping that are associated with the increased ESR mainly reflect the concentrations of fibrinogen and other acute-phase proteins (e.g. haptoglobin, caeruloplasmin, α_1-acid glycoprotein, α_1-antitrypsin, and CRP). Rouleaux formation is also enhanced by the immunoglobulins and is retarded by albumin. Defibrinated blood normally sediments extremely slowly (i.e. not more than 1 mm in 1 h) unless the serum globulin concentration is increased or there is an unusually high globulin:albumin ratio.

Anaemia, by altering the ratio of red cells to plasma, encourages rouleaux formation and accelerates sedimentation. In anaemia, cellular factors may also affect sedimentation. Thus, in iron deficiency anaemia, a reduction in the intrinsic ability of red cells to sediment may compensate for the accelerating effect of an increased proportion of plasma.

Sedimentation can be observed to take place in three stages: a preliminary stage of at least a few minutes during which time rouleaux occur and aggregates form; then a period in which the sinking of the aggregates takes place at a constant speed; and finally, a phase during which the rate of sedimentation slows as the aggregated cells pack at the bottom of the tube. It is obvious that the longer the tube used, the longer the second period can last and the greater the sedimentation rate may appear to be.

Although ESR is a nonspecific phenomenon, its measurement is clinically useful in disorders associated with an increased production of acute-phase proteins. In rheumatoid arthritis or tuberculosis it provides an index of progress of the disease, and it is of considerable value in the diagnosis of temporal arteritis and polymyalgia rheumatica. It is often used if multiple myeloma is suspected, but when the myeloma is nonsecretory or light chain type, a normal ESR does not exclude this diagnosis.

An elevated ESR occurs as an early feature in myocardial infarction.[15] Although a normal ESR cannot be taken to exclude the presence of organic disease, the vast majority of acute or chronic infections and most neoplastic and degenerative diseases are associated with changes in the plasma proteins that lead to an acceleration of sedimentation. An increased ESR in subjects who are human immunodeficiency virus (HIV) seropositive seems to be an early predictive marker of progression toward acquired immune deficiency syndrome (AIDS).[16] The ESR is less helpful in countries where chronic diseases are rife; however, one study has shown that very high ESRs (higher than 100 mm/h) have a specificity of 0.99 and a positive predictive value of 0.9 for an acute or chronic infection.[17] The ESR is influenced by age, stage of the menstrual cycle and medications taken (corticosteroids, oral contraceptives). It is especially low (0-1 mm) in polycythaemia, hypofibrinogenaemia and congestive cardiac failure and when there are abnormalities of the red cells such as

poikilocytosis, spherocytosis or sickle cells. In cases of performance-enhancing drug intake by athletes (discussed below) the ESR values are generally lower than the usual value for the individual and as a result of the increase in Hb (i.e. the effect of secondary polycythaemia).

Plasma viscosity

The ESR and plasma viscosity generally increase in parallel.[1] Plasma viscosity is, however, primarily dependent on the concentration of plasma proteins, especially fibrinogen, and it is not affected by anaemia. Changes in the ESR may lag behind changes in plasma viscosity by 24–48 h, and viscosity seems to reflect the clinical severity of disease more closely than does the ESR.[18]

There are several types of viscometers, including rotational and capillary types that are suitable for routine use,[1] and, as for ESR methods, automated closed-tube methods are available.[19] The main use of plasma viscosity is in the investigation of individuals with suspected hyperviscosity, myeloma and macroglobulinaemia. In conjunction with the ESR and CRP, the plasma viscosity can be used as a marker of inflammation. The viscosity test should be carried out as described in the instruction manual for the particular instrument used.

Reference values

Each laboratory should establish its own reference values for plasma viscosity. As a general guide, ICSH has recorded that with the Harkness capillary viscometer normal plasma has a viscosity of 1.16 to 1.33 mPa/s (if expressed in poise [P], 1 cP = 1 mPa/s) at 37 °C and 1.50 to 1.72 mPa/s at 25 °C.[20] Plasma viscosity is lower in the newborn (0.98 to 1.25 mPa/s at 37 °C), increasing to adult values by the third year; it is slightly higher in old age. There are no significant differences in plasma viscosity between men and women or in pregnancy. It is remarkably constant in health, with little or no diurnal variation, and it is not affected by exercise. A change of only 0.03 to 0.05 mPa/s is thus likely to be clinically significant.

WHOLE BLOOD VISCOSITY

The viscosity of whole blood reflects its rheological properties; it is influenced by PCV, plasma viscosity, red cell aggregation and red cell deformability. It is especially sensitive to PCV, with which it is closely correlated. The clinical interpretation of its measurement must also take into account the interaction of the red cells with blood vessels, which greatly influences blood flow *in vivo*.

Guidelines for measuring blood viscosity and red cell deformability by standardised methods have been published.[21] Rotational and capillary viscometers are suitable for measuring blood viscosity; deformability can be measured by recording the rate at which red cells in suspension pass through a filter with pores 3–5 mm in diameter.

HETEROPHILE ANTIBODIES IN SERUM: DIAGNOSIS OF INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis (IM) is caused by the Epstein–Barr virus.[22] The immune response that develops in response to virus-infected cells includes not only antibodies to viral antigens but also characteristic heterophile antibodies. Before the nature of this reaction was understood, Paul and Bunnell[23] demonstrated the antibodies as agglutinins directed against sheep red cells. They are, in fact, not specific for sheep red cells but also react with horse and ox, but not human, red cells. They are IgM globulins, which are immunologically related to, but distinct from, antibodies that occur in response to the Forssman antigens. The latter are widely spread in animal tissue; they occur at low titre in healthy individuals and at high titre in serum sickness and in some leukaemias and lymphomas.[24,25] In these non-IM conditions, the antibody can be absorbed out by guinea pig cells. Thus, for the diagnosis of IM, it is necessary to demonstrate that the antibody present has the characteristics of the Paul–Bunnell antibody (i.e. it is absorbed by ox red cells but not by guinea pig kidney). This is the basis of the absorption tests for IM (e.g. 'Monospot' test, www.meridianbioscience.com/diagnostic-products/mononucleosis/monospot/monospot-latex.aspx). Immunofluorescent antibody tests have been developed to distinguish the IgM antibody, which occurs at high titre in the early phase of IM and diminishes during convalescence, from the IgG antibody, which persists at high titre for years after infection[26,27] and which also occurs in the non-IM infections.[22,28]

Screening tests for infectious mononucleosis

The reagents for IM screening are available commercially in diagnostic kits from several manufacturers. Guinea pig cells can also be manufactured locally as described in previous editions. Some kits are based on agglutination of stabilised horse red cells or antigen-coated latex particles to which IM antibody binds. An extensive evaluation of 14 slide tests for the UK Medical Devices Agency (MDA) showed them to have a sensitivity between 0.87 and 1.00 and a specificity of 0.97 to 1.00, with an overall accuracy in the order of 91% to 100%.[25] False-positive reactions have been reported in malaria, toxoplasmosis, and cytomegalovirus infection; autoimmune diseases; and even occasionally without any apparent underlying disease.[29,30] False-negative reactions occur if the test is carried out before the level of heterophile antibody has increased or conversely when it has decreased. False-negative reactions may also occur in the very young and the very old. In the UK MDA study the best performance was obtained with the Clearview IM test (Alere Ltd, Stockport, UK, www.alere.com/en/home/product-details/clearview-mono-au.html?c=AU),

which uses latex-labelled bovine erythrocyte glycoprotein. IM heterophile antibody binds to this to form a complex that presents as a band in the result window (Fig. 6-3). The test can be performed with diluted whole blood as well as with plasma or serum.

Screening tests are also available based on enzyme-linked immunosorbent assay (ELISA) and immunochromatographic assay. These tests are more elaborate than the slide screening test described earlier, but they are less likely to give a false result.

Clinical value

Tests for the heterophile antibody are useful for diagnosis. Antibodies are often present as early as the 4th to 6th day of the disease and are almost always found by the 21st day. They disappear as a rule within 4–5 months. There is no unanimity as to how frequently negative reactions are found in 'true' IM. Occasionally, the characteristic antibodies develop very late in the course of the disease, perhaps weeks or even months after the patient becomes ill. It is also known that a positive reaction may be transient and that the antibodies may be present at such low titres that they may be missed or may produce anomalous agglutination reactions when associated with the naturally occurring antibody at similar titres. For all of these reasons, it is difficult to state categorically that any particular patient has not or will not produce antibodies. Antibodies specific for Epstein–Barr virus have been demonstrated in the serum of 86% of patients with clinical and/or haematological features of IM.[31]

There is no substantial evidence that sera containing agglutinins in high concentration giving the typical reactions of IM are found in diseases unless there is coexisting IM. In particular, the heterophile antibody titres in lymphomas are similar to those found in unselected patients not suffering from IM.[32]

FIGURE 6-3 Screening for infectious mononucleosis with *Clearview* slide test. The sample is added to the bottom window, where, if positive, antibodies combine with bovine erythrocyte glycoprotein attached to blue microspheres; migration to the test window (centre) occurs and here the complexes are bound to immobilised bovine erythrocytic glycoprotein, producing a blue line. The blue line in the upper window is a positive control.

DEMONSTRATION OF LUPUS ERYTHEMATOSUS CELLS

Antinuclear antibodies, or antinuclear factors (ANFs), occur in the serum in a wide range of autoimmune disorders, including systemic lupus erythematosus (SLE). Descriptions of the LE cell test, which has now been superseded by immunological tests, can be found in earlier editions of this book.

ERYTHROPOIETIN

Erythropoietin regulates red cell production. It is a heat-stable glycoprotein with a molecular weight of about 34 kDa. It is produced mainly in the kidney. Only a small quantity is demonstrable in normal plasma or urine.

A pure form of human erythropoietin from recombinant deoxyribonucleic acid (DNA) (recombinant human erythropoietin, r-HuEpo) is available for diagnostic assay methods by ELISA, enzyme immunoassay and radioimmune assay. Commercial kits are available that are reliable and sensitive,[33] although there is some intermethod variability.[34] Results are expressed in international units (iu) by reference to a World Health Organisation (WHO) standard. This was originally a urinary extract, and a preparation is available with a potency of 10 iu per ampoule.[35] The present standard has been established for r-HuEpo with a potency of 86 iu per ampoule.[36]

Reference range

The normal reference range in plasma or serum varies considerably according to the method of assay.[33] For the ELISA method used by the UK supraregional service, the normal range is 9.1 to 30.8 iu/l. With test kits, in the steady state without anaemia, it is usually given as 5 to 25 iu/l or slightly higher. In normal children, the levels are the same as those in adults, except for infants younger than 2 months when the levels are lower.[37]

There is a diurnal variation, with the highest values at night.[38] In pregnancy, erythropoietin concentration increases with gestation.[39]

Significance

Increased levels of erythropoietin are found in the plasma (or serum) in various anaemias,[40] and there is normally an inverse relationship between haemoglobin and erythropoietin. In thalassaemia, erythropoietin is lower than in iron deficiency with the same degree of anaemia, but there is a close inverse correlation with the red cell count.[41] In renal disease, there is a progressive decline in the erythropoietin response to anaemia, and in end-stage renal failure the concentration is normal or even lower than normal despite increasing anaemia. In renal patients receiving dialysis, erythropoietin treatment may cause functional iron deficiency.[42]

Some impairment of production of erythropoietin may occur in association with neoplasms and chronic inflammatory diseases. Increased concentrations of erythropoietin occur in secondary polycythaemia as a result of respiratory and cardiac disease; in the presence of abnormal haemoglobins with high oxygen affinity; and in association with carcinoma of the kidney and other erythropoietin-secreting tumours such as hepatoma, uterine fibroma and ovarian carcinoma.[40]

In primary polycythaemia ('polycythaemia vera'), the plasma erythropoietin level is usually lower than normal even when the Hb has been reduced by venesection.[43,44] In secondary polycythaemia, the level of erythropoietin is never below normal. An assay is particularly useful in patients with erythrocytosis of undetermined cause; low erythropoietin has a specificity of 0.92 with moderate sensitivity for diagnosing primary polycythaemia.[43] However, in such cases there may be an intermittent increase in erythropoietin secretion. Thus determining its level in a single sample of plasma may be misleading. Low levels have been found in one-third of cases of primary (essential) thrombocythaemia, especially when Hb is at a high normal level.[43]

AUTONOMOUS *IN VITRO* ERYTHROPOIESIS

When mononuclear cells from blood or bone marrow are cultured, erythroid colonies (CFU-E) will normally develop only when erythropoietin is present in the culture medium. However, growth will occur in erythropoietin-free medium in primary polycythaemia. This provides a method for distinguishing primary from secondary polycythaemia.[45–47]

To demonstrate CFU-E formation collect mononuclear cells from a blood sample by density separation (see p. 57–58) and add them to an appropriate serum-free liquid culture medium[46,47] or collagen gel medium.[48] Divide this into two portions. Add 1 iu/ml of erythropoietin to one portion. Plate both portions and incubate for 7 days at 37 °C. Stain with benzidine and examine directly under an inverted microscope or after spreading onto slides. The numbers of benzidine-positive cell clusters in the erythropoietin-free and erythropoietin-containing samples are counted and compared. A diagnosis of primary polycythaemia is indicated if there is an approximately equal growth in both samples. A method has been described in which flow cytometry with immunofluorescence is used to detect growth of the erythroid cells after only 2–5 days of culture.[49]

THROMBOPOIETIN

Thrombopoietin regulates megakaryocyte development and platelet production. It is a protein produced by the liver and has been purified from serum.[50] It is considerably larger than erythropoietin, with a molecular weight of about 335 kDa. A recombinant human thrombopoietin (rhTPO) has been produced and used to prepare a monoclonal antibody and develop a sensitive and specific ELISA. This has been used to measure thrombopoietin in normal serum and serum from patients with various blood disorders.[51] The normal range (mean ± 2SD) is 0.79 ± 0.35 fmol/ml for men and 0.70 ± 0.26 fmol/ml for women. It is increased in thrombocytopenias and is especially high (18.5 ± 12.4 fmol/ml) in aplastic anaemia with severe thrombocytopenia. In essential thrombocythaemia, thrombopoietin is in the range of 1.01 to 4.82 fmol/ml.[51]

Haematological tests in sports medicine

Assays to detect the illicit use of hormones such as erythropoietin in endurance sports are becoming increasingly important.[52,53] Some of the current test methods for detecting erythropoietin used in this manner[54] are described below.

Blood doping, often called induced erythrocythaemia, is the practice of increasing the number of red blood cells through an intravenous infusion of blood, thereby enhancing performance in sports through the increase in red blood cell mass with an increased oxygen-carrying capacity.[52] Alternatively, recombinant hormones such as erythropoietin can be used to induce erythropoiesis. Blood doping is an illegal practice as it provides an unfair advantage of endurance and performance over other athletes.[52,53] It is also potentially dangerous due to the abnormal increase in red cell mass and the risk of acquiring infection from contaminated blood.[53] The International Doping Test Management[55] collaborates with the World Anti-Doping Agency and other international and national sports authorities to coordinate the collection of blood and urine samples to be analysed in accredited laboratories.[56]

The full blood count and reticulocyte count are relatively fast and less expensive than direct erythropoietin measurement,[53] and are useful since abnormal blood counts may suggest doping. The sports administrative bodies collect blood profiles on individual athletes and these are monitored over time so changes in blood parameters due to doping can be detected. Compared with population-derived

upper limits of the reference range such as the 0.5 Hct limit or the 2.5% reticulocyte limit, the fluctuations allowed are smaller when using individual-based cut-offs.[52,54] Blood samples need to be analysed within 24 h of venesection[52] and the security and confidentiality of blood samples obtained should be maintained at all times. The abnormalities in the blood profile which may suggest doping are outlined in the following section.

Red cell parameters

Most red cell parameters within the full blood count can be used to indirectly detect blood doping. This is due to the increased Hb either as a result of a raised erythropoietin or a direct transfusion of red blood cells in cases of blood doping.

Reticulocytes

The administration of recombinant erythropoietin can be suspected from a raised reticulocyte count.[57] Erythropoietin causes increased production of erythroblasts and immature reticulocytes, and accelerates their release from the bone marrow into peripheral blood. The mean haemoglobin content of the reticulocyte fraction is also raised.

Haemoglobin concentration and haematocrit

Exogenous erythropoietin and intravenous infusion of blood both increase the Hb and Hct.[57]

Whole blood viscosity and erythrocyte sedimentation rate

A large infusion of red blood cells can increase whole blood viscosity and reduce the ESR due to the change in red cell count:plasma ratio.

Erythropoietin

Changes in one or more of the full blood count parameters are only suggestive of the possible use of erythropoietin so they should be followed by tests to directly detect recombinant erythropoietin in the plasma.[53,58] The structural differences between the endogenous and the recombinant erythropoietin isoforms[59] make it possible to separate the two isoforms of erythropoietin, providing the samples are collected within 24 h of erythropoietin administration.[60] Alternatively, isoelectric focusing can detect exogenous (recombinant) erythropoietin in urine specimens.[61,62]

PRINCIPLES OF DETECTION OF MICROORGANISMS

The essential method for a definitive diagnosis of malaria remains the finding of parasites on microscopy of a blood film, followed by the identification of the particular species based on fine morphological detail. Examination of a thick blood film remains the most sensitive routinely applied technique where microscopy expertise is available. Only brief outlines of how microscopic diagnoses may be reached are given in this chapter, and for more detailed accounts, readers are referred to a parasitology textbook. Where microscopy expertise is not available, antibody-based 'rapid diagnostic tests' (RDTs) are increasingly applied. RDTs have widespread application in developing countries, but increasingly are gaining use in all laboratories to screen potentially infected samples and to supplement diagnosis by microscopy. It is important, however, that users appreciate the strengths and limitations that govern selection and interpretation of RDTs. Molecular approaches to malaria diagnosis and, in particular, to species identification employ polymerase chain reaction (PCR)-based assays and have the capability to be highly sensitive and specific.[63] Cost and time constraints, however, mean that at present molecular techniques are employed principally in reference or research laboratories. Molecular techniques in parasite diagnosis are not discussed in this book.

In addition to the plasmodia that give rise to malaria, the other important microorganisms to be found in the blood are leishmaniae, babesia, trypanosomes, microfilariae and ehrlichiae. Thick blood films are also useful for the detection of microfilariae. When they are used for this purpose, it is important to scan the entire film using a low-power objective, or parasites may be missed. Examination of wet preparations of blood can also be used for diagnosis of microfilariae and this has the advantage that the parasites are easily detected because they are moving. A stained film is necessary for confirmation of species. Wet preparations are also useful for the detection of trypanosomes and the spirochaetes of relapsing fever. The presence of small numbers of trypanosomes or spirochaetes is revealed by occasional slight agitation of groups of red cells. Examination of a stained film confirms their nature. In addition to ehrlichiae and spirochaetes, other bacteria and fungi are occasionally observed in blood films, either free or within neutrophils.

EXAMINATION OF BLOOD FILMS FOR PARASITES

General principles

Thick films are extremely useful when parasites are scanty, and these should be prepared and examined as a routine where malaria is suspected. Identification of the species is less easy than in thin films, and mixed infections may be missed, but if 5 min are spent examining a thick film, this is equivalent to about 1 h spent in traversing a thin film. Once the presence of parasites has been confirmed, a thin film should be used for determining the species and,

in the case of *Plasmodium falciparum,* for assessing the severity of the infection by counting the percentage of parasitised cells. Low levels of parasitaemia may be missed by microscopy, and proficiency testing studies have demonstrated the need for all laboratories, and especially those lacking expertise, to take part in external quality control programmes and to refer problematic cases to more experienced centres.[64,65]

Staining thin films

Thin films should be stained with Giemsa stain or Leishman stain at pH 7.2, not with a standard May–Grünwald–Giemsa stain. The pH is important to maximise the visibility of cytological features that are important for diagnosis (Fig. 6-4).

MICROSCOPIC DIAGNOSIS OF MALARIA

Morphological criteria for differentiation of malaria parasites are given in Table 6-2 and illustrated in Figures 6-5 to 6-8. Mixed species infections are well recognised, and microscopists should be alert to morphological features that cannot be reconciled to a single disease type (Fig. 6-9). Films for malaria diagnosis must be made no longer than 3–4 h after blood collection. Films prepared later may still reveal parasites, but the parasite morphology will differ from that of fresh samples, making species identification more difficult and in some cases causing the appearance of parasite stages not normally occurring in blood (Fig. 6-10).

Two other morphology-based screening methods can be used for malaria diagnosis.

Fluorescence microscopy

Red cells containing malaria parasites fluoresce when examined by fluorescence microscopy after staining with acridine orange. This has a sensitivity of about 90% in acute infections but only 50% at low levels of parasitaemia, and false-positive readings may occur with Howell–Jolly bodies and reticulocytes. When positive, it is necessary to examine a conventionally stained blood film to identify the species.[66]

Quantitative buffy coat method

The quantitative buffy coat (QBC) method is another procedure for detection of parasites by fluorescent microscopy. The blood is centrifuged in capillary tubes that are coated with acridine orange. It is fairly sensitive but requires expensive equipment and has the disadvantage of false-positive results in the presence of Howell–Jolly bodies and reticulocytes. When positive, identification of species requires examination of a stained blood film, but it is useful as an initial screening test.[67]

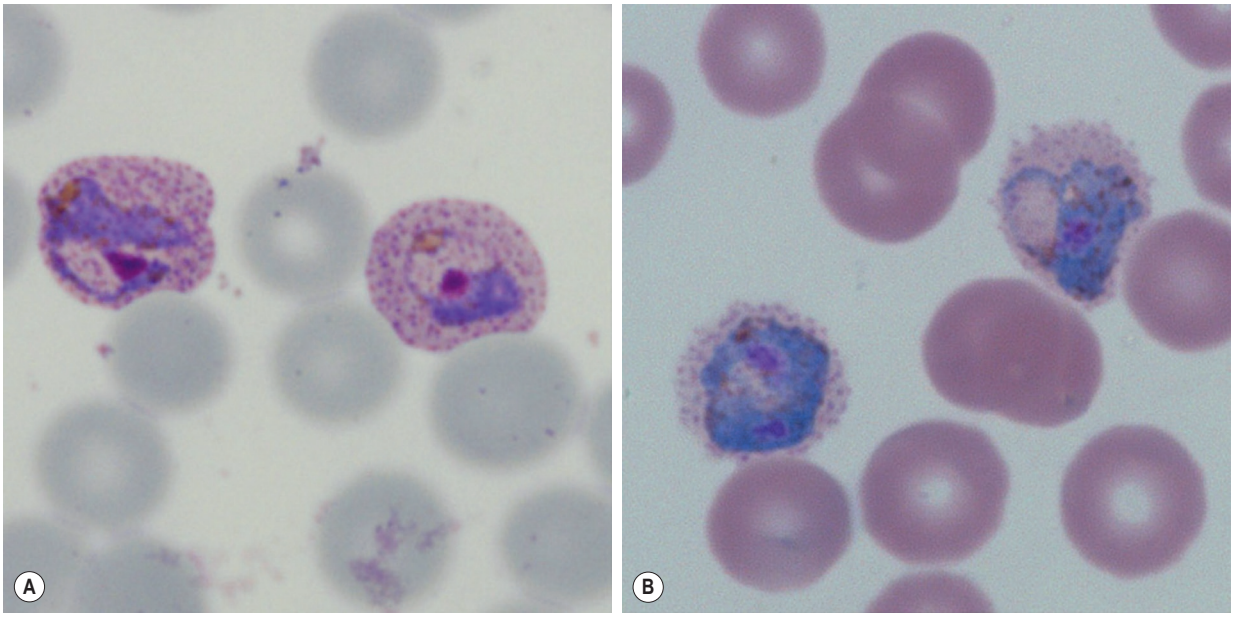

FIGURE 6-4 Effects of staining pH on parasite staining characteristics (*P. vivax*). At pH 7.2 **(A)** the parasite is readily distinguished from the adjacent blue/grey erythrocytes, chromatin staining is prominent and Schüffner dots are readily distinguished. At pH 6.9 **(B)** the parasite remains visible, but there is less contrast from surrounding erythrocyte cytoplasm, relatively weak chromatin staining and poor resolution of Schüffner dots (which may not be visible at this pH).

TABLE 6-2

MORPHOLOGICAL DIFFERENTIATION OF MALARIA PARASITES

	P. falciparum	*P. vivax*	*P. ovale*	*P. malariae*
Infected red cells	Normal size;* Maurer clefts†	Enlarged; Schüffner dots‡	Enlarged; oval and fimbriated; Schüffner dots‡	Normal or microcytic; stippling not usually seen
Ring forms (early trophozoites)	Delicate; frequently 2 or more; accolé forms;§ small chromatin dot	Large, thick; usually single (occasionally 2) in cell; large chromatin dot	Thick, compact rings	Very small, compact rings
Later trophozoites	Compact, vacuolated; sometimes 2 chromatin dots	Amoeboid; central vacuole; light blue cytoplasm	Smaller than *P. vivax;* slightly amoeboid	Band across cell; deep blue cytoplasm
Schizonts	18–24 merozoites filling two-thirds of cell	12–24 merozoites, irregularly arranged	8–12 merozoites filling three-fourths of cell	6–12 merozoites in daisy-head around central mass of pigment
Pigment	Dark to black clumped mass	Fine granular; yellow-brown	Coarse light brown	Dark, prominent at all stages
Gametocytes	Crescent or sausage-shaped; diffuse chromatin; single nucleus	Spherical, compact, almost fills cell; single nucleus	Oval; fills three-fourths of cell; similar to but smaller than *P. vivax*	Round; fills one-half to two-thirds of cell; similar to *P. vivax* but smaller, with no Schüffner dots

*In *P. falciparum,* it is important to report the percentage of red cells that are infected.
† Large, irregularly shaped, red-staining dots.
‡ Fine stippling.
§ Parasite that is marginalised to edge of cell.

P. knowlesi infection

It is now recognised that *P. knowlesi* is a significant human pathogen in areas where contact between humans and its monkey host is frequent. Infection is seen in areas throughout Southeast Asia and fatal infections have been reported. Morphologically, early trophozoites resemble those of *P. falciparum;* later forms more closely resemble the corresponding stages of *P. malariae* (differences may include double chromatin dots, multiple parasites within a single erythrocyte and increased merozoite numbers within typical schizonts). Rapid diagnostic tests may not detect the infection since currently both sensitivity and specificity are poor. Diagnosis therefore requires awareness of geographical risk areas. Molecular confirmation can be made by reference laboratories using PCR-based assays (for review, see reference 68).[68]

RAPID DIAGNOSTIC TESTS FOR MALARIA

Rapid diagnostic tests for malaria employ specific antibodies that detect malaria antigens in the blood of infected individuals. RDTs use small blood samples obtained by finger prick or by venepuncture and employ a 'lateral diffusion' system to generate results. RDTs therefore display results in the form of visible 'bands' that can be interpreted by nonexpert users with limited facilities. In general, a blood specimen to be tested (2–50 μl) is lysed in buffer solution containing one or more malaria-specific 'detection antibodies'. The detection antibody is coupled to a visually observable label. Where specific antigen is present, a complex is formed between that antigen and its cognate labelled antibody. The labelled antigen–antibody complex generated is then bound by a second 'capture-antibody' that recognises the same antigen, and which is immobilised as a line on the test strip. A positive result therefore generates a visible line of antigen–antibody complex. A separate immobilised capture antibody recognises the labelled detection antibody alone; this control band will produce a line in the absence of malaria antigen and confirms that the test has been performed correctly and that the result can be interpreted (Fig. 6-11).

The antigen targets detected by RDTs fall into two groups. The first group of antigens are expressed in all malarial species. Antigens from this group therefore confirm malarial infection is present, but do not allow the parasite species to be determined. Antigens from this group are *Plasmodium* aldolase (PMA) or parasite lactate dehydrogenase (pLDH). The second group of antigens are specific for *P. falciparum.* Antigens from this group are histidine-rich protein-2 of *P. falciparum* (pfHRP2) or a *P. falciparum*-specific form of LDH (pfLDH). Antibodies from the two groups are used individually, or in combination, to produce two different test formats. A 'two line' test uses an anti-pfHRP2 band

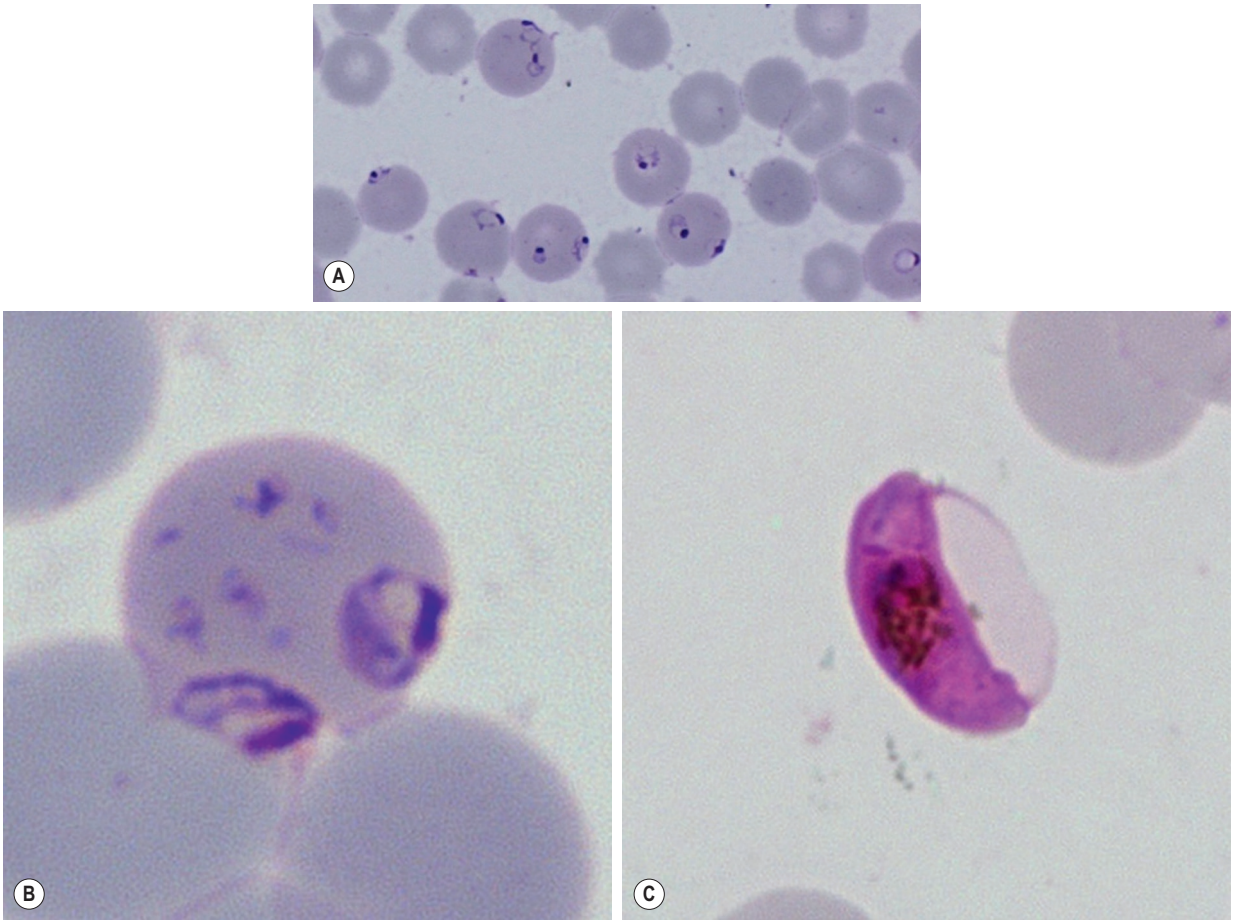

FIGURE 6-5 Morphology of *P. falciparum*. Note that erythrocytes throughout this series are not enlarged or distorted. Early trophozoites **(A)** show high parasitaemia, with accolé (appliqué, edge or shoulder) forms, multiply-infected erythrocytes and double chromatin dot forms. The late trophozoite **(B)** shows two thickened ring forms with characteristic Maurer dots (clefts) in the erythrocyte cytoplasm. **(C)** A typical crescent ('banana-shaped') gametocyte is shown. Schizonts are not shown since they rarely circulate in *P. falciparum* infection.

together with the positive control band to recognise *P. falciparum* only. A 'three line' test uses a *P. falciparum*-specific antibody band, together with PMA or pLDH and the positive control antibody. The three-line test can therefore indicate the presence of *P. falciparum*, or if *P. falciparum* is not present, the presence of other malarial species. Since the second antibody is panmalarial, the three-line test does not distinguish between infection by *P. vivax*, *P. ovale* and *P. malariae* and will not detect mixed infection. For field diagnosis in malaria-endemic areas the selection of a two-line (*P. falciparum* only) test, or a three-line (panmalarial) test, will depend on local species prevalence. It is considered that if >90% of malaria cases in an area are caused by *P. falciparum* an RDT that detects only that species is appropriate for use. The introduction of such tests in malaria endemic areas also requires careful consideration of ease of use, cost and limitations imposed by transport, distribution and storage.[69]

In terms of diagnostic sensitivity, the WHO requires that RDTs reliably detect infections of 100 parasites per ml of blood (95% sensitivity).[70] This is equivalent to the diagnostic sensitivity reasonably expected of a field microscopist diagnosing malaria in endemic regions.[71] Sensitivity becomes less reliable below 100 parasites per ml, and this contrasts with the 'gold standard' sensitivity achieved by an expert microscopist in good conditions, who should detect 5–10 parasites per ml.[71] Sensitivity does depend on species. For *P. falciparum* parasites, RDT sensitivity frequently exceeds 100 parasites per ml, although genetic variation of *P. falciparum* antigens may reduce sensitivity in some instances.[70] For other malarial species, sensitivity of detection is recognised to be less good, particularly for *P. ovale* and *P. malariae* where RDTs may not detect infections that are clinically significant. There is also a recognised incidence of false-positive reactions caused by cross-reaction with autoantibodies (particularly with rheumatoid factor)

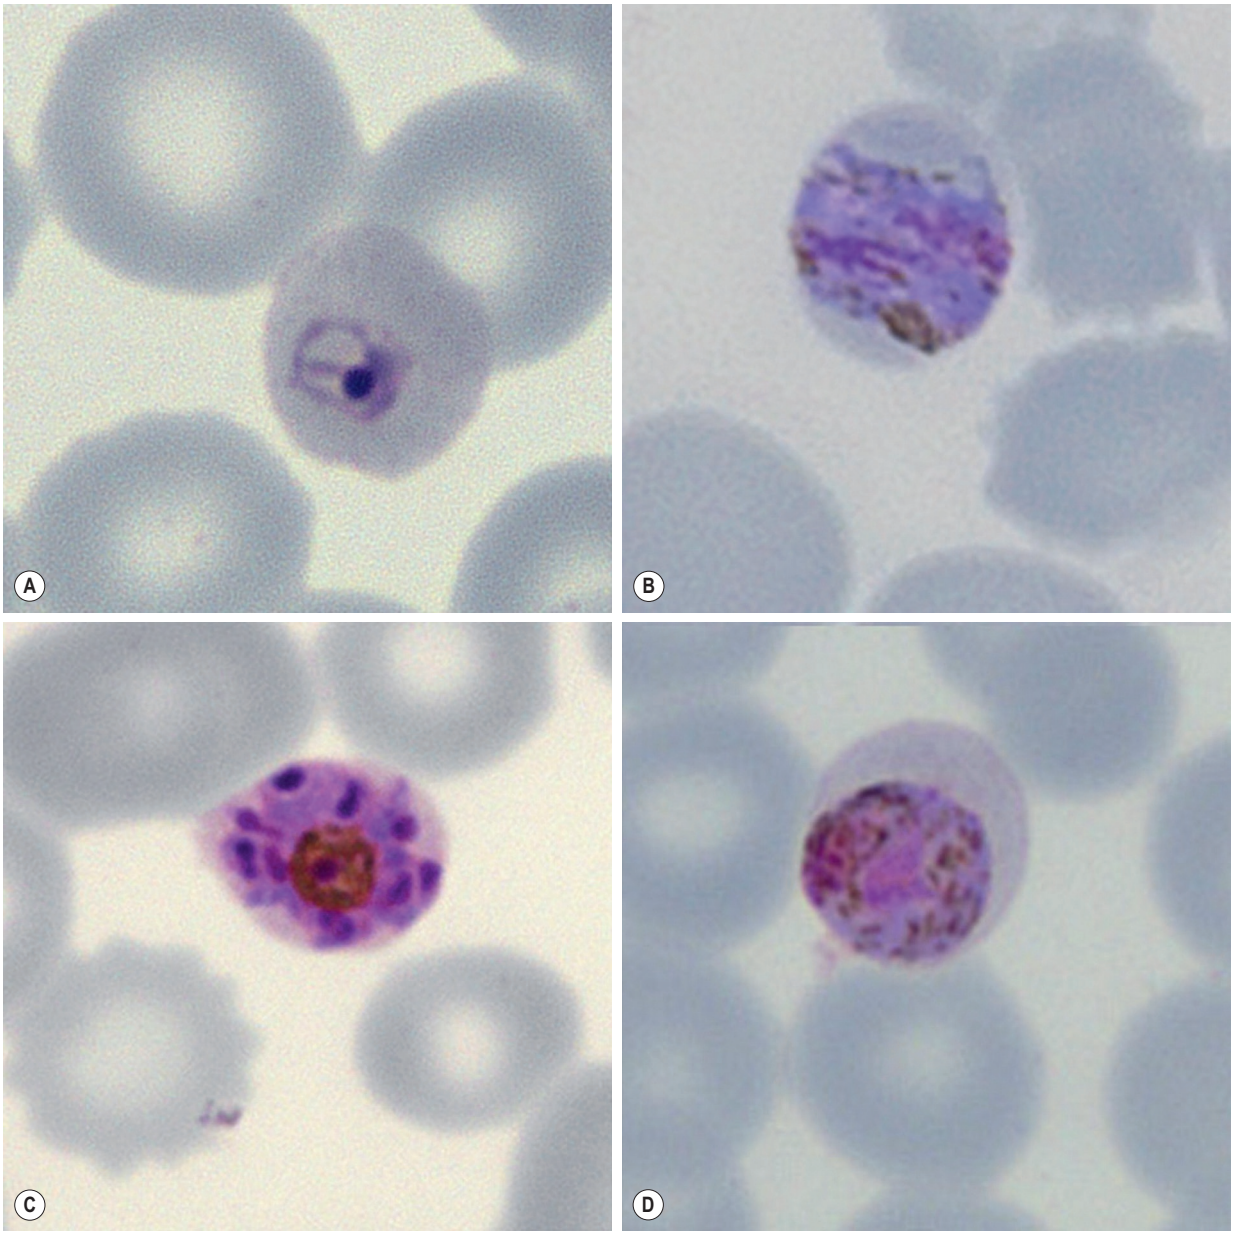

FIGURE 6-6 Morphology of *P. malariae*. Early trophozoites **(A)** are small but less fine than those of *P. falciparum;* in this case the ring is irregular and the chromatin dot is within the main parasite cytoplasm. A late trophozoite **(B)** spans the erythrocyte as a thick 'band form'. A characteristic 'daisy head' schizont **(C)** has eight merozoites arrayed around the central pigment. Finally, the gametocyte **(D)** is typically small and does not fill the normally sized erythrocyte.

that varies between detection systems. In all instances, malaria antigens are known to persist for a number of weeks following successful treatment, and in these circumstances a positive result may not indicate current infection.

The lower sensitivity of RDTs when compared with expert microscopic diagnosis means that all positive and negative results should be confirmed using microscopy. Symptomatic parasitaemia in nonimmune subjects may occur with fewer than 100 parasites per ml of blood, and repeat testing of negative samples may be required to confirm a diagnosis. Users should also be aware that the positive line on the test only indicates a correctly performed test, and does not confirm effectiveness of parasite detection or accuracy of the test. Awareness of diagnostic

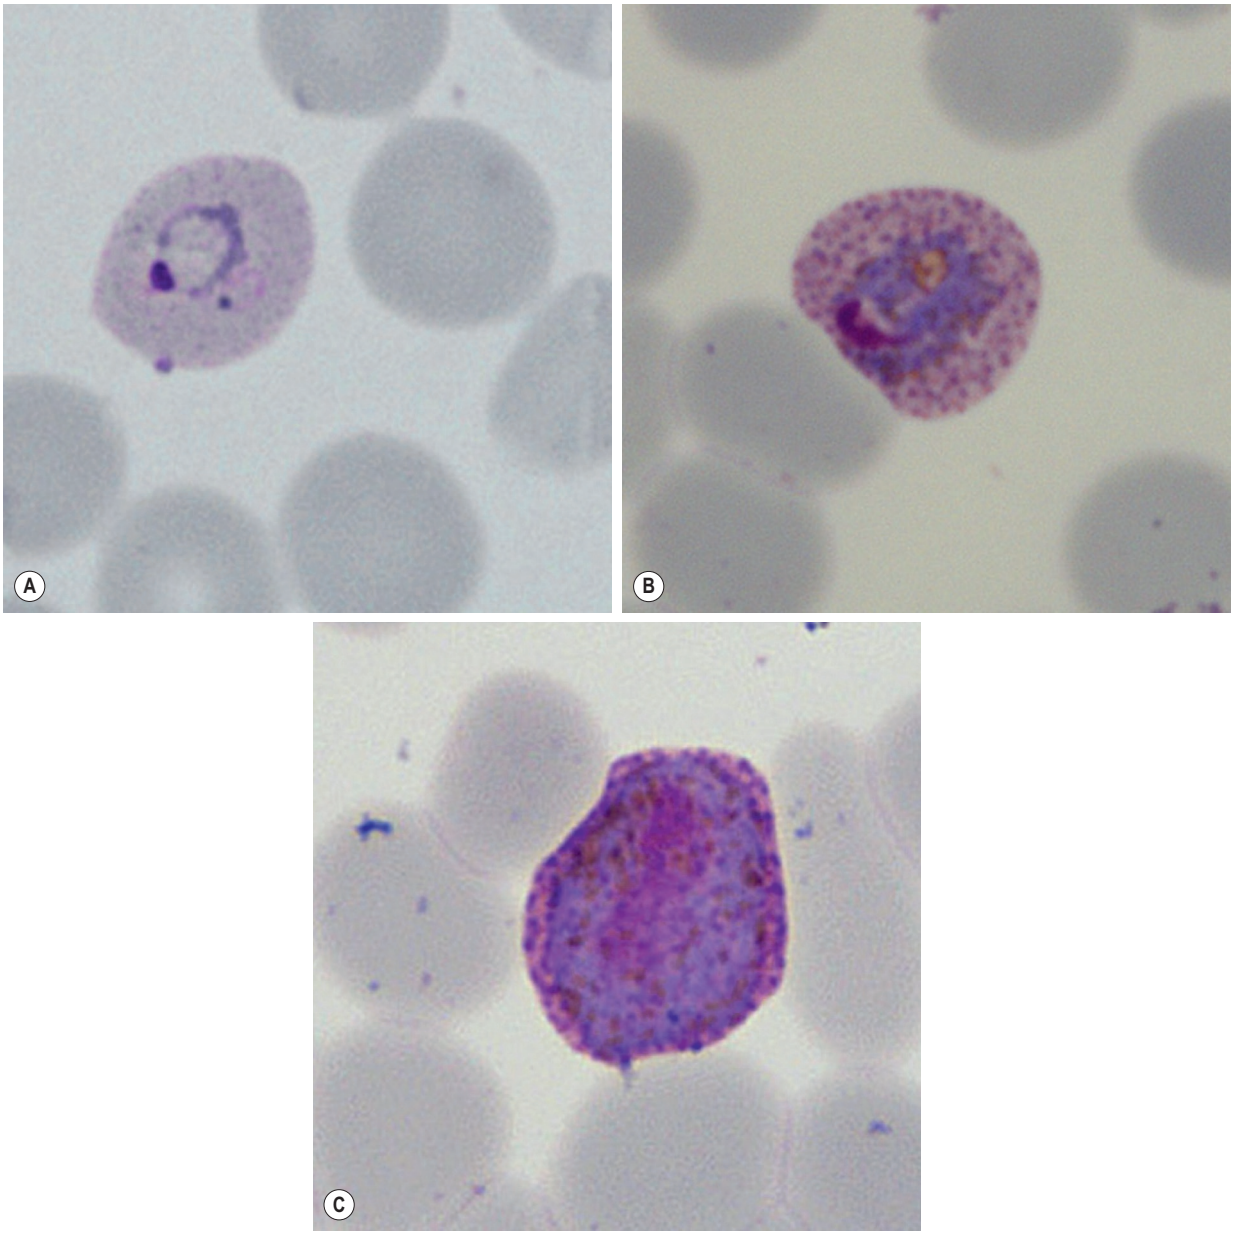

FIGURE 6-7 Morphology of *P. vivax*. The red cells are enlarged, distorted and contain visible Schüffner dots in all these images. Note that the parasites are larger than in the other malarial forms. The early trophozoite **(A)** in this figure has the form of a thick ring with a large chromatin dot, but the later trophozoite **(B)** has a distorted 'amoeboid' form. Note that the large macrogametocyte **(C)** fills the enlarged erythrocyte.

performance for the selected test in the user's laboratory is therefore mandatory.[70] There is a continual development cycle for RDT kits, and it is clear that the sensitivity and specificity between tests is not equivalent. Kit choice must depend on local conditions, parasite prevalence and the requirements of use. Important limitations must be recognised. For example, it is recognised that kits are unreliable for the detection of *P. knowlesi*, and that HRP-2 is not expressed by some parasites in South America and India. The WHO continues to monitor kit performance, undertaking product testing to assess use in different contexts. When selecting kits for local use it is therefore advisable to check the WHO website www.who.int/malaria/publications/diagnostic_testing/en/ for the most current review.

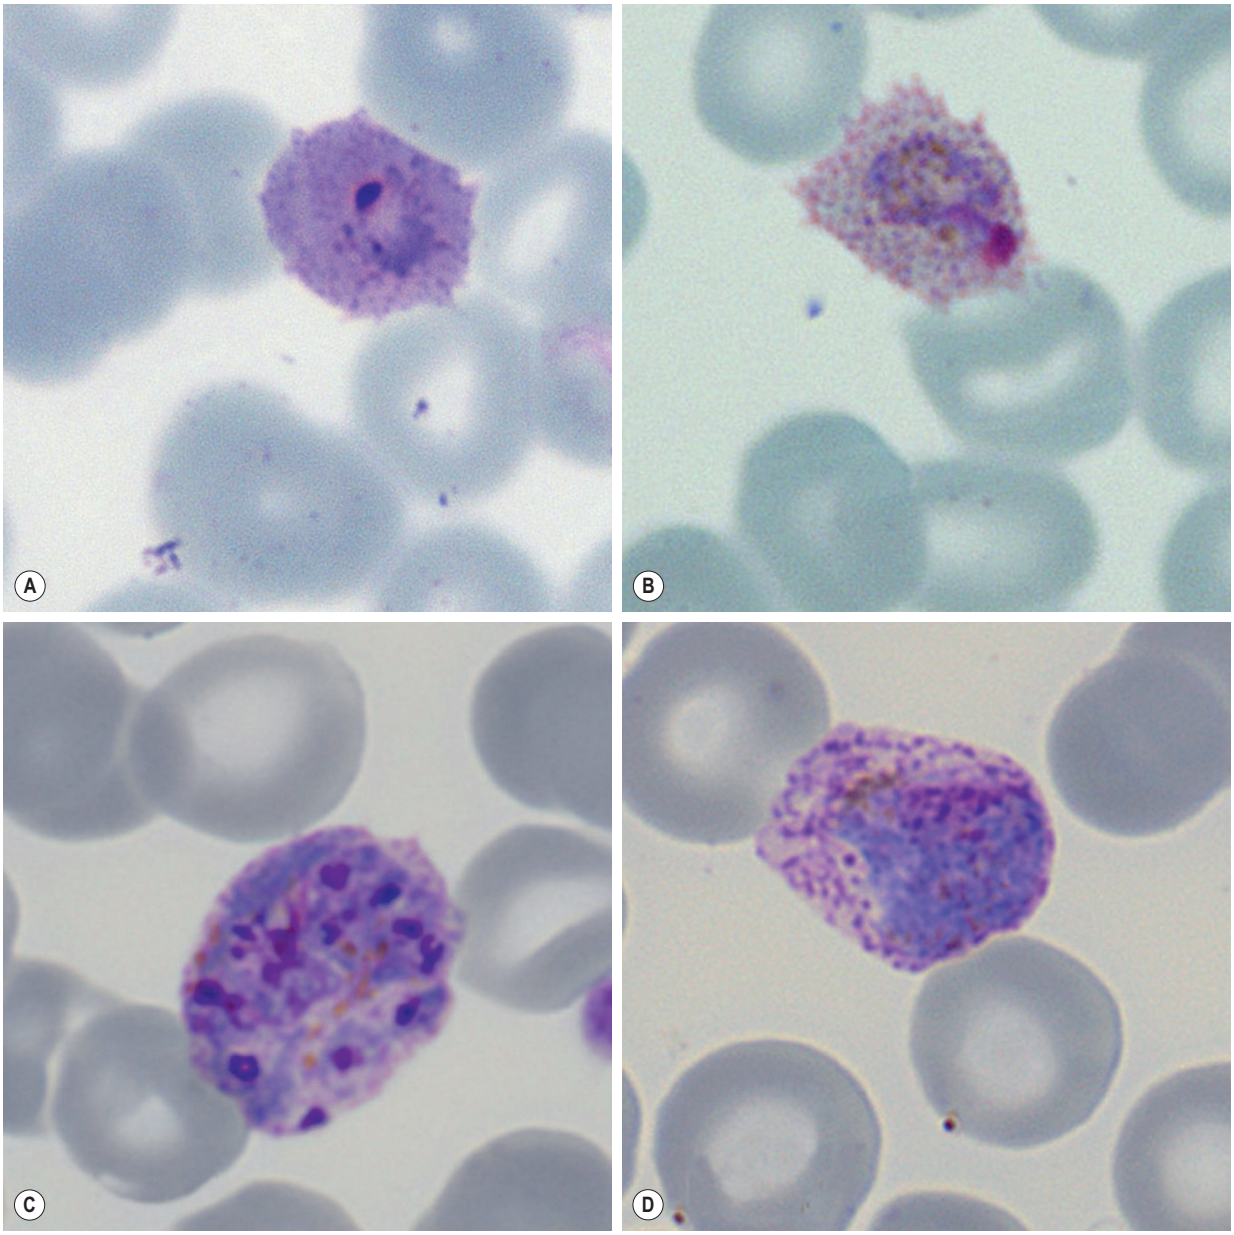

FIGURE 6-8 Morphology of *P. ovale*. Distinguishing *P. ovale* from *P. vivax* is perhaps the most difficult morphological distinction in malaria diagnosis. For both species, the red cells are enlarged and distorted and contain visible Schüffner dots. The features that help distinguish these forms are given in Table 6-2. In this figure, note that the parasites and erythrocytes are smaller than for *P. vivax,* and that in some cases the cytoplasm is fimbriated. Both early **(A)** and late trophozoites **(B)** have coarse 'ring' forms. The schizont **(C)** contains fewer than 16 developing merozoites. A microgametocyte **(D)** does not fill the erythrocyte and numerous dots can be seen in the erythrocyte cytoplasm.

LEISHMANIASIS

Leishmania species are transmitted by the bite of an infected female sandfly and are associated with a variety of clinical conditions including visceral and mucocutaneous leishmaniasis. Visceral leishmaniasis may present to the haematologist as splenomegaly, hepatomegaly, fever, lymphadenopathy or pancytopenia, and is being increasingly reported in patients with HIV infection. Serological studies are recommended as the initial diagnostic tests in suspected leishmaniasis. In advanced stages of the disease, parasites can be found in phagocytic cells in spleen, lymph nodes, bone marrow and peripheral blood. Culture is more sensitive than microscopy, and splenic aspiration provides the highest sensitivity. However, aspiration from the spleen carries clinical risk,

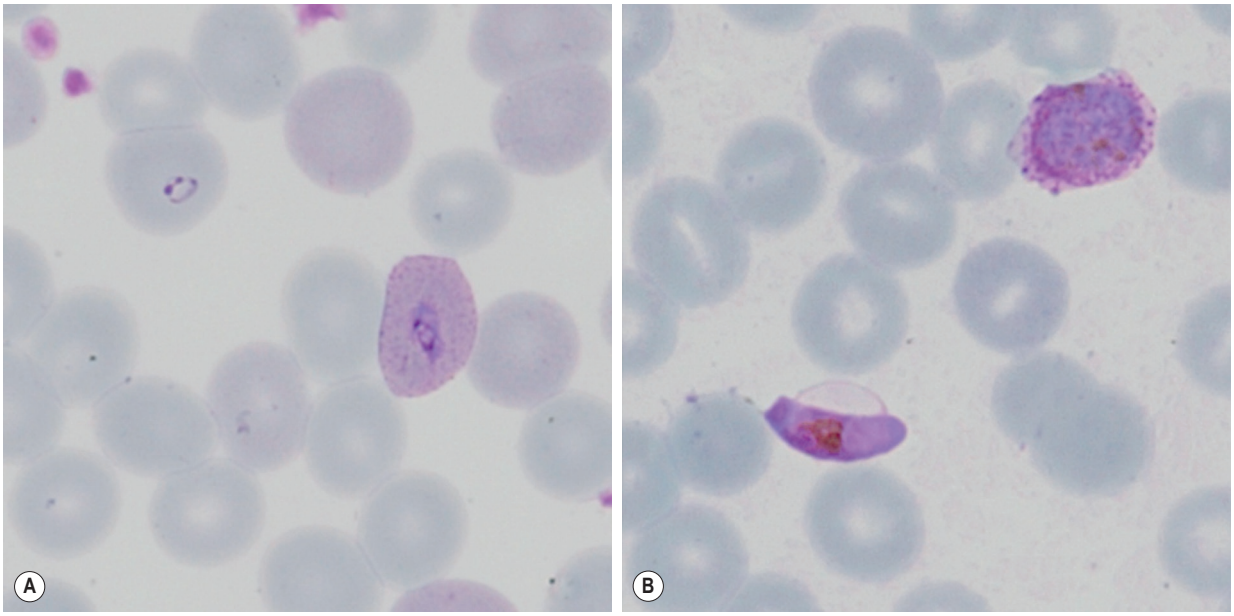

FIGURE 6-9 Mixed infection of *P. falciparum* and *P. ovale*. Diagnosis depends on recognition of features that cannot be reconciled with a single malarial species. **(A)** A typical fine double dot ring form of *P. falciparum* coexists with an enlarged ovoid erythrocyte containing a thickened parasite and numerous Schüffner dots (*P. ovale*). **(B)** Gametocytes of *P. falciparum and P. ovale* with contrasting appearances and causing different effects on the host erythrocyte.

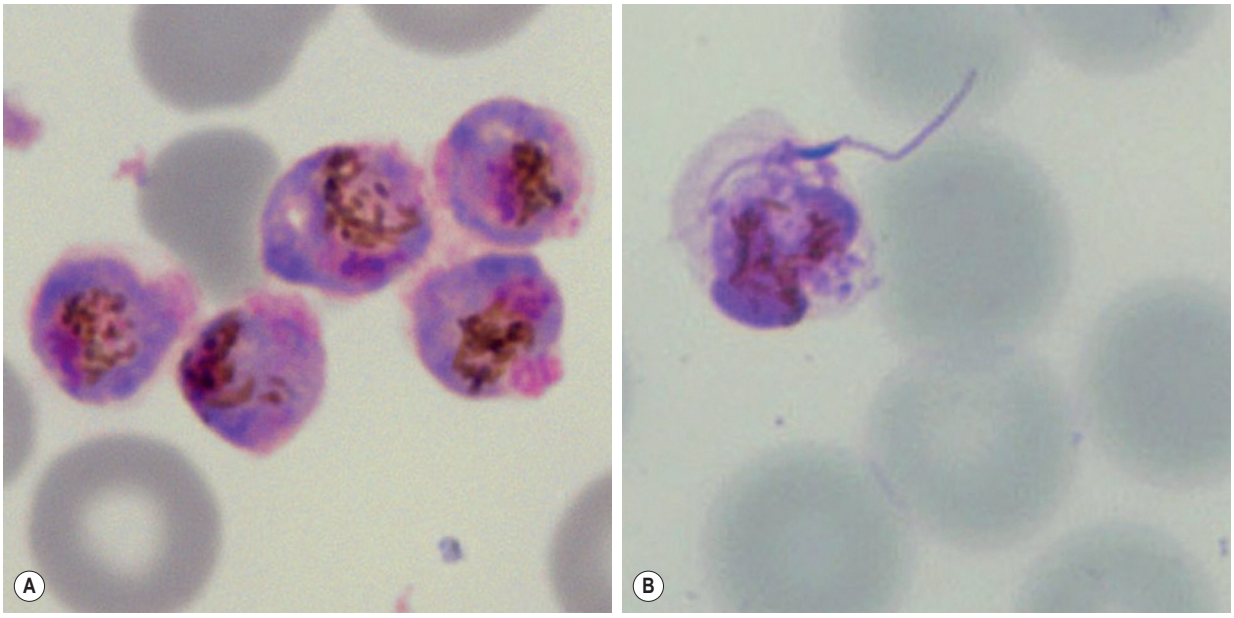

FIGURE 6-10 Delayed film preparation. These gametocytes of *P. falciparum* have very atypical morphology, showing rounding up and clumping **(A)** or exflagellation of microgametocytes **(B).** Biologically, such changes occur within the mosquito stomach during sexual reproduction of the parasite; when present on a blood film they indicate a delay in preparation.

and samples may therefore be taken from any suspected infected site including bone marrow. Culture is frequently combined with PCR testing to identify parasite and species. Serological testing using an RDT approach is increasingly employed for the diagnosis of visceral leishmaniasis. The RDT is highly specific (>95%) and easy to use, but sensitivity is generally around 90% and may be lower in the context of HIV infection. Serology therefore cannot currently be used to fully exclude a diagnosis of visceral leishmaniasis.

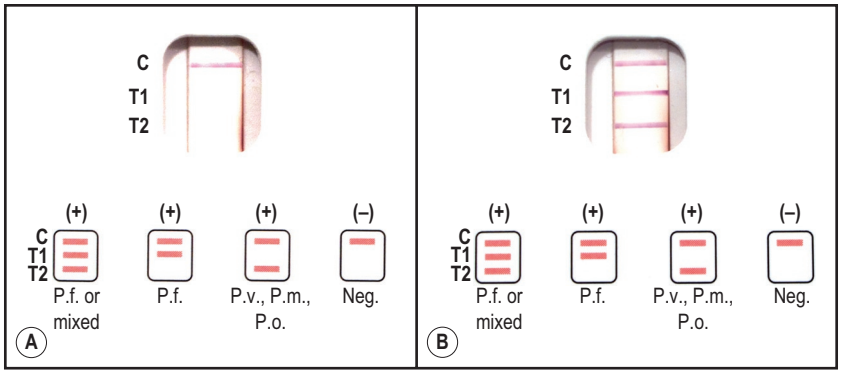

FIGURE 6-11 Rapid diagnostic tests for malaria. An RDT of the 'three line' format; the image shows the output window. **(A)** The results of a negative test in which the positive control line shows a positive band to indicate the technical validity of the result. **(B)** The positive lines in all three positions (i.e. a technically interpretable result) (control line positive), with *P. falciparum*-specific antigen detected *(line T1),* and panmalarial antigen detected *(line T2)*. This patient had a single-species infection *(P. falciparum),* although the test does not allow a mixed infection to be excluded.

Diagnosis of leishmaniasis in the haematology laboratory

Leishmaniasis is diagnosed in the haematology laboratory by direct visualization of the amastigotes (often referred to as Leishman–Donovan bodies). Buffy coat preparations of peripheral blood or aspirates (see p. 57 for preparation of buffy coats) from marrow, spleen, lymph nodes or skin lesions should be spread on a slide to make a thin smear and stained with Leishman or Giemsa stain (pH 7.2) for 20 min (see p. 55). Amastigotes are seen within monocytes or, less commonly, in neutrophils in peripheral blood and in macrophages in bone marrow aspirates. They are small, round bodies 2–4 μm in diameter with indistinct cytoplasm, a nucleus, and a small rod-shaped kinetoplast (Fig. 6-12, *A*). Occasionally, amastigotes are seen lying free between cells.

TRYPANOSOMIASIS

African trypanosomiasis

African trypanosomiasis (sleeping sickness) is caused by *Trypanosoma brucei gambiense* (West Africa and western Central Africa) and *Trypanosoma brucei rhodesiense* (East, Central and Southern Africa); it is transmitted by a few species of tsetse fly. The trypomastigotes can be found in blood, lymph node aspirates and cerebrospinal fluid, but repeated examinations and concentration techniques may be needed before they are detected. Serological investigations may also be helpful in diagnosis.

American trypanosomiasis

American trypanosomiasis (Chagas disease) is caused by *Trypanosoma cruzi,* which is transmitted by the Reduviidae bug, subfamily Triatominae. Chagas disease is only found in tropical and subtropical South and Central American countries. Trypomastigotes can only be found circulating in the blood in the acute form of Chagas disease. Because the trypomastigotes are more fragile than those causing African trypanosomiasis, serology rather than morphology is recommended for initial screening. In the haematology laboratory, tests that detect motile organisms are more sensitive than those that require fixed, stained preparations.

Diagnosis of trypanosomiasis in the haematology laboratory

Care should be taken when handling samples suspected of being infected with trypomastigotes because infection can occur if the organisms penetrate the skin. Several techniques are available for examining specimens for the presence of trypomastigotes.

Wet preparations

If present in high concentrations, trypomastigotes can be seen thrashing among the cells on a fresh, unstained wet preparation of blood or lymph node fluid. Preparations should be examined within 4 h of sampling (this time can be extended if a few milligrams of glucose are added to the specimen) using a ×40 objective and a partially closed condenser iris or dark-field or phase-contrast microscopy.

Thick blood films or chancre aspirates

Examination of a thick film allows more of the sample to be examined rapidly, but *T. cruzi* are easily damaged by the spreading of specimens for thick films. Thick films are prepared by spreading a drop of blood on a slide to cover a 15–20 mm diameter area and staining with Giemsa staining technique or Field rapid technique (see p. 59) as for malaria films. Microscopically, *T. b. gambiense* and *T. b. rhodesiense* cannot be distinguished from each other; they are 13–42 mm long with a single flagellum, a centrally placed nucleus and a small dot-like kinetoplast. *T. cruzi*

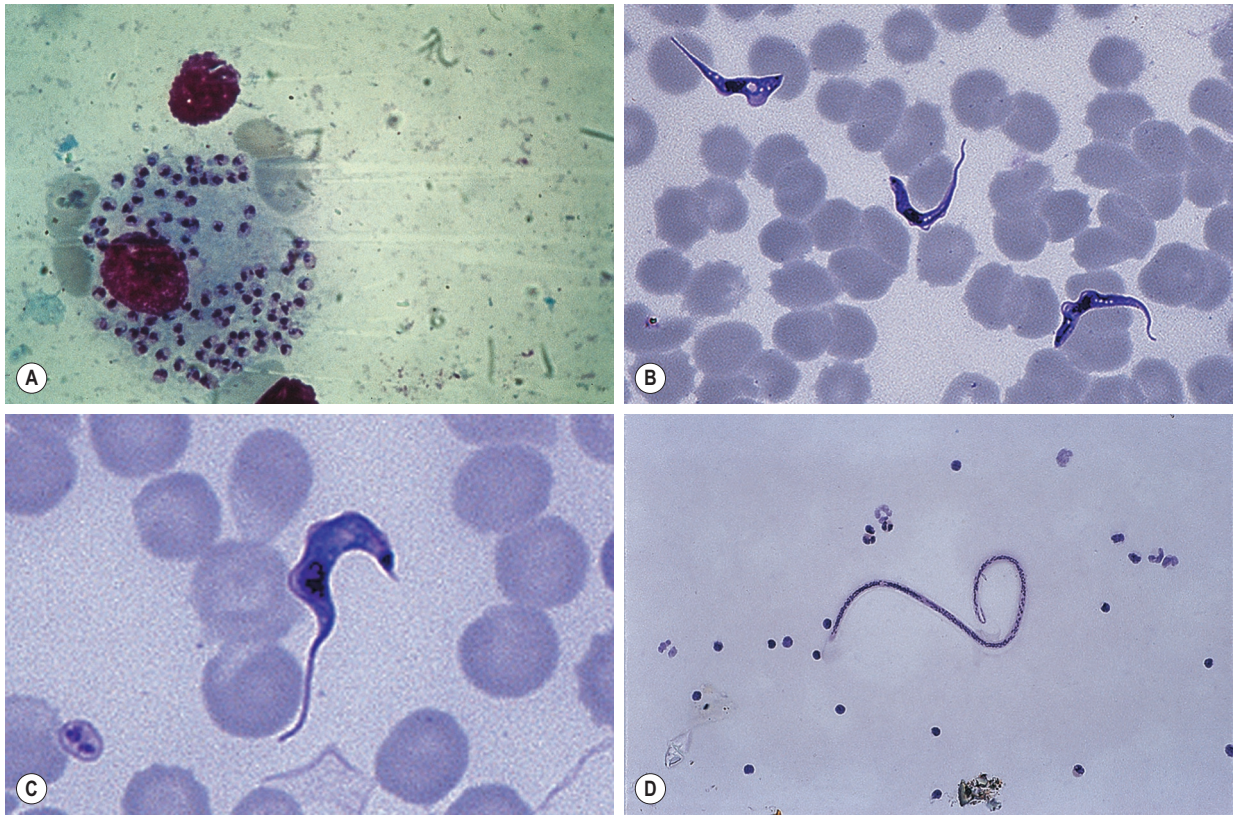

FIGURE 6-12 Bone marrow and blood parasites. (A) Leishmaniasis (Leishman–Donovan bodies); **(B)** African trypanosomiasis; **(C)** American trypanosomiasis (*T. cruzi*); and **(D)** microfilaria.

measures 12–30 mm and has a larger kinetoplast than *T. b. gambiense* and *T. b. rhodesiense* (Fig. 6-12, *B, C*).

Concentration techniques

Quantitative buffy coat method. The QBC method[72] is referred to on page 101. After centrifugation, stand the tube upright for 5 min, and examine the plasma interface for motile trypomastigotes. This has been suggested as the 'gold standard' for diagnosis.

Capillary tube method. Fill one or two microhaematocrit capillary tubes with EDTA-anticoagulated or citrated blood. Seal the ends and centrifuge for about 5 min as for microhaematocrit. Lay the capillary tubes adjacent to each other on a microscope slide and secure both ends onto the slide with adhesive tape (Fig. 6-13). Examine the plasma just below the red cell and buffy layer immediately for motile trypomastigotes using a ×20 or ×10 objective with the condenser iris partially closed or by dark-field microscopy.

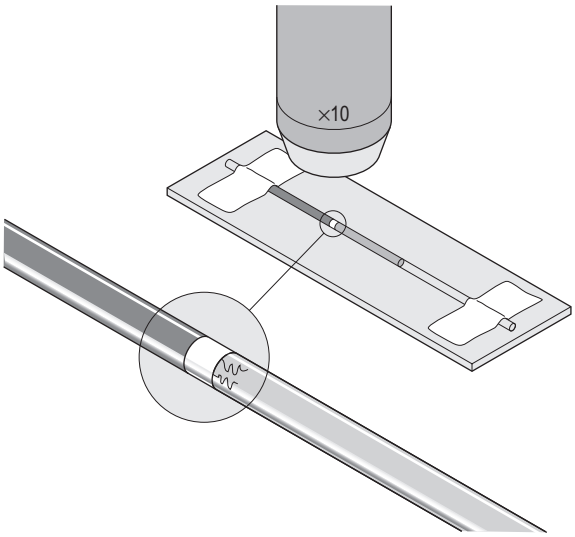

FIGURE 6-13 Capillary tube concentration method. Method used for detecting trypomastigotes or microfilariae in blood.

FILARIASIS AND LOIASIS

Filariasis involving the lymphatics is the cause of elephantiasis. It is caused by the filarial worms *Brugia malayi, Wuchereria bancrofti* and *Brugia timori,* whereas filarial infection of the subcutaneous tissues is caused by *Loa loa.* The larvae of these worms, microfilariae, are transmitted by mosquitoes to man. They can be found in the blood and show periodicity with fluctuating levels at different times of the day (Fig. 6-12, *D*).

Diagnosis of filariasis in the haematology laboratory

Blood concentrations of microfilariae are often higher in capillary blood than in venous blood. However, even when blood has been collected at the appropriate time, microfilariae can be scanty, so that serological or rapid immunochromatographic tests and concentration techniques may be required.

Wet preparation

Prepare a thick blood film from 20 µl of blood and stain as for malaria films (see p. 101).

Concentration techniques

Filtration method. The filtration method is the most sensitive concentration method for microfilariae, but samples must be handled gently to preserve the organisms. Pass anticoagulated blood (10 ml), followed by 10 ml of methylene blue or azure B saline solution, through a transparent polycarbonate membrane filter of 3 mm porosity attached to a syringe. Place the filter face upwards on a slide, add a drop of saline, and place a coverslip on top. Examine the entire membrane microscopically for motile microfilariae using a ×10 objective and a partially closed condenser iris or dark-field microscopy.

Quantitative buffy coat and microhaematocrit methods. Microfilariae can be detected using the same methods as for detection of trypomastigotes (see above).

Lysed capillary blood. Mix blood (1 ml) with 9 ml of 2% formalin and centrifuge at 1000 *g* for 5 min. Place all the deposit on a slide and add 1 drop of Field stain A or 1% methylene blue to facilitate species identification. Motile microfilariae can be seen using a ×10 objective with a partially closed condenser iris or dark-field microscopy.

BABESIOSIS

Babesiosis results from a tick-borne intraerythrocytic protozoan, *Babesia*. Humans are infected by chance in the natural cycle of transmission between the tick and its domestic or wild animal host. It is especially prevalent in subtropical and tropical countries. The infection results in high fever accompanied by jaundice and severe haemolytic anaemia with haemoglobinuria; there is a leucocytosis with neutrophilia.

The parasites can be seen in the erythrocytes in Giemsa-stained blood films. Morphologically they are variable round or oval bodies that may be mistaken for the ring form of plasmodium. However, in babesiosis the dividing cells characteristically consist of two daughter cells held together by a thin strand of cytoplasm and, unlike malaria, no pigment is present in erythrocytes infected with later stages of babesia.

EHRLICHIOSIS AND ANAPLASMOSIS

Ehrlichiosis and anaplasmosis are tick-borne fevers in which clusters of small organisms may be seen in Giemsa-stained blood smears. The detection of organisms within neutrophils or monocytes is important for their diagnosis.

Bone Marrow Biopsy

Imelda Bates • John Burthem

CHAPTER OUTLINE

Biopsy of the bone marrow is an indispensable adjunct to the study of diseases of the blood and may be the only way in which a correct diagnosis can be made. Marrow can be obtained by needle aspiration, percutaneous trephine biopsy or surgical biopsy. When performed correctly, bone marrow aspiration and trephine biopsy are simple and safe procedures that can be repeated many times and can be performed on outpatients.

The morphological assessment of aspirated or core biopsy specimens of bone marrow is based on two principles: first, that bone marrow has an organised structure such that in normal health bone marrow cells display distinct numerical and spatial relationships to each other; second, that individual bone marrow cells have distinctive cytological appearances that reflect the lineage and stage of maturation. Each or all of these features may specifically be disordered in disease. The specimens obtained by bone marrow aspiration or by bone marrow trephine biopsy are very different samples (Fig. 7-1) and contribute differently to diagnosis. Trephine biopsies provide excellent appreciation of spatial relationships between cells and of overall bone marrow structure; aspirated material provides information about the numerical and cytological features of marrow cells. It is clear, therefore, that bone marrow aspirate and bone marrow biopsy specimens have important and complementary roles in clinical investigation and may

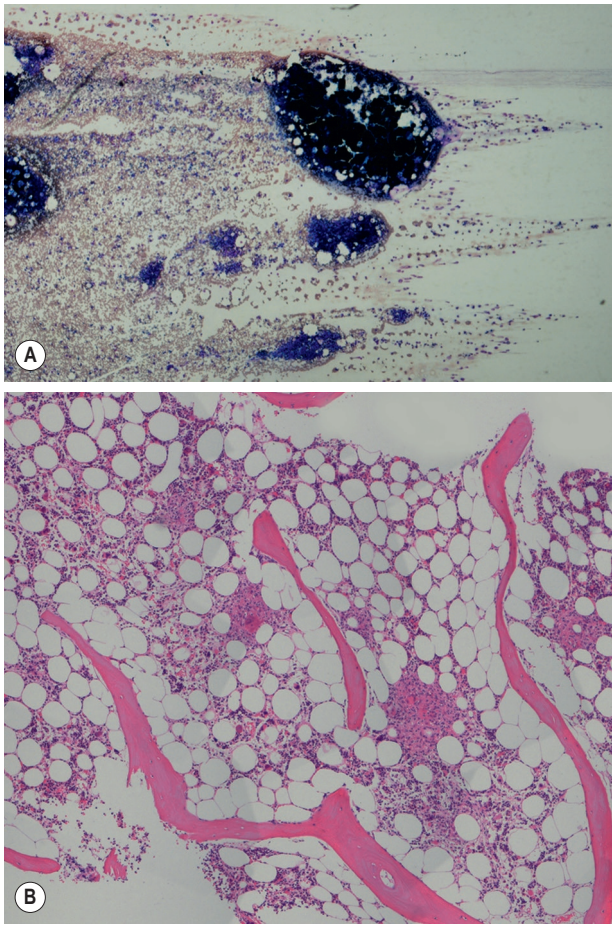

FIGURE 7-1 Low-power appearances of spread bone marrow aspirate showing particles of bone marrow at the end of cellular trails **(A)** and part section of bone marrow trephine biopsy section showing that cellularity and the structural relationships between cells are maintained **(B).**

have different relative merits in the assessment of marrow disease. Furthermore, in almost all cases marrow assessment is only one part of the overall diagnostic work-up.[1–3]

ASPIRATION OF THE BONE MARROW

Satisfactory samples of bone marrow can usually be aspirated from the sternum, iliac crest or anterior or posterior iliac spines. In the majority of patients, the procedure can be performed with local and oral analgesia without recourse to intravenous sedation.[4] In most circumstances the posterior superior iliac spine is the preferred biopsy site and selection of this site has the advantage that, if no material is aspirated, a trephine biopsy can be performed immediately. Biopsy from the posterior iliac spine may, however, be technically difficult in subjects who are obese or immobile, and puncture of the sternum is occasionally necessary. However, for safety reasons, sternal puncture should be used only when there is a very specific indication.

Consent and safety

Consent for the procedure of aspiration or trephine biopsy should take place according to local standard operating procedures, but should always include a discussion of the risks and benefits of the procedure. The risks associated with bone marrow aspiration and biopsy have been assessed using voluntary register data. Results show that risks are not dependent on operator experience and have a low incidence (around 0.1%). However, adverse events continue to be reported and may be severe. The most frequent adverse events relate to haemorrhage and are most often seen in the context of myeloproliferative neoplasms and thrombocytopenia or other bleeding disorders (including the use of antiplatelet agents).[5,6] Particular risks are associated with aspiration from the sternum. The operator should be aware of the additional risks and contraindications associated with aspiration from that site. The sternum should not be used as a site of biopsy in children or be used in adults if there is a disorder associated with increased bone resorption, such as myeloma. Operators should also be aware that unless the needle is correctly inserted in the sternum with an appropriate guard, there is a danger of perforating the inner cortical layer and damaging the underlying large blood vessels and right atrium, with serious consequences.[7]

Performing a bone marrow aspiration

Only needles designed for the purpose should be used for marrow aspiration (discussed later). The operator should always wear surgical gloves to obtain a biopsy of bone marrow and should take great care to avoid needlestick injuries. A marrow aspiration or trephine biopsy should be performed in accordance with local guidelines for sterile procedures. Skin around the area should be cleaned, for example, with 70% alcohol or 0.5% chlorhexidine (5% diluted 1 in 10 in ethanol). Infiltrate the skin, subcutaneous tissue and periosteum overlying the selected site with a local anaesthetic such as 2–5 ml of 2% lidocaine. Wait until anaesthesia has been achieved. With a boring movement, pass the needle perpendicularly into the cavity of the ilium at the centre of the oval posterior superior iliac spine or 2 cm posterior and 2 cm inferior to the anterior superior iliac spine. When the bone has been penetrated, remove the stilette, attach a 1 ml syringe and suck up marrow contents for making films. If a larger sample is needed (e.g. for cytogenetic or immunophenotypic analysis), attach a second 5 or 10 ml syringe and aspirate a second sample. As a rule, material can be sucked into the syringe without difficulty; occasionally it may be necessary to reinsert the stilette, push the needle in a little

further and suck again. Failure to aspirate marrow – a 'dry tap' – suggests bone marrow fibrosis or infiltration. Computed tomography–guided marrow sampling may be helpful in patients who are obese, in whom it is difficult to locate the iliac spines.[8]

Because bone marrow clots faster than peripheral blood, films should be made from the aspirated material without delay at the bedside. The remainder of the material may then be delivered into a bottle containing an appropriate amount of ethylenediaminetetra-acetic acid (EDTA) anticoagulant and used later to make more films. Preservative-free heparin should be used rather than EDTA if immunophenotyping or cytogenetic studies are needed. Some material can be preserved in fixative rather than anticoagulant for preparation of histological sections (see p. 123). Fix some of the films in absolute methanol as soon as they are thoroughly dry for subsequent staining by a Romanowsky method or Perls stain for iron. Appropriately fixed films are also suitable for cytochemical staining (Chapter 15). If there has been a 'dry tap', insert the stilette into the needle and push any material in the lumen of the needle onto a slide and spread it; in lymphomas and carcinomas, especially, sufficient material may be obtained using this approach to allow a diagnosis.[9] Squash preparations of marrow fragments can be a useful supplement to bone marrow films and one such preparation should be made from each marrow aspirate. In preparing a squash preparation, a drop of aspirated marrow is placed in the centre of a slide and, unless the aspirate is very cellular, the fragments are concentrated by removing the more dilute part of the aspirate with a plastic pipette. A second slide is then placed on top of the first and the fragments are crushed by rotating one slide on the other. Both wedge-spread films and squashes are then fixed and stained. Bone marrow aspirates in adults can be performed from the ilium, the sternum or the spinous processes of the vertebrae; the latter site is rarely used and the procedure is described in the 10th edition of this book.

Puncture of the ilium

The usual sites for puncture in adults are the posterior superior and, less commonly, the anterior superior iliac spine. If serial punctures are being performed, a different site should be selected for each puncture to avoid aspirating marrow that has been diluted by intramedullary haemorrhage resulting from previous punctures. The posterior iliac spine overlies a large marrow-containing area and relatively large volumes of marrow can be aspirated from this site. Posterior iliac puncture can be carried out with the patient lying sideways, as for a lumbar puncture, or prone. The anterior superior iliac spine may be easier to locate in individuals who are very obese and the bone overlying it is said to be thinner than that of the iliac crest.

Puncture of the sternum

The specific risks of sternal marrow aspiration were discussed earlier (see p. 113). Puncture of the sternum must be performed with care to avoid pushing the aspiration needle through the bone. The usual site for puncture is the manubrium or the first part of the body of the sternum. It is essential to use a needle with a guard that cannot slip, such as a Klima type. After piercing the skin and subcutaneous tissues, when the needle point reaches the periosteum, adjust the guard on the needle to allow it to penetrate about 5 mm further. If the guard cannot be advanced to this extent, it is not safe to proceed. Push the needle with a boring motion into the cavity of the bone. It is usually easy to appreciate when the cavity of the bone has been entered. Aspiration is then carried out as described earlier.

Comparison of different sites for marrow puncture

There is considerable variation in the composition of cellular marrow withdrawn from adjacent or different sites. Aspiration from only one site may give misleading information; this is particularly true in aplastic anaemia since the marrow may be affected patchily.[10] In general, however, the overall cellularity, the haemopoietic maturation pathways and the balance between erythropoiesis and leucopoiesis are similar at all sites. In practice, it is an advantage to have a choice of several sites for puncture, particularly when a potential site has been previously irradiated, when a puncture at one site results in a 'dry tap' or when only peripheral blood is withdrawn. Aspiration at a different site may yield cellular marrow or strengthen suspicion of a widespread change affecting the bone marrow, such as fibrosis or hypoplasia. In aplastic anaemia an aspirate may not be fully informative and a trephine biopsy should also be performed.

ASPIRATION OF THE BONE MARROW IN CHILDREN

Iliac puncture, particularly in the region of the posterior superior spine, is usually the method of choice in children. Occasionally, in an older child who is obese, the posterior superior iliac spine cannot be felt. In this case a satisfactory sample usually can be obtained from the anterior ilium. In small babies, marrow can be withdrawn from the medial aspect of the upper end of the tibia just below the level of the tibial tubercle. This site should be used with caution because it is vulnerable to fractures and laceration of the adjacent major blood vessels. In older children, the tibial cortical bone is usually too dense and the marrow within is normally less active. It must be remembered that

sternal puncture in children should be avoided because the bone is thin and the marrow cavities are small.

MARROW PUNCTURE NEEDLES

Needles should be stout and made of hard stainless steel, about 7–8 cm in length, with a well-fitting stilette and they must be provided with an adjustable guard. With reusable needles, the point of the needle and the edge of the bevel must be kept well sharpened. The most common reusable needles are the Salah and Klima needles (Fig. 7-2). A slightly larger needle with a T-bar handle at the proximal end was developed by Islam (Fig. 7-3); it provides a better grip, is more manoeuvrable and is more successful for biopsies of excessively hard (e.g. osteosclerotic) or soft (e.g. profoundly osteoporotic) bone.[11] A modified version of the Islam needle has multiple holes in the distal portion of the shaft in addition to the opening at the tip to overcome sampling error when the marrow is not uniformly involved in a pathological lesion. Several types of disposable bone marrow aspiration and trephine biopsy needles are now available; their design is similar to that of the traditional reusable needles (Fig. 7-4). The increasing use of disposable needles by haematologists is based on considerations of safety for patient and operator.

PROCESSING OF ASPIRATED BONE MARROW

There is little advantage in aspirating more than 0.3 ml of marrow fluid from a single site for morphological examination because this increases peripheral blood dilution. If large amounts of marrow are needed for several tests, such as immunophenotyping, cytogenetic analysis and molecular studies, the syringe can be detached from the aspiration needle and the stilette can be replaced, leaving the aspiration needle in the bone. After the marrow smears have been prepared, the same or another syringe can be attached to the needle and another 5–10 ml of marrow can be aspirated.

It is good practice to obtain a sample of peripheral blood from the patient at the same time as the bone marrow so that films from both specimens can be examined and stored together. This can be done simply by preparing some films from blood obtained from a finger prick after completing the bone marrow sampling or by venepuncture so that a full blood count can be obtained. The blood film should be permanently stored with the bone marrow films.

Preparing films from bone marrow aspirates

Make films, 3–5 cm in length, of the aspirated marrow using a smooth-edged glass spreader no more than 2 cm in width (Fig. 7-5). The marrow fragments are dragged behind the spreader and leave a trail of cells behind them. Spreading should be toward the area to which the label is to be applied to avoid having particles dragged to the tip of the slide, where it is difficult to examine them. If there are insufficient fragments, they can be concentrated. This is not usually necessary for marrows that are very cellular such as in acute and chronic myelogenous leukaemia and megaloblastic anaemia. Concentration of marrow can be achieved by delivering single drops of aspirate onto slides about 1 cm from one end. Most of the blood is quickly sucked off from the edge of the drop with the marrow syringe or a fine plastic pipette. The irregularly shaped marrow fragments tend to be left behind on the slide and can be lifted off with the spreader; films can then be prepared as explained earlier.

After thorough drying, fix the films of bone marrow and stain them with Romanowsky dyes, as for peripheral blood films. However, a longer fixation time (at least 20 min in methanol) is essential for high-quality staining. If a film needs to be stained urgently, fix and stain one film only and permit the others to dry thoroughly. This avoids having all films showing artefacts caused by fixation of slides before thorough drying has been achieved. Films can also be stained by Perls method (see p. 313) to demonstrate the presence or absence of iron.

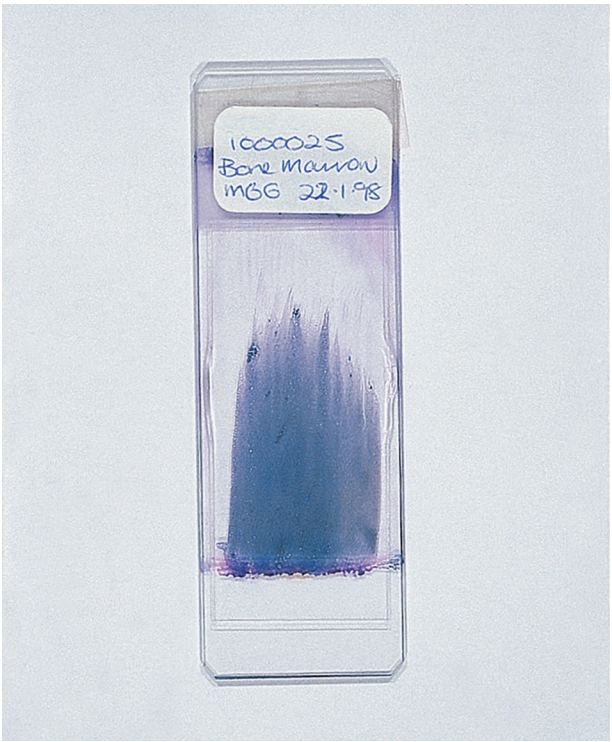

FIGURE 7-5 Film of aspirated bone marrow. The marrow particles are easily visible, mostly at the tail of the film (×1.5). Note that the bone marrow has been spread toward the label. This ensures that the area that is optimal for examination is easily positioned beneath the objective when the slide is placed on the stage.

The preparation can be considered satisfactory only when marrow particles and free marrow cells can be seen in stained films. It is in the cellular trails that differential counts should be made, commencing from the marrow fragment and working back toward the head of the film; in this way, smaller numbers of cells from the peripheral blood are included in a differential count.

When the aspirated marrow is put into an anticoagulant in a tube (e.g. EDTA) care should be taken that appropriate amounts are used for the volume of marrow to be anticoagulated. When films of marrow containing a gross excess of anticoagulant are spread (as when a few drops of marrow are added to a tube containing sufficient EDTA to prevent the clotting of 5 ml of blood), masses of pink-staining amorphous material may be seen and some of the erythroblasts and reticulocytes may clump together.

Concentration of bone marrow by centrifugation

Centrifugation can be used to concentrate the marrow cells and to assess the relative proportions of marrow cells, peripheral blood and fat in aspirated material. Although

concentration of poorly cellular samples is useful, especially when an abnormal cell is present in small numbers,[12] it is unnecessary when the aspirated material is of average or increased cellularity. Volumetric data, too, are of little value in individual patients because of the wide range of values encountered, even in health. Methods for separation of marrow cells are described on page 58.

Preparation of films of postmortem bone marrow

Films made of bone marrow obtained postmortem are seldom satisfactory. If satisfactory results are to be achieved, the procedure must be carried out as soon after death as possible. When the marrow is spread in the ordinary way, the majority of the cells tend to disintegrate and appear as smears. The rate and pattern of cellular autolysis during the first 15 h after death have been studied and the differences between the changes of postmortem autolysis and those that occur in life as a result of blood diseases have been defined.[13] Blood cells are much better preserved if a small piece of marrow is suspended in 1–2 ml of 5% bovine albumin (1 volume of 30% albumin, 5 volumes of 9 g/l NaCl). The suspension is then centrifuged and the deposited marrow cells are resuspended in a volume of supernatant approximately equal to, or slightly less than, that of the deposit. Films are made of this suspension in the usual way.

EXAMINATION OF ASPIRATED BONE MARROW

Principles of marrow aspirate examination

Aspirated bone marrow material spread on glass slides yields individual separate bone marrow cells that have not been subject to prior processing or been cut to form sections. The specimen may therefore be examined using an oil-immersion lens to allow excellent assessment of cytological detail. Marrow aspiration therefore has particular value where recognition of individual cells or abnormal cytological features is paramount or where individual cells need to be recognised, classified and counted. Examples where bone marrow aspiration is of major value include the cytological assessment of abnormal cell maturation of bone marrow cells or the cytological classification and numerical assessment of acute leukaemia (Fig. 7-6). Aspirated bone marrow cells are also well suited to further examination by cytogenetic, molecular or flow cytometric methods. However, the aspiration process generally disrupts structural elements within the marrow, preventing assessment of the structural relationships of normal or abnormal elements within marrow, and loose structural features such as lymphoid aggregates or granulomas are often not detected. The bone marrow aspirate may also be misleading if the cells of interest do not 'spill' from marrow particles and therefore do not appear on the slides. This problem is most readily apparent when marrow is subject to fibrotic processes (e.g. the reticulin fibrosis of hairy cell leukaemia or the collagenous fibrosis of established myelofibrosis) but is also sometimes true of systemic mastocytosis and multiple myeloma. An aspirate is also frequently insufficient when infiltrating cells form cohesive structures. Clumps of cells from carcinoma may

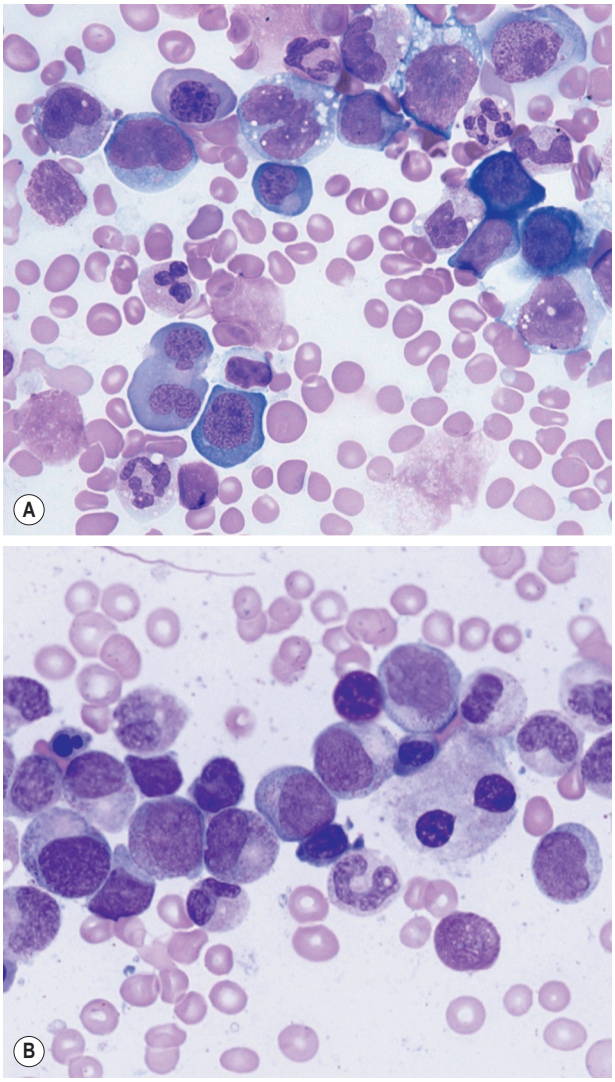

FIGURE 7-6 **(A)** Aspirated cells from a case of megaloblastic anaemia. **(B)** Marrow aspirate spread of acute myeloid leukaemia arising from myelodysplastic syndrome. The films each illustrate very abnormal cells (megaloblastic and dysplastic, respectively) within the mature or maturing compartments. These cells are best recognised by their characteristic abnormal cytology.

on occasion be seen in aspirates, but are usually better revealed by biopsy. Lymphomatous infiltrates are sometimes also very cohesive and are not represented in an aspirate.

Quantitative cell counts on aspirated bone marrow

A number of values for the cell content of aspirated normal bone marrow have been given in the literature.[14,15] The percentage of marrow in the sternum of healthy adults that is cellular rather than fatty is 48–79%. However, quantification of the cell content of aspirated marrow is not reliable in view of the tendency of the marrow to be aspirated in the form of particles of varying size as well as free cells and the uncontrollable factor of dilution with peripheral blood, which according to some authors may amount to 40–100% in 0.25–0.5 ml bone marrow samples.

Quantitative cell counts on aspirated marrow are therefore difficult to interpret. For practical purposes, the degree of marrow cellularity can be assessed within broad limits as increased, normal or reduced by inspection of a stained film containing marrow particles, the assessment being made with knowledge of the age of the patient. As a rough guide, if less than 25% of the particle is occupied by haemopoietic cells, it is hypocellular; and if more than 75–80% is occupied, it is hypercellular. Less subjective quantitative measurement can be obtained by 'point counting' of sections; a normal range of 30% to 80% has been reported for the anterior iliac spine.

Physiological variation in the cell content has to be taken into account. In adults, a smaller proportion of the marrow cavity is occupied by haemopoietic marrow than in children and the proportion of fat cells to cellular marrow is increased. In one study, by means of point counting of sections from the iliac crest, the range of cellularity in children younger than 10 years was reported as 59% to 95% with a mean of 79%; at 30 years, the mean was 50%; and at 70 years, it was 30% with a range of 11% to 47%. The decrease in cellularity in elderly subjects is even more marked in the manubrium sterni. The marrow undergoes slight to moderate hyperplasia in pregnancy.

Differential cell counts on aspirated bone marrow

For general purposes, it is not usually necessary to document the proportion of every stage of each cell type on the marrow slide. A 200–500-cell differential using the categories erythroid, myeloid, lymphoid and plasma cells is generally adequate providing that a systematic scheme for examining the morphology of these, and all other, cells is also used. In some conditions, such as acute and chronic myelogenous leukaemia and myelodysplastic syndromes, detailed differential counts are important because precise counts are essential for diagnosis and the results may indicate prognosis and affect treatment. Occasionally, it may be important to specifically count one cell type (e.g. blasts in acute leukaemia for assessing response to chemotherapy). Follow-up bone marrows should always be compared with previous bone marrow films to assess the course of a disease or the effect of treatment.

Sources of error and physiological variations

Because of the naturally variegated pattern of the bone marrow, the irregular distribution of the marrow cells when spread in films and the variable amount of dilution with blood, differential cell counts on marrow aspirated from normal subjects vary widely. Aspirating only a small volume and counting cells in the trails left behind marrow particles as they are spread on the slide minimises the dilutional effect of blood. When there is an increase in associated reticulin, some cell types may resist aspiration or remain embedded in marrow fragments and will therefore be under-represented in the differential count. Megakaryocytes in particular are irregularly distributed and tend to be carried to the tail of the film. The chance aspiration of a lymphoid follicle would result in an abnormally high percentage of lymphocytes.[16]

Ideally, differential counts should be performed on sectioned material, but difficulties in identification make this impractical. Methacrylate embedding offers a better opportunity for correctly identifying cells but is not widely used. The incidence of the various cell types is usually expressed as percentages. The normal values for cell differentials in bone marrow (Table 7-1) can only be taken

TABLE 7-1

NORMAL RANGES FOR DIFFERENTIAL COUNTS ON ASPIRATED BONE MARROW

	95% Range	Mean*	Mean†

as an approximate guide.[14,15] The cellular composition of the bone marrow varies between normal infants, children and young adults. Variation is marked in the first year, particularly in the first month. The percentage of erythroblasts decreases from birth, and at 2–3 weeks they constitute only about 10% of the nucleated cells. Myeloid cells (granulocyte precursors) increase during the first 2 weeks of life, following which a sharp decrease occurs at about the third week; however, by the end of the first month about 60% of the cells are myeloid. Lymphocytes constitute up to 40% of the nucleated cells in the marrow of small infants; the mean value at 2 years is approximately 20%, falling to about 15% during the rest of childhood. The percentage of plasma cells is especially low from infancy up to the age of 5 years.

The hyperplasia that occurs in pregnancy affects both erythropoiesis and granulopoiesis, the latter proportionately less, although with some increase in the relative proportion of immature cells. The hyperplasia is maximal in the third trimester; a return to the normal nonpregnant state begins in the puerperium but is not completed until at least 6 weeks postpartum.

Cellular ratios

Ratios based on a count of 200–500 cells can provide useful quantitative information. A 200-cell differential count is adequate if the differential count is normal. However, if there is an abnormality and the precise percentage is of diagnostic importance (e.g. a blast cell count of around 5%, 10% or 20%, or an increased plasma cell percentage), 500 cells should be counted. The myeloid:erythroid ratio has been widely used and is the ratio of neutrophil and neutrophil precursor cells to erythroid precursors. The inclusion of monocytes, eosinophils and basophils is controversial but in practice makes little difference to the overall ratio, which varies from 2:1 to 4:1. The myeloid:lymphoid ratio varies widely, from 1–17:1, and the lymphoid:erythroid ratio has a similarly wide variation, from 0.2–4.0:1.

REPORTING BONE MARROW ASPIRATE FILMS

A systematic examination of the marrow aspirate, combined with knowledge of the clinical context, provides the best chance of arriving at a diagnosis.[3] Choose several of the best-spread stained films that contain easily visible marrow particles. Several particles should then be examined with a low-power (×10) objective to estimate whether the marrow is hypocellular, normocellular or hypercellular. Megakaryocytes and clumps of nonhaemopoietic cells (e.g. metastatic carcinoma cells) should be looked for at this stage of the examination; they are most often found toward the tail of the film.

Select for detailed examination – still using the ×10 objective – a cellular area of the film where the nucleated cells are well stained and well spread. Areas such as these can usually be found toward the tails of films behind marrow particles. The cells in these cellular areas should then be examined with a higher-power (e.g. ×40) objective and, subsequently, if necessary, with the ×100 oil-immersion objective. It is important always to examine marrows in a systematic fashion because it is easy to overlook subtle abnormalities. A suggested scheme for this is outlined below.

Systematic scheme for examining bone marrow aspirate films

Low power (×10)

Determine cellularity by examining several particles.

Identify megakaryocytes and note morphology and maturation sequence (higher power may be needed for smaller immature megakaryocytes and micromegakaryocytes).

Look for clumps of abnormal cells that could indicate infiltration by metastatic tumour (higher power may be needed to examine content and morphology of clumps).

Identify macrophages and examine at higher power for evidence of haemophagocytosis, malaria pigment and bacterial or fungal organisms that may be present in the cytoplasm.

Higher power (×40, ×100 oil-immersion)

Identify all stages of maturation of myeloid and erythroid cells. This is usually easiest to achieve by starting with mature red cells and working backward to the most immature cells. Repeat the process for the myeloid series starting with mature neutrophils. Maturation abnormalities, such as giant proerythroblasts or evidence of dysfunctional maturation, including nuclear–cytoplasmic asynchrony, will suggest specific diagnoses such as parvovirus B19 infection in the first instance or either a myelodysplastic syndrome or megaloblastic anaemia in the second. Changes in the proportion of primitive to mature myeloid cells may reflect response to treatment in leukaemia or recovery from agranulocytosis. The actual percentage of blast cells is of significance in differentiating myelodysplastic syndromes from acute leukaemia, in determining prognosis in myelodysplastic syndromes and in assessing whether chronic myelogenous leukaemia is in chronic, accelerated or acute phase.

Determine the myeloid:erythroid ratio. Whereas a lack of myeloid cells may be obvious without performing a formal differential count, it is easy to overlook an increase in erythroid cells, which might suggest blood loss or peripheral destruction.

Perform a differential count using the categories erythroid, myeloid, lymphoid, plasma cell and ‘others’, simultaneously noting any morphological abnormalities. The normal lymphocyte percentage in the marrow is 5% to 20%; moderate increases to 30–40%, which may indicate a significant disorder such as lymphoma, are not likely to be identified simply by rapidly surveying the slide. Plasma cells should be less than 2%; in plasma cell neoplasms,

they may be increased, occur in clumps or have an abnormal morphological appearance.

Look for areas of bone marrow necrosis.[17] In necrotic areas, the cells stain irregularly, with blurred outlines, cytoplasmic shrinkage and nuclear pyknosis. Bone marrow necrosis may occur in sickle cell disease; it also occurs occasionally in lymphomas, acute lymphoblastic and chronic lymphocytic leukaemia, myeloproliferative neoplasms and metastatic carcinoma, as well as in septicaemia, tuberculosis and anorexia nervosa.[18] In patients with anorexia nervosa or cachexia, there may be gelatinous transformation of the ground substance of the marrow.[18]

Assess the iron content of macrophages and look for iron granules in erythroid cells on a slide stained with a Perls stain. At least seven particles should be examined to optimally assess a bone marrow aspirate for iron stores.[19] If fewer particles are available, a diagnosis of iron deficiency can only be tentative. In sideroblastic anaemia, the granules incompletely encircle the nucleus. Abnormal patterns of iron staining may also be seen in dyserythropoietic anaemias such as the thalassaemias.

Reporting results

It is helpful to report bone marrow films on a printed form or a computer template on which the report and conclusion can be set out in an ordered fashion (Fig. 7-7).[3] Where a computerised reporting system is in use, the template should have appropriate headings to ensure that the marrow reports are systematic and consistent. A list of the various descriptive comments that may be used can be provided in coded form to facilitate data entry. The report should end with a conclusion in which the important findings are summarised, bearing in mind that this may be the only section of the report that is read by clinical staff other than haematologists.

PREPARATION OF SECTIONS OF ASPIRATED BONE MARROW FRAGMENTS

If it is not possible to obtain a trephine biopsy (see below), the small fragments obtained by marrow aspiration can be fixed, stained and examined to contribute to diagnosis. Such samples are useful for assessing cellularity and for detecting granulomas and tumour cells. If sections are required, it is convenient to let residual aspirated marrow clot within a plastic syringe and tease the sample out into the fixative once it has clotted.

PERCUTANEOUS TREPHINE BIOPSY OF THE BONE MARROW

Like marrow aspirations, a trephine biopsy may be carried out in the inpatient ward or in outpatient departments. The posterior superior iliac spine is the usual site, although the anterior superior iliac spine can also be used. The posterior superior iliac spine has been reported to provide samples that are longer and larger and the aspiration is less uncomfortable for the patient.[20]

The trephine specimen is obtained by inserting the biopsy needle into the bone, using a backwards and forwards rotation and then rocking the needle gently from side to side to detach a core of tissue that can be extracted within the needle. The main problems with this method are that the specimen may be crushed, thereby distorting the architecture, and it can be difficult to detach the core of bone from inside the marrow space. Trephine biopsy needles, both reusable and disposable, have been specifically designed to overcome these problems. The Jamshidi needle has a tapering end to reduce crush artefact (Fig. 7-8) and the Islam trephine has a core-securing device (Fig. 7-9). If larger specimens are needed, trephine needles that have bores of 4–5 mm may be used. Other needles occasionally used for trephine biopsy specimens are a 2 mm bore 'microtrephine' needle and a Vim-Silverman needle. However, compared with other needles, these yield smaller specimens of marrow that are prone to fracturing.

For the investigation of thrombocytopenia and neutropenia in neonates, sections of aspirated bone marrow can be obtained that allow assessment of marrow cellularity and architecture.[21] A 19G, half-inch Osgood needle (BDMedical Radiology and Biopsy Products, www.bd.com) is introduced 2 cm below the tibial tuberosity. The trocar is removed and the hollow needle is advanced by twisting 2–3 mm into the marrow space. A syringe is used to apply suction to the needle until marrow appears; then the needle and syringe are withdrawn. The marrow clot is gently dislodged with the tip of a needle and placed into fixative. The specimen is processed as if it were an adult biopsy except that decalcification is not required.

Principles behind marrow trephine biopsy examination

Bone marrow trephine biopsy provides a core of tissue, which is fixed and embedded to yield a histological specimen in which the structural relationships between cells, bone and bone marrow stroma are preserved. The nature of the specimen allows cellular distributions to be recognised: for example, the tendency for precursor myeloid cells to mature close to bony trabeculae or the normal development of erythroid cells in the form of small islands (Fig. 7-10). Bone marrow biopsy also delineates the abnormal distribution of cells that is characteristic of particular pathological conditions, for example, the paratrabecular collection of abnormal cells that is typical of follicular lymphoma or the clustered megakaryocytes seen in certain myeloproliferative neoplasms (Fig. 7-11). In addition, since a trephine biopsy specimen is a core of tissue, all cells present within the specimen will be represented, irrespective of fibrosis or cohesion. Cell types within a bone

marrow biopsy may be recognised by cytological characteristics, but that identification is reinforced by their distribution within the biopsy sections. Cellular recognition on trephine biopsy sections is frequently supplemented by immunostaining in which monoclonal or polyclonal antibodies are used (cytochemical reactions are much less often used) to detect a range of lineage, maturational or cell type–restricted markers. Such markers allow confirmation of cell lineage or of maturation stage within a particular lineage (Fig. 7-12). Markers may also highlight abnormal distribution of cells: for example, markers of B-cell lineage may highlight infrequent paratrabecular aggregates of cells

FIGURE 7-8 Jamshidi trephine needle for bone marrow biopsy.

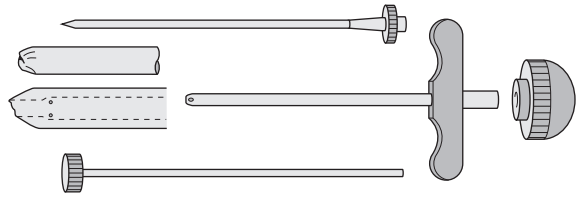

FIGURE 7-9 Islam trephine needle for bone marrow biopsy. The distal cutting edge is shaped to hold the core secure during extraction of the material.

in cases of follicular lymphoma. Specific cell markers may highlight infrequent abnormal cells that represent residual or recurrent disease (e.g. CD72 [DBA.44] can be used to highlight neoplastic cells in hairy cell leukaemia). Finally, since trephine biopsy tissue is fixed and preserved, additional tests may be performed some time after the specimen was obtained.

Imprints from bone marrow trephine biopsy specimens

Whenever a trephine biopsy is obtained, imprints can be taken before the specimen is transferred into fixative. This is particularly useful if the bone marrow aspirate is inadequate. The bony core is gently dabbed or rolled across the

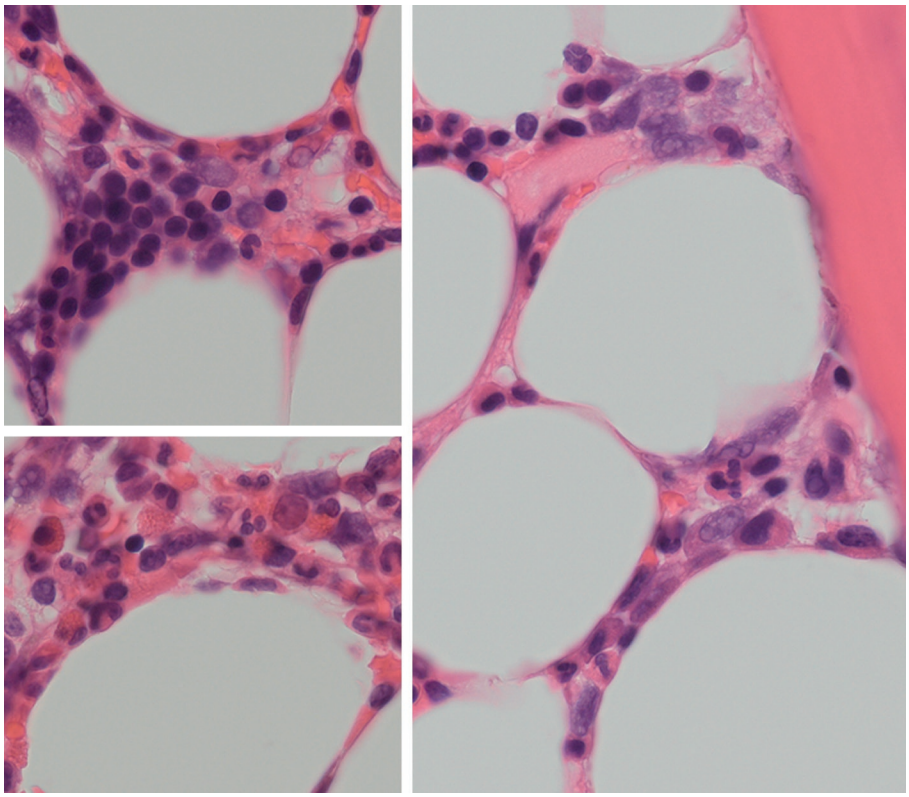

FIGURE 7-10 Areas of bone marrow trephine biopsy section stained with haematoxylin and eosin (H&E) showing an erythroid island *(upper left),* maturing myeloid lineage cells *(lower left)* and the paratrabecular area with early precursor cells *(right)*.

slide, with the preparation then being fixed and stained as for bone marrow films (see p. 116). This allows immediate examination of cells that fall out of the specimen onto the slide and may provide a diagnosis several days before the trephine biopsy specimen has been processed.

Processing of bone marrow trephine biopsy specimens

The specimen should be fixed in 10% formal saline, buffered to pH 7.0, for 12–48 h prior to decalcifying, dehydrating and embedding in paraffin wax by the usual histological procedures. Cell shrinkage and distortion from the decalcification process may obscure cellular detail. These disadvantages can be overcome by methyl methacrylate ('plastic') embedding (Fig. 7-13). Details of the preparation of sections of bone marrow biopsies can be found in reference 22.

Staining of sections of bone marrow trephine biopsy specimens

Bone marrow sections should be routinely stained with haematoxylin and eosin (H&E) and a silver impregnation method for reticulin. Sections can also be stained for iron by Perls reaction. H&E staining is excellent for demonstrating the cellularity (Fig. 7-14) and pattern of the marrow and for revealing pathological changes such as fibrosis or the presence of granulomas or carcinoma cells. Haemopoietic cells may be more easily visualised with a Giemsa stain, which is also useful for identifying mast cells and showing the structure of bone. Both paraffin- and plastic-embedded specimens are suitable for immunohistochemistry.

Silver impregnation stains the glycoprotein matrix, which is associated with connective tissue. The bone marrow always contains a small amount of this material, which is referred to as 'reticulin' and is an early form of collagen. The normal reticulin content of iliac bone marrow is shown in Figure 7-15, *A*. An increase in marrow reticulin appears as an increase in the number, thickness and length of fibres (Fig. 7-15, *B*). Increased reticulin deposition can occur in myeloproliferative neoplasms, particularly those associated with proliferation of megakaryocytes and in lymphoproliferative disorders, secondary carcinoma with marrow infiltration, osseous disorders such as hyperparathyroidism and Paget disease and inflammatory reactions.[23]

Molecular and Cytogenetic Analysis

Letizia Foroni • Alistair G. Reid • Gareth Gerrard • Sarmad Toma • Sandra Hing

CHAPTER OUTLINE

Our understanding of the molecular basis of both inherited and acquired haematological disorders is now considerable and there are several ways in which this knowledge is being applied in diagnostic haematology. These include the identification of genetic defects in haemoglobinopathies allowing the provision of early prenatal diagnosis, the assessment of genetic risk factors in thrombophilia, the diagnosis and characterisation of leukaemias, the monitoring of minimal residual disease and the study of host-donor chimaerism following bone marrow transplantation.

In this chapter we shall describe some of the methods that can be applied in these situations, although this cannot be exhaustive and will reflect both the specific interests of our laboratory and the clinical practice of our institution.

The ability to manipulate deoxynucleic acid (DNA) as recombinant molecules followed from the discovery of bacterial DNA-modifying enzymes. This allowed genes to be isolated as cloned recombinant DNA molecules and their DNA to be sequenced. The sequence of the human genome is now virtually complete.[1,2] It has been extensively annotated and is accessible through a number of genome browsers. The ability to amplify specific DNA fragments from small amounts of starting material using the polymerase chain reaction (PCR)[3] is now the cornerstone of most routine DNA analysis. Because this technique is relatively simple, rapid and inexpensive and requires only some basic laboratory equipment, it has made molecular genetic analysis readily accessible in many laboratories.

Guidelines from the American Association for Molecular Pathology address the choice and development of appropriate diagnostic assays, quality control, validation and implementation of molecular diagnostic tests.[4,5]

The development, validation and implementation of quality control methods and assurance standards are

established in the UK and elsewhere and guidelines for validation of molecular genetic tests have been published.[6] At national and international levels, several groups have agreed on standardisation of molecular methodologies applied to fusion gene quantification (*BCR-ABL1* and *PML-RARA* among others) in myeloid malignancies as well as the molecular monitoring of residual disease using antigen receptor targets in acute and chronic lymphoid malignancies.[7,8]

In this chapter, some of the applications of PCR in a diagnostic haematology laboratory are described. For the reasons just mentioned, the analysis of PCR products has largely superseded other techniques, including Southern blot analysis, and capillary electrophoresis has replaced polyacrylamide gel electrophoresis. For situations in which these are still appropriate, the reader is referred to previous editions of this book.

METHODOLOGIES

DNA extraction

DNA can be extracted from a blood or tissue sample. The quality and quantity of the DNA obtained will vary depending on the size, time from collection and cell count of the sample. As a rule, 5–10 ml of blood in ethylenediaminetetra-acetic acid (EDTA) will suffice. The DNA is extracted from all nucleated cells and is called genomic DNA.

In the nucleus, the DNA is tightly associated with many different proteins as chromatin. It is important to remove these as well as other cellular proteins to extract the DNA. This is achieved through the use of organic solvents, salt precipitation or DNA-affinity columns. An aqueous solution of DNA is obtained, from which the DNA is further purified by precipitation. Currently, there are a number of commercially available DNA extraction kits for general and specialist applications. They all produce good quality DNA from various starting materials. These kits, as well as being reliable, are also cost effective. In addition, automation, which can achieve simultaneous extraction of a large number of samples, can significantly reduce the amount of time required for DNA extraction, bypass the use of organic solvents and provide good quality control of the reagents used. Automation is highly suited to high throughput laboratories and some of these procedures will be described below.

DNA extraction kits

We are currently using two different types of DNA extraction kits, depending essentially on the quantity of DNA required. The first – the *Qiagen* system – is a robust method for obtaining ≈ 5 µg of DNA from 200 µl of whole blood (www.qiagen.com). This method utilises a high-affinity DNA binding matrix in a spin column, which can be used in a microcentrifuge or in an automated platform, such as the Qiacube. The DNA obtained is generally of high quality and sufficient in amount for most routine analyses.

When a larger amount of DNA is required – perhaps for storage and more extensive analysis of critical samples – we use from 3–10 ml of blood with the *Gentra* Puregene blood extraction kit (Qiagen), which can yield upward of 100 µg of DNA. This method depends on a salting-out of proteins after sequential red cell and then white cell lysis, followed by an isopropanol precipitation of the DNA. Other nucleic acid high throughput systems also exist such as MagNA Pure 96 System (Roche, http://lifescience.roche.com) and the Maxwell® rapid sample concentrator (RSC) Instrument (www.promega.com).

Protocols will be provided in the latter part of this chapter. For preparation of reagents and a protocol for the manual extraction of DNA from blood using organic solvents, the reader is referred to previous editions of this book.

Polymerase chain reaction

Development of PCR[3] has had a dramatic impact on the study and analysis of nucleic acids. Through the use of a thermostable DNA polymerase, Taq polymerase extracted from the bacterium *Thermus aquaticus,* PCR results in the amplification of a specific DNA fragment such that it can be visualised using intercalating SYBR Safe (www.thermofisher.com) added to agarose gels. Ethidium bromide, a mutagenic product, is no longer in use for health and safety reasons. The procedure can take as little as an hour and requires only a small amount of starting material.

Principle

A DNA polymerase will synthesise the complementary strand of a DNA template *in vitro.* A stretch of double-stranded DNA is required for synthesis to be initiated. This double-stranded sequence can be generated by annealing an oligonucleotide ('oligo'), which is a short, single-stranded DNA molecule usually between 18 and 25 bases in length, to a single-stranded DNA template. These oligos, which are synthesised *in vitro,* will prime the DNA synthesis and are therefore referred to as 'primers'.

In PCR, two oligo-primers are used. Each primer will generate a copy of the complementary strand. For instance, the sense primer will anneal to the antisense sequence and prime it in a 5′ to 3′ direction and in doing so generate a new sense strand. The antisense primer will anneal to the sense strand and prime it generating a new antisense strand. The other components of the reaction are the DNA template from which the DNA fragment will be amplified, the four deoxynucleotide triphosphates (dATP, dTTP, dCTP and dGTP) required as the building blocks of the newly synthesised DNA, a salt buffer containing $MgCl_2$ and the thermostable DNA polymerase (Taq polymerase).

The first step of the reaction is to denature the DNA, generating single-stranded templates, by heating the reaction mixture to 95 °C. The reaction is then cooled, usually to a temperature between 50 °C and 68 °C, which permits the annealing of the oligos to the DNA template but only at their specific complementary sequences. The temperature is then raised to 72 °C, at which temperature the

Taq polymerase efficiently synthesises DNA, extending from the oligo in a 5′ to 3′ direction. Cyclical repetition of the denaturing, annealing and extension steps, by simply changing the temperature of the reaction in an automated heating block, results in exponential amplification of the DNA that lies between the two primers (Fig. 8-1). So-called fast-cycling Taq kits are now available, often with highly modified cycling conditions that can bring the time of a PCR reaction down to below an hour.

The specificity of the DNA fragment that is amplified is therefore determined by the sequences of the primers used. A sequence of 18–25 base pairs (bp) is theoretically unique in the human genome, and so primers of this length and longer will anneal at only one specific place on a template of genomic DNA, or at least one combination within an amplifiable distance (typically no more than 2–3 kilobases for standard cycling conditions). One general requirement of PCR is therefore some knowledge of the DNA sequence of the gene that is to be amplified. The relative positioning of the two primers is another important consideration. They must prime DNA synthesis in opposite directions but pointing toward one another and each must anneal to one of the complementary strands. There is also an upper limit to the distance apart that the oligos can be placed; fragments of several kilobase (kb) pairs in length can be amplified, but the process is most efficient for fragments of several hundred base pairs. Long-range PCR kits are available, which in combination with optimised cycling conditions can amplify fragments of 10–20 kb.

Methodology

Reagents

Taq polymerase and oligonucleotide primers. These can be purchased from a variety of different companies. The oligos are usually 18–25 bases in length.

PCR buffers. These are usually supplied along with the Taq polymerase and consequently manual preparation may no longer be required. Three different buffers can be prepared as follows:

- *×10 PCR buffer I:* 100 mmol/l Tris-HCl, pH 8.3, 500 mmol/l KCl, 15 mmol/l $MgCl_2$, 0.1% (w/v) gelatine, 0.5% (v/v) NP40, and 0.5% (v/v) Tween 20.
- *×10 PCR buffer II:* 670 mmol/l Tris, pH 8.8, 166 mmol/l $(NH_4)_2SO_4$, 25 mmol/l $MgCl_2$, 670 µmol/l Na_2EDTA, 1.6 mg/ml bovine serum albumin (BSA), and 100 mmol/l β mercaptoethanol. This buffer is used in conjunction with 10% dimethyl sulphoxide (DMSO) in the final reaction mixture.
- *×10 PCR buffer III:* 750 mmol/l Tris, pH 8.8, 200 mmol/l $(NH_4)_2SO_4$, 0.1% (v/v) Tween 20. A solution of 25 mmol/l $MgCl_2$ is also prepared and added separately to the PCR reaction.
- *dNTP, 10 mmol/l.* Take 10 µl of 100 mmol/l dATP, 10 µl of 100 mmol/l dTTP, 10 µl of 100 mmol/l dCTP, 10 µl of 100 mmol/l dGTP and 60 µl of water to make 100 µl of 10 mmol/l dNTP.

Agarose, Type II medium electroendosmosis.

- *×10 Tris–borate–EDTA (TBE) buffer*. Add 216 g of Trizma base, 18.6 g of EDTA, and 110 g of orthoboric acid to 1600 ml water. Dissolve and top up to 2 litres; dilute 1 in 20 for use as ×0.5 TBE buffer.
- *SYBR Safe DNA Stain (www.thermofisher.com) (×10 000 concentrated)*. Add 5 µl to every 50 ml of agarose gel preparation
- *Tracking dye*. Weigh 15 g of Ficoll (type 400), 0.25 g of bromophenol blue and 0.25 g of xylene cyanol. Make up to 100 ml with water, cover, and mix by inversion; it will take a considerable amount of mixing to get the solution homogeneous. Dispense into aliquots.

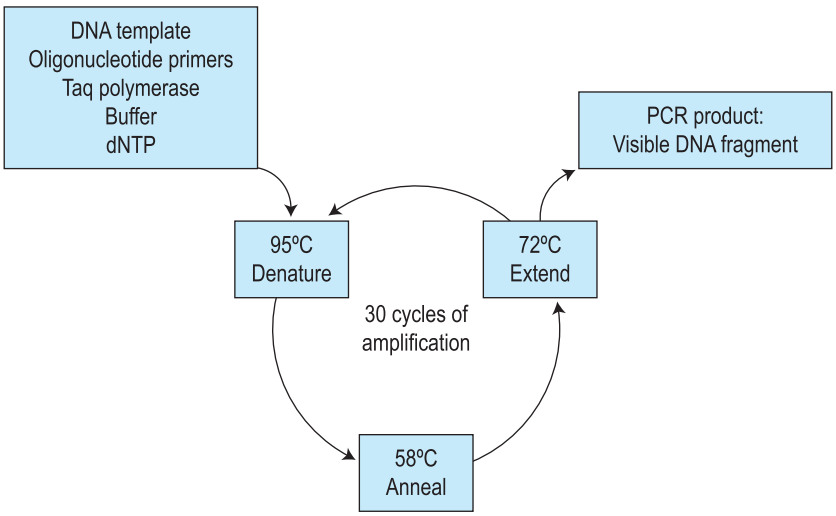

FIGURE 8-1 The polymerase chain reaction. Cyclical repetition of three temperatures for denaturing, annealing and extending DNA, respectively, gives rise to an exponential amplification of a DNA fragment between two primer sequences directing DNA synthesis on opposite strands of the DNA template.

Method. Optimal conditions for the reaction have to be derived empirically, with the magnesium concentration and annealing temperature being the most important parameters. The choice of buffer depends on the enzyme being used, and the company will usually supply the most appropriate one. For genes with a high GC content, buffer II in combination with 10% DMSO may give better amplification. In most cases, a 25-µl reaction volume suffices. A no template control (NTC) should always be included (i.e. a reaction without any DNA or complementary DNA [cDNA]: the template) to control for contamination. If the NTC yields a product, the analysis is invalid. A DNA sample that is known to amplify can also be included and this sample may then be used as a positive control.

The risk of contamination cannot be over emphasised. This can be minimised by using plugged tips and having dedicated micropipettes and areas for each step of the analysis. The optimum cycling conditions need to be determined for each thermocycler. Specificity is often improved by 'hot start' PCR. This is achieved by setting up all the PCR tests on wet ice and transferring the tubes to the thermocycler once it reaches 95 °C or by using an enzyme that only becomes activated when heated at 95 °C for several minutes. In preparing a group of reactions, a premix solution is prepared that can be dispensed into microcentrifuge tubes, tube strips or PCR reaction 96-well plates to which the template DNA is added. When a particular PCR is to be performed repetitively over a period of time, it is helpful to prepare a large volume (e.g. 10 ml) of the reaction mixture (without DNA or Taq polymerase), aliquot it in amounts sufficient for 20 reactions and store it at −20 °C.

1. Prepare a PCR mixture for 20 reactions (with a final volume of 25 µl for each DNA sample) as follows:

Stock Solution	*Vol (µl)*	*Final Concentration*
×10 PCR buffer III	50	×1
25 mmol/l $MgCl_2$	40	2.0 mmol/l
10 mmol/l dNTP	10	0.02 mmol/l
10 µmol/l Primer (1)	20	0.04 µmol/l
10 µmol/l Primer (2)	20	0.04 µmol/l
5 u/µl Taq polymerase	2	0.02 µ/ml
Water	358	
Final volume	*500*	

   Add the Taq polymerase last, mix well and pulse-spin in a microcentrifuge to bring down the contents of the tube.

2. Aliquot 24 µl of the PCR reaction mix into each tube. Add 1 µl of template DNA at approximately 0.05 mg/ml into all bar one (the NTC) of the reaction tubes.
3. Place the tubes in a PCR machine, using a heated lid, programmed for the following conditions: an initial step of 5 min at 95 °C and then 30 cycles of 95 °C for 45 sec, 58 °C for 45 sec, and 72 °C for 1 min in sequence followed by a final extension step at 72 °C for 10 min. These conditions are suitable for many primer pairs, although some will require different annealing temperatures or longer extension times. These two parameters need to be optimised in advance.
4. While the PCR program is running, a 1.5% agarose minigel is prepared: add 0.75 g of agarose to 50 ml of ×0.5 TBE buffer and heat until completely dissolved. Add 2 µl of SYBR Green, allow the agarose to cool slightly and pour with the appropriate comb in position.
5. To check if the amplification has been successful, add 1 µl of tracking dye to a 10-µl aliquot of the PCR reaction mixture, being careful not to pipette the mineral oil overlaying the PCR reaction.
6. Load the gel and run at a constant voltage of 100 V for 1 hour in ×0.5 TBE buffer. A molecular size marker should be included to establish the size of the amplified fragment; these are commercially available.
7. Visualise the DNA on an ultraviolet (UV) transilluminator and take a photograph.

Modifications and developments

The procedure described above is a guide for setting up and checking a standard PCR amplification. As the test dictates, modifications can be used, such as the following:

- *Radiolabelling.* A PCR can be labelled with ^{32}P by adding 0.1 µl of [α-^{32}P]dCTP per tube to the reaction mixture (rarely used).
- *Multiplex.* More than one fragment can be amplified in the same tube simply by adding in further primer pairs. It is important that the different pairs all work equally well under the same conditions.
- *Nested PCR.* This involves successive rounds of amplification using two pairs of primers; the second pair, located within the sequence amplified by the first, allows products to be generated from as little as a single cell.
- *Long-range amplification.* Fragments upward of 10 kb can now be generated by PCR using modified polymerases.
- *Automation.* High throughput PCR amplification is being achieved through the use of robots and 96-well plate technology.
- *Automated fragment analysis.* The method of gel electrophoresis is modified for the detection of fluorescently labelled PCR products on DNA fragment analysers (e.g. the ABI 3700 DNA analyser, www.thermofisher.com).

Interpretation

If the amplification has been successful, a discrete fragment of the expected size is seen in a SYBR Safe-stained agarose gel in all samples, except in the NTC lane. If a

product is seen in the NTC, then one of the solutions has been contaminated and the results cannot be relied on. All the working solutions must be discarded and the micropipettes must be cleaned. Cleaning micropipettes and work surfaces prior to the start of each run is highly recommended. To avoid contamination, making up a stock master mix of all reagents is recommended before DNA samples are added to each tube. If possible the use of separate pre- and post-PCR laboratories is highly recommended. This reduces the risk of contamination significantly. At a minimum the use of distinct areas of the laboratory for each activity is recommended.

Problems

The absence of a fragment in all tracks, including the positive control, indicates that the PCR has failed. This can occur for a number of reasons, including poor quality template or omission of one of the essential reagents. The reaction may also fail if the magnesium concentration is too low (standard concentration 1.5 mM) or if the annealing temperature is too high. However, DNA quality and amount in the reaction is often one of the major reasons for failure. If one particular DNA sample repeatedly fails to amplify, then the sample should be re-extracted using Proteinase K (www.thermofisher.com) and phenol/chloroform and re-precipitated, adding in one-tenth of the total volume of 3 M sodium acetate (pH 4.8) followed by the addition of 2.5 volumes of −20 °C cold ethanol.

We have also found that using the *Gentra* blood extraction kit (Qiagen) or passing the DNA through a Qiagen column substantially improves DNA quality and PCR efficiency.

Another problem is the presence of nonspecific fragments or just a smear of amplified product. This can occur if the magnesium concentration is too high or if the annealing temperature is too low.

Presence or absence of a PCR product and sizing PCR products. Initially, PCR products were commonly visualised by agarose gel electrophoresis or using a fast automated system such as Qiaxcel equipment (Qiagen). However, it has also become commonplace to visualise PCR products directly on DNA analysers – in particular the Applied Biosystems 3130xl, 3500 or similar models (www3.appliedbiosystems.com). These read fluorescently labelled DNA fragments as they exit from the gel and enable single-base resolution from around 50–800 bp. If appropriate primers and controls are included in an experiment, the actual presence of a product can be highly informative.

Deletions and insertions can be easily identified when the size of the PCR product significantly differs from the size in the normal control. An example of this analysis is given for α globin gene Gap analysis on page 136.

Higher resolution of fragment sizes is obtained by capillary electrophoresis, which is particularly appropriate in the analysis of short tandem repeat (STR) sequences, which can be highly variable in length and therefore useful as genetic markers of different individuals. High resolution sizing of DNA fragments is now often performed on DNA analysers as mentioned above. Several examples of these applications are given in this chapter, in particular in the section describing chimaerism analysis on page 159.

Amplification refractory mutation system (ARMS)

Principle

Point mutations and small insertions or deletions can be identified directly by the presence or absence of a PCR product using allele-specific primers.[9,10] Two different oligos are used that differ only at the site of the mutation (the amplification refractory mutation system, or ARMS, primers) with the mismatch distinguishing the normal and mutant base located at the 3′ end of the oligo. An oligo with a mismatch at its 3′ end will fail to prime the extension step of the reaction. Each test sample is amplified in two separate reactions containing either a mutant ARMS primer or a normal ARMS primer. The mutant primer will prime amplification in combination with one common primer from DNA with this mutation but not from a normal DNA. A normal primer will do the opposite. To increase the instability of the 3′ end mismatch, and so prevent the failure of the amplification, it is sometimes necessary to introduce a second nucleotide mismatch three or four bases from the 3′ end of both oligos. A second pair of primers located at a distance from the ARMS primers is also included in the reactions as an internal control for the efficient amplification of DNA. This is essential because a failure of the ARMS primer to amplify is interpreted as a significant result and must not be the result of suboptimal amplicon reaction.

Interpretation

The fragment produced by amplification with the internal control primers must be seen in all the samples, except for the NTC. Then the presence or absence of a mutation is simply determined by the presence or absence of the amplification with the mutant ARMS primer. Similarly, the presence or absence of the normal allele is determined in the same way with the normal ARMS primer. In this way, heterozygous, homozygous normal, and homozygous mutant genes can be distinguished. An example of the application of this technique will be presented with the diagnosis of β thalassaemia mutations on page 135.

Gap-PCR

Large deletions can be detected by Gap-PCR. Primers located 5′ and 3′ to the breakpoints of a deletion will be too far apart on the normal chromosome to generate a fragment in a standard PCR. When the deletion is present, these

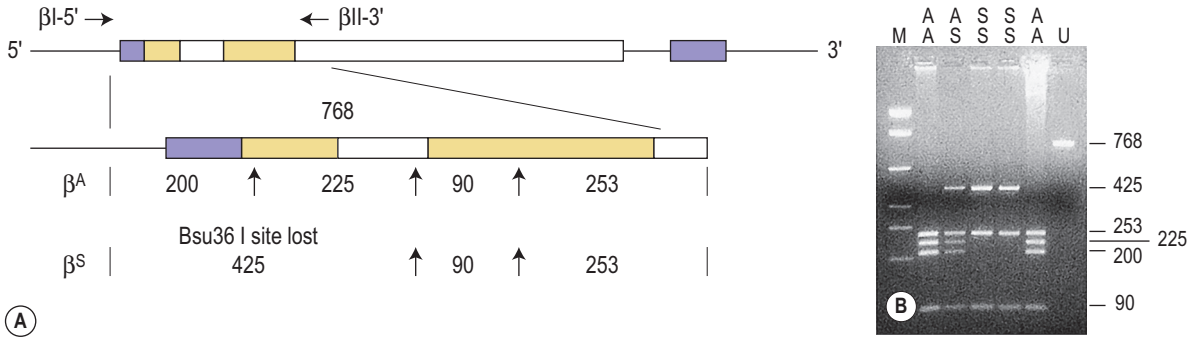

FIGURE 8-2 Detection of the sickle cell mutation using restriction enzyme analysis. A, A sketch of the β globin gene shows the position of the primers used to amplify a 768 bp fragment in a polymerase chain reaction *(PCR)*. The sequence of β I–5′ is 5′ TAAGCCAGTGCCAGAAAGAGCC 3′ and that of β II-3′ is 5′ CATTCGTCTGTTTCCCATTCTA 3′. Maps of the Bsu36 I restriction sites and the fragment sizes from βA and βS genes are shown below. **B,** An ethidium bromide–stained minigel illustrates the fragment sizes generated by Bsu36 I digestion of the PCR product from normal *(A/A)*, sickle cell trait *(A/S)* and sickle cell anaemia *(S/S)* individuals, along with the undigested amplified fragment *(U)* and the molecular size marker *(M)*.

primers will be brought closer together, enabling them to give rise to a product. An example of this is given for the detection of deletions in α^0 thalassaemia on page 136.

Fusion gene analysis

Primers can be brought together by chromosomal translocation, giving rise to a diagnostic product. Breakpoints may be spread over too large a region for genomic DNA to be amplified. However, translocations in leukaemic cells can give rise to fusion genes, which lead to the formation of new fusion proteins with oncogenic effect. Primers for the different genes (generally corresponding to the exons flanking the breakpoint) are then juxtaposed in a hybrid messenger ribonucleic acid (mRNA) molecule and can give rise to a product generated through reverse transcription from the fusion mRNA or product, using a reverse transcriptase polymerase chain reaction (RT-PCR). Examples of this are given for the analysis of minimal residual disease in chronic myeloid leukaemia (CML) and other leukaemias on pages 142 and 156.

Restriction enzyme digestion

Principle

Restriction enzymes (REs) cleave DNA at short specific sequences. Because many REs are available, it is not uncommon for a single point mutation to coincidentally create or destroy an RE recognition sequence. If this is the case, digestion of the appropriate PCR product prior to agarose gel electrophoresis enables the mutation to be identified. A difference in the size of the restriction fragments seen in normal and mutant samples can be predicted from a restriction map of the amplified fragment and the site of the mutation that changes a restriction site. The observed fragments should be consistent with either the mutant or the normal pattern. An example of this technique is shown in Figure 8-2.

Methodology

Reagents. A number of companies now supply a comprehensive range of restriction enzymes (REs), but they may vary greatly in their cost. Those that are in regular use are generally quite inexpensive compared with the more specialised enzymes that are used only occasionally and that may be 10–100 times more expensive. RE buffers are now almost always supplied with each RE. Buffer compositions are always given and will vary from enzyme to enzyme. Many commonly used REs cut perfectly well in a single 'universal' buffer. This is prepared using the following stock solutions:

1. *Tris-acetate, 2 mol/l, pH 7.5.* Dissolve 24.2 g of Trizma base in 60 ml of water, adjust the pH to 7.5 with glacial acetic acid and make up to 100 ml.
2. *Potassium acetate, 2 mol/l.* Weigh out 19.62 g, make up to 100 ml with water and dissolve.
3. *Magnesium acetate, 2 mol/l.* Weigh out 42.89 g, make up to 100 ml with water and dissolve.
4. *BSA fraction V (molecular biology grade), 20 mg/ml.*
5. *Dithiothreitol (DTT), 0.5 mol/l.* Weigh out 0.771 g, make up to 10 ml with water, dissolve and store at −20 °C.
6. *Spermidine (N-(3-aminopropyl)-1,4-butane-diamine), 1 mol/l.* Weigh out 1.273 g, make up to 10 ml with water, dissolve and store at −20 °C.
7. *×10 RE buffer.* For a ×10 concentrated buffer, prepare a solution that is 300 mmol/l Tris-acetate, pH 7.5, 660 mmol/l potassium acetate, 100 mmol/l magnesium acetate, 1 mg/ml BSA, 10 mmol/l DTT, and 30 mmol/l spermidine; aliquot into microcentrifuge tubes and store at −20 °C.

Method

1. To a 20-µl aliquot of a PCR product add 2.5 µl of ×10 restriction enzyme buffer, 2 µl of double-distilled water, and 2–5 units of the appropriate RE (usually 0.5 µl), giving a final volume of 25 µl. In preparing more than one digestion with the same restriction enzyme, sufficient buffer, enzyme, and water can be premixed and dispensed into the PCR products.
2. Incubate at 37 °C (or other temperature as specified by the manufacturer) for a minimum of 4 h.
3. Pour a 2.5% agarose minigel in a taped casting tray with the appropriate comb. The gel is made up of 1:1 mixture of type II medium electroendosmosis agarose and NuSieve agarose (www.thermofisher.com) (i.e. 0.675 g of agarose and 0.675 g of NuSieve agarose in 50 ml of half-strength [×0.5] TBE buffer).
4. After the incubation period, add 2 µl of tracking dye to the digests and load the samples on to the gel. The electrophoresis is continued until a clear separation of all the expected fragments is achieved, which may be checked at intervals by placing the gel on a UV transilluminator.

Allele-specific oligonucleotide hybridisation

Principle

Under appropriate conditions, short oligonucleotide probes will hybridise to their exact complementary sequence but not to a sequence in which there is even a single base mismatch.[11] A pair of oligos is therefore used to test for the presence of a point mutation: a variant oligo complementary to the variant sequence and a reference oligo complementary to the reference sequence, with the sequence difference placed near the centre of each oligo.

The stability of the duplex formed between the oligo and the target DNA being tested (the PCR product) depends on the temperature, the base composition and length of the oligo, and the ionic strength of the washing solution. For allele-specific oligonucleotide hybridisation (ASOH) studies, an empirical formula has been derived for the dissociation temperature (T_d), the temperature at which half of the duplexes are dissociated. This value is used as a guide; the exact temperature at which only perfect base pairing is maintained is usually determined by trial and error.

This methodology has been widely applied for the detection of single nucleotide variations (SNVs) using fluorescently labelled hydrolysis probes (such as *TaqMan* probes) that distinguish the two alleles. Two short allele-specific probes are used, one of which will hybridise only to the wild-type allele and one of which will hybridise only to the mutant allele. The two probes are labelled with different fluorophores, which are quenched (preferably using a non-fluorescent quencher) while the probes remain intact, but are released if and when the probe hybridises to its perfectly complementary sequence during the reaction, as it will then be broken up by the exonuclease activity of the Taq polymerase.

Interpretation

The oligos will hybridise to their perfectly complementary DNA sequence, such that the variant oligo gives a signal only when the mutant allele is present, and similarly for the wild-type allele. When this is the case, the interpretation of the result is straightforward; a positive signal from a particular oligo indicates the presence of that allele in the test sample. Heterozygotes and homozygotes are distinguished by using the variant and reference oligos in tandem. With the two fluorescent colours of the hydrolysis probes, the heterozygote is identified as the sum of the two fluorochromes.

Other non-radioactive probes, with detection systems involving horse-radish peroxidase, have also been quite widely used in this procedure.[12] The technique has also been modified such that the allele-specific oligonucleotides are immobilised onto nylon membranes and the patient-specific PCR product is used as the probe – the reverse dot blot procedure.[13] This allows several different mutations to be analysed simultaneously and has proved particularly useful in the diagnosis of β thalassaemia mutations.[14]

DNA sequencing by Sanger sequencing technology

Principle

The Sanger chain termination method for direct DNA sequencing has become a standard diagnostic tool. In many laboratories this procedure has superseded targeted mutation detection as it provides a robust and relatively rapid method to identify all sequence changes that may be present in a particular DNA fragment. This approach is particularly relevant where multiple different mutations may underlie a particular disorder. This is the case for β thalassaemia and for glucose-6-phosphate dehydrogenase (G6PD) deficiency, so it is not surprising that DNA sequencing has often become the method of choice for the molecular diagnosis of these disorders.

The method involves the de novo synthesis of DNA strands in one direction from a PCR-derived template amplicon. The chain is lengthened by a thermostable DNA polymerase using deoxynucleotide triphosphates in the normal way. However, included in the reaction mixture is a small proportion of fluorescently labelled dideoxynuclotide triphosphates (ddNTPs), which when incorporated will prevent any further extension of the chain. This process happens millions of times along a relatively short piece of DNA (typically 30–400 and no more than 800–1000 bases), which means that chain-termination will occur many times at each position along the fragment. In the *ABI BigDye* system (Life Technologies,

www.thermofisher.com), each of the ddNTPs is labelled with a different fluorochrome, and so the products of the sequencing reaction will consist of single-stranded DNA fragments, each differing in size by one base pair and each labelled with a different colour. These fragments can then be separated by capillary electrophoresis according to size, and the order with which the different colours exit from the capillary will correspond to the sequence of the DNA template.

Methodology

Reagents and equipment

- *ExoSapIt,* a mixture of exonuclease and shrimp alkaline phosphatase (www.affymetrix.com)
- *BigDye Terminator v3.1 cycle sequencing kit* (www.thermofisher.com)
- *125 mM EDTA*
- *MicroAmp optical plates* (www.thermofisher.com)
- *100% and 70% ethanol*
- *HiDi formamide* (www.thermofisher.com)

Method. The PCR product that requires to be sequenced is firstly mixed with 2 µl of ExoSapIt and is incubated at 37 °C for 45 min and then at 80 °C for 15 min. Then cool to 4 °C until ready for use. Prepare 10-µl sequencing reactions by mixing 1–4 µl of the ExoSapIt-treated PCR product, 2 µl of the relevant oligonucleotide primer (diluted to 0.8 pmol/µl), 1 µl of the 5X reaction buffer and 2 µl of the BigDye dideoxy NTP terminator mix (both supplied with the kit), made up to 10 µl with water. Transfer the reaction to a PCR machine and run the sequencing reaction, with the following cycling conditions: 96 °C for 10 s, 50 °C for 5 s and 60 °C for 4 min for 25 cycles. Then cool samples to 4 °C. Add 2.5 µl of 125 mM EDTA to each sample and mix well and then add 30 µl of ice-cold ethanol and mix again. Incubate on ice for 10 min in a sealed MicroAmp plate. Centrifuge at 2000 *g* for 20 min to pellet the DNA. Carefully remove the seal, invert the plate onto some absorbent tissue and centrifuge the plate upside down for ≈ 10 sec to remove all residual liquid. Again add 125 µl of 70% ethanol and centrifuge at 2000 *g* for 5 min. Invert and briefly spin the plate upside down again. Place on a preheated 95 °C block for 10 s to remove any residual ethanol. Resuspend in 10 µl of HiDi formamide, cover with the grey septa mat, heat to 95 °C for 5 min, snap-cool on ice and place in the DNA sequence analysis platform and run, using the appropriate DNA fragment analysis protocol for sequencing.

Interpretation

Reading the DNA sequence from a trace – known as an electrophoretogram – is relatively straightforward as long as the quality of the trace is satisfactory: an A is shown as a green peak, T as a red, C as a blue and G as a black. Free software packages are available for viewing these traces, and indicate the DNA sequence in the file. Simple alignment of this sequence to the GenBank reference sequence can be performed at the National Center for Bioinformatics (NCBI) (www.ncbi.nlm.nih.gov) using the Blast program, and will identify any sequence changes. Heterozygous point mutations will be seen as double peaks, with two colours overlaid. Small heterozygous insertions or deletions (indels) are harder to decipher, as the sequence 3′ of the mutation will be a double sequence, with the reference and indel-variant allele superimposed on one another: the extent of the indel can be defined by subtracting from the expected normal sequence.

High resolution melt curve analysis

Principle

High resolution melt (HRM) curve analysis is a post-PCR analytical methodology used for identifying genetic variants in suitable regions of interest in candidate genes. Once optimised, it is simple and fast with no post-PCR manipulation. Analysis is performed using Applied Biosystems High Resolution Melt Software (www.appliedbiosystems.com).

HRM analysis is performed on double-stranded (ds) DNA samples. Firstly the DNA is amplified using a real-time platform prior to the HRM melt phase. The HRM process is a slow denaturation of the dsDNA from 50–95 °C in conjunction with an intercalating fluorescent dye, SYTO9 (www.thermofisher.com). When the melting temperature of the ds DNA is reached, the two strands 'melt' apart. The midpoint of the melt curve is described as the point when 50% of the DNA is double stranded and 50% is single stranded. The shape of the curve is dependent upon the characteristics of the ds DNA, which relate to whether it is homozygous wild-type, homozygous mutant or heterozygous wild-type and mutant. When the two strands 'melt' apart the fluorescence level drops. As the HRM is monitored in real-time, this curve gives a real time picture of the characteristics of the DNA being tested.

The lower limit sensitivity of HRM, as determined by our laboratory using the ABI3100 instrument (www.appliedbiosystems.com), is approximately 10%. However, this is dependent upon the mutation being tested as sensitivity is partly determined by the base change. The greater the temperature shift, the more sensitive the test will be.

Methodology

Reagents

- HRM Melt Doctor Reagent Kit (www.thermofisher.com)
- AmpliTaq Gold 360 Buffer 10X and AmpliTaq Gold polymerase (www.thermofisher.com)
- 25 mM magnesium chloride
- GeneAmp dNTP blend 10 mM (www.thermofisher.com)
- Melt Doctor HRM Dye 20X (Syto9) (www.thermofisher.com)
- Invitrogen Molecular biology grade H_2O (www.thermofisher.com)
- Oligonucleotides

All primers are diluted to 100 pmol/ml once received and are then set up at 5 pmol/ml. These are made by preparing a 1:20 dilution from the master stock of 100 pmol/ml and storing it at −20 °C.

When setting up a mixture, calculate that for each reaction you will require a final volume of 20 µl per test. Calculate the number of tests to be performed and add an extra 2 tubes to allow for wastage.

Equipment. *ABI3100 Instrument.* The ABI3100 machine needs to be calibrated for HRM using the relevant plate and dye using a calibration plate ordered through Applied Biosystems (Fast 96-well MeltDoctor calibration plate, catalogue number 4425618; www.appliedbiosystems.com).

Clear Polyolefin StarSeal StarLabs (catalogue number E2796-9793; www.starlab.co.uk). Pipettes, tips and bijou tubes, 1.5-ml Eppendorf tubes (www.eppendorf.com).

All DNA should be quantified and diluted to 100 ng/µl. DNA samples for testing are stored at −20 °C. DNA for HRM is subsequently diluted to 20 ng/µl by preparing a 1:5 dilution in water.

Method

1. All samples including control samples and negative controls are tested in triplicate or at least in duplicate.
2. The controls used are dependent upon the test in question but must include at least one positive control, one wild-type control and a no template (water) control.
3. Working in the clean room, referring to the worksheet, prepare all the reagents required and thaw them.
4. Make up an appropriate volume of the master mix. If making up master mix for a full 96-well plate, use a bijou not an Eppendorf due to the total volume required.
5. Add the appropriate volume, 0.2 µl per reaction of Platinum AmplTaq 360 DNA polymerase, mix well and aliquot 19 µl to each well.
6. Take the 96-well plate to the set-up room and place in the PCR hood.
7. Take out all DNA samples to be tested and place in worksheet order
8. These DNA samples will be at a concentration 100 ng/µl.
9. Make up a 20 ng/µl dilution by adding 1 µl of DNA to 4 µl of H_2O. This is sufficient for 3 tests. Discard after use.
10. Wild-type control DNA, cell line DNA or appropriate positive controls are stored at 20 ng/µl dilutions in the control DNA box. Add 1 µl to each relevant tube.
11. Seal the plate using plate adhesive film and the rubber sealer. Take care not to leave fingerprints on the film by wearing protective gloves.
12. Run the reaction in the ABI3100 by using the appropriate programme.

All appropriate controls must be used in each run. This includes a positive control (preferably a cell line or a previously identified positive patient), a negative control (usually DNA wild-type) and water as a non template control (NTC).

Interpretation

Homoduplexes, whether wild-type or mutant, will display the same curve shape but will be distinguished primarily by the shift on the temperature axis (*x* axis). Heteroduplexes are discriminated by a change in the shape of the curve.

CLINICAL APPLICATIONS

Investigation of haemoglobinopathies

Sickle cell disease

The presence of haemoglobin S and thus the presence of the sickle cell gene can be determined by haemoglobin cellulose acetate electrophoresis, high performance liquid chromatography (HPLC) or a 'sickling test'. However, there are occasions when it is beneficial to make a diagnosis by DNA analysis (e.g. in prenatal diagnosis, which can be performed at 10 weeks of pregnancy, with the aim of identifying sickle cell anaemia and haemoglobin S/β thalassaemia, or to confirm the diagnosis of sickle cell anaemia in a neonate). For the type of specimens collected for prenatal diagnosis, refer to page 310.

The sickle cell mutation, c.20A > T; p.Glu7Val in codon 7 of the β globin gene, *HBB,* results in the loss of a Bsu36 I (or Mst II, Sau I, OxaN I or Dde I) restriction enzyme site that is present in the normal *HBB* gene. It is therefore possible to detect the mutation directly by restriction enzyme analysis of a DNA fragment generated by PCR. A pair of primers are used to amplify exons 1 and 2 of the β globin gene and the products of the PCR are digested with Bsu36 I. The loss of a Bsu36 I site in the sickle cell gene gives rise to an abnormally large restriction fragment that is not seen in normal individuals (Fig. 8-2). This mutation can also be detected by ARMS PCR using two reactions per sample, one specific for the mutant allele and the other for the wild-type allele. The 3′-end nucleotide of the mutation-specific primer should be specifically complementary to the mutation, while the primer specific for the wild-type sequence should contain a nucleotide complementary to the wild-type sequence at this end. A common reverse primer allows the production of an amplification band similar in size in the two reactions, hence the use of two reaction tubes per sample. Primers specifically used for this analysis are listed below.

Homozygosity for the mutation will produce amplification in the mutation PCR reaction, while the absence of the mutation will result in amplification in the wild-type PCR only. Heterozygous samples will have amplification in both reactions. An extra pair of

primers amplifying another part of the gene should be used to produce control bands. The primers used for this method are Haemoglobin S Forward, Wild-Type (WT) Forward, Common Reverse, Control Forward, and Control Reverse and are listed here: Haemoglobin S Forward Mutant: 5′-CCC ACA GGG CAG TAA CGG CAG ACT TCT GCA 3′; Haemoglobin S Forward WT: 5′-CCC ACA GGG CAG TAA CGG CAG ACT TCT GCT 3′; Common Reverse: 5′-ACC TCA CCC TGT GGA GCC AC 3′; Control Forward: 5′-GAG TCA AGG CTG AGA GAT GCA GGA 3′; Control Reverse: 5′-CAA TGT ATC ATG CCT CTT TGC ACC 3′.

β thalassaemia

The ethnic groups with the highest incidence of β thalassaemia are the Mediterranean populations, Indian subcontinent populations, Chinese and Africans. Although more than 100 β thalassaemia mutations are known, each of these groups has its own subset of mutations, so that as few as five different mutations may account for more than 90% of the affected individuals in a population. This makes the direct detection of β thalassaemia mutations a reasonable possibility, and it has become the method of choice where it is most important – in prenatal diagnosis.[14,15]

The majority of mutations causing β thalassaemia are point mutations affecting the coding sequence or splice sites and nowadays they are detected by direct DNA sequence analysis. Unstable and other unusual haemoglobins may also cause disease, and can similarly be identified by direct DNA sequence analysis. An example of such a case is shown in Figure 8-3, where a picture of moderate anaemia is seen in the heterozygote due to the highly unstable and electrophoretically silent variant *HBB* Durham-N.C.

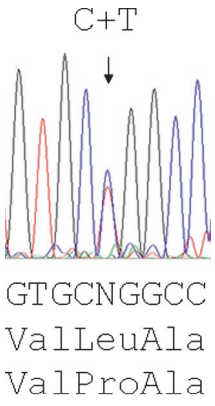

FIGURE 8-3 Sequencing of the β globin gene reveals haemoglobin Durham-N.C. The sequencing electrophoretogram clearly shows the heterozygous mutation *(arrowed)* where a C peak and a T peak are superimposed and called as N. This mutation is c.344T>C causing a p.Leu115Pro substitution (traditionally named as codon 114). *(Courtesy A. Tibepu.)*

α thalassaemia

In contrast to the β thalassaemias, the most common α thalassaemia mutations are large deletions. Two categories exist: those that remove only one of the two α globin genes on one chromosome (α^+ thalassaemia) and those that remove both of the α genes from one chromosome (α^0 thalassaemia). Although PCR amplification around the α globin locus has proved to be rather difficult, the common deletions can now be identified by a reasonably robust Gap-PCR.[16] In these reactions dimethyl sulphoxide (DMSO) (see Buffer II, p. 128) and betaine are added. Two different multiplex PCR reactions are set up: one for the common α^+ thalassaemias ($\alpha^{-3.7}$ and $\alpha^{-4.2}$) and one for the common α^0 thalassaemias ($--^{SEA}$, $--^{MED}$, $--^{FIL}$ and $\alpha^{-20.5}$). The fragment generated by these primers across the deletion breakpoint is different in size from the fragment generated from the normal chromosome. The primers that flank the deletion breakpoint are too far apart to generate a fragment from the normal chromosome in the PCR. Only when these are brought closer together as a result of the deletion, can a fragment be produced. Primer sequences used in this analysis are given in Table 8-1 and an example of their application in the detection of α^0 thalassaemias is shown in Figure 8-4.

Recently, with the development of new and better PCR reagents, it has been possible to perform a multiplex PCR for the detection of the common α globin gene deletions in one reaction tube.[16] These reagents do not need the addition of DMSO or betaine. More than 30 non-deletional forms of α thalassaemia have been described. Of these, haemoglobin Constant Spring and the α^{HphI} mutation are relatively common in Southeast Asian and Mediterranean populations, respectively. These can be detected by ASOH, ARMS, restriction enzyme digestion or direct sequencing of the appropriate PCR product. Unlike the β thalassaemias, α thalassaemias are not easily diagnosed using routine haematological techniques. The diagnosis of α thalassaemia is often made following exclusion of β thalassaemia and iron deficiency. Because the vast majority of cases of α thalassaemia are of the clinically benign type (i.e. α^+ thalassaemia), it is debatable whether molecular analysis is justified to reach a diagnosis in these individuals. However, it is important that individuals with α^0 thalassaemia are identified and the only definitive diagnostic test is DNA analysis. The α^0 thalassaemias are almost entirely restricted to certain ethnic groups, namely, those of Chinese, Southeast Asian and Mediterranean origin; and so it is most efficient to target these groups specifically. The diagnosis of α^0 thalassaemia is particularly relevant if prenatal diagnosis is to be offered to a couple who are at risk of having a foetus with hydrops, since there is an increased risk of maternal death at delivery. Guidelines derived from the UK experience as to how and when DNA analysis should be implemented are available.[17] Primers used for this analysis are listed in Table 8-1 and an example is illustrated in Figure 8-4.

TABLE 8-1

PRIMERS USED IN GAP-PCR ANALYSIS FOR α THALASSAEMIA[85]

Primer Name	Sequence, 5′ → 3′	Concentration (μmol/l)
α^0	**Multiplex PCR**	**Clark and Thein (2004)[15]**
20.5(F)	GGGCAAGCTGGTGGTGTTACACAGCAACTC	0.1

PCR, polymerase chain reaction.

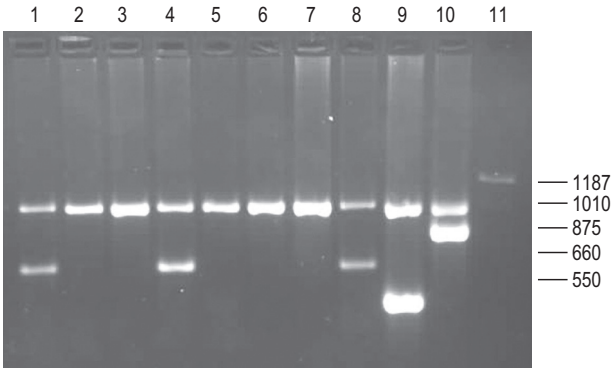

FIGURE 8-4 Detection of α^0 thalassaemia by multiplex Gap-PCR. The sequences of the primers used are shown in Table 8-1. A normal fragment of 1010 bp is generated by the primers α/SEA(F) and α/(R) in all lanes (although this is very faint in lane 11). In addition, a fragment of 660 bp is generated by the primer pair α/SEA(F) and SEA(R) in lanes 1, 4 and 8 in individuals who are heterozygous for the $--^{SEA}$ deletion; a fragment of 550 bp is generated by the primer pair FIL(F) and FIL(R) in lane 9 in an individual who is heterozygous for the $--^{FIL}$ deletion; a fragment of 875 bp is generated by the primer pair MED(F) and MED(R) in lane 10 in an individual who is heterozygous for the $--^{MED}$ deletion; and a fragment of 1187 bp is generated by the primer pair 20.5(F) and 20.5(R) in lane 10 in an individual who is heterozygous for the $-\alpha^{20.5}$ deletion.

Coagulopathies

Thrombophilia screening

Considerable advances have been made in our understanding of the genetic risk factors found in patients with venous thromboembolism (VTE).[18] Among these are the diverse mutations causing protein C, protein S and anti-thrombin deficiency. An increased factor VIII level is also a risk factor for VTE, but the genetic determinants of this are unclear. Homozygosity for the common C677T mutation of the methylenetetrahydrofolate reductase gene (*MTHFR*), which gives rise to a thermolabile variant of this protein, has been reported to be a risk factor for VTE, although other studies have not supported this claim and we no longer provide this test as it appears to have no clinical impact.

A point mutation in the 3′ UTR of the prothrombin gene (*FII*) associated with elevated protein levels has been identified as a genetic risk factor for VTE.[19] The most common of the known genetic risk factors for VTE is a resistance to the anticoagulant effect of activated protein C caused by the Arg506Gln substitution in the factor V gene (*FV*).[20] Around 20% of subjects of north European origin presenting for the first time with thromboembolism are heterozygous for this mutation, designated factor V Leiden (FVL). Because of their prevalence and because the tests have become relatively simple, there is a tendency toward indiscriminate testing for these genetic risk factors in thrombophilia, but without careful and informed counselling this may often be inappropriate.[21] (See also Chapter 19.)

Methodology. A variety of different methods have been used to detect these mutations, but we have recently adopted a hydrolysis probe (TaqMan) based assay. The reagents are provided by Thermo Fisher (www.thermofisher.com) and the protocol provided has been adapted as described here. Differentially labelled, but quenched, TaqMan probes hybridise specifically to the reference and variant alleles in a given patient's sample. Detection of the fluorescent signal, which is emitted as the probes are hydrolysed and the

reporter fluorophore dequenched during the PCR amplification, is used to discriminate between the presence of normal and mutant alleles in the sample.

Reagents and equipment. Requirements are a 96-well optical PCR plate, optical adhesive lid, pipettes and tips, TaqMan Genotyping Master Mix, FVL genotyping assay (C_11975250_10), PTM genotyping assay (C_8726802_20), ddH_2O, Applied Biosystems (www.appliedbiosystems.com) 3100HT Fast, Step-One-Plus or equivalent Real-Time PCR apparatus.

Method. Defrost the genotyping assay mixes on ice. In each experiment, include a normal, heterozygous and homozygous control for both the factor V Leiden and the prothrombin mutations. Also include three blanks to which no template DNA is added. In the remaining wells, aliquot 2 µl of test DNA into the bottom of the appropriate well. Prepare a PCR mix for each test using 0.5 µl of the relevant genotyping assay, 10 µl of water and 12.5 µl of the TaqMan Genotyping master mix per sample to be analysed. Aliquot 23 µl of this PCR mix into each well, seal the plate with the optical adhesive lid and spin briefly. Use the 'Allele Discrepancy Assay' on the computer associated with the Applied Biosystems 3100HT Real-Time PCR System. Thermocycling conditions are a denaturation at 95 °C, for 10 min for 1 cycle followed by denaturation at 92 °C for 15 sec, and annealing/extension at 60 °C for 60 sec, repeated for 40 cycles.

Interpretation. The results can be evaluated using the allelic discrimination plots for the individual genotyping test. Each data point represents one sample and they can be seen to fall into four clusters according to the genotype of the sample or the absence of the signal (NTC) (Fig. 8-5). If the assay has worked, these clusters should be clearly distinct. An automatic genotype annotation is then based on this clustering. Some points will not be automatically identified by the software: these data points can be annotated manually by assigning them to the appropriate cluster.

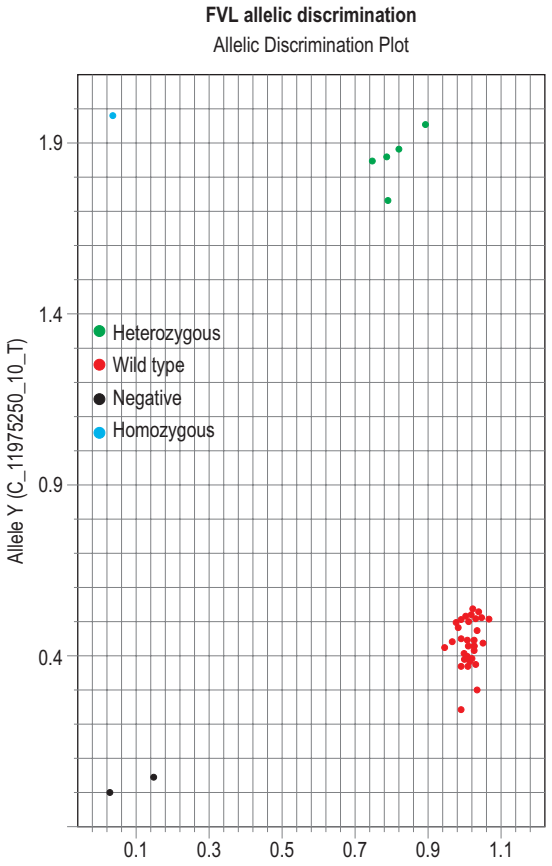

FIGURE 8-5 Allelic discrimination of Factor V Leiden using the TaqMan assay system. Each spot on the graph represents one well of the plate in which one DNA template is under test. In each well we either see no signal *(negative: bottom left)* – NTC; only 'red' signals, coming from the wild-type probe *(bottom right)* – homozygous wild-type; only blue signals coming from the FVL probe *(top left)* – homozygous FVL; or a mixture of signals to give green spots coming from both the wild-type and FVL probes *(top right)* – heterozygous for FVL.

Clotting disorders

Diverse mutations underlie haemophilia A and haemophilia B and these are usually identified in specialised laboratories by screening exons for mutation by single-strand conformation polymorphism analysis (SSCP), denaturing HPLC or direct DNA sequence analysis.[22] It may still be relevant to determine carrier status and offer prenatal diagnosis through genetic linkage analysis. Problems with this include the number of sporadic cases, lack of informative markers, unavailable family members and the possibility of recombination.

Of particular diagnostic significance is the fact that from between one third and one half of all patients with severe haemophilia A have a large genomic inversion mutation involving recombination between a region in intron 22 of the factor VIII gene and telomeric homologous sequences.[23] These inversions are readily detected by Southern blot analysis applying the p482.6 probe[24] to Bcl I digests of genomic DNA. A method has also recently been described using long-distance PCR, enabling identification of these deletion mutations in a single tube reaction.[25] (See Chapter 18 for more information on bleeding disorders.)

Leukaemia and lymphoma

Cytogenetic analysis

Principles and Terminology. Cytogenetic analysis is usually carried out by specially trained scientists in a separate laboratory that often has no specific relationship to the routine haematology laboratory. For this reason no details of techniques will be given. However, cytogenetic analysis

is so crucial to the diagnosis and management of haematological neoplasms that it is necessary for haematologists to understand the principles and be able to understand the reports that are received. In addition, haematologists are often involved in collection of appropriate samples.

Classical cytogenetic analysis is carried out on cells that have entered mitosis and have been arrested in metaphase so that individual chromosomes can be recognised by their size and their banding pattern following staining (e.g. Giemsa staining [G-banding] or staining with a fluorescent dye). Alternating dark and light bands are numbered from the centromere toward the telomere to facilitate description of any abnormalities detected. An example showing the balanced translocation t(9;22)(q34;q11.2) in CML is shown in Figure 8-6. The standard terminology applied to chromosomes is shown in Table 8-2.

The results of cytogenetic analysis may be displayed visually (a karyogram) or written according to standard conventions (a karyotype). Thus 46, XY, t (3;3)(q21;q26) [20] indicates a pseudodiploid karyotype in a male. A reciprocal translocation has occurred between the paired chromosomes 3 following a break at 3q21 on one chromosome (i.e. involving the long arm of chromosome 3, band 2, sub-band 1) and at 3q26 on the other. The abnormality has been detected in 20 metaphases, indicated by the number in the square brackets. 46,XY,inv(3)(q21q26) indicates a pseudodiploid karyotype with a paracentric inversion of the long arm of a single chromosome 3; the breakpoints are the same as in the first instance but are on a single chromosome. Note the use of semicolons in describing a translocation involving breaks on different chromosomes, whereas these are absent from the notation of an inversion arising from breaks on the same chromosome. Karyotypically distinct normal or abnormal clones are separated by a slash. 46,XY,inv(3)(q21q26)[6]/46,XY[4] therefore describes a total of 10 analysed metaphases, of which six carried the chromosome three inversion and four had a normal male karyotype.

Methodology. Cytogenetic analysis can be carried out on the following types of tissue:

1. Skin fibroblasts or phytohaemagglutinin (PHA)-stimulated lymphocytes (to study constitutional abnormalities)

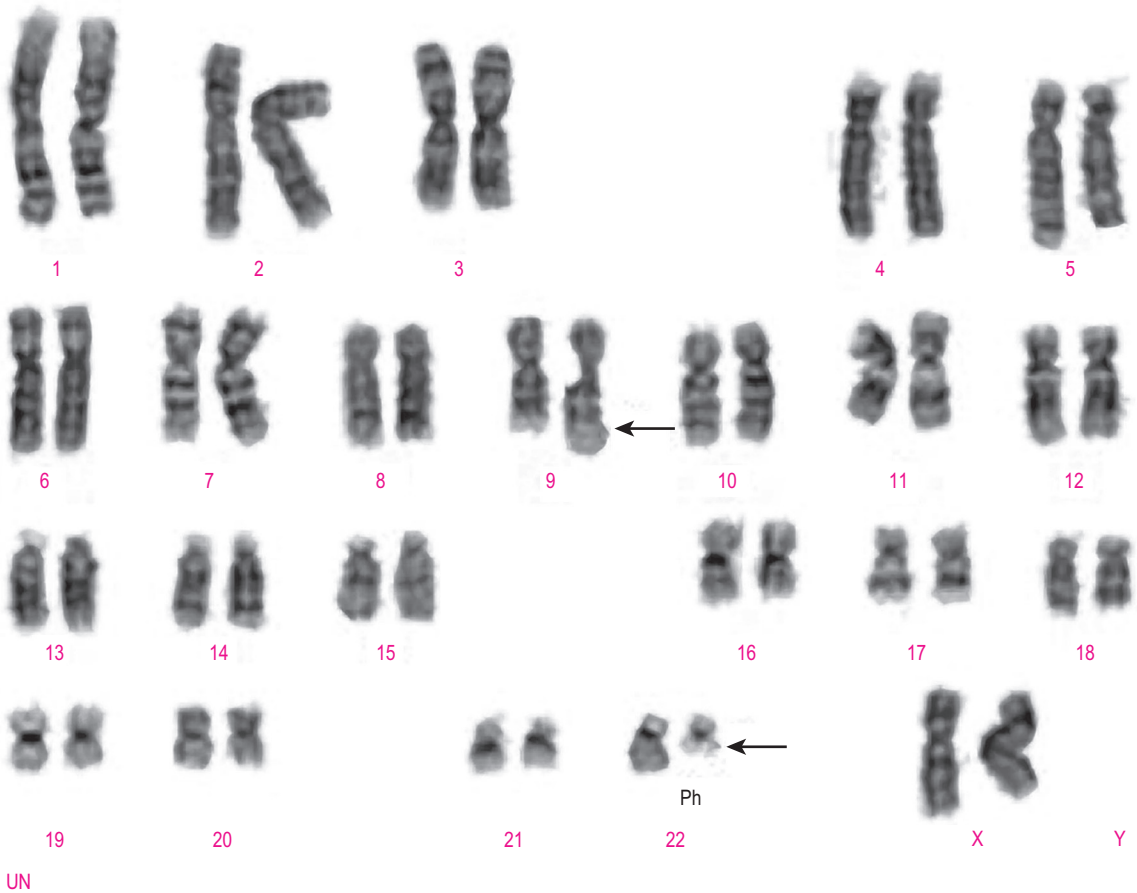

FIGURE 8-6 G-Banded karyotype. Female karyotype with a balanced reciprocal translocation between chromosomes 9 and 22 *(arrowed)* giving rise to the Philadelphia (Ph) chromosome. *(Courtesy J. Howard.)*

TABLE 8-2

TERMINOLOGY AND ABBREVIATIONS USED IN CLASSICAL CYTOGENETIC ANALYSIS[86]

Term	Abbreviation	Explanation
Centromere	cen	The junction of the short and long arms of a chromosome
Telomere	ter	The termination of the short or long arm of a chromosome, pter or qter
Long arm	q	The longer of the two arms of the chromosome that are joined at the centromere
Short arm	p	The shorter of the two arms of the chromosome that are joined at the centromere
Diploid		Having the full complement of 46 chromosomes, 44 paired autosomes, and two sex chromosomes in a cell or clone
Haploid		Having 23 chromosomes, a single copy of each autosome, and either an X or a Y chromosome in a cell or clone
Tetraploid		Having a total of 92 chromosomes, four of each autosome and four sex chromosomes in a cell or clone
Aneuploid		Having a chromosome number that is neither diploid nor a fraction or a multiple of the diploid number, in a cell or clone
Pseudodiploid		Having 46 chromosomes in a cell or clone but with either structural abnormalities or with loss and gain of different chromosomes so that not all chromosomes are paired
Hyperdiploid		The presence of more than 46 chromosomes in a cell or clone
Hypodiploid		The presence of fewer than 46 chromosomes in a cell or clone
Monosomy	− (a minus sign before the chromosome number, e.g. −7)	Loss of one of a pair of chromosomes
Trisomy	+ (a plus sign before the chromosome number, e.g. +13)	Gain of a chromosome so that there are three rather than two copies
Deletion	del or a minus sign after the number and the designation of the arm of a chromosome, e.g. del(20q) or 20q−	Loss of part of the long or the short arm of a chromosome
Translocation	t	Movement of a chromosomal segment or segments between two or more chromosomes; a translocation can be reciprocal or nonreciprocal
Reciprocal translocation		Exchange of segments between two or more chromosomes
Nonreciprocal translocation		Movement of a segment of a chromosome from one chromosome to another but without reciprocity
Balanced translocation		A translocation that occurs without loss of chromosomal material, or at least without loss of sufficient chromosomal material to be detectable by microscopic examination of chromosomes
Unbalanced translocation		A translocation that is associated with gain or loss of part of a chromosome
Inversion	inv	The inversion of a part of a chromosome, either pericentric or paracentric
Pericentric inversion		An inversion that follows breaking of both the long and short arms so that the part of the chromosome that is inverted includes the centromere
Paracentric inversion		An inversion that follows the occurrence of two breaks in either the long or the short arm of a chromosome so that the part of the chromosome that is inverted does not include the centromere
Insertion	ins	The insertion of a segment of one chromosome into another chromosome or into a different position on the same chromosomes. Can be direct or inverted
Isochromosome	i	A chromosome with two long arms or two short arms joined at the centromere, e.g. i(17q)
Derivative	der	A chromosome that is derived from another; a derivative chromosome derived from two or more chromosomes carries the number of the chromosome that contributed the centromere
Duplication	dup	The duplication of part of a chromosome
Clone		A population of cells derived from a single cell; in cytogenetic analysis a clone is considered to be present if two cells share the same structural abnormality or extra chromosome or if three cells have lost the same chromosome
Marker	mar	An abnormal chromosome of uncertain origin that 'marks' a clone
Constitutional	c	A chromosomal abnormality that is part of the constitution of an individual rather than being acquired, e.g. +21c in Down syndrome

2. Bone marrow cells
3. Blood cells
4. Cells isolated from lymph nodes or other organs suspected of being infiltrated by a lymphoid or other neoplasm
5. Cells isolated from serous effusions

In studying suspected haematological neoplasms, there are two reasons for seeking to detect constitutional abnormalities. First, there may be a constitutional abnormality underlying a haematological neoplasm as when megakaryoblastic leukaemia occurs in Down syndrome. Second, there may be an irrelevant and previously undetected constitutional chromosomal abnormality that has to be recognised so that it can be distinguished from an acquired chromosomal abnormality associated with a neoplastic process.

The indications for cytogenetic analysis in a definite or suspected haematological neoplasm are as follows:

- To provide evidence of clonality and permit a diagnosis of a neoplastic condition when this is not otherwise demonstrated (e.g. in some patients with eosinophilia or an increase in natural killer lymphocytes)
- To confirm a specific diagnosis (e.g. acute promyelocytic leukaemia and Burkitt lymphoma)
- To permit classification (e.g. to apply the World Health Organisation classification of acute myeloid leukaemia [AML] and the myelodysplastic syndromes [MDS])
- To give prognostic information (e.g. the detection of prognostically good hyperdiploidy in acute lymphoblastic leukaemia [ALL])
- To indicate which fusion genes are likely to be present and thus give information permitting detection of minimal residual disease by molecular analysis
- To distinguish a phenotypic switch occurring within a single clone from a therapy-related secondary leukaemia.
- To distinguish therapy-related acute leukaemia following alkylating agents from that following topoisomerase II–interactive drugs.

For investigation of haematological neoplasms, a bone marrow aspirate is usually the preferred tissue. It is also possible to disaggregate bone marrow cells from a trephine biopsy specimen into tissue culture medium. Peripheral blood may yield metaphases when large numbers of immature cells are present, but it is generally less reliable than the bone marrow in yielding dividing cells. In theory, any infiltrated tissue can provide cells that can be disaggregated and analysed. In haematological practice it is mainly lymph node cells that are studied, but clinically relevant information is sometimes obtained from other infiltrated tissues.

A bone marrow aspirate for cytogenetic analysis should be anticoagulated by the addition of preservative-free heparin or tissue culture medium containing heparin. Many laboratories provide referring clinics with prefilled collection tubes for this purpose. The specimen can be stored at room temperature for some hours or at 4°C if delay in analysis is expected, with the exception of samples from patients with suspected lymphoid malignancy, which should be stored at room temperature, since disease cells may rapidly die at low temperatures. If it is being sent to a central laboratory, detailed clinical and haematological information must accompany the sample so that the central laboratory is aware if there is clinical urgency in obtaining results and so that appropriate techniques are used.

Fluorescence *in situ* hybridisation. Fluorescence *in situ* hybridisation (FISH) bridges classical cytogenetic analysis and molecular diagnostic techniques. Chromosomes can be stained and visualised but the technique is also dependent on the recognition of specific DNA sequences by means of a fluorescent probe that can anneal to a specific DNA sequence. FISH can be carried out on metaphase preparations or on cells in interphase.

FISH probes may identify the following:

- Centromeres of a specific chromosome (useful for detecting trisomy or monosomy and chimaerism following sex-mismatched bone marrow transplantation; Fig. 8-7, *A*)
- Specific oncogenes (locus-specific probe, useful for detecting translocations; Fig. 8-7, *B, C*)
- Specific tumour-suppressor genes (locus-specific probe, loss is relevant to tumour progression)
- Other diagnostically useful genes (locus-specific probe, for example, for the *CHIC2* gene, which is lost when an interstitial deletion leads to formation of a *FIP1L1-PDGFRA* fusion gene)
- Whole chromosomes (whole chromosome painting, useful in identifying complex chromosomal rearrangements).

Advantages of FISH analysis in comparison with conventional chromosomal analysis include the following:

- Many more cells can be examined (useful for detecting residual disease)
- Metaphases are not essential, so abnormalities can be detected in non-dividing cells (useful in chronic lymphocytic leukaemia, in which cells rarely divide in culture)
- FISH can be performed in a shorter period of time (may be critical in rapidly confirming a diagnosis of acute promyelocytic leukaemia)
- Abnormalities that are too subtle to be detected by conventional cytogenetic analysis may be detected (e.g. *STIL-TAL* fusion in T-lineage ALL or t(12;21)(p12;q22) in B-lineage ALL)

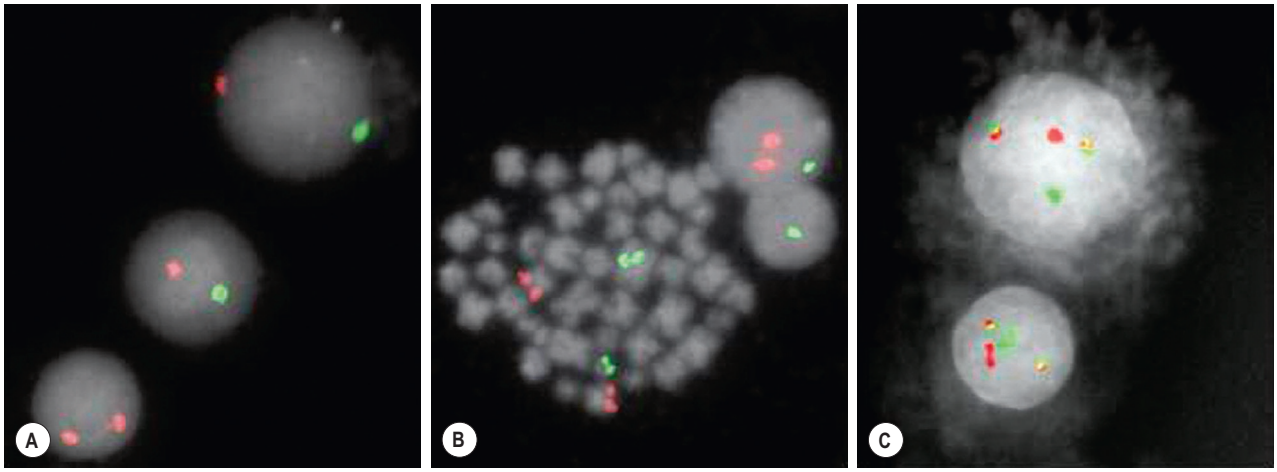

FIGURE 8-7 Fluorescence *in situ* hybridisation (FISH). A, Use of the X/Y dual-label Vysis probe (www.abbottmolecular.com) in a sex-mismatched bone marrow transplant patient. Two interphases show 1 red signal (X chromosome) and 1 green signal (Y chromosome) indicating male cells, whereas one interphase shows 2 red signals (X chromosomes) indicating a female cell. **B,** Use of the *BCR/ABL* dual-colour, dual-fusion translocation probe (www.abbottmolecular.com). One metaphase and one interphase cell show 2 red signals (from the *ABL1* gene locus on chromosome 9) and 2 green signals (from the *BCR* gene locus on chromosome 22). These cells are therefore negative for the *BCR-ABL1* fusion gene. **C,** Use of the *BCR-ABL1* dual-colour, dual-fusion translocation probe (www.abbottmolecular.com). Interphase cells show 2 red/green fusion signals (from the *BCR-ABL1* fusion on chromosome 22 and the *ABL1-BCR* fusion on chromosome 9), 1 red signal (*ABL1* gene locus on chromosome 9), and 1 green signal (*BCR* gene locus on chromosome 22). This sample is therefore positive for the *BCR-ABL1* fusion gene. *(Courtesy J. Howard.)*

The main disadvantage is that only those abnormalities that are specifically sought will be found, whereas conventional cytogenetic analysis permits all chromosomes to be evaluated.

Translocations, molecular analysis and minimal residual disease

The accurate characterisation of haematological malignancies at the chromosomal and molecular level has advanced greatly over the last decade or so and now makes an important contribution to initial treatment decisions. For example, many patients with acute leukaemia, chronic myeloid leukaemia and lymphomas have specific chromosomal and/or molecular lesions known to be associated with favourable or unfavourable prognoses and the proportion of such patients with defined genetic lesions is increasing. The presence of a specific genetic abnormality may indicate the need for specific treatment (e.g. all-*trans*-retinoic acid [ATRA] or As_2O_3 when *PML–RARA* is detected or the use of a tyrosine kinase inhibitor when *BCR-ABL1* is detected). Evidence of a recurrent translocation by microscopic analysis is usually indicative of the presence of a particular gene fusion but in some cases, such as cryptic translocations, and for residual disease monitoring, molecular techniques may be more informative.

Chronic myeloid leukaemia (CML)

The Philadelphia (Ph) chromosome resulting from the t(9;22) translocation is detectable in 95% of cases of CML by routine cytogenetic studies but the abnormality is sub-microscopic in the remaining 5%. In all cases its presence can be confirmed by detection of the *BCR-ABL1* fusion gene, by FISH, or by detection of its transcript by RT-PCR. The Ph chromosome is also be found in *c.* 25% and 5% of adult and childhood ALL, respectively,[26] where it is associated with relatively poorer prognosis and indicates the need to include a tyrosine kinase inhibitor (TKI) in addition to standard chemotherapy. Patients suspected of having CML or another myeloproliferative neoplasm should be tested for *BCR-ABL1* for definitive diagnosis. To optimise clinical management, patients with ALL should also be tested for *BCR-ABL1*.

Follicular and mantle cell lymphomas

Small cleaved lymphoid cells are observed in a number of conditions with different treatments and prognoses. In such cases, detection of a translocation involving *BCL1* is indicative of mantle cell lymphoma with t(11;14)(q13;q32), whereas identification of *BCL2* involvement implies a follicular lymphoma with t(14;18)(q32;q21).[27] The former is much more aggressive with poor prognosis, thus requiring a more intensive treatment. Translocations associated with lymphomas usually lead to the deregulation of a normal gene – for example, t(14;18) places the *BCL2* gene adjacent to the *IGH* gene, leading to deregulation of the former. In contrast, the leukaemia-associated translocations often give rise to a chimaeric gene that is transcribed, for example, t(15;17), which yields a novel *PML-RARA* fusion gene.[28]

Frequently, the locations of the genomic breakpoints of a translocation are variable, occurring within intronic or intergenic regions that are too large to allow direct

amplification of DNA by PCR with a common set of primers. In such cases, the mRNA from the fusion gene can be reverse transcribed using RT to yield complementary DNA (cDNA), which can then be amplified by PCR. A fusion gene can be more readily demonstrated by RT-PCR because exon-to-exon junctions are often highly consistent and thus amenable to amplification using a common pair of PCR primers. In addition, when used quantitatively, RT-PCR is an exquisitely sensitive tool that has been exploited in the detection of residual disease.[29] We will illustrate this in the analysis of the *BCR-ABL1* fusion gene, and describe in outline the analysis of other translocations below.

BCR-ABL1 reverse transcriptase-polymerase chain reaction

Principle. *BCR-ABL1* screening analysis is typically performed by two-stage RT-PCR. The RNA extracted from nucleated cells is reverse transcribed by RT using random hexamer (6 bp) primers to generate cDNA (first strand synthesis). This cDNA can then be used in a multiplex PCR reaction, to test for the presence or absence of the *BCR-ABL1* fusion transcript.[30] Multiplex PCR is similar to conventional PCR, but includes more than one pair of primers in a single PCR reaction, and this strategy enables the detection of the majority of the *BCR-ABL1* transcripts. The most commonly observed transcripts are e14a2 (b3a2), e13a2 (b2a2) and e1a2, giving rise to 385, 310 and 481 bp amplicons, respectively (Fig. 8-8).

In addition to *BCR-ABL1*, the normal *BCR* gene is co-amplified, yielding an 808 bp amplicon. The co-amplification of *BCR* is an indication of the quality of RNA and the efficiency of cDNA synthesis. Absence of this fragment indicates failure of the procedure. The latter is often the result of an aged sample (i.e. sample processed more than 72 hours from when it was taken). For RT-PCR analysis, the sample should be processed to lysate stage (see below) ideally within 24 hours but no later than 72 hours – this is to avoid false-negative results due to RNA degradation. It should be noted that the *BCR* fragment may not observed in diagnostic samples where the smaller *BCR-ABL1* transcript, present at very high levels, is preferentially amplified.

Methodology

Reagents

- *×10 concentrated red cell lysis buffer (RCLB).* For 3 l, weigh 248.7 g of NH_4Cl (1.55 mol/l), 30.03 g of $KHCO_3$ (0.1 mol/l). Add 6 ml of 0.5 mol/l EDTA (0.1 mmol/l), pH 7.4, make up to 3 l with sterile water and store at 4 °C.
- *RCLB.* Make 500 ml of ×10 RCLB up to 5 l with sterile water and cool to 4 °C. Adjust the working solution pH to 7.4 with HCl, and store at 4 °C.
- *1 mol/l citrate, pH 7.0.* Neutralise 1 mol/l trisodium citrate with 1 mol/l citric acid.
- *Sodium acetate.* 3 mol/l sodium acetate is adjusted to pH 5.2 with glacial acetic acid.

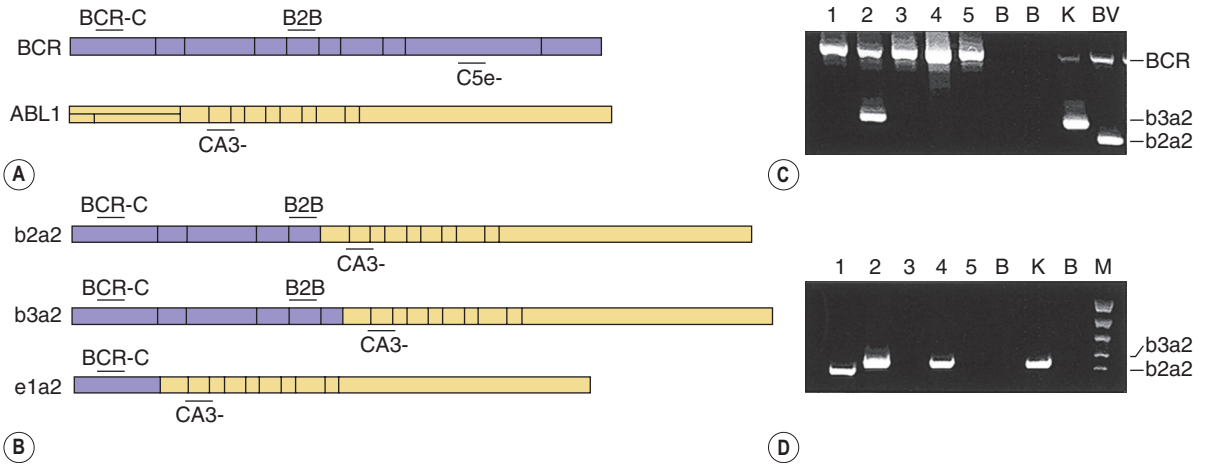

FIGURE 8-8 Detection of minimal residual disease in chronic myeloid leukaemia (CML) by reverse transcriptase-polymerase chain reaction (RT-PCR). A, Diagrammatic representation of the processed exons of the *BCR* and *ABL1* genes together with the relative position of the B2B and C5e primers used to co-amplify *BCR* in the multiplex PCR. **B,** Commonly observed *BCR-ABL1* derivatives, b2a2 and b3a2 which give rise to p210 *BCR-ABL1,* and e1a2, which gives rise to p190 *BCR-ABL1.* The relative positions of the primers used to amplify the chimaeric transcripts by multiplex PCR are shown. **C,** A 2.0% agarose gel containing ethidium bromide through which amplicons generated by multiplex PCR using complementary DNA (cDNA) from 5 patients (lanes 1–5) were electrophoresed. The co-amplified normal *BCR* fragment, 808 bp in length, is seen in all samples except for the lanes containing the blank controls (*B*). The diagnostic sample from a patient with suspected CML, in lane 2, revealed a fragment corresponding to the b3a2 *BCR-ABL1* transcript, 385 bp in length, in addition to the *BCR* amplicon. *BCR-ABL1* is not detectable in lanes 1, 3, 4 and 5 containing follow-up samples from patients following stem cell transplant (SCT). **D,** The cDNA of these individuals was subjected to nested PCR to exclude residual disease. This reveals *BCR-ABL1* transcripts, e14a2 (385 bp) and e13a2 (310 bp) in lanes 1 and 4, previously undetectable by the less sensitive multiplex PCR. However, *BCR-ABL1* is not detectable in lanes 3 and 5, implying these samples are from patients in molecular remission post-SCT. *B,* Blank controls; *K (K562-b3a2)* and *BV (BV173-b2a2),* positive controls; *M,* molecular size marker.

- *Guanidinium thiocyanate (GTC)*. Because GTC is highly toxic, it is advisable to use the entire amount as purchased from the manufacturer, rather than weighing a required amount. Thus, with 1 kg of GTC add 21.15 ml of 0.5 mol/l EDTA (5.0 mmol/l), pH 8.0, 52.87 ml of 1 mol/l citrate, pH 7.0, 35.25 ml of 30% sarcosyl (0.5%) and make up to 2.1151 with sterile water. Store this solution in 50-ml aliquots. Add 7.1 µl of β mercapto-ethanol per ml of GTC immediately before use.

Methods

Nuclear lysate preparation

1. Either blood or a bone marrow aspirate can be analysed for minimal residual disease (MRD) in CML, although bone marrow aspirates are preferred for ALL MRD studies. Centrifuge the anticoagulated peripheral blood sample at 700 *g* for 15 min. Bone marrow aspirates can be dealt with in the same way as buffy coats by proceeding directly to step 4.
2. Carefully remove and discard the plasma, taking care not to disturb the buffy coat.
3. Using a sterile plastic Pasteur pipette, collect the buffy coat and transfer it to a 50-ml polypropylene tube. It is not necessary to collect all of the buffy coat layer if the white cell count is $>50 \times 10^9$/l.
4. To lyse the contaminating red cells, resuspend the buffy coat in ice-cold RCLB to a final volume of 50 ml, and vortex for a few seconds. The suspension is then incubated on wet ice for 10 min, inverting the tube occasionally.
5. Centrifuge again at 700 *g* for 10 min and discard the supernatant by inverting the tube, taking care not to lose the nuclear pellet.
6. Repeat steps 4 and 5 until the nuclear pellet is void of pink-red colour. Usually two washes with RCLB are sufficient.
7. Wash the nuclear pellet once with 20–30 ml of phosphate-buffered saline (PBS) by centrifuging at 700 *g* for 10 min.
8. Resuspend the nuclear pellet in 1–2 ml of GTC containing β mercapto-ethanol. Homogenise the suspension by passing it through a 2-ml syringe and 21G needle repeatedly until it loses its viscosity (i.e. the DNA is degraded). In some cases, it may be necessary to add more GTC.
9. The lysate can now be stored at −20 to −70 °C for several years.

RNA extraction. There are several protocols, including commercially available kits, yielding RNA of varying qualities. Qiagen extraction columns are used in our laboratory. The following protocol can easily be applied in a clinical laboratory.

1. Add 50 µl of 2 M NaOAc, pH 4.0, to 500 µl of GTC lysate in a 1.5-ml microcentrifuge tube and vortex briefly.
2. Add 500 µl of un-neutralised water-saturated phenol and 100 µl of chloroform. Vortex the mixture for 10 s and transfer to wet ice for 20 min.
3. Centrifuge at 13,000 rpm in a microfuge for 30 min at 4 °C.
4. After centrifugation, two distinct layers should be clearly discernible; if not, add a further 50 µl of chloroform. Vortex for 10 s and centrifuge again for 30 min at 4 °C. Transfer the upper aqueous layer to another 1.5-ml microcentrifuge tube, taking care not to disturb the interface.
5. Add an equal volume of propan-2-ol (isopropanol), cap the tube, mix by inverting, and incubate at −20 °C for 2 h or overnight.
6. Microcentrifuge for 30 min at 4 °C and discard the supernatant, taking care not to lose the pellet, which may be hard to see.
7. Wash the pellet in 1 ml of 80% ethanol. Do not mix. Centrifuge directly for 30 min at 4 °C, and discard the supernatant. Recentrifuge briefly to collect the residual ethanol and discard using a micropipette.
8. Air-dry the pellet for 10 min and reconstitute in 20–40 µl of sterile water. The RNA must be stored at −70 °C. However, immediate reverse transcription is the preferred option.

cDNA synthesis

Solutions for the complementary DNA mix

- For 5 mg/ml random hexamer primers: reconstitute 50 u of pdN_6 (Life Technology, www.thermofisher.com; catalogue number N8080127) with 539 µl of sterile water and add 21 µl of 0.5 mol/l KCl.
- 5′ RT-buffer (usually supplied) with M-MLV reverse transcriptase (RT): 0.25 mol/l Tris-HCl, pH 8.3, 0.375 mmol/l KCl, 15 mmol/l $MgCl_2$.
- 25 mM dNTP stock: Mix an equal volume of ultrapure 100 mmol/l dATP, dCTP, dGTP and dTTP; 0.1 M dithiothreitol (DTT), which is usually supplied with M-MLV RT.
- cDNA mix: To 428 µl of 5′ RT-buffer, add 21.5 µl of DTT, 85.5 µl of 25 mmol/l dNTPs, and 45 µl of 5 mg/ml random hexamers; make up to 1000 µl with sterile water.

The compositions for the multiplex and nested PCR mixes are given in Table 8-3, including the optimum $MgCl_2$ concentration for each mix as well as the primers used in the different PCR reactions.

Procedure

1. Incubate 19 µl of RNA in a 1.5-ml microcentrifuge tube (approximately 20 µg) at 65 °C for 10 min. This is to denature the RNA, which readily forms secondary structures reducing the efficiency of the reverse transcriptase. Centrifuge at 12,000 *g* briefly to collect the condensation to the bottom of the tube. Transfer the tube to wet ice.

TABLE 8-3

COMPOSITION OF PCR MIXES USED IN THE AMPLIFICATION OF BCR-ABL1[89]

	Multiplex PCR	Nested PCR			
		p210		p190	
		1st step	2nd Step	1st step	2nd Step
PCR buffer (×10)	1.2×	1.25×	1.0×	1.25×	1.0×
$MgCl_2$ (mmol/l)	1.8	3.125	1.75	2.25	1.75
dNTP (μmol/l)	240	250	200	250	200
Primer 1 (μmol/l)	C5e− (0.6)	NB1+ (0.625)	CA3− (0.5)	BCR 1+ (0.625)	CA3− (0.5)
Primer 2 (μmol/l)	CA3− (0.6)	Abl3− (0.625)	B2A (0.5)	Ab13− (0.625)	E1N+ (0.5)
Primer 3 (μmol/l)	B2B (0.6)				
Primer 4 (μmol/l)	BCR-C (0.6)				

Primer sequences are as follows:
BCR1+: 5′ GAACTCGCAACAGTCCTTCGAC 3′
BCR-C: 5′ ACCGCATGTTCCGGGACAAAAG 3′
*C5e−: 5′ ataggaTCCTTTGCAACCGGGTCTGAA 3′
NB1+: 5′ GAGCGTGCAGAGTGGAGGGAGAACA 3′
Ab13−: 5′ GGTACCAGGAGTGTTTCTCCAGACTG 3′
B2A: 5′ TTCAGAAGCTTCTCCCTGACAT 3′
CA3−: 5′ TGTTCACTGGCGTGATGTAGTTGCTTGG 3′
E1N+: 5′ AGATCTGGCCCAACGATGACGA 3′

PCR, polymerase chain reaction.
*Lower case letters represent changes introduced to create restriction enzyme site.

2. On the wet ice, add 21 μl of cDNA mix containing 300 u of M-MLV RT and 30 u of RNA inhibitor (RNasin; www.promega.co.uk; catalogue N2611).
3. Incubate the mixture at 37 °C for 2 h. When using gene-specific primers in this reaction, the temperature should be increased to 42 °C.
4. Terminate the reaction by incubating the mixture at 65 °C for 10 min. cDNA can be stored at −20 °C.

Multiplex PCR

Add 2 μl of cDNA to 20 μl of multiplex PCR mix (see Table 8-4; add 0.5 u of Taq polymerase). Overlay with 1 drop of mineral oil and amplify using conditions as standard PCR amplification except that the annealing temperature is set at 68 °C. Carry out electrophoresis on the PCR products through 2.0% agarose gel containing SYBR Green staining and visualise on an ultraviolet transilluminator.

Real-time quantitative PCR (RQ-PCR) for *BCR-ABL1*

Reagents

- ×2 *Universal master mix*. The ×2 Universal master mix contains dATP, dCTP, dGTP and dTTP at 200 μmol/l each, 5.5 mmol/1 $MgCl_2$, and 0.025 μmol/l AmpliTaq-Gold. It also contains the passive background reference dye ROX (6-carboxy-X-rhodamine) (www.sigmaaldrich.com). The Universal master mix can be purchased with or without uracil DNA glycosylase, which degrades

TABLE 8-4

25-μl RQ-PCR ASSAY[90]

Stock Solution	Concentration	Volume (μl)	Volume (μl, 110 Reactions)	Working Concentration
Universal Master Mix	×2	12.5	1375	×1
Forward primer	80 μmol/l	0.094	10.31	300 nmol/l
Reverse primer	189 μmol/l	0.04	4.37	300 nmol/l
Dual-labelled probe	20 μmol/l	0.125	13.75	100 nmol/l

Sterile water	—	7.24	796.6	—

RQ-PCR, real-time quantitative polymerase chain reaction.

any contaminating products prior to starting the PCR by heating the plate to 95 °C for 10 min (see below). It is possible to assemble master mixes by purchasing various components, such as dNTP, buffer, $MgCl_2$ and hot-start *Taq* DNA polymerase. However, in-house preparation of master mixes is not recommended to minimise intra-assay and inter-assay variation and contamination, essential for monitoring patients' response to therapy.

- *Probe-primer mix.* For convenience and to minimise inter-assay variation a bulk preparation of the RQ-PCR assay mix, containing the probes and primers at required concentration, minus the master mix, is recommended. The mixture is stored at −20 °C or −70 °C. This also avoids repeated freezing and thawing of probes and primers, which may affect the probe-primer integrity. Furthermore, the probe should not be left exposed for prolonged periods to direct sunlight because this leads to degradation. In general 300 nmol/l of each primer and 200 nmol/l of probe permit optimum RQ-PCR sensitivity; however, this should be determined for each assay by titrating one primer against the other. The optimum concentration of the primers is one that gives the lowest cycle threshold (Ct). Similarly; the optimum probe concentration is determined by varying the quantity of the probe. The quantity yielding the lowest Ct is the optimum probe concentration. The probe-primer mixture is then prepared using the determined optimum concentrations. The mixture can then be aliquotted into micro-centrifuge tubes for a required number of samples, allowing for standards and positive and negative controls. Furthermore, for MRD studies it is advisable to measure the target gene in replicates of three to minimise sampling error at low copy number values. Because the endogenous control gene copy number is expected to be relatively high, assays in duplicate will suffice. However, standards for the target gene should be performed in triplicate.
- *Designing probe and primers.* The probe and primers are typically designed using Primer Express Software (www.appliedbiosystems.com/absite/us/en/home/support/software-community/free-ab-software.html), although online alternatives exist, such as Primer 3 (www.thermofisher.com). Optimum design of probes and primers is critical to sensitivity of RQ-PCR. The probe is designed such that it has higher melting temperature (T_m) than the primers (typically 8–10 °C) and works optimally at default PCR conditions settings using the universal master mix. The probe should not have a guanine base at the 3′ end, and the number of guanine bases should be fewer than the number of cytosine bases. Furthermore, there should not be more than 4 guanine bases in tandem. Similar rules apply to design of primers. The annealing temperature of the probe should be 10 °C greater than that of the primers. It is essential to design probes and primers such that the assay is RNA specific. This is achieved by positioning the forward and reverse primers in separate exons or by placing either of the primers or the probe across a splice site.
- *Standard curve.* It is acceptable to report data as Cq (quantification threshold), with an increase of 3.32 being clinically significant, because this represents 1 log increase in *BCR-ABL1* copies; it takes 3.32 cycles for every log increase in amplicons. For clinical samples, however, it is essential to generate a standard curve from which unknowns can be calculated. The standard curve can be generated using serially diluted cDNA derived from a cell line expressing the target gene at high levels (e.g. K562 (www.sigmaaldrich.com) for *BCR-ABL1*). As an alternative to using cDNA, a plasmid can be used to create this curve, which provides stability over time. The method of preparation of the plasmid is beyond the scope of this book. Serially diluted plasmids for commonly occurring fusion genes and endogenous control genes are commercially available. In the absence of a standard curve, the MRD values are reported as a delta-delta Ct (ΔΔCt). This is calculated by first normalising the fusion gene Ct to the control gene (CtCG) to obtain a ΔCt for the follow-up samples – that is, the ΔCt (follow-up) = $Ct_{FG} - Ct_{CG}$. The same calculation is performed for the Ct value for the sample taken at diagnosis to obtain a ΔCt (diagnosis). The ΔCt (diagnosis) is then subtracted from the ΔCt (follow-up) to obtain a ΔΔCt. From this the MRD value is calculated as $10^{\Delta\Delta Ct/3.3}$. To apply the ΔΔCt method of reporting the slope and intercept, values for the control and fusion genes must be similar. More precisely, it is recommended that the slope values for the fusion and control gene should not differ by more than 0.01 (i.e. the PCR efficiency for control gene and fusion gene are similar). The major advantage of using ΔΔCt is it obviates the need for a standard curve. Therefore eliminating the need for a plasmid- or RNA-based standard curve reduces the risk of contamination further and frees microtitre plate wells for patient samples.
- *PCR cycling conditions.* It is convenient to design the probes and primers so that they are able to work efficiently using standard RQ-PCR conditions to amplify the cDNA, these being 2 min at 50 °C (to allow uracil DNA glycosylase-mediated elimination of exogenous PCR product contamination), an enzyme heat-activation step of 10 min at 95 °C, followed by 50 cycles of 15 s at 95 °C for denaturation and 1 min at 60 °C for annealing and extension.

Method. The RQ-PCR assay is typically performed in 96-well microtitre plates in a 25-µl final reaction volume containing universal master mix. The composition of a 25 µl of RQ-PCR reaction is shown in Table 8-4.

1. Dispense 20 µl of RQ-PCR mixture into the required number of microtitre wells. To minimise intersample differences an 8 channel automatic pipette is recommended to dispense the RQ-PCR assay mix. Note the location of each sample, including the standards and controls, on a grid map in which each of the 96 wells is represented.
2. Using the grid map, add 5 µl of the appropriate cDNA or standard to each well.
3. In the no template control (NTC) wells, genomic DNA is included in mRNA-based studies. Add HL60 (*BCR-ABL1*-negative cell line; www.sigmaaldrich.com) derived cDNA to the no amplification control wells for *BCR-ABL1* RQ-PCR assays because this cell line does not express this fusion gene.
4. Also included are cDNA derived from the *BCR-ABL1*+ K562 and BV-173 (www.dsmz.de) cell lines diluted to give a known number of copies.
5. On dispensing all the samples, secure the wells with optical caps or a film adhesive.
6. Centrifuge the plate for 2–3 seconds at 1000 revolutions per minute (rpm) to collect all the contents at the bottom of the wells and expel any trapped bubbles prior to placing it in the instrument.
7. Initiate the run according to the manufacturer's instructions, adjusting the sample volume and number of cycles accordingly. The plate is normally subjected to between 40 and 50 cycles.
8. On completion, assign the microtitre wells as per grid map and analyse the assay according to the manufacturer's instructions.

The instrument sets the threshold at ×10 the standard deviation of baseline emission; however, this can be reset manually within the exponential phase of the PCR to avoid any background fluorescence interference. Alternatively, the threshold can be set at the same value for each assay, for instance, at 0.05, assuming this is within the exponential phase of PCR, thus avoiding operator variation. The Ct threshold for positivity is set at the Y-intercept +1 Ct (typically around 40 cycles), as per Europe Against Cancer (EAC) recommendations.

The baseline limits are set by the instrument; however, this should be adjusted so that the upper limit of the baseline is 4 cycles less than the lowest Ct value for a sample. For example, if the lowest Ct is 20, then the upper baseline limit is set at 16, thus giving a clear margin between the baseline and the samples. The lower limit set by instrument rarely requires adjusting.

The standard curve is generated and accepted if the slope value is between −3.2 and −3.6. A slope value of −3.32 represents 100% PCR efficiency because it takes 3.32 cycles for every $\log_{10}$ increase in PCR products. Ideally the curve correlation coefficient should not be less than 0.98. If the standard curve is acceptable, then the copy number for the samples can be recorded. The RQ-PCR for the endogenous control gene is performed similarly using the appropriate probes and primers. On completion of RQ-PCR for target and endogenous control, the data are reported as a percentage ratio (i.e. [*BCR-ABL1/ABL1*] × 100).

Notes. To minimise sampling error, the target gene and the standards are assayed in triplicate. It is essential to include positive controls with a known number of transcripts. To minimise the risk of contamination, patients' samples and standards should be handled in geographically separate locations. Because RQ-PCR assays are *BCR-ABL1* transcript-type specific it is essential to perform a multiplex PCR on a presentation sample to assign the transcript type expressed by the patient. This ensures that correct RQ-PCR assay is used. An RQ-PCR assay designed for e13a2 or e14a2, would give rise to false-negative data in patients expressing e13a3 and/or e14a3. A single RQ-PCR for e13a2 and e14a2 is recommended rather than two separate assays. This is achieved by designing the assay such that the probe and reverse primer map to the second exon (i.e. a2) of the *ABL1* gene and the forward primer maps to the e13 exon (i.e. b2) of the *BCR* gene (see Fig. 8-9).

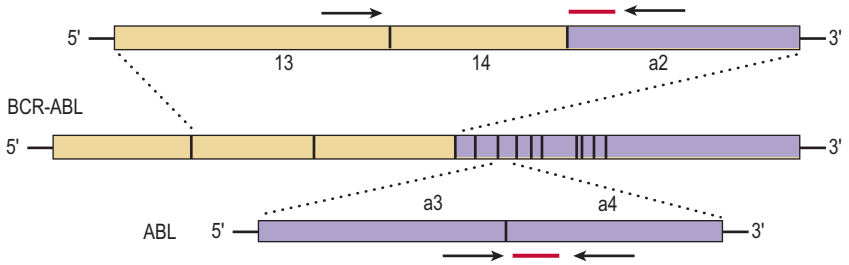

FIGURE 8-9 Probes and primers. The position of probes and primers used for quantification of *BCR-ABL1* and *ABL1* transcripts are shown. The *BCR-ABL1* fusion gene is shown in yellow- and purple-filled boxes, with the yellow representing the exons derived from the *BCR* gene and purple those originating from the *ABL1* gene. The dual-labelled probes are shown as red lines, and primers are shown as arrows. Probes and primers were designed using the Primer Express software to detect e13a2 and e14a2 junctions in a single reaction by RQ-PCR. The *BCR-ABL1* (FAM-CCCTTCAGCGGCCAGTAGCATCTGA-TAMRA) and *ABL1* (FAM-CCATTTTTGGTTTGGGCTTCACACCATT-TAMRA) probes are dual labelled with 6-carboxyfluorescein (FAM) and 6-carboxy-tetramethyl-rhodamine (TAMRA). *BCR-ABL1* forward primer: 5′-TCCGCTGACCATCAAYAAGGA-3′; *BCR-ABL1* reverse primer: 5′- CACTCAGACCCTGAGGCTCAA-3′; *ABL1* forward primer: 5′-TGGAGATAACACTCTAAGCATAACTAAAGGT-3′; *ABL1* reverse primer: 5′GATGTAGTTGCTTGGGACCCA-3′. Both probe and primer sets were designed by the Europe Against Cancer collaborative study.[51,52]

Apart from being cost effective and efficient, this increases the accuracy of the assay because a significant minority of patients with single nucleotide polymorphism in exon 13 of the *BCR* gene have the potential to express both e13a2 and e14a2 through alternative splicing.

Interpretation. If *BCR-ABL1* transcript is undetectable by multiplex PCR when a sample is first tested in the laboratory this may be because the patient does not have CML or because he or she is undergoing therapy. In the latter instance, the cDNA can be tested at a higher level of sensitivity by nested PCR, but this has now been almost entirely replaced by RQ-PCR.[31] Nested PCR enables the detection of at least 50–100 leukaemic cells in a background of up to 5×10^4 normal cells. However, this increased sensitivity comes with the added risk of false-positive results through contamination during the necessary manipulation of post-PCR materials and we rarely perform this analysis nowadays. Therefore we refer the reader to previous editions of this chapter or specific papers for further information.

Monitoring and minimal residual disease

Effective clinical management of haematological malignancies depends on accurate and precise measurement of a patient's response to therapeutic agents. This includes examination of cellular morphology in peripheral blood and marrow specimens. Although these studies are essential, they lack sensitivity and often the clinician is faced with a situation where the malignant clone has advanced to levels at which it is refractory to further treatment, before relapse is morphologically and clinically recognised; therefore a more sensitive technology is required.

The last three decades have seen remarkable advances in the development of technology to monitor patients' response to therapy to a sensitivity of 1 in 10^{-5} (i.e. the detection of one malignant cell in a background of 100,000 normal cells). To enable this, a disease-specific marker is essential, as illustrated by targeting the novel fusion gene *BCR-ABL1,* which maps to the Philadelphia chromosome associated with CML. The clinical utility of such studies has been amply confirmed by close and regular measurement of MRD in patients with CML, both in adult and childhood leukaemias, using disease-specific markers. The principal aim is to accurately determine disease levels at key time-points and longitudinally by monitoring MRD, both to detect early signs of relapse and to identify the attainment of deep molecular response.[32,33]

CML is often thought of as a model leukaemia, so it is fitting to use it to describe the principle and aims of MRD studies. Although qualitative PCR (i.e. multiplex and nested PCR as mentioned above) is very useful, it provides no information about the kinetics of the disease, which can only be obtained by quantification of *BCR-ABL1* mRNA transcript levels.

Because the amount of total RNA added to each first-strand synthesis reaction and its quality (i.e. the degree of degradation) are variable, the transcripts of an endogenous control gene are also quantified to normalise this variation in input. This is important, because the point at which the assay is quantitated (the quantification cycle or Cq) is a function of the amount of amplifiable target transcript in the reaction volume. There are a number of control genes that have been validated for use in haematological malignancies, with *ABL1, GUSB* and *B2M* being recommended.[34] An endogenous control gene should not be too highly expressed and should show no inter-sample variation in levels of expression. Also, it should not have pseudogenes that can be co-expressed or be affected by alternative splicing.[35]

Principle. RQ-PCR permits quantification of number of transcripts of the gene of interest at high levels of sensitivity. This is achieved by measuring in real-time the amplification of the target gene. Furthermore, because of the exponential nature of PCR, the rate of accumulation is proportional to the number of mRNA molecules of the target gene in the starting material during the exponential phase of the PCR. The accumulation of amplicons is detected by including a sequence-specific probe labelled with fluorophores in addition to the primers (Fig. 8-9). Since the advent of RQ-PCR several types of probes have been developed, although all are dependent on the fluorescence resonance energy transfer (FRET) principle. The most commonly used platform involves dual-labelled hydrolysis (TaqMan) probes. This technology exploits the inherent 5′ to 3′ exonuclease activity of the *Taq* DNA polymerase.[35] The *Taq* DNA polymerase cleaves a fluorescently labelled probe annealed to the target sequence during PCR amplification (Fig. 8-10, *A*). Briefly, the cDNA is synthesised from total RNA by first-strand synthesis and is added to the PCR reaction containing standard PCR components plus a probe that anneals to the template between the two primers. The probe has a fluorescent reporter dye, typically 6-FAM (6′-carboxyfluorescein; emission $\lambda_{max} = 518$ nm), at the 5′-end and a quencher moiety, typically TAMRA (6-carboxytetramethylrhodamine; emission $\lambda_{max} = 582$ nm) (www.thermofisher.com), or a non-fluorescent quencher, such as BHQ-1 (Black Hole 1) at the 3′ end. While the probe is intact, the proximity of the quencher greatly reduces the fluorescence emitted by the reporter dye through the effect of fluorescence resonance energy transfer.[36]

Thus, while TAMRA and FAM are attached to the probe, fluorescence from the reporter dye is quenched by TAMRA. During PCR, as the *Taq* DNA polymerase replicates the DNA strand to which the TaqMan probe is annealed, the probe is degraded by the intrinsic 5′- 3′ exonuclease activity of the polymerase. The effect is to dissociate FAM from TAMRA. Therefore FRET is no longer applicable and fluorescence from FAM can then be detected by the detector optics. Fluorescence increases, in each cycle, proportional to the rate of probe degradation. The early part of the cycling fluorescence signal (typically 3–15 cycles) is used to set the baseline to calibrate the later

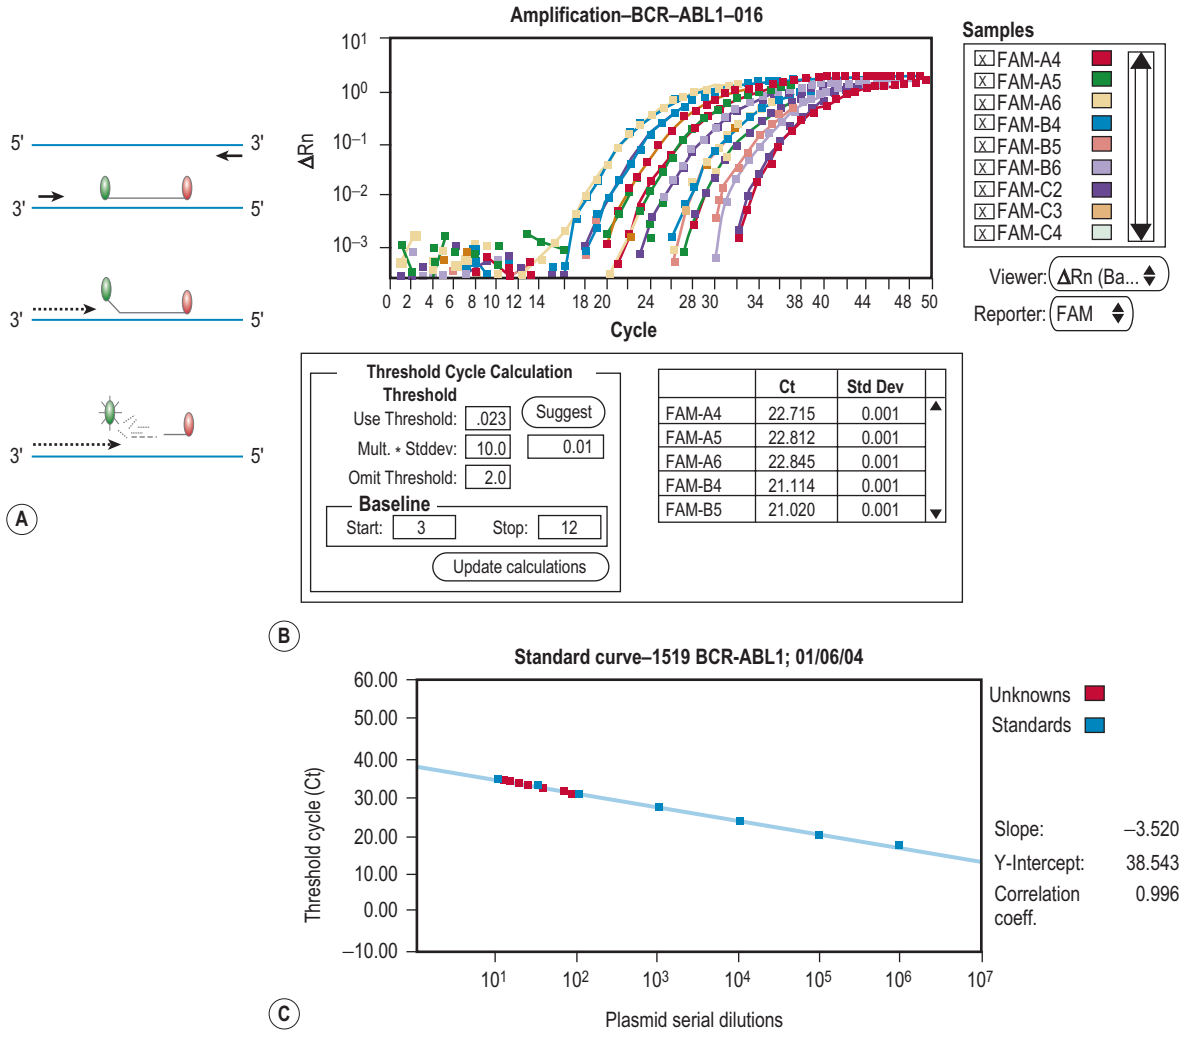

FIGURE 8-10 Reverse transcription quantitative polymerase chain reaction (RQ-PCR). A, Schematic representation of the principle of RQ-PCR. The forward and reverse primers *(blue lines)* are extended by the *Taq* DNA polymerase as in conventional PCR. The quencher *(red oval)* suppresses the fluorescence from the reporter *(green oval)* dye when the two are attached to the probe. As the forward primer is extended, the probe is displaced and is cleaved by the *Taq* DNA polymerase 5′–3′ exonuclease activity. Fluorescence is detected once the reporter dissociates from the quencher on the probe being degraded and the synthesis of the new DNA continues to completion. Therefore the fluorescence increases with increasing numbers of amplicons. **B,** Amplification plot. The RQ-PCR amplification plot of the standards in log increments is shown. A 0.5 log standard between 10 and 100 *BCR-ABL1* copies is included. The number of cycles for the fluorescence to cross the threshold is reported as Ct (cycle threshold). The greater the number of copies, the lower the Ct value (i.e. it is inversely proportional). **C,** A standard curve. A standard curve drawn from RQ-PCR data from serial dilutions of plasmid containing *BCR-ABL1 (blue squares)* is shown. The *BCR-ABL1* transcripts for the unknown samples *(red squares)* are read off the standard curve.

quantitative measurement. A threshold is set significantly above the baseline and typically in the central region of the log-linear phase of the amplification signal and it can be adjusted manually or automatically. A passive reference fluorophore, ROX, is optionally included in the RQ-PCR master mix (RQ-PCR mixes for non-ABI machines typically omit the ROX to free up channel bandwidth for multiplexing). This passive reference is used to normalise the interwell fluorescence signal to compensate for small changes in reaction volume through pipetting error or in background fluorescence. This normalised fluorescence is plotted as ΔRN against number of cycles.

The number of cycles taken to achieve this is called the quantification cycle (Cq) although, this is often given as Ct (for cycle threshold) or even Cp (crossing point) and it is inversely proportional to the starting material of the target. An estimate of the number of transcripts of the target gene is interpolated by means of a standard curve, derived from standards of a known quantity or dilution factor. The number of transcripts of the target

gene and endogenous control gene are measured from the respective standard curves. The level of expression of the target gene is reported as a percentage ratio to obtain a normalised value for the gene of interest independent of the integrity of the RNA and efficiency of the reverse transcription reaction.

Typically the gene of interest and the control gene (in the case of CML, *BCR-ABL1* and *ABL1,* respectively) are measured in separate reactions (most commonly as duplicates or triplicates either in different sections of the same PCR plate or in two separate plates). However, high throughput laboratories may choose to employ a duplex reaction, in which both genes are measured simultaneously in the same reaction. To achieve this, the *BCR-ABL1* and *ABL1* probes must be labelled with different fluorophores, such as 6-FAM (www.thermofisher.com) for the *BCR-ABL1* and VIC (www.biotechniques.com) for the *ABL1*. VIC emits at a longer wavelength than 6-FAM (max = 554 nM) and is detected by a different detector channel in the RQ-PCR machine, allowing simultaneous quantification and thus doubling the throughput, whilst halving the amount of RQ-PCR master mix needed.[37]

Interpretation. Patients who achieve complete cytogenetic remission may still harbour up to 1×10^{10} leukaemic cells. The kinetics of the leukaemic load in these patients and their response to therapeutic agents can only be monitored by measuring MRD[33] although it should be noted that patients in whom RQ-PCR fails to detect *BCR-ABL1* may still harbour up to 1×10^{6} leukaemic cells. *BCR-ABL1* RQ-PCR is the keystone to monitoring patients being treated with TKIs, such as imatinib. Early results from an international multicentre study indicated that a 3 log reduction in *BCR-ABL1* copies, particularly when achieved during the first 12 months of treatment, is indicative of a good prognosis.[32,33,38] More recently, it has been shown that the achievement of <10% *BCR-ABL1/ABL1* at 3 months from the start of TKI treatment correlated strongly with a favourable outcome.[32]

Throughout treatment, quantification of *BCR-ABL1* also helps to identify patients at risk of relapse and therefore provides a window for early clinical intervention with the aim of reversing disease progression. For patients who have undergone allogeneic stem cell transplantation this invariably means infusion of lymphocytes isolated from the original donor (donor lymphocyte infusion; DLI).

Although there is some debate as to the precise criteria for molecular relapse,[39] there is little doubt that a confirmed 1 log increase in *BCR-ABL1* transcripts (i.e. from 0.002–0.02%) is clinically significant. Patients who achieve a 0.02% *BCR-ABL1/ABL1* percentage on three consecutive occasions are said to be in molecular relapse. The converse is also true, with patients with a sustained molecular response now being eligible for TKI withdrawal, since 40% will experience a continued molecular response even in the absence of TKI.[40]

Advantages of quantitative PCR

The major advantage of RQ-PCR is the ability to detect accumulation of amplicons during the exponential phase of PCR. This permits quantification of the target of interest in the starting material. This is not possible with conventional PCR, because samples are analysed at the end of the PCR run and therefore any differences in the copy number between samples in the starting material are generally not discernible. This is illustrated by the amplification plot shown in Figure 8-10, *B,* where all the samples at the end of 50 cycles have the same level of fluorescence, despite having varying target copy numbers in the starting material as seen in the exponential phase of the PCR. Post-PCR handling is eliminated: on completion of an assay, the sealed micro-titre plate is discarded, thereby minimising risk of contamination. This also eliminates the need to handle stained gels on completion of a RQ-PCR assay. RQ-PCR offers higher level of specificity because, in addition to primers annealing to the DNA sequence of interest, a third oligonucleotide (the probe) anneals to the region between the primers with high stringency. Also, because the entire RQ-PCR workflow can be readily automated, inter-laboratory variation should be minimised. This permits rapid evaluation of new therapeutic modalities because methodology and protocols can be standardised, paving the way for international inter-laboratory studies.

Tyrosine kinase domain mutation analysis

Principle. Since the introduction of TKIs in the early 2000s the management of CML patients has been revolutionised and the vast majority of patients respond very effectively to any of the first (imatinib), second (dasatinib and nilotinib) or subsequent (bosutinib and ponatinib) generation TKIs. However, approximately 20–25% of patients lose the initial response or do not achieve optimal response, along the European LeukemiaNet (ELN) guidelines.[39] The mechanisms behind the loss of response are complex and to date the best explored are mutations in the tyrosine kinase domain of the *BCR-ABL1* gene. The best technology so far applied to the identification of such mutations is Sanger sequencing of the tyrosine kinase domain. The strategy of this sequencing involves the initial stage of amplification of the *BCR-ABL1* fusion gene using primers specific for *BCR* exon 13 and exon 10 of *ABL1* to make sure that only the leukaemia-specific fusion gene is targeted for analysis. This is followed by a nested amplification between exon 4 and exon 9 of the *ABL1* gene. The nested product is then purified and the chain termination approach (by Sanger sequencing) is used.

This protocol has been extensively detailed in a recent publication[41] to which we refer the reader.

Interpretation. Mutations in the tyrosine kinase domain (TKD) are a well-recognised mechanism of resistance to treatment with TKI. Mutation analysis is carried out at any stage during treatment when clinical evidence of resistance emerges. This is normally detected during molecular monitoring as a rise in the ratio of *BCR-ABL1* in patients who had previously responded (i.e. had achieved major molecular remission or even complete molecular remission). However, in our experience mutations of the TKD only account for 30% of all resistant patients, clearly indicating that other biological mechanisms can lead to a rise of *BCR-ABL1* load.

The lymphoproliferative disorders

The majority of lymphoproliferative disorders can be readily diagnosed using cytochemical and immunological techniques, as described in Chapters 15 and 16, supplemented when necessary by histology. However, in monitoring residual disease and in certain cases in which the diagnosis is uncertain, genetic techniques may be useful.[42–46] Examples include cases of ambiguous lineage, lymphomas in which there is no clear histological diagnosis, and occult lymphomas. DNA analysis may also help in determining whether a lymphocytosis is monoclonal, oligoclonal or polyclonal. Translocations do occur in these disorders and may be used in monitoring disease, as described for CML earlier. However, the most commonly used markers, because they are more universally applicable, are the rearranged immunoglobulin and T-cell receptor (*TCR*) genes.

Principle. This analysis is possible because the immunoglobulin and *TCR* genes undergo a rearrangement during the normal differentiation of B and T lymphocytes, respectively, but not during differentiation of other cells. This rearrangement results in a unique fusion of variable, diversity and joining (VDJ) segments, interdigitated by random nucleotide (N region) insertion or deletion. The sequence and length of the DNA at these sites of recombination are therefore characteristic of a particular lymphocyte clone.

For many years, Southern blot analysis was the gold standard for the detection of rearranged immunoglobulin and *TCR* genes. For details on how this was performed and interpreted, we refer the reader to previous editions of this book. More recently, because of its simplicity, the small amount of DNA required and much increased sensitivity, PCR has been used to detect rearrangement of the immunoglobulin and *TCR* genes. Because of the N region diversity, a polyclonal population of cells will give rise to a ladder of various fragment sizes. However, if one clone becomes predominant, a discrete fragment size will begin to dominate the products of the PCR – the basis of the so-called fingerprinting method for the diagnosis of lymphoproliferative disorders.[43] This analysis can be refined using heteroduplex analysis or SSCP gels in which the sequence as well as the size of the amplified product determines its mobility. To gain further sensitivity in following disease, the product of a 'clonal' amplification can be sequenced to derive a clone-specific sequence at the site of rearrangement. This sequence can then be used for the design of clone-specific oligonucleotide probes or primers that can be used in ASOH, ARMS, or RQ-PCR. This methodology has been used to monitor MRD in lymphoproliferative disorders.[42–46]

A comprehensive report has been published on the design and standardisation of PCR primers and protocols for the detection of immunoglobulin and *TCR* gene rearrangements.[42,45] The detection rate of clonal rearrangements is very high, but the comprehensive nature of the test requires 107 primer pairs in 18 multiplex PCR tubes, which are now commercially available. The methods described here are more restricted but more widely applicable. There is at present extensive effort being made by applying next generation sequencing both for the detection of the clonal markers as for the molecular monitoring of residual disease, but its complexity precludes wide application at this time.

Methodology

Immunoglobulin gene rearrangement. To study immunoglobulin gene rearrangement, the locus of choice is the heavy chain locus, *IGH*. A single primer can be used, which will anneal to a consensus sequence shared by all joining (JH) segments. The choice of variable (VH) segment primers is more difficult and for the more comprehensive analysis, primers from all three framework regions for each of the six or seven VH families are used.[43] A reasonable starting point, however, is to use the JH primer in conjunction with a different primer derived from a consensus sequence of the framework 1 region for each VH family. These primers are as follows:

JH 5′ ACCTGAGGAGACGGTGACCAGGGT 3′
VH1 5′ CCTCAGTGAAGGTCTCCTGCAAGG 3′
VH2 5′ GAGTCTGGTCCTGCGCTGGTGAAA 3′
VH3 5′ GGTCCCTGAGACTCTCCTGTGCA 3′
VH4 5′ TTCGGA(GC)ACCCTGTCCCTCACCT 3′
VH5 5′ AGGTGAAAAAGCCCGGGGAGTCT 3′
VH6 5′ CCTGTGCCATCTCCGGGGACAGTG 3′

PCR buffer I (see p. 128) is used in these reactions, with an annealing temperature of 60 °C. The products of the reactions are in the order of 310–350 bp and can be visualised as either a smear or as discrete bands in high percentage agarose gels (1.5–2%). However, better resolution is obtained when the products are resolved by capillary electrophoresis on an automated fragment analyser (e.g. the *ABI 3130xl DNA Analyser,* www.appliedbiosystems.com). Fragments are visualised by attaching a fluorescent label to the JH primer or different fluorochromes to the VH primers and reading the peaks of fluorescence as a 'GeneScan'. Alternatively, the PCR products can be subjected to heteroduplex analysis, denaturing them at 95 °C for 5 min and

annealing at 5 °C for 1 h, prior to electrophoresis in a non-denaturing 6% polyacrylamide gel.

InVivoscribe (www.invivoscribe.com) provides an extensive range of primer combinations for all *IGH, IGK* and *IGL* gene rearrangement analysis for gene scanning technology and although the reagents are rather expensive they provide a validated method which is easily applied in many routine laboratories and which is therefore highly recommended.

Interpretation. Because of the variable number of nucleotides either removed or added at the point of joining of VDJ segments of the *IGH* locus, the distance between V segment and J segment primers will alter accordingly. For the gene to be functional, the reading frame must be maintained, and therefore variations in length must be in multiples of 3 bp, although this may not always be the case in acute leukaemias where non-productive rearrangements may occur. The polyclonal population of B cells therefore gives rise to a characteristic 'ladder' or Gaussian size distribution, with maximal intensity observed at the median length at its centre. However, if one B-cell clone is abnormally large, it will give rise to a disproportionately intense peak at the size (and using a V primer from the appropriate family) corresponding to the length of VDJ fragment derived from that clone. At presentation of a B-cell malignancy, this band may be the only one visible, confirming the presence of an abnormal B-cell clone. Subsequently, an abnormal intensity of this fragment size in the background of a ladder can be used to monitor the disease.

In heteroduplex analysis, the polyclonal population of B cells will give rise to fragments with many different sequences, which, on denaturing and reannealing, will generate heteroduplexes that will appear as a smear spreading across the gel. If one large B-cell clone is present, however, homoduplexes will form and these will migrate as a discrete fragment with a migration consistent with its size alone.

There are two main problems that can be encountered in this analysis. The first is that the consensus V primers may not amplify all V segments because of mutations in the sequence of the region recognised by the primers (either J, V or both). To overcome this problem, primers for the leader region of the V gene and for the constant region of the heavy chain identified by immunofluorescence on the surface of cells of the B-cell clone may be used on cDNA. The distance between the leader primers and the constant regions may be too large for DNA amplification. It is therefore paramount that in patients with chronic lymphocytic leukaemia (CLL), B-cell lymphomas and myeloma, RNA is also stored from diagnostic samples in case this approach is required. However, it is also important that diagnostic material is appropriately referred for analysis. For instance, lymph nodes in case of lymphomas, a bone marrow (BM) aspirate in case of myeloma and peripheral blood (PB) in the case of confirmed CLL. In lymphoma, PB and BM samples may be totally 'empty' of disease and in this case they are not suitable for this type of investigation.

Another problem encountered especially in ALL is the evolution of a B-cell clone or the emergence of other subclones during the course of the disease that may result in a change in the fragment size and family.

T-cell receptor gene rearrangement

The first choice of locus for PCR analysis for *TCR* gene rearrangement is the *TCR* gamma locus as it is rearranged in the vast majority of T-cell clones and does not have the complexity of the *TCR* β locus, which has 24 different V segment families. Amplification of DNA around the joining region of the *TCR* gamma gene is performed in a similar way to that described above earlier for the *IGH* locus, using a consensus primer for the joining segment (JγC) and one for each of the four variable segment families (Vγ1–4).[47] Primer sequences are as follows:

JγC: 5′ CAACAAGTGTTGTTCCAC 3′
Vγ1: 5′ TGCAGCCAGTCAGAAATCTTCC 3′
Vγ2: 5′ TGCAGGTCACCTAGAGCAACCT 3′
Vγ3: 5′ AGCAGTTCCAGCTATCCATTTCC 3′
Vγ4: 5′ TGCAATTGCACTTGGGCAGTTG 3′

Standard PCR amplification conditions can be employed using these primer combinations, and analysis is again performed on acrylamide gels or an automated fluorescence analyser.

Interpretation. As in the analysis of the *IGH* locus, discrete bands of amplified product are obtained from clonal T-cell populations, whereas smears are obtained from polyclonal populations. The main problem with the interpretation of these kinds of data is that because the number of V segments is so small, it does not distinguish reactive T-cell clones from malignant T-cell clones. Three different patterns are clearly distinguished: a large malignant clonal population, an oligoclonal population and a polyclonal population. Because of the sensitivity of this method, problems can arise in trying to detect a small malignant clone against a polyclonal population compared with a clonal population stimulated by antigen, particularly when a patient is lymphopenic.

Immunoglobulin and T-cell receptor gene rearrangements as targets for minimal residual disease analysis

Patients with ALL can carry a burden of up to 10^{12} lymphoblasts at presentation. Chemotherapy achieves complete remission (CR), as defined morphologically, within 1 month in the majority of children (>95%) and adults (>70%). Currently, the first aim of all post-induction treatment regimens is to achieve and sustain continuous complete remission (CCR). At five years, 70% of children and 35% of adults survive. Improvement in survival in

adults is modest, especially in older patients, with up to 65% relapsing mainly in the first five years. Disease undetected by light microscopy (up to 10^{10} leukemic cells) may expand at any time, leading to relapse.

Interpretation. The value of detecting residual disease with greater sensitivity than light microscopy, using molecular or immunological techniques, has been extensively evaluated in childhood and adult ALL. Minimal residual disease is defined as the 'lowest level of disease detectable in patients in CR by the methods available'. The newly developed RQ-PCR techniques have revolutionised MRD investigation and patient management. The methodology makes use of the information derived from the cloning and sequencing of the rearranged clonal leukemic cells and the generation of an allele-specific primer able to identify the unique rearrangement belonging to the leukaemic cell with a sensitivity of 1 in 100,000 normal cells. Guidelines for the interpretation of RQ-PCR data in the analysis of MRD by immunoglobulin/*TCR* gene rearrangement have been generated by a European study group.[42,45] These are currently being followed and applied in a large study at international level and we refer the reader to the relevant publication[48,49] for further information.

In brief, these studies in children have concluded that conversion to MRD negativity shortly after induction therapy and maintenance of MRD negativity are prerequisites for long-term disease-free survival, and that MRD-positivity often precedes clinical relapse.[44] In adults also, MRD analysis carried out during induction therapy provides a strong predictor of outcome[45,46] and should also be applied to harvested BM[45,47] to exclude patients with detectable leukaemia burden of more than $1{:}10^3$ normal cells. Finally, predictions of outcome based on MRD analysis in children and adults are more accurate than predictions based on other prognostic indicators, such as age, gender, immunophenotype, presenting WBC count, karyotype and time taken to achieve first CR.[44–50]

Extensive work using fusion genes to monitor MRD in both adults and children has also been described and can be applied in the absence of sufficiently sensitive *IGH* or *TCR* markers when the translocation is identified at diagnosis[51,52] and will be further discussed below.

Myeloproliferative neoplasms

JAK2 mutation analysis

In 2005 several groups independently identified a unique mutation in the JAK homology 2 (JH2) pseudokinase domain of the Janus kinase 2 (*JAK2*) gene in patients with a variety of myeloproliferative neoplasms (MPNs) including polycythaemia vera (PV), essential thrombocythaemia (ET) and primary myelofibrosis (PMF)[53–57] and was shown to be associated with worse outcome particularly in PMF.[57] The mutation was reported in up to 90%, 40% and 25% of patients in the three diseases respectively but was not found in CML or in 700 normal controls. It consisted of a G to T substitution at nucleotide 1849 of exon 14 leading to a valine to phenylalanine substitution at codon 617 (c.1894G>T, p.Val617Phe). This mutation caused loss of *JAK2* auto-inhibition and constitutive activation of the cytoplasmic JAK2 kinase and has become the definitive molecular diagnostic test in PV patients. In this group of patients the distinction between primary (*JAK2* mutated) and secondary polycythaemia had sometimes been difficult prior to the identification of this mutation.

A variety of molecular methods have been employed to establish the presence of this mutation including direct Sanger sequencing, allele-specific PCR, ARMS, RQ-PCR and melting curve analysis as a semi-quantitative method, RFLP analysis and pyrosequencing. There are other methods which would lend themselves to this type of mutation analysis including SSCP and denaturing HPLC, both of which are technically challenging and labour intensive.

More recently, some relatively rare mutations in exon 12 of *JAK2* have been identified in Val617Phe-negative patients with PV or unexplained erythrocytosis using PCR and direct DNA sequencing as well as allele-specific PCR.[58,59]

In our laboratory we currently screen for these mutations by DNA fragment analyser and pyrosequencing as described below. We also refer to recently published guidelines for the molecular testing of JAK2 for further information on this test.[60] Granulocytes are the preferred source for DNA or RNA preparation, but total white blood cells are also commonly used.

Principles. Mutation of exon 14 of *JAK2* in MPNs is characterised by a single nucleotide mutation which is identical in all patients carrying this defect. PCR amplification can be designed to exploit the specific annealing of a primer at the 3′ end in single or multiplex conditions. By designing a primer that matches the wild-type (G) sequence, the primer will bind and amplify only the wild-type DNA. Conversely, the primer designed to match the mutant sequence (T) will amplify the mutant allele and not the wild-type. After the PCR has been carried out, the products can be visualised in several ways. One can simply run the product on a 2% agarose gel through the incorporation of SYBR Safe dye in the gel and using a UV transilluminator. This methodology is marred by problems, such as possible lack of specificity and lack of sensitivity.

A more successful approach in our hands is the use of primers designed to include a different fluorescent label in the wild-type and mutant primers. The PCR product can then be run on a fragment analyser *(ABI3130)* with the wild-type and mutant alleles appearing as two distinct fragments of the expected size in separate channels (Fig. 8-11). This represents a rapid and cost effective method for the analysis of large cohorts of patients. 100–200 ng of total DNA or 1/20 of a cDNA reaction (normally containing 2 µg of total RNA in a 50 µl final volume

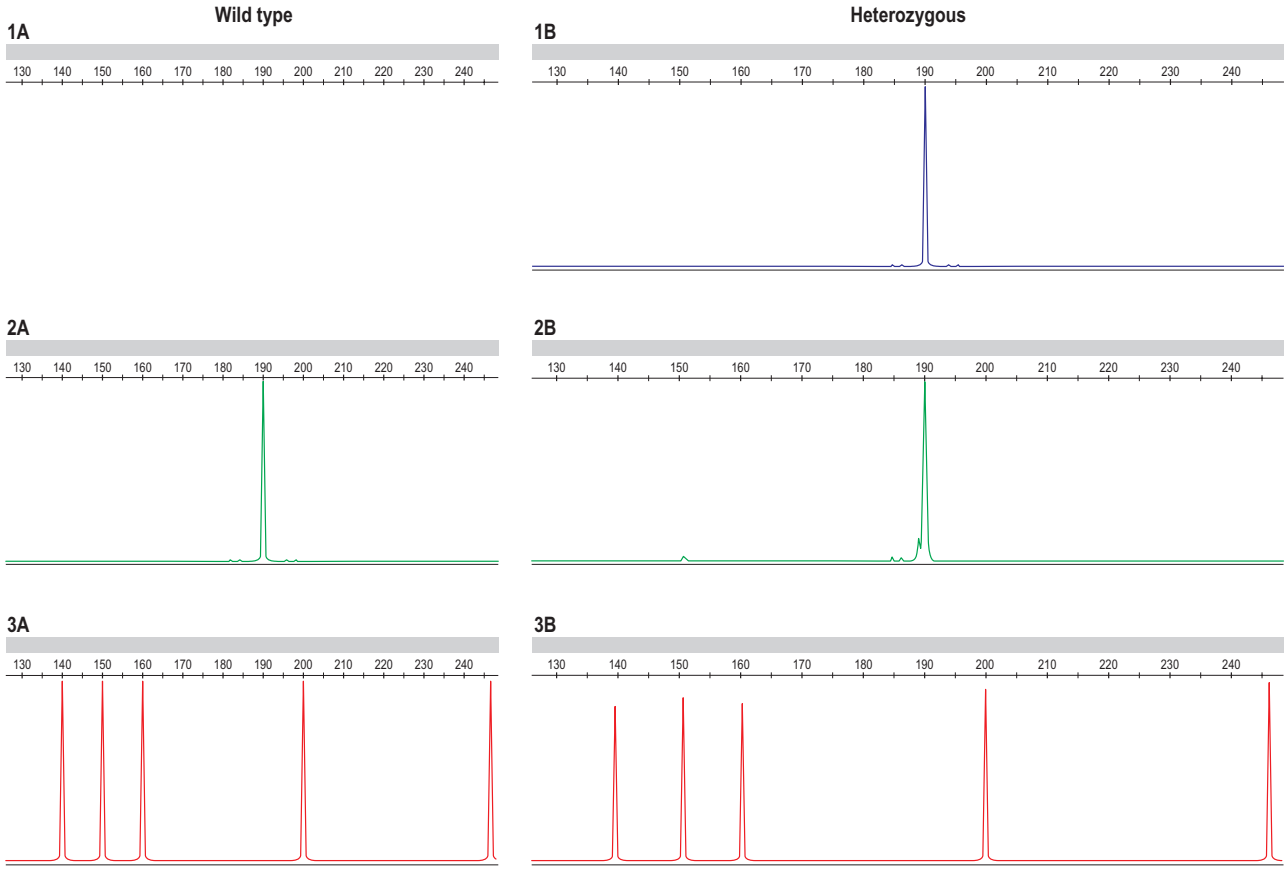

FIGURE 8-11 *JAK2* **genotype analysis by gene-scanning.** Primers specific for the wild-type *JAK2* sequence *(green fluorescent signal)* and for the mutant allele *(blue fluorescent signal)* have been applied to two samples and run on a gene-scanning ABI apparatus. **Panel 1A and 2A:** The presence of a single signal in the wild-type amplification (2A) indicates that this sample is wild-type for the G>T mutation. **Panel 1B and 2B:** The presence of a signal on both PCR amplifications indicates that this sample is heterozygous for the mutation. **Panels 3A and 3B:** These panels illustrate the traces of the molecular weight marker used to accurately assess the amplicons' size.

reaction) is sufficient for this test which is described in more details below.

A different approach, pyrosequencing, is also extensively used in our laboratory and the method is based on a single nucleotide polymorphism (SNP)-pyrosequencing test. This approach involves the amplification of a fragment containing the potentially mutated base by PCR using a biotinylated primer. The amplified product is captured on streptavidin-coated beads and is then used as a substrate for sequencing of the region containing the mutation. As the different nucleotides are dispensed, the incorporation of the mutant or wild-type nucleotide will be captured and converted into a light signal – the emission of which can be measured and quantified by comparing the intensity of the signal obtained by the amplification of the two sequences and is expressed as a percentage of mutant and wild-type amplification. In this respect, pyrosequencing is a quantitative method and therefore offers a great advantage compared with other methodologies.

Methodology

DNA fragment analyser. In this protocol a reverse common primer (5′ CCT ACA GTG TTT TCA GTT TCA AAA ATA 3′) is used in combination with two different forward primers in two separate reactions. The two forward primers differ by one nucleotide at their 3′ end with a G in the wild-type (exon14 Forward wild-type: 5′ AGC ATT TGG TTT TAA ATT ATG GAG TAT GT**G** 3′) and a T in the mutated PCR reaction (exon 14 Forward mutated 5′ AGC ATT TCC TTT TAA ATT ATG GAG TAT GT**T** 3′) and by being labelled with a different fluorochrome.

1. Set up a PCR reaction, with 100–200 ng of genomic DNA in the presence of 100 ng of each nucleotide and 1.5 mM final concentration of $MgCl_2$. PCR cycling conditions are as follows: 94 °C for 5 min; 94 °C for 30 s; 61 °C for 30 s; 72 °C for 1 min; 72 °C for 10 min; repeat cycling for 30 cycles.
2. Check the amplicons by agarose gel electrophoresis to verify amplification of the correct size fragment.
3. Run these fragments on the ABI 3130 genetic analyser to determine the presence or absence of the mutant allele. DNA from HEL cell line (homozygous mutant for *JAK2* V617F, www.thermofisher.com) is used as a positive control in each experiment.

Pyrosequencing. Primer sequences have been generated in house and are as follows:

1. Pyro-JAK2Ex14 Forward: 5′ GAA GCA GCA AGT ATG ATG AGC A 3′; Pyro-JAK2 Ex14Reverse-BIO: 5′-[Btn]TAT AGT TTA CAC TGA CAC CTA GCT-3′; JAK2 SNP: 5′TTT TAA ATT ATG GAG TAT GT 3′.
2. Prepare 1 ml of the *JAK2* exon 14 master mix as follows: 10× PCR buffer: 100 µl; 50 mM $MgCl_2$: 36 µl; primers Pyro-JAK2Ex14 Forward and Pyro-JAK2 Ex14Reverse-BIO, both to 500 nM; 15 mM dNTP: 17 µl; ddH_20: 815 µl.
3. Taq polymerase enzyme per sample is added to the master mix (as described above) before distributing 28 µl of the master mix into each PCR tube. 2 µl of DNA from each patient's sample is added to each tube except for the blank in which water is added.
4. Cycling conditions are as follows: initial denaturation at 94 °C for 5 min. Then 94 °C for 30 s, 57 °C for 1 min and 72 °C for 2 min with repeated cycling for 28 cycles. Then a final extension of 72 °C for 7 min.
5. Check for PCR amplification on a 2% agarose gel running at 100 V for approximately 1 h.
6. Prepare the pyrosequencing sequence analysis (SQA) SNP pyrosequencing kit, which includes the lyophilised enzymes, substrate mix and reconstituted nucleotides (including the α-thio form of dATP), 70% ethanol; 0.2 M NaOH, wash buffer (10× stock, working solution 1×), ddH_2O; 96-well microtitre plate/caps, pyrosequencing, binding buffer and annealing buffer; streptavidin-coated sepharose beads (www.gelifesciences.com); and vacuum pump.
7. Prepare the pyrosequencing binding mixture for double the number of samples as follows: for each well use 38 µl binding buffer, 30 µl water and 2 µl sepharose beads.
8. Add 70 µl of this mix is to each well. Then add 10 µl of the PCR product to the relevant well. Shake the plate for 10–15 min on a shaker with mixing rate of 1200 rpm at room temperature.
9. Meanwhile, prepare the annealing mixture consisting of 11.5 µl annealing buffer and 0.5 µl 10 µM JAK2 SNP primer for each well. 12 µl of this mixture is added to each well in the pyro-plate.
10. Remove the caps from the microtitre plate after the end of shaking. The biotinylated strand is separated from the unlabelled complementary strand by sequentially washing with 70% ethanol, 0.2 M NaOH and washing buffer using a vacuum pump. The biotinylated strand is then transferred to the related well in the pyro-plate.
11. Transfer the pyro-plate into a thermocycler, heat to 80 °C for 2 min and then slowly cool to room temperature to allow annealing of JAK2 SNP primer to the biotinylated DNA strand.
12. Transfer the plate in the pyrosequencing machine. Instructions for the operation of equipment may vary from model to model.

This analysis will produce a measurement of the amplification of each product as a percentage of the wild-type and mutated allele. Normally any amplification of the mutated allele above 5% is considered to be positive. Between 1% and 5% is borderline and a repeat sample is recommended. Below 1% is reported as negative.

New guidelines have been recently published and any laboratory investigation should comply with such guidelines.[60]

Interpretation. All tests are carried out including a positive control (DNA from HEL cell line or any other DNA from cell lines or patients carrying a homozygous mutant allele), a negative control (DNA from a normal individual) and a no template control (NTC) containing all reagents and water in place of DNA. Samples are tested in triplicate for the pyrosequencing. The samples are evaluated for the presence of a peak in the amplification well containing primers for the mutant allele. If using agarose gels, the presence of a band in the wild-type combination but not in the mutant will identify a wild-type patient; the presence of a band only in the mutant reaction will identify a homozygous patient, while the heterozygous cases will correspond to patients with an amplification in both wild-type and mutant wells. The same principle applies when using a fragment analyser (see Fig. 8-11). Pyrosequencing will provide also quantification expressed as a percentage of the wild-type and mutant allele amplicon.

CALR (calreticulin) gene analysis

Principle. Somatic insertion and/or deletion mutations within exon 9 of the calreticulin (*CALR*) gene have been found to be associated with MPN.[61–64] They are detected in peripheral blood in about 65–85% of ET and PMF patients who are *JAK2* exon 12 and 14 and *MPL* exon 10 mutation negative. Molecular analysis of these three genes now allows disease markers to be identified in >90% of MPN patients, enabling classification of the disease and differentiating it from a reactive process. *CALR* mutations are very rarely reported in PV patients. In two studies with a total of 430 PV patients, no mutations were found. Testing can therefore be used to distinguish PV patients from those with ET or PMF. Mutations are reported in 8% of patients with MDS, are rarely found in (CMML) or atypical CML and are not reported in lymphoid leukaemia or solid tumours.

CALR mutations occur in approximately 25% of ET overall and in 49–67% of *JAK2*- and *MPL*-negative ET. Patients with *CALR*-mutated ET tend to be younger and have higher platelet counts and a lower haemoglobin concentration than those with *JAK2* mutated-ET. Risk of thrombosis is lower in *CALR*-mutated ET patients than in those with *JAK2* or *MPL* mutations and is comparable with the risk in mutation-negative patients. Evidence for long-term prognosis of *CALR*-mutated ET is unfolding. Longer overall survival for these patients, compared with *JAK2*-positive ET, has been reported[2] but not observed in all studies. An increased incidence of transformation to myelofibrosis was seen in one study but not observed in others. *CALR* mutations were detected in 88% of PMF patients without *JAK2* or *MPL* mutation. PMF patients with *CALR* mutations are reported to have longer overall survival than those with *JAK2* and *MPL* mutations.[65]

Initial reports support *CALR* mutations as early and disease-initiating mutations that favour expansion of the megakaryocytic lineage. *CALR* mutations are mutually exclusive with *JAK2* and *MPL* mutations. Thirty six different somatic *CALR* exon 9 mutations have been identified in ET and PMF to date. The most common mutation type deletes 52 bp at (*c*.1092_1143del chr19:12915565_12915616del) (Type 1). There are other types that delete 52 bp but at different breakpoints. Insertions and deletions have been described in the same patient.

Mutation status is determined by PCR amplification across the region using fluorescent-labelled primer pairs, and subsequent fragment size analysis using capillary electrophoresis on the ABI3130 Genetic Analyser.

Methodology

Reagents and equipment

- DNA extraction procedure and ABI 3130 Genetic Analyser
- *Reagent:* Fast Cycling PCR Kit (*Product Number:* Kit: 203745; Qiagen)
- *HiDi Formamide* (4311320; Applied Biosystems)
- *Reagent:* GeneScan-500 LIZ Size Standard (*Product Number:* 4322682; Applied Biosystems)
- *PCR primers: Sequence*
  - CALR_e9GS_FAM: [6FAM] 5′ GGCAAGGCCCTGA GGTGT 3′
  - CALR_e9GS_R: 5′ GGCCTCAGTCCAGCCTG 3′

Positive and negative controls and a blank are needed. Each reaction will contain 18 µl of the master mix and 2 µl of DNA (total of 20 µl). Defrost all reagents required for *CALR* mix and prepare the master mix according to volumes required.

Reagent	*Volume in µl per reaction*
Qiagen Fast Cycling 2x MMx	10
Qiagen Q solution	4
H_2O	3
CALR_e9GS_FAM (10 µM)	0.5
CALR_e9GS_R (10 µM)	0.5
Total	18
DNA	2

Spin and set PCR according to the conditions specified below.

PCR amplification is carried out as follows; 1 cycle including 5 min of denaturation followed by 30 cycles including denaturation at 95 °C for 45 s, annealing at 62 °C for 15 s and extension at 72 °C for 30 s and a final extension at 72 °C for 7 min.

Once the PCR run has completed, check PCR amplification using agarose gel electrophoresis or a QIAxcel PCR analyser. If the samples produced adequate amplification, this should result in a wild-type band of 263 bp and a mutant (deletion type 1 the most common of approximately 52 bp shorter) at 211 bp. Then place the tubes on a rack and prepare a plate for the ABI 3130. Aliquot 9 µl

of formamide/LIZ500 mixture to each well on the ABI plate. Ensure that the wells are used in blocks of four if using the 3130 genetic analyser or all the wells within the three columns-injection are used if using the 3500xl Dx genetic analyser. If no PCR product will be added to the well, ensure that formamide/LIZ500 is added to prevent air bubbles from entering the array of the ABI.

The amplification should result in the production of one peak of 263 bp, which corresponds to the wild-type amplification for genomic DNA. The mutant allele would be a larger or smaller peak of variable size depending on the size of the insertion and/or deletion.

The samples can be reported as wild-type or mutated and the size of the mutant allele should be noted in the database (in bp).

Interpretation. There are at least two major mutant types identified in MPNs cases, type 1 and type 2. The most common mutation types are a 52-bp deletion (c.1092_1143del, p.L367fs*46) and a 5-bp insertion (*c*.1154_1155insTTGCC, p. K385fs*47), and they comprise approximately 85% of *CALR* mutations in MPN.[61,62] *CALR* mutations have been found in haemopoietic stem and progenitor cells in MPN patients[61] and may activate the STAT5 signaling pathway.[62–64]

MPL mutation analysis

Acquired mutations in the juxtamembrane region of the thrombopoietin receptor gene, *MPL,* have been described in PMF and in ET.[66,67] Such mutations are known to lead to cytokine-independent growth and constitutive phosphorylation of JAK2, STAT3-5, AKT and ERK. *MPL* mutations in PMF appear to be particularly associated with lower haemoglobin levels at diagnosis leading to increased transfusion dependence.

MPL mutations appear to concentrate in exon 10 as identified in several studies using Sanger sequencing of PCR products from peripheral blood granulocytes, allele-specific PCR assays or pyrosequencing. All such techniques can be used and mutations, *MPL W515L, MPL W515K* and *MPL S505N* have in the past been identified and quantified using pyrosequencing.

We have limited experience of MPL somatic mutations identification detected mainly by pyrosequencing and hence we refer to other recent reviews for the methodological approach to this disease.[66,67]

Fusion gene analysis in acute leukaemia

Testing for other common fusion gene products

In addition to the *BCR-ABL1* fusion gene, a variety of fusion genes have been identified and characterised at the molecular level in other acute and chronic leukaemias, all suitable for PCR amplification and for use as markers at diagnosis and for MRD detection. The identification of these at the time of diagnosis may carry prognostic significance and subsequently influence treatment choice. There are a great number of potential fusion partners, but the *PML-RARA, ETV6-RUNX1* and *KMT2A-AFF1* (previously designated *MLL-AF4*) are among the most frequent targets of investigation in AML and ALL. They are the result of the t(15;17), t(12;21)(p13;q22) and t(4;11)(q21;q23) translocations, respectively. The former two chromosomal aberrations are commonly associated with good response to therapy and patients rarely require transplantation. However, t(4;11) is associated with a less favourable response to therapy. For this group even the option of transplantation offers limited advantages for long term survival, and this is especially so in adults. Each of these translocations will be discussed briefly in the following section; they have been extensively reviewed in relevant studies previously referred to.[68,69]

t(15;17)(q22;q21); the *PML-RARA* fusion gene

The t(15;17)(q22;q21) translocation, associated with acute promyelocytic leukaemia (APL), French–American–British (FAB) M3, fuses the *PML* gene, at 15q22, to the *RARA* gene on 17q21. The breakpoint cluster region on chromosome 17 localises within *RARA* intron 2. Within *PML* there are three breakpoint cluster regions: breakpoint cluster region 3 (BCR 3) in intron 3, bcr2 in exon 6 (rarely in intron 5) and bcr1 in intron 6. At the messenger RNA level, bcr1, bcr2 and bcr3 are also known as the long (L), variant (V) and short (S) isoforms, respectively. Alternative splicing within *PML* transcripts and the alternative use of two *RARA* polyadenylation sites are responsible for the production of additional *PML-RARA* transcripts of different sizes.

There are at least four variant translocations involving the *RARA* gene, with the same breakpoint, associated with a phenotype resembling, but not necessarily identical to, that of APL. The fusion partners are *NPM1* at 5q35, *ZBTB16* (previously designated *PLZF*) at 11q23, *NUMA1* at 11q13 and *STAT5B* at 17q21.

As a consequence of the t(15;17)(q22;q21) translocation, *PML-RARA* is consistently transcribed, while *RARA-PML* is detectable in about 70% of cases. Thus *PML-RARA* is suitable for diagnosis and MRD monitoring in APL. This transcript can be detected by RT-PCR with a sensitivity of $1:10^4$.

At least 50% of patients with APL are MRD positive after the first cycle of chemotherapy plus the differentiation agent all-*trans*-retinoic acid (ATRA). Most positive patients show a progressive decrease in MRD during the 4 or 5 chemotherapy blocks. Patients who are in molecular remission post-consolidation have a high probability of CCR. Patients who revert to PCR positivity after the end of treatment, however, have a high probability of relapse. Patients with a low MRD level ($<10^{-5}$) at the end of consolidation include a large proportion of patients who subsequently relapse and monitoring should therefore continue at 2–3 month intervals for 1–2 years after completion of treatment.

The *PML-RARA* transcript can be detected with increased sensitivity by RQ-PCR compared with semi-quantitative nested/two-round PCR techniques. Accurate quantification can identify patients with an increasing number of transcripts preceding haematological relapse. Patients treated at the time of molecular relapse have 2-year event-free survival rates superior to those treated at the time of haematological relapse.

11q23 abnormalities

Rearrangements involving the lysine (K)-specific methyltransferase 2A (*KMT2A,* previously known as mixed leukaemia lymphoma, *MLL* or *ALL1*, *HRX* or *Htrx1*) on chromosome 11q23 and multiple partner genes are found in precursor B-ALL, T-ALL, AML, MDS and in secondary leukaemia. The presence of *KMT2A* rearrangements is usually associated with a poor prognosis.

In ALL, the most common translocation partner of *KMT2A* is the AF4/FMR2 family, member 1 (*AFF1*) gene on chromosome 4q21 although other partner chromosomes have been described.[68] About 50–70% of infant ALL cases and approximately 5% of paediatric and adult ALL cases are positive for the *KMT2A-AFF1* fusion gene, this being associated with a pro-B-ALL ('null') phenotype (CD19+, CD34+, terminal deoxynucleotidyl transferase+, cytoplasmic CD79a+, CD10−). There is also frequent expression of myeloid antigens (CD15 and/or CD65).

The *KMT2A* and *AFF1* genes are composed of 37 and 20 exons, respectively, and at least 10 different fusion transcripts have been identified due to translocation breakpoints occurring in different introns of the two genes. Breakpoints downstream of the *KMT2A* exon 9 in adult and paediatric ALL but downstream of exon 11 in infant ALL and upstream of exon 4 of the *AFF1* gene are commonly detected by PCR. Variable splicing is a common finding leading to more than one fusion transcript in some patients. All t(4;11)-positive cases transcribe the *KMT2A-AFF1* fusion gene while only 70% of cases transcribe the reciprocal, *AFF1-KMT2A* product. Interestingly, low levels of the *KMT2A-AFF1* transcript have been detected in some ALL cases without cytogenetically detectable t(4;11) and in haemopoietic tissues of healthy individuals.

Using a nested PCR strategy the various *KMT2A-AFF1* transcripts can be identified with a detection limit of 1 in 10^4–10^5. For a comprehensive description of the methodology used for the detection and molecular monitoring of this translocation and others in this section we refer to a very comprehensive report.[42] MRD studies have shown that early conversion and persisting MRD negativity is consistently associated with CCR.

t(12;21)(p13;q22); the *ETV6-RUNX1* fusion gene

The t(12;21)(p13;q22) is a cryptic translocation (not readily observed by conventional cytogenetics) between the ets-variant 6 gene (*ETV6*) on 12p13 and the core binding factor α2, known as Runt-related transcription factor 1 (*RUNX1*) on chromosome 21q22. The translocation leads to the fusion transcript which can be detected in patients with and without a cytogenetically visible chromosome 12 and/or 21 abnormality. FISH and PCR are therefore important techniques employed for its identification.

The t(12;21) is usually associated with common ALL and more rarely occurs with a pre-B ALL phenotype. It is rarely seen in adult ALL although it is the commonest translocation in childhood ALL (≥25%) with a peak incidence in the 2–5 year age group. The breakpoint region usually lies between exons 5 and 6 of the *ETV6* gene and between exon 1 and 3 of *RUNX1*. Fusion transcripts resulting from splicing of *ETV6* exon 5 to other *RUNX1* exons can also be formed. The majority of positive patients have *ETV6* deleted from the chromosome not involved in the translocation. It has been suggested that the translocation occurs during fetal development. The *ETV6-RUNX1* fusion transcript can be identified with a sensitivity of 1 leukaemic cell in 10^4–10^5 normal cells using a nested RT-PCR approach. Accurate quantification of *ETV6-RUNX1* has shown that MRD measurements are a good prognostic indicator of future outcome.

Method and Interpretation. The above three translocations are determined and monitored by amplification of the mRNA resulting from the fusion gene, as this is leukaemia-specific, on the same model as *BCR-ABL1* testing for t(9;22). Therefore, we refer to the section above for the preparation of cDNA and conditions of PCR amplification. However, for primers specific for amplification at diagnosis and for RQ-PCR for follow-up samples we follow the protocols and guidelines for interpretation of results provided by the Europe Against Cancer Consortium.[51,52]

It is worth noting that due to the multiplicity of the *KMT2A-AFF1* fusion products and the limitations of hydrolysis probe amplicon size, a genomic DNA-based assay may be employed for following affected patients as previously described.[68] This involves the characterisation of the individual break-point by direct sequencing and designing an ASOH in a manner similar to that for immunoglobulin/*TCR*-based MRD.[48,49] As controls for amplification, we use the Ipsogen plasmids (www.ipsogen.com). For interpretation of data we refer the reader to the Europe Against Cancer guidelines.[51,52]

Acute myeloid leukaemia, FLT3 and NPM1 analysis

FLT3 PCR-based mutation analysis

In the past 20 years genetic changes identified in the leukaemic cells at the time of diagnosis have greatly influenced treatment and management of AML. In addition to chromosomal abnormalities, mutations in specific genes have emerged as important prognostic indicators. Among the most common are mutations in the tyrosine kinase genes such as *FLT3* and *NMP1*.[70–72]

Principle. The *fms-like tyrosine kinase 3 (FLT3)* gene is mutated in approximately 20–30% of patients with AML. The mutations are restricted to the leukaemic cells and patients with mutations of the *FLT3* have a poorer outcome and may require transplantation or more aggressive chemotherapy. Therefore, the rapid identification of these leukaemia-specific changes is important and analysis should be carried out in pre-treatment samples of all AML patients.

Two types of mutations are predominantly identified. The most frequent are internal tandem duplication (ITD) mutations with higher frequency in older adults than younger patients. Mutations map to the negative regulatory juxtamembrane (JM) domain and change the amino acid sequence, which subsequently interrupts inhibition and constitutively activates the protein.

Five to 12% of AML patients have *FLT3* mutations that map to the activation loop, most frequently involving aspartic acid 835 or the immediately adjacent isoleucine 836. The latter mutation does not carry prognostic significance and therefore it is less routinely tested for.

Methodology. To investigate the presence of a mutation in *FLT3* the method of choice is PCR amplification using primers flanking the region containing the mutation, which can be carried out on DNA or cDNA.

For DNA amplification the following primers can be used:

G11F 5′ GCAATTTAGGTATGAAAGCCAGC 3′
G12R 5′ CTTTCAGCATTTTGACGGCAACC 3′

For cDNA amplification:

R5F: 5′ TGTCGAGCAGTACTCTAAACATG 3′,
R6R: 5′ VIC-GAGTTTGGGAAGGTACTAGGGAT 3′

See Figure 8-12 for PCR strategy and amplicon size.

PCR cycling conditions are: 95 °C for 5 min initial denaturation and then 30 cycles using 95 °C for 30 s denaturation step, 56 °C for 45 s annealing step, 72 °C for 30 s extension with a final 72 °C for 7 min extension step. Analysis of amplicon size is carried out using Genescanning on a fragment analyser (Applied Biosystems 3130, www.thermofisher.com).

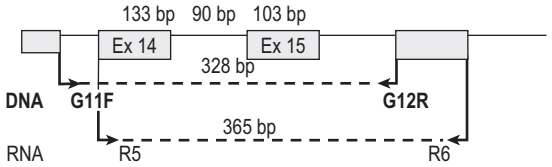

FIGURE 8-12 *FLT3* **mutation analysis.** Primers specific for the DNA amplification (G11-G12) and RNA amplification (R5 and R6) can be used on DNA and RNA, respectively. The amplicon size in an unmutated/wild-type allele is given in bp. In the presence of an internal tandem duplication (ITD) the size will increase according to the size of the insertion and consequently this may vary from individual to individual and will be restricted to the leukaemic cell population.

Interpretation. A 328 bp amplicon using cDNA (R5F-R6R primers; Fig. 8-12) or a 365 bp amplicon when using DNA (and G11F and G12R primers; Fig. 8-12) is detected in the presence of a wild-type allele. The mutant allele gives rise to a larger amplicon of variable size depending on the size of the ITD, which differs between patients. Because the wild-type and mutant amplicons are very similar in size, the PCR product is better visualised using a fragment analyser. This offers a more accurate separation of similarly sized product but requires one of the primers used in the reaction to be fluorescently labelled. The samples can be reported as 'wild-type' or 'mutated', depending on the results obtained, and the size of the mutant allele should be noted in the report (in bp).

The other common *FLT3* mutation (D835) results in the introduction of an EcoRV restriction site absent in the wild-type allele. This facilitates the identification of this mutation by digestion of the PCR product containing this site. The presence of this mutation carries, as for *FLT3*-ITD, a poor prognosis.

NPM1 PCR-based mutation analysis

The nucleophosmin-1 *(NPM1)* gene maps to chromosome 5q35. The cDNA has a coding sequence equivalent to a protein of 294 amino acids. Nucleophosmin is an abundant nucleolar phosphoprotein constantly shuffling between the nucleus/nucleolus and cytoplasm. *NPM1* mutations represent the most frequent gene alteration in AML. More than 26 different *NPM1* mutations have been identified, at breakpoint positions 956 through 971, characterised by simple 1- or 2-tetranucleotide insertions, a 4-bp or 5-bp deletion combined with a 9-bp insertion, or a 9-bp deletion combined with a 14-bp insertion. *NPM1*-mutated AML encompasses all FAB/World Health Organisation categories except FAB M3 (APL). However, the frequency among the FAB subgroups varies: it is lower in M2 (about 20%) and higher in M4 (acute myelomonocytic leukaemia, 40–50%), M5a (acute monoblastic leukaemia, 40–50%), and especially M5b (acute monocytic leukaemia, up to 90%). The most common *NPM1* mutation type, accounting for 75–80% of cases, is referred to as mutation A (NPM1-mutA). *NPM1* gene mutations are common in AML with a normal karyotype, occurring in 50–60% of cases. There is a high frequency of *FLT3* gene mutations in *NPM1*-mutated AML, mostly *FLT3*-ITD. However, no association between *NPM1* gene mutations and *TP53, NRAS, CEBPA* (*CCAAT/enhancer binding protein-α*) and *KMT2A* mutations, or recurrent genetic abnormalities has been found. These *NPM1* alterations have been shown to possess prognostic significance because they appear to identify patients who will respond well to chemotherapy and may not require transplantation.

Methodology. It is important to note that since analysis for *NPM1* mutations is carried out on cDNA samples, an effort to reduce DNA contamination should be made to avoid cross-amplification of DNA regions that contain

pseudogenes. These may amplify using the primers commonly used for this test. To this end, samples are treated with DNAse prior to RNA extraction using Qiagen DNAse Free RNA extraction kit (cat #79294, www.qiagen.com).

The primers' sequence for the test and PCR amplification strategy on cDNA are as follows:

Forward: NPM1-F2 5′ ATC AAT TAT GTG AAG AAT TGC TTC C 3′
Reverse: NPM1-Rev6: 5′ FAM-ACC ATT TCC ATG TCT GAC CAC C 3′

PCR amplification conditions are standard using a 20 µl final volume and 1.5 mM $MgCl_2$ concentration. Amplification is carried out using the following cycling conditions: initial extended denaturation at 95 °C for 5 min; then 30 cycles using a denaturation at 95 °C for 30 s, annealing at 56 °C for 45 s; extension at 72 °C for 30 s; and a final 72 °C for 7 min extension.

Interpretation. *NPM1* amplification should result in the production of peaks corresponding to a 348 bp wild-type amplicon and a 352 bp mutant amplicon, when the mutant version with an insertion of 4 bp is present. The samples can be reported as 'wild-type' or 'mutated' and the size of the mutant allele should be noted in the report (in bp).

The test is analysed on gene scanning apparatus and is frequently run as a duplex test in combination with *FLT3*. This is possible because primers have been designed to yield fragments of different sizes.

Host-donor chimaerism studies

Following allogeneic stem cell transplantation it is important to monitor the engraftment of donor cells in the host. This can be achieved in a number of ways, one of which is by the use of DNA markers. The method of choice is PCR amplification of STR polymorphism loci, which, because of their highly polymorphic nature, are likely to give informative differences between any host-donor pair.[73–75]

Principle. Provided the amplification cycle number is kept reasonably low (25 cycles) the PCR reaction is semi-quantitative, and the amount of product will reflect the amount of starting material. Therefore, once an informative difference is identified, the amount of PCR product of the different host and donor alleles will reflect the proportions of host and donor DNA in a sample. Fluorescent-labelled primers are used in multiplex PCR reactions run on a capillary-based genetic analyser.

Methodology. This method has been modified from Mann *et al.*[76] by Griffiths and Mason (personal communication). Five primer pairs are used, as listed in Table 8-5. PCR reactions are carried out using buffer III with 1.5 mM $MgCl_2$. Amplification conditions are 94 °C for 5 min, then 25 cycles of 94 °C for 30 s, 57 °C for 1 min, and 72 °C for 2 min followed by an extension at 72 °C for 5 min. No oil is used when products are to be run on the DNA analyser. One µl of the PCR product, which may need to be diluted either 1 in 4 to 1 in 10, in water, is added to 10 µl of formamide containing the size marker ROX 500 (diluted

PCR, polymerase chain reaction; STR, short tandem repeat.

7.5 µl per 500 µl of formamide), aliquotted into an optical 96-well reaction plate, and run on the ABI 3700 DNA analyser (www.thermofisher.com) or equivalent. Peaks representing the DNA fragments are visualised with the Genotyper software (ABI).

More recently the use of commercial kits using a number of STR loci has been introduced. The one currently employed in our laboratory is the Promega PowerPlex16 kit (www.promega.com) comprising markers: Penta E, D18S51, D21S11, TH01, D3S1358, FGA, TPOX, D8S1179, vWA, Amelogenin, Penta D, CSF1PO, D16S539, D7S820, D13S317 and D5S818. The advantage of using such kits is the potential number of informative markers available for analysis. Software packages such as ChimerMarker which enable analysis to be performed smoothly are also available at a cost (www.softgenetics.com/chimerMarker.html).

Interpretation. Comparing the host (pre-transplant) and donor DNA samples, an informative difference is sought at one or more of the STR loci such that host- and/or donor-specific alleles are identified. Correction factors are established by comparing the relative peak heights of the two host or donor alleles at these STRs. Post-transplant, the area under each informative peak is recorded and used to assess the relative proportion of host and donor DNA. Examples of full-engraftment and mixed chimaerism are given in Figure 8-13. Guidelines for interpretation of the analysis have recently been published and use of a minimum of 3 informative markers is recommended.[77]

Emerging technologies

Next generation sequencing

Since 2001 and the completion of the Human Genome Project[1,2,78] the introduction of next generation sequencing (NGS), also referred to as high throughput sequencing or parallel sequencing, has revolutionised the study of mutation analysis in cancer and rare diseases to an extent unthinkable until five years ago. First introduced in 2005, the technology has very quickly been applied in various fields including clinical genetics, haemato-oncology and forensic pathology and has altered approaches to diagnosing genetic disorders and to the clinical management of cancer patients. Several projects utilising the power of this technology, such as the currently ongoing NHS England (UK) initiative of sequencing 100,000 genomes, (www.genomicsengland.co.uk) will further consolidate the place of this technology in clinical practice, facilitating the provision of effective personalised medicine.

Principle and Methodology. The principle of NGS is based on the ability to sequence several thousand times nucleic acids fragments anchored via an adaptor to a solid surface or a bead. The nucleic acid could be fragmented DNA, RNA or amplicons generated by PCR. The workflow can be summarised as follows: DNA fragmentation or amplicon generation followed by adaptor ligation to generate a library, library amplification via emulsion PCR or bridge amplification and finally sequencing. Sequencing can use a variety of processes but the basic

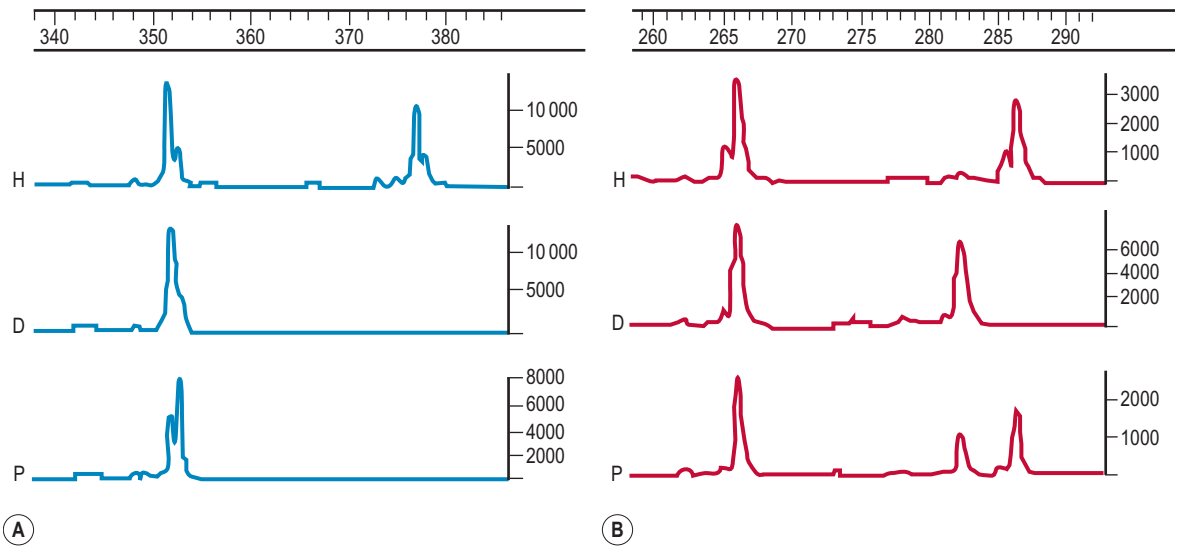

FIGURE 8-13 Short tandem repeat (STR) analysis of bone marrow engraftment. Capillary electrophoresis of the polymerase chain reaction (PCR) products of STR amplification as viewed by the Genotyper software. H, host DNA; D, donor DNA; P, post-transplant DNA. **Panel A:** the host and donor share an allele at 352 bp, whereas a host-specific allele is seen at 376 bp with the marker D18S386 (Table 8-5); the latter is not detected in the post-transplant sample. **Panel B:** the host and donor share an allele at 266 bp but have specific alleles at 286 and 282 bp, respectively. All three alleles are seen in the post-transplant DNA, indicating that the sample is chimaeric. From the relative area under the host- and donor-specific peaks, the proportion of donor DNA is estimated at 39%.

principles are mainly either a chain termination approach (Sanger sequencing and modifications thereof) or pyrosequencing based, where the incorporation of a nucleotide leads to light emission or pH change. We refer to some excellent recent reviews for a detailed description of each technology.[79–88]

Applications. The extent of NGS application in diagnostic laboratories is increasing as technologies improve and cost decreases. For instance, targeted massively parallel amplicon NGS technology has been applied in our laboratory for the diagnosis of Diamond–Blackfan anaemia.[89] This type of bone marrow failure is predominantly associated with the mutation of one of the 80 genes encoding the small and large ribosomal subunits which presents a huge diagnostic challenge. Sequencing each individual gene is a labour intensive and costly approach. The approach used so far in many laboratories has been to sequence only the six or seven most frequently mutated genes; however this leads to incomplete genetic analysis and false negative results. The use of NGS for sequencing simultaneously all 80 genes in up to 16 patients per screening has improved substantially the rate of mutation detection from 25% to 85%, with new mutations being described regularly.

Amplicon Deep NGS has been applied for the investigation of *BCR-ABL1* TKD mutation analysis.[90–93] However, the 'gold standard' sequencing approach to TKD mutation analysis remains Sanger sequencing; we refer to a recent paper for the full methodology.[41]

Digital PCR

Digital PCR (dPCR) is an increasingly popular application of PCR which has the capability for single molecule quantification. dPCR offers a number of unique advantages when applied to clinical research, particularly when used to detect rare mutations and for the precise quantification of nucleic acids as in MRD quantification.

Principle and methodology. The principle of dPCR relies on diluting the sample before partitioning it into small reaction chambers so that each chamber receives one or no target molecules. Poisson statistics are then applied to provide the precise copy number of the interrogated target per reaction volume. Two main advantages of dPCR are its ability to perform absolute quantification without the need for a standard curve and its ability to reduce the noise-to-background ratio, thus increasing the likelihood of detecting rare targets otherwise masked by abundant wild-type alleles in the bulk reaction mix. Both features serve to highlight the growing importance of this platform in clinical diagnostics.

Applications. dPCR has many advantages compared to RQ-PCR, including improved sensitivity, specificity and precision. These characteristics are translated to applications such as rare variant detection, absolute quantification of low target molecules and small copy number variations (CNV). We provide herein several reviews and articles with examples for each of the applications mentioned.[94–100]

This technology is relatively new and at the moment is used in specialist areas mainly to complement RQ-PCR. However, we estimate that once the nanofluidic technologies improve to become high throughput, dPCR will supersede RQ-PCR in clinical applications. We estimate that it will be another three to four years before this technology is established.

ACKNOWLEDGEMENTS

We would like to thank Dr Tom Vulliamy and other previous authors for their past contribution in the preparation of this chapter and we refer to past editions for a full extent of their work.

CHAPTER OUTLINE

IRON METABOLISM

The iron content of the body and its distribution among the various proteins are summarised in Table 9-1. Most of the iron is present in the oxygen-carrying protein of the red blood cell, haemoglobin, the synthesis and breakdown of which dominate iron turnover. Haem of haemoglobin is synthesised in nucleated red cells in the bone marrow and in reticulocytes by a pathway ending with the incorporation of iron into protoporphyrin IX by ferrochelatase. Haem breakdown from haemoglobin takes place mainly in phagocytic cells, largely those in the spleen, liver and bone marrow. Iron is released from haem by haem oxygenase and is largely reused for haem synthesis. Every day about 30 mg of iron is used to synthesise haemoglobin and most of this is obtained from the breakdown of old red cells.

Relatively little iron is lost from the body (about 1 mg/d in men) and these losses are not much influenced by body iron content or the requirement of the body for iron. The body iron content is maintained by variation in the amount of iron absorbed. In women, menstruation and childbirth increase iron losses to about 1.5 mg/d. Iron absorption may not increase sufficiently to compensate for these iron losses and this may eventually lead to the development of iron deficiency anaemia. In most men and post-menopausal women there is some 'storage' iron. This is iron in ferritin or its insoluble derivative haemosiderin, which is available for haem synthesis if necessary. Many young women and children have little or no storage iron.

The iron-binding protein transferrin is responsible for extracellular transport. Each molecule of transferrin can bind up to two molecules of ferric iron. Most cells obtain iron from diferric transferrin, which binds to transferrin receptors (TfRs) on the cell surface. This is followed by internalization into vesicles, release of iron, transport of iron into the cytoplasm and recycling of the apotransferrin (the protein without iron) into the plasma (Fig. 9-1).

TABLE 9-1

DISTRIBUTION OF IRON IN THE BODY IN A 70 kg MAN*

Protein	Location	Iron Content (mg)
Haemoglobin	Red blood cells	3000
Myoglobin	Muscle	400
Cytochromes and iron sulphur proteins	All tissues	50
Transferrin	Plasma and extravascular fluid	5
Ferritin and haemosiderin	Liver, spleen and bone marrow	100–1000

*The numbers are different for women.

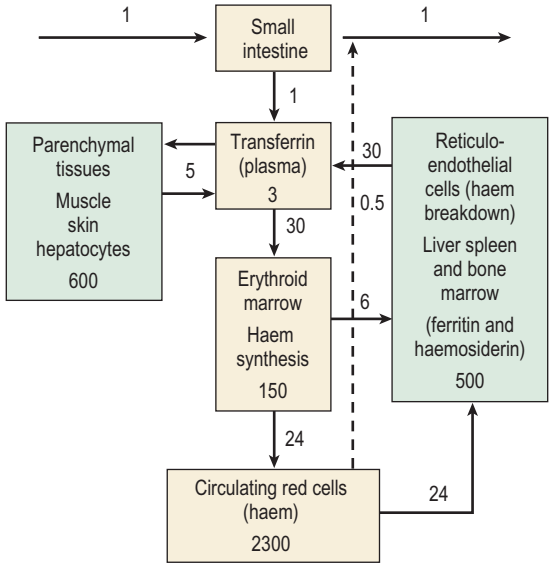

FIGURE 9-1 Iron exchange within the body. Numbers in boxes refer to amount of iron (mg) in the various compartments and the numbers alongside arrows indicate transfer in mg/d. The iron in parenchymal tissues is largely haem in muscle and ferritin/haemosiderin in hepatic parenchymal cells. The dashed line indicates the small daily loss of iron (0.5 mg) into the gut from red cells; the remaining iron loss is mostly in exfoliated gut cells and bile.

Dietary iron absorption

Iron absorption[1] depends on the amount of iron in the diet, its bioavailability and the body's need for iron. A normal Western diet provides approximately 15 mg of iron daily. Of that iron, digestion within the gut lumen releases about half in a soluble form, from which only about 1 mg (5–10% of dietary iron) is transferred to the portal blood in a healthy adult male.

Dietary and luminal factors

Most of the dietary iron is non-haem iron derived from cereals (often fortified with additional iron), with a lesser, but well-absorbed, component of haem iron from meat and fish. With iron deficiency, the maximum iron absorption from a mixed Western diet is no more than 3–4 mg daily. This amount is much less in the more vegetarian, cereal-based diets of many populations.

Non-haem iron is released from protein complexes by acid and proteolytic enzymes in the stomach and small intestine. It is maximally absorbed from the duodenum and less well from the jejunum, probably because the increasingly alkaline environment leads to the formation of insoluble ferric hydroxide complexes. Many luminal factors enhance (e.g. meat and vitamin C) or inhibit (e.g. phytates and tannins) non-haem iron absorption. Therapeutic ferrous iron salts are well absorbed (approximately 10–20%) on an empty stomach, but when taken with meals, absorption is reduced by the same dietary interactions that affect non-haem food iron.

Iron absorption at the molecular level

Several membrane transport proteins, regulatory proteins and associated oxidoreductases involved in iron transport through the intestinal cell have been identified. Non-haem iron is released from food as Fe^{3+} (ferric iron) and reduced to Fe^{2+} (ferrous iron) by a membrane-bound, ferrireductase, duodenal cytochrome *b* (DCYTB). Iron is then transported across the brush-border membrane by the divalent metal transporter DMT1. Some iron is incorporated into ferritin and lost when the cells are exfoliated. Iron destined for retention by the body is transported across the serosal membrane by ferroportin-1. Before uptake by transferrin, Fe^{2+} is oxidised to Fe^{3+} by hephaestin (a membrane protein homologous to the plasma copper-containing protein caeruloplasmin) or by plasma caeruloplasmin.

Haemoglobin and myoglobin are digested in the stomach and small intestine. Haem is initially bound by haem receptors at the brush border membrane and the iron is released intracellularly by haem oxygenase before entering the labile iron pool and following a common pathway with iron of non-haem origin.

Regulation of iron absorption

Iron absorption may be regulated both at the stage of mucosal uptake and at the stage of transfer to the blood. Recent studies show that in mice HIF-2α, a mediator of cellular adaptation to hypoxia, regulates transcription of *SLC11A2* (the gene encoding divalent metal transporter 1, DMT1) and thus mucosal uptake of iron.[2] As the epithelial cells develop in the crypts of Lieberkühn, their iron status reflects that of the plasma (transferrin saturation) and this programmes the cells to absorb iron appropriately as they differentiate along the villus. Transfer to the plasma depends on the requirements of the erythron for iron and the level of iron stores. This regulation is mediated directly by hepcidin, a peptide synthesised in the liver in response to iron and inflammation.[3]

Cellular iron uptake and release

Diferric transferrin binds with high affinity to TfR1 on the membrane of the cell to form a complex which initiates endocytosis of the local membrane. The resulting endosome contains the holotransferrin–transferrin receptor complex.[4] The pH of the endosome is reduced by a proton pump, and a conformational change in holotransferrin is induced, causing iron release. Iron is then reduced by a membrane-bound ferrireductase (six-transmembrane epithelial antigen of the prostate 3, STEAP3, in erythroid cells[5]) and transported into the cytoplasm by DMT1. This iron is then either stored as ferritin or used within the cell. Iron destined for haem and mitochondrial iron-sulphur (Fe-S) clusters is transported into mitochondria by mitoferrin for incorporation into protoporphyrin by ferrochelatase[6] and for Fe-S cluster assembly on the scaffold protein ISCU.[7] Export by ABCB7 of an as yet unknown component (possibly a glutathione persulphide[7] or a glutathione–co-ordinated [2Fe-2S] cluster[8]) to the cytoplasm stimulates Fe-S cluster protein assembly there, essential for cellular iron homeostasis.[9] Apotransferrin and the transferrin receptor of the endosome return rapidly to the cell surface where they dissociate at neutral pH so that the cycle can start again.[10]

The reticuloendothelial macrophages play a major role in recycling iron resulting from the degradation of haemoglobin from senescent erythrocytes. They engulf red blood cells and release the iron within the cells using haem oxygenase. The iron is rapidly released to plasma transferrin or stored as ferritin. The protein transporting iron to plasma is ferroportin or SLC40A1. Ferroportin activity is regulated in a negative manner by the mainly liver-derived peptide hepcidin that binds to ferroportin externally, inducing endocytosis and degradation.

Hepcidin synthesis in the hepatocyte is controlled at the transcriptional level through the alteration of levels within the nucleus of different transcription factors able to bind to the gene. Interaction of diferric transferrin, bone morphogenetic proteins (BMPs), interleukin (IL) 6 and other inflammatory cytokines with cell surface receptors TfR1, TfR2, hemojuvelin (haemojuvelin) (HJV) and IL6 receptor leads to upregulation of the hepcidin gene through different and sometimes interacting signalling pathways. Matriptase-2 (gene *TMPRSS6*), a plasma membrane serine protease, inhibits the HJV-BMP-SMAD signalling pathway by cleaving HJV from the surface of the cell, thus preventing overproduction of hepcidin and maintaining iron homeostasis.[11,12] A soluble form of HJV (sHJV) produced within the cell by the enzyme furin and released into the plasma antagonises and also inhibits this pathway.[13]

The mechanism of action of the HFE protein is less clear. HFE binds to both TfR1 and TfR2, decreasing the affinity of each for transferrin. Stabilization and endocytosis of TfR2 stimulate hepcidin production and there is evidence that diferric transferrin displaces the protein HFE from TfR1, leaving it free to interact with TfR2, thus stimulating hepcidin production in response to plasma iron levels.[14–16] More recent studies have failed to demonstrate an HFE-TfR2 complex and suggest that the actions of HFE and TfR2 on hepcidin regulation may be independent.[17,18]

Increased erythropoiesis causes decreased hepcidin, increased iron absorption and increased iron availability for haemoglobin production. So far, two plasma antagonists of the BMP-HJV-SMAD pathway, GDF15 and TWSG1, produced by erythroid cells and associated with expanded ineffective erythropoiesis, have been found.[19,20] In addition, acting through an unknown and apparently distinct pathway to suppress hepcidin production, erythroferrone (ERFE), a member of the tumour necrosis factor-α (TNF-α) superfamily, has been identified as a mediator of the erythroid-hepatic signal to

respond to acute blood loss.[21] The extent and the manner in which these regulatory pathways vary between different tissues await further investigation. Genetic alteration of the function of key regulators leads to body iron overload or iron deficiency (see later).

Iron storage

All cells require iron for the synthesis of proteins but have the ability also to store excess iron. There are two forms of storage iron: a soluble form, known as ferritin and insoluble haemosiderin.[22] Ferritin consists of a spherical protein (molecular mass 480 000 Da) enclosing a core of ferric-hydroxy-phosphate, which may contain up to 4000 atoms of iron. The protein component of ferritin is designated specifically 'apoferritin', with the term 'ferritin' being usually used to indicate both apoferritin and iron-containing ferritin. Haemosiderin is a denatured form of ferritin in which the protein shells have partly degraded, allowing the iron cores to aggregate. Haemosiderin deposits are readily visualised with the aid of the light microscope as areas of Prussian-blue positivity after staining of tissue sections with potassium ferrocyanide in acid (see Perls stain, Chapter 15). Ferritin is found in all cells and in the highest concentration in liver, spleen and bone marrow.

Regulation of iron metabolism

The expression of a number of iron proteins involved in both transport and storage is largely controlled post-transcriptionally by iron regulatory proteins (IRP1 and IRP2).[4] The conformation of IRP1 required for binding to messenger ribonucleic acid (mRNA) iron-responsive elements (IREs) and the turnover of IRP2 are directly affected by the amount of iron within a cell. Depending on where the target IRE elements are found, these proteins may inhibit or enhance translation of many proteins involved in iron metabolism.

IREs are regions of mRNA that form hairpin-like stem-loop structures. These consist of a base-paired stem of variable length interrupted by an asymmetrical region including a 5′ unpaired cytosine, followed by an upper stem of five paired bases and a six-membered loop. When the labile iron pool is deficient in iron, IRP1 has an available binding site for IRE. When the labile iron pool is saturated with iron, the iron binds to IRP1 to produce a 4Fe-4S cluster, which blocks the IRE-binding site and prevents IRP1 binding to the IRE. Fe-saturated IRP1 is then able to function as the enzyme aconitase. In the presence of iron, IRP2 (which is not an Fe-S protein) is degraded. The turnover of IRP1 is also affected by iron levels.

Different iron proteins are regulated by IRP in different ways, depending on where the IRE is located. If the IRE is at the 3′ untranslated region (UTR) of the mRNA, IRP binding will stabilise translation by protecting the translation product from endonucleolytic cleavage (e.g. TfR1 and DMT1). If the IRE is at the 5′ UTR of the mRNA, IRP binding will inhibit the translation of mRNA. Both L and H ferritin subunits have 5′ UTR IRE. When iron is abundant, the IRP does not bind to the 5′ IRE so ferritin expression is not inhibited and excess iron can be stored adequately. When iron is scarce, the IRP binds to the IRE and inhibits ferritin synthesis.

Plasma iron transport

Almost all the iron in plasma is tightly bound to transferrin, which is usually less than 50% saturated with iron. Transferrin, when incompletely saturated with iron, exists in four forms: apo, monoferric (A) (iron bound at the 'A' site), monoferric (B) and diferric. The distribution may be determined by urea-polyacrylamide electrophoresis.[23] Delivery to cells requires specific binding to transferrin receptors. The plasma iron pool (transferrin-bound iron) is about 3 mg, although the daily turnover is more than 10 times this amount. In addition, smaller amounts of iron are carried in the plasma by other proteins.

Haptoglobin is a serum glycoprotein that avidly binds haemoglobin αβ dimers released into the bloodstream by haemolysis. The haemoglobin–haptoglobin complex is rapidly removed from the plasma by a specific receptor, CD163, highly expressed on tissue macrophages.[24]

Hemopexin[25] is a plasma glycoprotein of molecular mass approximately 60 kDa that binds haem and transports the haem to cells by a process that involves receptor-mediated endocytosis and recycling of the intact protein.

Low concentrations of *ferritin* are found in the plasma and ferritin concentrations in healthy subjects reflect body iron stores. Much of this ferritin appears to be glycosylated and has a relatively low iron content.[26] Such ferritin has a half-life ($T_{1/2}$) of approximately 30 h. Ferritin is also released into the circulation as a result of tissue damage (most strikingly after necrosis of the liver). Tissue ferritin is cleared rapidly from the circulation ($T_{1/2}$ in approximately 10 min) by the liver.

Non-transferrin–bound iron describes a form of iron that is not bound to transferrin, is of low molecular mass and can be bound by specific iron chelators.[27] Several assays have been described that have demonstrated such a fraction in plasma from patients with iron overload. The chemical form of this iron is unknown, but it is probably rapidly removed from the circulation by the liver. Various ferrireductases and divalent metal transporters (ZIP14, ZIP8, DMT1) are implicated in this process. [28]

IRON STATUS

Normal iron status implies a level of erythropoiesis that is not limited by the supply of iron and the presence of a small reserve of 'storage iron' to cope with normal physiological needs. The ability to survive the acute loss of blood

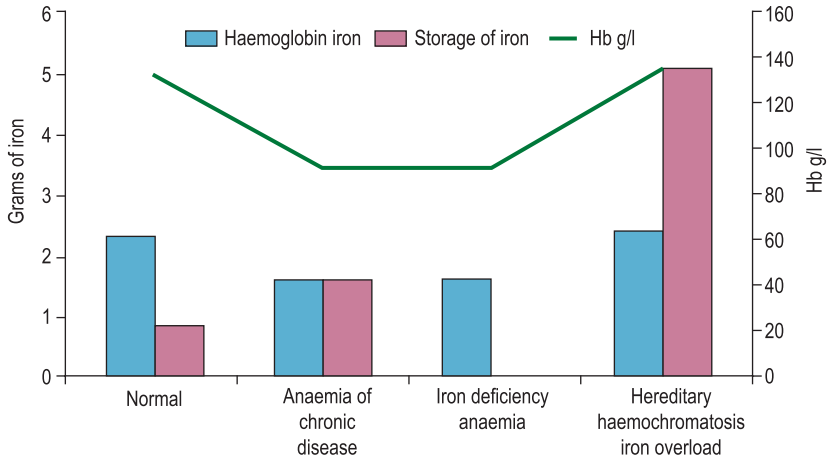

FIGURE 9-2 Body iron content and distribution in different conditions.

(and thus iron) that may result from injury is also an advantage. The limits of normality are difficult to define and some argue that physiological normality is the presence of only a minimal amount of storage iron[29] but the extremes (i.e. iron deficiency anaemia and haemochromatosis) are well understood.

Apart from too little or too much iron in the body, there is also the possibility of a maldistribution (Fig. 9-2). An example is anaemia associated with inflammation or infection, usually known as 'the anaemia of chronic disease' but also as 'the anaemia of inflammation', where there is a partial failure of erythropoiesis and of iron release from the phagocytic cells in liver, spleen and bone marrow, which results in accumulation of iron as ferritin and haemosiderin in these cells.

Determination of iron status requires an estimate of the amount of haemoglobin iron (usually by measuring the haemoglobin concentration [Hb] in the blood; see Chapter 3) and the level of storage iron (usually by measuring serum ferritin concentration). Iron deficiency should be suspected in hypochromic, microcytic anaemia, but in the early stages of iron deficiency red cells may be normocytic and normochromic. Another feature of iron deficiency is an increased concentration of protoporphyrin in the red cells; normally, there is a small amount present, but defective haem synthesis caused by lack of iron results in the accumulation of zinc protoporphyrin and occasionally free protoporphyrin is increased as well.[30]

Additional assays are sometimes required. In hereditary haemochromatosis, early iron accumulation is indicated by increased transferrin saturation alone. The serum ferritin concentration increases only later as the level of stored iron increases. In the anaemia of chronic disease, patients often have normal serum ferritin concentrations even when storage iron in the bone marrow is absent. In this situation, the assay of serum transferrin receptor (also known as soluble transferrin receptor) may help detect tissue iron deficiency.

DISORDERS OF IRON METABOLISM

Clinical aspects of iron metabolism have been reviewed[31–33] and are summarised in Table 9-2. Guidelines on the management of hereditary haemochromatosis are available.[34,35]

METHODS FOR ASSESSING IRON STATUS

The methods used to assess iron status are summarised in Table 9-3.[36] Some are not generally applicable but have value in the standardisation of indirect methods. The determinations of Hb and red cell indices are described in Chapter 3.

Serum ferritin assay

With the recognition that the small quantity of ferritin in human serum (15–300 µg/l in healthy men) reflects body iron stores, measurement of serum ferritin has been widely adopted as a test for iron deficiency and iron overload. The first reliable method to be introduced was an immunoradiometric assay in which excess radiolabelled antibody was reacted with ferritin and antibody not bound to ferritin was removed with an immunoadsorbent.[37] This assay was supplanted by the two-site immunoradiometric assay, which is sensitive and convenient. Since then the principle of this assay has been extended to non-radioactive labelling, including enzymes (enzyme-linked immunosorbent assay or ELISA). Most current laboratory immunoassay systems for clinical laboratories include ferritin in the assay repertoire. Factors to be considered when selecting an immunoassay system are discussed later. A detailed method, for which the most sophisticated equipment required was a microtitre plate reader, is described in the previous edition of this book.

TABLE 9-2

DISORDERS OF IRON METABOLISM

Iron Deficiency

Deficient Iron Intake

Diet of low bioavailability

Increased physiological requirements due to rapid growth in early childhood and in adolescence

Blood loss

Physiological (e.g. menstruation)

Pathological (e.g. gastrointestinal)

Malabsorption of Iron

Reduced or absent gastric acid secretion (e.g. after partial or total gastrectomy or with atrophic gastritis)

Reduced duodenal absorption (e.g. in coeliac disease)

Bypass of stomach and duodenum (bariatric surgery)

Rare, inherited iron-refractory iron deficiency anaemia (e.g. deficiency of TMPRSS6 [transmembrane protease, serine 6], also known as matriptase-2)

Redistribution of Iron

Macrophage iron accumulation in reticuloendothelial system in inflammatory, infectious or malignant diseases (anaemia of chronic disease, also known as anaemia of inflammation)

Macrophage iron accumulation within the lungs in idiopathic pulmonary haemosiderosis

Iron Overload

Due to Increased Iron Absorption

Hereditary haemochromatosis – commonly (amongst Northern Europeans) homozygosity for *HFE* C282Y but sometimes involving non-C282Y *HFE* or other genes (*HAMP, HFE2* [encoding hemojuvelin], *TFR2, SLC40A1*)

Substantial ineffective erythropoiesis (e.g. β thalassaemia intermedia and major, some types of sideroblastic anaemia, congenital dyserythropoietic anaemia)

Sub-Saharan iron overload ('Bantu siderosis') – only in combination with increased dietary iron

Other rare inherited disorders (e.g. congenital atransferrinaemia, DMT1 deficiency, acaeruloplasminaemia)

Inappropriate iron therapy (rare)

Due to Multiple Blood Transfusions for Refractory Anaemias or for other Reasons

Thalassaemia major

Aplastic anaemia

Myelodysplastic syndromes

Sickle cell disease (when regularly transfused)

Immunoassay for ferritin

Selecting an assay method

The following notes may be of use for those considering introducing a ferritin assay into a clinical laboratory using an immunoassay system. The major manufacturers of immunoassay analysers include ferritin in the test menu and allow for either batch or random access operation. Most use chemiluminescent signal detection with microparticle separation of free and ferritin-bound labelled antibody.

1. *Limit of detection.* Most current assays have a lower limit of <1 μg/l. This is adequate for all clinical purposes.
2. *The 'high-dose hook'.* This is a problem peculiar to labelled-antibody assays when sera with very high ferritin concentrations give anomalous readings in the lower part of the standard curve. Most current commercial assays are not affected. Because of the wide range of serum ferritin concentrations that may be encountered in hospital patients (0–40 000 μg/l), it is essential to dilute and re-assay any samples giving readings higher than the working range of the assay. This may be done automatically in some systems but might require manual dilution.
3. *Interference by non-ferritin proteins in serum.* This may occur with any method but particularly with labelled-antibody assays. Serum proteins may inhibit the binding of ferritin to the solid phase when compared with binding in buffer solution alone. Such an effect may be avoided by diluting the standards in a buffer containing a suitable serum or by diluting serum samples as much as possible. For example, in the assay described in the previous edition of this book, the sample is diluted 20 times with buffer. Another cause of error, difficult to detect, is interference by antibodies to animal immunoglobulins.[38] These antibodies bind to the animal immunoglobulins used to detect the antigen and form artefactual 'sandwiches', thereby falsely elevating the reading. Such antibodies are found in up to 10% of patients and normal subjects. Interference may be reduced by adding the appropriate species of animal immunoglobulins to block the cross-reaction, but this is not always successful.[39] One solution is to use antibodies from different species as solid-phase and labelled antibodies. Thus one may use a polyclonal, rabbit antiferritin to coat plates in the ELISA with a polyclonal sheep antiferritin labelled with horseradish peroxidase as the second antibody.
4. *Reproducibility.* Most assays are satisfactory. With microtitre plate assays there may be 'edge' effects (differences between readings for inner and outer wells).
5. *Dilution of serum samples.* It should be established that both standard and serum samples dilute in parallel over a 100-fold range.
6. *Accuracy.* The use of the WHO standard ferritin preparation is recommended. Calibrate the working standard against that of the World Health Organisation (WHO) (standard for the assay of serum ferritin 94/572, recombinant human L type ferritin-information available at www.nibsc.org).

Interpretation

The use of serum ferritin for the assessment of iron stores has become well-established.[37] In most normal adults, serum ferritin concentrations lie within the range of 15–300 μg/l. During the first months of life, mean serum ferritin concentrations change considerably, reflecting changes in storage iron concentration. Concentrations are lower in children (<15 years) than in adults and from puberty to middle life are higher in men than in women. In adults,

TABLE 9-3

ASSESSMENT OF BODY IRON STATUS AND CONFOUNDING FACTORS

Measurement	Reference Range (Adults)	Diagnostic Use	Confounding Factors
Full Blood Count			
Haemoglobin concentration	Male: 130–170 g/l Female: 120–150 g/l	Defining anaemia and assessing its severity; response to a therapeutic trial of iron confirms iron deficiency anaemia	Other causes of anaemia besides iron deficiency
Mean cell volume	83–98 fl	Low values may indicate iron deficient erythropoiesis	May be reduced in disorders of haemoglobin synthesis other than iron deficiency (thalassaemia, sideroblastic anaemias, anaemia of chronic disease). May be reduced in other conditions.
Mean cell haemoglobin	27–32 pg	Low values may indicate iron deficient erythropoiesis	May be reduced in disorders of haemoglobin synthesis other than iron deficiency (see above)
Tissue Iron Supply			
Serum iron	10–30 μmol/l	Low values in iron deficiency, high values in iron overload	Labile, but use of a fasting morning sample reduces variability; reduced in acute and chronic disease
Total iron-binding capacity (TIBC)	47–70 μmol/l	High values are characteristic of tissue iron deficiency Low values in iron overload May also be calculated from transferrin concentration (transferrin g/l × 25)	Rarely used on its own Reliable reference ranges not available
Unsaturated iron-binding capacity (UIBC)	See text		
Transferrin saturation [iron/TIBC] × 100	16–50%	Low values in iron deficiency, high values in iron overload Raised level is an early indicator of iron accumulation in hereditary haemochromatosis	See serum iron (above)
Iron Supply to the Bone Marrow			
Serum transferrin receptor (sTfR)	2.8–8.5 mg/l*	Increased sTfR, ZPP or % hypochromic red cells, or reduced red cell ferritin, may indicate impaired iron supply to the bone marrow. sTfR is useful for identifying early iron deficiency and, with a measure of iron stores, distinguishing this from ACD. In ACD, sTfR only increases in the presence of tissue iron deficiency.	sTfR concentration is related to extent of erythroid activity as well as iron supply to cells; ZPP, red cell ferritin and % hypochromic cells are stable measures determined at the time of red cell formation. ZPP may be increased by other causes of impaired iron incorporation into haem (some sideroblastic anaemias, lead poisoning, inflammation and in X-linked protoporphyria); % hypochromic cells will be affected by change in red cell volume on sample storage
Red cell zinc protoporphyrin (ZPP)	<80 μmol/mol haemoglobin		
Red cell ferritin ('L' type)	3–40 ag/cell		
% Hypochromic red cells	<6%		
Iron Stores			
Serum ferritin	Male: 15–300 μg/l Female: 15–200 μg/l	Correlated with body iron stores from deficiency to overload	Increased: as acute-phase protein and by release of tissue ferritin after organ damage (particularly liver disease) Increased in rare inherited disorders of ferritin overproduction Decreased: vitamin C deficiency
Tissue Iron			
Chemical assay: liver	3–33 μmol/g dry weight	Confirmation of iron overload	Adequate biopsy sample required

Continued

TABLE 9-3

ASSESSMENT OF BODY IRON STATUS AND CONFOUNDING FACTORS—CONT'D

Measurement	Reference Range (Adults)	Diagnostic Use	Confounding Factors
Perls stain of liver	(Grade)	Confirmation of iron overload, also to distinguish between parenchymal and macrophage iron accumulation	Adequate biopsy sample required
Perls stain of bone marrow	(Grade)	Graded as absent, present or increased Most commonly used to differentiate ACD from iron deficiency anaemia	Adequate biopsy sample required
Quantitative phlebotomy	<2 g Fe	Assessment of the amount of storage iron for confirmation of iron overload in hereditary haemochromatosis and other iron-loading conditions with simultaneous treatment of the iron overload.	Interpretation should take into account that early diagnosis will be associated with lower iron loads than used to be obtained when late diagnosis was more common
Urine-chelatable Fe (after intramuscular injection of deferoxamine)	<2 mg/24 h	Rarely used but may provide confirmation of iron overload	
Imaging			
MRI (magnetic resonance imaging)		Available both for hepatic and for cardiac iron deposition	Machines only widely available in developed countries
SQUID (superconducting quantum interface device)		Quantitation of liver iron overload using magnetic properties of iron	Not available in UK and rarely available worldwide

Modified from Pippard MJ. Iron-deficiency anemia, anemia of chronic disorders and iron overload. In: Wickramasinghe SL, McCullough J, editors. *Blood and bone marrow pathology.* London: Churchill Livingstone; 2003, pp 203–228.
ACD, anaemia of chronic disease; sTfR, soluble transferrin receptor; TIBC, total iron-binding capacity; ZPP, zinc protoporphyrin.
*Units and reference ranges are specific to method.

concentrations <15 μg/l indicate an absence of storage iron. Reference ranges quoted by kit manufacturers vary and this is partly a result of the selection of 'normal' subjects. Sometimes subjects with iron deficiency are included and sometimes they are excluded. The interpretation of serum concentration in many pathological conditions is less straightforward, but concentrations <15 μg/l indicate depletion of storage iron. In children, mean levels of storage iron are lower and a 12 μg/l threshold has been found to be appropriate for detecting iron deficiency.[40]

Iron overload causes high concentrations of serum ferritin, but these may also be found in patients with liver disease, infection, inflammation or malignant disease.[37] In addition some rare inherited causes of increased ferritin production unlinked to iron stores occur. Careful consideration of the clinical evidence is required before concluding that a high serum ferritin concentration is primarily the result of iron overload and not a result of tissue damage or enhanced synthesis of ferritin. A normal ferritin concentration provides good evidence against iron overload but does not exclude hereditary haemochromatosis. This is because the most common type of hereditary haemochromatosis in Northern Europeans is a late-onset condition and iron stores may remain within the normal range for many years.

Serum ferritin concentrations are high in patients with advanced haemochromatosis, but since the serum ferritin may be within the normal range its estimation should not be used alone to screen the relatives of patients or to assess re-accumulation of storage iron after phlebotomy. The early stages of iron accumulation are detectable by an increased serum iron concentration, a decreased unsaturated iron-binding capacity and increased transferrin saturation. In this situation, the measurement of serum iron and total iron-binding capacity provides useful clinical information not given by the ferritin assay.

In patients with acute or chronic disease, interpretation of serum ferritin concentrations is less straightforward and patients may have serum ferritin concentrations up to 100 μg/l despite an absence of stainable iron in the bone marrow. Ferritin synthesis is enhanced by interleukin-1 (IL1) – the primary mediator of the acute-phase response.[41] In patients with chronic disease, the following approach should be adopted: low serum ferritin concentrations indicate absent iron stores, values within the normal range indicate either low or normal levels and high values indicate either normal or high levels. In elderly patients a ferritin below 45 μg/l is usually indicative of iron deficiency[42] with a ferritin level of up to 75 or 100 μg/l

in the elderly being compatible with iron deficiency. In terms of adequacy of iron stores for replenishing haemoglobin in patients with anaemia, the degree of anaemia must also be considered. Thus a patient with Hb of 100 g/l may benefit from iron therapy if the serum ferritin concentration is <100 μg/l because below this level there is unlikely to be sufficient iron available for full regeneration. Here, measurement of serum transferrin receptor concentration may be of value (see p. 182).

Immunologically, plasma ferritin resembles the 'L-rich' ferritins of liver and spleen and only low concentrations are detected with antibodies to heart or HeLa cell ferritin, ferritins rich in 'H' subunits. The heterogeneity of serum ferritin on isoelectric focusing is largely the result of glycosylation and the presence of variable numbers of sialic acid residues and not variation in the ratio of H to L subunits.[43] Attempts to assay for 'acidic' (or 'H'-rich) isoferritins in serum as tumour markers have not been successful.[43] The iron content of serum ferritin is low[43] and measurement of this iron has no diagnostic use.[44]

ESTIMATION OF SERUM IRON CONCENTRATION

Iron is carried in the plasma bound to the protein transferrin (molecular mass 78 000 Da). This molecule binds two atoms of iron as Fe^{3+} and delivers iron to cells by interaction with membrane transferrin receptors. The following method is a modification of that recommended by the International Council for Standardisation in Haematology (ICSH) and is based on the development of a coloured complex when ferrous iron released by serum protein denaturation in the presence of reducing agent is treated with a chromogen solution.[45]

Reagents and materials

Reagents must be at least of analytical grade with the lowest obtainable iron content. Before handling any of the reagents and materials described below a risk assessment should be carried out. If there is significant risk of harm, the word 'caution' has been added.

Preparation of glassware

It is essential to avoid contamination by iron. If possible, use disposable plastic tubes and bottles. If glassware is to be used, wash in a detergent solution, soak in 2 mol/l HCl (caution) for 12 h and finally rinse in iron-free water.

Protein precipitant

100 g/l trichloroacetic acid (0.61 M) and 22.7 mmol/l ascorbic acid in 0.9 mol/l HCl. The original reducing agent was thioglycolic acid.[45] Ascorbic acid is an alternative reducing agent, although there may be more interference from copper. However, any benefit from reduced copper interference is usually outweighed by the associated health and safety problems of working with thioglycolic acid. To 45 ml of 1 mol/l HCl in a 50-ml screwcap polypropylene tube add 5 ml of 6.1 mol/l trichloroacetic acid solution (Sigma–Aldrich T0699; caution). Add 200 mg of ascorbic acid and mix. Make a fresh solution when required and discard after 4 h.

Chromogen solution (ferrozine)

In 100 ml of 1.5 mol/l sodium acetate dissolve 25 mg of ferrozine [Sigma–Aldrich 82950, monosodium 3-(2-pyridyl)-5,6-bis(4-phenylsulphonic acid)-1,2,4-triazine] (caution). Store in the dark for up to 4 weeks.

Iron-free water

Use deionised water for the preparation of all solutions.

Iron standard 80 μmol/l

Add 22.1 ml of deionised water to a universal container (the easiest way is by weight). Add 200 μl of 2 mol/l HCl and mix. Add 100 μl of iron standard solution (1000 μg of Fe/ml in 1% v/v HCl, Sigma–Aldrich 30595–2) and mix. Store for up to 2 months at room temperature.

Method

Place 0.5 ml of serum (must be free of haemolysis), 0.5 ml of working iron standard and 0.5 ml of iron-free water (as a blank), respectively, in each of three 1.5-ml polypropylene microcentrifuge tubes with lids. Add 0.5 ml of protein precipitant to each and replace the lid. Mix the contents vigorously (e.g. with a vortex mixer) and allow to stand for 5 min. Centrifuge the tube containing the serum at 13 000 *g* for 4 min (in a microfuge) to obtain an optically clear supernatant. To 0.5 ml of this supernatant and to 0.5 ml of each of the other mixtures, add 0.5 ml of chromogen solution with thorough mixing. After standing for 10 min, measure the absorbance in a spectrophotometer against water at 562 nm. If a microcentrifuge is not available, use double the volume of serum and reagents in a 3-ml plastic tube with lid and centrifuge at 1500 *g* for 15 min in a bench centrifuge.

If ethylenediaminetetra-acetic acid (EDTA)–plasma is used, the colour develops more slowly and its use is therefore not recommended. Iron chelators (e.g. deferoxamine) also delay colour development.[46]

Calculation

$$\text{Serum iron}\,(\mu\text{mol/l}) = \frac{(A_{562}\,\text{test} - A_{562}\,\text{blank})}{(A_{562}\,\text{standard} - A_{562}\,\text{blank})} \times 80$$

ALTERNATIVE PROCEDURE: SERUM IRON WITHOUT PROTEIN PRECIPITATION

This is a microtitre plate method developed from the assay of Persijn *et al.*[47]

Reagents and materials

Iron standards 80 µmol/l and 40 µmol/l (see p. 173)

Dilute with an equal volume of water to make the 40 µmol/l standard.

Phosphate–ascorbate buffer (stock)

Add approximately 200 ml of deionised water to an acid-washed plastic beaker. Add 17.5 g of sodium dihydrogen orthophosphate ($NaH_2PO_42H_2O$) to the water and dissolve fully by stirring (plastic stirrer). Adjust the pH to 4.9 using 2 M NaOH solution (2 g of NaOH in 25 ml of water; caution). Make the volume up to 250 ml and add 25 ml of the buffer to 10 universal containers. Store for up to 1 month at room temperature. Prior to use, add 50 mg of ascorbic acid to each universal container required and shake to dissolve. Discard after 4 h.

Chromogen solution

Add 50 mg of ferrozine (see p. 173) to 25 ml of deionised water and shake to dissolve. Store for up to 1 month in the dark at room temperature.

Microtitre trays

Microtitre trays should be optical grade, with flat-bottomed wells.

Control serum

Suitable control sera are Lyphochek Assayed Chemistry Control (Bio-Rad, www.bio-rad.com).

Method

Add 80 µl of deionised water ('O'), standard solution (40, 80 µmol/l), controls (C1, C2) and samples (S1, S2, etc.) to the microtitre plate (see plate map, Table 9-4).

Add 80 µl of phosphate–ascorbate buffer to each well, using a multichannel pipette. Tap the tray to mix. Leave for 20 min at room temperature. During this time, take an initial absorbance reading of the tray at 560–570 nm on a microtitre plate reader. Add 40 µl of chromogen solution to each well, then tap the tray to mix. Cover with a film or lid. Incubate for 40 min at 37 °C. Take a second absorbance reading. Calculate the net absorbance increment values.

Calculations

Calculate the difference in absorbance (δA) between the final and initial readings for the water blank (δA_0), each standard (δA_{40}, δA_{80}) and serum sample (δA_{sample}).

The approximate values are 0.015–0.03 for the water blank (zero standard) and 0.25–0.28 for the 40 µmol Fe/l standard. Subtract the mean net value of the zero standard (δA_0) from each standard or sample (δA_{sample}). The net value of the 80 µmol/l standard δA_{80} should be 2× that of the 40 µmol/l standard δA_{40}.

Serum iron concentrations are:

$$\left(\delta A_{sample} - \delta A_0\right) \times 40 / \delta A_{40} - \delta A_0 \mu mol / l$$

The data may be downloaded from the plate reader and imported into a suitable spreadsheet or statistical programme for these calculations.

Automated methods for serum iron

Procedures for measuring serum iron are available for most clinical chemistry analysers. A non-precipitation method similar to that described above is available from Randox Ltd (www.randox.com). The performance of several methods was reviewed by Tietz *et al.*,[48] who found differences between the various methods, particularly at low values of serum iron concentration. Subsequently, Blanck *et al.*[49] carried out an interlaboratory comparison and found no significant differences in results generated by methods currently in use. Variability across laboratories and across methods was low. Serum iron concentrations may be measured by atomic absorption spectroscopy, but this has the disadvantage of measuring any haem iron present as a result of haemolysis and is not used for diagnostic purposes.

SERUM IRON CONCENTRATIONS IN HEALTH AND DISEASE

Jacobs *et al.*[50] measured serum iron concentrations in a random sample of 517 women and 499 men in the general population of Wales. Serum iron concentrations approximated to a normal distribution. The mean ± standard deviation (SD) of 16.1 ± 7.4 µmol/l in women was slightly lower than that for men (18.0 ± 6.3 µmol/l). These figures do not refer to 'iron replete' subjects because subjects with absent iron stores or with frank anaemia were included. Using the microtitre plate method described earlier, Jackson and co-workers[51] determined serum iron concentrations in 10 500 blood donors from South Wales. For 1502 'first time' donors, mean age of 28 years, the mean ± SD was 16.7 ± 6.0 µmol/l for men and 14.4 ± 6.7 µmol/l for women. Again subjects included potential donors who failed the screening test for anaemia and were not permitted to give blood on that occasion. In the first month of life mean concentration of serum iron is higher (22 µmol/l) than in adults, falls to about 12 µmol/l by the age of 1 year and remains at that level throughout childhood.[52,53]

Measurement of the serum iron concentration alone provides little useful clinical information because, although methodological variation is low, there is considerable variation from hour to hour and day to day in normal individuals (see p. 180). Low concentrations are found in patients with iron deficiency anaemia; in chronic disease (including inflammation, infection and cancer); and during the acute-phase response, including after surgery. Therefore, low serum iron concentrations do not necessarily indicate an absence of storage iron. High concentrations are found in liver disease, hypoplastic anaemias, ineffective erythropoiesis and iron overload.

ESTIMATION OF TOTAL IRON-BINDING CAPACITY

In the plasma, iron is bound to transferrin and the total iron-binding capacity (TIBC) is a measure of this protein. The additional iron-binding capacity of transferrin is known as the unsaturated iron-binding capacity (UIBC). The serum iron concentration plus the UIBC together give TIBC.

Iron-binding capacity is usually measured by adding an excess of iron and measuring the iron retained in solution after the addition of a suitable reagent such as 'light' magnesium carbonate or an ion-exchange resin that removes excess iron. All methods are empirical and none is completely satisfactory. The method described as follows was developed by the ICSH.[54]

Principle

Excess iron as ferric chloride is added to serum. Any iron that does not bind to transferrin is removed with excess magnesium carbonate. The iron concentration of the iron-saturated serum is then measured.

Reagents

Basic magnesium carbonate, $MgCO_3$, 'light grade'
Saturating solution (100 µmol Fe/l)

Add 17.7 ml of deionised water to a universal container (by weight is most convenient). Add 100 µl of 1 mol/l HCl. Add 100 µl of commercial iron standard solution (see p. 173). Mix and store for up to 2 months at room temperature. The 'saturating iron solution' contains 5.6 µg of Fe/ml (100 µmol Fe/l).

Method

Place 0.5 ml of serum (EDTA-plasma should not be used) in a 1.5-ml polypropylene microcentrifuge tube and add 0.5 ml of saturating iron solution. Mix carefully by hand and leave at room temperature for 15 min. Use a plastic scoop or tube to add 100 mg (±15 mg) of light magnesium carbonate and cap the tube. Shake vigorously and allow to stand for 30 min with occasional mixing. Centrifuge at 13 000 *g* for 4 min in a microcentrifuge. If the supernatant contains traces of magnesium carbonate, remove the supernatant and re-centrifuge. Carefully remove 0.5 ml of supernatant and treat as serum for the iron estimation described earlier (p. 173). Multiply the final result by 2.

DETERMINATION OF UNSATURATED IRON-BINDING CAPACITY

The UIBC may be determined by methods that detect iron remaining and able to bind to chromogen, after adding a standard and excess amount of iron to the serum.[47] The UIBC is the difference between the amount added and the amount binding to the chromogen.

Reagents and materials

Saturating solution

2000 µmol iron/l. Add 7.95 ml of deionised water to a universal container (by weight is most convenient). Add 1.0 ml of Commercial Iron Standard Solution (1000 µg Fe/ml; see p. 173). Mix. Store for up to 2 months at room temperature.

Tris buffer (stock)

0.22 M, pH 7.8. Add approximately 200 ml of deionised water to a weighed acid-washed plastic beaker. Add 6.8 g of Tris to the water and fully dissolve by stirring with a magnetic stirrer. Adjust the pH to 7.8 using 2 M HCl. Adjust the volume to 250 ml with water (by weight), mix and dispense 24.5 ml (24.5 g) into universal containers. Store for up to 1 month at room temperature.

Tris–ascorbate–iron buffer

Immediately prior to use, add 50 mg of ascorbic acid to each universal container of Tris buffer required and dissolve by mixing. Add 0.5 ml of saturating solution (2000 µmol Fe/l) and mix. Discard after 4 h.

Chromogen solution

See page 173.

Microtitre trays

See page 174.

Control serum

See page 174.

Method

Add 80 µl of deionised water ('O'), control (C1, C2) and sample (S1, S2, etc.) to the microtitre plate (Table 9-5). Add 160 µl of Tris–ascorbate–iron buffer to each well, using a multichannel pipette. Tap the tray to mix. Leave the tray for 20 min. During this time, take an initial reading ($A_{initial}$) of the $A_{560–570\ nm}$. Add 40 µl of chromogen solution to each sample and tap the tray to mix; cover with a film or lid. Incubate for 40 min at 37 °C. Take a final absorbance reading (A_{final}).

Calculations

The saturating solution added to each well (160 µl) contains 6.4 nmol of Fe. Calculate the absorbance reading corresponding to 6.4 nmol of Fe from the mean value of the readings in column 1 as $A_{final} - A_{initial}$ (A_s). (Note: this absorbance reading should be within 5% of the 80 µmol/l value for the iron determination.)

Once A_s has been calculated, it is used in the following equation:

For controls 1 and 2 and samples:

$$UIBC = \left[1 - \left(A_{final} - A_{initial}\right)\right] / A_s \times 80\,\mu mol/l$$

Data may be imported into a spreadsheet for calculation. As with the serum iron determination, protocols for clinical chemistry analysers sometimes include a method for UIBC.

Determination of total iron-binding capacity from UIBC:

$$TIBC = serum\ iron + UIBC\left(\mu mol/l\right)$$

FULLY AUTOMATED METHODS

A number of methods to determine the TIBC using clinical chemistry analysers require a pretreatment step. Direct (fully automated) procedures have been developed.[55] A non-precipitation method (UIBC) similar to that described above is available from Randox Ltd (Cat. No. S1250) (www.randox.com).

SERUM TRANSFERRIN

An alternative approach is to measure transferrin directly by an immunological assay. This avoids some of the spuriously high values of TIBC found when the transferrin is saturated and non-transferrin iron is measured.[45] Rate immunonephelometric methods are rapid and precise. There is generally a good correlation between the chemical and immunological TIBC,[56,57] although when TIBC was calculated as the serum Fe + UIBC, values were lower than the direct TIBC.[55] Transferrin concentrations (g/l) may be converted to TIBC (µmol/l) by multiplying by 25.

Normal ranges of transferrin and total iron-binding capacity

In health, the serum transferrin level is 2.0–3.0 g/l and 1 mg of transferrin binds 1.4 µg of iron. The normal serum TIBC (mean ± SD) was 68.0 ± 12.6 µmol/l in a random sample of 517 women and 63.2 ± 9.1 µmol/l for 499 men.[50] For 890 first-time, female blood donors of mean age 27 years the mean TIBC (determined by the UIBC method described earlier) was 56.7 ± 12.1 µmol/l. In 612 first-time, male blood donors of mean age 28 years the mean was 54.2 ± 10 µmol/l (mean ± SD).[51] In both surveys, the sample included some individuals with iron deficiency. Note the comment earlier about lower values given by the colorimetric UIBC method. The TIBC is increased in iron deficiency anaemia and in pregnancy; it is lower than normal in infections, malignant disease and renal disease. In pathological iron overload, the TIBC of the serum is reduced.

Diagnostically, although a raised TIBC is characteristic of iron deficiency anaemia, the TIBC is usually used to cal-

TABLE 9-5

PLATE MAP FOR UNSATURATED IRON-BINDING CAPACITY (UIBC) DETERMINATION

culate the transferrin saturation. The UIBC has attracted little diagnostic use, but is being evaluated as a screening test for iron overload in hereditary haemochromatosis. In hereditary haemochromatosis (subjects homozygous for *HFE* C282Y), a UIBC (determined as described earlier) of <20 μmol Fe/l was found in most men and in about 50% of women.[51] UIBC and transferrin saturation were equally sensitive and specific. For UIBC methods, optimum thresholds for detecting subjects with hereditary haemochromatosis have varied. Murtagh and co-workers[58] determined the optimum threshold to be 25.6 μmol/l (sensitivity 0.91 and specificity 0.95). In this case, fasting blood samples were taken. UIBC was as reliable as transferrin saturation in detecting HFE haemochromatosis in both reports.

TRANSFERRIN SATURATION

The transferrin saturation is the ratio of the serum iron concentration and the TIBC expressed as a percentage. If transferrin is measured immunologically, then the corresponding TIBC (μmol/l) may be calculated by multiplying the transferrin concentration (g/l) by 25. In a sample of the Welsh population, the mean transferrin saturation in 499 men was 29.1 ± 11.0%; in 517 women it was 24.6 ± 11.8%.[50] For first-time blood donors from South Wales the mean transferrin saturation was 31.1 ± 10.9% for 612 men and 25.5 ± 12.9% for 890 women.[51] A transferrin saturation of <16% is usually considered to indicate an inadequate iron supply for erythropoiesis.[59] The most valuable use of transferrin saturation is for the detection of hereditary haemochromatosis. Even in the early stages of the development of iron overload,[51,60] an elevated transferrin saturation is indicative of the disorder. The European Association for the Study of the Liver (EASL) guideline suggests thresholds of >50% for men and >45% for women.[34]

SERUM TRANSFERRIN RECEPTOR

Almost all cells in the body obtain iron from the plasma protein transferrin, but transferrin has a very high affinity for iron at neutral pH and iron release takes place through a specific membrane receptor. There are two types of transferrin receptors – TfR1 and TfR2 – encoded by different genes. TfR1 is essential for tissue iron delivery and is a homodimer consisting of two identical protein subunits of molecular mass 95 kDa. Transferrin binds to TfR1, the complex is internalised and iron is released when the pH of the internal vesicles is reduced to about 5.5. After iron release, apotransferrin remains bound to the receptor until exposed to an alkaline pH at the cell surface, returns to the circulation and can undertake further cycles of iron uptake and delivery.[61] The cells that require most iron are the nucleated red cells in the bone marrow, which synthesise haemoglobin and have the greatest number of transferrin receptors. TfR1 synthesis is also controlled by iron supply. The mechanism involves five IREs (see p. 168) at the 3′ untranslated region of the receptor mRNA. In the absence of iron, an IRP binds to each RNA IRE, thus stabilizing it and permitting synthesis of the protein chain. In the presence of adequate iron concentrations, binding of iron by the IRP changes the conformation of the protein and prevents its binding to the mRNA. The mRNA is rapidly broken down and synthesis of transferrin receptors is reduced. The second receptor, TfR2, also binds transferrin, but it is not required for iron delivery to cells and its synthesis is not regulated by IRPs.[62]

In 1986, Kohgo and co-workers[63] reported that transferrin receptors were detectable in the plasma by immunoassay. Since then, there has been much investigation of the physiological and diagnostic significance of circulating transferrin receptors.[64] The protein is derived by proteolysis at the cell membrane and circulates bound to transferrin. Plasma concentrations reflect the number of cellular receptors and, in patients with adequate iron stores, the number of nucleated red cells in the bone marrow. Because the number of cellular transferrin receptors per cell increases in iron deficiency, concentrations also increase when erythropoiesis becomes iron limited. Table 9-6 summarises the conditions associated with reduced or elevated levels of circulating transferrin receptor.

TABLE 9-6

SERUM TRANSFERRIN RECEPTOR (sTfR) CONCENTRATIONS IN HUMAN DISEASE

sTfR Concentration	Condition
Increased	Increased erythroid proliferation:
	Autoimmune haemolytic anaemia
	Hereditary spherocytosis
	β thalassaemia intermedia or major
	β thalassaemia/haemoglobin E
	Haemoglobin H disease
	Sickle cell anaemia
	Polycythaemia vera
	Decreased tissue iron stores:
	Iron deficiency anaemia
Normal to increased	Primary myelofibrosis
	Myelodysplastic syndrome
	Chronic lymphocytic leukaemia
Normal	Haemochromatosis (but see text)
	Acute and chronic myeloid leukaemia
	Most lymphoid malignancies
	Solid tumours
	Anaemia of chronic disease
Decreased	Chronic renal failure
	Aplastic anaemia
	After bone marrow transplantation

Modified from Feelders RA, Kuiperkramer EPA, Vaneijk HG. Structure, function and clinical significance of transferrin receptors. *Clin Chem Lab Med* 1999;37:1–10.

Assays for the serum transferrin receptor

There has been no agreement about the source of transferrin receptor as standard or as an antigen for the raising of antibodies. Transferrin receptors have been purified from placenta and from serum. The receptor may or may not be bound to transferrin as a standard or to raise antibodies. No 'reference' method is therefore described here. Three enzyme immunoassay kits (Orion; Ramco laboratories, www.ramcolab.com; R&D Systems, www.rndsystems.com) for the determination of serum transferrin receptor concentrations were evaluated for the Medical Devices Agency.[65] All were approved for diagnostic purposes in the USA by the Food and Drug Administration but the Orion kit is no longer available. Assays for fully automated, diagnostic, immunoassay systems are now being introduced and offer improved sensitivity, reproducibility and speed.

The different reference ranges in the available commercial assays reflect the differences in preparations of transferrin receptor used to raise antibodies and as a standard in the various assays. For the Orion, Ramco and R&D kits Akesson *et al*.[66] and Worwood *et al*.[65] noted some assay drift but found acceptable intra-assay coefficient of variation (CV) values. The determined sensitivity was adequate for clinical purposes for the three assay systems. Four different units (nmol/l, μg/ml, mg/l and ku/l) and different normal ranges are in use.[67] At the present time, serum transferrin receptor (sTfR) is not included in the National External Quality Assessment Service for the UK (NEQAS) or the Welsh External Quality Assessment Service (WEQAS). A WHO reference reagent for the serum transferrin receptor has now been established and an international collaborative study showed that using this reagent as a standard markedly improved agreement between methods. Commercial assays available at the time are listed in that report.[68]

Reference ranges

sTfR concentrations are high in neonates and decline until adult concentrations are reached at 17 years. Concentrations are similar in normal men and non-pregnant women. During pregnancy sTfR levels increase, returning to non-pregnant values 12 weeks after delivery.[69] sTfR concentrations obtained with different assay systems cannot be directly compared because reference ranges differ.

Samples

The information provided by the manufacturers shows good recovery of standard and linearity but some problems with interference.[65] Although serum is the preferred matrix, the R&D and Ramco assays give the same results with EDTA, heparin and citrate plasma. It is recommended that sera are stored for no more than 2 days at room temperature, 7 days at 2–8 °C, 6 months at −20 °C and 1 year at −70 °C. Repeated freezing and thawing are not advisable. Moderate haemolysis is not a problem.

Transferrin receptor concentrations in diagnosis

Erythropoiesis

The function of the TfR1 in delivering iron to the immature red cell immediately suggested an application in the clinical laboratory for the assay of circulating sTfR. The use of the assay to monitor changes in the rate of erythropoiesis has been explored by several authors.[70] When iron supply is not limiting, the assay can provide a replacement for ferrokinetic investigations that required the injection of radioactive iron.

Iron deficiency

The major application of the serum transferrin receptor assay has been to detect patients with an absence of stored iron (ferritin and haemosiderin in cells). In infants (age 8–15 months) sTfR concentration increases with increased severity of iron deficiency.[71] When normal subjects undergo quantitative phlebotomy, serum ferritin concentrations decrease steadily as iron stores are depleted, but there is little change in sTfR concentration. As iron stores become exhausted (serum ferritin <15 μg/l), sTfR levels increase and continue increasing as Hb decreases[72]; in this study the increased rate of erythropoiesis during phlebotomy had little effect on sTfR levels as long as iron stores were adequate so that most of the increase in sTfR level was the result of iron deficiency rather than increased erythropoiesis. However, the rate of phlebotomy was only 250 ml per week (about 450 ml per week is usually removed during treatment of haemochromatosis) and higher rates might cause an immediate increase in sTfR levels during phlebotomy. The log[sTfR/serum ferritin] gives a linear relationship with storage iron that has considerable potential for assessing iron stores in epidemiological studies.[73]

Circulating transferrin receptor levels increase, not only in patients with simple iron deficiency but also in patients with the anaemia of chronic disease who lack stainable iron in the bone marrow.[74] Identifying a lack of storage iron in patients with the anaemia of chronic disease is difficult without this measurement because serum iron concentrations are low regardless of iron stores and serum ferritin concentrations are higher than in patients not suffering from chronic disease who have similar

levels of stainable iron in the bone marrow (see p. 315). Unfortunately, the sTfR has not proved to be superior to serum ferritin for detecting iron deficiency in all studies (Table 9-7).[75–86]

In both iron deficiency anaemia and the anaemia of chronic disease, sTfR levels are also influenced by changes in the rate of erythropoiesis. Ineffective erythropoiesis – an increase in the proportion of immature red cells destroyed within the bone marrow – increases in iron deficiency anaemia.[87] In the anaemia of chronic disease, erythropoiesis is normal or depressed;[88] nevertheless, iron deficiency increases the number of receptors.

Although it has been claimed that sTfR measurements provide a sensitive indicator of iron deficiency in pregnancy,[89] questions remain about the decreased erythropoiesis in early pregnancy because this may mask iron deficiency at this time[90] and increases in sTfR in later pregnancy appear to relate to increased erythropoiesis rather than iron depletion.[69] Measurement of sTfR did not enhance the sensitivity and specificity for the detection of iron deficiency anaemia in pregnant women from Malawi, where anaemia and chronic disease are both common.[91]

Iron overload

Normal concentrations of sTfR have been reported for patients with hereditary haemochromatosis (although some had been venesected) and also for patients with African iron overload.[92] In contrast, lower mean values of sTfR were found in subjects with a raised transferrin saturation.[93,94] However, there is considerable overlap with the normal range of sTfR concentration and measurement of sTfR in iron overload is unlikely to be of diagnostic value.

ERYTHROCYTE PROTOPORPHYRIN

Protoporphyrin IX is the immediate precursor to haem. The enzyme ferrochelatase is able to insert ferrous iron to produce haem or zinc cation to form zinc protoporphyrin (ZPP). When iron supply to ferrochelatase is limiting, ZPP increases. When ferrochelatase is limiting, free protoporphyrin accumulates. Different assays differ in the extent to which they measure and/or discriminate between these two forms of erythrocyte protoporphyrin. Assay of erythrocyte protoporphyrin[95] has been performed for many years as a screening test for lead poisoning. More recently, there has been considerable interest in its use in evaluating the iron supply to the bone marrow. The protoporphyrin concentration of red blood cells increases in iron deficiency. Usually, more than 95% is present as ZPP. The original method converts zinc to free protoporphyrin, and requires a chemical extraction and use of a fluorescence spectrometer.[95] This has now been largely replaced for detection of iron deficiency by the direct measurement of

the fluorescence of ZPP (μmol/mol haem) in an instrument called a haematofluorometer.[30]

Analysers

A dedicated analyser is available, the ProtoFluor Z from Helena Laboratories, Beaumont, Texas (www.helena.com). It should be operated exactly as described by the manufacturer. The small sample size (about 20 μl of venous or skin-puncture blood), simplicity, rapidity and reproducibility within a laboratory are advantages. Furthermore, the test has an interesting retrospective application. Because it takes weeks for a significant proportion of the circulating red blood cells to be replaced with new cells, it is possible to make a diagnosis of iron deficiency anaemia some time after iron therapy has commenced. Chronic diseases that reduce serum iron concentration, but do not reduce iron stores, also increase protoporphyrin levels.[96]

Diagnostic applications

The measurement of erythrocyte protoporphyrin levels as an indicator of iron deficiency has particular advantages in paediatric haematology and in large-scale surveys in which the small sample size and simplicity of the test are important. Normal range in adults is less than 70 μmol/mol haem. Mean values in normal women are slightly higher than in men.[97] One potential confounder is the contribution of other fluorescent compounds (including drugs) in the plasma and concentrations are lower if washed red cells are assayed.[85] However, washing is a tedious process and is rarely undertaken. Paediatric reference ranges have been determined in 6478 subjects (ages 0–17 years).[98] Mean ZPP values were higher in females than males and declined slightly with age. A diurnal variation was noted, with ZPP concentrations being higher between 18.00 h and midnight. No explanation was offered.

The WHO[40] has recommended levels for the detection of iron deficiency. For children younger than age 5 years, levels should be >61 μmol/mol haem; for all other subjects, levels should be >70 μmol/mol haem. These are higher than the 97.5 percentile established from surveys of healthy children[98] and are based on the sensitivity and specificity for detecting the absence of storage iron.

Units

To convert between the various units used to express protoporphyrin levels, the following calculations apply:

- μg erythrocyte protoporphyrin (EP)/dl red cell = (μg EP/dl whole blood)/haematocrit as %
- From μg EP/dl red cell to μg EP/g haemoglobin multiply by 0.037
- From μg EP/dl red cell to μmol EP/mol haem multiply by 0.87

These factors are based on an assumed normal mean cell haemoglobin concentration, although this may be measured in individual samples and an appropriate factor calculated.

Infection and inflammation, lead poisoning and haemolytic anaemia all cause significant elevation of ZPP. Measurement of ZPP is most useful when iron deficiency is common and the other conditions are rare. In the general clinical laboratory, therefore, ZPP provides less information about iron storage levels in patients with anaemia than does the serum ferritin assay.[99]

Although blood samples may be taken at any time of day, fresh blood is required (samples must not be frozen) and the method has not been automated.

HEPCIDIN

Reliable assays for serum hepcidin have now been developed but their role in the differential diagnosis of both iron deficiency and iron overload is not yet clear although a number of useful diagnostic applications are being investigated.[100] An international survey of urinary and plasma hepcidin assays demonstrated that absolute concentrations vary widely. However, analytical variation was generally low and similar for the six methods included in the study.[101]

METHODOLOGICAL AND BIOLOGICAL VARIABILITY OF ASSAYS

The blood assays vary greatly in both methodological and biological stability. Haemoglobin concentrations are stable and a simple and well-standardised method ensures relatively low day-to-day variation in individuals (Table 9-7). Automated cell counters analyse at least 10 000 cells and thus increase precision. ZPP values also appear to be relatively stable. The more complicated procedures involved in immunoassays result in higher methodological variation for serum ferritin assays (CV of about 5%) and this, coupled with some physiological variation, gives an overall CV for serum ferritin for an individual over a period of weeks of the order of 15%. There is, however, little evidence of any significant diurnal variation in serum ferritin concentration.[75] On the other hand, the serum iron determination has a reasonably low methodological variation coupled with extreme physiological variability, giving an overall 'within subject' CV of approximately 30% when venous samples are taken at the same time of day. A diurnal rhythm has been reported with higher values in the morning than in late afternoon, when the concentration may fall to 50% of the morning value.[46] However, variations are not consistently diurnal.[102] The circadian fluctuation is largely the result of variation in

the release of iron from the reticuloendothelial system to the plasma. It should be noted that for the studies summarised in Table 9-7 the type of blood sample, length of study period and statistical analysis vary. The somewhat higher variability for Hb and ferritin reported by Borel *et al*.[82] may be a result of their use of capillary blood and plasma. Pootrakul *et al*.[103] have demonstrated that mean plasma ferritin concentration is slightly higher in capillary specimens than venous specimens and that within- and between-sample variation was approximately three-fold greater. Variability was less for capillary serum than plasma but still greater than for venous serum. However, the increased variability of capillary samples may be related to sampling technique, because Cooper and Zlotkin[84] found little difference in variability between venous and capillary samples.

The effect of menstruation on iron-status indicators was examined in 1712 women aged 18–44 years after adjusting for potential confounders.[104] Adjusted mean values of Hb, transferrin saturation and serum ferritin were lowest for women whose blood was drawn during menses and highest for women examined in the luteal or late luteal phase of the menstrual cycle (Hb, 130 versus 133 g/l; transferrin saturation, 21.2% versus 24.8%, $p < 0.01$ for both; serum ferritin, 17.2 versus 24.0 μg/l, $p < 0.05$). The prevalence estimate of impaired iron status was significantly higher for women whose blood was drawn during the menstrual phase than for women whose blood was drawn during the luteal and late luteal phases. The authors concluded that cyclical variations in indicators of iron status are a potential source of error when iron status is assessed in large population surveys that include women of reproductive age.[104]

Starvation, or even fasting for a short period, can cause elevation of the serum ferritin concentration,[105] and vitamin C deficiency can reduce ferritin concentration.[106] Moderate exercise has little effect on serum ferritin concentration,[107] although exhausting exercise leads to increases in serum ferritin concentration as a result of muscle damage and inflammatory reactions.[108,109] Seasonal changes in red cell parameters have been reported[110] and Maes *et al*.[83] found statistically significant seasonal patterns for serum iron, transferrin, serum ferritin and sTfR. The peak–trough difference in the yearly variation, expressed as a percentage of the mean, was greatest for serum ferritin (39%) and least for sTfR and transferrin (12%).

These results have clear implications for the use of these assays in population studies. For accurate diagnosis, either a multiparameter analysis is required or several samples should be assayed. For Hb, one sample was required for 95% confidence and 20% accuracy;[111] for sTfR, one sample was required,[84,112] but for ferritin one to three samples were required.[84,111]

PREDICTIVE VALUE OF BLOOD TESTS FOR IRON DEFICIENCY

The major diagnostic use of the various measures of iron status is in the differential diagnosis of microcytic anaemia. The large amount of iron present as haemoglobin means that the degree of any anaemia must always be considered in assessing iron status. There is an overall reduction in body iron in iron deficiency anaemia. No single measurement of iron status is ideal for all clinical circumstances because all are affected by confounding factors (Table 9-3). The anaemia of chronic disorders is associated with normal or increased iron stores (normal or increased serum ferritin), accompanied by a reduced tissue iron supply (low serum iron and low to normal TIBC). Although the serum ferritin is an acute-phase reactant, values below 50 μg/l are usually associated with absent iron stores in rheumatoid arthritis, renal disease and inflammatory bowel disease. Serum transferrin receptor levels may also provide valuable diagnostic information on iron deficiency in chronic disease.

Despite years of investigations, there is little definitive evidence of how different measurements compare in their ability to diagnose iron deficiency. The main reason for this is the difficulty of distinguishing between the presence and absence of storage iron. Most investigators have used the grade of storage iron in the bone marrow as a 'gold standard'. This is an invasive procedure and therefore limits drastically the number of patients investigated. It is often difficult to justify bone marrow aspiration to determine a patient's iron status and even more difficult in the case of normal volunteers. Furthermore, bone marrow aspiration followed by staining for iron is not a reproducible procedure. Observer error,[113] inadequate specimens and lack of correlation with response to iron therapy[114] have been described. It is essential to examine at least seven bone marrow particles in a Perls-stained film to assess the presence and quantity or storage iron.[115] Demonstrating a response in Hb to oral iron therapy has been the method of choice to diagnose iron deficiency retrospectively in paediatric practice.

Iron deficiency anaemia in adults

Almost all measures show a high sensitivity and specificity for distinguishing between subjects with iron deficiency and those with iron stores and normal Hb in the absence of any other disease process. Guyatt *et al*.[116] conducted a systematic review of the diagnostic value of the various laboratory tests for iron deficiency. They concluded that serum ferritin was the most powerful test for simple iron deficiency and also for iron deficiency in hospital patients. However, this analysis did not include measurements of sTfR.

Detection of iron deficiency in acute or chronic disease

Table 9-8[117–123] summarises a number of studies in which bone marrow iron was assessed and the sensitivity and specificity of various assays was compared. Despite very different results between studies, some general points may be made.

Conventional red cell parameters, mean cell volume (MCV) and mean cell haemoglobin (MCH), do not distinguish between the presence or absence of bone marrow iron in patients with chronic disease. The serum iron concentration is almost invariably low in chronic disease and, although the TIBC (or transferrin concentration) is higher for patients with no storage iron, neither this measurement nor the transferrin saturation derived from the serum iron and TIBC provides useful discrimination.

In chronic disease, serum ferritin concentrations reflect storage iron levels but are higher than in normal subjects with the same amount of storage iron. It is necessary to set a threshold of 30–50 μg/l to distinguish between the presence and absence of storage iron. Even with this limit, sensitivity is low.

Combinations of serum ferritin, erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) either in a discriminant analysis[112] or in logistic regression[124] provide only marginal improvement in the ability to detect a lack of storage iron.

The serum transferrin receptor level discriminates between the presence and absence of storage iron, although there is disagreement as to whether the assay is superior to serum ferritin. Several studies show that the sTfR/$\log_{10}$ ferritin ratio provides superior discrimination to either test on its own. The use of log ferritin decreases the influence of serum ferritin (and thus the acute-phase response) on the overall ratio. Although the log[sTfR/ferritin] is an excellent measure of iron stores in healthy subjects,[73] this transformation (i.e. after calculating the ratio of sTfR/ferritin) may not provide the best discrimination for clinical applications. When the assay of sTfR is readily available on high-throughput immunoanalysers the sTfR/log ferritin ratio may provide the best discriminator for identifying the co-existence of iron deficiency in chronic disease. However, this will also require standardisation of units and ranges for the various sTfR assays if the use of the ratio is to gain wide acceptance.

Functional iron deficiency

Functional iron deficiency is the situation in which iron stores are apparently adequate but iron supply for erythropoiesis remains inadequate. This often occurs during erythropoietin treatment of patients with anaemia and renal failure. The diagnostic question is to identify those patients with a functional iron deficiency who will require parenteral iron therapy to respond to erythropoietin with an acceptable increase in Hb. The percentage hypochromic erythrocytes is a good predictor of response.[125] Fishbane and colleagues[126] concluded that reticulocyte haemoglobin content (CHr) was a markedly more stable analyte than serum ferritin or transferrin saturation and it predicted functional iron deficiency more efficiently. They did not include percentage hypochromic cells in their analysis. Fernandez-Rodriguez and colleagues[127] assessed the sensitivity and specificity of ferritin, TIBC, transferrin

saturation index (iron divided by transferrin), red blood cell ferritin and sTfR in 63 patients with anaemia and chronic renal failure undergoing dialysis, who were not being treated with erythropoietin. Storage iron was assessed by bone marrow iron staining. For serum ferritin, a cut-off value of 121 μg/l gave a sensitivity and specificity of 75%. Efficiency was lower for sTfR and RBC ferritin. MCV, transferrin saturation index and TIBC showed the lowest values for sensitivity and specificity.

Iron deficiency in infancy and childhood

In infants, thresholds for the diagnosis of iron deficiency and iron deficiency anaemia are not universally agreed. There are rapid changes in iron status in the first year of life as fetal haemoglobin is replaced by adult haemoglobin. The serum ferritin concentration is a less useful guide to iron deficiency than in adults partly because of the rapid decline in concentration in the first 6 months and the low concentrations generally found in children older than 6 months of age. Domellof *et al.*[128] have suggested revised cut-offs for iron deficiency, including serum ferritin and sTfR, for infants up to age 1 year.

In children, the reason for detecting iron deficiency is to identify those who will respond to iron therapy. Margolis *et al.*[129] found that the best predictor of response was the initial Hb, although sensitivity was only 66% and specificity was 60%. Serum ferritin, transferrin saturation and erythrocyte protoporphyrin had even lower efficiencies and combination of the various measures made little improvement. Hershko *et al.*[130] studied children in villages from the Golan Heights (Israel) and concluded that erythrocyte protoporphyrin was a more reliable index of iron deficiency than serum ferritin. They suggested that a significant incidence of chronic disease affected both ferritin and iron values. ZPP provides a useful indicator of iron-deficient erythropoiesis, although high values may indicate lead poisoning rather than iron deficiency. The small sample volume for ZPP determination is also an advantage in paediatric practice.

A report published in 2003 confirms the effect of low-level infection on measures of iron status. Abraham *et al.*[131] studied 101 healthy, 11-month-old infants. On the morning of blood sampling, slight clinical signs of airway infection were observed for 42 infants. Extensive blood analyses were done, including a high sensitivity assay for CRP. When measured by the routine methods, CRP gave values of <6 mg/l for all infants, but with the high sensitivity assay values were higher for many infants with symptoms of airway infection. Serum iron concentration was depressed in these children and correlated significantly with CRP level. When a further blood sample was taken, serum ferritin concentration was higher for the children with the higher CRP level, serum iron was reduced, but sTfR and transferrin levels were unaffected.

Pregnancy

In early pregnancy serum ferritin concentrations usually provide a reliable indication of iron deficiency. Haemodilution in the 2nd and 3rd trimesters of pregnancy reduces the concentrations of all measures of iron status and this means that the threshold values for iron deficiency established in non-pregnant women are not appropriate. In principle, determination of values as ratios (ZPP μmol/mol haem, transferrin saturation and sTfR/ferritin) should be more reliable. In healthy women who were not anaemic and who were supplemented with iron,[69] serum iron, transferrin saturation and serum ferritin fell from the 1st to the 3rd trimester and increased after delivery; TIBC increased during pregnancy and fell after delivery. sTfR concentrations showed a substantial increase (approximately two-fold) during pregnancy and this probably reflects increased erythropoiesis.[69] In contrast, Carriaga *et al.*[89] had reported that the mean sTfR concentration of pregnant women in the 3rd trimester did not differ from that in non-pregnant women and that sTfR concentration was not influenced by pregnancy *per se*. Choi *et al.*[69] suggest that different assays and different ages in the control groups may explain this discrepancy.

Evaluation of suspected iron overload

In hereditary haemochromatosis, the American Association for the Study of Liver Diseases[35] and EASL[34] recommend measurement of both transferrin saturation and serum ferritin for detection of iron accumulation. In thalassaemia major and other transfusion-dependent patients, monitoring iron overload is by measurement of serum ferritin, a serum ferritin of 1000 μg/l being a threshold for chelation in a patient with a known transfusion history.[132] Magnetic resonance imaging (MRI) may be used as well when the transfusion history is uncertain or inappropriate chelation may have been given.[132] In thalassaemia intermedia, including that due to β thalassaemia/haemoglobin E, the relationship between serum ferritin and the degree of iron overload differs from that in thalassaemia major and other transfusion-dependent states. If MRI is not available, serum ferritin should be kept below 800 μg/l with a level below 300 μg/l being an indication to interrupt chelation therapy and a level of 2000 μg/l being an indication for dose escalation.[133]

CONCLUSION

Body iron status can usually be assessed by considering the Hb, red cell indices and serum ferritin concentration, along with evidence of inflammation, infection and liver disease. The sTfR may provide useful discrimination between the presence and absence of iron stores in the anaemia of chronic disease, but its use is hindered by the lack of agreement about units and reference ranges.

Investigation of Megaloblastic Anaemia: Cobalamin, Folate and Metabolite Status

Dominic J. Harrington

CHAPTER OUTLINE

COBALAMIN ABSORPTION AND METABOLISM

Vitamin B_{12} (cobalamin, B_{12}) belongs to a group of compounds named corrinoids. It is composed of a corrin ring and a central cobalt atom that is bound to two ligands. The lower ligand consists of a benzimidazole group attached to the corrin ring through a ribose-phosphate group. To confer metabolic utility in humans the upper ligand must consist of either a methyl or 5′-deoxyadenosyl moiety.

Vitamin B_{12} is synthesised by microorganisms and enters the diet with food of animal origin. Although some edible green laver (*Enteromorpha* spp.) and purple laver (*Porphyra* spp.) contain substantial amounts of vitamin B_{12} (≈63.6 µg/100 g dry weight and 32.3 µg/100 g dry weight respectively), higher plants do not require the vitamin for any function and have no mechanism for its production or storage.

In man, vitamin B_{12} is required as a coenzyme for two reactions.[1] One of the reactions occurs in the cytosol and requires methylcobalamin as a cofactor for methionine synthase during the remethylation of methionine from homocysteine. The remethylation of cobalamin requires the donation of the methyl group from 5′-methyltetrahydrofolate as it is converted to tetrahydrofolate, thus linking cobalamin to folate and 1-carbon metabolism. The second cobalamin-dependent reaction requires adenosylcobalamin and occurs in mitochondria. Adenosylcobalamin is a cofactor for the enzyme methylmalonyl-CoA mutase, which converts methylmalonyl-CoA to succinyl-CoA. The UK government recommends a daily intake of 1.5 µg of vitamin B_{12}, with the European Union recommending 1 µg and the United States recommending 2.4 µg.[2]

Methionine produced in the methylcobalamin-dependent reaction is converted to adenosylmethionine and is a vital source of methyl groups critical for a series of methylation reactions involving proteins, phospholipids, neurotransmitters, ribonucleic acid (RNA) and deoxyribonucleic acid (DNA). Biochemical consequences of metabolic cobalamin insufficiency include an increase in the circulatory concentration of homocysteine and methylmalonic acid (Fig. 10-1). Pathological consequences of a deficiency state include megaloblastic anaemia and neuropathies. Vitamin B_{12} deficiency can cause lesions in the spinal cord, peripheral nerves and cerebrum. The most common symptoms are sensory disturbances in the extremities, memory loss, dementia and psychosis.

With the exception of those who consume a restricted diet (e.g. vegans and vegetarians), dietary intake of vitamin B_{12} greatly exceeds metabolic requirement. The typical Western diet contains ≈4–6 µg/day of the vitamin, of which 1–5 µg is absorbed.[1] Although the bioavailability of vitamin B_{12} is considered high, uptake from a single serving decreases drastically once the 1.5–2.5 µg capacity of ileal receptors for the vitamin has been exceeded. A second dose of vitamin B_{12} given 4–6 h later is once again

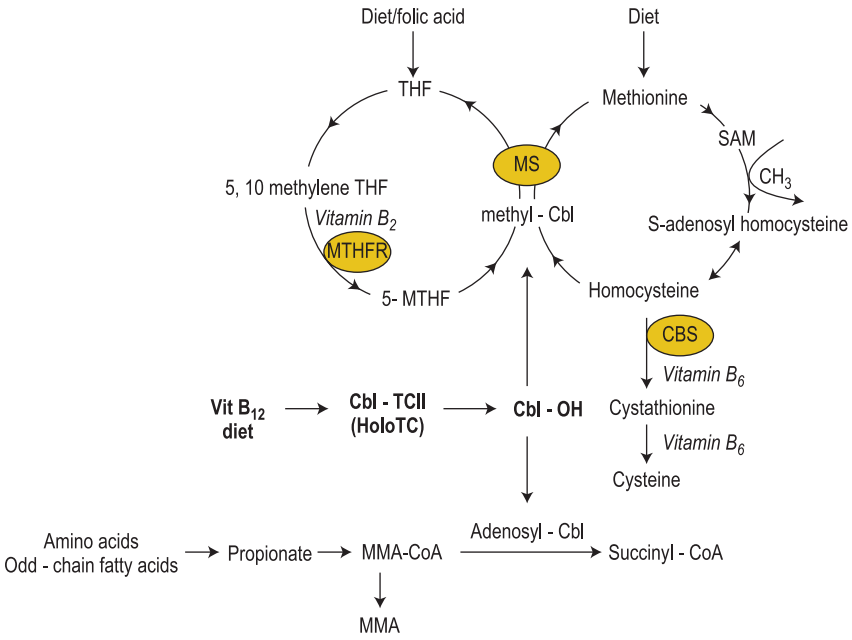

FIGURE 10-1 Homocysteine, folate, and vitamin B_{12} metabolism. Cbl, cobalamin; CBS, cystathionine beta-synthase; HoloTC, holotranscobalamin; MMA, methylmalonic acid; MMA-CoA, methylmalonyl acid-CoA; MS, methionine synthase; 5-MTHF, 5-methyltetrahydrofolate; MTHFR, methylenetetrahydrofolate reductase; OH-Cbl, hydroxocobalamin; SAM, S-adenosyl methionine, TC II, transcobalamin; THF, tetrahydrofolate. *(With permission from Sobczyńska-Malefora A, Harrington DJ, Voong K, Shearer MJ. Plasma and red cell reference intervals of 5-methyltetrahydrofolate of healthy adults in whom biochemical functional deficiencies of folate and vitamin B12 had been excluded.* Adv Hematol *2014;2014:465623.)*

absorbed with maximum efficacy.[3] Body stores typically contain 1–5 mg of vitamin B_{12} so that deficiency states may not develop until several years after the metabolic requirement has consistently exceeded dietary vitamin B_{12} intake and absorption.[4]

Vitamin B_{12} deficiency is relatively common, with significant and variable clinical sequelae.[2,5] Causes of deficiency are shown in Table 10-1. Estimates of the prevalence of vitamin B_{12} deficiency are dependent on the criteria used to define a deficient state. Using serum vitamin B_{12} of 200 pmol/l as a diagnostic cut-off, 3.9% of subjects over 60 years of age in the 2001–2004 National Health and Nutrition Examination Survey[6] in the USA were defined as deficient. Prevalence varied by ethnic group with 4.1, 2.0 and 1.7% of non-Hispanic white, non-Hispanic black and Mexican Americans respectively being defined as deficient. Using serum vitamin $B_{12} < 147$ pmol/l and homocysteine $>20\,\mu$mol/l, the prevalence of vitamin B_{12} deficiency was $\approx 5\%$ in people 65–74 years of age, and more than 10% in people 75 years of age or older.[7] Using holotranscobalamin (HoloTC) and methylmalonic acid in tandem, 11% of a hospital patient population in the UK were defined as deficient.[8]

An overview of the steps involved in the absorption of vitamin B_{12} is shown in Figure 10-2. Ingested cobalamin is released from food proteins by pepsin and gastric acid. Two proteins then compete for the free cobalamin: a glycoprotein named intrinsic factor, which is made in gastric parietal cells, and haptocorrin (previously known as transcobalamin I and also referred to as R binder), which is produced by salivary glands. At acidic pH, intrinsic factor (IF) has a very low affinity whilst haptocorrin has a high affinity for vitamin B_{12}. Thus vitamin B_{12} binds to haptocorrin in the stomach. Haptocorrin primarily serves to protect vitamin B_{12} from acid degradation in the stomach by producing a haptocorrin–vitamin B_{12} complex. Metabolically inert cobinamides (an intermediate in porphyrin and chlorophyll metabolism) that are present in the diet are also bound. As the contents of the stomach enter the first part of the duodenum a relatively alkaline environment is encountered. The haptocorrin is partly digested by proteases secreted by the pancreas, which frees the vitamin, permitting it to attach to IF. The intrinsic factor–cobalamin complex attaches to cubam receptors, which consist of amnionless and cubilin,[9] and the complex is taken up by endocytosis into the ileal cell. After internalisation, vitamin B_{12} is freed and transported into the blood, possibly by an adenosine triphosphate (ATP)-dependent carrier, where it meets transcobalamin (previously known as transcobalamin II) and haptocorrin. Unsaturated transcobalamin is more abundant so most newly absorbed vitamin B_{12} binds to it. Transcobalamin has a rapid turnover and is responsible for the daily transport of ≈ 4 nmol of vitamin B_{12} into cells.[10] Haptocorrin is almost fully saturated with vitamin B_{12} (and inactive vitamin B_{12} analogues) and carries the major part of the vitamin in the circulation. The metabolism of this protein, which attaches to cell surface receptors on liver and

TABLE 10-1

THE CAUSES OF VITAMIN B_{12} DEFICIENCY

Defect	Cause	Supportive Information/Diagnostic Tests
Decreased intake	Malnutrition Reduced intake of animal products Strict vegan diet Breastfed babies of mothers who are vegetarian or B_{12} deficient Poor dietary intake in elderly	Dietary history Ethnic origin/culture
Impaired gastric absorption	Atrophic gastritis with achlorhydria Gastrectomy – partial or total Zollinger–Ellison syndrome Addisonian pernicious anaemia	Endoscopic and gastric biopsy findings History of gastric surgery Multiple gastric and duodenal ulcers Pancreatic adenoma on imaging Diagnostic criteria for pernicious anaemia (see Table 10-4)
Failure of trypsin release of B_{12} from R binding proteins	Pancreatic insufficiency	Pancreatic function tests; exocrine pancreatic dysfunction results in reduced absorption but clinical deficiency is rare
Impaired intestinal absorption as a result of failure of B_{12}-intrinsic factor complex uptake in ileum	Ileal resection or disease e.g. Crohn disease Inflammatory bowel disease and tuberculous ileitis Tropical sprue Luminal disturbances: chronic pancreatic disease and gastrinoma Parasites: giardiasis, bacterial overgrowth and fish tapeworm Blind loop syndrome	Radiological, enteroscopic or capsule camera study of small bowel for Crohn disease of terminal ileum or tuberculous ileitis Small bowel biopsy Radiolabelled lactose breath tests for bacterial overgrowth. Absorption returns to normal after antibiotic therapy
Congenital/inherited	Intrinsic factor receptor deficiency/defect Imerslund–Gräsback syndrome Congenital deficiency of intrinsic factor – 'juvenile' pernicious anaemia Inborn errors of cobalamin metabolism	 Subjects of Scandinavian origin Serum and urinary methylmalonic acid and metabolite measurement
Abnormal transport proteins	Haptocorrin deficiency Transcobalamin deficiency Possible fall in holotranscobalamin levels in elderly	No evidence of clinical deficiency but low serum cobalamin levels Megaloblastic anaemia in presence of normal cobalamin levels; transcobalamin and holotranscobalamin levels reduced
Excess consumption	Haemolysis HIV infection	
Acquired drug effects	Alcohol: impedes absorption as consequence of gastritis Nitrous oxide: irreversibly binds to cobalt atom in B_{12} and deactivates it Proton pump inhibitors: reduce gastric acid production H_2 receptor antagonists: reduce gastric acid production Metformin: impedes absorption Colchicine: reduces IF-B_{12} receptors Slow K: impedes absorption Cholestyramine: decreases gastric absorption	Chronic repeated exposure

HIV, human immunodeficiency virus; IF, intrinsic factor.

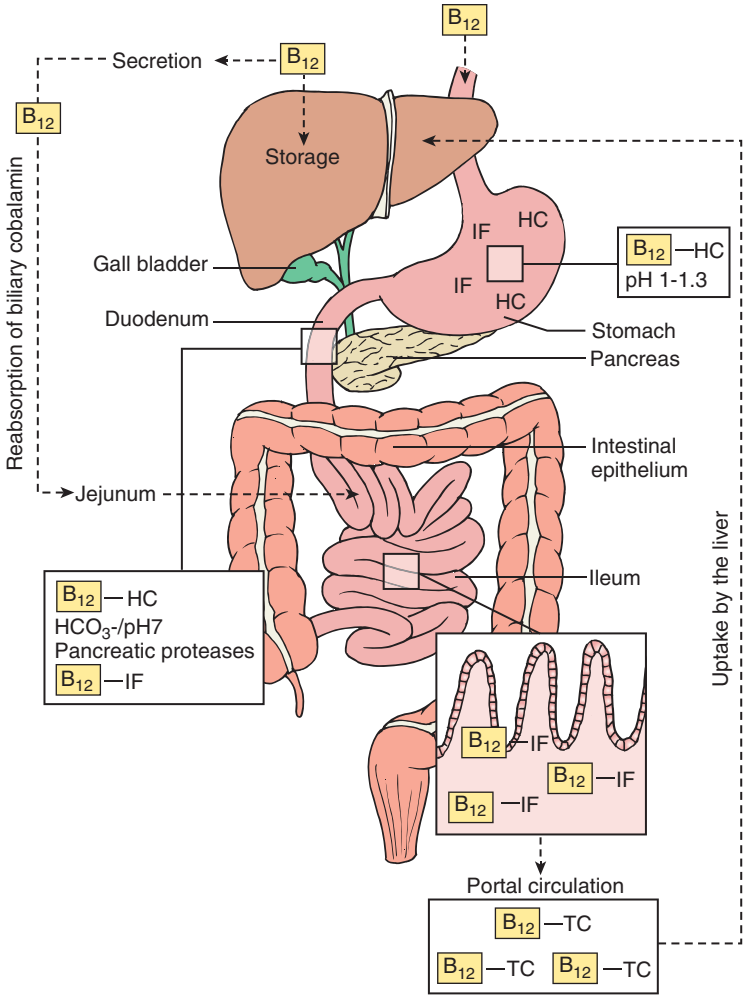

FIGURE 10-2 Mechanism of dietary vitamin B_{12} absorption. HC, holohaptocorrin; IF, intrinsic factor; TC, holotranscobalamin. *(Reproduced from Hunt A, Harrington D, Robinson S. Vitamin B_{12} deficiency.* BMJ *2014;***4***:349, with permission from BMJ Publishing Group Ltd.)*

other storage cells, is slow, with a turnover of 0.1 nmol of vitamin B_{12} daily.[11]

There are receptors for holotranscobalamin (TC receptors) on the surface of every DNA-synthesising cell in the human body. At the cellular level in the target tissue, HoloTC undergoes endocytosis via the transmembrane TC receptor before lysosomal degradation, releasing cobalamin for metabolic reactions.

Cobalamin undergoes enterohepatic circulation via the liver and bile ducts with 1.4 µg/day excreted in the bile, of which 1 µg/day is reabsorbed in the ileum.

FOLATE ABSORPTION AND METABOLISM

Folate is a generic term that refers to a group of water-soluble vitamins that function as cofactors by carrying and chemically activating single carbons to support biosynthetic pathways. Causes of folate deficiency are shown in Table 10-2.

Folate polyglutamates are thermolabile and found in fruits and vegetables, in particular in leafy green vegetables. Before absorption can take place, dietary folate polyglutamates must be hydrolysed to monoglutamates by hydrolases, operating maximally at pH 5.5 in the presence of zinc and then rapidly converted to polyglutamates in cells. Folate carriers transport polyglutamates rapidly into the luminal cells where they are methylated using methylcobalamin as a cofactor and reduced to 5-methyltetrahydrofolate (5-methyl THF) in the enterocyte before entering the portal venous system. Unconverted polyglutamates remain in the luminal cells.

There is significant enterohepatic recirculation of folate, amounting to 90 µg/day. Biliary drainage results in a rapid fall in serum folate levels,[12] whereas deprivation of dietary folate takes up to 3 weeks to cause a

TABLE 10-2

THE CAUSES OF FOLATE DEFICIENCY

Defect	Supportive Information/Diagnostic Tests
Reduced intake	
Poor diet, particularly alcoholics (wine and spirits because beer contains folate) Elderly or students ('tea and toast diet') Dietary fads Premature babies Unsupplemented parenteral nutrition	Dietary and alcohol history
Malabsorption	
Coeliac disease (often with coexisting iron deficiency) Tropical sprue Small bowel resection, malabsorption syndromes	Anti-endomysial, antigliadin tests, antitissue transglutaminase Small bowel biopsy
Drug effects	
Sulphasalazine, methotrexate, trimethoprim-sulphamethoxazole, pyrimethamine, phenytoin, sodium valproate, oral contraceptives	Drug history Bone marrow aspiration
Hereditary hyperhomocysteinaemia	
Homozygotes for C677T *MTHFR* may have lower total folate levels and/or proportionally lower availability of 5-methyl THF	
Increased folate turnover	
Pregnancy: progressive increase in requirement in third trimester Increased requirements for breastfeeding Skin disease – severe psoriasis or exfoliation Haemodialysis Haemolysis: haemoglobinopathy, paroxysmal nocturnal haemoglobinuria, autoimmune haemolytic anaemia (see Chapters 11–13)	

decrease in serum levels. Two-thirds of plasma folate is non-specifically bound to plasma folate-binding proteins including albumin, and one third circulates as free folate.

There is sufficient retention of folate by the renal tubules to prevent urinary folate loss; this is achieved by megalin uptake of filtered folate-binding protein[13] and the bound folate. Cubam,[9] which binds intrinsic factor-cobalamin complex, is also important in the uptake of albumin from the renal tubules, which may also contribute to folate retention.

Folate transport into cells is dependent upon two mechanisms: reduced folate carrier (58 kDa), which is a low-affinity high-capacity system; and reduced folate receptors (44 kDa), of which there are three isoforms – alpha and beta are attached to the cell surface through a glycosyl-phosphatidylinositol anchor and gamma is secreted by enteric mucosal cells. Methyltetrahydrofolate bound to the folate receptor undergoes endocytosis by clathrin-coated pits or caveolae. Passive diffusion is an alternative mechanism by which folate can enter cells. The relative contributions of the different mechanisms are not known. Folate receptors may be expressed on malignant cells and have become potential targets for delivery of cytotoxic agents linked to folate.

Folates participate in 1-carbon metabolism and thereby facilitate the essential cellular metabolism of methionine, serine, glycine, choline and histidine in the biosynthesis of purine and deoxythymidine monophosphate (dTMP) in the synthesis of pyrimidines and thus DNA (Fig. 10-1).

Intracellular folates are compartmentalised between the cytosol and mitochondria, and the major forms are tetrahydrofolate (THF), 5-methyl THF and 10-formyl THF. Homocysteine is converted to methionine by methionine synthase using methylcobalamin as a co-factor and 5-methyl THF as the methyl group donor. Cobalamin deficiency therefore results in inactivation of methionine synthase, leading to an accumulation of 5-methyl THF, which cannot be converted back to 5,10-methylene THF. Folate is then unavailable for pyrimidine and purine synthesis – this is known as the methyl-trap hypothesis, which was advanced to explain

why cobalamin deficiency often results in a functional folate deficiency. Furthermore, 5-methyl THF is a very poor substrate for the enzyme responsible for folate polyglutamation, folylpoly-γ-glutamate synthetase, which prefers THF and 10-formyl THF. Folate deficiency is thought to cause megaloblastic anaemia by inhibiting the production of 5,10-methylene THF polyglutamate, which acts as a cofactor in the rate-limiting step in the production of DNA, the synthesis of dTMP. Thus, in the absence of cobalamin, polyglutamate synthesis ceases and monoglutamate forms are not retained by cells. This explains why, in cobalamin deficiency, serum folate levels may be found to be elevated and red cell folate levels normal or low.

HAEMATOLOGICAL FEATURES OF MEGALOBLASTIC ANAEMIA

Macrocytosis is the most common reason that vitamin B_{12} status is investigated. Megaloblastic anaemia resulting from impaired DNA synthesis is characterised by the presence of megaloblastic red cell precursors in the bone marrow and occasionally also in the blood. Megaloblasts have a characteristic chromatin pattern (Fig. 10-3) and increased cytoplasm as a result of asynchrony of nuclear and cytoplasmic maturation with a relatively immature nucleus for the degree of cytoplasmic haemoglobinisation. A delay in nuclear maturation caused by impaired DNA synthesis resulting from a lack of vitamin B_{12} or folate is seen in all lineages, particularly granulocytic marrow precursors with giant metamyelocytes (Fig. 10-4) and hypersegmented neutrophils with increased lobe size as well as an increased number of nuclear segments (see Fig. 5-10). In severe pernicious anaemia, a mean red cell volume (MCV) up to 130 fl occurs, with oval macrocytes, poikilocytes and hypersegmentation of neutrophils (>5% with at least five nuclear lobes).[14] The neutrophil hypersegmentation index is an equivalent automated parameter on some cell counters. The mean platelet volume is decreased, and there is increased platelet anisocytosis, as detected by the platelet distribution width (PDW). The MCV falls to 110–120 fl or even lower as megaloblastic change advances, as a result of the appearance of red cell fragments and small poikilocytes. Howell–Jolly bodies and basophilic stippling may be seen in the red cells.

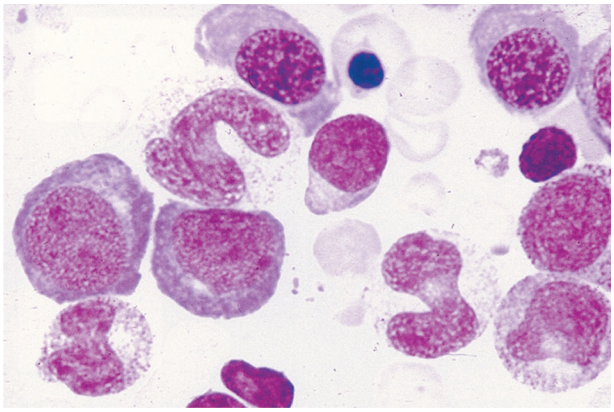

FIGURE 10-4 Photomicrograph of bone marrow film stained by MGG showing megaloblastic erythropoiesis and giant metamyelocytes.

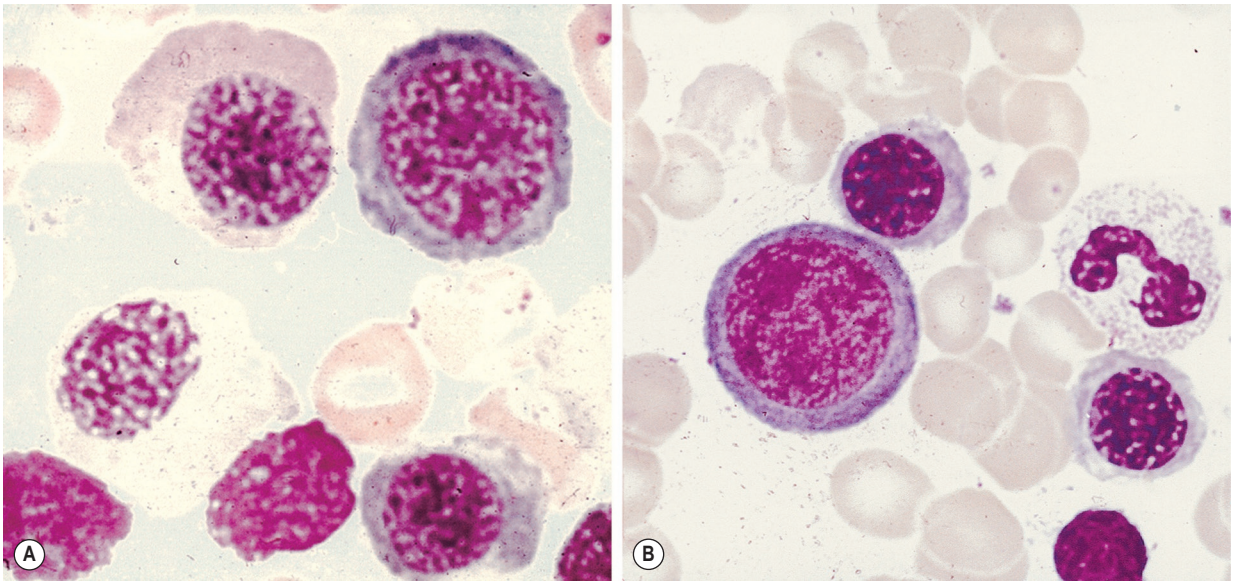

FIGURE 10-3 Photomicrographs of bone marrow films stained by May–Grünwald–Giemsa (MGG). (A) Megaloblasts. **(B)** Normoblasts for comparison.

Differential diagnosis of macrocytic anaemia

Macrocytic red cells are also seen in myelodysplastic syndromes and myelodysplastic/myeloproliferative neoplasms, which can be suspected from the presence of hypogranular neutrophils (see Fig. 5-76) or monocytosis. Excess alcohol consumption results in an increased MCV with round macrocytes, although rarely does the MCV exceed 110 fl unless coexisting folate deficiency is present. Hypothyroidism, liver disease, aplastic anaemia and the rare inherited orotic aciduria and Lesch–Nyhan syndromes also have a high MCV. Automated reticulocyte counts facilitate detection of increased red cell turnover and high MCV as a result of haemolysis or bleeding. Coexisting iron deficiency or thalassaemia trait may mask macrocytic changes, although a high red cell distribution width indicates anisocytosis and the need for blood film review. Congenital dyserythropoietic anaemias types I and III and erythroleukaemia exhibit some features of megaloblastic erythropoiesis that are unrelated to vitamin B_{12} and folate. Drugs interfering with DNA synthesis result in macrocytosis and megaloblastic erythropoiesis (Tables 10-1 and 10-2).

METABOLIC INSUFFICIENCY

No international consensus view on what constitutes vitamin B_{12} deficiency has been reached, partly because harmonised laboratory diagnostic standards have yet to be defined.[15] However, it is clear that the investigation of vitamin B_{12} and folate status must not be restricted to individuals with classic features of megaloblastic anaemia because neuropathy, optic atrophy and ≈ 20% of neuropsychiatric changes occur in the absence of macrocytosis or anaemia.[5,16–20] Metabolic evidence of insufficiency states (i.e. elevations in homocysteine and methylmalonic acid concentration) are frequently identified in the laboratory without clinical signs or symptoms.

Currently ≈ 75 countries require fortification of wheat flour produced in industrial mills with folic acid. In the USA and Canada, dietary supplementation with folate was introduced in 1998 to reduce neural tube defects. Subsequent follow-up showed a 25–46% reduction in the incidence of neural tube defects.[21]

Folate and/or vitamin B_{12} insufficiency causes an elevated circulatory concentration of homocysteine as a result of reduction in methionine synthesis (Fig. 10-1). Homocysteine is an independent risk factor for vascular disease[22,23] and is also associated with an increased risk of venous thrombosis.[24,25] Lowering homocysteine levels may reduce the incidence of myocardial infarction and stroke.

TESTING STRATEGY FOR SUSPECTED COBALAMIN OR FOLATE DEFICIENCY

The application of a suitable testing strategy for patients suspected of having cobalamin or folate deficiency is shown in Tables 10-3 and 10-4. Table 10-3 lists the important laboratory investigations that should be performed. Table 10-4 provides a list of clinical and laboratory features for the diagnosis of pernicious anaemia. Table 10-5 highlights the important clinical details that should be elicited by the clinician and submitted with the request to assist the laboratory in interpretation.

Utility of serum vitamin B_{12} assays

Most commonly vitamin B_{12} status is evaluated through the measurement of vitamin B_{12} in serum with a move away from microbiological assays and radioisotope-dilution assays (both described in detail in earlier editions of this book) to the use of automated platforms based on competitive-binding luminescence technologies. Status is estimated from the abundance of vitamin B_{12} in the circulation, and comparison against a predefined reference range. However, this approach gives no indication of vitamin B_{12} utilisation at the tissue level. Serum vitamin B_{12} assays generate a high rate of false-negative results.[26] It has been estimated that up to 45% of vitamin B_{12}-deficient subjects may be overlooked if only serum vitamin B_{12} is used as a screening test.[27] Studies have also shown poor positive predictive value (i.e. healthy persons with a low cobalamin level with no evidence of deficiency).[28,29]

In particular, clinical utility is limited when the serum B_{12} assay is applied to pregnant women, as there is an ≈ 50% decline in serum cobalamin at term when compared with nonpregnant women.[30] This is caused both by haemodilution and by a decrease in concentration of circulating haptocorrin. A second limitation is that in rare cases patients lack haptocorrin and therefore have a low serum vitamin B_{12} despite no signs of deficiency.[31]

Although ≈ 80% of vitamin B_{12} is carried by haptocorrin, extrahepatic cellular receptors for this form have not been identified. Circulatory levels of haptocorrin decline slowly in response to negative vitamin B_{12} balance (i.e. when metabolic requirements exceed absorption of dietary vitamin B_{12}) and may take 3–6 years to fall below the lower limit of assay reference ranges. It is cobalamin present in the HoloTC form that is metabolically active. Adoption of HoloTC assays[8,32,33] to determine the abundance of the physiologically active form of cobalamin[34] is increasingly widespread in Australia, Austria, Canada, Germany, the Netherlands, Nordic countries, the UK and Switzerland. However, the mode of application and the assignment of cut-off values is variable (i.e. used as a sole status indicator with a suggested optimal

TABLE 10-3

LABORATORY TESTS IN SUSPECTED COBALAMIN OR FOLATE DEFICIENCY

Diagnostic Tests	Diagnostic Features Suggestive of Cobalamin or Folate Abnormality	Will Help to Exclude	Pitfalls
Full blood count	Macrocytosis	–	Macrocytosis and anaemia may be absent despite neuropathy
Blood film	Oval macrocytes, hypersegmented neutrophils (>5% with ≥5 lobes); Howell–Jolly bodies suggests hyposplenism and therefore coeliac disease as a cause of the deficiency	Myelodysplastic syndromes (hypogranular or hypolobulated neutrophils, dimorphic red cells), alcohol excess/liver disease (round macrocytes, target cells, stomatocytes), haemolytic anaemia (see Chapter 5)	Hypersegmented neutrophils are not invariably present; they can also occur during cytotoxic therapy
Reticulocyte count	Absolute count low pretreatment	Reticulocyte response at day 6 post-therapy confirms response to B_{12} or folate therapy provided only low dose is given	Reticulocyte response may be blunted if inadequate iron stores
Bone marrow aspirate (including Perls stain) before treatment or within 24 h of cobalamin or folate therapy – indicated if severe, unexplained macrocytic anaemia	Megaloblastic erythropoiesis, giant metamyelocytes, hypersegmented neutrophils, ring sideroblasts infrequent	Myelodysplastic syndromes, aplastic anaemia	Megaloblastic change is not necessarily a result of deficiency; can be drug induced or a feature of a myelodysplastic syndrome
Serum B_{12}	B_{12} < 180 ng/l suggestive of cobalamin deficiency, may be a result of pernicious anaemia, veganism or gastrectomy; in the absence of these causes, may result from malabsorption of protein-bound B_{12} (e.g. as a result of achlorhydria) B_{12} < 150 ng/l highly suggestive of cobalamin deficiency	B_{12} < 180 ng/l with no clinical signs or symptoms and normal MMA and homocysteine reflects poor specificity of total B_{12} assay. B_{12} levels may be borderline low due to severe folate deficiency; give folic acid and monitor B_{12} level unless neurological abnormalities present	B_{12} > 180 ng/l but presence of neuropathy or strong clinical suspicion of B_{12} deficiency requires a therapeutic trial or additional tests, such as MMA, holotranscobalamin and homocysteine: if holotranscobalamin is low then treat with B_{12} and monitor response by repeat metabolite levels at day 6; B_{12} deficiency is confirmed by high MMA and homocysteine that fall on treatment
Serum folate	Low level, particularly if red cell folate also low confirms deficient state		Subject to diurnal variation. Low levels may result from recent deterioration in diet. Conversely low serum folate levels are rapidly corrected by improved diet.
Red cell folate	Low level, particularly if B_{12} deficiency is excluded		Low red cell folate and high serum folate occur in cobalamin deficiency – treat with B_{12}
Serum holotranscobalamin	Early marker of B_{12} deficiency. Holotranscobalamin <25 pmol/l highly suggestive of cobalamin deficiency. Often as low as 5 pmol/l in pernicious anaemia.	Holotranscobalamin 25–50 pmol/l suggests measure MMA (or homocysteine if MMA not available).	Subject to recent dietary change (within 24h). Particularly useful in pregnancy, where levels unaffected by trimester.

Continued

TABLE 10-3

LABORATORY TESTS IN SUSPECTED COBALAMIN OR FOLATE DEFICIENCY—CONT'D

Diagnostic Tests	Diagnostic Features Suggestive of Cobalamin or Folate Abnormality	Will Help to Exclude	Pitfalls
Elevation of serum holotranscobalamin levels at 24-48 h from baseline in response to oral 9 μg cyanocobalamin 6 hourly × 3 doses[96]	Subjects with dietary deficiency show rapid elevation of HoloTC by >10 pmol/l or >22% increase from baseline. Pernicious anaemia shows enhanced holotranscobalamin levels after addition of oral recombinant intrinsic factor.		
Intrinsic factor antibody test (test if serum B_{12} is <150 ng/l)	Positive in 50–60% of cases of pernicious anaemia and, when positive, obviates a B_{12} absorption test		False positive (rare). Negative in 40–50% of cases of pernicious anaemia; if negative, proceed to B_{12} absorption test
Schilling test (part I, basic test; part II, with intrinsic factor; part III, following course of antibiotics; part IV, pancreatic enzymes taken for 3 days)	Part I <5% and part II normal or near normal confirms malabsorption as a result of lack of intrinsic factor (e.g. pernicious anaemia). Parts I and II abnormal suggests malabsorption not resulting from intrinsic factor deficiency.* Part III abnormal indicates abnormal bacterial grown. Part IV abnormal indicates pancreatic insufficiency.		Reagents not currently available. Awaiting recombinant intrinsic factor supplier. Invalid in renal failure; Part II may not correct in pernicious anaemia if intrinsic factor antibodies are present at high concentration in gastric juice
Upper gastrointestinal endoscopy and duodenal biopsy†	Villous atrophy in coeliac disease. Coeliac disease indicated by positive serological tests for endomysial antibodies (EMA) and tissue transglutaminase antibodies (tTGA)		
Serum gastrin or gastric juice pH	Raised serum gastrin or gastric juice pH of >6 confirms achlorhydria: if not present, diagnosis of pernicious anaemia is suspect		
Serum MMA and plasma or serum homocysteine, before treatment or before and 6 days after treatment‡	Raised homocysteine in folate and B_{12} deficiency; raised MMA in B_{12} deficiency, which is helpful to confirm deficiency if B_{12} is low and IF antibodies are absent. Correction of elevated metabolite levels after cobalamin therapy provides evidence of biochemical response.	Lack of significance of low B_{12} is indicated by normal MMA and homocysteine and no clinical signs. Note serum homocysteine requires sample taken on ice and separated before any haemolysis. Alternatively serum can be collected into Kabevette sample collection tubes (www.kabe-labortechnik.de) and separated within 36 hrs.	Both MMA and homocysteine are elevated in renal impairment. MMA is often elevated in the elderly and cannot be used in isolation without either B_{12} or HoloTC measurement. Homocysteine is not specific for cobalamin deficiency, being elevated in folate deficiency, in smokers and in hyperhomocysteinaemia.

HoloTC, holotranscobalamin; IF, intrinsic factor; MMA, methylmalonic acid; MTHF, methyltetrahydrofolate.

* If Part II fails to correct, proceed to barium follow-through or small bowel enema to diagnose ileal disease (e.g. Crohn disease); Parts I and II abnormal, Part III normal indicates malabsorption resulting from bacterial overgrowth (e.g. blind loop syndrome).

† Upper gastrointestinal tract endoscopy is also useful if dyspepsia develops in known pernicious anaemia, to exclude gastric carcinoma.

‡ Plasma homocysteine assay is now widely available; in suspected B_{12} deficiency it provides a useful test of biochemical cobalamin deficiency. Correction of elevated levels after treatment provides confirmation of deficiency.

TABLE 10-4

CLINICAL AND LABORATORY CHECKLIST FOR DIAGNOSIS OF PERNICIOUS ANAEMIA

	Laboratory Criteria	Clinical Criteria
Minor criteria	Macrocytosis, anaemia	Parasthesiae, numbness or ataxia
	Raised plasma homocysteine	Hypothyroidism
	Gastric pH >6	Vitiligo
	Raised serum gastrin	Family history of pernicious anaemia or hypothyroidism
	Positive gastric parietal cell antibody	
Major criteria	Low serum B_{12} (<180 ng/l) or raised serum methylmalonic acid (>0.75 µmol/l) in presence of normal renal function	
	Megaloblastic anaemia not resulting from folate deficiency	
	Positive intrinsic factor antibodies using high-specificity test	
	Holotranscobalamin level <25 pmol/l	
Reference standard criteria	Schilling test* shows malabsorption of oral cyanocobalamin corrected by co-administration of intrinsic factor	

*Reagents for Schilling tests currently unavailable. A nonisotopic B_{12} absorption test has been reported.[96]

TABLE 10-5

SIGNIFICANCE OF CLINICAL DETAILS IN ASSESSING POSSIBLE DEFICIENCY OF B_{12} OR FOLATE

Symptoms or Signs	Possible Significance
Tiredness, palpitations, pallor	Anaemia
Slight jaundice	Ineffective erythropoiesis
Neurological	
Cognitive impairment, optic atrophy, loss of vibration sense, joint position sense; plantar responses normal or abnormal; tendon reflexes depressed or increased	Cobalamin deficiency, subacute combined degeneration of the spinal cord and optic/sensory/motor peripheral neuropathies
Dietary and Gastrointestinal History	
Vegetarian or vegan; poor nutrition (e.g. 'tea and toast diet' in elderly or students); dietary fads	Low iron stores and iron deficiency Cobalamin deficiency in babies born to mothers who are vegans Folate deficiency (often with iron deficiency)
Weight loss, bloating and steatorrhoea, particularly nocturnal bowel movements	Features of malabsorption and folate deficiency, e.g. due to coeliac disease, tropical sprue
Mouth ulcers, abdominal pain, perianal ulcers, fistulae	Terminal ileal Crohn disease – cobalamin deficiency
Glossitis, angular cheilosis and koilonychia	Cobalamin and combined iron deficiency
Alcohol history	Poor diet and interference with folate metabolism
History of Autoimmune Disease in Patient or Family	
Hypothyroidism, pernicious anaemia or coeliac disease	Increased likelihood of pernicious anaemia or coeliac disease
Surgery	
Gastrectomy/bowel resection	Cobalamin deficiency usually develops 2 years postgastrectomy Ileal disease resulting in cobalamin deficiency Blind loop syndromes
Physical Appearance	
Grey hair, blue eyes, vitiligo	Association with pernicious anaemia
Pregnancy	Increased iron and folate requirements. Cobalamin levels fall by 30% in the third trimester but without tissue deficiency Holotranscobalamin levels are unaltered in late pregnancy
Malabsorptive Syndrome	
Tropical sprue, bacterial overgrowth, fish tape worm in Scandinavian countries	Combined folate and iron deficiency Cobalamin deficiency
Drug History	See text
Other Haematological Disorders	
Myeloproliferative neoplasms, haemolytic anaemias, leukaemias	Increased folate utilisation may result in folate deficiency
Multiple myeloma	Paraprotein interference with cobalamin assays resulting in falsely low cobalamin levels, which normalise on treatment of myeloma

cut-off of 32 pmol/l[35]; first line screening test in conjunction with a functional marker to evaluate indeterminate results[8]; or second line test used in tandem to support indeterminate results from serum B_{12} measurement).[36]

Sensitivity and specificity of cobalamin assays

Utility of receiver operator characteristic curves

Defining the sensitivity and specificity of current vitamin B_{12} assays has been hampered by the difficulty in defining a truly deficient study population. Clarke *et al.*[26] provided data that permit calculation of the specificity and sensitivity of current immunoassays for vitamin B_{12} in the detection of cobalamin deficiency in a community study of 1621 subjects aged over 65 yr with normal renal function. Subjects were defined as cobalamin deficient if the methylmalonic acid was elevated above 0.75 µmol/l. Deficiency was found in 4.3% of subjects over 65 years of age with normal renal function. The mean vitamin B_{12} level of these subjects was 151 pmol/l (202 ng/l) using the Siemens Centaur assay (range 110–199 pmol/l). Table 10-6 illustrates the calculation to derive specificity and sensitivity for the Siemens Centaur B_{12} assay using a cut-off point of 200 pmol/l (270 ng/l).

This study demonstrates that, while values over 270 ng/l have a high (98.4%) negative predictive value for the presence of disease, values below 270 ng/l include a high percentage (28.2%) of individuals with normal methylmalonic acid levels and presumably no other evidence of cobalamin deficiency. This is reflected in the poor specificity (71.8%) of the assay using this cut-off point. The choice of the appropriateness of the cut-off point can be explored further using receiver operator characteristic (ROC) curves.

High vitamin B_{12} levels have been described in subjects with no myeloproliferative neoplasm and who are not on cobalamin therapy or vitamin supplementation.[37] This is thought to be due to immunoglobulin-complexed vitamin B_{12} resulting in assay interference. False-normal vitamin B_{12} levels[38,39] have been described in subjects with high-titre IF antibodies[39] and may also occur due to the presence of heterophile antibody interference.

Utility of holotranscobalamin II assay

In the same study Clarke *et al.*[26] demonstrated that the Axis-Shield/Abbott HoloTC assay has slightly superior ROC curves when compared with serum B_{12} levels (see Fig. 10-5). The HoloTC assays gave a greater area under the curve, 0.85 versus 0.76 (for serum vitamin B_{12}) and superior sensitivity and specificity. In common with many tests used in the diagnostic laboratory the vitamin B_{12} and HoloTC assays both generate a proportion of results that are considered to be indeterminate. This inherent limitation can be addressed through further secondary testing using a functional marker of status. Suitable functional markers include circulatory concentrations of methylmalonic acid and homocysteine. HoloTC has been shown to be unaffected by assay interference from high-titre IF antibodies.[40] In addition, HoloTC is not subject to the ≈ 50% fall in total vitamin B_{12} levels seen in normal pregnancy (Fig. 10-6).[30]

Utility of methylmalonic acid and homocysteine assays

In countries where the addition of folic acid to all enriched cereal-grain foods is not mandated, the utility of an elevation in plasma (total) homocysteine concentration to identify methionine synthase dysfunction in response to suboptimal vitamin B_{12} availability is limited by a codependency on 5-methyl THF abundance. 5-Methyl THF is a more powerful nutritional determinant of homocysteine (≈3.5 times) than methylcobalamin. It is good practice to apply reference ranges for the interpretation of homocysteine that are age, sex and renal function specific. Examples of reference ranges suitable for use in the clinical setting are: ≤10 µmol/l, children <15 yr; ≤13 µmol/l, females (during pregnancy <10 µmol/l); ≤15 µmol/l,

TABLE 10-6

THE CALCULATION TO DERIVE SPECIFICITY AND SENSITIVITY FOR THE *SIEMENS CENTAUR* B_{12} ASSAY

Community study of 1621 subjects with normal renal function in Banbury, UK	True cobalamin deficiency defined by methylmalonic acid of >0.75 µmol/l with normal renal function	Absence of cobalamin deficiency defined by methylmalonic acid of <0.75 µmol/l	
Siemens Centaur B_{12} assay <270 ng/l	53 true positives (TP)	437 false positives (FP) (27% of subjects studied)	Positive predictive value = TP/(TP + FP) = 53/490 = 13.2%
Siemens Centaur B_{12} > 270 ng/l	17 false negatives (FN)	1114 true negatives (TN)	Negative predictive value = TN/(TN + FN) = 1114/1131 = 98.4%
	70 cobalamin-deficient individuals (4.3% of subjects studied). Sensitivity = TP/(TP + FN) = 53/70 = 75.7%	1551 nondeficient. Specificity = TN/(TN + FP) = 1114/1551 = 71.8%	

False-positive rate (α) = FP/(FP + TN) = 437/1551 = 28.2% = 1 - specificity. False-negative rate (β) = FN/(TP + FN) = 17/70 = 24.3% = 1 − sensitivity.

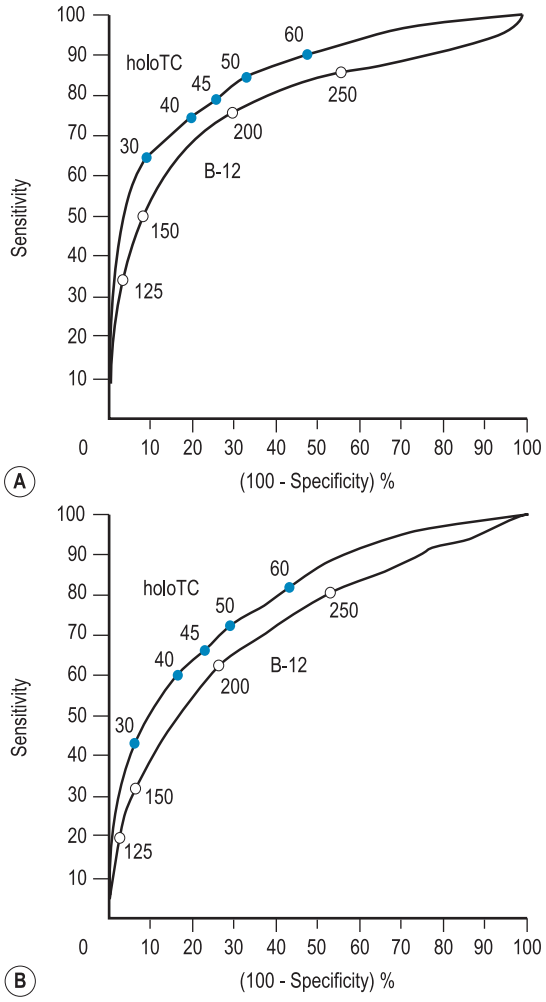

FIGURE 10-5 Receiver operator characteristic (ROC) curves showing holotranscobalamin (HoloTC) levels in pmol/l (abnormal <44 pmol/l) and B_{12} levels in pmol/l (1 pmol/l = 1.344 ng/l). **(A)** The ROC curve for methylmalonic acid levels >0.75 µmol/l (definite metabolic B_{12} deficiency). **(B)** Methylmalonic acid levels of >0.45 µmol/l (probable B_{12} deficiency). *(Redrawn with permission from Clarke R, Sherliker P, Hin H, Nexo E, Hvas AM, Schneede J, et al. Detection of vitamin B_{12} deficiency in older people by measuring vitamin B_{12} or the active fraction of vitamin B_{12} holotranscobalamin.* Clin Chem *2007;***53***:963–970)*

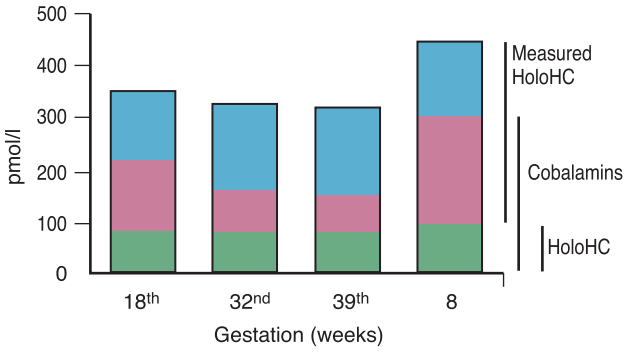

FIGURE 10-6 Comparison of HoloTC, cobalamins and HoloHC in pregnant women at 18th, 32nd and 39th gestational week and at 8 weeks postpartum (n = 141). Means and 95% CI (calculated from the normally distributed log transformed data) for HoloTC (green), cobalamins (green plus pink) and measured HoloHC (pink plus blue) are shown. The pink shaded area indicates HoloHC saturated with true cobalamins (cobalamins – HoloTC) and the blue area indicates HoloHC saturated with analogues (measured HoloHC + HoloTC – cobalamins). CI, confidence interval; HoloHC, holohaptocorrin; HoloTC, holotranscobalamin. *(Redrawn with permission from Morkbak A, Hvas A, Milman N, Nexo E. males aged 15–65 yr; ≤15 µmol/l, females; ≤17 µmol/l males aged 65–74 yr; ≤20 µmol/l all >74 yr.

The interpretation of methylmalonic acid is considered the gold standard and the most representative marker of metabolic vitamin B_{12} insufficiency. The four primary determinants of the serum concentration of methylmalonic acid are age, vitamin B_{12} status, renal function and sex.[41] The interpretation of methylmalonic acid results is therefore complex in elderly populations and those with impaired renal function. Examples of upper limits of the range are 280 nmol/l (<65 years of age) and 360 nmol/l for patients over the age of 65.

Clinical and diagnostic pitfalls of folate assays

Serum folate is altered by acute dietary change and interruption of enterohepatic recycling; it can therefore be low without significant tissue deficiency. Red cell folate was originally advocated as correlating better with megaloblastic change[42,43] reflecting the mean folate status over the lifespan of the red cells (2–3 months), but a subsequent study suggested that little was to be gained by the addition of red cell folate analysis.[44] Minor haemolysis *in vitro* may cause spurious elevation of serum folate levels because the red cell folate may be 10–20 times the serum value. More than half of patients with severe cobalamin deficiency have a low red cell folate because impaired methionine synthesis results in accumulation of 5-methyl THF monoglutamate, which diffuses out of cells resulting in a high serum folate.[45,46] Treatment with cobalamin alone will correct the low red cell folate and high serum folate levels. The interplay between serum vitamin B_{12}, serum folate, red cell folate, plasma homocysteine and methylmalonic acid is shown in Table 10-7. In the USA, some authors have advocated cessation of folate testing because folate deficiency has become very unusual since the introduction of dietary supplementation of flour. The causes of clinical deficiency and supportive information or diagnostic tests are shown in Table 10-2.

TABLE 10-7

INTERACTION BETWEEN SERUM COBALAMIN, SERUM FOLATE, RED CELL FOLATE, PLASMA HOMOCYSTEINE, SERUM METHYLMALONIC ACID, URINARY METHYLMALONIC ACID AND HOLOTRANSCOBALAMIN

Clinical Status	Normal B_{12} and Folate Status	B_{12} Deficient	Folate Deficient
Serum B_{12}*	Usually normal, but may be high in liver disease, myeloproliferative neoplasms, acute inflammation, recovery from autoimmune neutropenia. High levels may be due to immunoglobulin-complexed B_{12}. Low total B_{12} in 25% of elderly subjects.	Usually low, but up to 5% of patients with megaloblastic anaemia may have results within reference range	Usually normal, but low B_{12} may be seen in severe folate deficiency, which corrects when monotherapy with folic acid is given
Serum folate*	Usually normal	Usually normal; high serum folate may occur in B_{12} deficiency	Usually low, but normal levels are found with recent dietary improvement
Red cell folate*,†	Usually normal	Low	Usually low, but normal in very acute deficiency state
Plasma homocysteine	Usually normal; but may be high in renal failure or in *MTHFR* C677T mutation. Levels may fall with folate supplements.	High in B_{12} deficiency and in 50% of samples from patients with low B_{12} consistent with metabolic B_{12}-deficient state	High in folate deficiency – corrected with folic acid therapy
Serum methylmalonic acid	Usually normal; high in 10% of normals and those with high intake of methionine or renal failure	High in B_{12} deficiency and in 50% of samples from patients with low B_{12} consistent with metabolic B_{12}-deficient state	Usually normal, but high in 5% of patients who are folate deficient
Urinary methylmalonic acid	Normal even in renal failure	High	Normal
Holotranscobalamin	Normal although lower levels in elderly	Low (<25 pmol/l) in B_{12} deficiency	Normal

* For normal reference values, see Chapter 2.
† Folate assays may exhibit different responses to folic acid compared with methylenetetrahydrofolate. Assays may not be optimised for haemolysate matrix. Definition of reference range requires reference method and population studies.

Standards, accuracy and precision of cobalamin and folate assays

There are no internationally recognised reference methods for serum cobalamin measurement, but isotope dilution liquid chromatography tandem mass spectrometric methods are accepted as international reference methods for the quantification of folate species in serum.[47,48] As a result, international reference materials have been developed (by the World Health Organisation, WHO 03/178, and by the National Institute of Standards and Technology, NIST SRM).[49] Although reference methods have not been verified for the whole blood matrix as yet, there is a WHO whole blood international standard (95/528) with consensus values for total folate.[50]

Evaluation of commercial automated binding assays by recovery experiments has shown under-recovery of added 5-methyl THF and over-recovery of pteroylglutamic acid (PGA),[51] whereas a suitably calibrated microbiological assay recovers closer to 100%.[52] Differential sensitivity of assays to PGA and genetic variability in the proportion of *in vivo* formyl folates may be a factor in intermethod variability.

A microbiological assay was the method used to assign a potency value to the British Standard for human serum B_{12},[53] and this was later reclassified as the 1st WHO International Standard (IS) (81/563). The 2nd WHO IS for serum B_{12}, 03/178, was ratified in 2007,[49] the values adopted being a consensus of the contemporary B_{12} protein-binding assays. A consensus HoloTC value of 107 pmol/l for 03/178 was subsequently assigned using the Axis-Shield/Abbott Architect assay and was ratified in 2015.[97]

External quality assessment schemes have shown serum vitamin B_{12} intramethod coefficients of variation (CV) of 6–10% and as much as 20% at clinically relevant levels; there is thus a substantial 'grey' indeterminate range between normal and low values. Serum folate intramethod CVs are between 6% and 12% and higher CVs of up to 20% are seen for red cell folate assays. Overall between-method CVs may be as high as 35% for the serum methods and can reach 50% for the whole blood assays, suggesting considerable method differences.

Genetic factors

A number of polymorphisms in *MTHFR*, encoding methylenetetrahydrofolate reductase, that alter the proportion of

formylfolate in serum have been described.[54] Individuals homozygous for the *MTHFR* C677T polymorphism have 25% higher plasma homocysteine levels than controls.[55] Cigarette smoking, age, renal disease, drugs including levodopa, and folate supplements all affect homocysteine levels.

Pre-analytical sample preparation

Serum vitamin B_{12} is stable at room temperature, unless the sample is haemolysed. HoloTC is a sensitive marker of recent cobalamin intake and day-to-day variation is ≈ 10%. Folate is affected by recent dietary intake, and ideally fasting samples should be taken. Marked loss of folate activity is observed as a result of light and temperature instability. Because red cells contain 30–50 times more folic acid than serum, even slight haemolysis will affect serum folate analysis. Thus avoidance of haemolysis, rapid transportation and separation prior to analysis, avoidance of storage at room temperature and the storage of samples at 2–8 °C for a maximum of 48 h, or at −20 °C for no longer than 28 days are all critical factors in the accuracy and precision of serum folate assays. The presence of haemoglobin as a result of lysis in a plasma or serum sample can be readily determined and may be quantified by haemoglobinometry.

The addition of sodium ascorbate 5 mg/ml will stabilise folate in serum, extending sample storage times,[51] but necessitates introduction of separate B_{12} and folate sample tubes since ascorbate interferes with cobalamin analysis. Samples must be fibrin free and without bubbles.

Analytical factors

Analytical sensitivity or limit of detection (LOD) varies between methods. It is defined as the concentration of analyte at 2SD of 20 replicates above the zero standard and for vitamin B_{12} assays is normally in the region of 22 pmol/l (30 ng/l) and for folate in the region of 0.68 nmol/l (0.3 µg/l). This is sometimes confused with the functional sensitivity of an assay, a term that defines the analyte concentration at which the CV of the assay is 20%. It is preferable that the functional sensitivity limit of serum vitamin B_{12} assays is closer to 37 pmol/l (50 ng/l) than the 111 pmol/l (150 ng/l) quoted by some kits because this provides increased sensitivity at the clinically important lower end of the reference range.

For many folate assays, functional sensitivity is in the region of 2.26 nmo1/l (1.0 µg/l) or less, although the Roche Elecsys assay quotes 4.5 nmol/l (2.0 µg/l).

Limitations and interference

Methotrexate and folinic acid interfere with folate measurement because these drugs cross-react with folate-binding proteins. Minor degrees of haemolysis significantly increase serum folate values as a result of high red cell folate levels. Lipaemia with >2.25 mmol/l (2 g/l) of triglycerides and bilirubin >340 µmol/l (200 mg/l) may affect assays.

'Unusually' high cobalamin levels are often due to vitamin B_{12} therapy, vitamin supplementation, myeloproliferative neoplasms or liver disease. In the absence of these factors, assay interference may result from immunoglobulin–B_{12}–transcobalamin complexes.[37]

Post-analytical factors

The clinical interpretation of laboratory data should take account of the positive or negative predictive value of a result. The measurement of uncertainty should also be known and available to requesting users on request. The report should include a reference range, the derivation of which should also be readily available to users.

METHODS FOR COBALAMIN AND FOLATE ANALYSIS

Microbiological bioassays and radiodilution assays for serum vitamin B_{12} and folate[56] are still used, albeit by a decreasing minority of laboratories, and continue to play an important role in the evaluation of new automated methods. They are also used in population studies where they are useful in providing information on the long-term comparability of results. (They are detailed in the 9th edition of this book.)

Modern methods are highly automated, heterogeneous, competitive protein-binding assays with chemiluminescence or fluorescence detection systems.

GENERAL PRINCIPLES OF COMPETITIVE PROTEIN-BINDING ASSAYS

The majority of automated single-platform, multianalyte, random-access analysers offer assays for serum vitamin B_{12}, folate and homocysteine by nonisotopic competitive protein-binding or immunoassay. Second antibodies may be utilised as part of the separation procedures.

SERUM B_{12} ASSAYS

Release from endogenous binders and conversion of analyte to appropriate form

Approximately 99% of serum vitamin B_{12} is bound to endogenous binding proteins (haptocorrin and transcobalamin) and must be released from these before measurement. The release step utilises alkaline hydrolysis

(NaOH at pH 12–13) in the presence of potassium cyanide (KCN), which converts cobalamin to the more stable cyanocobalamin, and dithiothreitol (DTT) to prevent rebinding of released vitamin B_{12}. Alkaline hydrolysis requires subsequent adjustment of pH to be optimal for the binding agent.

Binding of B_{12} to kit binder

The binding of vitamin B_{12} to kit binder is the competitive step of the assay. Serum-derived cyanocobalamin competes with labelled cobalamin, which is usually complexed to a chemiluminescent or fluorescent substrate or enzyme, for limited binding sites on porcine IF. Specificity for cobalamin is ensured by purification of the IF or by blocking contaminating corrinoid binders (R binders) by addition of excess blocking cobinamide. Specificity of pure and blocked IF can be demonstrated by the addition of cobinamide to sera. There should be no increase in assay value. Some assays use only the alkaline denaturation step to inactivate the endogenous binders. It is important that assays are not affected by the presence of high-titre anti-intrinsic factor antibody in patient sera.[57] Examples of diagnostic failures with assays based on competitive-binding luminescence assays are widespread and have been associated with all the commonly used platforms. Some assays now carry product literature warnings to this effect. A study illustrated failure rates of cobalamin assays in the analysis of samples from patients with proven pernicious anaemia as a function of diagnostic platform: 6 of 23 (26%) Beckman Coulter Access assay, which used the UniCel DxI 800 Immunoassay System, 5 of 23 (22%) Roche Elecsys Systems Modular Analytics E170 and 8 of 23 (35%) Siemens Advia Centaur assay.[57] The HoloTC assay by Axis-Shield is unaffected.[32,39,40]

Separation of bound and unbound B_{12}

Following competitive binding, the separation of bound and unbound vitamin B_{12} is achieved by a number of electro- or physico-chemical and immunological methods. The Roche Elecsys utilises an electrochemiluminescence measuring cell in which the bound B_{12}–ruthenium–IF complex, attached to paramagnetic particles by biotin–streptavidin, is magnetically captured onto the surface of an electrode. The Abbott Architect uses polymer microparticles (beads) with an iron core, coated with porcine IF to bind vitamin B_{12}. The bound vitamin B_{12} is then immobilised by positioning the assay reaction vessel in front of a magnet that pulls the paramagnetic microparticles onto the side wall of the reaction vessel. The reaction vessel contents are then aspirated and the reaction vessel refilled with buffer (in total the aspiration and refill step is repeated three times). These steps are designed to improve separation of bound and unbound B_{12}.

Signal generation

The bound fraction is then detected by the addition of a chemiluminescent, fluorescent or colorimetric enzyme substrate, which results in generation of fluorescence or light emission. There are two types of signal: flash, which is pH or electrically induced, and plateau, which is sustained. The initial rate of reaction or the area under the curve is used to calculate the result.

Electrochemiluminescence immunoassay

In the Roche Elecsys platforms a voltage is applied to the electrode on which the bound vitamin B_{12}–ruthenium–IF complexes have been immobilised by magnetic attraction. This generates electrochemical luminescence that is measured by the photomultiplier, the relative light units (RLUs) being inversely proportional to the sample vitamin B_{12} concentration. The signal that is produced is timed and integrated by the instrument's software.

Enzyme-linked fluorescence generation

The Siemens Centaur and the Abbott Architect use acridinium esters bound to vitamin B_{12}–IF complex coupled to paramagnetic particles; photons are emitted in response to pH change. The Siemens Immulite 2000/2500 (formerly *DPC*) uses adamantyl dioxetane phosphate as an alternative substrate, this being cleaved by alkaline phosphatase-labelled B_{12}–IF complex, resulting in generation of a plateau chemiluminescent signal. Alkaline phosphatase/4 methyl-umbelliferyl phosphate is utilised by the Tosoh Eurogenetics method, and Beckman Coulter Access employs alkaline phosphatase/dioxatane phosphate (Lumi-Phos) for signal generation. Precise descriptions of the assay methods are given in the product literature.

HOLOTRANSCOBALAMIN ASSAYS

Principle

As a sensitive marker of cobalamin malabsorption, HoloTC levels that correct with small oral doses of vitamin B_{12} and the use of recombinant IF[58–61] could provide the basis for a nonisotopic B_{12} absorption test to replace the unavailable Schilling test. The assay is based on a monoclonal antibody to cobalamin bound to TCII. To some extent levels are elevated by renal failure, but are unaffected by pregnancy.[30] One caveat is the recent discovery of molecular TCII variants of low prevalence that are not recognised by the assay monoclonal antibody but that do not appear to compromise the binding affinity for vitamin B_{12}.[98] Results from these patients are generated as <5 pmol/l independent of methylmalonic acid or homocysteine concentration.

HoloTC levels do not correlate with total serum vitamin B_{12}. HoloTC <25 pmol/l occurs in ≈5% of laboratory requests in a general hospital population; and are indeterminate (25–50 pmol/l) for ≈25% of requests.[8] However elevations in metabolic markers of vitamin B_{12} status are known to occur at HoloTC levels 50–70 pmol/l at a frequency (in the author's laboratory) of: 50–54 pmol/l, 17%; 55–59 pmol/l, 21%; 60–64 pmol/l, 15% and 65–70 pmol/l, 14%.[8,62]

Holotranscobalamin 'active B_{12}' immunoassay

The only automated random-access analyser currently offering the HoloTC (marketed as 'Active' B_{12}) assay is the Abbott Architect. It is a two-step quantitative immunoassay that uses chemiluminescent microparticle immunoassay technology. During the first step, sample and antiholotranscobalamin-coated paramagnetic microparticles are combined. HoloTC present in the sample binds to the antiholotranscobalamin-coated microparticles. After washing, the second assay step involves the addition of antitranscobalamin acridinium-labelled conjugate to create a reaction mixture. Following another wash cycle, Pretrigger and Trigger solutions are added to the reaction mixture. The resulting chemiluminescent reaction is measured as RLUs. There is a direct relationship between the amount of HoloTC in the sample and the RLUs detected by the Architect I System optics. The assay is designed to have a limit of quantification of ≤5 pmol/l with a percent cross-reactivity of ≤10% from vitamin B_{12}-binding proteins apotranscobalamin and haptocorrin.

In February 2016 Siemens launched the Centaur Active-B_{12} (AB_{12}) assay for use outside of the United States.

Holotranscobalamin radioimmunoassay

The HoloTC radioimmunoassay[32] uses magnetic microspheres coated with monoclonal antibody to HoloTC and achieves separation from haptocorrin by a magnetic separator. $A^{57}Co$ B_{12} tracer together with a reducing and a denaturing agent are then added to destroy the HoloTC linkage. When the vitamin B_{12} binder containing IF is added, the free vitamin B_{12} and tracer compete for binding. The unbound tracer is removed by centrifugation and the bound fraction is measured using a gamma counter. The measured radioactivity reflects the competition between tracer and vitamin B_{12} bound to transcobalamin (i.e. HoloTC). The concentration of vitamin B_{12} in the sample is calculated from a calibration curve using recombinant human HoloTC. The assay only requires a 0.4 ml sample volume, the coefficient of variation is <10%, the limit of detection is 10 pmol/l and the assay time is 4 h.

Quantification of transcobalamin saturation

Nexo and colleagues[63,64] described a method permitting measurement of total transcobalamin and HoloTC. The method uses vitamin B_{12} modified by acid treatment and bound to magnetic beads, which can then be used to remove unsaturated transcobalamin or apotranscobalamin from serum. The remaining HoloTC is then measured by an enzyme-linked immunosorbent assay (ELISA). Thus the total and HoloTC can be measured and the transcobalamin saturation (HoloTC/total transcobalamin) can be quantitated.

In a study of 137 healthy blood donors the reference range for HoloTC was 40–150 pmol/l. Some 10% of circulating transcobalamin is saturated with a reference range of 5–20%; 15–50% of B_{12} is bound to transcobalamin. In subjects who were B_{12} deficient, HoloTC was 2–34 pmol/l and the TC saturation was 0.4–3%, well below the reference interval, providing a clear cut-off from normal sera. Nexo's method combines a sensitive ELISA[65] for HoloTC with a simple procedure for removal of the unsaturated TC or apoTC.

SERUM FOLATE METHODS

The first methods used for measurement of serum folate were microbiological assays. Radioisotope dilution (RID) assays were subsequently developed, and the newer commercial, automated, competitive-binding assays are based on similar principles to those of vitamin B_{12} assays. Definition of assay response to different forms of folate is crucial for inter-assay comparisons.

Release from endogenous binders

Serum folate present as 5-methyl THF is released from endogenous binders (≈66% is weakly bound to serum proteins and the remainder to membrane-derived soluble folate receptors) by alkaline denaturation. DTT or monothioglycerol (MTG) is used in most folate assays to prevent reattachment of folate to the endogenous binders and to keep the folate in its reduced form.

Binding of folate to folate-binding protein

β lactoglobulin, isolated from cow's milk, is commonly used as a binding agent in folate assays, (i.e. as the folate-binding protein (FBP)). Unfortunately, these lactoglobulins are not specific for the attachment of 5-methyl THF and, depending on pH, will bind many forms of folate. These properties have been utilised for the standardisation of folate assays. PGA, present in vitamin supplements, which is more stable than the physiologically active 5-methyl THF form, binds to FBP and has been used as an

alternative standard for the folate assays. The use of PGA as a standard depends on the observation that the binding affinities for 5-methyl THF and PGA are equivalent at pH 9.3 ± 0.1.[65] It is therefore essential that the pH is strictly maintained at the binding stage of the procedure. In most of these assays, serum-derived folate competes with chemiluminescent or enzyme-labelled folate for limited sites on FBP. In the *Roche Elecsys* methods the FBP is labelled with ruthenium and competition exists between endogenous and biotin-labelled folate.

Separation of bound and unbound folate

Following competitive binding, the separation of bound and unbound folate is achieved by a number of electro- or physico-chemical and immunological methods. The Abbott Architect uses polymer microparticles (beads) with an iron core, coated with FBP to bind sample folate, and the bound folate is then immobilised by positioning the assay reaction vessel in front of a magnet, which pulls the paramagnetic microparticles onto the side wall of the reaction vessel. The reaction vessel contents are then aspirated and the reaction vessel refilled with buffer. After washing, pteroic acid-acridinium-labelled conjugate is added and binds to unoccupied sites on the FBP-coated microparticles. Pre-Trigger and Trigger Solutions are then added to the reaction mixture; the resulting chemiluminescent reaction is measured as RLUs. The Beckman Access uses murine anti-FBP goat antimouse IgG coated on paramagnetic particles. The Siemens Immulite platforms use murine anti-FBP coated onto polystyrene beads with separation by centrifugation.

Signal generation

Generation of electro-chemiluminescence, chemiluminescent, fluorescent or light emission is similar to that for B_{12} methods. In assays where the bound B_{12} complex is labelled with chemiluminescent esters, signal is generated in response to pH change or is electrically induced.

RED CELL FOLATE METHODS

Whereas *Lactobacillus casei* responds equally to triglutamates and monoglutamates, the affinity of the FBP varies with the number of glutamate residues. Reproducible protein-binding assays for red cell folate can only be achieved by release and conversion of the protein-bound folate polyglutamates, mainly 5-methyl THF with four or five additional glutamate moieties, to a monoglutamate form. There must be adequate dilution of the red cells in hypotonic solution, a pH between 3.0 and 6.0 (ideally pH 4.5–5.2) for optimal conditions for plasma folate deconjugase (polyglutamate hydrolase) and ascorbic acid to stabilise the reduced forms.[66,67]

Haemolysate preparations for the assay platforms vary widely. The concentration of ascorbic acid varies from 0.09% to 1%, dilution factors from 1:5 to 1:31 and the duration of haemolysate preparation from 40 to 180 min. Some assays require the addition of protein to lysates before analysis and use bovine serum or human serum albumin, whereas others need only aqueous solutions. The pH of lysing diluent varies from 3.0 to 4.0 and that of the deconjugase step from 4.0 to 6.8 (the final pH of the lysate after protein addition varies from 4.4 to 7.5). These various factors may help to explain the large intermethod differences detected in external quality assessment surveys. Inadequate lysis and deconjugation will give falsely low results.[68,69]

Manual haemolysate preparation

Red cell folate samples are usually collected in ethylenediaminetetra-acetic acid (EDTA) tubes and may be stored at 4 °C for up to 48 h prior to lysate preparation. The lysate is prepared by adding 0.1 ml of whole blood of known haematocrit (Hct) to 1.9 ml of 1 g/dl freshly prepared aqueous ascorbic acid, incubated at room temperature for 60 min in the dark. The ascorbic acid stabilises the folate and the pH of 4.6 allows plasma folate deconjugase to convert the polyglutamate forms to the monoglutamate form. Folate activity should be assayed straight away although the lysate may be stored at 4 °C for no more than 24 h prior to analysis. Storage at −20 °C for longer periods is permissible, but approximately 10% decrease in activity is noted following a single freeze/thaw cycle. Whole blood in heparin, EDTA, or citrate–phosphate–dextrose (CPD) can be used in some, but not all, assays.

Calculation of red blood cell folate from haemolysate folate result

1. Multiply the haemolysate folate value by the dilution factor (e.g. 22 if a 1:21 dilution) to obtain the folate concentration of whole blood in μg/l.
2. For an uncorrected red cell folate value in μg/l, divide the whole blood folate result in (1) by the Hct (l/l).
3. The result obtained in (2) should, if possible, be corrected for the serum folate value, which for patient populations taking supplemented dietary folate may now be quite significant, as is illustrated in this worked example:

   Corrected red cell folate (μg/l) =

   Red cell folate in μg/l − [serum folate in μg/l × (1 − Hct)/Hct]

   e.g. when Hct is 0.45, red cell folate is 180 μg/l and serum folate is 28 μg/l, then

   Corrected red cell folate (μg/l) = 180 − [28 × (1 − 0.45)/0.45] = 145.8.

Many serum assays have an upper limit of 22–28 µg/l and the serum sample must therefore also be diluted and retested to obtain accurate results. Serum folate is traditionally quoted as µg/l or ng/ml; to convert to SI units (Système International d'Unités); µg/l × 2.265 = nmol/l, and nmol/l × 0.44 = µg/l.

Serum vitamin B_{12} and folate and red cell folate assay calibration

Cobalamin in serum is protein bound and therefore standards for total vitamin B_{12} assays should be gravimetrically prepared cyanocobalamin in either a lyophilised serum or protein-adjusted matrix. A WHO lyophilised serum standard with consensus values for serum vitamin B_{12} is available from the National Institute for Biological Standards and Control (NIBSC) (www.nibsc.org);[49] however, protein binding vitamin B_{12} assays are not usually calibrated with this material.

For serum folate analysis, 5-methyl THF is the physiologically active folate form, and therefore should be used as the standard. However, 5-methyl THF is relatively unstable and historically PGA has been used as the primary calibrator either gravimetrically added to aqueous standards or used to assign values to secondary serum matrix standards. The principle underlying the use of PGA is dependent on the equimolar binding of 5-methyl THF or PGA at pH 9.3.[65] More recent work suggests the pH of equimolar binding may be nearer 8.9 than 9.3.

The development of isotope dilution, liquid chromatography, tandem mass spectrometry (ID-LC/MS/MS) reference methods for folate derivatives in serum[47,48] has permitted the introduction of higher-order serum and plasma reference materials with accurate values for folates. A lyophilised serum standard (WHO 03/178)[49] is available from NIBSC and three frozen plasma preparations (FPP) with assigned values for 5-methyl THF, folic acid (FA) and homocysteine are available from the NIST in the USA (www.nist.gov/index.html).

Whole blood folate standards

An international reference preparation for whole blood folates[50] is available from NIBSC (95/258) with an assigned content of 13 ng/ampoule. The standard is for use in microbiological assays and binding assays for whole blood folate, although the haemolysate preparations are generally analysed using the serum method protocols and calibration curves.

Primary instrument calibration

The recent introduction of ISO 15189 – the international standard that specifies requirements for quality and competence in medical laboratories – has a particular emphasis on the need for demonstrable metrological traceability of calibration standards. The majority of manufacturers still use gravimetric PGA calibrators or PGA values assigned to serum matrix calibrators referenced to older RID methods as their primary instrument calibration. Siemens utilises 5-methyl THF as its instrument calibrator, although this is referenced to aqueous gravimetric factory standards. Methods calibrated in this way should be optimised for the detection of 5-methyl THF and should not require the adjustment of the binding pH to 9.3. Currently only one major manufacturer has opted to harmonise the calibration of its serum folate assay with the WHO 1st International Standard for Total Folate in Serum. Results from surveys of the UK National External Quality Assessment Service (NEQAS) Haematinics scheme suggest that this method (Abbott) is now accurate when compared with values obtained by the ID-LC/MS/MS reference method (UK NEQAS Haematinics steering committee report October 2009).

Internal adjustment calibration

Most automated assay systems use calibration curves that are stored on bar code systems with each reagent lot. The bar code also contains the mathematical formulae for shifting or adjusting the observed responses to the master curve when the instrument requires routine calibration.

Internal quality control

As a minimum requirement, two levels of quality control material should be assayed daily when samples are being analysed. A choice of batch analysis, or true random access, may be preferred by the operator, although in view of folate instability prolonged on-board times are to be avoided. Suitable controls are available commercially (Bio-Rad Laboratories, www.bio-rad.com).

DIRECT MEASUREMENT OF 5-METHYLTETRAHYDROFOLATE IN PLASMA, RED CELLS AND CEREBROSPINAL FLUID BY HIGH PERFORMANCE LIQUID CHROMATOGRAPHY

Common polymorphisms in the *MTHFR* gene influence the relative abundance of folates. 5-Methyl THF may be a cardiovascular risk factor independent of homocysteine.[70] Direct measurement of 5-methyl THF is also valuable for confirmation of cerebral folate deficiency (CFD).

Analytical procedure

The method described here is a variation on that published by Pfeiffer *et al.*,[47] and was used to establish reference ranges for 5-methyl THF.[71]

Folates contain acidic and basic sites, which are able to ionise simultaneously in the pH range 2–4. There are two carboxylic groups on the L-glutamate part of the molecule and basic nitrogen atoms in the pteridine ring. Pteridine also contains an amide group. These ionic species must be masked to achieve a satisfactory interaction with the nonpolar stationary phases used in reversed phase high performance liquid chromatography (HPLC). To achieve this, an acidic mobile phase can be employed to protonate the carboxyl function, or an ion-pairing reagent can be added to mask the carboxyl function.

Preparation

A freshly collected EDTA plasma sample (or one stored at −70 °C) is suitable for analysis. For the determination of 5-methyl THF in red blood cells, after Hct determination add 900 µl freshly made 0.5% ascorbic acid solution to 100 µl of fresh EDTA blood. Samples can be frozen at this point at −20 °C for subsequent analysis within 1 month, or −70 °C for longer. Samples are not suitable for repeated freeze-thaw cycles. On the day of analysis, whole blood lysates must be incubated at 37 °C for 4 h to allow for deconjugation of polyglutamates to monoglutamates in the presence of endogenous folylpolyglutamate hydrolases.

Extraction

To 300 µl plasma or deconjugated whole blood lysate are added 700 µl of 10 g/l ammonium formate with 1 g/l ascorbic acid adjusted to pH 3.2 with formic acid (buffer A) and 50 µl of the assay internal standard p-aminoacetophenone (67.2 µg/ml). Samples are vortex mixed and incubated for 20 min at 4 °C. The extract is then purified using a solid phase extraction (SPE) cartridge (Bond Elut, C18, 1 ml, Agilent Technologies, www.agilent.com) conditioned with 1 ml of acetonitrile followed by 1 ml methanol and then 1 ml buffer A. The sample is loaded on the SPE and then washed with 1.5 ml of buffer B (1 g/l ammonium formate, with 1 g/l ascorbic acid, adjusted to pH 3.4 with formic acid).

The sample is eluted with 500 µl of elution solution (400 ml/l methanol, 100 ml/l acetonitrile, 10 ml/l acetic acid, 1 g/l ascorbic acid). Post elution, 350 µl of 0.5% ascorbic acid is added to each sample.

High performance liquid chromatography

Chromatographic resolution of folate species is achieved using a C18 column (ACE C10, 3 µm HPLC column, dimensions 125 × 4.6 mm or equivalent) and an isocratic mobile phase consisting of 89% of 0.033 nmol/l potassium phosphate buffer, 6.6% acetonitrile and 4.4 % methanol – adjusted to pH 2.28 with orthophosphoric acid. Prior to the injection of 10 µl of the prepared extract onto the HPLC system, sample extracts should be stored in the auto-sampler at 4 °C. The mobile phase is delivered to the column at a flow rate of 0.34 ml/min, and the column is kept at 25 °C. The native fluorescence of folates is detected using fluorescence detection set at λ_{ex} 290 nm, λ_{em} 365 nm. Typical peak retention times are 11 min for 5-methyl THF and 26 min for the internal standard.

METHYLMALONIC ACID MEASUREMENT

Principle

The urine concentration of methylmalonic acid (MMA) is higher than that of plasma and needs to be normalised for urine creatinine concentration and corrected for the effects of renal impairment or dehydration before interpretation. Serum measurement offers added convenience, in that it is unaffected by diet and can use the same sample as that obtained for vitamin B_{12}.

Methods

Automated liquid chromatography tandem mass spectrometry with electrospray ionisation-based method

An automated method capable of processing >200 samples daily has been used regularly in the author's laboratory since 2012. Analysis is carried out using a Gerstel Multipurpose Sampler (MPS) coupled to a liquid chromatography tandem mass spectrometry with electrospray ionisation (LC-ESI-MS/MS). For sample preparation, 200 µl of serum or plasma is placed in a 2 ml glass screw top auto-sampler vial and the vial is capped using magnetically transportable PolyMag caps (GESRTEL, Germany, www.gerstelus.com). The sample is then placed on the vial tray of the MPS.

Extraction of methylmalonic acid from serum or plasma is achieved through protein precipitation. 800 µl of acetonitrile containing 0.5% acetic acid and the internal standard MMA-d3 at a concentration of 165 nmol/l is added to the sample. The vial is then moved using the magnetic transport to the CF-100 centrifuge whereby the contents are thoroughly vortexed for 30 s to assist in the protein precipitation. The vial is then centrifuged at 3000 rpm for 1 min to separate the proteins from the supernatant in preparation for injection.

Sample analysis is fully automated by means of an external injection valve and loop fitted onto the MPS; 20 µl of extract is injected. Separation is achieved by means of a Merck PEEK ZIC-HILIC 2.1 I.D. × 100 mm; 3.5 µm particle size column (www.nestgrp.com). The chromatographic

mobile phases consist of acetonitrile and 100 nM ammonium acetate adjusted to pH 4.5 with formic acid in water. An isocratic elution followed by a gradient column reconditioning is performed. LC run time is 8 min; column temperature is maintained at 30 °C. The limit of quantification in a 200 µl sample is 60 nmol/l.

Gas chromatography–mass spectrometry-based method

Plasma or serum methylmalonic acid is extracted, purified and, using *tert*-butyldimethylsilyl derivatives of methylmalonic acid, measured by gas chromatography–mass spectrometry (GC-MS). A deuterated stable isotope of methylmalonic acid is used as an internal standard. The use of dicyclohexyl, another derivative of methylmalonic acid, is described by Rasmussen.[72]

High performance liquid chromatography-based method

Methylmalonic acid is extracted from 250 µl serum/EDTA plasma into ethyl acetate along with the internal standard: ethylmalonic acid (EMA).[73] To achieve sufficient assay sensitivity it is necessary to generate fluorescent derivatives of these analytes with dicyclohexylcarbodiimide prior to their separation by reversed phase HPLC with an acidified mix of acetonitrile, tetrahydrofuran and water containing dibutylamine. Using this method, the limit of detection and quantification for the measurement of MMA in a 250 µl sample is 15.4 nmol/l and 20.3 nmol/l respectively.

HOMOCYSTEINE MEASUREMENT

Principle

Homocysteine is a disulphide amino acid present at low concentrations in cells (<1 µmol/l) and in plasma at 5–15 µmol/l.[74] Homocysteine has a reactive sulphydryl group that forms disulphide bonds with homocysteine or cysteine or protein sulphydryl groups to form the oxidised form of homocysteine: homocystine, homocysteine-cysteine mixed disulphide and protein-bound homocysteine. The free homocysteine is <2% of plasma homocysteine and 80% is as protein-bound homocysteine; the remainder is homocystine or mixed disulphides. Reducing conditions convert all these species to homocysteine by reduction of disulphides; therefore total homocysteine is measured.

For quantification, plasma homocysteine requires protein precipitation and reduction of disulphide bonds. The S-H group of homocysteine is derivatised using a thiol-specific reagent and the resulting adduct is detected. A variety of methods have evolved[75] including ion-exchange amino acid analysers,[69] radioenzymatic determination, capillary gas chromatography[76] stable isotope dilution combined with capillary GC-MS,[77] liquid chromatography electrospray tandem mass spectrometry[78] and HPLC methods using fluorochromophore detection.

HPLC methods that use fluorochromophore detection systems are still available but are not as widely used in clinical laboratories as previously. These methods first reduce the disulphide bonds followed by the removal of protein and the derivatisation of the thiol groups to support detection by fluorescence.

Immunoassay for homocysteine measurement

Automated enzyme immunoassays[79] for homocysteine are available from a number of manufacturers. The general principle of these methods is that bound or dimerised homocysteine (oxidised form) is reduced to free homocysteine by the use of buffered DTT. Free homocysteine is then enzymatically converted to S-adenosyl-L-homocysteine (SAH) by bovine SAH hydrolases in the presence of excess adenosine. Competitive reactions are used to quantify total homocysteine, and methods are further subclassified based on differences in the separation and detection of SAH. These include fluorescence polarisation immunoassay (FPIA), chemiluminescent immunoassay (CIA), enzyme-linked immunosorbent assay (ELISA) and other enzyme immunoassays (EIA). Latex-enhanced agglutination immunoassays have also been developed for homocysteine quantification.

In the Axis-Shield, Abbot Architect, Siemens Centaur and Siemens Immulite 2000/2500 (formerly Diagnostic Products) methods, synthetically derived SAH is bound to the separator system (coated wells, paramagnetic particles or polystyrene beads). Labelled murine anti-SAH is added and in the presence of sample-derived SAH competes for binding to immobilised SAH. The concentration of labelled anti-SAH bound to the separation-phase SAH is inversely proportional to the concentration of SAH derived from the original sample. An appropriate substrate and suitable conditions for colour, chemiluminescence or fluorescence generation permit analyte quantification.

The enzyme immunoassays methods utilise enzyme systems in the detection phase of the assay. For example, in the Axis-Shield EIA method a second rabbit antimouse antibody labelled with enzyme horseradish peroxidase is added to the bound fraction. Colour is generated by the addition of the substrate, tetramethylbenzidine, and is read at 450 nm.

Immunoturbidimetric assays, suitable for use on a coagulation analyser, have also been developed. One such method has been produced by Instrumentation Laboratory (IL). This assay converts all homocysteine forms enzymatically to SAH in the same way as described above. Plasma-derived SAH and a homocysteine conjugate with multiple binding sites compete for limited binding sites

on microlatex particles coated with anti-SAH antibodies. The resultant agglutination is measured at 405 nm.

Other enzyme assays for homocysteine

One of the more novel methods for homocysteine measurement is described by its manufacturer (Diazyme Europe GmbH) as an enzyme cycling system with amplification of the detection signal. The kit is transferable to a number of platforms, including the Roche Diagnostics Hitachi, Siemens (formerly Dade) Vista Dimension and the Beckman Synchron CX, LX and DXC.

Standardisation of homocysteine methods

Although the exact process differs between techniques, the chromatographic methods are calibrated, using gravimetrically prepared standards of homocysteine and other closely related thiol compounds, as a ratio to a stable internal standard such as 2-mercaptoethylamine. The ratio of the sample signal to internal standard is used to quantify the unknown concentration. Where this is described in any detail, most immunoassays are standardised with synthetically derived SAH, which may be dispersed in buffered aqueous solution or added in modified human serum. This means that the standard material is not subject to the release, reduction and enzymatic conversion of the endogenous homocysteine but has the advantage of stability.

Reference methods for homocysteine

There are three procedures quoted on the Joint Committee for Traceability in Laboratory Medicine (JCTLM) database as high-order reference procedures for homocysteine measurement in human serum.[80,81] Methods include isotope dilution, gas chromatography, mass spectrometry (ID/GC/MS) and two methods based on isotope dilution, liquid chromatography, tandem mass spectrometry (ID/LC/MS/MS). These methods are used to assign homocysteine (and folate) values to frozen serum reference material (SRM 1955) produced by NIST in the USA.

Pre-analytical variables in homocysteine testing

Plasma homocysteine is elevated in both vitamin B_{12} and folate deficiency and in individuals with a common genetic polymorphism of *MTHFR*, the C677T polymorphism. Inborn errors in metabolism that manifest with greatly elevated serum homocysteine include those found in the *CBS* gene that encodes cystathionine β synthase (CBS), (EC 4.2.1.22). CBS catalyses the first step of the transsulfuration pathway from homocysteine to cystathionine using the cofactor vitamin B_6 (pyridoxalphosphate). Deficiency in vitamin B_6 may therefore also cause mild elevations in serum homocysteine. Factors affecting albumin levels will alter homocysteine because it is protein bound and venepuncture should not be performed after venous stasis or following the subject resting in supine position. Plasma is preferred because cells leak homocysteine; samples should be kept on ice and centrifuged as soon as possible, at least within 1 h.

DYNAMIC TESTING OF COBALAMIN FOLATE METABOLISM

Measurement of metabolite response at 1 week following cobalamin or folate treatment provides the opportunity to perform an *in vivo* dynamic function test of the cobalamin–folate metabolic pathways and confirm a diagnosis of tissue deficiency of one vitamin or the other.

Another dynamic functional test of cobalamin–folate metabolism, utilised primarily in research laboratories, is the deoxyuridine suppression test;[82] the method was described in the 9th edition of this book.

INVESTIGATION OF THE CAUSE OF COBALAMIN DEFICIENCY

Once cobalamin deficiency has been confirmed, the aetiology of the low cobalamin should be elucidated as in Table 10-1. Gastric parietal cell antibodies are present in 90% of patients with pernicious anaemia, but this is of low specificity, being found in 15% of elderly subjects, and is therefore of little discriminatory use. Achlorhydria as a cause of cobalamin malabsorption may be suspected by the presence of raised gastrin levels.[83]

INTRINSIC FACTOR ANTIBODY MEASUREMENT

Principle

Two types of antibody to IF have been detected in the sera of patients with pernicious anaemia. Type I (blocking) blocks the binding of vitamin B_{12} to IF, whereas type II prevents the attachment of IF or the IF–B_{12} complex to ileal receptors. Type II antibodies (precipitating antibodies) may be precipitated by IF–B_{12} complex and sodium sulphate at pH 8.3 in barbitone buffer. More than 60% of patients with pernicious anaemia are reported to have type I or type II antibodies.[84,85]

Assay methods have been reviewed[84] and one method for detection of types I and II IF antibody based on radiodilution competitive binding was described in the 9th edition of this book.

Intrinsic factor antibody kits

ELISA (enzyme-linked immunosorbent assay) kits that detect both type I and type II antibodies are available from a number of companies and have largely superseded radiodilution based assays. These range from the fully automated to the manual. The more commonly used assays include those supplied by Orgentec, Beckman Access, Alphadia, Euroimmun, Genisis, Cambridge Life Sciences, Alegria, D-Tek and Inova. Other ELISA and non-ELISA kits are available. The UK NEQAS Haematinics scheme has shown poor diagnostic agreement between these kits for a minority of patient-derived samples.

Principle of binding assay for type I intrinsic factor antibodies

Patient serum is incubated with an IF–alkaline phosphatase conjugate and IF antibody in the patient sample binds to the IF conjugate. Paramagnetic particles coated with murine monoclonal antibody specific for the vitamin B_{12} binding site on IF are added to the reaction vessel, and IF conjugate that has not been blocked by sample IF antibody binds to the mouse monoclonal antibody on the solid phase (paramagnetic particles). Separation is achieved by the application of a magnetic field to hold the particles, and the excess unbound material (IF conjugate) is washed away. The chemiluminescent substrate is added to the reaction vessel and the light generated is read at 530 nm in a luminometer.

This type of method is potentially subject to interference from free vitamin B_{12} in the patient's serum because it binds to the IF conjugate, which is then removed in the washing step. Under normal circumstances 99% of B_{12} in serum is bound, but patients with high levels of circulating free B_{12} (>444 ng/l) – as might be the case following treatment with intramuscular B_{12} – may record disproportionately elevated levels of IF antibody.

Enzyme-linked immunosorbent assay methods for type I and type II intrinsic factor antibodies

Serum is incubated in the presence of IF bound to a solid phase in such a way that both the type I and type II binding sites are available for binding IF antibody.[85] Excess unbound serum is removed and the solid phase is further incubated with conjugate-labelled (e.g. horseradish peroxidase) antihuman immunoglobulin IgG. Unbound conjugate is removed and substrate is added to develop the signal, which is proportional to the amount of IF antibody in the original serum. The specificity of the IF antibody assay will depend on the purity of the solid-phase IF. Purified porcine IF or recombinant IF is used in different ELISAs and the UK NEQAS IF antibody quality control surveys have shown variable positive rates for different types of ELISA,[86] perhaps reflecting different sensitivities and specificity of patient sera.

Interpretation

International reference and calibration material for IF antibody is not available and results of both types of method are expressed in arbitrary units or as a ratio to a cut-off deemed as positive by each manufacturer. As a consequence of the use of arbitrary units and the requirement to detect both antibodies concurrently, independent quality control material is not available.

INVESTIGATION OF ABSORPTION OF B_{12}

In patients who are B_{12} deficient and who are IF antibody negative, it is important to establish whether the capacity to absorb the vitamin is normal. Absorption tests should be reserved for those individuals in whom low vitamin B_{12} levels result in genuine tissue deficiency, confirmed by supportive laboratory or clinical findings (e.g. macrocytosis, hypersegmented neutrophils, megaloblastic anaemia, neuropathy, neuropsychiatric features or elevation of cobalamin-dependent metabolites) to avoid excessive investigation of 'falsely low or indeterminate' serum B_{12} levels.

The withdrawal of reagents for the traditional radiolabelled Schilling tests has hampered the full investigation of patients with cobalamin deficiency.

Development of non-isotopic B_{12} absorption tests using holotranscobalamin levels and recombinant intrinsic factor

HoloTC levels increase 3–4 h after oral cobalamin intake and, after 3 doses of 9 μg cyanocobalamin given 6-hourly on day 1, peak serum HoloTC was detected at 24 h in healthy adults maintained on a normal diet and given bread and juice to aid absorption of each cobalamin dose. Cellular uptake of HoloTC will be greater in deficient individuals, and therefore the time course of a rise in HoloTC and the dose of cyanocobalamin may vary.[58,59] Bhat *et al.*[61] gave 10 μg of cyanocobalamin at 6-hourly

intervals ×3 and defined a normal response as a rise in plasma HoloTC of >15% and >15 pmol/l above baseline measurement; the majority of Asian women studied corrected low HoloTC levels, suggesting dietary deficiency as the cause.

Non-isotopic B_{12} absorption test utilising recombinant intrinsic factor in combination with holotranscobalamin levels

Human or bovine IF is no longer commercially available. Hvas *et al.*[59] utilised recombinant IF from 1 g of the plant leaves of transgenic *Arabidopsis thaliana* (Pharma Skan, Skanderborg, Denmark, www.pharma-skan.dk) to show enhanced cobalamin absorption and HoloTC levels in subjects with B_{12} deficiency.

Urinary excretion of radiolabelled B_{12} with and without intrinsic factor (Schilling test)

Radiolabelled cyanocobalamin and bovine IF reagents are no longer available. (Details of the principles of the Schilling tests can be found in references 87 and 88 and in the 10th edition of this book.)

B_{12} BINDING CAPACITY OF SERUM OR PLASMA: TRANSCOBALAMIN MEASUREMENT

Principle

Haptocorrin (R binder) binds 80% or more of the total serum B_{12}, and the B_{12}–haptocorrin complex is known as holohaptocorrin. Transcobalamin is normally virtually unsaturated unless an individual is undergoing B_{12} treatment. Transcobalamin should therefore be measured prior to vitamin B_{12} treatment. Haptocorrin includes two glycosylated proteins, previously known as transcobalamins I and III, that differ in their sugar moiety. Chronic myeloid leukaemia, primary myelofibrosis and other myeloproliferative neoplasms are characterised by increased levels of haptocorrin and therefore total serum B_{12}. Primary liver cancer (fibrolamellar hepatoma) is also associated with synthesis of large quantities of an abnormal form of haptocorrin. It has been suggested that some low B_{12} levels without evidence of B_{12} deficiency may result from a decrease in R binder concentration.[89] Congenital absence of haptocorrin results in very low serum B_{12} but no evidence of B_{12} deficiency.[90] In congenital absence of transcobalamin,[91,92] which results in fulminating pancytopenia and megaloblastosis within 2 months of birth, the serum B_{12} is normal, unsaturated B_{12} binding capacity is decreased as a result of absent transcobalamin and B_{12} absorption is reduced; the deoxyuridine suppression test is abnormal and is corrected by B_{12}.

UNSATURATED B_{12} BINDING CAPACITY AND TRANSCOBALAMIN IDENTIFICATION AND QUANTIFICATION

Measurement of unsaturated B_{12} binding capacity is rarely undertaken and is only available in reference laboratories (details of the method were given in the 9th edition of this book). It is mainly of use for detection of haptocorrin deficiency as a cause for very low serum B_{12} with no clinical features of cobalamin deficiency. It is also required for diagnosing the rare transcobalamin deficiency. In addition, the assay has been used as a tumour marker for primary liver cancer.

Reference ranges for transcobalamins

The normal range[66] for serum unsaturated B_{12} binding capacity is 670 to 1200 ng/l; for plasma collected into EDTA-sodium fluoride it is 505 to 1208 ng/l;[93] for haptocorrin (transcobalamin I), 49 to 132 ng/l; transcobalamin, 402 to 930 ng/l and for haptocorrin (transcobalamin III), 80 to 280 ng/l.

ACKNOWLEDGEMENTS

Many thanks indeed to Dr Malcolm Hamilton and Mrs. Sheena Blackmore, authors of this chapter in editions 10 and 11 of this series. The descriptions of metabolic pathways for cobalamin, folate and homocysteine were assisted by *Hematology Basic Principles and Practice*[94] and *Homocysteine in Health and Disease*.[95] Thank you Annie Lee, Julie Bonser, staff at UK NEQAS Haematinics Department of Haematology and Good Hope NHS Trust. Thanks to Dr Agata Sobczynska-Malefora, Renata Gorska, David Card, Denise Oblein and the Nutristasis Unit at Guy's and St. Thomas' Hospital NHS Foundation Trust for ongoing expertise in the development and application of assays to establish vitamin status.

Laboratory Methods Used in the Investigation of the Haemolytic Anaemias

Lynn D. Robertson • David Roper

CHAPTER OUTLINE

Red cells are typically removed from the circulation at the end of their lifespan of about 120 days. A shortened lifespan due to premature destruction may lead to haemolytic anaemia when bone marrow activity cannot compensate for the erythrocyte loss. The causes can be divided into three groups:

1. Defects within red cells from dysfunction of enzyme-controlled metabolism, abnormal haemoglobins or thalassaemias
2. Loss of structural integrity of red cell membrane and cytoskeleton in hereditary spherocytosis, hereditary elliptocytosis, paroxysmal nocturnal haemoglobinuria (PNH) and immune and drug-associated antibody damage
3. Damage by extrinsic factors such as mechanical trauma, microangiopathic conditions (including thrombotic thrombocytopenic purpura) and chemical toxins.

At the end of a normal lifespan, red cells are destroyed within the reticuloendothelial system in the spleen, liver and bone marrow. In some haemolytic anaemias, the haemolysis occurs predominantly in the reticuloendothelial system (extravascular) and the plasma haemoglobin

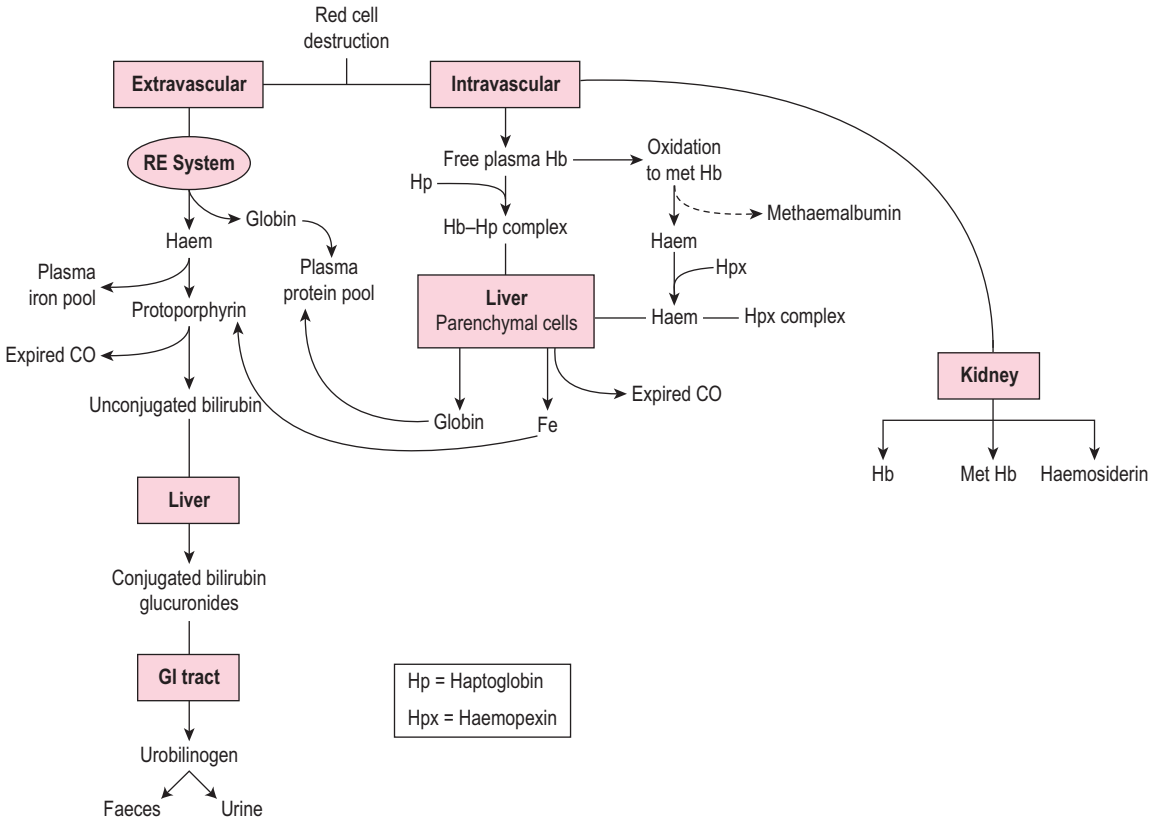

FIGURE 11-1 Catabolic pathway of haemoglobin.

concentration is barely increased. In other disorders a major degree of haemolysis takes place within the bloodstream (intravascular haemolysis), the plasma haemoglobin concentration increases substantially and in some cases the amount of haemoglobin liberated is sufficient to lead to its being excreted in the urine (haemoglobinuria). However, there is often a combination of both mechanisms. The two pathways by which haemoglobin derived from effete red cells is metabolised are illustrated in Figure 11-1.

INVESTIGATION OF HAEMOLYTIC ANAEMIA

The cardinal signs of haemolysis in adults (anaemia, jaundice and reticulocytosis) may also be seen in infants resulting from the shift from γ to β globin production, changes in glycolytic enzyme activities and reduction or absence of haptoglobins during the first month or so of life, and so it is essential to compare results with age-matched sample(s) or age-specific reference values.

The clinical and laboratory associations of increased haemolysis reflect the nature of the haemolytic mechanism, where the haemolysis is taking place and the response of the bone marrow to the resultant anaemia, namely erythroid hyperplasia and reticulocytosis.

The investigation of patients suspected of suffering from a haemolytic anaemia comprises several distinct stages: recognising the existence of increased haemolysis, determining the haemolytic mechanism and making a precise diagnosis. In practice, the procedures are often telescoped because the diagnosis in some instances may be obvious to the experienced observer from a glance down the microscope at the patient's blood film.

The following practical scheme of investigation is recommended. In each group, tests are listed in order of importance and practicability.

Is there evidence of increased haemolysis?

1. Estimation of haemoglobin concentration (Hb); reticulocyte count; inspection of a stained blood film for the presence of spherocytes, elliptocytes, irregularly contracted cells, schistocytes or agglutination (see Chapters 3 and 5)
2. Tests for increased unconjugated serum bilirubin and urinary urobilinogen excretion; measurement of haptoglobin or haemopexin
3. Detection of urinary haemoglobin or haemosiderin

What is the haemolytic mechanism?

1. Direct antiglobulin test (DAT) with broad-spectrum antiserum
2. Osmotic fragility and glycerol lysis test
3. Measurement of haemoglobin concentration in urine and plasma; Schumm test

What is the precise diagnosis?

1. If a hereditary haemolytic anaemia is suspected:
   a. Eosin-5-maleimide (EMA) dye binding test or osmotic-fragility determination after 24 h of incubation at 37 °C; screening test for red cell glucose-6-phosphate dehydrogenase (G6PD) deficiency (or quantitative assay if reticulocytosis is present); red cell pyruvate kinase assay; assay of other red cell enzymes involved in glycolysis; estimation of red cell glutathione (see Chapter 12)
   b. Estimation of percentage of haemoglobins A_2 and F; high performance liquid chromatography or electrophoresis for an abnormal haemoglobin; tests for sickling; tests for an unstable haemoglobin; blood count parameters, especially mean cell volume (MCV), mean cell haemoglobin (MCH) and mean cell haemoglobin concentration (MCHC); gene analysis (see Chapter 8)
   c. Examination of the proteins of the red cell membrane and cytoskeleton (e.g. spectrin) by gel electrophoresis and by specific radioimmunoassay
2. If an autoimmune acquired haemolytic anaemia is suspected:
   a. Direct antiglobulin test using anti-immunoglobulin and anticomplement sera; tests for autoantibodies in the patient's serum; titration of cold agglutinins; Donath–Landsteiner test; electrophoresis of serum proteins; demonstration of thermal range of autoantibodies; tests for agglutination and/or lysis of enzyme-treated cells by autoantibodies; tests for lysis of normal cells by autoantibodies
3. If a drug-induced haemolytic anaemia is suspected:
   a. Screening test for red cell G6PD; glutathione stability test; staining for Heinz bodies; identification of methaemoglobin (Hi) and sulphaemoglobin (SHb); tests for drug-dependent antibodies
4. If mechanical stress is suspected:
   a. Red cell morphology; platelet count; renal function tests; coagulation screen; fibrinogen assay; test for fibrinogen/fibrin degradation products (see Chapters 5 and 18)
5. In obscure cases:
   a. Investigations for PNH, such as acidified serum test (Ham test), sucrose lysis test, flow cytometric immunophenotyping for erythrocyte and neutrophil glycosylphosphatidylinositol (GPI)-linked antigens (see Chapter 13)
   b. Measurement of lifespan of patient's red cells (see Chapter 17)
   c. If splenectomy is contemplated, determination of sites of haemolysis by radionuclide imaging (see Chapter 17)

PLASMA HAEMOGLOBIN

Methods for estimation of plasma haemoglobin concentration are based on (1) a peroxidase reaction and (2) direct measurement by spectrometry. In the peroxidase method, the catalytic action of haem-containing proteins brings about the oxidation of tetramethylbenzidine by hydrogen peroxide to give a green colour, which changes to blue and finally to reddish violet. The intensity of reaction may be compared using a spectrometer with that produced by solutions of known concentration. Methaemoglobin and haemoglobin are measured together.

A pink tinge to the plasma is detectable by eye when the concentration is higher than 200 mg/l. When the concentration is >50 mg/l, it can be measured as haemiglobincyanide (HiCN) or oxyhaemoglobin by a spectrometer at 540 nm (p. 21).[1] Lower concentrations can also be measured reliably provided that the spectrometer plots of concentration/absorbance give a linear slope passing through the origin. This facility is provided by the Low Hb HemoCue (Hemocue Ltd, www.hemocue.com), which can reliably measure plasma haemoglobin at a concentration of 100 mg/l or higher.[2]

Sample collection

Every effort must be made to prevent haemolysis during the collection and manipulation of the blood. For this, it may be preferable to use a syringe rather than an evacuated tube system. A clean venepuncture is essential; a plastic syringe and relatively wide-bore needle should be used. When the required amount of blood has been withdrawn, the needle should be detached with care and 9 volumes of blood should be added to 1 volume of 32 g/l sodium citrate.

Peroxidase method[3]

The test is now rarely performed and readers are referred to previous editions of this book.

Spectrophotometric method

Red cells from a normal ethylenediaminetetra-acetic acid (EDTA)-anticoagulated blood sample should be washed three times in isotonic saline (0.15 mol/l). Lyse 1 volume of washed packed red cells in 2 volumes of water. Alternatively, lyse by freezing and thawing. Centrifuge the haemolysate at 3000 rpm (1200 *g*) for 30 min and transfer the clear solution to a clean tube. Adjust the haemoglobin concentration to 80 g/l.

Dilute 1 in 100 with phosphate buffer, pH 8, to obtain a concentration of 800 mg/l. By six consecutive double dilutions with phosphate buffer, make a set of seven lysate standards with values from 800 to 12.5 mg/l.

Read the absorbance of each solution at 540 nm, with water as a blank. Prepare a calibration graph by plotting the readings of absorbance (on *y* axis) against haemoglobin concentration (on *x* axis) on arithmetic graph paper and draw the slope. Check that the slope is linear.

Read the absorbance of the plasma directly at 540 nm with a water blank and read the haemoglobin concentration from the calibration graph. If absorbance is greater than the maximum value plotted on the graph, repeat the reading with a sample diluted with buffer.

When using the Low Hb HemoCue haemoglobinometer, fill the special cuvette with plasma and carry out the test in accordance with the instructions that are provided.

Normal range

The normal range is 10 to 40 mg/l.

Significance of increased plasma haemoglobin

Haemoglobin liberated by the intravascular or extravascular breakdown of red cells interacts with plasma haptoglobin to form a haemoglobin–haptoglobin complex,[4] which, because of its size, does not undergo glomerular filtration, but it is removed from the circulation by – and is degraded in – reticuloendothelial cells. Haemoglobin in excess of the capacity of haptoglobin to bind it passes into the glomerular filtrate; it is then partly excreted in the urine in an uncomplexed form, resulting in haemoglobinuria, and partly reabsorbed by the proximal glomerular tubules where it is broken down into haem, iron and globin. The iron is retained in the cells and eventually lost in the urine (as haemosiderin). The haem and globin are reabsorbed into the plasma.

The haem complexes with albumin forming methaemalbumin and with haemopexin (p. 220); the globin competes with haemoglobin to form a complex with haptoglobin. Plasma haemoglobin concentration is further increased in haemolytic anaemias when haemolysis is sufficiently severe for the available haptoglobin to be fully bound. The highest levels are found when haemolysis is predominantly intravascular. Thus marked haemoglobinaemia, with or without haemoglobinuria, may be found in PNH, paroxysmal cold haemoglobinuria, cold-haemagglutinin syndromes, blackwater fever, march haemoglobinuria and other mechanical haemolytic anaemias (e.g. that after cardiac surgery). In warm autoimmune haemolytic anaemia, sickle cell anaemia and severe β thalassaemia, the plasma haemoglobin concentration may be slightly or moderately increased, but in hereditary spherocytosis, in which haemolysis occurs predominantly in the spleen, the levels are normal or only very slightly increased.

Haem within the proximal tubular epithelium undergoes further degradation to bilirubin with liberation of iron, some of which is retained intracellularly and incorporated into ferritin and haemosiderin. When haemolysis is severe, the haemoglobin that appears in the glomerular filtrate leads to an accumulation of intracellular haemosiderin in the glomerular tubular cells; when these cells slough, haemosiderin appears in the urine (p. 221).

The presence of excess haemoglobin in the plasma is a reliable sign of intravascular haemolysis only if the observer can be sure that the lysis has not been caused during or after the withdrawal of the blood. It is also necessary to exclude colouring of the plasma from certain foods and food additives.

Increased levels may occur as a result of violent exercise, as well as occurring in runners and joggers as a result of mechanical trauma caused by continuous impact of the soles of the feet on hard ground.[4]

SERUM HAPTOGLOBIN

Haptoglobin is a glycoprotein that is synthesised in the liver. It consists of a pair of α chains and a pair of β chains. Following haemolysis, free haemoglobin readily dissociates into dimers of α and β chains; the α chains bind avidly with the β chains of haptoglobin in plasma or serum to form a complex that can be differentiated from free haemoglobin by column chromatographic separation or by its altered rate of migration in the α_2 position on electrophoresis.

Direct measurement of haptoglobin is also possible by turbidimetry or nephelometry and by radial immunodiffusion.[5] The methods described below are cellulose acetate electrophoresis and radial immunodiffusion.

Electrophoretic method[6,7]

Principle

Known amounts of haemoglobin are added to serum. The haemoglobin–haptoglobin complex is separated by electrophoresis on cellulose acetate; the presence of bound and free haemoglobin is identified in each sample and the amount of haptoglobin is estimated by noting where free haemoglobin appears.

Reagents

Buffer (pH 7.0, ionic strength 0.05). $Na_2HPO_4.H_2O$ 7.1 g/l, 2 volumes; $NaH_2PO_4.H_2O$ 6.9 g/l, 1 volume. Store at 4 °C.

Haemolysates. Red cells from a normal EDTA-anticoagulated blood sample are washed three times in isotonic saline (0.15 mol/l). Lyse 1 volume of washed packed red cells in 3 volumes of water. Alternatively, lyse by freezing and thawing. Centrifuge the haemolysate at 3000 rpm (1200 *g*) for 30 min and transfer the clear

solution to a clean tube. Adjust the Hb to 30 g/l with water and dilute this preparation further with water to obtain a batch of solutions with Hb of 2.5, 5, 10, 20 and 30 g/l. These solutions are stable at 4 °C for several weeks.

Stain. Dissolve 0.5 g of *o*-dianisidine (3,3′-dimethoxybenzidine) in 70 ml of 95% ethanol; prior to use, add together 10 ml of acetate buffer, pH 4.7 (sodium acetate 2.92 g, glacial acetic acid 1 ml, water to 1 litre), 2.5 ml of 3% (10 volumes) H_2O_2 and water to 100 ml.

Clearing solution. Glacial acetic acid 25 ml, 95% ethanol 75 ml.

Acetic acid rinse. Glacial acetic acid 50 ml/l.

Method

Serum is obtained from blood allowed to clot undisturbed at 37 °C. As soon as the clot starts to retract, remove the serum with a pipette and centrifuge it to rid it of suspended red cells. The serum may be stored at −20 °C until used.

Mix well 1 volume of each of the diluted haemolysates with 9 volumes of serum. Allow to stand for 10 min at room temperature.

Impregnate cellulose acetate membrane filter strips (12 × 2.5 cm) in buffer solution and blot to remove all obvious surface fluid. Apply 0.75 ml samples of the serum–haemolysate mixtures across the strips as thin transverse lines. As controls, include strips with serum alone and haemoglobin alone. Electrophorese at 0.5 mA/cm width. Good separation patterns about 5–7 cm in length should be obtained in 30 min (see Fig. 11-2).

After electrophoresis is completed, immerse the membranes in freshly prepared *o*-dianisidine stain for 10 min. Then rinse with water and immerse in 50 ml/l acetic acid for 5 min. Remove the membranes and place in 95% ethanol for exactly 1 min. Transfer the membranes to a tray containing freshly prepared clearing solution and immerse for exactly 30 s. While they are still in the solution, position the membranes over a glass plate placed in the tray. Remove the glass plate with the membranes on it, drain the excess solution from the membranes, transfer the glass plate to a ventilated oven preheated to 100 ° C and allow the membranes to dry for 10 min.

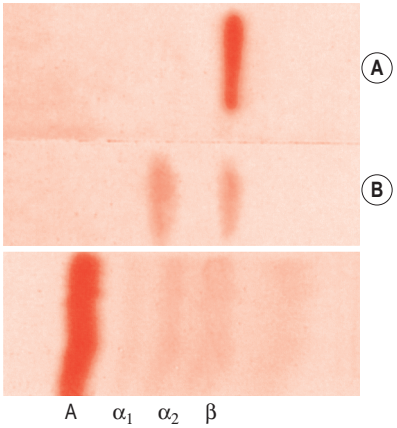

FIGURE 11-2 Demonstration of serum haptoglobin. (A) Serum from case of haemolytic anaemia with no haptoglobin: the added haemoglobin is demonstrated as a band in the β globulin position. **(B)** Normal serum with added haemoglobin: there are bands in the β globulin (haemoglobin) and α_2 globulin (haemoglobin–haptoglobin complex) positions, respectively. The line of origin is indicated by the arrow. The pattern of serum electrophoresis is shown below. **A,** albumin; α_1, α_2 and β components of globulin.

Interpretation. The patterns of free haemoglobin and haemoglobin–haptoglobin complex migration are shown in Figure 11-2. The complex appears in the α_2 globulin position. When there is more haemoglobin than can be bound to the haptoglobin, the free haemoglobin migrates in the β globulin position. The amount of haptoglobin present in the serum is determined semiquantitatively as between the lowest concentration of haemoglobin, which shows only a free haemoglobin band, and the adjacent strip, which shows a band of haemoglobin–haptoglobin complex. In the total absence of haptoglobin, a haemoglobin band alone will be seen, even at 2.5 g/l. In severe intravascular haemolysis with depleted haptoglobin, some of the haem may bind in the β globulin position to haemopexin (see below) and some to serum albumin to form methaemalbumin.

The concentration of haptoglobin can be determined quantitatively with a densitometer. The test is carried out as described earlier, but only one haemolysate is required with an Hb of 30–40 g/l. After the plate has cooled, the membranes are scanned by a densitometer at 450 nm with a 0.3-mm slit width. The density of the haptoglobin band is calculated as a fraction of the total Hb in the electrophoretic strip:

$$\text{Haptoglobin}\,(\text{g}/\text{l}) = \text{Haptoglobin fraction} \times \text{Hb}\,(\text{g}/\text{l})$$

Radial immunodiffusion method

Principle

The test serum samples and reference samples of known haptoglobin concentration are dispensed into wells in a plate of agarose gel containing a monospecific antiserum to human haptoglobin. Precipitation rings form by the reaction of haptoglobin with the antibody; the diameter of each ring is proportional to the concentration of haptoglobin in the sample.

Reagents

Phosphate buffer, iso-osmotic, pH 7.4:

(A) $NaH_2PO_4 \cdot 2H_2O$ (150 mmol/l) – 23.4 g/l
(B) NaH_2PO_4 (150 mmol/l) – 21.3 g/l.

Add 18 ml reagent A to 82 ml reagent B.

Single diffusion plates*. Dissolve agarose (20 g/l) in boiling phosphate buffered water, pH 7.4. Allow to cool to 50 °C. Add 5% sheep or goat antihuman haptoglobin antiserum diluted in buffered water, pH 7.4. Mix well but without creating bubbles. Pour the gel onto thin plastic trays (plates) to a thickness of <1 mm. After the gel has set, cut out a series of wells about 2 mm in diameter, about 2 cm apart. Extract the core by using a pipette tip with a negative pressure pump. Cover the plates with fitted lids and store in sealed packets at 4 °C until used.

Reference sera. Preparations of human serum with stated haptoglobin concentration are available commercially (e.g. from www.thermofisher.com/uk/en/home/brands/invitrogen.html or www.sigmaaldrich.com). They should be stored at 4 °C.

Test serum. Test serum can be kept at 4 °C for 2–3 days, but if it is not used within this time, store at −20 °C. Thaw completely and mix well immediately before use.

Method

Allow the plate (in its sealed packet) and the sera to equilibrate at room temperature for 15 min. Remove the lid from the plate. Check for moisture; if present, allow to evaporate. Add 5 µl of each serum into one of the wells in the plate. Stand for about 10 min to ensure that the serum is completely absorbed into the gel. Then cover the plate, return it to its container and reseal the packet. Leave on a level surface at room temperature for 18 h. From measurements of the reference sera, construct a reference curve on log-linear graph paper by plotting haptoglobin concentration on the vertical axis (logarithmic scale) and the diameter of the rings on the horizontal scale (linear scale). Measure the diameter of the precipitation ring formed by the test serum and express concentration in g/l (Fig. 11-3).

Normal ranges

By direct measurement[5] results are expressed as haptoglobin concentration; slightly different reference values have been reported for the different methods:

RID: 0.8 to 2.7 g/l
Nephelometry: 0.3 to 2.2 g/l
Turbidimetry: 0.5 to 1.6 g/l

When measured as haemoglobin-binding capacity, in normal sera, haptoglobin will bind 0.3–2.0 g/l of haemoglobin. With this wide range of values there are no obvious sex differences, but in both men and women levels increase after the age of 70 years.

*Gel plates containing the antiserum are available commercially (e.g. The Binding Site Group Ltd, www.thebindingsite.com/radial-immunodiffusion.

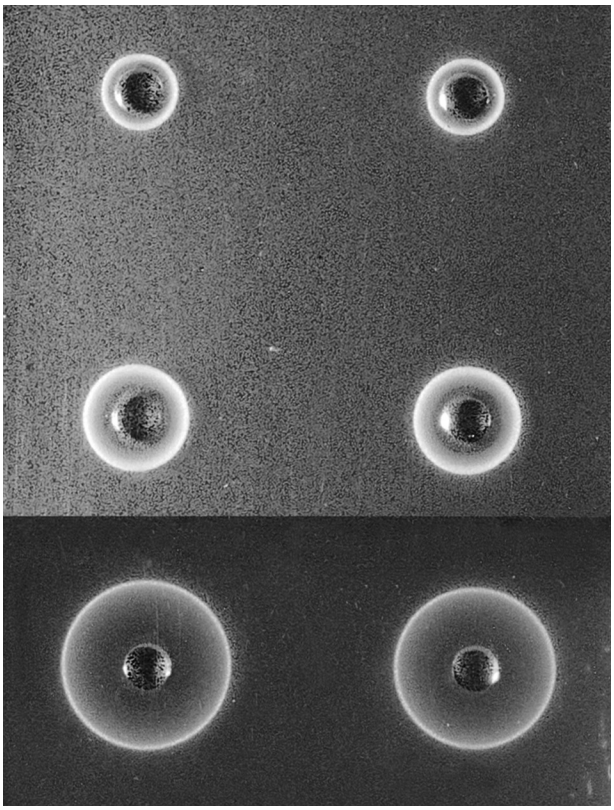

FIGURE 11-3 Demonstration of serum haptoglobin. Radial immunodiffusion: *top,* low; *middle,* normal; and *bottom,* increased concentrations.

Significance

Haptoglobin begins to be depleted when the daily haemoglobin turnover exceeds about twice the normal rate.[6] This occurs irrespective of whether the haemolysis is predominantly extravascular or intravascular; but rapid depletion, often with the formation of methaemalbumin, occurs as a result of small degrees of intravascular haemolysis, even when the daily total turnover is not increased appreciably above normal. Low concentrations of haptoglobin, in the absence of increased haemolysis, may be found in hepatocellular disease and are characteristic of congenital anhaptoglobinaemia, which is uncommon except in populations of African origin.[8] Low concentrations may also be found in megaloblastic anaemias, probably because of increased haemolysis and ineffective erythropoiesis, and following haemorrhage into tissues.

The haptoglobin–haemoglobin complex is cleared by the reticuloendothelial system, mainly in the liver. The rate of removal is influenced by the concentration of free haemoglobin in the plasma: at levels <10 g/l, the clearance $T_{1/2}$ is 20 min; at higher concentrations, clearance is considerably slower.

Increased haptoglobin concentrations may be found in pregnancy, chronic infections, malignancy, tissue damage, Hodgkin lymphoma, rheumatoid arthritis, systemic lupus erythematosus and biliary obstruction and as a consequence of steroid therapy or the use of oral contraceptives. Under these circumstances, a normal haptoglobin concentration does not exclude haemolysis.

SERUM HAEMOPEXIN

Haemopexin is a β_1 glycoprotein of molecular weight 70 000, synthesised in the liver. It has a transport function. Haem derived from haemoglobin, which fails to bind to haptoglobin, complexes with either haemopexin or albumin. The former has a much higher affinity and only when all the haemopexin has been used up will the haem combine with albumin to form methaemalbumin. The haem–haemopexin complex is eliminated from the circulation (e.g. by the liver Kupffer cells) over a period of several hours, depleting the haemopexin.

Haem binds in a 1:1 molar ratio to haemopexin; 6 µg/ml of free haem is required to saturate the normal binding levels of haemopexin. In normal adults of both sexes, its concentration is 0.5–1.15 g/l (by nephelometry) or 0.5–1.5 g/l (by electrophoresis);[5] there is a lower concentration in newborn infants, about 0.3 g/l, but adult levels are reached by the end of the first year of life. In severe intravascular haemolysis, when haptoglobin is depleted, haemopexin is low or absent and plasma methaemalbumin is elevated. With less severe haemolysis, although haptoglobin is likely to be reduced or absent, haemopexin may be normal or only slightly lowered. Haemopexin seems to be disproportionately low in thalassaemia major, and low levels may be found in certain pathological conditions other than haemolytic disease, namely renal and liver diseases. The concentration is increased in diabetes mellitus, infections and carcinoma.[9]

Haemopexin can be measured by the same methods as for haptoglobin with radial immunodiffusion or electrophoresis.[10]

EXAMINATION OF PLASMA (OR SERUM) FOR METHAEMALBUMIN

A simple but not very sensitive method is to examine the plasma using a hand spectroscope.

Free the plasma from suspended cells and platelets by centrifuging at 1200–1500 *g* for 15–30 min. Then view it in bright daylight with a hand spectroscope using the greatest possible depth of plasma consistent with visibility. Methaemalbumin gives a rather weak band in the red (at 624 nm) (Fig. 11-4). Because oxyhaemoglobin is usually present as well, its characteristic bands in the yellow–green may also be visible. The position of the methaemalbumin absorption band in the red can be readily differentiated from that of Hi by means of a reversion spectroscope.

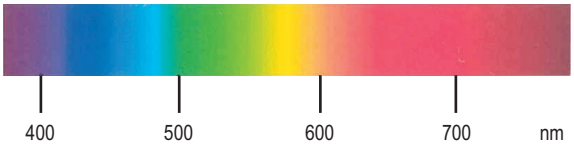

FIGURE 11-4 Visible light spectrum showing wavelengths of the colours of the spectrum. This ranges from 380 to 780 nm. Fraunhofer lines should be seen at approximately 431 nm, 486 nm, 518 nm, 527 nm, 589 nm, 656 nm and 687 nm.

Presumptive evidence of the presence of small quantities of methaemalbumin, giving an absorption band too weak to recognise, can be obtained by extracting the pigment by ether and then converting it to an ammonium haemochromogen, which gives a more intense band in the green (Schumm test).

Schumm test

Method

Cover the plasma (or serum) with a layer of ether. Add a one-tenth volume of saturated yellow ammonium sulphide and mix it with the plasma. Then view it with a hand spectroscope. If methaemalbumin is present, a relatively intense narrow absorption band at 558 nm will be seen in the green.

Significance of methaemalbuminaemia

Methaemalbumin is found in the plasma when haptoglobin is absent in haemolytic anaemias in which lysis is predominantly intravascular. It is a haem–albumin compound formed subsequent to the degradation of haemoglobin liberated into plasma. It remains in the circulation for several days or until the haem is transferred from albumin to the more highly avid haemopexin.

Quantitative estimation by spectrometry

To 2 ml of plasma (or serum) add 1 ml of iso-osmotic phosphate buffer, pH 7.4. Centrifuge the mixture for 30 min at 1200–1500 *g* and measure its absorbance in a spectrophotometer at 569 nm. Add about 5 mg of solid sodium dithionite to the diluted plasma. Shake the tube gently to dissolve the dithionite and leave for 5 min to allow complete reduction of the methaemalbumin. Remeasure the absorbance. The difference between the two readings represents the absorbance due to methaemalbumin; its concentration can be read from a calibration graph.

Calibration graph

Prepare solutions containing 10 to 100 mg/l methaemalbumin by dissolving appropriate amounts of haemin (bovine or equine) (www.sigmaaldrich.com) in a minimum

volume of 40 g/l human serum albumin. Measure the absorbance of each solution in a spectrophotometer at 569 nm and draw a graph from the figures obtained.

DEMONSTRATION OF HAEMOSIDERIN IN URINE

Method

Centrifuge 10 ml of urine at 1200 *g* for 10–15 min. Transfer the deposit to a slide, spread out to occupy an area of 1–2 cm and allow to dry in the air. Fix by placing the slide in methanol for 10–20 min and then stain by the method used to stain bone marrow films for haemosiderin (p. 313). Haemosiderin, if present, appears in the form of isolated or grouped blue-staining granules, usually from 1 to 3 μm in size (Fig. 11-5); they may be both intracellular and extracellular. If haemosiderin is present in small amounts and especially if distributed irregularly on the slide or if the findings are difficult to interpret, the test should be repeated on a fresh sample of urine collected into an iron-free container and centrifuged in an iron-free tube. (For the preparation of iron-free glassware: wash thoroughly in a detergent solution, then soak in 3 mol/l HCl for 24 h; finally, rinse in deionised, double-distilled water.)

Significance of haemosiderinuria

Haemosiderinuria is a sequel to the presence of haemoglobin in the glomerular filtrate. It is a valuable sign of intravascular haemolysis because the urine will be found to contain iron-containing granules even if there is no haemoglobinuria at the time. However, haemosiderinuria is not found in the urine at the onset of a haemolytic attack even if this is accompanied by haemoglobinaemia and haemoglobinuria because the haemoglobin has first to be absorbed by the cells of the renal tubules. The intracellular breakdown of haemoglobin liberates iron, which is then lost in the urine. Haemosiderinuria may persist for several weeks after a haemolytic episode.

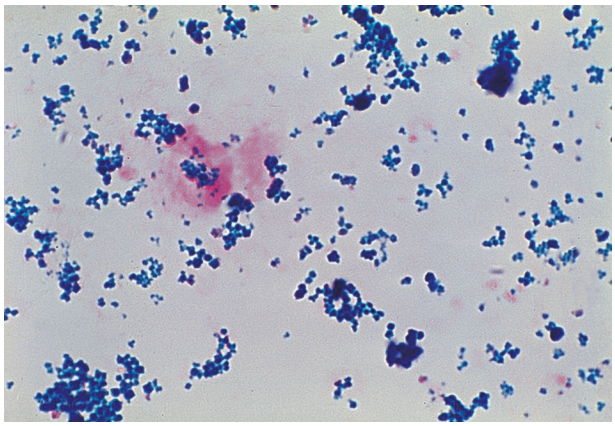

FIGURE 11-5 Photomicrograph of urine deposit stained by Perls reaction.

CHEMICAL TESTS OF HAEMOGLOBIN CATABOLISM

Measurement of serum or plasma bilirubin, urinary urobilin and faecal urobilinogen can provide important information in the investigation of haemolytic anaemias. In this section, their interpretation and significance in haemolytic anaemias will be described, but because currently the tests are seldom performed in a haematology laboratory, for details of the techniques readers are referred to textbooks of clinical chemistry.[5]

Serum bilirubin

Bilirubin is present in serum in two forms: as unconjugated prehepatic bilirubin and bilirubin conjugated to glucuronic acid. Normally, the serum bilirubin concentration is <17 μmol/l (10 mg/l) and mostly unconjugated. As illustrated in Figure 11-1, when there is increased red cell destruction, the protoporphyrin gives rise to an increased amount of unconjugated bilirubin and carbon monoxide. The bilirubin is then conjugated in the liver and this bilirubin glucuronide is excreted into the intestinal tract. Bacterial action converts bilirubin glucuronide to urobilin and urobilinogen. In haemolytic anaemias, the serum bilirubin usually lies between 17 and 50 μmol/l (between 10 and 30 mg/l) and most is unconjugated. Sometimes the level may be normal, despite a considerable increase in haemolysis. Levels >85 μmol/l (50 mg/l) and/or a large proportion of conjugated bilirubin suggest liver disease or posthepatic obstruction.

In haemolytic disease of the newborn (HDN), the bilirubin level is an important factor in determining whether an exchange transfusion should be carried out because high values of unconjugated bilirubin are toxic to the brain at this age and can lead to kernicterus. In normal newborn infants, the level often reaches 85 μmol/l, whereas in infants with HDN, levels of 350 μmol/l are not uncommon and need to be urgently reduced by phototherapy or exchange transfusion. Moderately raised serum bilirubin levels are frequently found in dyserythropoietic anaemias (e.g. pernicious anaemia). Although part of the bilirubin comes from red cells that have circulated, a major proportion is derived from red cell precursors in the bone marrow that have failed to complete maturation (ineffective erythropoiesis).

Total bilirubin can be measured by direct reading spectrophotometry at 454 (or 461) and 540 nm; the former are the selected wavelengths for bilirubin, whereas the latter automatically corrects for any interference by free haemoglobin. The instrument can be calibrated with bilirubin solutions of known concentration or with a

coloured glass standard. Another direct reading method is by reflectance photometry on a drop of serum that is added to a reagent film.

An alternative 'wet chemistry' method is by the reaction with aqueous diazotised sulphanilic acid. A red colour is produced, which is compared in a photoelectric colorimeter with that of a freshly prepared standard or read in a spectrophotometer at 600 nm. Only conjugated bilirubin reacts directly with this aqueous reagent; unconjugated bilirubin, which is bound to albumin, requires either the addition of ethanol to free it from albumin or an accelerator such as methanol or caffeine to enable it to react. A positive urine spot test indicates a condition in which there is an elevated serum conjugated bilirubin. There is also a simple optical method, the Lovibond Comparator (Tintometer Group, www.lovibond.com), in which the colour produced by reaction with sulphanilic acid is matched against graded colour scales.

Bilirubin is destroyed by exposure to direct sunlight or any other source of ultraviolet (UV) light, including fluorescent lighting. Solutions are stable for 1–2 days if kept at 4 °C in the dark.

Urobilin and urobilinogen

Urobilin and its reduced form urobilinogen are formed by bacterial action on bile pigments in the intestine. The excretion of faecal urobilinogen in health is 50–500 µmol (30–300 mg) per day. It is increased in patients with a haemolytic anaemia. Quantitative measurement of faecal urobilinogen should, in theory, provide an estimate of the total rate of bilirubin production. This is, however, a crude method of assessing rates of haemolysis, and minor degrees are more reliably demonstrated by red cell lifespan studies. Urobilinogen excretion is also increased in dyserythropoietic anaemias such as pernicious anaemia because of ineffective erythropoiesis.

The amount of urobilinogen in the urine in health is up to 6.7 µmol (4 mg) per day. However, these measurements are method dependent, and laboratories should establish their own reference values. This is not a reliable index of haemolysis, as excessive urobilinuria can be a consequence of liver dysfunction as well as of increased red cell destruction.

For estimation in the faeces, the bile-derived pigments (stercobilin) are reduced to urobilinogen, which is extracted with water. The solution is then treated with Ehrlich's dimethylaminobenzaldehyde reagent to produce a pink colour, which can be compared with either a natural or an artificial standard in a quantitative assay.

Qualitative test for urobilinogen and urobilin in urine

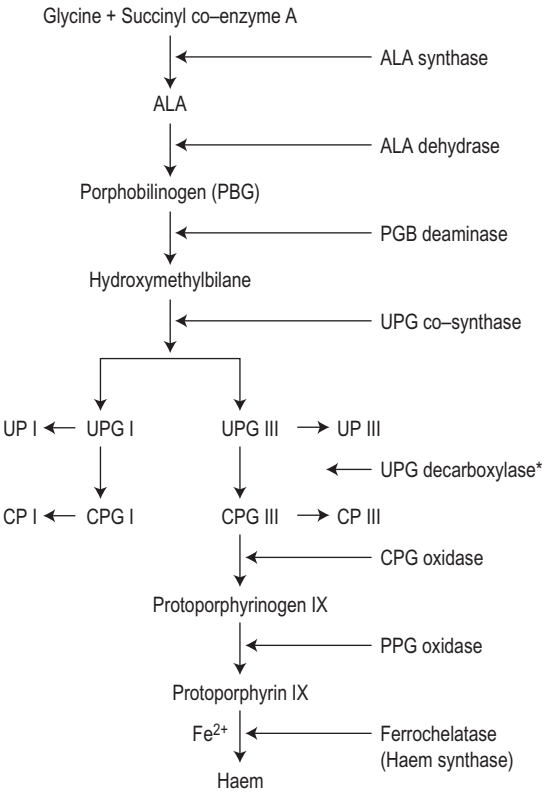
Schlesinger zinc test

The test is now rarely performed and readers are referred to previous editions of this book.

Urobilinogen can also be detected in freshly voided urine by commercially available reagent strip methods.

PORPHYRINS

Haem synthesis is initiated by succinyl coenzyme A and glycine, activated by the rate-limiting enzyme δ-aminolaevulinic (ALA)-synthase. ALA is the precursor of the porphyrins (Fig. 11-6). The porphyrins of clinical importance in man are protoporphyrin, uroporphyrin and coproporphyrin together with their precursor ALA. Protoporphyrin is widely distributed in the body, and in addition to its main role as a precursor of haem in haemoglobin and myoglobin, it is a precursor of cytochromes and catalase. Uroporphyrin and coproporphyrin, which are precursors of protoporphyrin, are normally excreted in small amounts in urine and faeces. Red cells normally contain a small amount of coproporphyrin (5–35 nmol/l) and protoporphyrin (0.2–0.9 µmol/l). Deranged haem synthesis (e.g. in sideroblastic anaemias or lead toxicity) and iron deficiency anaemia result in an increased concentration of protoporphyrin in the red cells.



**acts on both isomer I and isomer III*

FIGURE 11-6 Biosynthesis of porphyrin. (See Table 11-1 for explanation of abbreviations.)

Appropriate tests are usually performed in clinical chemistry laboratories, including sophisticated methods for measuring red cell porphyrins, as described in an Association of Clinical Pathology Best Practice document.[11] Simple qualitative screening tests for urinary porphobilinogen and urinary porphyrin are described later. Urinary porphobilinogen will help to diagnose the acute forms of porphyria, particularly when the patient is symptomatic and this test can lead to a definite diagnosis in a critical clinical situation.

Demonstration of porphobilinogen in urine

Principle

Ehrlich's dimethylaminobenzaldehyde reagent reacts with porphobilinogen to produce a pink aldehyde compound, which can be differentiated from that produced by urobilinogen by the fact that the porphobilinogen compound is insoluble in chloroform.

Ehrlich's reagent

Dissolve 0.7 g of *p*-dimethylaminobenzaldehyde in a mixture of 150 ml of 10 mol/l HCl and 100 ml of water.

Method

Specimens must be protected from light, and the test is best carried out on freshly passed urine. Mix a few ml of urine and an equal volume of Ehrlich's reagent in a large test tube. Add 2 volumes of a saturated solution of sodium acetate. The urine should then have a pH of about 5.0, giving a red reaction with Congo red indicator paper.

If a pink colour develops in the solution, add a few ml of chloroform and shake the mixture thoroughly to extract the pigment. The colour due to urobilinogen or indole will be extracted by the chloroform, whereas that owing to porphobilinogen will not and remains in the supernatant aqueous fraction. A kit is available for a semi-quantitative test using anion-exchange resin (Microgenics, ThermoFisher Scientific, www.thermofisher.com). When present, the concentration of porphobilinogen in the urine can be measured quantitatively by a test kit method (Bio-Rad Laboratories, www.bio-rad.com/en-cn/sku/1876001-pbg-column-testporphobilinogen) or by spectrophotometry at 555 nm.

Aminolaevulinic acid

When ALA is present in the urine, it can be concentrated with acetyl acetone. It then reacts with Ehrlich's reagent in the same way as porphobilinogen to give a red solution with an absorbance maximum at 553 nm. It can be separated from porphobilinogen by ion-exchange resins and estimated quantitatively by a spectrometric method.

Demonstration of porphyrins in urine

Principle

Porphyrins exhibit pink-red fluorescence when viewed by UV light (at 405 nm). Uroporphyrin can be distinguished from coproporphyrin by the different solubilities of the two substances in acid solution.

Method

Mix 25 ml of urine with 10 ml of glacial acetic acid in a separating funnel and extract twice with 50 ml volumes of ether. Set the aqueous fraction (Fraction 1) aside. Wash the ether extracts in a separating funnel with 10 ml of 1.6 mol/l HCl and collect the HCl fraction (Fraction 2). View both fractions in UV light (at 405 nm) for pink-red fluorescence. Its presence in Fraction 1 indicates uroporphyrin; its presence in Fraction 2 indicates coproporphyrin. The presence of the porphyrins should be confirmed spectroscopically (described later).

If uroporphyrin has been demonstrated, the reaction can be intensified by the following procedure. Adjust the pH of Fraction 1 to 3.0–3.2 with 0.1 mol/l HCl and extract the fraction twice with 50 ml volumes of ethyl acetate. Combine the extracts and extract three times with 2 ml volumes of 3 mol/l HCl. View the acid extracts for pink-red fluorescence in UV light and spectroscopically for acid porphyrin bands.

Spectroscopic examination of urine for porphyrins

Spectroscopic examination of urine for porphyrins is carried out on extracts, made as described earlier, or on urine that is acidified with a few drops of 10 mol/l HCl. If porphyrins are present, a narrow band will appear in the orange at 596 nm, and a broader band will appear in the green at 552 nm (see Fig. 11-4). Qualitative tests are adequate for screening purposes. Accurate determinations require spectrophotometry or chromatography. Porphyrins are stable in EDTA-anticoagulated blood for up to 8 days at room temperature if protected from light. Urine should be collected in a brown bottle or, if in a clear container, kept in a light-proof bag. If the urine is rendered alkaline to pH 7–7.5 with sodium bicarbonate, porphyrins will not be lost for several days at room temperature.

Significance of porphyrins in blood and urine

Normal red cells contain <650 nmol/l of protoporphyrin and <64 nmol/l of coproporphyrin.[11] Increased amounts are present during the first few months of life. At all ages, there is an increase in red cell protoporphyrin in iron deficiency anaemia or latent iron deficiency, lead poisoning, thalassaemia, some cases of sideroblastic anaemia and the anaemia of chronic disease. Zinc protoporphyrin is also elevated in these conditions (p. 179).

Normally, a small amount of coproporphyrin is excreted in the urine (<430 nmol/day). This is demonstrable by the qualitative test described earlier, the intensity of pink-red fluorescence being proportional to the concentration of coproporphyrin. The excretion of coproporphyrin is increased when erythropoiesis is hyperactive (e.g. in haemolytic anaemias and polycythaemia), in pernicious anaemia and in sideroblastic anaemias. It is high in liver disease; renal impairment results in diminished excretion. In lead poisoning, there is an increase in red cell protoporphyrin and coproporphyrin, with excretion of exceptionally high levels of urinary ALA, coproporphyrin III and uroporphyrin I.

Normally, porphobilinogen cannot be demonstrated in urine and only traces of uroporphyrin (<50 nmol/day), not detectable by the qualitative test described earlier, are present.[11] ALA excretion is normally <40 mmol/day; it is increased in lead poisoning.

The increase in urinary coproporphyrin excretion occurring in the previously mentioned conditions is known as porphyrinuria. There is no increase in uroporphyrin excretion. The porphyrias, however, are a group of disorders associated with abnormal porphyrin metabolism.

There are several forms of porphyria, caused by specific enzyme defects, each with a different clinical effect and pattern of excretion of porphyrin and precursors[12] (Table 11-1). The most common type is acute intermittent porphyria, in which the defect in the enzyme porphobilinogen deaminase presents in one of three ways:

Type 1: Decreased enzyme activity together with reduced amount of the enzyme in the red cells
Type 2: Decreased enzyme activity in lymphocytes and liver cells but normal red cell activity
Type 3: Reduced red cell enzyme activity but normal amount of enzyme in the red cells.

The different mutations of the porphobilinogen deaminase in the three types can be identified by deoxyribonucleic acid (DNA) hybridisation using specific oligonucleotides.[13] Other acute forms are variegate porphyria and coproporphyria.

The most common hepatic type is *porphyria cutanea tarda,* which results in photosensitivity, dermatitis and often hepatic siderosis; it is the result of a defect in uroporphyrinogen decarboxylase. In this and other porphyrias associated with photosensitive dermatitis (see Table 11-1) plasma

TABLE 11-1

DISTRIBUTION OF PORPHYRINS IN RED CELLS, URINE AND FAECES IN DIFFERENT FORMS OF PORPHYRIA

Disease	Clinical Effect	Enzyme Defect*	Red Cells	Urine	Faeces
ALA dehydratase deficiency porphyria	(a)	ALA dehydratase (porphobilinogen synthase)	ZnP ALA	CPIII	–
Acute intermittent porphyria	(a)	PBG deaminase	–	PBG ALA	–
Congenital erythropoietic porphyria	(b)	UPG III cosynthase	UP I C PI ZnP	UP I CP I	UP I CP I
Acquired cutaneous hepatic porphyria (symptomatic)	(b)	UPG decarboxylase	–	UP I CP III	–

(b) Photosensitive dermatitis.
ALA, δδ-aminolaevulinic acid; CP, coproporphyrin; CPG, coproporphyrinogen; PBG, porphobilinogen; PP, protoporphyrin; PPG, protoporphyrinogen; UP, uroporphyrin; UPG, uroporphyrinogen; ZnP, zinc protoporphyrin.

porphyrins are elevated. There are two erythropoietic types: *congenital erythropoietic porphyria,* caused by defective uroporphyrinogen cosynthase, and *erythropoietic protoporphyria,* caused by defective ferrochelatase. In the former, uroporphyrin and coproporphyrin are present in red cells and urine in increased amounts; in the latter, increased protoporphyrin is found in the red cells, but the urine is normal. In erythropoietic porphyria, haemolytic anaemia can occur.

ABNORMAL HAEMOGLOBIN PIGMENTS

Methaemoglobin (Hi; also called MetHb), sulphaemoglobin (SHb) and carboxyhaemoglobin (HbCO) are of clinical importance and each has a characteristic absorption spectrum demonstrable by simple spectroscopy or, more definitely, by spectrometry. If the absorbance of a dilute solution of blood (e.g. 1 in 200) is measured at wavelengths between 400 and 700 nm, characteristic absorption spectra are obtained[14–16] (Fig. 11-7 and Table 11-2). In practice, the abnormal substance represents usually only a small fraction of the total haemoglobin (except in carbon monoxide poisoning) and its identification and accurate measurement may be difficult. Hi can be measured more accurately than SHb.

Absorption spectroscopy is a method by which a substance can be characterised by the wavelengths at which the colour spectrum is absorbed when light is passed through a solution of the substance. The specific absorption bands are identifiable by their positions (see Fig. 11-4).

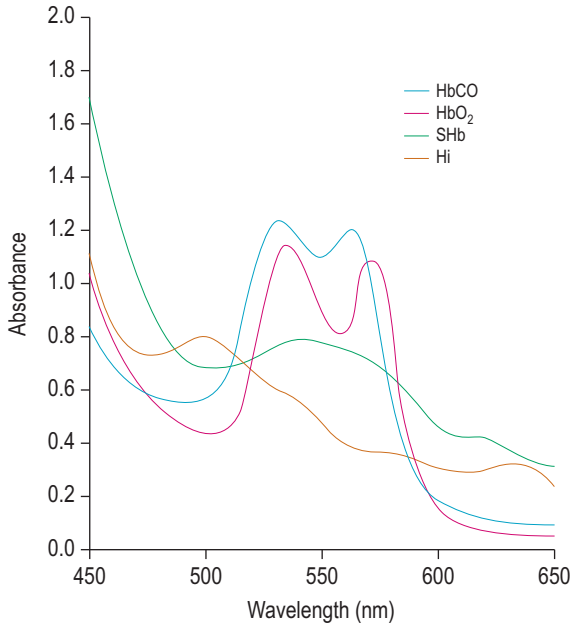

FIGURE 11-7 Absorption spectra of various haemoglobin pigments. HbCO, carboxyhaemoglobin; HbO_2, oxyhaemoglobin; SHb, sulphaemoglobin; Hi, methaemoglobin.

TABLE 11-2

POSITIONS IN SPECTRUM FOR OPTIMAL ABSORBANCE OF HAEMOGLOBIN AND ITS DERIVATIVES IN ABSORPTION SPECTROMETRY (in nm)

Oxyhaemoglobin	541, 576
Deoxyhaemoglobin	431, 556
Carboxyhaemoglobin	538, 568
Methaemoglobin	500, 630
Sulphaemoglobin	620
Methaemalbumin	624
Haemochromogen (Schumm test)	558

Approximations with slightly different figures have been reported in different studies.

Spectroscopic examination of blood for methaemoglobin and sulphaemoglobin

Method

Dilute blood 1 in 5 or 1 in 10 with water and then centrifuge. Examine the clear solution, if possible in daylight, using a hand spectroscope. It is important that the greatest possible depth or concentration of solution consistent with visibility is examined and that a careful search is made (with varying depths or concentrations of solution) for absorption bands in the red part of the spectrum at 620–630 nm. If bands are seen in the red, add a drop of yellow ammonium sulphide to the solution. A band caused by Hi, but not that caused by SHb, will disappear. For comparison, lysed blood may be treated with a few drops of potassium ferricyanide (50 g/l) solution, which will cause the formation of Hi; SHb may be prepared by adding to 10 ml of a 1 in 100 dilution of blood, 0.1 ml of a 1 g/l solution of phenylhydrazine hydrochloride and a drop of water that has been previously saturated with hydrogen sulphide. The spectra of the unknown and the known pigments may then be compared in a reversion spectroscope. The absorption band in the red caused by Hi is at 630 nm (compare with methaemalbumin at 624 nm) (see Fig. 11-4).

Hi and SHb are formed intracellularly; they are not found in plasma except under very exceptional circumstances (e.g. when their formation is associated with intravascular haemolysis).

Measurement of methaemoglobin

Principle

Hi has a maximum absorption at 630 nm. When cyanide is added, this absorption band disappears and the resulting change in absorbance is directly proportional to the concentration of Hi. Total haemoglobin in the sample is

then measured after complete conversion to HiCN by the addition of ferricyanide–cyanide reagent. The conversion will measure oxyhaemoglobin and Hi but not SHb. Thus, the presence of a large amount of SHb will result in an erroneously low measurement of total Hb. Turbidity of the haemolysate can be overcome by the addition of a nonionic detergent.[14,15]

Reagents

Phosphate buffer: 0.1 mol/l, pH 6.8:

(A) Weigh out 7.45 g of Na_2HPO_4, dissolve in distilled water and adjust final volume to 500 ml.

(B) Weigh out 6.8 g of KH_2PO_4, dissolve in distilled water and adjust final volume to 500 ml.

Add 2 volumes of solution (A) to 1 volume of solution (B).

Potassium cyanide: 50 g/l

Potassium ferricyanide: 50 g/l

Nonionic detergent: 10 ml/l (Triton X-100 or Nonidet P40, www.sigmaaldrich.com/)

Method

Lyse 0.2 ml of blood in a solution containing 4 ml of buffer and 6 ml of detergent solution. Divide the lysate into two equal volumes (A and B). Measure the absorbance of A in a spectrophotometer at 630 nm (D_1). Add 1 drop of potassium cyanide solution and measure the absorbance again, after mixing (D_2). Add 1 drop of potassium ferricyanide solution to B, and after 5 min, measure the absorbance at the same wavelength (D_3). Then add 1 drop of potassium cyanide solution to B and after mixing make a final reading (D_4). All the measurements are made against a blank containing buffer and detergent in the same proportion as present in the sample.

Calculation

The test should be carried out within 1 h of collecting the blood. After dilution, the buffered lysate can be stored for up to 24 h at 2–4 °C without significant auto-oxidation of haemoglobin to Hi.

Screening method for sulphaemoglobin

Principle

An absorbance reading at 620 nm measures the sum of the absorbance of oxyhaemoglobin and SHb in any blood sample. In contrast to oxyhaemoglobin, the absorption band caused by SHb is unchanged by the addition of cyanide. The residual absorbance, as read at 620 nm, is therefore proportional to the concentration of SHb. The absorbance of the oxyhaemoglobin alone at 620 nm can only be inferred from a reading at 578 nm and a conversion factor, A^{578}/A^{620}, has to be determined experimentally for each instrument on a series of normal blood samples.[16,17] The absorbance of SHb is obtained by subtracting the absorbance of the oxyhaemoglobin from that of the total haemoglobin. This provides an approximation only, but it may be regarded as adequate for clinical purposes in the absence of a more reliable method.

Method

Mix 0.1 ml of blood with 10 ml of a 20 ml/l solution of a nonionic detergent (Triton X-100 or Nonidet P40, www.sigmaaldrich.com). Record the absorbance (A) at 620 nm (total haemoglobin). Add 1 drop of 50 g/l potassium cyanide, and after letting it stand for 5 min, record A at 620 nm and at 578 nm.

Calculation

$$\mathrm{SHb}(\%) = \frac{2 \times A^{620}\mathrm{SHb}}{A^{620}\mathrm{HbO_2}}$$

$$\text{where } A^{620}\mathrm{HbO_2} = \frac{\text{Absorbance read at 578 nm}}{\text{Conversion factor}}$$

$$\text{and } A^{620}\,\mathrm{SHb} = A^{620}\text{ total Hb} - A^{620}\mathrm{HbO_2}$$

Significance of methaemoglobin and sulphaemoglobin in blood. Hi is present in small amounts in normal blood and constitutes 1–2% of the total haemoglobin. Its concentration is very slightly higher in infants – especially in premature infants – than in older children and adults. An excessive amount of Hi occurs as the result of oxidation of haemoglobin by drugs and chemicals such as phenacetin, sulphonamides, aniline dyes, nitrates and nitrites.

The Hi produced by drugs is chemically normal, and the pigment can be reconverted to oxyhaemoglobin by reducing agents such as methylene blue.

Other (rare) types of methaemoglobinaemia are caused by inherited deficiency of the enzyme NADH-Hi reductase and by haemoglobinopathies (types of haemoglobin M). The absorption spectra of the haemoglobin Ms differ from that of normal Hi and they react slowly and incompletely with cyanide; their concentration cannot be estimated by standard methods. Methaemoglobinaemia leads to cyanosis which becomes obvious with as little as 15 g/l of Hi: that is, about 10%.

SHb is usually formed at the same time as methaemoglobin; it represents a further and irreversible stage in haemoglobin degradation. It is present as a rule at a much lower concentration than is Hi.

Demonstration of carboxyhaemoglobin

Principle

Oxyhaemoglobin, but not HbCO, is reduced by sodium dithionite and the percentage of HbCO in a mixture can be determined by reference to a calibration graph. HbCO can also be determined on a blood gas analyser.

Calibration graph

Dilute 0.1 ml of normal blood in 20 ml of 0.4 ml/l ammonia and divide into two parts. To each add 20 mg of sodium dithionite. Then bubble pure carbon monoxide into one for 2 min so as to provide a 100% solution of HbCO.

Add various volumes of the HbCO solution to the reduced haemoglobin solution to provide a range of concentrations of HbCO. Within 10 min of adding the dithionite, measure the absorbance of each solution at 538 nm and 578 nm. Plot the quotient A^{538}/A^{578} on arithmetic graph paper against the % HbCO in each solution.

Method

Dilute 0.1 ml of blood in 20 ml of 0.4 ml/l ammonia and add 20 mg of sodium dithionite. Measure the absorbance in a spectrophotometer at 538 nm and 578 nm within 10 min. Calculate the quotient A^{538}/A^{578} and read the % HbCO in the blood from the calibration curve[16] or calculate it from the equation.[16,17]

$$\%\text{HbCO} = \frac{\left\{2.44 \times A^{538}\right\}}{A^{578}} - 2.68$$

Significance of carboxyhaemoglobin in circulating blood. Carbon monoxide has an affinity for haemoglobin *c.* 200 times that of oxygen. This means that even low concentrations of carbon monoxide rapidly lead to the formation of HbCO. Less than 1% of HbCO is present in normal blood and up to 10% in smokers.[17,18] There is also an increased production and excretion in the lungs in haemolytic anaemias. A high concentration in blood from inhalation of the gas causes tissue anoxia and can lead to death. However, recovery can take place because HbCO dissociates in time in the presence of high concentrations of oxygen.

Identification of myoglobin in urine

Myoglobin is the principal protein in muscle and it may be released into the circulation when there is cardiac or skeletal muscle damage. Because the absorption spectra of myoglobin and haemoglobin are similar, although not identical, it is not possible to distinguish them readily by spectroscopy or spectrometry of urine, but they can be separated by column chromatography.[19]

Investigation of the Hereditary Haemolytic Anaemias: Membrane and Enzyme Abnormalities

Mark Layton • David Roper

CHAPTER OUTLINE

The various initial steps to be taken in the investigation of a patient suspected of having a haemolytic anaemia are outlined in Chapter 11 and the changes in red cell morphology that may be found in haemolytic anaemias are illustrated in Chapter 5. This chapter describes procedures useful in investigating haemolytic anaemias suspected to result from defects within the red cell membrane or deficiency of enzymes important in red cell metabolism.

The precise identification of an enzyme defect is beyond the scope of most haematology laboratories; it may require the isolation and purification of the enzyme and the determination of its kinetic and structural properties. In a service laboratory, it is sufficient to identify the general nature of the defect, whether it be in the membrane or the metabolic pathways of the red cell. In the case of putative metabolic defects, an attempt should be made, where possible, to pinpoint the enzyme involved. The first part of this chapter describes screening tests for spherocytosis, including hereditary spherocytosis (HS) and for glucose-6-phosphate dehydrogenase (G6PD) deficiency.

The later sections of the chapter describe specific enzyme assays and the measurement of 2,3-diphosphoglycerate (2,3-DPG) (also known as 2,3-bisphosphoglycerate, 2,3-BPG) and reduced glutathione (GSH).

Most of the enzyme assays have been standardised by the International Council for Standardisation in Haematology (ICSH). Commercial kits are also available for some quantitative assays and screening tests. These are noted in the relevant sections.

INVESTIGATION OF MEMBRANE DEFECTS

The osmotic fragility test gives an indication of the surface area/volume ratio of erythrocytes. Its greatest usefulness is in the diagnosis of HS. The test may also be used in screening for thalassaemia. Red cells that are spherocytic, for whatever cause, take up less water in a hypotonic solution before rupturing than do normal red cells.

Other tests that demonstrate red cell membrane defects include glycerol lysis time, cryohaemolysis, autohaemolysis and, more specifically, membrane protein analysis.

Procedures to assess red cell flexibility (rigidity) using polycarbonate membrane filtration,[1] and red cell deformability measurements on specialised equipment such as the Laser-assisted Optical Rotational Cell Analyser (Lorrca)[2] have been described elsewhere.

OSMOTIC FRAGILITY AS MEASURED BY LYSIS IN HYPOTONIC SALINE

Principle

The method to be described is based on that of Parpart *et al*.[3] Small volumes of blood are mixed with a large excess of buffered saline solutions of varying concentration. The fraction of red cells lysed at each saline concentration is determined colorimetrically. The test is normally carried out at room temperature (15–25 °C).

Reagents

Prepare a stock solution of buffered sodium chloride, osmotically equivalent to 100 g/l (1.71 mol/l) NaCl, as follows: dissolve NaCl, 90 g; Na_2HPO_4, 13.65 g (or $Na_2HPO_4 2H_2O$, 17.115 g); and $NaH_2PO_4.2H_2O$, 2.34 g in water. Adjust the final volume to 1 litre. This solution will keep for months at 4 °C in a well-stoppered bottle. Salt crystals may form on storage and must be thoroughly redissolved before use.

In preparing hypotonic solutions for use, it is convenient to make first a 10 g/l solution from the 100 g/l NaCl stock solution by dilution with water. Dilutions equivalent to 9.0, 7.5, 6.5, 6.0, 5.5, 5.0, 4.0, 3.5, 3.0, 2.0 and 1.0 g/l are convenient concentrations. Intermediate concentrations such as 4.75 and 5.25 g/l are useful in critical work and an additional 12.0 g/l dilution should be used for incubated samples.

It is convenient to make up 50 ml of each dilution. The solutions keep well at 4 °C if sterile, but should be inspected for moulds before use and discarded if moulds develop.

Method

Heparinised venous blood or defibrinated blood may be used; oxalated or citrated blood is not suitable because of the additional salts added to it. The test should be carried out within 2 h of collection with blood stored at room temperature or within 6 h if the blood has been kept at 4 °C.

1. Deliver 5.0 ml of each of the 11 saline solutions into 12 × 75 mm test tubes. Add 5.0 ml of water to the 12th tube.
2. Add to each tube 50 µl of well-mixed blood and mix immediately by inverting the tubes several times, avoiding foam.
3. Leave the suspensions for 30 min at room temperature. Mix again and then centrifuge for 5 min at 1200 *g*.
4. Remove the supernatants and estimate the amount of lysis in each using a spectrometer at a wavelength setting of 540 nm or a photoelectric colorimeter provided with a yellow–green (e.g. Ilford 625) filter. Use as a blank the supernatant from tube 1 (osmotically equivalent to 9 g/l NaCl).
5. Assign a value of 100% lysis to the reading with the supernatant of tube 12 (water) and express the readings from the other tubes as a percentage of the value of tube 12. Plot the results against the NaCl concentration (Fig. 12-1).

Notes

1. The measurement of osmotic fragility is a simple procedure that requires a minimum of equipment. It will yield gratifying results if carried out carefully.
2. The blood must be delivered into the 12 tubes with great care. The critical point is not that the amount be exactly 50 µl, but rather that the amount added to each tube must be the same. Two methods are recommended:
   a. Using an automatic pipette, after aspirating the blood gently, wipe the outside with tissue paper, taking care not to suck out any blood from the inside of the tip by capillary action. The blood is then delivered into the saline solution and the pipette is rinsed in and out several times until no blood is visible inside its tip.

      The tip has to be changed before moving on to the next tube. This procedure takes time and may result in an increased exposure for the first few tubes. It is

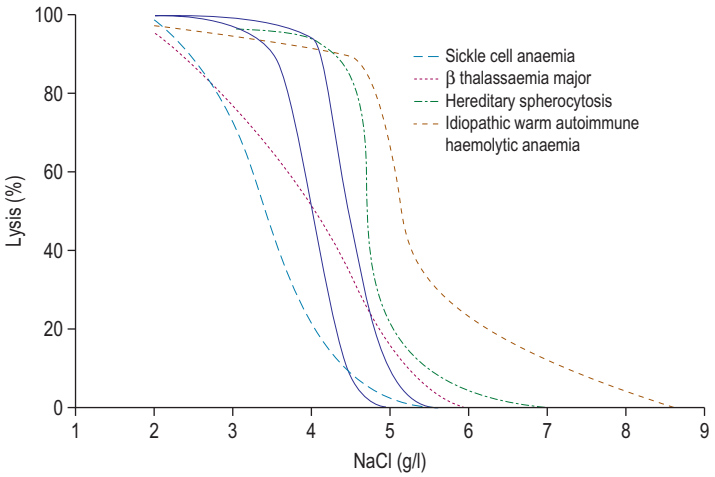

FIGURE 12-1 Osmotic fragility curves. Osmotic fragility curves of patients suffering from the following: sickle cell anaemia, β thalassaemia major, hereditary spherocytosis and 'idiopathic' warm autoimmune haemolytic anaemia. The normal range is indicated by the unbroken lines.

therefore advisable to start the timing only after the addition of the sample to the first tube.

b. Using a Pasteur pipette with a perfectly flat end, 1 mm in diameter, suck up about 1 ml of blood, avoiding any bubbles and wipe the outside of the pipette. With the pipette held vertically above tube 1, deliver a single drop (about 50 µl) without the blood touching the wall of the tube. Then deliver single drops into the remaining 11 tubes.

Method (b) appears to be primitive, but with practice it is perfectly satisfactory; it is also more economical and much faster than method (a). With either method, the best way to test its accuracy is to do a preliminary test by delivering the blood into several tubes all containing the same saline solution (e.g. either 3.0 or 1.0 g/l). The readings with the supernatants should be all within 5% of each other.

3. If the amount of blood available is limited (e.g. from babies) and the spectrometer takes 1 ml cuvettes, the volumes can be scaled down to 1 ml of saline solution and 10 µl of blood. However, to deliver 10 µl of blood reproducibly is not easy. With method (b), a Pasteur pipette or capillary pipette with a much smaller diameter, calibrated to give 10 µl drops of blood, would have to be used. It is then more difficult to maintain accuracy. Method (a) may be preferable in this case.
4. With the method using 50 µl of blood and with non-anaemic blood, the reading for 100% lysis will be about 0.7. With a modern spectrometer, any figure between 0.5 and 1.5 is acceptable. If the value is lower than 0.5, the test should be repeated using more blood or less saline (the reverse if the reading is higher than 1.5). With photoelectric colorimeters, values higher than 0.5 are often not very accurate.
5. When transferring the supernatant from a tube to the spectrometer cuvette, care has to be taken not to disturb the pellet. If it is well packed, the supernatant can simply be poured from the tube into the cuvette; with a spectrometer provided with an automatic suction device, this is usually satisfactory. Alternatively, a plastic Pasteur pipette can be used.
6. Even when a normal range has been established, it is essential always to run a normal control sample along with that of the patients to be tested to check, for example, the saline solutions.

The sigmoid shape of the normal osmotic fragility curve indicates that normal red cells vary in their resistance to hypotonic solutions. Indeed, this resistance varies gradually (osmotically) as a function of red cell age, with the youngest cells being the most resistant and the oldest cells being the most fragile. The reason for this is that old cells have a higher sodium content and a decreased capacity to pump out sodium.

Osmotic fragility after incubating the blood at 37 °C for 24 H

Method

Defibrinated blood should be used, care being taken to ensure that sterility is maintained.

Incubate 1 ml or 2 ml volumes of blood in sterile 5 ml bottles. It is advisable to set up the samples in duplicate in case one has become infected, as indicated by gross lysis and change in colour.

After 24 h, if no infection is evident, pool the contents of the duplicate bottles after thoroughly mixing the sedimented red cells in the overlying serum and estimate the fragility as previously described.

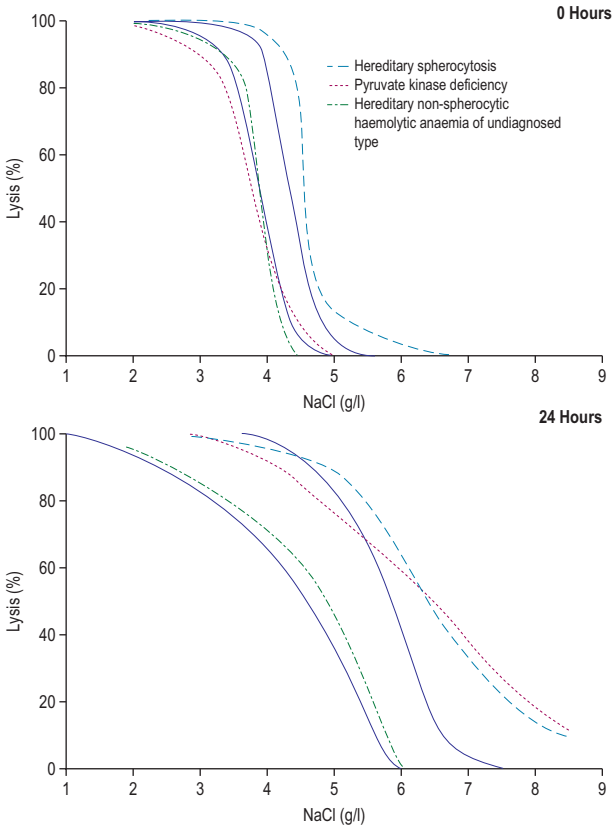

FIGURE 12-2 Osmotic fragility curves before and after incubating blood at 37°C for 24 h. Results are from patients suffering from the following: hereditary spherocytosis, pyruvate kinase deficiency and hereditary nonspherocytic haemolytic anaemia of undiagnosed type. The normal range is indicated by the unbroken lines.

Because the fragility may be markedly increased (Fig. 12-2), set up additional hypotonic solutions containing 7.0 g/l and 8.0 g/l NaCl. In addition, use a solution equivalent to 12.0 g/l NaCl because sometimes, as in HS, lysis may take place in 9.0 g/l NaCl. In this case, use the supernatant of the tube containing 12.0 g/l NaCl as the blank in the colorimetric estimation.

The incubation fragility test is conveniently combined with the estimation of the amount of spontaneous autohaemolysis (p. 235).

Factors affecting osmotic fragility tests

In carrying out osmotic fragility tests by any method, three variables capable of markedly affecting the results must be controlled, quite apart from the accuracy with which the saline solutions have been made up. These are as follows:

1. The relative volumes of blood and saline
2. The final pH of the blood in saline suspension
3. The temperature at which the tests are carried out.

A proportion of 1 volume of blood to 100 volumes of saline is chosen because the concentration of blood is so small that the effect of the plasma on the final tonicity of the suspension is negligible. When weak suspensions of blood in saline are used, it is necessary to control the pH of the hypotonic solutions and it is for this reason that phosphate buffer is added to the saline. Even so, small differences will be found between the fragility of venous blood and maximally aerated (i.e. oxygenated) blood. For the most accurate results, it is recommended that the blood is mixed until bright red. Finally, it is ideal for tests to be carried out always at the same temperature, although for most purposes room temperature is sufficiently constant.

The extent of the effect of pH and temperature on osmotic fragility was well illustrated in the paper of Parpart *et al*.[3] The effect of pH is more important: a shift of 0.1 of a pH unit is equivalent to altering the saline concentration by 0.1 g/l, the fragility of the red cells being increased by a decrease in pH. An increase in temperature decreases the fragility, an increase of 5°C being equivalent to an increase in saline concentration of about 0.1 g/l.

Lysis is virtually complete at the end of 30 min at 20°C and the hypotonic solutions may be centrifuged at the end of this time.

Further details of the factors that affect and control haemolysis of red cells in hypotonic solutions were given by Murphy.[4]

Recording the results of osmotic fragility tests

In the past, osmotic fragility most often has been expressed in terms of the highest concentration of saline at which lysis is just detectable (initial lysis or minimum resistance) and the highest concentration of saline in which lysis appears to be complete (complete lysis or maximum resistance). It is, however, useful also to record the concentration of saline causing 50% lysis (i.e. the median corpuscular fragility, MCF) and to inspect the entire fragility curve (Fig. 12-1). The findings in health are summarised in Table 12-1.

Alternative methods of recording osmotic fragility. Two simple alternative methods of recording the results quantitatively are available: the data may be plotted on probability paper or increment-haemolysis curves can

TABLE 12-1

OSMOTIC FRAGILITY IN HEALTH (AT 20°C AND PH 7.4)

	Fresh Blood (g/l NaCl)	Blood Incubated 24 h, 37°C (g/l NaCl)
Initial lysis	5.0	7.0
Complete lysis	3.0	2.0
MCF (50% lysis)	4.0–4.45	4.65–5.9

MCF, median corpuscular fragility.

be drawn. Both methods emphasise heterogeneity of the cell population with respect to osmotic fragility. If the observed amounts of lysis of normal blood are plotted on the probability scale against concentrations of saline, an almost straight line can be drawn through the points; the line is only skewed where lysis is almost complete. This method enables the MCF to be read off with ease.

In disease, tailed curves also skew the line to varying degrees at the other end of the probability plot. To obtain increment-haemolysis curves, the differences in lysis between adjacent tubes are plotted against the corresponding saline concentrations. Definitely bimodal curves may be obtained during recovery from a haemolytic episode.[5]

Interpretation of results

The osmotic fragility of freshly taken red cells reflects their ability to take up a certain amount of water before lysing. This is determined by their volume-to-surface area ratio. The ability of the normal red cell to withstand hypotonicity results from its biconcave shape, which allows the cell to increase its volume by about 70% before the surface membrane is stretched; once this limit is reached lysis occurs.[6] Spherocytes have an increased volume-to-surface area ratio; their ability to take in water before stretching the surface membrane is thus more limited than normal, and they are therefore particularly susceptible to osmotic lysis. The increase in osmotic fragility is a property of the spheroidal shape of the cell and is independent of the cause of the spherocytosis. Characteristically, osmotic fragility curves from patients with HS who have not been splenectomised show a 'tail' of very fragile cells (Fig. 12-3). When plotted on probability paper, the graph indicates two populations of cells: the very fragile and the normal or slightly fragile. After splenectomy the red cells are more homogeneous, the osmotic fragility curve indicating a more continuous spectrum of cells, from fragile to normal.

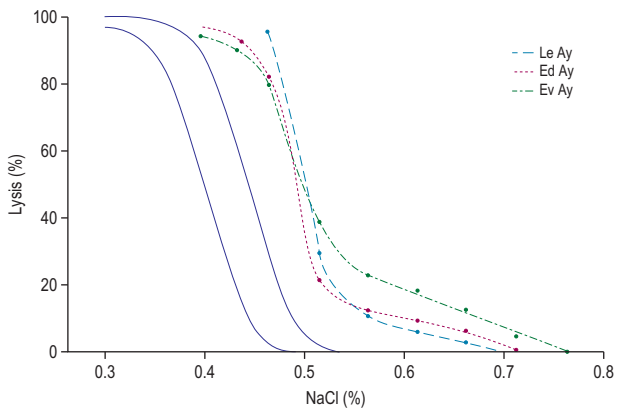

FIGURE 12-3 Osmotic fragility curves of three patients suffering from hereditary spherocytosis belonging to the same family (brother, sister and uncle). The area between the unbroken lines represents the normal range.

Decreased osmotic fragility indicates the presence of unusually flattened red cells (leptocytes) in which the volume-to-surface area ratio is decreased. Such a change occurs in iron deficiency anaemia and thalassaemia in which the red cells with a low mean cell haemoglobin (MCH) and mean cell volume (MCV) are unusually resistant to osmotic lysis (Fig. 12-1). A simple one-tube osmotic fragility is a useful screening test for β thalassaemia and some haemoglobinopathies in countries with a high incidence of these abnormalities (p. 556). Reticulocytes and red cells from patients who have been splenectomised also tend to have a greater amount of membrane compared with normal cells and are osmotically resistant. In liver disease, target cells may be produced by passive accumulation of lipid, and these cells, too, are resistant to osmotic lysis.[7]

The osmotic fragility of red cells after incubation for 24 h at 37 °C is also a reflection of their volume-to-surface area ratio, but the factors that alter this ratio are more complicated than in fresh red cells. The increased osmotic fragility of normal red cells, which occurs after incubation (Fig. 12-2), is mainly caused by swelling of the cells associated with an accumulation of sodium that exceeds loss of potassium. Such cation exchange is determined by the membrane properties of the red cell, which control the passive flux of ions, and the metabolic competence of the cell, which determines the active pumping of cations against concentration gradients. During incubation for 24 h, the metabolism of the red cell becomes stressed and the pumping mechanisms tend to fail, one factor being a relative lack of glucose in the medium.

The osmotic fragility of red cells that have an abnormal membrane, such as those of HS and hereditary elliptocytosis (HE), increases abnormally after incubation (Fig. 12-2). Similar results occur in hereditary stomatocytosis.[8] The results with red cells with a glycolytic deficiency, such as those of pyruvate kinase (PK) deficiency, are variable. In severe deficiencies, osmotic fragility may increase substantially (Fig. 12-2), but in other cases, the fragility may decrease owing to a greater loss of potassium than gain of sodium. In thalassaemia major and minor, osmotic fragility is frequently markedly reduced after incubation, again owing to a marked loss of potassium.[9] A similar, although usually less marked, change is seen in iron deficiency anaemia.

To summarise, measurement of red cell osmotic fragility provides a useful indication as to whether a patient's red cells are normal because an abnormal result invariably indicates abnormality. The reverse is, however, not true (i.e. a result that is within the normal range does not mean that the red cells are normal). The findings in some important haemolytic anaemias are summarised in Table 12-2.

TABLE 12-2

OSMOTIC FRAGILITY IN HAEMOLYTIC ANAEMIAS: A SUMMARY

Condition	Notes
A. Associated with Increased Osmotic Fragility (OF)	
Hereditary spherocytosis (HS)	Entire curve may be 'shifted to the right', or most of it may be within the normal range but with a 'tail' of fragile cells. Curve within normal range in 10–20% of cases. After incubation for 24 h, abnormalities usually more marked, but still some false-negative results. Splenectomy does not affect MCF but reduces the tail of fragile cells
Hereditary elliptocytosis (HE)	As in HS, but in general changes less marked. Abnormal OF usually correlates with severity of haemolysis (i.e. OF is normal in nonhaemolytic HE)
Hereditary stomatocytosis	As in HS with large osmotically fragile cells with low MCHC
Other inherited membrane abnormalities	Results variable; with milder disorders curve more likely to be abnormal after incubation for 24 h
Autoimmune haemolytic anaemia	Tail of fragile cells roughly proportional to number of spherocytes; rest of curve normal (or even left-shifted on account of reticulocytosis)
B. Associated with Decreased OF	
Thalassaemia	MCF decreased in all forms of thalassaemia, except in some α thalassaemia heterozygotes; usually the entire curve is left-shifted
Enzyme abnormalities	OF usually normal (anaemia originally referred to as hereditary nonspherocytic), but tail of highly resistant cells may be seen on account of high reticulocyte count. After incubation for 24 h, there may be a tail of fragile cells
Hereditary xerocytosis	Increased resistance to osmotic lysis and increased MCHC
Iron deficiency	Curve shifted to left, wholly or partly, depending on proportion of hypochromic red cells

MCF, median corpuscular fragility; MCHC, mean cell haemoglobin concentration.

FLOW CYTOMETRIC (DYE-BINDING) TEST

Principle

The osmotic fragility test lacks specificity and sensitivity and may fail to detect atypical or mild HS. Moreover, it can be affected by factors unrelated to red cell cytoskeletal defects; for example, positive results may be obtained for red cells from patients who are pregnant or who have immune or other haemolytic anaemias or renal failure. The flow cytometric (dye-binding) test of King and colleagues[10] measures the fluorescence intensity of intact red cells labelled with eosin-5-maleimide (EMA), which reacts covalently with Lys-430 on the first extracellular loop of Band 3 protein. The N-terminal cytoplasmic domain of Band 3 interacts with ankyrin and protein 4.2, which in turn crosslink with the spectrin-based cytoskeleton and stabilises the membrane lipid bilayer.[11] Deficiency or abnormality of Band 3 may result in decreased fluorescence. This is seen in HS red cells but has also been observed in cases of hereditary pyropoikilocytosis (HPP), Southeast Asian ovalocytosis, congenital dyserythropoietic anaemia Type II and the stomatocytic variant, cryohydrocytosis. Blood samples in ethylenediaminetetra-acetic acid (EDTA) can be analysed for up to 48 h after collection provided they have been stored in the refrigerator.

Reagents

Eosin-5-maleimide (EMA). EMA is light sensitive and must be kept in the dark, preferably wrapped in aluminium foil and stored at 4 °C. Prepare a stock solution by dissolving 1 mg in 1 ml of phosphate buffered saline (PBS). Mix well and store in 200 µl aliquots at −20 °C.

Bovine serum albumin (30%) solution (BSA). Available commercially. Dilute to 0.5% with PBS.

Phosphate buffered saline. Tablets are available commercially for dissolving in water (e.g. Oxoid Dulbecco 'A' tablets, www.oxoid.com/uk). Alternatively, prepare by adding equal volumes of iso-osmotic phosphate buffer and 9 g/l NaCl:

Phosphate buffer, iso-osmotic, pH 7.2:

(A) $NaH_2PO_4.2H_2O$ (150 mmol/l) – 23.4 g/l
(B) Na_2HPO_4 (150 mmol/l) – 21.3 g/l.
Add 24 ml reagent A to 76 ml reagent B.

Method

Thaw a tube of stock EMA solution in the dark at room temperature and dilute with an equal volume of PBS to obtain a working solution of 0.5 mg/ml. Mix 5 µl of washed packed red cells with 25 µl of EMA working solution in a plastic microfuge tube. Set up control tubes from blood

of normal individuals, and perform all tests in duplicate. Leave a rack with the tubes in a cupboard in the dark at room temperature for 30 min. Mix and return to the cupboard for a further 30 min.

Then, spin the tubes in a bench-top microfuge for 5–10 s and remove the supernatant dye carefully with a fine-tip pipette.

Wash the labelled red cells three times with 500 µl PBS containing 0.5% BSA. The third wash should be colourless. If it is still pink, suggesting that traces of dye particle remain in the tube, discard the sample and repeat the cell-labelling procedure.

Resuspend the packed red cells in 500 µl of the PBS–BSA wash solution. Transfer 100 µl of the cell suspension into a plastic flow cytometer tube and add 1.4 ml of wash solution. Keep the cell suspensions in the dark by wrapping in aluminium foil until use. Set the analyser thresholds (gate) for red blood cells and count each sample for a minimum of 15 000 events. Select the FITC (fluorescein isothiocyanate) channel and record the mean fluorescence intensity (MFI). Compare the test with the mean value of several control samples analysed at the same time.

Interpretation of results

Results are expressed as a ratio of mean value of the test to control samples. Each laboratory should set the reference range and cut-off values for its own instrument. In our laboratory, a range of 0.83 to 1.17 is considered normal. HS red cells give a ratio of less than 0.8. Values as low as 0.6 may be seen in classic HS. Similar or even lower values are seen in the much rarer HPP, but the latter is readily distinguished from HS on the basis of red cell morphology and a very low MCV. A reduced ratio may also be encountered in cases of Southeast Asian ovalocytosis, congenital dyserythropoietic anaemia Type II and cryohydrocytosis, but these are associated with different types of red cell atypia and may generally be ruled out by examination of a stained blood film. EMA binding has a high sensitivity in the diagnosis of HS, however in a very small number of cases of typical HS the MFI ratio is normal. If HS is suspected and EMA binding normal, a second screening test may be informative.

GLYCEROL LYSIS-TIME TESTS

The osmotic fragility test is somewhat cumbersome and requires 2 ml or more of whole blood. It is thus not suitable for use in newborn babies or as a population screening test. In 1974, Gottfried and Robertson[12] introduced a glycerol lysis-time (GLT) test, a one-tube test to measure the time taken for 50% haemolysis of a blood sample in a buffered hypotonic saline–glycerol mixture. The original method had greater sensitivity in the osmotic-resistant range, but it also could identify most patients with HS by a shorter GLT_{50}. Better differentiation of HS blood from normal was obtained by 24 h incubation of samples and by modifying the glycerol reagent.[13] Zanella *et al.* modified the original test further by decreasing the pH.[14] There is some loss of specificity for HS with the acidified glycerol lysis-time test (AGLT) compared with the original method, but in practice this loss is unimportant.

Acidified glycerol lysis-time test

Principle

Glycerol present in a hypotonic buffered saline solution slows the rate of entry of water molecules into the red cells so that the time taken for lysis may be more conveniently measured. Like the osmotic fragility test, differentiation can be made between spherocytes and normal red cells.

Reagents

Phosphate buffered saline. Add 9 volumes of 9.0 g/l (154 mmol/l) NaCl to 1 volume of 100 mmol/l phosphate buffer (2 volumes of 14.9 g/l Na_2HPO_4 added to 1 volume of 13.61 g/l KH_2PO_4). Adjust the pH to 6.85 ± 0.05 at room temperature (15–25 °C). This adjustment must be accurate.

Glycerol reagent. 300 mmol/l. Add 23 ml of glycerol (27.65 g AR grade) to 300 ml of PBS and bring the final volume to 1 litre with water.

Method

Add 20 µl of whole blood, anticoagulated with EDTA, to 5.0 ml of PBS, pH 6.85. Mix the suspension carefully.

Transfer 1.0 ml to a standard 4 ml cuvette of a spectrometer equipped with a linear-logarithmic recorder. Fix the wavelength at 625 nm and start the recorder. Add 2.0 ml of the glycerol reagent rapidly to the cuvette with a 2 ml syringe or automatic pipette and mix well.

The rate of haemolysis is measured by the rate of fall of turbidity of the reaction mixture. The results are expressed as the time required for the optical density to fall to half the initial value ($AGLT_{50}$). The test can also be carried out using a colorimeter and stopwatch.

Results

Normal blood takes more than 30 min (1800 s) to reach the $AGLT_{50}$. The time taken is similar for blood from normal adults, newborn infants and cord samples. In patients with HS, the range of the $AGLT_{50}$ is 25–150 s. A short $AGLT_{50}$ may also be found in chronic renal failure, chronic leukaemias and autoimmune haemolytic anaemia; it also may be found in some pregnant women.[14]

Significance of the acidified glycerol lysis-time test

The same principles apply as with the osmotic fragility test. Cells with a high volume-to-surface area ratio resist swelling for a shorter time than normal cells. This applies to all spherocytes, whether the spherocytosis is caused by

HS or other mechanisms. The test is particularly useful in screening family members of patients with HS where morphological changes are too minor to indicate clearly whether the disorder is present.

CRYOHAEMOLYSIS TEST

Principle

Whereas osmotic fragility may be abnormal in any condition where spherocytes occur, it has been suggested that cryohaemolysis is specific for HS.[15] This appears to result from the fact that the latter is dependent on factors that are related to molecular defects of the red cell membrane rather than to changes in the surface area-to-volume ratio. The test can be carried out on EDTA blood up to 1 day old.

Reagent

Buffered 0.7 mol/l sucrose

Dissolve 23.96 g sucrose in 100 ml of 50 mmol/l phosphate buffer, pH 7.4. This can be stored frozen in 2 ml aliquots in tubes ready for use.

Method[15]

1. Centrifuge the blood and wash the red cells three times with cold (4 °C) 9 g/l NaCl. Make a suspension of 50–70% cells in the saline and keep on ice until tested.
2. Prepare 2 ml volumes of reagent, thawing if frozen, and stand for 10 min in a 37 °C water bath to equilibrate.
3. Pipette 50 µl of the cell suspension into each of 2 tubes of the warmed reagent, vortex immediately for a few seconds and then incubate for exactly 10 min at 37 °C.
4. Without delay, transfer the tubes to an ice bath for another 10 min, vortex for a few seconds and then centrifuge to sediment the remaining cells. Transfer some of the supernatant to a clean tube.
5. Prepare a 100% haemolysate solution by pipetting 50 µl of the original sample into 2 ml of water. Centrifuge and dilute 200 µl of the supernatant in 4 ml of water.
6. Read absorbance at 540 nm of the test and the 100% lysis samples.

$$\%\,\text{cryohaemolysis} = \left[\frac{A^{540}\text{test}}{A^{540}\text{haemolysate} \times 21}\right] \times 100$$

Interpretation

Streichman *et al*.[15] reported the range of cryohaemolysis in normal subjects to be 3–15%, whereas in HS there was >20% lysis. However, it is recommended that individual laboratories establish their own reference values for the method. We have found that most normal samples give <3% lysis. Increased lysis is not exclusive to HS and may be observed in hereditary stomatocytosis.

AUTOHAEMOLYSIS: SPONTANEOUS HAEMOLYSIS DEVELOPING IN BLOOD INCUBATED AT 37 °C FOR 48 H

The autohaemolysis test is useful as an initial screen in suspected cases of haemolytic anaemia. It provides information about the metabolic competence of the red cells and helps to distinguish membrane and enzyme defects if the results of the tests are taken together with other observations such as morphology, inheritance and the presence or absence of associated clinical disorders.[16]

Principle

Aliquots of blood are incubated both with and without sterile glucose solution at 37 °C for 48 h. After this period, the amount of spontaneous haemolysis is measured colorimetrically.

Method

It is essential to use aseptic techniques in setting up the autohaemolysis test to maintain sterility throughout the incubation period.

Use blood collected into ACD or defibrinated blood (see previous editions). Deliver four 1 ml or 2 ml samples into sterile 5 ml capped bottles. Retain a portion of the original sample; separate and store this as the preincubation serum.

Add to two of the bottles 50 or 100 µl of sterile 100 g/l glucose solution, so as to provide a concentration of glucose in the blood of at least 30 mmol/l. Make sure that the caps of the bottles are tightly closed and place the series of bottles in the incubator at 37 °C. A sample from a known normal individual should be run in parallel as a control.

After 24 h, thoroughly mix the content by gentle swirling. After incubating for a further 24 h, inspect the samples for signs of infection, thoroughly mix again, then from each bottle remove a sample for the estimation of the packed cell volume (PCV) (by the microhaematocrit method) and haemoglobin concentration (Hb) and centrifuge the remainder to obtain the supernatant serum.

Estimate the spontaneous lysis by means of a colorimeter or a spectrometer at 540 nm.

As a rule, it is convenient to make a 1 in 10 dilution of the incubated serum in cyanide-ferricyanide (Drabkin) solution (p. 20), unless there is marked haemolysis, when a 1 in 25 or 1 in 50 dilution is more suitable. A corresponding dilution of the preincubation serum is used as a blank and a 1 in 100 or 1 in 200 dilution of the whole blood in Drabkin solution indicates the total amount of Hb present and serves as a standard.

Calculate the percentage lysis, allowing for the change in PCV resulting from the incubation as follows:

$$\text{Lysis}(\%) = \frac{R_t - B}{R_0} \times \frac{D_0}{D_t} \times (1 - PCV_t) \times 100$$

where R_0 = reading of diluted whole blood; R_t = reading of diluted serum at 48 h; B = reading of blank; PCV_t = packed cell volume at time *t*; D_0 = dilution of whole blood (e.g. 1 in 200 = 0.005); and D_t = dilution of serum (e.g. 1 in 10 = 0.1).

The reading at time *t* is multiplied by $(1 - PCV_t)$ so as to give the concentration that would be found if the liberated haemoglobin were dissolved in whole blood (i.e. in both plasma and red cell compartments), not in the plasma compartment alone.

Normal range of autohaemolysis

Lysis at 48 h: without added glucose, 0.2% to 2.0%; with added glucose, 0% to 0.9%.

The results obtained are sensitive to slight differences in technique and each laboratory should use a carefully standardised procedure and establish its own normal range. If the amount of liberated haemoglobin is small, it is more accurate (although more time consuming) to measure lysis by a chemical method rather than by a direct spectrometric method (p. 216). It can also be measured directly by a simple and rapid procedure with a HemoCue Plasma/Low Hb system (www.hemocue.com).[17]

Significance of increased autohaemolysis

Little or no lysis takes place when normal blood is incubated for 24 h under sterile conditions and the amount present after 48 h is small.[16] If glucose is added so that it is present throughout the incubation, the development of lysis is markedly slowed. The amount of autohaemolysis that occurs after 48 h with and without glucose is determined by the properties of the membrane and the metabolic competence of the red cell. In membrane disorders such as HS, the rate of glucose consumption is increased to compensate for an increased cation leak through the membrane.[8] During the 48 h incubation, glucose is therefore used up relatively rapidly so that energy production fails more quickly than normal unless glucose is added. This is one factor that contributes to the increased rate of autohaemolysis in HS. Usually, but not always, the addition of glucose to the blood decreases the rate of autohaemolysis in HS. This was referred to as Type 1 autohaemolysis.[16] When the utilisation of glucose via the glycolytic pathway is impaired, as in PK deficiency, the rate of autohaemolysis at 48 h is usually increased but glucose fails to correct or may even aggravate lysis (Type 2 autohaemolysis).[8] Although a similar result may be seen in severe HS (Type B), in the absence of spherocytosis, failure of glucose to diminish autohaemolysis is a strong indication of a glycolytic block. Blood from patients with G6PD deficiency or other disorders of the pentose phosphate pathway may undergo a slight increase in autohaemolysis (without additional glucose), which is corrected by the addition of glucose. Commonly, the result is normal, but examination of the incubated blood may show an increase in methaemoglobin (Hi) (discussed later). Not all glycolytic enzyme deficiencies give a Type 2 reaction so that a Type 1 result does not exclude the possibility of such a defect.

In the acquired haemolytic anaemias, the results of the autohaemolysis test are variable and generally not very helpful in diagnosis. In the autoimmune haemolytic anaemias, lysis may be increased in the absence of additional glucose but the effect of added glucose is unpredictable. In paroxysmal nocturnal haemoglobinuria (PNH), the autohaemolysis of aerated defibrinated blood is usually normal.

Autohaemolysis may be increased in haemolytic anaemias caused by oxidant drugs or when there are defects in the reducing power of the red cell. Heinz bodies, Hi or both will be detectable at the end of incubation. Normally, red cells produce <4% Hi after 48 h incubation and Heinz bodies are not seen. Red cells containing an unstable haemoglobin also contain Heinz bodies at the end of the incubation period and increased amounts of Hi.

The nucleosides adenosine, guanosine and inosine, like glucose, diminish the rate of autohaemolysis when added to blood. Remarkably, adenosine triphosphate (ATP) strikingly retards haemolysis in PK deficiency, although glucose itself is ineffective.[18] ATP does not pass the red cell membrane.

The autohaemolysis test lacks specificity. This has drawn much criticism on the test, including the suggestion that it has no place in the screening of blood for inherited defects.[19] The best way to detect metabolic defects in red cells is undoubtedly to measure glucose consumption, lactate production and the contribution to metabolism of the pentose phosphate pathway. These measurements are, unfortunately, difficult and are likely to be undertaken only by specialised laboratories. The autohaemolysis test does provide some information about the metabolic competence of the red cells and helps to distinguish membrane defects from enzyme defects.

In summary, we feel that the autohaemolysis test is still useful in the investigation of patients who have or who may have chronic haemolytic anaemia for the following reasons:

1. If the result is entirely normal, an intrinsic red cell abnormality is unlikely.
2. If abnormal haemolysis is fully corrected by glucose, a metabolic abnormality is unlikely and a membrane abnormality is likely.
3. If abnormal haemolysis shows little or no correction by glucose, a metabolic abnormality is likely, provided that obvious features of spherocytosis are not present on the blood film.

Thus, in our experience, a combination of red cell morphology with the results of the autohaemolysis tests makes it possible to differentiate membrane abnormalities from enzyme deficiencies in the vast majority of cases.

MEMBRANE PROTEIN ANALYSIS

Defects of red cell membrane proteins that constitute the cytoskeleton are associated with congenital haemolytic anaemias accompanied by characteristic morphological features. Their analysis is generally only possible in the setting of a reference laboratory. Sodium dodecyl sulphate – polyacrylamide gel electrophoresis (SDS-PAGE) of the membranes will identify qualitative and quantitative alterations in the specific proteins. Densitometry of protein bands on the gel gives an overall profile showing spectrin, ankyrin, Band 3 (the anion transport protein) and protein 4.2. Spectrin variants may be detected after limited trypsin digestion of spectrin extracted from the red cell membranes; an increase in spectrin dimer is indicative of an unstable tetramer, leading to susceptibility to red cell fragmentation in HE and HPP.[20]

Quantitative and qualitative defects of cytoskeletal and other membrane proteins found in hereditary haemolytic anaemias are listed in Table 12-3.

TABLE 12-3

HAEMOLYTIC ANAEMIAS ASSOCIATED WITH DEFECTS OF RED CELL MEMBRANE PROTEINS[20]

Band	Protein	Haemolytic Anaemia
1	α spectrin	HE, HS, HPP
2	β spectrin	HE, HS
2.1	Ankyrin	HS
3	Anion exchanger	HS, SAO, CDAII, CHC
4.1	Protein 4.1	HE
4.2	Pallidin (Protein 4.2)	HS
7.2b	Stomatin	OHSt, CHC
PAS-1	Glycophorin A	CDAII
PAS-2	Glycophorin C	HE
ND	Rh-associated glycoprotein	OHSt
ND	Glucose transporter (Glut 1)	CHC
ND	Piezo 1	DHSt
ND	Gardos channel (KCa3.1)	DHSt
ND	ABCB6	FP

ABCB6, ATP-binding cassette transporter sub-family B member 6; CDAII, congenital dyserythropoietic anaemia Type II; CHC, cryohydrocytosis; DHSt, dehydrated hereditary stomatocytosis (xerocytosis); FP, familial pseudohyperkalaemia; HE, hereditary elliptocytosis; HPP, hereditary pyropoikilocytosis; HS, hereditary spherocytosis; ND, not detected by SDS-PAGE; OHSt, overhydrated hereditary stomatocytosis; SAO, Southeast Asian ovalocytosis.

DETECTION OF ENZYME DEFICIENCIES IN HEREDITARY HAEMOLYTIC ANAEMIAS

It is feasible for most haematology laboratories to identify deficiencies of G6PD and PK and to indicate where the probable defect lies in less common disorders. Detailed investigation of the aberrant enzymes and of the metabolism of the abnormal cells is probably best undertaken by specialised laboratories. Comprehensive accounts of methods available for studying red cell metabolism are to be found in Beutler's *Red Cell Metabolism, a Manual of Biochemical Methods*[21] and in the ICSH recommendations.[22]

There are two stages in the diagnosis of red cell enzyme defects: first, screening procedures; and second, specific enzyme assays. The simple nonspecific screening procedures such as the osmotic fragility and autohaemolysis tests, which have already been described, may indicate the presence of a metabolic disorder, and simple biochemical tests are available to show whether the disorder is in the pentose phosphate or the Embden–Meyerhof pathways; these intermediate stages of glycolysis are illustrated in Figure 12-4.

These investigations may be augmented by quantitation of the major red cell metabolites 2,3-DPG, ATP and GSH, which are present at millimolar concentrations and which can be assayed conveniently by spectrometric techniques. Metabolic block in the Embden–Meyerhof pathway is most accurately pinpointed by measurement of the concentration of glycolytic intermediates with demonstration of accumulation of metabolites proximal and depletion of metabolites distal to the defective step (Fig. 12-4). These assays, which are generally confined to specialised laboratories, must be performed on deproteinised red cell extracts immediately after preparation.

Screening tests for G6PD deficiency and other defects of the pentose phosphate pathway

Many variants of the red cell enzyme G6PD have been detected and the methods used to identify variants have been standardised.[23] Inheritance is sex-linked since the enzyme is encoded by a gene on the X chromosome. Variants that have deficient activity produce one of several types of clinical disorders. The two most common variants are the Mediterranean type, which has very low activity and which may lead to favism (i.e. acute intravascular haemolysis following the ingestion of broad beans), and the A– type found in Black populations in West Africa, the USA, the UK and elsewhere, which leads to primaquine sensitivity. Both groups are susceptible to haemolysis produced by oxidant drugs and infections.

Much less frequently, a chronic nonspherocytic haemolytic anaemia is produced by rare variants of the enzyme.

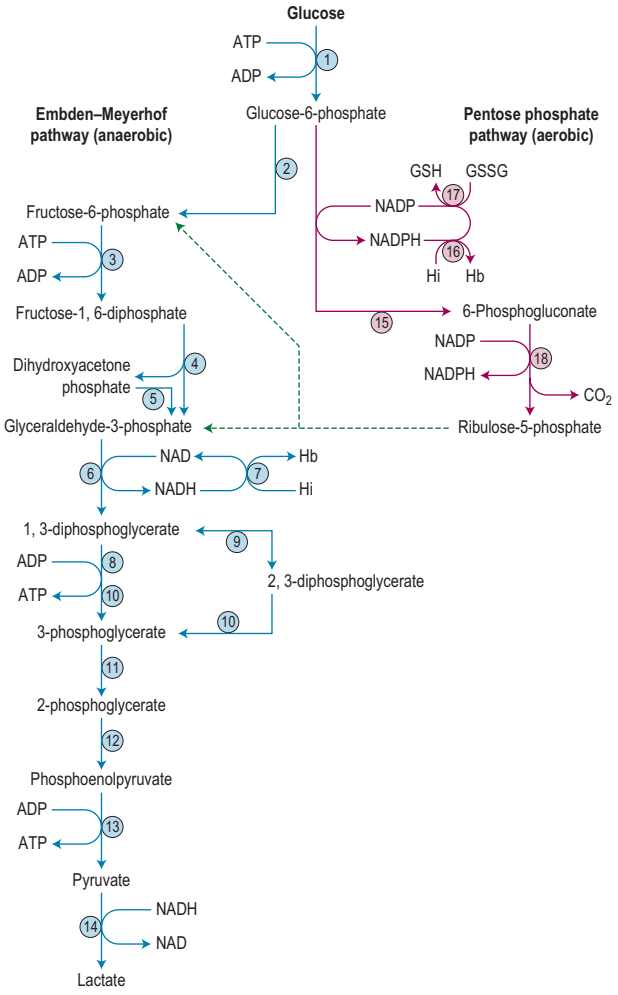

FIGURE 12-4 Schematic representation of red cell glycolytic pathways. The enzymes are indicated as follows: (1) hexokinase; (2) glucosephosphate isomerase; (3) phosphofructokinase; (4) aldolase; (5) triose phosphate isomerase; (6) glyceraldehyde-3-phosphate dehydrogenase; (7) NADH-methaemoglobin reductase; (8) phosphoglycerate kinase; (9) diphosphoglyceromutase; (10) diphosphoglycerate phosphatase; (11) phosphoglyceromutase; (12) enolase; (13) pyruvate kinase; (14) lactate dehydrogenase; (15) glucose-6-phosphate dehydrogenase; (16) NADPH-methaemoglobin reductase; (17) glutathione reductase; (18) 6-phosphogluconate dehydrogenase. NADH, reduced form of nicotinamide adenine dinucleotide; NADPH, reduced form of nicotinamide adenine dinucleotide phosphate.

Severe neonatal jaundice with anaemia occurs in about 5% of patients who have major deficiencies of enzyme activity.

G6PD deficiency in hemizygous (male) or homozygous (female) individuals may be readily detected by screening tests, but it is more difficult to detect heterozygous (female) carriers. Other defects of the pentose phosphate pathway also lead to deficiency in the reducing power of the red cell. The clinical syndromes associated with these defects include intravascular haemolysis, with or without methaemoglobinaemia, in response to oxidative drugs.

G6PD catalyses the oxidation of glucose-6-phosphate (G6P) to 6-phosphogluconate (6PG) with the simultaneous reduction of nicotinamide adenine dinucleotide phosphate (NADP) to reduced NADP (NADPH):

$$G6P + NADP \xrightarrow{G6PD} 6PG + NADPH$$

In a second, consecutive, oxidative reaction, 6PG is converted to 6-phosphogluconolactone, with reduction of a further molecule of NADP to NADPH. The lactone then undergoes decarboxylation to ribulose 5-phosphate through a reaction catalysed by a specific lactonase, but which can also take place spontaneously. Thus the overall reaction catalysed by 6PG dehydrogenase (6PGD) can be written as follows:

$$6PG + NADP \xrightarrow{6PGD} Ru5P + CO_2 + NADPH$$

The release of CO_2 drives the reaction to the right so that in practice the pathway is not reversible.

NADPH is an important reducing compound for the conversion of oxidised glutathione (GSSG) to GSH (Fig. 12-4) and under conditions of stress, the reconversion of Hi to haemoglobin. Screening tests for G6PD deficiency depend on the inability of cells from deficient subjects to convert an oxidised substrate to a reduced state. The substrates used may be the natural one of the enzyme, NADP or other naturally occurring substrates linked by secondary reactions to the enzyme, for example, GSSG or Hi or artificial dyes such as methylene blue. The reaction is demonstrated by fluorescence,[24] colour change when a dye is used[25] or deposit of a dye (e.g. a blue ring of formazan from diphenyltetrazolium bromide in the presence of phenazine methosulphate).[26]

Which screening test is used in any particular laboratory will depend on a number of factors such as cost, time required, temperature and humidity and availability of reagents. Two tests that are commonly used and that are generally reliable are described here.

Fluorescence screening test for G6PD deficiency

The method of fluorescent screening test for G6PD deficiency is that of Beutler and Mitchell[24] modified as recommended by ICSH.[22]

Principle

NADPH, generated by G6PD present in a lysate of blood cells, fluoresces under long-wave ultraviolet

(UV) light. In G6PD deficiency, there is an inability to produce sufficient NADPH; this results in a lack of fluorescence.

Reagents

D-glucose-6-phosphate. 10 mmol/l. Dissolve 305 mg of the disodium salt or an equivalent amount of the potassium salt in 100 ml of water.

$NADP^+$. 7.5 mmol/l. Dissolve 60 mg of $NADP^+$, disodium salt, in 10 ml of water.

Saponin (white, suitable for haemolysis). 1%.

Tris-HCl buffer. 750 mmol/l, pH 7.8. Dissolve 9.1 g of Tris(hydroxymethyl)aminomethane in 80 ml of water. Adjust the pH to 7.8 with HCl and make up the volume to 100 ml with water.

Oxidised glutathione (GSSG). 8 mmol/l. Dissolve 49 mg of GSSG in 10 ml of water.

Mix the reagents in the following proportion: 2 volumes of G6P, 1 volume of $NADP^+$, 2 volumes of saponin, 3 volumes of buffer, 1 volume of GSSG and 1 volume of water.

The combined reagent is stable at −20 °C for 2 or more years and for at least 2 months if kept at 4 °C. Azide may be added to prevent growth of contaminants without loss of activity. Dispense 100 µl volumes into appropriate small tubes and keep at −20 °C ready for use.

Method

Thaw out sufficient tubes to set up test and controls. Allow reagents to reach room temperature before use.

Add 10 µl of whole blood (in EDTA, heparin, ACD [acid–citrate–dextrose] or CPD [citrate–phosphate–dextrose]) to 100 µl volumes of the reagent mixture and keep at room temperature (15–25 °C).

Place 10 µl of the reaction mixture on a Whatman No. 1 filter paper at the beginning of the reaction and again after 5–10 min. A shorter interval may be appropriate at a high ambient temperature (*c.* 25–30 °C). Allow to air dry thoroughly before examining the spots under UV light. Record whether fluorescence is present (+) or absent (−). Always set up samples of normal blood and known G6PD-deficient blood in parallel.

If the samples are to be collected away from the laboratory or where delay is envisaged (e.g. during population screening) place about 10 µl of blood on Whatman No. 1 filter paper and allow it to dry. Cut out the disc of dried blood in the laboratory and add it to the reaction mixture. A sample of normal blood should be tested as a positive fluorescence (i.e. normal) control.

The test can be carried out on blood stored in ACD (provided it is sterile) for up to 21 days at 4 °C and for about 5 days at room temperature.

Interpretation

Fluorescence is produced by NADPH formed from $NADP^+$ in the presence of G6PD. Some of the NADPH produced is oxidised by GSSG, but this reaction, catalysed by glutathione reductase, is normally slower than the rate of NADPH production. Red cells with <20% of normal G6PD activity do not cause detectable fluorescence.

Like all screening tests, this method is useful when large numbers of samples are to be tested, but the result must be interpreted with caution in an individual patient. The main causes of erroneous interpretations are as follows:

False-normal. If there is reticulocytosis, a vivid fluorescence may be seen with a genetically G6PD-deficient blood sample because young red cells have more G6PD activity. If the test is carried out during an acute haemolytic episode, the patient's blood should be retested when the reticulocyte count has returned to normal.

False-deficient. If the patient is anaemic, very little fluorescence may be seen despite the G6PD being genetically normal, simply because there are relatively few red cells in the 10 µl of blood used.

Although it is possible to correct for either or both of these contingencies, if in doubt, it is best to proceed directly to a quantitative enzyme assay (discussed later).

The test is meant to give only a + or − (normal or deficient) result by comparison with the controls, and it does not make sense to grade by eye the intensity of fluorescence. If a control G6PD-deficient sample is not available, the appearance of the 'zero time' spot can be used for reference. The threshold for a 'deficient' result can be worked out by making dilutions of a normal blood sample in saline and is best set by regarding as deficient the fluorescence obtained when G6PD activity is 20% of normal or less (corresponding to a 1 in 5 dilution of normal blood). This means that very mildly deficient variants and a substantial proportion of heterozygotes (see below), will be missed. However, clinically important haemolysis is unlikely to occur in subjects who have more than 20% G6PD activity and therefore this seems an appropriate (although arbitrary) threshold for a diagnostic laboratory. Because the test depends on visual inspection, it is best to select the time of incubation in relation to ambient temperature in preliminary trials. NADPH production is a cumulative process. Therefore, given enough time, a G6PD-deficient sample will fluoresce. The time allowed for the reaction should be one at which the contrast in fluorescence between a G6PD-normal and a G6PD-deficient sample is maximal.

Methaemoglobin reduction test

Principle

Sodium nitrite converts haemoglobin to Hi. When no methylene blue is added, methaemoglobin persists, but incubation of the samples with methylene blue allows

stimulation of the pentose phosphate pathway in subjects with normal G6PD levels. The Hi is reduced during the incubation period. In G6PD-deficient subjects, the block in the pentose phosphate pathway prevents this reduction.[25]

Reagents

Sodium nitrite. 180 mmol/l.

Dextrose. 280 mmol/l. Dissolve 5 g of dextrose (analytical grade) and 1.25 g of $NaNO_2$ in 100 ml of water.

Methylene blue. 0.4 mmol/l. Dissolve 150 mg of methylthionine chloride (methylene blue chloride, Sigma) in 1 litre of water.

Nile blue sulphate. 22 mg in 100 ml of water. This may be used as an alternative to methylene blue.

The reagents may be used in a variety of ways to suit the convenience of the laboratory. A batch of tubes may be prepared in advance of use by mixing equal volumes of the reagents (sodium nitrite with methylene blue or Nile blue sulphate) and pipetting 0.2 ml of the combined reagent into individual glass tubes. Glass tubes must be used because plastic may adsorb some reagents. The contents of the tubes are allowed to evaporate to dryness at room temperature (15–25 °C) or in an oven at a temperature not exceeding 37 °C. The tubes must then be tightly stoppered. The reagent will keep for 6 months at room temperature. The reagents may however be used fresh, without drying.

Method

Use anticoagulated blood (EDTA or ACD) and test the samples preferably within 1 h of collection if left on the bench or within 6 h if kept at 4 °C. Blood in ACD can be stored for up to 1 week but will be unsatisfactory if there is any haemolysis. With blood from patients who are severely anaemic, adjust the PCV to 0.40 ± 0.05.

Add 2 ml of blood to the tube containing 0.2 ml of the combined reagent either freshly prepared or dried. Close the tube with a stopper and gently mix the contents by inverting it 15 times.

Prepare control tubes by adding 2 ml of blood to a similar tube without reagents (normal reference tube) and to a tube containing 0.1 ml of sodium nitrite–dextrose mixture without methylene blue ('deficient' reference tube).

Incubate the samples at 37 °C for 90 min. If the blood has been heparinised, incubation should be continued for 3 h.

After the incubation, pipette 0.1 ml volumes from the test sample, the normal reference tube and the deficient reference tube into 10 ml of water in separate, clear glass test tubes of identical diameter. Mix the contents gently. Compare the colours in the different tubes (see below).

Interpretation

Normal blood yields a colour similar to that in the normal reference tube (i.e. a clear red). Blood from deficient subjects gives a brown colour similar to that in the deficient reference tube. Heterozygotes give intermediate reactions.

Although this method takes longer than the fluorescent test, its advantages include the fact that it is extremely inexpensive and that the only equipment required is a water bath. In addition, the test can be complemented by cytochemical analysis that lends itself to detecting G6PD deficiency in patients with reticulocytosis and in heterozygotes.

Detection of heterozygotes for G6PD deficiency

Females heterozygous for G6PD deficiency have two populations of cells, one with normal G6PD activity and the other with deficient G6PD activity. This is the result of inactivation of one of the two X chromosomes in individual cells early in the development of the embryo. All progeny cells (i.e. somatic cells) in females will have the characteristics of only the active X chromosome.[27] The total G6PD activity of blood in the female will depend on the proportion of normal to deficient cells. In most cases, the activity will be between 20% and 80% of normal. However, a few heterozygotes (about 1%) may have very largely normal or very largely G6PD-deficient cells.

Screening tests for G6PD deficiency fail to demonstrate most heterozygotes. The deficient red cells may, however, be identified in blood films by a cytochemical elution procedure (see below).

Test kits

Several commercial kits are available for detection of G6PD deficiency. A fluorescent spot test (Trinity Biotech 203-A) and a test based on reduction of the dye dichloroindophenol to a colourless state in the presence of phenazine methosulphate (Trinity Biotech 400) are available commercially (www.trinitybiotech.com).

The Quantase kit (www.bio-rad.com) is a photometric method for use on whole blood or dried blood spots; NADPH produced by oxidation of G6P to 6PG is measured by an increase in absorption at 340 nm.

Each test or batch of tests should include a normal and a G6PD-deficient sample. Sheep blood is a useful source of naturally deficient blood. Where possible, participation in an external quality assessment (or proficiency testing) scheme is also recommended.

CYTOCHEMICAL TESTS FOR DEMONSTRATING DEFECTS OF RED CELL METABOLISM

Cytochemical methods have been developed by means of which some of these defects are demonstrable in individual cells. Thus tests have been described for demonstrating red cells deficient in G6PD.[28–30] The principle on which the methods are based is that red cells are treated with sodium nitrite to convert their oxyhaemoglobin (HbO_2) to methaemoglobin (Hi). In the presence of G6PD, Hi reconverts to HbO_2, but in G6PD deficiency, Hi persists. The blood is then incubated with a soluble tetrazolium compound (MTT), which will be reduced by HbO_2 (but not by Hi) to an insoluble formazan form.

Attempts have been made to improve the reliability of the test for detecting heterozygotes (e.g. by controlled slight fixation of the red cells and accelerating the reaction with an exogenous electron carrier, 1-methoxyphenazine methosulphate).[31] These cytochemical procedures are not more sensitive in the demonstration of G6PD deficiency than are the simple screening tests described above. They may, however, be useful in genetic studies and when assessing G6PD activity in women;[32] they may be the only straightforward way to detect deficiency in the heterozygous state.

Demonstration of G6PD-deficient cells

Reagents

Sodium nitrite. 0.18 mol/l (12.5 g/l). The solution must be stored in a dark bottle and made up monthly.

Incubation medium. 9 g/l NaCl, 4 ml; 50 g/l glucose, 1.0 ml; 0.3 mol/l phosphate buffer, pH 7.0, 2.0 ml; 0.11 g/l Nile blue sulphate, 1.0 ml; water, 2.0 ml.

MTT tetrazolium. 5 g/l of 3-(4,5-dimethyl-thiazolyl-1–2)-2,5 diphenyltetrazolium bromide in 9 g/l NaCl.

Hypotonic saline. 6 g/l NaCl.

Method

Venous blood collected into ACD should be used. The test should be carried out within 8 h of collection and the blood should be kept at 4 °C until it is tested. Centrifuge the blood at 4 °C for 20 min at 1200–1500 *g*.[28]

Discard the supernatant and add 0.5 ml of the packed red cells to 9 ml of 9 g/l NaCl and 0.5 ml of sodium nitrite solution contained in a 15 ml glass centrifuge tube. Incubate at 37 °C for 20 min. Centrifuge at 4 °C for 15 min at approximately 500 *g*, then discard the supernatant fluid without disturbing the buffy coat and uppermost layer of red cells. Wash the cells three times in cold saline. After the last washing, remove the buffy coat, mix the packed cells well and transfer 50 µl to a glass tube containing 1 ml of the incubation medium. Incubate the suspension undisturbed at 37 °C for 30 min. Then add 0.2 ml of MTT solution, shake gently and incubate at 37 °C for 1 h. Resuspend the cells thoroughly. Place one drop adjacent to one drop of hypotonic saline on a glass slide, mix the drops thoroughly and cover with a coverslip.

Examine the red cells with an oil-immersion objective, noting the presence of formazan granules (Fig. 12-5).

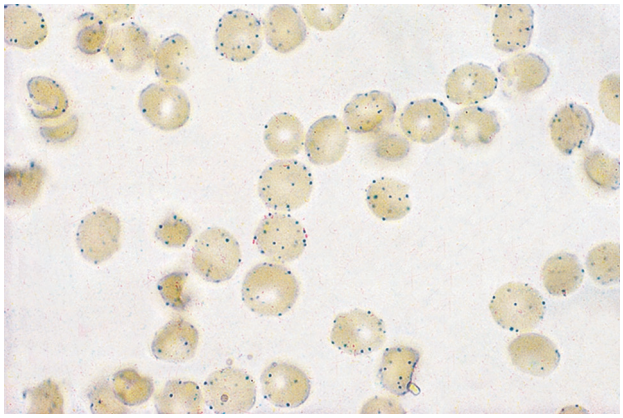

FIGURE 12-5 Cytochemical demonstration of G6PD (glucose-6-phosphate dehydrogenase) activity. Normal blood; positive reaction with formazan granules in the red cells.

Interpretation

When G6PD activity is normal, all the red cells are stained. In hemizygotes for G6PD deficiency, the majority of the red cells are unstained. In heterozygotes, mosaicism is usually seen; usually 40–60% of the cells are unstained, but the proportion may be much less and in extreme cases as few as 2–3% may be unstained.

PYRIMIDINE-5′-NUCLEOTIDASE SCREENING TEST

Pyrimidine-5′-nucleotidase (P5N) was first described by Valentine *et al.*[33] as a cytosolic enzyme in human red cells. Deficiency of P5N-1 (uridine monophosphate hydrolase-1), which shows autosomal recessive inheritance, is associated with congenital haemolytic anaemia. Heterozygotes are clinically and haematologically normal and typically have about half the normal red cell P5N activity. Homozygous P5N deficiency, in which enzyme activity is generally 5–15% of normal, results in a chronic nonspherocytic haemolytic anaemia. This is characterised by mild to moderate haemolysis, pronounced

basophilic stippling visible in up to 5% of red cells and marked increase in both red cell glutathione and pyrimidine nucleotides. Osmotic fragility is normal. The rate of autohaemolysis is increased with little or no reduction in lysis by added glucose.[8]

P5N deficiency appears to be a comparatively rare cause of hereditary nonspherocytic haemolytic anaemia. Because lead is an inhibitor of P5N, an acquired deficiency occurs in lead toxicity, and this may be important in the pathogenesis of the associated anaemia. The definitive diagnostic test is a quantitative assay of P5N activity; but the finding of supranormal levels of red cell nucleotides (mostly pyrimidines) is strongly suggestive and can be used for screening.

Activity of P5N may be measured by a colorimetric method[33] or by a radiometric method.[34] For the screening of P5N deficiency, the method recommended by ICSH is the determination of the UV spectra of a blood extract.[35]

Principle

The nucleotide pool of normal red cells consists largely (>96%) of purine (adenine and small amounts of guanine) derivatives. The levels of cytidine and uridine are normally extremely low. However, in P5N-deficient cells, more than 50% of this pool consists of pyrimidine nucleotides.

In acidic solutions, cytidine nucleotides have an absorbance maximum at approximately 280 nm, whereas adenine, guanine and uridine nucleotides absorb maximally at 260 nm. The ratio of absorbance at 260 nm to absorbance at 280 nm reflects the relative abundance of cytidine nucleotides; the absorbance ratio is lower when pyrimidine derivatives are increased.

Reagents

Sodium chloride solution. NaCl, 9 g/l.

Perchloric acid. 4%. 28.6 ml of a 70% perchloric acid (PCA) solution are diluted to a final volume of 500 ml with water.

Glycine buffer. 1 mol/l, pH 3.0. 7.51 g of glycine are dissolved in about 80 ml of water, the pH is adjusted to 3.0 with concentrated hydrochloric acid (HCl) and the solution is made up to a final volume of 100 ml with water.

Method

For sample preparation, centrifuge blood freshly collected in EDTA at 1200 *g* for 5 min, remove the plasma and wash the cells three times with ice-cold 9 g/l NaCl solution. Add 1 ml of a 50% suspension of the washed red cells to 4 ml of ice-cold 4% PCA solution and then shake vigorously for 30 s. Transfer the clear supernatant obtained after centrifugation at 1200 *g* for 15 min to a small test tube. Prepare a sham extract by adding 1 ml of 9 g/l NaCl to 4 ml of 4% PCA solution.[35]

Add 500 µl of water and 300 µl of 1 mol/l glycine buffer to each of two cuvettes. To correct for optical differences between the cuvettes, read the sample cuvette against the blank at 260 and at 280 nm, giving readings B^{260} and B^{280}. Add 200 µl of the red cell extract to the sample cuvette and 200 µl of the sham extract to the blank cuvette. With the spectrometer zeroed at 260 nm on the blank cuvette, read the sample cuvette to obtain the value S^{260}. Repeat the process at 280 nm to obtain the reading S^{280}.

The A^{260}/A^{280} absorbance ratio (R) is calculated by subtracting the cuvette blank readings (positive or negative) at 260 and 280 nm from the readings obtained on the red cell extract when blanked against the sham extract:

$$R = \frac{S^{260} - B^{260}}{S^{280} - B^{280}}$$

Interpretation

The A^{260}/A^{280} absorbance ratio of freshly collected washed red cells has been reported to be 3.11 ± 0.41 (mean ± SD). Absorbance ratios of <2.29 imply that the concentration of cytidine nucleotide is increased and suggest a reduced level of P5N. Selective accumulation of pyrimidines owing to putative deficiency of cytidine diphosphate-choline phosphotransferase has been reported in rare patients with a disorder characterised by haemolytic anaemia and basophilic stippling, thus resembling P5N deficiency.

Samples showing a significantly reduced absorbance ratio should have a specific assay for P5N carried out.[36] This is likely to require referral to a reference laboratory where a nucleotide profile may also be undertaken. Nucleotide extraction followed by radiolabelling and separation by high-performance liquid chromatography can be performed. The nucleotides have characteristic UV absorption spectra and retention times, which permit subsequent radiodetection and quantification.

RED CELL ENZYME ASSAYS

As is illustrated in Figure 12-4, a large number of enzymes play a part in the metabolism of glucose in the red cell and genetically determined variants of almost all the enzymes are known to occur. This means that in investigating a patient suspected of suffering from a hereditary enzyme-deficiency haemolytic anaemia, multiple enzyme assays may be needed to identify the defect. In practice, however, G6PD deficiency and PK deficiency should be excluded first because of the relative frequency (common in the case of G6PD, not rare in the case of PK) with which variants of these enzymes are associated with deficiency and increased haemolysis.

Many methods are available for assaying each enzyme and for this reason the ICSH has produced simplified methods suitable for diagnostic purposes.[37] These methods are not necessarily the most appropriate for detailed

study of the kinetic properties of the variant enzymes, but they are relatively simple to set up and allow comparison of results between different laboratories.

General points of technique

Collection of blood samples

Blood samples may be anticoagulated with heparin (10 iu/ml blood), EDTA (1.5 mg/ml blood) or ACD (for formulae and volumes see below). In any of these anticoagulants, all normal enzymes are stable for 6 days (and most for 20 days) at 4 °C and for 24 h at 25 °C. However, enzyme variants in samples from patients may be less stable. Therefore, we recommend that ACD is used as anticoagulant and that the samples are tested promptly. Ideally, samples of blood should be transferred to central laboratories in tubes surrounded by wet ice at 4 °C. Frozen samples are unsuitable because the cells are lysed by freezing. Further details of enzyme stability were given by Beutler.[21] Approximately 1 ml of blood is required for each enzyme assay.

Preparation of acid–citrate–dextrose (ACD) solution – NIH-A

- Trisodium citrate, dihydrate (75 mmol/l) – 22 g
- Citric acid, monohydrate (42 mmol/l) – 8 g
- Dextrose (139 mmol/l) – 25 g
- Water to 1 litre.

Sterilise the solution by autoclaving at 121 °C for 15 min. Its pH is 5.4. For use, add 10 volumes of blood to 1.5 volumes of solution.

Separation of red cells from blood samples

Leucocytes and platelets generally have higher enzyme activities than red cells. Moreover, with many enzyme deficiencies, notably PK deficiency, the decrease in enzyme activity may be much less pronounced in leucocytes and platelets than in red cells or it even may be absent. It is therefore necessary to prepare red cells which are as free from contamination as possible. Various methods are suitable (see ICSH);[37] two are described in the following.

Washing the red cells

Centrifuge the anticoagulated blood at 1200–1500 *g* for 5 min and remove the plasma together with the buffy coat layer.

Resuspend the cells in 9 g/l NaCl (saline) and repeat the procedure three times. This will remove about 80–90% of the leucocytes.

This simple method is adequate in most instances when more complicated manoeuvres are impractical, but it has the disadvantage that some of the reticulocytes and young red cells are lost together with the buffy coat. In addition, the remaining leucocytes may still be sufficient to cause misleading results – for instance, in PK deficiency. Therefore, ideally the following method should be adopted.

Filtration through microcrystalline cellulose mixtures

Pure red cell suspensions can be made from whole blood by filtering the blood through a mixed bed of microcrystalline cellulose (mean size 50 μm) and α cellulose. Mix approx. 0.5 g of each type of cellulose with 20 ml of ice-cold saline; this gives sufficient slurry for 3–5 columns. The barrel of a 5 ml syringe is used as a column. The outlet of the syringe is blocked with absorbent cotton wool, equal in volume to the 1 ml mark on the barrel. Pour the well-shaken slurry into the column to give a bed volume of 1–2 ml after the saline has run through. Wash the bed with 5 ml of saline to remove any 'fines.' When the saline has run through, pipette 1–2 ml of whole blood onto the column, taking care not to disturb the bed. Collect the filtrate, and once the blood has completely run into the bed, wash the column through with 5–7 ml of saline. The column should be made freshly for each batch of enzyme assays and used promptly.

By this method, about 99% of the leucocytes and about 90% of the platelets are removed. About 97% of the red cells are recovered and reticulocytes are not removed selectively. The procedure should not alter the age or size distribution of the recovered red cells compared to native blood. This should be checked with each new batch of cellulose by counting reticulocytes.

Wash the cells collected from the column twice in 10 volumes of ice-cold saline and finally resuspend them in the saline to give a 50% suspension.

Determine the Hb and/or red cell count in a sample of the suspension.

Preparation of haemolysate

Mix 1 volume of the washed or filtered suspension with 9 volumes of lysing solution consisting of 2.7 mmol/l EDTA, pH 7.0, and 0.7 mmol/l 2-mercaptoethanol (100 mg of EDTA disodium salt and 5 μl of 2-mercaptoethanol in 100 ml of water); adjust the pH to 7.0 with HCl or NaOH.

Ensure complete lysis by freeze-thawing. Rapid freezing is achieved using a dry-ice acetone bath or methanol that has been cooled to −20 °C. Thawing is achieved in a water bath at 25 °C or simply in water at room temperature. Usually the haemolysate is ready for use without further centrifugation, but a 1-min spin in a Microfuge (www.sigma-centrifuges.com) is recommended to remove any turbidity (this may be unsuitable for some red cell enzymes that are stroma-bound). Dilutions, when necessary, are carried out in the lysing solution. The haemolysate should be prepared freshly for each batch of enzyme assays. Most enzymes in haemolysates are stable for 8 h at 0 °C, but it is best to carry out assays immediately. G6PD is one of the least stable enzymes in this haemolysate, and its assay should be

conducted within 1 or 2 h of the lysate being prepared. The storing of frozen cells or haemolysates is not recommended; it is preferable to store whole blood in ACD.

Control samples

Control samples should always be assayed at the same time as the test samples even when a normal range for the various enzymes has been established.

Take the control samples of blood at the same time as the test samples and treat them in the same way. When receiving samples from outside sources, always ask for a normal 'shipment control' to be included.

Reaction buffer

The ICSH recommendation is for a Tris-HCl/EDTA buffer that is appropriate for all the common enzyme assays. The buffer consists of 1 mol/l Tris-HCl and 5 mmol/l Na_2EDTA, the pH being adjusted to 8.0 with HCl.

Dissolve 12.11 g of Tris(hydroxymethyl)methylamine and 168 mg of Na_2EDTA in water; adjust the pH to 8.0 with 1 mol/l HCl and bring the volume to 100 ml at 25 °C.

Only two assays will be described in detail – those for G6PD and PK. However, the principles of these assays apply to all other enzyme assays. The assays are carried out in a spectrometer at a wavelength of 340 nm unless otherwise indicated. A final reaction mixture of 1.0 ml (or 3.0 ml) is suitable, the quantities given in the text being for 1.0 ml reaction mixtures unless otherwise stated. All dilutions of auxiliary enzymes are made in the lysing solution, and all working materials should be kept in an ice bath until ready for use. The assays are carried out at a controlled temperature, 30 °C being the most appropriate. Cuvettes loaded with the assay reagents should be preincubated at this temperature for 10 min before starting the reaction. In most cases, the reaction is started by the addition of substrate. Many spectrometers have a built-in or attached recorder, by which the absorbance changes can be conveniently measured. If no recorder is available, visual readings should be made every 60 s. In any case, the reaction should be followed for 5–10 min and it is essential to ensure that during this time the change in absorbance is linear with time.

G6PD assay

The reactions involving G6PD have already been described (p. 238). The activity of the enzyme is assayed by following the rate of production of NADPH, which, unlike NADP, has a peak of UV light absorption at 340 nm.

Method

The assays are carried out at 30 °C; the cuvettes containing the first four reagents and water are incubated for 10 min before starting the reaction by adding the substrate, as shown in Table 12-4. Commercial kits are also available (www.trinitybiotech.com).

TABLE 12-4

GLUCOSE-6-PHOSPHATE DEHYDROGENASE ASSAY

Reagents	Assay (µl)	Blank (µl)
Tris-HCl EDTA buffer, pH 8.0	100	100
$MgCl_2$ 100 mmol/l	100	100
NADP 2 mmol/l	100	100
1:20 haemolysate	20	20
Water	580	680
Start reaction by adding: G6P 6 mmol/l	100	–

EDTA, ethylenediaminetetra-acetic acid; G6P, glucose-6-phosphate; NADP, nicotinamide adenine dinucleotide phosphate.

The change in absorbance following the addition of the substrate is measured over the first 5 min of the reaction. The value of the blank is subtracted from the test reaction, either automatically or by calculation.

Calculation of enzyme activity

The activities of the enzymes in the haemolysate are calculated from the initial rate of change of NADPH accumulation:

$$\text{G6PD activity in the lysate (in mol/ml)} = \Delta A / \text{min} \times \frac{10^3}{6.22}$$

where 6.22 is the mmol extinction coefficient of NADPH at 340 nm and 10^3 is the factor appropriate for the dilutions in the reaction mixture. Results are expressed per 10^{10} red cells, per ml red cells or per g haemoglobin by reference to the respective values obtained with the washed red cell suspension. However, the ICSH recommendation is to express values per g haemoglobin and it is ideal to determine the Hb of the haemolysate directly. When doing this, use a haemolysate to Drabkin solution ratio of 1:25.

G6PD is very stable and, with most variants, venous blood may be stored in ACD for up to 3 weeks at 4 °C without loss of activity. A well conserved sample may therefore still be of diagnostic utility with the caveat some enzyme-deficient variants lose activity more rapidly, which will cause the deficiency to appear more severe.

Normal values

The normal range for G6PD activity should be determined in each laboratory. If the ICSH method is used, values should not differ widely from the given values. Results are expressed in enzyme units (eu), which are the µ moles (µmol) of substrate converted per min.

For adults, these values are 8.83 ± 1.59 eu/g haemoglobin at 30 °C. However, newborns and infants may have

enzyme activity that deviates appreciably from the adult value.[37,38] In one study, the newborn mean activity was about 150% of the adult mean.[39]

Interpretation of results

In assessing the clinical relevance of a G6PD assay result, three important facts must be kept in mind:

1. The gene for G6PD is on the X-chromosome, and therefore males, having only one G6PD gene, can be only either normal or deficient hemizygotes. By contrast, females, who have two allelic genes, can be either normal homozygotes or heterozygotes with 'intermediate' enzyme activity or deficient homozygotes.
2. Red cells are likely to haemolyse on account of G6PD deficiency only if they have less than about 20% of the normal enzyme activity.
3. G6PD activity falls off markedly as red cells age. Therefore, whenever a blood sample has a young red cell population, G6PD activity will be higher than normal, sometimes to the extent that a genetically deficient sample may yield a value within the normal range. This usually, but not always, will be associated with a marked reticulocytosis.

In practice, the following notes may be useful:

1. In males, diagnosis does not present difficulties in most cases because the demarcation between normal and deficient subjects is sharp. There are very few acquired causes of reduced G6PD activity (an exception is pure red cell aplasia where there is reticulocytopenia), whereas an increased G6PD activity is found in all acute and chronic haemolytic states with reticulocytosis. Therefore a G6PD value below a well-established normal range almost always indicates G6PD deficiency. A value in the low-normal range in the face of reticulocytosis should also raise the suspicion of G6PD deficiency because, with reticulocytosis, G6PD activity should be *higher* than normal. In such cases, G6PD deficiency can be confirmed by repeating the assay when reticulocytosis has subsided, by measuring the activity of a second red cell enzyme affected similarly by reticulocytosis, such as hexokinase, by assay of G6PD activity in older red cells after density fractionation or by testing other family members.
2. In females, all the same criteria apply, with the added consideration that heterozygosity can *never* be rigorously ruled out by a G6PD assay; for this purpose, the cytochemical test described on p. 241 is more useful than a spectrometric assay, and a counsel of perfection is to use the two in conjunction with each other and with family studies. However, in most cases, a normal value in a female means that she is a normal homozygote, and a value of <10% of normal means that she is a deficient homozygote (Table 12-5); however a few heterozygotes fall in one or other of these ranges because of the 'extreme phenotypes' that can be associated with an unbalanced ratio of the mosaicism consequent on X-chromosome inactivation. Any value between 10% and 90% of normal usually means a heterozygote, except for the complicating effect of reticulocytosis. As far as the clinical significance of heterozygosity for G6PD deficiency is concerned, it is important to remember that, because of mosaicism, a fraction of red cells in heterozygotes (on the average, 50%) is as enzyme-deficient as in a hemizygous male and therefore susceptible to haemolysis. The severity of potential clinical complications is roughly proportional to the fraction of deficient red cells. Therefore, within the heterozygote range, the actual value of the assay (or the proportion of deficient red cells estimated by the cytochemical test) correlates with the risk of haemolysis. During an acute episode, heterozygotes may be missed if their deficient red cells have undergone haemolysis, thus leaving only the normal population in circulation. This can occur before a reticulocyte response becomes apparent and may result in G6PD activity within the normal range.

TABLE 12-5

GLUCOSE-6-PHOSPHATE DEHYDROGENASE IN VARIOUS CLINICAL SITUATIONS (ACTIVITY IN ENZYME UNITS [EU] PER G HAEMOGLOBIN)

Male genotypes	Gd^+	Gd^-	
Female genotypes	Gd^+/Gd^+	Gd^-/Gd^-	Gd^+/Gd^-
In health	7–10	<2	2–7
In increased haemolysis unrelated to G6PD deficiency	15	4	4–9
During recovery from G6PD-related anaemia	–	6.5	6–10

G6PD, glucose-6-phosphate dehydrogenase.
The values quoted are examples. *Gd+* designates an allele encoding normal G6PD; *Gd–* designates an allele encoding a variant associated with G6PD deficiency.

Identification of G6PD variants

There are many variants of G6PD in different populations with enzyme activities ranging from nearly 0% to 500% of normal activity.[40] Classification and provisional identification of variants are based on their physicochemical and enzymic characteristics.[41] Criteria were laid down by a World Health Organisation scientific group[23] for the minimum requirements for identification of such variants and these recommendations were subsequently revised.[42] The tests are carried out on male hemizygotes and are as follows:

Red cell G6PD activity
Electrophoretic migration
Michaelis constant (K_m) for G6PD

Relative rate of utilisation of 2-deoxy-G6P (2dG6P)
Thermal stability

The full amino acid sequence of G6PD has been established and definitive identification can be made by sequence analysis at the DNA level.[43,44] Diagnosis of G6PD deficiency by molecular analysis may be clinically useful when a patient has received a large volume of transfused blood or when a reticulocytosis results in a normal enzyme assay level; also, females who are heterozygous deficient can readily be identified.

PYRUVATE KINASE ASSAY

Many variants of PK have deficient enzyme activity *in vivo*.[45,46] In most cases, deficient activity can be identified by simple enzyme assay. However, PK activity in red cells is subject to regulation by a number of effector molecules. With some PK variants, the maximum velocity (V_{max}) of the enzyme is normal or nearly so, but at the low-substrate concentrations found *in vivo*, PK activity may be sufficiently low to cause haemolysis, either because affinity for the substrates, phosphoenolpyruvate (PEP) and adenosine diphosphate (ADP), is low or because binding of the important allosteric ligand, fructose-1,6-diphosphate, is altered. Some of these unusual variants can be identified by carrying out the enzyme assay not only under standard conditions but also at low-substrate concentrations. Functional PK deficiency can also be identified by finding high concentrations of the substrates immediately above the block in the glycolytic pathway, particularly 2,3-DPG.[47] (For measurement of 2,3-DPG, see p. 249).

PK deficiency is inherited as an autosomal recessive condition.

Method

The preparation of haemolysate, buffer and lysing solution is exactly the same as for the G6PD assay. In the PK assay it is particularly important to remove as many contaminating leucocytes and platelets as possible because these cells may be unaffected by a deficiency affecting the red cells and may have high activities of PK. The principle of the assay is as follows:

$$\text{PEP} + \text{ADP} \xrightarrow{\text{PK}} \text{pyruvate} + \text{ATP}$$

The pyruvate so formed is reduced to lactate in a reaction catalysed by lactate dehydrogenase (LDH) with the conversion of NADH (reduced form of nicotinamide adenine dinucleotide) to NAD:

$$\text{pyruvate} + \text{NADH} \xrightarrow{\text{LDH}} \text{lactate} + \text{NAD}$$

To ensure that this secondary reaction is not rate limiting, LDH is added in excess to the reaction mixture and the PK activity is measured by the rate of fall of absorbance at 340 nm.

The reaction conditions are established in a 1 ml cuvette at 30 °C by adding all the reagents shown in Table 12-6, except the substrate PEP, to the cuvette and incubating them at 30 °C for 10 min before starting the reaction by the addition of the PEP.

The amounts to be added for low-substrate conditions are also shown in Table 12-6.

The change in absorbance (A) is measured over the first 5 min and the activity of the enzyme in micromoles of NADH reduced/min/ml haemolysate is calculated as follows:

$$\frac{\Delta A / \text{min}}{6.22} \times 10$$

where 6.22 is the millimolar extinction coefficient of NADH at 340 nm.

Express results as for G6PD.

A blank assay should be carried out to be certain that the LDH is free of PK activity. Use the 2-mercapto-ethanol-EDTA stabilizing solution (p. 243) in

TABLE 12-6

REAGENTS FOR PYRUVATE KINASE ASSAY

Reagents	Assay (µl)	Blank (µl)	Low-S (µl)
Tris-HCl EDTA buffer, pH 8.0	100	100	100
KCl 1 mol/l	100	100	100
$MgCl_2$ 100 mmol/l	100	100	100
NADH 2 mmol/l	100	100	100
ADP, neutralised 30 mmol/l	50	–	20
LDH 60 u/ml	100	100	100
1:20 haemolysate	20	20	20
Water	330	380	455
PEP 50 mmol/l	100	100	5

ADP, adenosine diphosphate; EDTA, ethylenediaminetetra-acetic acid; LDH, lactate dehydrogenase; Low-S, low-substrate conditions; NADH, reduced form of nicotinamide adenine dinucleotide; PEP, phosphoenolpyruvate.

place of haemolysate for both the blank and system mixtures. If no change in absorbance is observed, indicating that the LDH is free of contaminating PK, it is unnecessary to recheck on subsequent assays. Otherwise, the blank rate must be subtracted in computing the true enzyme activity each time.

Normal values

As with all enzyme assays, a normal range should be determined for each laboratory. Values should however, not be widely different between laboratories if the ICSH methods are used. The normal range of PK activity at 30 °C is 10.3 ± 2 eu/g haemoglobin. At a low-substrate concentration, the normal activity is 15 ± 3% of that at the high-substrate concentration. Mean neonatal value is about 140% that of adults.[39]

Interpretation of results

PK, like G6PD, is an age-dependent red cell enzyme. But unlike G6PD deficiency, PK deficiency is usually associated with *chronic* haemolysis. Therefore patients in whom PK deficiency is suspected almost invariably have a reticulocytosis, and if their PK level is below the normal range, they can be considered to be PK deficient. Thus, once the technique and normal values are well established in a laboratory, and provided controls are always included, the main problem is of underdiagnosis rather than of overdiagnosis of PK deficiency. One additional way to pick up abnormal variants has been included in the method recommended (i.e. the use of low-substrate concentrations). Even so, PK deficiency may be missed because marked reticulocytosis may increase PK activity significantly. This means that a PK activity in the normal range in the presence of a marked reticulocytosis is highly suspicious of inherited PK deficiency (because with reticulocytosis the activity ought to be *higher* than normal). In such cases, the importance of family studies cannot be overemphasised. Heterozygotes have about 50% of the normal PK activity, sometimes less, but they do not suffer from haemolysis. Therefore, the heterozygous parents of a patient may have a red cell PK activity lower than that of their homozygous PK-deficient offspring; this finding may clinch the diagnosis. In this context, assay of an alternative red cell age-dependent enzyme (e.g. G6PD or hexokinase) may be a useful aid to interpretation.

ESTIMATION OF REDUCED GLUTATHIONE

The red cell has a high concentration of the sulphydryl-containing tripeptide GSH. An important function of GSH in the red cell is the detoxification of low levels of hydrogen peroxide, which may form spontaneously or as a result of drug administration. GSH may also function in maintaining the integrity of the red cell by reducing sulphydryl groups of haemoglobin, membrane proteins and enzymes that may have become oxidised. Maintenance of normal levels of GSH is a major function of the hexose monophosphate shunt. Reduction of GSSG (oxidised glutathione) back to the functional GSH is linked to the rate of reduction of $NADP^+$ in the initial step of the shunt.[48]

Principle

The method described is based on the development of a yellow colour when 5,5′-dithiobis (2-nitrobenzoic acid) (Ellman reagent, DTNB) is added to sulphydryl compounds. The colour that develops is fairly stable for about 10 min and the reaction is little affected by variation in temperature.

The reaction is read at 412 nm. GSH in red cells is relatively stable, and venous blood samples anticoagulated with ACD maintain GSH levels for up to 3 weeks at 4 °C. GSH is slowly oxidised in solution, so only fresh lysates should be used for the assay.

Reagents

Lysing solution. Disodium EDTA, 1 g/l.

Precipitating reagent. Metaphosphoric acid (sticks), 1.67 g; Na_2EDTA, 0.2 g; NaCl, 30 g; water to 100 ml.

Solution is more rapid if the reagents are added to boiling water and the volume is made up after cooling. This solution is stable for at least 3 weeks at 4 °C. If any EDTA remains undissolved, the clear supernatant should be used.

Disodium hydrogen phosphate. 300 mmol/l. $Na_2HPO_4.12H_2O$, 107.4 g/l or $Na_2HPO_4.2H_2O$, 53.4 g/l or anhydrous Na_2HPO_4, 4.6 g/l.

Sodium citrate. 34 mmol/l, pH 8.0. Dissolve 1 g of sodium citrate (trisodium salt) in 100 ml water.

DTNB reagent. Dissolve 20 mg of DTNB in 100 ml of 34 mmol/l sodium citrate solution.

The solution is stable for up to 3 months at 4 °C.

Glutathione standards. When standard curves are constructed, suitable dilutions are made from a 1.62 mmol/l (0.5 g/l) stock solution of GSH.

The stock solution should be made freshly with degassed (boiled) water or saline for each run because GSH oxidises slowly in solution.

Method

Add 0.2 ml of well-mixed, anticoagulated blood of which the PCV, red cell count and Hb have been determined, to 1.8 ml of lysing solution and allow to stand at room temperature for no more than 5 min for lysis to be completed, because glutathione oxidises very rapidly when exposed to air.

Add 3 ml of precipitating solution, mix the solution well and allow to stand for a further 5 min.

After re-mixing, filter through a single-thickness Whatman No. 42 filter paper.

Add 1 ml of clear filtrate to 4 ml of freshly made Na_2HPO_4 solution. Record the absorbance at 412 nm (A_1). Then add 0.5 ml of the DTNB reagent and mix well by inversion.

The colour develops rapidly but begins to fade after about 10 min so the second reading should be within this period. Record the absorbance at 412 nm (A_2) and calculate the change in absorbance (ΔA^{412}).

A reagent blank is made using saline or plasma instead of whole blood.

If assays are carried out frequently, it is not necessary to construct standard curves for each batch. They are, however, essential initially to calibrate the apparatus used and should be done regularly to check the suitability of the reagents. Suitable dilutions of GSH are achieved by substituting 5, 10, 20 and 40 µl of the 1.62 mmol/l stock solution (make up to 0.2 ml with lysing solution) for the blood in the reaction.

Calculation

Determination of extinction coefficient (ε). The molar extinction coefficient of the chromophore at 412 nm is 13 600. This only applies when a narrow band wavelength is available. When a broader waveband is used, the extinction coefficient is lower.

The system may be calibrated by comparing the extinction absorbance in the test system (D_2) with that obtained in a spectrometer with a narrow band at 412 nm (D_1). The derived correction factor, E_1, is given by D_1/D_2 and is constant for the test system.

Calculation of GSH concentration

The amount of GSH in the cuvette sample (GSH_c) is given by the following:

$$\Delta A^{412} \times \frac{E_1}{\varepsilon} \times 5.5\,\mu mol$$

The concentration of GSH in the whole blood sample is as follows:

$$\frac{GSH_c \times 5}{0.2}\,\mu mol / ml$$

The unit is often expressed in terms of mg/dl of red cells. The molecular weight of GSH is 307. Thus, GSH in mg/dl packed red cells is given by the following:

$$\frac{GSH_c \times 5}{0.2} \times \frac{1}{PVC} \times 307 \times 100$$

Normal range

The normal range may be expressed in a number of ways (e.g. 6.57 ± 1.04 µmol/g haemoglobin or 223 ± 35 µmol (or 69 ± 11 mg)/dl packed red cells). Neonatal mean value is about 150% that of adults.[39]

Significance

Glutathione replenishment in mature red cells is accomplished through the consecutive action of two enzymes: γ-glutamylcysteine synthetase and glutathione synthetase. Although very rare, hereditary deficiency of either enzyme virtually abolishes the synthesis of GSH. The deficient cells are very prone to oxidative destruction and are short lived, resulting in a nonspherocytic haemolytic anaemia.

Increases in GSH have been described in various conditions such as dyserythropoiesis, primary myelofibrosis, pyrimidine 5′-nucleotidase deficiency and other rare congenital haemolytic anaemias of unknown aetiology.

Glutathione stability test

Principle

In normal subjects, incubation of red cells with the oxidising drug acetylphenylhydrazine has little effect on the GSH content because its oxidation is reversed by glutathione reductase, which in turn relies on G6PD for a supply to NADPH. Therefore, in subjects who are G6PD deficient, the stability of GSH is significantly reduced.

Reagents

Acetylphenylhydrazine. 670 mmol/l. Dissolve 100 mg in 1 ml of acetone.

Transfer 0.05 ml volumes (containing 5 mg of acetylphenylhydrazine) by pipette to the bottom of 12×75 mm glass tubes. Dry the contents of the tubes in an incubator at 37 °C, stopper and store in the dark until used.

Method

Venous blood, anticoagulated with EDTA, heparin or ACD, may be used; it may be freshly collected or previously stored at 4 °C for up to 1 week.

Add 1 ml to a tube containing acetylphenylhydrazine and place another 1 ml in a similar tube not containing the chemical. Invert the tubes several times and then incubate them at 37 °C.

After 1 h, mix the contents of the tubes once more and incubate the tubes for a further 1 h. At the end of this time determine and compare the GSH concentration in the test sample and in the control sample.

Interpretation

In normal adult subjects, red cell GSH is lowered by not more than 20% by incubation with acetylphenylhydrazine. In subjects who are G6PD deficient, it is lowered by more than this: in heterozygotes (females), the fall may amount to about 50%, whereas in hemizygotes (males) the fall is often much greater, and almost all may be lost.

The test is not specific for G6PD deficiency and other rare defects of the pentose phosphate pathway may give abnormal results.

Glutathione and glutathione stability in infants

During the first few days after birth, the red cells have a normal or high content of GSH. On the addition of acetylphenylhydrazine, the GSH is unstable in both normal infants and infants who are G6PD deficient. In normal infants, however, the instability can be corrected by the addition of glucose, and by the time the normal infant is 3–4 days old, the cells behave like adult cells.[49,50]

2,3-DIPHOSPHOGLYCERATE

The importance of the high concentration of 2,3-DPG in the red cells of man was recognised at about the same time by Chanutin and Curnish[51] and Benesch and Benesch.[52] 2,3-DPG binds to a specific site in the β chain of haemoglobin, and it decreases its oxygen affinity by shifting the balance of the so-called T and R conformations of the molecule. The higher the concentration of 2,3-DPG, the greater the partial pressure of oxygen (pO_2) needed to produce the same oxygen saturation of haemoglobin. This is reflected in a 2,3-DPG-dependent shift in the oxygen dissociation curve.

Measurement of the concentration of 2,3-DPG in red cells may also be useful in identifying the probable site of an enzyme deficiency in the metabolic pathway. In general, enzyme defects cause an increase in the concentration of metabolic intermediates above the level of the block and a decrease in concentration below the block. Thus 2,3-DPG is increased in PK deficiency and decreased in hexokinase deficiency. In most other disorders of the glycolytic pathway, however, the 2,3-DPG concentration is normal because increased activity through the pentose phosphate pathway allows a normal flux of metabolites through the triose part of the glycolytic pathway.

Measurement of red cell 2,3-diphosphoglycerate

Various methods have been used to assay 2,3-DPG. Krimsky[53] used the catalytic properties of 2,3-DPG in the conversion of 3-phosphoglycerate (3PG) to 2-phosphoglycerate (2PG) by phosphoglycerate mutase (PGM). At very low concentrations of 2,3-DPG, the rate of conversion is proportional to the concentration of 2,3-DPG. This method is elegant and extremely sensitive but too cumbersome for routine use. A fluorometric method was described by Lowry *et al.*,[54] and this has been modified for spectrometry. Rose and Liebowitz[55] found that glycolate-2-phosphate increased the 2,3-DPG phosphatase activity of PGM, and a quantitative assay of the substrate, 2,3-DPG, was evolved on this basis.

Principle

2,3-DPG is hydrolysed to 3PG by the phosphatase activity of PGM stimulated by glycolate-2-phosphate. This reaction is linked to the conversion of NADH to NAD by glyceraldehyde-3-phosphate dehydrogenase (Ga3PD) and phosphoglycerate kinase (PGK):

$$\text{2,3-DPG} \xrightarrow[\text{(glycolate-2-phosphate)}]{\text{2,3-DPG phosphatase}} \text{3PG} + \text{Pi}$$

$$\text{3PG} + \text{ATP} \xrightarrow{\text{PGK}} \text{1,2-DPG} + \text{ADP}$$

$$\text{1,3-DPG} + \text{NADH} \xrightarrow{\text{Ga3PD}} \text{Ga3P} + \text{Pi} + \text{NAD}^+$$

The fail in absorbance at 340 nm, as NADH is oxidised, is measured.

Reagents

Triethanolamine buffer. 0.2 mol/l, pH 8.0.

Dissolve 9.3 g of triethanolamine hydrochloride in *c.* 200 ml of water; then add 0.5 g of disodium EDTA and 0.25 g of $MgSO_4.7H_2O$. Adjust the pH to 8.0 with 2 mol/l KOH (approx. 15 ml) and make up the volume to 250 ml with water.

ATP, sodium salt. 20 mg/ml. Dissolved in buffer, this is stable for several months when frozen.

NADH, sodium salt. 10 mg/ml. When dissolved in buffer, this is relatively unstable and should be made freshly each day.

Glyceraldehyde-3-phosphate dehydrogenase/phosphoglycerate kinase. Mixed crystalline suspension in ammonium sulphate.

Phosphoglycerate mutase. Crystalline suspension from rabbit muscle in ammonium sulphate (*c.* 2500 u/ml).

Glycolate-2-phosphate. 2-Phosphoglycolic acid, 10 mg/ml. After dissolving in water, this is stable for several months if kept frozen.

Method

Freshly drawn blood in EDTA or heparin may be used. If there is an unavoidable delay in starting the assay, blood (4 volumes) should be added to CPD anticoagulant (1 volume) and stored at 4 °C. A control blood sample should be taken at the same time.

2,3-DPG levels are stable for 48 h if the blood is stored in this way. The Hb, red cell count and PCV should be measured on part of the sample. It is not necessary to remove leucocytes or platelets.

Deproteination. Add 1 ml of blood to 3 ml of ice-cold 80 g/l trichloroacetic acid (TCA) in a 10 ml conical centrifuge tube.

Shake the tube vigorously, preferably on an automatic rotor mixer, and then allow to stand for 5–10 min for

complete deproteination. The shaking is important, otherwise some of the precipitated protein will remain on the surface of the mixture.

Centrifuge at about 1200 *g* for 5–10 min at 4 °C to obtain a clear supernatant. The 2,3-DPG in the supernatant is stable for 2–3 weeks when stored at 4 °C; it is stable indefinitely if frozen.

Reaction

Deliver the reagents into a silica or high-quality glass cuvette, with a 1 cm light path. The quantities in Table 12-7 are for a 4 ml cuvette:

Warm the mixtures at 30 °C for 10 min and record the absorbance of both test and blank mixtures at 340 nm. Then start the reaction by the addition of 100 µl of glycolate-2-phosphate.

Remeasure the absorbance (at 35 min) of the test and blank mixtures on completion of the reaction.

Make further measurements after another 5 min to make sure the reaction is complete.

Only one blank is required for each batch of test samples.

Calculation

2,3-DPG (µmol/ml blood)

$$= (\Delta A \text{ test} - \Delta A \text{ blank}) \times \frac{3.10}{6.22} \times 16$$

$$= (\Delta A \text{ test} - \Delta A \text{ blank}) \times 8 = D$$

where 3.10 = the volume of reaction mixture, 6.22 = mmolar extinction coefficient of NADH at 340 nm and 16 = dilution of original blood sample (1 ml in 3.0 ml of TCA, 0.25 ml added to cuvette).

The results of 2,3-DPG assays are best expressed in terms of haemoglobin content or red cell volume. Thus, if the result of the previous calculation is represented by D, then:

TABLE 12-7

QUANTITIES FOR A 4 ML CUVETTE FOR DEPROTEINATION

	Test	Blank
Triethanolamine buffer	2.50 ml	2.50 ml
ATP	100 µl	100 µl
NADH	100 µl	100 µl
Deproteinised extract	250 µl	–
Ga-3-PD/PGK mixture	30 µl	30 µl
PGM	20 µl	20 µl
Water	–	250 µl
Total volume	3.00 ml	3.00 ml

Ga-3-PD/PGK, glyceraldehyde-3-phosphate dehydrogenase/phosphoglycerate kinase; PGM, phosphoglycerate mutase.

$$\frac{D \times 1000}{(Hb)} = 2,3\text{-DPG in } \mu\text{mol/g haemoglobin}$$

or

$$\frac{D \times 1000}{(Hb)} \times \frac{64}{1000} = 2,3\text{-DPG in } \mu\text{mol}/\mu\text{mol Hb}$$

and

$$D \times \frac{1}{PCV} = 2,3\text{-DPG in } \mu\text{mol/ml (packed) red cells}$$

where Hb = Hb in g/l of whole blood and 64 is the molecular weight of haemoglobin $\times 10^{-3}$.

The molar ratio of 2,3-DPG to haemoglobin in normal blood is about 0.75:1.

Normal range

The normal range is 4.5 to 5.1 µmol/ml packed red cells or 10.5 to 16.2 µmol/g haemoglobin. Neonatal values are about 20% lower than adult.[39]

Each laboratory should determine its own normal range.

Significance of 2,3-DPG concentration

An increase in 2,3-DPG concentration is found in most conditions in which the arterial blood is undersaturated with oxygen, as in congenital heart and chronic lung diseases, in most acquired anaemias, at high altitudes, in alkalosis and in hyperphosphataemia. Decreased 2,3-DPG levels occur in hypophosphataemic states and in acidosis.

Acidosis, which shifts the oxygen dissociation curve to the right, causes a fall in 2,3-DPG, so that the oxygen dissociation curve of whole blood from patients with chronic acidosis (such as patients in diabetic coma or pre-coma) may have nearly normal dissociation curves. A rapid correction of the acidosis will lead to a major shift of the curve to the left (i.e. to a marked increase in the affinity of haemoglobin for oxygen, which may lead to tissue hypoxia). Caution should therefore be exercised in correcting acidosis. Measurement of oxygen dissociation is described below.

From the diagnostic point of view, the main importance of 2,3-DPG determination is (1) in haemolytic anaemias and (2) in the interpretation of changes in the oxygen affinity of blood.

1. As already mentioned, increased or decreased 2,3-DPG may be associated with glycolytic enzyme defects, and increased 2,3-DPG (up to 2 to 3 times normal) is particularly characteristic of most patients with PK deficiency. Although this finding certainly cannot be regarded as diagnostic, a normal or low 2,3-DPG makes PK deficiency most unlikely.
2. Whenever a shift in the oxygen dissociation curve is observed and an abnormal haemoglobin with altered

oxygen affinity is suspected, determination of 2,3-DPG is essential. Indeed, there is a simple correlation between 2,3-DPG level and p_{50}, from which it is possible to work out whether any change in p_{50} is explained by an altered level of 2,3-DPG.[56]

2,3-DPG levels are generally slightly lower than normal in HS, and this probably accounts for the slight erythrocytosis that is sometimes seen after splenectomy. Extremely low red cell 2,3-DPG concentration associated with erythrocytosis has been reported in a kindred with complete 2,3-DPG mutase deficiency.[57]

OXYGEN DISSOCIATION CURVE

The oxygen dissociation curve is the expression of the relationship between the partial pressure of oxygen and oxygen saturation of haemoglobin. Details of this relationship and the physiological importance of changes in this relationship were worked out in detail at the beginning of the last century by the great physiologists Hüfner, Bohr, Barcroft, Henderson and many others. Their work was summarised by Peters and Van Slyke in *Quantitative Clinical Chemistry*.[58] The relevant chapters of this book have been reprinted and it would be difficult to improve their description of the importance of the oxygen dissociation curve.

The physiological value of haemoglobin as an oxygen carrier lies in the fact that its affinity for oxygen is so nicely balanced that in the lungs haemoglobin becomes 95%–96% oxygenated, whereas in the tissues and capillaries it can give up as much of the gas as is demanded. If the affinity were much less, complete oxygenation in the lungs could not be approached; if it were greater, the tissues would have difficulty in removing from the blood the oxygen they need. Because the affinity is adjusted as it is, both oxyhaemoglobin and reduced haemoglobin exist in all parts of the circulation but in greatly varied proportions.

Determining the oxygen dissociation curve

Determination of the oxygen dissociation curve depends on two measurements: pO_2 with which the blood is equilibrated and the proportion of haemoglobin that is saturated with oxygen. Methods for determining the dissociation curve fall into three main groups:

1. The pO_2 is set by the experimental conditions, and the percentage saturation of haemoglobin is measured.
2. The percentage saturation is predetermined by mixing known proportions of oxygenated and deoxygenated blood, and the pO_2 is measured.
3. The change in oxygen content of the blood is plotted continuously against pO_2 during oxygenation or deoxygenation, and the percentage saturation is calculated.

The multiplicity of methods available for measuring the oxygen dissociation curve suggests that no method is ideal. The advantages and disadvantages of the various techniques have been reviewed.[59,60] The standard method with which new methods are compared is the gasometric method of Van Slyke and Neill.[61] This method is slow, demands considerable expertise and is not suitable for most haematology laboratories. Commercial instruments are now available for performing the test and drawing the complete oxygen dissociation curve, for example, Hemox Analyzer (www.tcssci.com). Such analysers are extremely quick and accurate and are therefore ideal for laboratories performing multiple determinations. Approximate measurement of oxygen saturation of haemoglobin can also be obtained at the bedside by noninvasive pulse oximetry.

Interpretation

Figure 12-6 shows the sigmoid nature of the oxygen dissociation curve of haemoglobin A and the effect of hydrogen ions on the position of the curve. A shift of the curve to the right indicates decreased affinity of the haemoglobin for oxygen and hence an increased tendency to give up oxygen to the tissues. A shift to the left indicates increased affinity and so an increased tendency for haemoglobin to take up and retain oxygen. Hydrogen ions, 2,3-DPG and some other organic phosphates such as ATP shift the curve

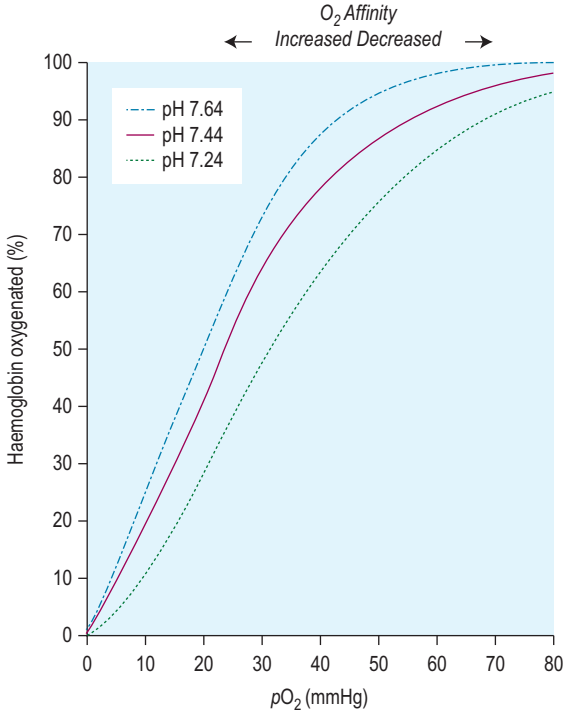

FIGURE 12-6 Effect of pH on the oxygen dissociation curve.

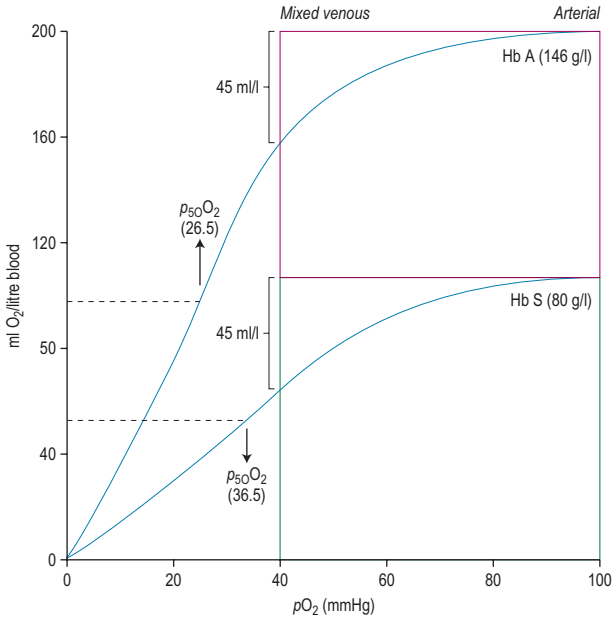

FIGURE 12-7 Effect of O_2 affinity on O_2 delivery to tissues.

to the right. The amount by which the curve is shifted may be expressed by the $p_{50}O_2$ (i.e. the partial pressure of oxygen at which the haemoglobin is 50% saturated).

The oxygen affinity, as represented by the $p_{50}O_2$, is related to compensation in haemolytic anaemias;[62] 1 g of Hb can carry about 1.34 ml of O_2. Figure 12-7 shows the O_2 dissociation curves of Hb A and Hb S plotted according to the volume of oxygen contained in 1 litre of blood when the Hb is 146 g/l and 80 g/l, respectively. The $p_{50}O_2$ of haemoglobin A is given as 26.5 mmHg (3.5 kPa) and of haemoglobin S as 36.5 mmHg (4.8 kPa). It will be seen that in the change from arterial to venous saturation, the same volume of oxygen is given up despite the difference in Hb. Patients with a high $p_{50}O_2$ achieve a stable Hb at a lower level than normal and this should be taken into account when planning transfusion for these patients.

Bohr effect

An increase in CO_2 concentration produces a shift to the right (i.e. a decrease in oxygen affinity). This effect, originally described by C. Bohr,[63] is mainly a result of changes in pH, although CO_2 itself has some direct effect. The Bohr effect is given a numeric value, $\Delta\log p_{50}O_2/\Delta pH$, where $\Delta\log p_{50}O_2$ is the change in $p_{50}O_2$ produced by a change in pH (ΔpH). The normal value of the Bohr effect at physiological pH and temperature is about 0.45.

Hill constant (‘*n*’)

The Hill constant or coefficient (‘*n*’) represents the number of molecules of oxygen that combine with one molecule of haemoglobin.[64] Experiments showed that the value was 2.8–3.0 rather than the expected 4. The explanation for this lies in the effect of binding one molecule of oxygen by haem on the affinity for oxygen of further haem groups, the so-called allosteric (cooperativity) effect of haem–haem interaction: ‘*n*’ is a measure of this effect and the calculation of the ‘*n*’ value helps in identifying abnormal haemoglobins, the molecular abnormality of which leads to abnormal haem–haem interaction.[65]

Acquired Haemolytic Anaemias

Nay Win • Stephen J. Richards

CHAPTER OUTLINE

ASSESSING THE LIKELIHOOD OF ACQUIRED HAEMOLYTIC ANAEMIA

Haemolytic anaemia may be suspected from either clinical or laboratory abnormalities. Suggestive clinical features include anaemia, jaundice and splenomegaly. Other relevant clinical features that should be sought are a history of autoimmune disease, recent blood transfusion, recent infection, exposure to drugs or toxins, the presence of a cardiac prosthesis and risk of malaria. Previous clinical history and laboratory results will help to establish that the disorder is acquired. The basic laboratory investigations when a haemolytic anaemia is suspected are listed in Chapter 11. In this chapter, tests are described that are more specific for the diagnosis of acquired haemolytic anaemia.

ASSESSMENT OF THE BLOOD FILM AND COUNT IN SUSPECTED ACQUIRED HAEMOLYTIC ANAEMIA

If haemolytic anaemia is suspected, a full blood count, reticulocyte count and blood film should always be performed. The blood count shows a reduced haemoglobin concentration (Hb) and, usually, an increased mean cell volume (MCV). The increased MCV is attributable to the fact that reticulocytes, which may constitute a significant proportion of total red cells, are larger than mature red cells. The abnormalities that may be detected in the blood film and their possible significance in acquired haemolytic anaemia are shown in Table 13-1. Abnormalities detected in the blood film will direct further investigations.

TABLE 13-1

ABNORMALITIES THAT MAY BE DETECTED ON BLOOD FILM EXAMINATION AND THEIR POSSIBLE SIGNIFICANCE

Morphological Abnormality Observed on Blood Film Examination	Type of Acquired Haemolytic Anaemia Suggested
Schistocytes	Fragmentation syndromes including microangiopathic haemolytic anaemia and mechanical haemolytic anaemia (but note that schistocytes can be due to dyserythropoiesis as well as haemolysis)
Spherocytes	Autoimmune, alloimmune or drug-induced immune haemolytic anaemia, paroxysmal cold haemoglobinuria, burns, *Clostridium perfringens* sepsis
Microspherocytes	Burns, fragmentation syndromes
Irregularly contracted cells	Oxidant damage, Zieve syndrome
Ghost cells, hemi-ghosts and suspicion of Heinz bodies	Acute oxidant damage
Marked red cell agglutination	Cold-antibody-induced haemolytic anaemia
Minor red cell agglutination	Warm autoimmune haemolytic anaemia, paroxysmal cold haemoglobinuria
Red cell agglutination plus erythrophagocytosis	Particularly characteristic of paroxysmal cold haemoglobinuria
Hypochromia, microcytosis and basophilic stippling	Lead poisoning
Erythrophagocytosis	Paroxysmal cold haemoglobinuria
Atypical lymphocytes	Cold-antibody-induced haemolytic anaemia associated with infectious mononucleosis or, less often, other infections
Lymphocytosis with mature small lymphocytes and smear cells	Autoimmune haemolytic anaemia associated with chronic lymphocytic leukaemia
Thrombocytopenia	Autoimmune haemolytic anaemia (Evans syndrome), thrombotic thrombocytopenic purpura, microangiopathic haemolytic anaemia associated with disseminated intravascular coagulation, paroxysmal nocturnal haemoglobinuria
Neutropenia	Paroxysmal nocturnal haemoglobinuria
No specific red cell features	Paroxysmal nocturnal haemoglobinuria

For example, a Heinz body preparation would be relevant if irregularly contracted cells were present, particularly if there appeared to be red cell inclusions. Similarly, a direct antiglobulin test (DAT) would be indicated if the blood film showed spherocytes. Various inherited forms of haemolytic anaemia enter into the differential diagnosis of suspected acquired haemolytic anaemia. Thus, spherocytes could be attributable to hereditary spherocytosis as well as to autoimmune or alloimmune haemolytic anaemia. Haemolysis with irregularly contracted cells could be attributable not only to oxidant exposure but also to an unstable haemoglobin, homozygosity for haemoglobin C or glucose-6-phosphate dehydrogenase (G6PD) deficiency.

IMMUNE HAEMOLYTIC ANAEMIAS

Acquired immune-mediated haemolytic anaemias are the result of autoantibodies to a patient's own red cell antigens or alloantibodies in a patient's circulation, either present in the plasma or completely bound to red cells. Alloantibodies may be present in a patient's plasma and react with antigens on transfused donor red cells to cause haemolysis. Alloantibodies from maternal plasma may cause haemolytic disease of the newborn. Autoimmune haemolytic anaemia (AIHA) may be 'idiopathic' or secondary, associated mainly with lymphoproliferative disorders and autoimmune diseases, particularly systemic lupus erythematosus. AIHA may also follow atypical (*Mycoplasma pneumoniae*) pneumonia or infectious mononucleosis and other viral infections. Paroxysmal cold haemoglobinuria (PCH) also belongs to this group of disorders. Blood transfusion may induce red cell autoantibody formation.[1] AIHA has been reported in pregnancy but is rare.[2] Close observation throughout pregnancy has been recommended because immunoglobulin (Ig)G autoantibody can cross the placenta and can induce fetal haemolysis and haemolytic disease of the newborn.[2,3] AIHA has also been reported following allogeneic bone marrow transplantation[4] and other haemopoietic stem cell transplantation in both adult[5] and paediatric patients.[6] Occasionally, drugs may give rise to a haemolytic anaemia of immunological origin that closely mimics idiopathic AIHA both clinically and serologically. This was a relatively common occurrence with α-methyldopa, a drug that is now used infrequently, but it also occurs occasionally with other drugs. A larger group of drugs give rise to an antibody that is directed primarily against the drug and only secondarily involves the red cells. This is an uncommon occurrence. Such drugs

include penicillin, phenacetin, quinidine, quinine, the sodium salt of *p*-aminosalicylic acid, salicylazosulphapyridine and cephalosporins.[7]

Types of autoantibody

The diagnosis of an AIHA requires evidence of anaemia and haemolysis and demonstration of autoantibodies attached to the patient's red cells (i.e. a positive DAT, see p. 260). A positive DAT may also be caused by the presence of *allo*antibodies (e.g. owing to a delayed haemolytic transfusion reaction), so details of any transfusion in previous months must be sought.

Autoantibodies can often be demonstrated free in the serum of a patient suffering from an AIHA. The ease with which the antibodies can be detected depends on how much antibody is being produced, its affinity for the corresponding antigen on the red cell surface and the effect that temperature has on the adsorption of the antibody, as well as on the technique used to detect it. The autoantibodies associated with AIHA can be separated into two broad categories depending on how their interaction with antigen is affected by temperature: warm antibodies, which are able to combine with their corresponding red cell antigen readily at 37 °C; and cold antibodies, which cannot combine with antigen at 37 °C but form an increasingly stable combination with antigen as the temperature falls from 30–32 °C to 2–4 °C.

Cases of AIHA can similarly be separated into two broad categories according to the temperature characteristics of the associated autoantibodies: warm-type AIHA and the less frequent cold-type AIHA.[8,9] The relative frequencies of the two types are shown in Table13-2. In unusual instances, both warm autoantibody and cold autoantibody are detected in the patient's serum, and those cases are referred to as mixed-typed AIHA.[10,11]

Warm autoantibodies

The most common type of warm autoantibody is an IgG antibody, which behaves *in vitro* very similarly to an Rh alloantibody; indeed, many IgG autoantibodies have a mimicking Rh specificity.

Frequently, patients with warm-type AIHA have complement adsorbed onto their red cells and the red cells are therefore agglutinated by antisera specific for complement or a complement component such as C3d. In these cases, the complement is probably not being bound by an IgG antibody but is on the cell surface as the result of the action of small and otherwise undetected amounts of IgM autoantibody.

However, IgG can fix complement and sometimes patients with warm-type AIHA appear to have a positive DAT with complement components only on the red cell surface. Similar results (positive DAT with complement only) are seen in some patients with no evidence of increased red cell destruction, due to binding of circulating immune complexes to the red cells.

TABLE 13-2

CLASSIFICATION OF AUTOIMMUNE HAEMOLYTIC ANAEMIA[4,5,8–11,58–60]

Warm Autoantibodies (70–80%)
Idiopathic
Secondary
Malignancy: lymphoma, chronic lymphocytic leukaemia, ovarian dermoid cyst, Kaposi sarcoma
Autoimmune disorders: SLE, rheumatoid arthritis, ulcerative colitis
Infection: hepatitis C
Immunodeficiency: HIV infection, common variable immune deficiency, autoimmune lymphoproliferative disease
After allogeneic bone marrow or other haemopoietic stem cell transplantation
Cold Autoantibodies (10–15%)
Idiopathic
Secondary
Malignancy: lymphoma, chronic lymphocytic leukaemia, IgM gammopathy
Waldenström macroglobulinaemia
Infection: atypical or *Mycoplasma pneumoniae* infection, infectious mononucleosis
After allogeneic bone marrow or other haemopoietic stem cell transplantation
Paroxysmal Cold Haemoglobinuria (1–2%)
Idiopathic
Secondary
Viral infection, syphilis
Combined Warm and Cold Autoantibodies (Mixed Type AIHA) (6–8%)
Idiopathic
Secondary
SLE, lymphoma
Drug-induced AIHA

AIHA, autoimmune haemolytic anaemia; HIV, human immunodeficiency virus; SLE, systemic lupus erythematosus.

Warm autoantibodies free in the patient's serum are best detected by means of the indirect antiglobulin test (IAT) or by the use of enzyme-treated (e.g. trypsinised or papainised) red cells. (Antibodies that agglutinate unmodified cells directly *in vitro* are seldom present.) Not infrequently, antibodies that agglutinate enzyme-treated cells, sometimes at high titres, are present in the sera of patients in whom the IAT using unmodified cells is negative (Table 13-3).[8–10,54] Occasionally, too, they are present in the sera of patients in whom the DAT is negative.

Antibodies in serum that can be shown to lyse (rather than simply agglutinate) unmodified red cells at 37 °C in the presence of complement (warm haemolysins) are rarely demonstrable. If they are present, the patient is likely to suffer from extremely severe haemolysis. Antibodies in

TABLE 13-3

RESULTS OF TESTING FOR FREE AUTOANTIBODIES IN THE SERA OF 210 PATIENTS WITH WARM-ANTIBODY AUTOIMMUNE HAEMOLYTIC ANAEMIA[8]

Indirect Antiglobulin Test (IAT)	Agglutination of Enzyme-Treated Red Cells at 37 °C	Lysis of Enzyme-Treated Red Cells at 37 °C	Agglutination of Normal Red Cells at 20 °C	No. and Percentage of Patients in Group	
+	+	+	+	4	
+	+	+	–	16	
+	+	–	–	64	41%
+	–	–	–	2	
+	–	–	+	1	
–	+	+	+	16	
–	+	+	–	31	
–	+	–	–	29	40%
–	+	–	+	7	
–	–	–	–	39	19%

Notes
1. In 41% of the patients, the IAT was positive, and in 80% of the patients, the tests with enzyme-treated cells were positive (in half of these patients, the IAT was negative).
2. In 19% of the patients, all tests were negative.
3. In 13% of the patients, normal red cells were agglutinated at 20 °C, probably by cold agglutinins.

serum that lyse as well as agglutinate enzyme-treated cells but do not affect unmodified cells are, however, quite common. Their specificity is uncertain – they are not anti-Rh – and their presence is not necessarily associated with increased haemolysis *in vivo*.

Cold autoantibodies

Cold autoantibodies are nearly always IgM in type. *In vivo* the majority do not cause haemolysis, although a minority can cause chronic intravascular haemolysis, the intensity of which is characteristically influenced by the ambient temperature. The resultant clinical picture is generally referred to as the cold haemagglutinin syndrome or disease (CHAD). Haemolysis results from destruction of the red cells by complement that is bound to the red cell surface by the antigen–antibody reaction, which takes place in the blood vessels of the exposed skin where the temperature is 28–32 °C or less. The cold autoantibody in CHAD is monoclonal because this syndrome is the result of a low-grade lymphoproliferative disorder.

The red cells of patients suffering from CHAD characteristically give positive antiglobulin reactions only with anticomplement (anti-C′) sera. (The C′ notation is used to distinguish anticomplement antibodies from anti-C antibodies of the Rh system.) This is because of the presence of red cells that have irreversibly adsorbed sublytic amounts of complement; it is an indication of an antigen–antibody reaction that has taken place at a temperature below 37 °C. The complement component responsible for the reaction with anti-C′ sera is the C3dg derivative of C3 (see p. 448).

In vitro, a cold-type autoantibody will often lyse normal red cells at 20–30 °C in the presence of fresh human complement, especially if the cell–serum mixture is acidified to pH 6.5–7.0; it will usually lyse enzyme-treated red cells readily in unacidified serum and agglutination and lysis of these cells may still occur at 37 °C. Most of these cold-type autoantibodies have anti-I specificity (i.e. they react strongly with the vast majority of adult red cells and only weakly with cord-blood red cells). A minority are anti-i and react strongly with cord-blood cells and weakly with adult red cells. Rarely, the antibodies have anti-Pr or anti-M specificity and react with antigens on the red cell surface that are destroyed by enzyme treatment.

Combined warm and cold autoantibodies

In approximately 7% of cases with AIHA, warm IgG antibody and cold IgM autoantibody are simultaneously detected in the patient's serum.[10,11] These cases are referred to as 'combined warm and cold AIHA' or mixed-type AIHA. The serological characteristics in these patients are the presence of IgM cold autoantibody with a high thermal amplitude (reacting at or above 30 °C) in association with a warm IgG autoantibody. In some cases, high-titre cold agglutinins (>1024 at 4 °C) were reported,[12,13] and in others the cold agglutinin titre were reported as >64 at 4 °C.[14,15] This can be further classified into idiopathic or secondary, the latter often associated with systemic lupus erythematosus or lymphoma.[10,11]

Another quite distinct, but rarely encountered, type of cold antibody is the Donath–Landsteiner (D–L) antibody. This is IgG and has anti-P specificity. The clinical syndrome the antibody produces is PCH.

PCH is caused by a biphasic IgG autoantibody, usually with anti-P specificity, and is commonly seen as an acute condition in children. This antibody binds to the red cells in the cold but activates complement and causes

haemolysis on rewarming to 37 °C. Cases may be idiopathic or secondary to acute viral infection in children. Other tests of value in the diagnosis of PCH are discussed on p. 266.

The DAT is positive for complement only. A negative antibody screen by the standard IAT at 37 °C is a common finding in a suspected case of PCH because of the low thermal amplitude of the autoantibody. If the antibody investigation is carried out at a lower temperature in PCH cases, panreactive cold antibodies may be detected because the majority of autoantibodies show anti-P specificity with thermal amplitude range up to 15–24 °C. Usually the antibody titre is low (<64), even when investigated at 4 °C.

The clinical, haematological and serological aspects of the AIHAs have been summarised by Dacie[16] and others.[17–20]

AIHAs are classified as indicated in Table 13-2. Some of the characteristics of IgG, IgM and IgA antibodies are listed in Table 13-4.

Methods of investigation

Many of the methods used in the investigation of a patient suspected of suffering from AIHA are described in Chapter 21. Detailed description is given here of precautions to be taken when collecting blood samples from patients and of methods of particular value in the investigations.

Collection of samples of blood and serum

To determine the true thermal amplitude or titre of cold agglutinins requires that the blood sample is collected and maintained strictly at 37 °C until serum and cells are separated. This can be achieved by collecting venous blood (clotted and ethylenediaminetetra-acetic acid (EDTA)–anticoagulated samples) and keeping it warmed at 37 °C – ideally in an insulated thermos, but usually, in practice, by placing the sample tube in a beaker containing water at 37 °C.

The red cells are available for antibody elution and the serum can be examined for free antibody or other abnormalities. The clotted sample should then be centrifuged to separate the serum at 37 °C (e.g. in an ordinary centrifuge into the buckets of which has been placed water warmed to 37°–40 °C). The EDTA sample is used for the DAT and other tests involving the patient's red cells. If the autoantibody in a particular case is known to be warm in type, the blood may be separated at room temperature; otherwise, as already indicated, separation should be carried out at 37 °C. When samples are sent by post, it is best to send separately: (1) serum (separated at 37 °C), and (2) whole blood added to acid–citrate–dextrose (ACD) or citrate–phosphate–dextrose (CPD) solution. Sterility must be maintained.

Storage of samples

Samples of a patient's blood, while keeping quite well in ACD or CPD at 4 °C, are more difficult to preserve than normal red cells. In particular, if marked spherocytosis is present, considerable lysis develops on storage. However, satisfactory eluates can be made from washed red cells that have been frozen at –20 °C for weeks or months.

The patient's serum should be stored at –20 °C or below in small (1–2 ml) volumes. If complement is to be titrated and the titration is not performed immediately, the serum should be frozen as soon as practicable at –70 °C or below.

TABLE 13-4

MAIN CHARACTERISTICS OF IgG, IgM AND IgA AUTOANTIBODIES

	IgG	IgM	IgA
Molecular weight (daltons)	146 000	970 000	160 000
Sedimentation constant (s)	7	19	7
Number of heavy-chain subclasses	4	1	2
Cross placenta	Yes	No	No
Cause activation of complement	Yes	Yes	No
Cause monocyte/macrophage attachment	Yes	No	No
Number of antigen-binding sites	2	5 or 10	2
Types of AIHA produced	Warm; PCH	Usually cold	Warm

AIHA, autoimmune haemolytic anaemia; Ig, immunoglobulin; PCH, paroxysmal cold haemoglobinuria.

Scheme for serological investigation of haemolytic anaemia suspected to be of immunological origin

It is important to consider which are the most useful tests to carry out and the order in which they should be done. A suggested scheme has been set out in the form of answers to questions.[21] Whereas some information may be helpful in classifying the type of AIHA, the single most important practical consideration is to determine whether, in addition to an autoantibody, there is any underlying alloantibody present. This should be identified before transfusion is undertaken to avoid a delayed haemolytic transfusion reaction that would compound existing haemolysis.

1. **Are the patient's red cells 'coated' by immunoglobulins or complement (indicating an antigen–antibody reaction)?**
   Perform a DAT using a polyspecific 'broad-spectrum' reagent, which contains both anti-IgG and anti-C′. (If the DAT is negative, it is unlikely, although not impossible, that the diagnosis is AIHA. See DAT-negative AIHA, p. 261).

2. **If the DAT is positive, are immunoglobulins or complement adsorbed to the red cells?**
   Repeat the DAT using monospecific sera (see p. 453) (i.e. anti-IgG and anti-C3d).
3. **If immunoglobulins are present on the red cells, is there antibody specificity?**
   Prepare eluates from the patient's red cells. Test these later (see item 6).
4. **What is the patient's blood group?**
   Determine the patient's ABO, RhD and Kell type. The Rh phenotype is particularly important in warm-type AIHA; other antigens must be determined if alloantibodies are to be differentiated from autoantibodies (see p. 447).
5. **Is there free antibody in the serum? How does it react and at what temperatures and by what methods can it be demonstrated? Is there any underlying alloantibody present?**
   Screen the serum with two or three red cell suspensions suitable for routine pretransfusion antibody screening (see p. 480) looking for agglutination and lysis at 37 °C by the IAT (see p. 453). If positive, identify the antibody using an antibody identification panel.
   a. If an alloantibody is identified, blood lacking the corresponding antigen must be selected for transfusion.
   b. If no alloantibody is identified in the serum or plasma, it is safe to assume there is no alloantibody present unless the patient has been transfused in the last month; in the latter case, a red cell eluate is required because an alloantibody may be bound to the recently transfused cells and there may not be free antibody detectable in the serum/plasma.
   c. If the autoantibody is panreacting (i.e. is reacting against all panel cells), antibody adsorption tests are needed to remove the autoantibody so as to identify any underlying alloantibody. If the patient has not had a transfusion within the previous 3 months, a ZZAP autoadsorption test is appropriate (see p. 263). If the patient has had a transfusion within the last 3 months, differential alloadsorption tests are needed. However, if the patient has had a transfusion within the last month, an eluate is required, irrespective of results of adsorption tests.
6. **If there is a warm autoantibody, what is the specificity of the autoantibody?**
   Test the serum also at 20 °C against antibody-screening cells to show whether cold or warm antibodies (or a mixture of the two) are present in the serum. Test the eluate against the antibody identification panel of red cells by IAT and by using enzyme-treated red cells (see p. 451). Titration of autoantibody may be useful in the presence of a strong alloantibody. Titrate the serum/plasma by the methods that have given positive results in the screening test using the same panel of red cells (see item 5a).
7. **If there is a cold antibody:**
   a. Has the antibody any specificity? Is it an autoantibody or an alloantibody? What is its titre?
   b. What is the thermal range of the antibody? Test the serum/plasma against a panel of O cells, O cord cells and patient's own cells at 20 °C. If an autoantibody is found, titrate at 4 °C with ABO-compatible adult (I) cells, cord blood (i) cells, the patient's cells and adult (i) cells (if possible):
      i. Determine the highest temperature at which autoagglutination of the patient's whole blood takes place (see p. 266).
      ii. Titrate the patient's serum/plasma at 20 °C, 30 °C and 37 °C with pooled O adult cells, O cord cells, patient's own cells and the panel of O cells. If there was any agglutination or lysis at 37 °C in the screening test (item 5), titrate with the appropriate cells at this temperature.
      iii. If PCH is suspected, carry out the direct and two-stage indirect Donath–Landsteiner tests (see p. 266).
8. **Is there is a mixture of both warm autoantibody and cold autoantibody?**
   The diagnosis of mixed-type AIHA can only be made after appropriate characterisation of the serum autoantibodies. The serological characteristic in these cases is the presence of a cold IgM antibody with a high thermal amplitude (reacting at or above 30 °C) in association with a warm IgG autoantibody.[11,12]
9. **Is a drug suspected as the cause of the haemolytic anaemia?**
   a. If a penicillin-induced haemolytic anaemia is suspected, test for antibodies using cells preincubated with penicillin (see p. 269).
   b. If haemolysis induced by other drugs is suspected, add the drug in solution to a mixture of the patient's serum, normal cells and fresh normal serum (see p. 270). Look for agglutination of normal and enzyme-treated cells and use the IAT.
10. **Are there any other serological abnormalities?**
    Consider carrying out the following tests: serum protein electrophoresis and quantitative estimation of immunoglobulins, estimation of complement, tests for antinuclear factor, a screening test for heterophile antibodies (infectious mononucleosis screening test) and a test for mycoplasma antibodies.

This suggested scheme summarises what may be done by way of serological investigation of a patient suspected of having AIHA. Close collaboration between clinician and laboratory helps in deciding what tests should be done in any particular case.

Detection of incomplete antibodies by means of the direct antiglobulin (Coombs) test

Principle. As already described, the DAT involves testing the patient's cells without prior exposure to antibody *in vitro*. For the investigation of cases of AIHA, antiglobulin reagents specific for IgG, IgM, IgA, C3c and C3d can be used.

Precautions. A blood sample in EDTA is preferred. (If a clotted sample is used, complement could be bound by normal incomplete cold antibody and give a false-positive result with anti-C3d.) Certain precautions are necessary when investigating a patient with possible AIHA. If a cold-reacting autoantibody is present, the patient's red cells should be washed four times in a large volume of saline (throughout this chapter, 'saline' refers to 9 g/l NaCl buffered to pH 7.0), warmed to 37 °C to wash off cold antibodies and obtain a smooth suspension of cells. There is no risk of washing off adsorbed complement components. However, the washing process should be accomplished as quickly as possible and the test should be set up immediately afterward because bound warm antibody occasionally elutes from the cells when they are washed and false-negative results may be obtained. If for any reason the washing process has to be interrupted once it has begun, the cell suspension should be placed at 4 °C to slow down the dissociation of the antibody.

Method. A spin tube technique, as described on p. 454, is recommended.

Make a 2–5% suspension of red cells that have been washed four times in saline. Add 1 volume (drop) of the cell suspension to 2 volumes (drops) of antiglobulin reagent. Centrifuge for 10–60 s. Refer to reagent manufacturer's instructions for specific details.

Examine for agglutination after gently resuspending the button of cells. A concave mirror and good light help in macroscopic readings. If the result appears to be negative, confirm this microscopically.

Each DAT or batch of tests should be carefully controlled as previously described.

Check negative results with the polyspecific antihuman globulin (AHG) or anti-IgG reagents by the addition of IgG-sensitised cells and anti-C′ by the addition of complement-coated cells.

Direct antiglobulin test using column agglutination technology

A card of several microtubes enables multiple sample testing. The microtubes contain a solid-phase matrix and the antiglobulin reagent to which the patient's red cells are added. During centrifugation, unagglutinated cells pass to the tip of the tube, but agglutinates fail to pass through the gel, which acts as a sieve. As the antiglobulin reagent is already present in the microtubes, no washing or addition of IgG-coated cells to negative tests is required. Refer to individual manufacturer's instructions for details of methods for performing the tests.

Significance of positive direct antiglobulin test

A positive DAT plus anaemia does not necessarily mean that the patient has autoimmune haemolysis.[8,22] The causes of a positive test include the following:

1. An autoantibody on the red cell surface with or without haemolytic anaemia
2. An alloantibody on the red cell surface, as for example in haemolytic disease of the newborn or after an incompatible transfusion
3. Antibodies provoked by drugs adsorbed to the red cell (see p. 269)
4. Normal globulins adsorbed to the red cell surface as the result of damage by drugs (e.g. some cephalosporins)
5. Complement components alone:
   a. About 10–11% of patients with warm AIHA have red cells with a positive DAT as a result of C3 coating alone[10]
   b. Cold haemagglutinin disease/paroxysmal cold haemoglobinuria
   c. Drug-dependent immune haemolytic anaemia (complement-induced lysis)
   d. Adsorption of immune complexes to the red cell surface. This may be the mechanism of the (usually weak) reactions that are found in approximately 8% of hospital patients suffering from a wide variety of disorders (see below)
6. Passive infusion of alloantibodies in donor plasma/derivatives that react with recipient's red cells:
   a. Transfusion of group O platelets with high-titre anti-A, -B to group A or B recipient
   b. Administration of intravenous immunoglobulin, which may contain ABO or anti-D antibodies.[23] In one study of patients treated with intravenous immunoglobulin after bone marrow transplantation, 49% of recipients developed a positive DAT and 25% had a positive antibody screen (passively transfused anti-A, -B, -D or -K) of short duration (2–5 days)
7. Administration of anti-D for the treatment of autoimmune thrombocytopenia purpura
8. Antibodies produced by passenger lymphocytes in solid organ transplant and bone marrow transplantation[24,25]
9. Nonspecific binding of immunoglobulins to red cells in patients with hypergammaglobulinaemia or multiple myeloma and in recipients of antilymphocyte globulin and antithymocyte globulin.[26] Szymanski *et al.*[27] used an AutoAnalyser and used Ficoll and polyvinylpyrrolidone (PVP) to enhance agglutination by an anti-IgG serum highly diluted (usually to 1 in 5000) in 0.5% bovine serum albumin. In this sensitive

system, the strength of agglutination was positively correlated with the serum γ-globulin concentration, being subnormal in hypogammaglobulinaemia and supranormal in hypergammaglobulinaemia.[28] Similar findings were observed in patients with multiple myeloma. Nonspecific binding of IgG to red cells was related to the level of monoclonal protein in the patient's serum.[28] Usually, in patients with hypergammaglobulinaemia in whom the DAT is positive, attempts to demonstrate antibodies in eluates fail (i.e. eluates are nonreactive).[29,30]

10. Cross-reacting antiphospholipid antibodies adsorbing nonspecifically onto red cell membrane and binding to phospholipid-dependent epitopes. Positive DAT as a result of antiphospholipid antibodies has been documented in patients with primary antiphospholipid syndrome and antiphospholipid syndrome with systemic lupus erythematosus.[31] It has also been described in healthy blood donors.[32]
11. Incidental findings of positive DAT with no clear correlation between DAT and anaemia. A positive DAT is a common finding in patients with sickle cell disease because of abnormal amounts of IgG coating red cells. There was no correlation between the amount of IgG on the patient's red cells and the severity of anaemia.[33] There was an association demonstrated between an elevated blood urea nitrogen and a positive DAT.[34] Elevated blood urea may alter the red cell membrane and enhance nonspecific IgG adsorption.[34]
12. Sensitization *in vitro* if a sample other than EDTA is used. If, for instance, clotted or defibrinated normal blood is allowed to stand in a refrigerator at 4 °C or even at room temperature, and the antiglobulin test is subsequently carried out, the reaction may be positive because of the adsorption of incomplete cold antibodies and complement from normal sera. Samples of blood taken into EDTA or ACD and subsequently chilled do not give this type of false-positive result because the anticoagulant inhibits the complement reaction.
13. False-positive agglutination may occur with a silica gel derived from glass.[35] Also, albeit rarely, the DAT has been positive with the blood of apparently perfectly healthy individuals (e.g. blood donors). Such occurrences have not been satisfactorily explained (see below).

Positive direct antiglobulin tests in normal subjects

The occurrence of a clearly positive DAT in an apparently healthy subject is a rare but well-known phenomenon. Worlledge[22] reported a prevalence in blood donors of approximately 1 in 9000. In a later report, Gorst *et al*.[36] estimated that the prevalence was approximately 1 in 14 000, with an increasing likelihood of a positive test with increasing age. Their report and subsequent reports[27,37] suggest that the finding of a positive DAT using an anti-IgG serum in an apparently healthy person is usually of little clinical significance and that, although overt AIHA may subsequently develop, this is infrequent. In some such individuals the DAT eventually becomes negative.

Positive direct antiglobulin tests in hospital patients

In contrast to the rarity of positive DATs in healthy people, positive tests are much more frequent in hospital patients. Worlledge[22] reported that the red cells of 40 out of 489 blood samples (8.9%) submitted for routine tests were agglutinated by anti-C′ sera. Only one sample was agglutinated by an anti-IgG serum and this had been obtained from a patient being treated with α-methyldopa. Freedman[38] reported a similar incidence: 7.8% positive tests with anti-C′ sera. Lau *et al*.[39] used anti-IgG sera only. The tests were seldom positive (0.9% positive out of 4664 tests). The probable explanation for the relatively high incidence of positive tests with anti-C′ sera is that the reaction is between anti-C′ antibodies and immune complexes adsorbed to the red cells.

False-negative antiglobulin test results

There are several causes of false-negative test results:

1. Failure to wash the red cells properly: the antisera may then be neutralised by immunoglobulins or complement in the surrounding serum or plasma (see p. 454)
2. Excessive agitation at the reading stage: this may break up agglutinates, leading to a false-negative result
3. The use of impotent antisera so that weakly sensitised cells are not detected
4. The use of antisera lacking an antibody corresponding to the subclass of immunoglobulin responsible for the red cell sensitisation
5. The presence of an antibody that is readily dissociable and is eluted in the washing process.

These phenomena are largely negated by the use of column agglutination technology.

Direct antiglobulin test-negative autoimmune haemolytic anaemia

Most hospital blood banks use polyspecific 'broad-spectrum' AHG reagents for screening for diagnosis of AIHA. These reagents contain antibody to human IgG and the C3d component of human complement and have little activity against IgA and IgM proteins. The prevalence of IgA-only warm AIHA has been reported as 0.2% to 2.7%[40] and the diagnosis may be missed if such polyspecific AHG is used for the DAT screen. In approximately 2–6% of patients who present with the clinical and haematological features of AIHA, the DAT is negative on repeated testing.[22,41,42]

Low-affinity IgG autoantibodies dissociate from the red cells during the washing phase if a tube technique is used, resulting in a negative DAT. Alternatively, there may be few IgG molecules coating the red cells and this number may fall below the threshold of detection, which is 300 to 4000 molecules per red blood cell if a tube technique is used. In such cases, a positive DAT may be demonstrated by a more sensitive technique, such as a column agglutination method, an enzyme-linked immunoabsorbant assay or flow cytometry.[43–45]

If polyspecific AHG is used and the DAT remains negative with clinical evidence of haemolysis, a more sensitive technique should be used for further investigation.[46]

The DiaMed DAT gel card, which contains a set of monospecific AHG reagents (i.e. anti-IgG, -IgA, -IgM, -C3c, -C3d and an inert control) can be used (www.diamed.com). Because there is no washing phase, this permits the detection of low-affinity IgG, IgA and IgM antibodies. A gel card can also pick up the rare IgA-only AIHA. In warm-type AIHA the DAT may be positive with anti-IgG or anti-IgG plus anti-C3d. In cold-type AIHA the DAT may be positive with anti-IgM or anti-IgM plus anti-C3d and in mixed-type AIHA the DAT may be positive with anti-IgG, anti-IgM and anti-C3d.

Manual direct polybrene test

The following method[47] is modified from that of Lalezari and Jiang.[48] Polybrene (www.sigmaaldrich.com) is a polyvalent cationic molecule, hexadimethrine bromide, which can overcome the electrostatic repulsive forces between adjacent red cells, bringing the cells closer together. When low levels of IgG are present on the red cell surface, antibody linkage of adjacent red cells is enhanced. The Polybrene is then neutralised using a negatively charged molecule such as trisodium citrate. Sensitised red cells remain agglutinated after neutralization of the Polybrene. Unsensitised red cells will disaggregate after neutralisation.

Reagents

- *Polybrene stock.* 10% Polybrene in 9 g/l NaCl, pH 6.9 (saline).
- *Working Polybrene solution.* Dilute the stock Polybrene solution 1 in 250 in saline.
- *Resuspending solution.* 60 ml of 0.2 mol/l trisodium citrate added to 40 ml of 50 g/l dextrose.
- *Washing solution.* 50 ml of 0.2 mol/l trisodium citrate in 950 ml of saline.
- *Low-ionic medium.* 50 g/l dextrose containing 2 g/l disodium EDTA. Adjust the pH of half the batch to 6.4. Store the remainder at the original pH (approx. 4.9); use this to repeat tests that are negative using a low-ionic medium at pH 6.4.

Method. Ensure that all reagents are at room temperature.

Positive control. Dilute an IgG anti-D in normal group AB serum. Find a dilution that gives a positive result with papainised cells but is negative by the IAT on standard testing with group O, D-positive red cells (a dilution of 1 in 10 000 is often suitable).

Negative control. Normal group AB serum that fails to agglutinate papainised group O, D-positive red cells.

1. Wash the cells four times in saline and make 3–5% suspensions of test and normal group O RhD red cells in saline.
2. Set up three 75 × 10 mm tubes as shown in Table 13-5. Leave at room temperature for 1 min.
3. Add 1 drop of working Polybrene solution to each tube and mix gently. Leave for 15 s at room temperature.
4. Centrifuge for 10 s at 1000 *g*. Decant, taking care to remove all the supernatant.
5. Leave for 3–5 min at room temperature before adding 2 drops of resuspending solution and mixing gently. Within 10 s aggregates will dissociate, leaving true agglutination in the positive tubes.
6. Read macroscopically after 10–60 s. Check all negative results microscopically and compare with the negative control.
7. Repeat negative tests using low-ionic medium at the lower pH (about 4.9).

If the direct Polybrene test is negative, a supplementary antiglobulin test may be performed by washing the cells twice in the washing solution and testing with an anti-IgG antiglobulin reagent.

Determination of the blood group of a patient with autoimmune haemolytic anaemia

ABO grouping

No difficulty should be encountered in ABO grouping patients with warm-type AIHA using monoclonal reagents, but the presence of cold agglutinins may cause difficulties. The cells should in all cases be washed in warm (37 °C) saline. They should then be groupable without any problem; the reactions must, however, be controlled with normal AB serum. Reverse grouping should be performed strictly at 37 °C. Warm the known A_1, B and O cells to 37 °C before adding them to the patient's serum at 37 °C. Read the results macroscopically.

TABLE 13-5

SETTING UP A DIRECT MANUAL POLYBRENE TEST

	Test	Positive Control	Negative Control
AB serum (drops)	2	0	2
Dilute anti-D in AB serum (drops)	0	2	0
3–5% test cells (drops)	1	0	0
3–5% normal O RhD cells (drops)	0	1	1
Low ionic-strength medium	0.6 ml	0.6 ml	0.6 ml

RhD grouping

When the DAT is positive, monoclonal anti-D reagents should be used; if cold agglutinins are present, perform the test at 37 °C. Appropriate controls should be included (see p. 475).

Demonstration of free antibodies in serum

The sera of patients suffering from AIHA often contain free autoantibodies. However, free autoantibody is also found in the absence of haemolysis. As a result of improved reagent sensitivity, any clinically significant IgG complement-binding antibodies will be detected by current antibody screening methods.

Identification by adsorption techniques of coexisting alloantibodies in the presence of warm autoantibodies

Adsorption techniques for the detection of alloantibodies present in the sera or eluates of patients with suspected or proved AIHA can be helpful in the following situations:

1. In screening for coexisting alloantibodies in patients with AIHA who have been pregnant or previously transfused and are found to have a panreactive antibody in their serum
2. In differentiating between autoantibodies and alloantibodies in the eluate of recently transfused patients with AIHA
3. In investigating haemolytic transfusion reactions owing to red cell alloantibodies in patients with AIHA.

In some cases of AIHA, an underlying alloantibody may be detected by titrating the patient's serum and eluate against a panel of phenotyped reagent red cells. However, a high-titre autoantibody may mask the alloantibody; hence the need for adsorption techniques, especially in the situations outlined earlier.

Use of ZZAP reagent in autoadsorption techniques

'ZZAP' reagent is a mixture of dithiothreitol and papain.[49] It dissociates an autoantibody already coating the patient's red cells and enzyme treats the cells, thus increasing the amount of autoantibody that can subsequently be adsorbed onto the patient's cells *in vitro*.

Reagents

- *Dithiothreitol* (DTT). 0.2 mol/l.
- *Papain*. 1%.
- *Phosphate-buffered saline* (PBS). pH 6.8–7.2.

Prepare a suitable volume of ZZAP by making up the reagents in the following ratio: 0.2 mol/l DTT 5 volumes; and 1% papain 1 volume.

Check the pH and adjust to pH 6.0–6.5 using one drop at a time of 0.2 mol/l HCl or 0.2 mol/l NaOH.

Method

1. Add 2 volumes of ZZAP to 1 volume of packed red cells that have been washed four times. Incubate at 37 °C for 30 min, mixing occasionally.
2. After incubation, wash the cells four times in saline, packing hard after the last wash.
3. Divide the cells into two equal volumes. To one volume, add an equal volume of the serum to be adsorbed. Incubate at 37 °C for 1 h.
4. Centrifuge at 1000 *g*. Remove the serum and add to the remaining volume of cells.
5. Repeat the adsorption procedure.
6. Remove the adsorbed serum and store at −20 °C or below for alloantibody screening or cross-matching, which may be performed by standard techniques.

Notes. The autoadsorption techniques should only be used in the following circumstances:

1. When the patient has not had a transfusion in the previous 3 months because the presence of transfused red cells may allow the adsorption of alloantibody as well as autoantibody
2. When at least 2 to 3 ml of packed red cells are available from the patient
3. When the autoantibodies present react well with enzyme-treated red cells. If they do not, heat elution should be substituted for ZZAP treatment. Heat elution may be performed by shaking the washed cells for 5 min in a 56 °C water bath and then washing the cells.

Alloadsorption using papainised R_1R_1, R_2R_2 and rr cells

The method of alloadsorption using papainised R_1R_1, R_2R_2 and rr cells may be used when autoadsorption is not appropriate, for instance, when the patient has had a transfusion in the previous 3 months or when less than 2–3 ml of the patient's red cells are available.

1. Select three group O antibody screening cells, which individually lack some of the blood-group antigens that commonly stimulate the production of clinically significant antibodies (e.g. c, e, C, E, K, Fy^a, Fy^b, Jk^a, Jk^b, S, s) (Table 13-6).
2. Papainise 2 ml of packed cells from each sample after washing the cells in saline four times.
3. Add to 1 ml of each sample of washed, packed, papainised cells, 1 ml of the patient's serum. Incubate for 20 min at 37 °C.
4. Centrifuge to pack the cells. Remove the supernatant serum and add it to the second 1 ml volume of papainised cells. Incubate for 1 h at 37 °C.
5. Centrifuge again to pack the cells. Remove the supernatant and store at −20 °C or below for further testing (e.g. alloantibody screening and cross-matching).

Method for testing alloadsorbed sera

For alloantibody screening, each adsorbed serum is tested against a panel of phenotyped red cells by the IAT. For cross-matching, each adsorbed serum must be tested separately against the donor red cells by the IAT, using undiluted serum.

Example of alloantibody detection using the alloadsorption technique in a recently transfused patient with AIHA. The patient's serum when first tested against a panel of group O phenotyped red cells revealed only panreactive antibodies. In contrast, three absorbed sera, A, B and C, obtained by adsorbing the patient's serum with three selected phenotyped samples of group O cells, were shown to contain anti-E and anti-Jk^a when tested against a panel of phenotyped group O cells using the IAT. The results of testing the adsorbed sera, A, B and C, are shown in Table 13-6. The patient's red cell phenotype was R_1r Jk (a– b–).

Explanation of the results of testing alloadsorbed sera, A, B and C

1. Because the R_1R_1-adsorbing cells were negative for the E and Jk^a antigens, adsorbed serum A could contain anti-E and anti-Jk^a. Testing the adsorbed serum A against the panel of cells suggested that this was the case.
2. Because the R_2R_2-adsorbing cells were positive for the E antigen but negative for the Jk^a antigen, adsorbed serum B could contain anti-Jk^a but not anti-E. Testing adsorbed serum B against the panel of cells confirmed the presence of anti-Jk^a.
3. Because the rr-adsorbing cells were negative for the E antigen but positive for the Jk^a antigen, adsorbed serum C could contain anti-E but not anti-Jk^a. Testing adsorbed serum C against the panel of cells confirmed the presence of anti-E.
4. Because the phenotype of the patient's own red cells was R_1r, Jk (a– b–), the anti-E and anti-Jk^a detected in the alloadsorbed sera must be alloantibodies. Blood for transfusion should be E-negative, Jk^a-negative.

Additional notes on adsorption techniques

1. If the patient has had a transfusion in the previous month, an eluate must also be tested because alloantibody may be present on red cells but not in serum/plasma.
2. If the patient's serum contains a haemolytic antibody, EDTA should be added to prevent the uptake of complement and subsequent lysis of the cells used for adsorption. Add 1 volume of neutral EDTA (potassium salt) (see p. 562) to 9 volumes of serum. More commonly, a plasma sample is used.
3. It is often useful to alloadsorb both serum and eluate to differentiate between autoantibodies and alloantibodies, particularly if the autoantibody is the mimicking type described by Issitt.[20]
4. If the autoantibody does not react with papainised cells, do *not* papainise the cells for adsorption.

Preparing and testing a concentrated eluate

The eluate technique concentrates low levels of immunoglobulin present on the red cell surface so that antibody

IAT, indirect antiglobulin test.

may then be detected by screening the eluate with group O red cells by the IAT. Elution techniques reverse or neutralise the binding forces that exist between the red cell antigens and the antibody coating the cells. This may be achieved by several techniques (e.g. heat or alterations to the pH).

Elution of antibodies from red cells

The selection of any elution technique is often based on personal choice and the availability of the necessary reagents and equipment. However, heat elution techniques are best used for the elution of primary cold reactive (IgM) antibodies such as anti-A, anti-N, anti-M and anti-I, and IgG, anti-A and anti-B antibodies associated with ABO haemolytic disease of the newborn (HDN). The Lui freeze and thaw technique (see below) may also be used for investigation of ABO HDN. Commercially prepared kits that alter the pH of the red blood cells are equally effective and circumvent the hazards of using organic solvents. Refer to the manufacturer's instructions for details. Methods for heat elution and Lui's elution techniques are given below. Commercial kits are now widely available.

Notes

1. A large volume of red blood cells is required to obtain enough eluate for testing.
2. The red blood cells must be washed at least six times and the last wash must be kept for testing to ensure removal of all free antibody.
3. Depending on the elution technique used, the prepared eluate may be frozen if testing is not possible immediately after preparation.

Heat elution

Mix equal volumes of washed packed cells and saline or 6% bovine serum albumin (BSA). Incubate at 56 °C for 5 min. Agitate periodically. Centrifuge to pack the red cells. Remove the supernatant (the eluate), which may be haemoglobin stained. Test the eluate[50] by appropriate techniques in parallel with the last wash from the red cells.

Freeze and thaw elution (Lui)

Mix 0.5 ml of washed packed red cells with 3 drops of PBS or AB serum. Stopper the tube and rotate to coat the glass surface with red cells. Place at −20 °C for 10 min. Thaw the red cells rapidly in a 37 °C water bath. Remove the stopper and centrifuge to sediment red cell stroma. Remove the supernatant and test in parallel with the last wash from the red cells by appropriate techniques.[51]

Screening eluates

The eluate and the saline of the last wash (control) are first screened against two or three samples of washed normal group O cells to see if they contain any antibodies using the IAT. If anti-A or anti-B is suspected, include A and B cells. To 4–6 drops of eluate and control, add 2 drops of a 2% suspension of *normal ionic strength saline* (NISS).

Incubate for 1–1.5 hours at 37 °C. Wash four times, and, using optimal dilutions of anti-IgG, carry out the IAT by the tube method.

If the control preparation (the supernatant saline from the last washing) gives positive reactions, the possibility that an eluate contains serum antibody has to be considered.

Determination of the specificity of warm autoantibodies in eluates and sera

When tested against a phenotyped panel, about two-thirds of autoantibodies appear to have Rh specificity and in about half of these cases specificity against a particular antigen can be demonstrated.[8,12,20] Within the Rh system, anti-e-like is the most common specificity. D – – and Rh_{null} cells are an advantage.

The other one-third of autoantibodies may show specificity against other, very high incidence antigens (e.g. Wrb and Ena) and rarely other blood-group specificities are involved. It is essential to differentiate between autoantibodies and alloantibodies, especially if transfusion is being considered. The presence of alloantibodies in addition to autoantibodies is suggested by any discrepancy between the serum and eluate results.

As already mentioned, the presence of alloantibodies in a serum complicates the determination of the specificity of an autoantibody, and it can be argued that it would be better to test only the eluted autoantibody and to leave the serum strictly alone. However, only a small volume of an eluate may be available, especially in patients who are anaemic, and it is generally wise to test both serum and eluate. The procedure is the same for both.

Titration of warm antibodies in eluates or sera

The methods used are those described in Chapter 21. The exact technique chosen, and the red cells used, should be those that have given the clearest results in the screening tests. Titration of the eluate can be useful in the presence of a panreacting autoantibody to exclude an underlying alloantibody.

In investigating cold autoantibodies, the following tests may sometimes provide clinically useful information.

Determination of the specificity of cold autoantibodies

High-titre cold autoantibodies have a well-defined blood-group specificity, which is very often within the I/i system.[20,52,53] Because the I antigen is poorly developed in cord-blood red cells, whereas the i antigen is well developed, group O cord blood red cells should be included in the panel used to test for I/i specificity. Adult

cells almost always have the I antigen well expressed, but the strength of expression varies, and it is of considerable advantage to have available adult cells known to possess strong I antigen. (The rare adult i cells, if available, can also be used.)

Titration of cold antibodies

If the screening test is positive for cold auto-agglutinins, titrate as follows.

Prepare doubling dilutions of the serum in saline ranging from 1 in 1 to 1 in 512 and add 1 drop of each serum dilution into three series of (12×75 mm) tubes so that three replicate titrations can be made. Add 1 drop of a 2% suspension of pooled saline-washed adult group O (I) cells to the first row, 1 drop of cord-blood group O (i) cells to the second row and 1 drop of the patient's own cells to the third row. Mix and leave for several hours at 4 °C. Before reading, place pipettes and a tray of slides at 4 °C. Read macroscopically at room temperature using chilled slides.

Normal range. Using sera from normal Caucasian adults and normal adult I red cells, the cold-agglutinin titre at 4 °C is 1 to 32; and with cord-blood (i) cells the titre is 0 to 8. In chronic CHAD, the end-point may not have been reached at a dilution of 1 in 512; if that is the case, further dilutions should be prepared and tested.

If a cold agglutinin is present at a raised titre, the presence of a cold alloantibody has to be excluded. In this case, the patient's own red cells will be found to react *much* less strongly than do normal adult I red cells. It should be noted that in CHAD the patient's cells commonly react less strongly than do normal adult I cells (Table 13-7).

Cold agglutinin titration patterns

The presence of high-titre cold agglutinins in a patient's serum will be indicated by the screening procedure described earlier. To demonstrate that the agglutinins are autoantibodies, it is necessary to show that the patient's own cells are also agglutinated. The titre using the patient's cells is usually less than that of control normal adult red cells (one-half or one-quarter) (Table 13-7).

In CHAD, whether 'idiopathic' or secondary to mycoplasma pneumonia or lymphoma, the autoantibodies usually have anti-I specificity (Patient A.G. in Table 13-7).

In rare cases of haemolytic anaemia associated with infectious mononucleosis, an autoantibody of anti-i specificity has been demonstrated (Patient F.B. in Table 13-7), and this specificity, too, has been found in certain patients with lymphoma. Rarely, in CHAD, the antibody has been shown to have anti-Pr or anti-M specificity: if enzyme-treated red cells are used, then in either type of case the antigen is destroyed by enzyme treatment (Patient A.R. in Table 13-7).

TABLE 13-7

AGGLUTINATION TITRES USING VARIOUS TYPES OF COLD AUTOANTIBODIES AND NORMAL ADULT AND NORMAL CORD RED CELLS, THE PATIENT'S RED CELLS AND ENZYME-TREATED (PAPAINISED) NORMAL ADULT RED CELLS

Patient	Agglutination Titre (4 °C)			
	Adult (I) Cells	Cord (i) Cells	Patient's Cells	Papainised Adult (I) Cells
A.G.	4000	512	2000	8000
F.B.	512	32 000	128	8000
A.R.	2000	2000	2000	16

A.G: This patient had chronic cold haemagglutinin disease. The antibody was of the common anti-I type.
F.B: This patient had haemolytic anaemia associated with a lymphoma. The antibody was of the anti-i type.
A.R: This patient had chronic cold haemagglutinin disease. The antibody was of the rare anti-Pr type.

Determination of the thermal range of cold agglutinins

From a series of master doubling dilutions of serum in saline, place 1 drop of serum or serum dilution into three rows of (12×75 mm) tubes. Set them up at 30 °C and at room temperature (20–25 °C); to each tube add 1 drop of a 2% saline suspension of one of the following cells:

1. Pooled normal adult group O (I) red cells
2. Pooled cord-blood group O (i) red cells
3. Patient's red cells.

Titration should also be carried out at 37 °C, if there was agglutination at this temperature in the screening tests. After incubation at the appropriate temperature for 1 h, determine the presence or absence of agglutination macroscopically over a light. The determination of autospecificity is not required for diagnosis of CHAD, but confirmation of high thermal amplitude (i.e. cold autoagglutinin reacting at or above 30 °C) is essential.[54]

Detection and titration of the Donath–Landsteiner antibody

The D–L antibody of PCH differs from the high-titre cold antibodies referred to previously in that it is an IgG antibody and has a quite different specificity. It is also far more lytic to normal cells in relation to its titre than are anti-I or anti-i. The lysis titre of a D–L antibody may be the same or greater than its agglutination titre. Almost maximal lysis develops in unacidified serum.

Direct Donath–Landsteiner test

Collect two samples of venous blood into tubes containing no anticoagulant, previously warmed at 37 °C. Incubate the first sample at 37 °C for 1.5 h. Put the second sample in a beaker packed with ice and allow to stand for 1 h, then place this tube at 37 °C for a further 20 min. Centrifuge both tubes at 37 °C and examine the supernatant serum for lysis. A positive test is indicated by lysis in the sample that had been chilled. If positive, investigate the antibody specificity (as described later). If negative, proceed to an indirect Donath–Landsteiner test.

A false-negative direct Donath–Landsteiner test result is not uncommon for several reasons:

1. Low antibody level
2. Low complement level (complement is consumed during the haemolytic process)
3. Presence of C3dg on the patient's red cells (does not lead to complement-mediated haemolysis)

This can be overcome by performing an indirect Donath–Landsteiner test.

Indirect Donath–Landsteiner test

Serum obtained from the patient's blood that has been allowed to clot at 37 °C is used for this test. Add 1 volume of a 50% suspension of washed normal group O, P-positive red cells to 9 volumes of the patient's unacidified serum in a tube. Chill the suspension in crushed ice at 0 °C for 1 h, then place the tube at 37 °C for 30 min. Centrifuge at 37 °C and examine for lysis. Three controls should be set up at the same time:

1. A duplicate of the test cell–serum suspension but kept strictly at 37 °C for the duration of the test
2. A duplicate of the test cell–serum suspension, except that an equal volume of ABO-compatible fresh normal serum is first added to the patient's serum as a source of complement. One volume of the 50% cell suspension is added and the suspension is chilled and subsequently warmed in the same way as the test suspension. (This control excludes false-negative results owing to the patient's serum being deficient in complement.)
3. A duplicate of the test cell–serum suspension, except that fresh normal serum is used in place of the patient's serum. This control also is chilled and subsequently warmed.

A positive test will be indicated by lysis in the test suspension and in control No. 2. If ABO-compatible *pp* cells are available, they should be used in a duplicate set of tubes. No lysis will develop, confirming the P specificity of the antibody.

A false-negative indirect Donath–Landsteiner test can occur. This is a result of the presence of globoside in the serum added as a source of complement. Globoside is the most abundant red cell membrane glycolipid and is present in the serum of all P+ individuals. Addition of ABO-compatible fresh serum as a source of complement could result in cross-reacting with anti-P and this can lead to a false-negative indirect Donath–Landsteiner test. Therefore the indirect Donath–Landsteiner[55] test can be modified into two stages.

Two-stage indirect Donath–Landsteiner test

ABO-compatible fresh serum is only added to the red cell–serum suspension after the initial 1 h incubation at 0 °C. This prevents antibody inhibition during the cold phase and allows maximum sensitisation of the red cells.[12]

Another possible cause of a false-negative indirect Donath–Landsteiner test result is a low antibody level. Papain treatment of the red cells will expose P antigen and can enhance the sensitization.[55]

Titration of a Donath–Landsteiner antibody

Prepare doubling or fourfold dilutions of the patient's serum in fresh normal human serum. To each tube, add a one-tenth volume of a 50% suspension of washed group O, P-positive red cells and immerse each of the tubes in crushed ice at 0 °C. After 1 h, place in a 37 °C incubator for a further 30 min. Then centrifuge and inspect for lysis.

Detection of a Donath–Landsteiner antibody by the indirect antiglobulin test

Because the D–L antibody is an IgG antibody, it can be detected by the IAT using an anti-IgG serum if the cells that have been exposed to the antibody in the cold are washed in cold (4 °C) saline. At this temperature, the antibody will not be eluted during washing. It should be noted, however, that exposing normal red cells at 4 °C to many fresh normal sera results in a positive IAT with broad-spectrum antiglobulin sera because of the adsorption of incomplete anti-H (a normally occurring cold antibody) onto the red cells. At a low temperature, complement is bound too, and it is its adsorption that gives rise to the positive tests with broad-spectrum sera. The adsorption of complement can be prevented by adding a chelating agent, such as EDTA, to the serum.

Method. Add a one-tenth volume of EDTA, buffered to pH 7.0 (see p. 562) to the patient's serum. Prepare doubling dilutions in saline from 1 in 1 to 1 in 28.

Add 1 volume (drop) of a 50% suspension of group O, P-positive red cells to 10 volumes (drops) of each dilution. Mix and chill at 4 °C (preferably in a cold room).

After 1 h, wash the red cells four times in a large volume of cold (4 °C) saline. Then carry out an antiglobulin test using an anti-IgG reagent, as described on p. 454, but keeping the red cell-antiglobulin serum suspension at 4 °C.

As controls, set up a series of tests using a serum known to contain a D–L antibody (if available) and a normal serum, respectively.

This technique is the most sensitive way of detecting – especially in stored sera – the presence of a D–L antibody in an amount insufficient to bring about actual lysis.

Thermal range of Donath–Landsteiner antibody. The highest temperature at which D–L antibodies are usually adsorbed onto red cells is about 18 °C. Hence little or no lysis can be expected unless the cell–serum suspension is cooled below this temperature. Chilling in crushed ice results in maximum adsorption of the antibody and leads to the binding of complement, which brings about lysis when the cell suspension is subsequently warmed at 37 °C. Hence the 'cold-warm' biphasic procedure necessary for lysis to be demonstrated with a typical D–L antibody.

Specificity of the Donath–Landsteiner antibody. The D–L antibody appears to have a well-defined specificity within the GLOB blood-group system: namely, anti-P. However, in practice, almost all samples of red cells are acted upon because the cells that will not react (P^k and pp) are extremely rare.[56] Cord blood cells are lysed to about the same extent as are adult P_1 and P_2 cells.

Treatment of serum with 2-mercaptoethanol or dithiothreitol

Weak solutions of 2-mercaptoethanol (2-ME) or dithiothreitol (DTT) destroy the inter-chain sulphydryl bonds of gamma globulins. IgM antibodies treated in this way lose their ability to agglutinate red cells while IgG antibodies do not.[20] IgA antibodies may or may not be inhibited depending upon whether or not they are made up of polymers of IgA. Since almost all autoantibodies are either IgM or IgG, treatment of serum or an eluate with 2-ME or DTT gives a reliable indication of the Ig class of autoantibody under investigation.[20,57]

Method

2-mercaptoethanol. To 1 volume of undiluted serum add 1 volume of 0.1 mol/l 2-ME in phosphate buffer, pH 7.2 (see p. 563).

As a control, add a volume of the serum to the phosphate buffer alone. Incubate both at 37 °C for 2 h. Then titrate the treated serum and its control with the appropriate red cells.

If IgG antibody is present, the antibody titration in the control serum will be the same as that of the treated serum. However, if the antibody is IgM, the treated serum will fail to agglutinate the test cells or will agglutinate them to a much lower titre compared with the control untreated serum.

The control must remain active to show that the absence of agglutination is the result of reduction of IgM antibody and not dilution.

Dithiothreitol. 0.01 mol/l DTT can be used in place of 0.1 mol/l 2-ME in the previous method.

Drug-induced haemolytic anaemias of immunological origin

As already mentioned, acquired haemolytic anaemias may develop as the result of immunological reactions consequent on the administration of certain drugs.[12,58–60] Clinically, these cases often closely mimic AIHA of 'idiopathic' origin and for this reason a careful enquiry into the taking of drugs is a necessary part of the interrogation of any patient suspected of having an acquired haemolytic anaemia.

Two immunological mechanisms leading to a drug-induced haemolytic anaemia are recognised. These mechanisms can be referred to as 'drug-dependent immune' and 'drug-induced autoimmune'. Both types of antibody may be present in some patients.[61,62] In a unifying concept, the target orientation of these antibodies covers a spectrum in which the primary immune response is initiated by an interaction between the drug or its metabolites and a component of the blood cell membrane to create a neoantigen.[63] Drug-dependent antibodies bind to both the drug and the cell membrane but not to either separately. If the drug is withdrawn, the immune reaction subsides. It has been postulated that in the case of the autoantibodies, the greater part of the neoantigen is sufficiently similar to the normal cell membrane to allow binding without the drug being present. Similar mechanisms have been described for drug-induced immune thrombocytopenia and neutropenia of immunological origin (see p. 461).

In drug-dependent immune haemolytic anaemia, the drug is required in the *in vitro* system for the antibodies to be detected. The red cells become damaged by one of two mechanisms:

1. *Complement lysis.* A typical history is for haemolysis, which may be severe and intravascular, to follow the readministration of a drug with which the patient has previously been treated and for the haemolysis to subside when the offending drug is withdrawn. The DAT is likely to become strongly positive during the haemolytic phase, the patient's red cells being agglutinated by anti-C′ and sometimes by anti-IgG. Drugs that have been shown to cause haemolysis by the previously explained mechanism include quinine, quinidine and rifampicin, chlorpropamide, hydrochlorothiazide, nomifensine, phenacetin, salicylazosulphapyridine, the sodium salt of *p*-aminosalicylic acid and stibophen. Petz and Branch listed 25 drugs reported to have brought about haemolysis by this mechanism.[59]
2. *Extravascular haemolysis.* This is brought about by IgG antibodies that usually do not activate complement, or if they do, not beyond C3. The DAT will be positive with anti-IgG and sometimes also with anti-C′. The haemolytic anaemia associated with prolonged high-dose penicillin therapy is caused by the previously mentioned mechanism; other penicillin derivatives, as well as cephalosporins and tetracycline, may cause haemolysis in a similar fashion. Haemolysis ceases when the offending drug has been withdrawn.

Cephalosporins, in addition to causing the formation of specific antibodies, may alter the red cell surface so as to cause nonspecific adherence of complement and

immunoglobulins. This may lead to a positive DAT but is seldom associated with haemolysis, although where it occurs it can be very severe.

Acquired immune-mediated haemolytic anaemias are the result of autoantibodies. Once the evidence of anaemia and haemolysis is established, findings of a positive DAT and demonstration of autoantibodies will assist in reaching diagnosis of AIHA.

The nature of the positive DAT and the characteristic features of autoantibodies in AIHA are highlighted in Table 13-8.

Drug-induced autoimmune haemolytic anaemias

In the case of drug-induced autoimmune haemolytic anaemias, the antibody reacts with the red cell in the absence of the drug (these are sometimes referred to as 'drug-independent antibodies'). The anti-red cell autoantibodies seem to be serologically identical to those of 'idiopathic' warm-type AIHA. When the drug was widely used, the great majority of cases followed the use of the antihypertension drug α-methyldopa. The red cells are coated with IgG and the serum contains autoantibodies that characteristically have Rh specificity.

Other drugs that have been reported to act in a similar fashion to α-methyldopa include levodopa, chlordiazepoxide, mefenamic acid, flufenamic acid and indomethacin.[8]

Typical serological features of the different types of drug-induced haemolytic anaemia of immunological origin are summarised in Table 13-9.

Detection of antipenicillin antibodies

The characteristic features of penicillin-induced haemolytic anaemia are as follows:

1. Haemolysis occurs only in patients receiving large doses of a penicillin for long periods (e.g. weeks).
2. The DAT is strongly positive with anti-IgG reagents.
3. The patient's serum and antibody eluted from the patient's red cells react *only* with penicillin-treated red cells – they do not react with normal untreated red cells.

Reagents

- *Barbitone buffer.* 0.14 mol/l, pH 9.5 (see p. 563).
- *Penicillin solution.* 0.4 g of penicillin G dissolved in 6 ml of barbitone buffer.

Penicillin-coated normal red cells

Wash group O reagent red cells three times in saline and make an approximately 15% suspension in saline to which a one-tenth volume of barbitone buffer has been added. Add 2 ml of the red cell suspension to 6 ml of penicillin solution and incubate at 37 °C for 1 h. Then wash four times in saline and make 2% red cell suspensions in saline (for tube tests).

Control normal red cells. Control normal red cells should be treated in exactly the same way as the penicillin-coated

TABLE 13-8

POSITIVE DAT FINDINGS, CHARACTERISTIC FEATURES OF AUTOANTIBODY IN AIHA

	Warm AIHA	CHAD	Mixed-AIHA	PCH	IgA AIHA
DAT	IgG or IgG + C3 or IgG + C3 + IgM	C3 or C3 + IgM	IgG + C3 + IgM	C3	Neg with polyspecific reagent Pos with anti-IgA
Antibody characteristic					
1) Antibody subclass	IgG	IgM	IgG + IgM	IgG	IgA
2) Specificity	Apparent Rh specificity (common)	I, i, Pr		P	
3) Thermal reactivity (*in vitro*)	Optimal at 37 °C by IAT	0– > 30 °C by saline agglutination	Combined	0–<24 °C biphasic in nature	
4) Antibody titre at 4 °C	Not applicable	≥256	Usually <64 but can be >256	Usually <32	
Autoagglutination	No	Common	Common	Less common	No

AIHA, autoimmune haemolytic anaemia; C, complement; CHAD, cold haemagglutinin disease; DAT, direct antiglobulin test; Ig, immunoglobulin; Neg, negative; Pos, positive.

The determination of autospecificity is not required for diagnosis of CHAD, but confirmation of high thermal amplitude (i.e. cold autoagglutinin reacting at or above 30 °C) is essential.[55]

TABLE 13-9

SEROLOGICAL FEATURES OF THE DIFFERENT TYPES OF DRUG-INDUCED HAEMOLYTIC ANAEMIA OF IMMUNOLOGICAL ORIGIN

Mechanism	Prototype drug	DAT	IAT		
Drug-dependent antibody			**No drug**	**Serum + drug**	**Eluate + drug**
C' activation	Quin(id)ine	C′*	Neg	C′*	Neg
No C' activation	Penicillin	IgG	Neg	IgG	IgG
Autoantibody	α-Methyldopa	IgG	IgG	NA	NA

C′, complement; NA, not applicable; Neg, negative.
*Occasionally also IgG.

red cells except that the 6 ml of penicillin solution is replaced by 6 ml of barbitone buffer.

Method. Antipenicillin antibodies can be detected by the IAT in the usual way using the penicillin-coated red cells in place of normal unmodified cells. However, three extra controls are necessary.

1. Red cells that have not been exposed to penicillin should be added to the patient's serum.
2. Penicillin-treated red cells should be added to two normal sera known not to contain antipenicillin antibodies (*negative controls*).
3. Penicillin-treated red cells should be added to a serum (if one is available) known to contain antipenicillin antibodies (*positive control*).

Cephalosporin can be used in a similar way to sensitise red cells. Control (item 2) is particularly important when drugs such as cephalosporins are used because overexposure *in vitro* to these drugs can lead to positive results with normal sera.

Note. Some drugs do not dissolve easily; incubation at 37 °C, crushing tablets with a pestle and mortar and vigorous shaking of the solution may help.

High-titre IgG antipenicillin antibodies often cause direct agglutination of penicillin-treated red cells in low dilutions of serum. The antibodies can be differentiated from IgM agglutinating antibodies by treatment with 2-ME or DTT (see p. 268).

Detection of antibodies against drugs other than penicillin

In a patient with an immune haemolytic anaemia whose serum and red cell eluate does *not* react with normal red cells, and who is receiving a drug or drugs other than penicillin or a penicillin derivative, antibodies that react with red cells only in the presence of the suspect drug or drugs should be looked for in the following way.

The patient's serum and red cell eluates should be tested with normal and enzyme-treated group O red cells, carrying out the tests with and without the drug that the patient is receiving. The approach is essentially empirical. A saturated solution of the drug or its metabolite should be prepared in saline and the pH should be adjusted to 6.5 to 7.0.

Set up six tubes containing the patient's serum and the drug solution in the proportions shown in Table 13-10 and add 1 drop of a 50% saline suspension of group O cells to each tube. Incubate at 37 °C for 1 h, then examine for agglutination and lysis. Wash the red cells four times in saline, and carry out an IAT using anti-IgG and anti-C′ separately.

Interpretation

Tubes 1 and 2 test the patient's serum and normal red cells in the presence of the drug (tube 1) and without the drug (tube 2), answering the question as to whether there is a drug-dependent antibody. Tubes 3 and 4 test the effect of added complement on the previous reactions. Tubes 5 and 6 without the patient's serum act as controls for tubes 3 and 4.

OXIDANT-INDUCED HAEMOLYTIC ANAEMIA

Oxidant-induced haemolytic anaemia should be suspected when the blood film of a patient exposed to an oxidant drug or chemical shows irregularly contracted cells. A Heinz-body test (see p. 316) is confirmatory. The oxidant may also cause methaemoglobinaemia or sulphaemoglobinaemia, both of which can be confirmed by spectroscopy

TABLE 13-10

INVESTIGATION OF A SUSPECTED DRUG-INDUCED IMMUNE HAEMOLYTIC ANAEMIA

	Tube No.					
	1	**2**	**3**	**4**	**5**	**6**
Patient's serum (drops)	10	10	5	5	0	0
Fresh normal serum (drops)	0	0	5	5	10	10
Drug solution volumes (drops)	2	0	2	0	2	0
Saline volumes (drops)	0	2	0	2	0	2
50% normal group O cells volumes (drops)	1	1	1	1	1	1

(see p. 225) or co-oximetry. The differential diagnosis of haemolysis induced by an exogenous oxidant includes other causes of haemolysis with irregularly contracted cells (e.g. Zieve syndrome), G6PD deficiency and the presence of an unstable haemoglobin. In Zieve syndrome (haemolysis associated with alcohol excess, fatty liver and hyperlipidaemia), the plasma may be visibly lipaemic; if this syndrome is suspected, further investigations should include liver function test and serum lipid measurements.

MICROANGIOPATHIC AND MECHANICAL HAEMOLYTIC ANAEMIAS

Microangiopathic or mechanical haemolytic anaemia should be suspected when a blood film shows schistocytes. Examination of the blood film is, in fact, the most important laboratory procedure in making this diagnosis, although some automated blood cell counters will also detect the presence of red cell fragments. Because haemolysis is intravascular, useful confirmatory tests include serum haptoglobin estimation (see p. 217) and, when the condition is chronic, a Perls stain of urinary sediment to detect the presence of haemosiderin (see p. 221). Because a microangiopathic haemolytic anaemia is often part of a more generalised syndrome resulting from microvascular damage or fibrin deposition, other tests are also indicated in unexplained cases. They include tests of renal function, a platelet count and a coagulation screen including tests for D-dimer or fibrin degradation products (see p. 405). Tests for verotoxin-secreting *E. coli* are indicated in cases of microangiopathic haemolytic anaemia with renal failure. Quantification of von Willebrand factor-cleaving protease (ADAMTS13) is indicated in suspected thrombotic thrombocytopenic purpura.

PAROXYSMAL NOCTURNAL HAEMOGLOBINURIA

Paroxysmal nocturnal haemoglobinuria (PNH) is an acquired clonal disorder of haemopoiesis, in which the patient's red cells are abnormally sensitive to lysis by normal constituents of plasma. In its classic form, it is characterised by haemoglobinuria during sleep (nocturnal haemoglobinuria), jaundice and haemosiderinuria. Not uncommonly, however, PNH presents as an obscure anaemia without obvious evidence of intravascular haemolysis, or it develops in a patient suffering from aplastic anaemia or more rarely from primary myelofibrosis or chronic myeloid leukaemia.[64,65]

PNH red cells are unusually susceptible to lysis by complement.[66,67] This can be demonstrated *in vitro* by a variety of tests (e.g. the acidified-serum (Ham),[68] sucrose,[69] thrombin,[70] cold-antibody lysis,[71] inulin[72] and cobra-venom[73] tests). In the acidified serum, inulin and cobra-venom tests, complement is activated via the alternative pathway, whereas in the cold-antibody test and probably in the thrombin test, complement is activated by the classical sequence initiated through antigen–antibody interaction. In the sucrose lysis test, a low ionic strength is thought to lead to the binding of IgG molecules nonspecifically to the cell membrane and to the subsequent activation of complement via the classical sequence. In addition, the alternative pathway appears to be activated.[74] In each test, PNH cells undergo lysis because of their greatly increased sensitivity to lysis by complement.

Minor degrees of lysis may be observed in the cold-antibody lysis and sucrose tests with the red cells from a variety of dyserythropoietic anaemias (e.g. aplastic anaemia, megaloblastic anaemia and primary myelofibrosis).[75,76] Weak positive results in these tests thus have to be interpreted with care. PNH red cells in patients with classic haemolytic PNH almost always undergo considerable lysis in these tests.

A characteristic feature of a positive test for PNH is that not all the patient's cells undergo lysis, even if the conditions of the test are made optimal for lysis (Fig. 13-1). This is because only a proportion of any PNH patient's red cell population is hypersensitive to lysis by complement. The size of this population varies from patient to patient, and there is a direct relationship between the proportion of red cells that can be lysed (in any of the diagnostic tests) and the severity of *in vivo* haemolysis.

The phenomenon of some red cells being sensitive to complement lysis and some being insensitive was studied quantitatively by Rosse and Dacie, who obtained two-component complement sensitivity curves in a series of patients with PNH.[67] Later, Rosse reported that in some cases three populations of red cells could be demonstrated:[77,78]

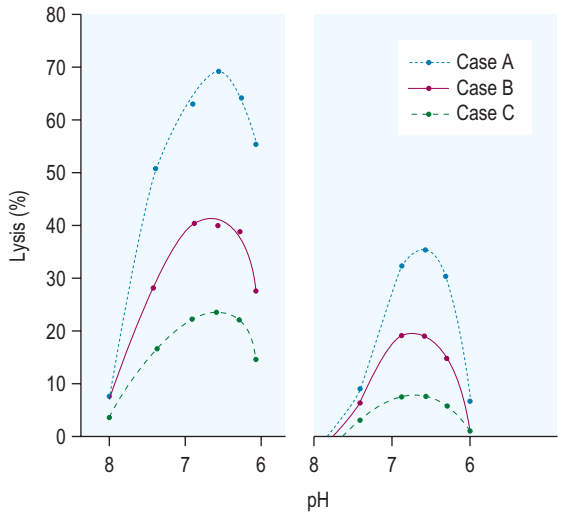

FIGURE 13-1 Effect of pH on lysis *in vitro* of paroxysmal nocturnal haemoglobinuria (PNH) red cells by human sera. The red cells of three patients with disease of different severity were used, plus two fresh normal sera, one serum being more potent than the other.

1. Very sensitive (type III) cells, 10–15 times more sensitive than normal cells
2. Cells of medium sensitivity (type II), 3–5 times more sensitive than normal cells
3. Cells of normal sensitivity (type I)

In vivo the proportion of type III cells parallels the severity of the patient's haemolysis.

PNH is an acquired clonal disorder[79] resulting from a somatic mutation occurring in a haemopoietic stem cell. It has been demonstrated that a proportion of neutrophils, platelets and lymphocytes are also part of the PNH clone.[80,81] The characteristic feature of cells belonging to the PNH clone is that they are deficient in several cell-membrane–bound proteins including red cell acetylcholinesterase,[82–84] neutrophil alkaline phosphatase,[85–87] CD55 (decay accelerating factor or DAF),[88,89] homologous restriction factor (HRF)[66,90] and CD59 (membrane inhibitor of reactive lysis or MIRL),[91–93] among others. CD55, CD59 and HRF all have roles in the protection of the cell against complement-mediated attack. CD59 inhibits the formation of the terminal complex of complement and it has been established that the deficiency of CD59 is largely responsible for the complement sensitivity of PNH red cells. PNH type III red cells have a complete deficiency of CD59, whereas PNH type II red cells have only a partial deficiency, and it is this difference that accounts for their variable sensitivities to complement.[94,95] The analysis of these deficient proteins on PNH cells by flow cytometry, particularly of the red cells and neutrophils, has become a useful research and diagnostic tool, but is only applicable in centres with a significant number of patients requiring investigation for PNH.

By comparing the proportion of cells with deficient CD59 to the percentage lysis in the Ham test, it has been possible to assess the sensitivity of the Ham test. The standard Ham test is reasonably good at estimating the proportion of PNH red cells as long as they are PNH type III cells and comprise <20% of the total. In cases in which the PNH cells are type II and >20% are present, the standard Ham test significantly underestimates the proportion of PNH red cells. The standard Ham test can be negative when there are <5% PNH type III cells or <20% PNH type II cells. When the Ham test is supplemented with magnesium, to optimise the activation of complement, the percentage lysis gives a more accurate estimation of the proportion of PNH cells (Fig. 13-2).[96]

Certain chemicals, in particular sulphydryl compounds, can act on normal red cells *in vitro* so as to increase their complement sensitivity. In this way, PNH-like red cells can be created in the laboratory and can be useful as reagent cells.

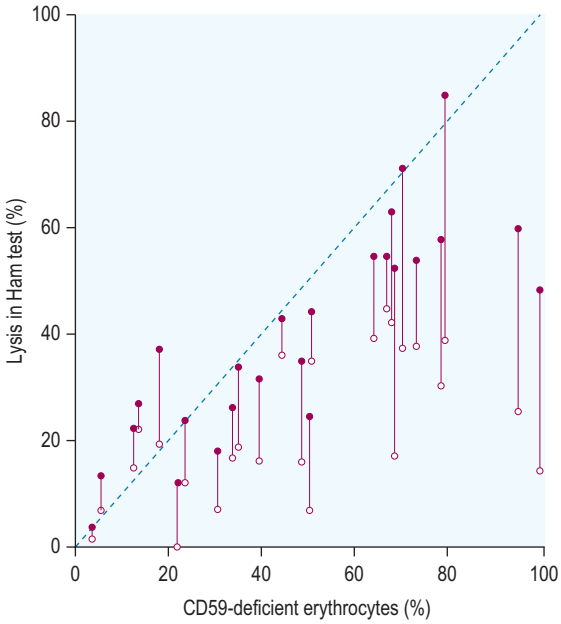

FIGURE 13-2 Comparison of the proportion of CD59-deficient red cells with the degree of lysis in the Ham test. The percentage lysis in the Ham test with added magnesium (solid circles) and without added magnesium (open circles) is plotted against the proportion of CD59-deficient red cells in the same samples from 25 patients with paroxysmal nocturnal haemoglobinuria (PNH). *(With thanks to Hillmen P, Bessler M, Roper D and Luzzatto L, unpublished observation.)*

Acidified-serum lysis test (Ham test)

Principle

The patient's red cells are exposed at 37 °C to the action of normal serum or the patient's own serum suitably acidified to the optimum pH for lysis (pH 6.5–7.0) (Table 13-11).

The patient's red cells can be obtained from defibrinated, heparinised, oxalated, citrated or EDTA-anticoagulated blood, and the test can be satisfactorily carried out even on cells that have been stored at 4 °C for up to 2–3 weeks in ACD or Alsever's solution, if kept sterile. The patient's serum is best obtained by defibrination because in PNH if it is obtained from blood allowed to clot in the ordinary way at 37 °C or at room temperature, it will almost certainly be markedly lysed. Normal serum should similarly be obtained by defibrination, although serum derived from blood allowed to clot spontaneously at room temperature or at 37 °C can be used. Normal serum known to be strongly lytic to PNH red cells is to be preferred to patient's serum, the lytic potentiality of which is unknown. However, if the test is positive using normal serum, it is important, particularly if the patient appears not to be suffering from overt intravascular haemolysis, to obtain a positive result using the patient's serum to exclude hereditary erythroid multinuclearity associated with a positive acidified-serum test (HEMPAS) (see p. 274). The variability between the sera of individuals in their capacity to lyse PNH red cells is shown in Figure 13-1. The activity of a single individual's serum also varies from time to time,[97] and it is always important to include in any test, as a positive control, a sample of known PNH cells or artificially created 'PNH-like' cells (see p. 278).

TABLE 13-11

THE ACIDIFIED-SERUM LYSIS TEST WITH ADDED MAGNESIUM

Reagent	Test (ml)		Controls (ml)			
Tube	**1**	**2**	**3**	**4**	**5**	**6**
Fresh normal serum	0.5	0.5	0	0.5	0.5	0
Heat-inactivated normal serum	0	0	0.5	0	0	0.5
0.2 mol/l HCl	0	0.05	0.05	0	0.05	0.05
50% patient's red cells	0.05	0.05	0.05	0	0	0
50% normal red cells	0	0	0	0.05	0.05	0.05

Lysis (in a positive modified test)	Trace (2%)	+++ (30%)	-	-	-	-

*Only for modified test.

The sera should be used within a few hours of collection. Their lytic potency is retained for several months at −70 °C, but at 4 °C, and even at −20 °C, this deteriorates within a few days.

Method

Deliver 0.5 ml samples of fresh normal serum, group AB or ABO-compatible with the patient, into three pairs of 75 × 12 mm tubes. Place two tubes at 56 °C for 10–30 min to inactivate complement. Keep the other two pairs of tubes at room temperature and add to the serum in two of these tubes one-tenth volumes (0.05 ml) of 0.2 mol/l HCl. Add similar volumes of acid to the inactivated serum samples. Then place all the tubes in a 37 °C water bath.

While the serum samples are being dealt with, wash samples of the patient's red cells and of control normal red cells (compatible with the normal serum) twice in saline and prepare 50% suspensions in the saline. Then add one-tenth volumes of either patient or control cell suspensions (0.05 ml) to each of the tubes containing unacidified fresh serum, acidified fresh serum and acidified inactivated serum, respectively. Mix the contents carefully and leave the tubes at 37 °C. Centrifuge them after about 1 h.

Add 0.05 ml of each of these six cell suspensions to 0.55 ml of water so as to prepare a standard for subsequent quantitative measurement of lysis and retain 0.5 ml of serum for use as a blank. For the measurement of lysis, deliver 0.3 ml of the supernatants of the test and control series of cell–serum suspensions into 5 ml of 0.4 ml/l ammonia or Drabkin reagent. Similarly, add 0.3 ml of the blank serum (equivalent to 0% lysis) and 0.3 ml of each lysed cell suspension (equivalent to 100% lysis) to 5 ml of 0.4 ml/l ammonia or Drabkin reagent. Measure the lysis in a photoelectric colorimeter using a yellow–green (e.g. Ilford 625) filter or in a spectrometer at a wavelength of 540 nm.

If the test cells are from a patient with PNH, they will undergo definite, although incomplete, lysis in the acidified serum. Much less lysis – or even no lysis at all – will be visible in the unacidified serum. No lysis will occur in the acidified inactivated serum. The normal control sample of cells should not undergo lysis in any of the three tubes.

In PNH, 10–50% lysis is usually obtained when lysis is measured as liberated haemoglobin. Exceptionally, there may be as much as 80% lysis or as little as 5%.

The red cells of a patient who has had a transfusion will undergo less lysis than they would have before the transfusion because the normal transfused cells do not have increased sensitivity to lysis. In PNH, it is characteristic that a young cell (reticulocyte-rich) population, such as the upper red cell layer obtained by centrifugation, undergoes more lysis than the red cells derived from mixed whole blood.

Acidified-serum lysis test with additional magnesium (modified Ham test)

Principle

The sensitivity of the Ham test can be improved by the addition of magnesium to the test to enhance the activation of complement.

Method

The method is identical to that for the standard Ham test (see above) with the addition of 10 µl of 250 mmol magnesium chloride (final concentration = 4 mmol) to each tube prior to the incubation (Table 13-11).

Significance of the acidified-serum lysis test

A positive acidified-serum test, carried out with proper controls, denotes the PNH abnormality, and PNH cannot be diagnosed unless the acidified-serum test is positive. The addition of magnesium chloride increases the sensitivity of the acidified-serum test.

When the acidified-serum test is positive, a direct antiglobulin test (see p. 453) should also be carried out. If this is positive, it could be the result of a lytic antibody that has given a false-positive acidified-serum test. This can be confirmed by appropriate serological studies. In such

complex cases, flow cytometry after reaction of the red cells with anti-CD59 is recommended because it is a more definitive test for PNH (see below).

The only disorder other than PNH that may appear to give a clear-cut positive test result is a rare congenital dyserythropoietic anaemia, congenital dyserythropoietic anaemia type II or HEMPAS.[98,99] In contrast to PNH, however, HEMPAS red cells undergo lysis in only a proportion (about 30%) of normal sera; moreover, they do not undergo lysis in the patient's own acidified serum and the sucrose lysis test is negative. In HEMPAS, the expression of glycosylphosphatidylinositol (GPI)-linked proteins, such as CD55 and CD59, is normal. Lysis in HEMPAS appears to be a result of the presence on the red cells of an unusual antigen, which reacts with a complement-fixing IgM antibody ('anti-HEMPAS') present in many, but not in all, normal sera.[99]

Heating at 56 °C inactivates the lytic system, and, if there is lysis in inactivated serum, the test cannot be considered positive. Markedly spherocytic red cells or effete normal red cells may lyse in acidified serum, probably owing to the lowered pH, and such cells may also lyse in acidified inactivated serum.

PNH red cells are not unduly sensitive to lysis by a lowered pH *per se*. The addition of the acid adjusts the pH of the serum–cell mixture to the optimum for the activity of the lytic system. As is shown in Figure 13-1, it is possible to construct pH–lysis curves, if different concentrations of acid are used. The optimum pH for lysis is between pH 6.5 and 7.0 (measurements made after the addition of the red cells to the serum).

Sucrose lysis test

An iso-osmotic solution of sucrose (92.4 g/l) is required.[100] This can be stored at 4 °C for up to 3 weeks.

For the test, set up two tubes, one containing 0.05 ml of fresh normal group AB- or ABO-compatible serum diluted in 0.85 ml of sucrose solution and the other containing 0.05 ml of serum diluted in 0.85 ml of saline. Add to each tube 0.1 ml of a 50% suspension of washed red cells. After incubation at 37 °C for 30 min, centrifuge the tubes and examine for lysis. If lysis is visible in the sucrose-containing tube, measure this in a photoelectric colorimeter or a spectrometer as described earlier, using the tube containing serum diluted in saline as a blank and a tube containing 0.1 ml of the red cells suspension in 0.9 ml of 0.4 ml/l ammonia in place of the sucrose–serum mixture as a standard for 100% lysis.

Interpretation

The sucrose lysis test is based on the fact that red cells absorb complement components from serum at low ionic concentrations.[97,101] PNH cells, because of their great sensitivity, undergo lysis but normal red cells do not. The red cells from some patients with leukaemia[75] or primary myelofibrosis may undergo a small amount of lysis, almost always <10%. In such cases, the acidified-serum test is usually negative and PNH should not be diagnosed. In PNH, lysis is usually between 10% and 80%, but exceptionally may be as little as 5%. Sucrose lysis and acidified-serum lysis of PNH red cells are fairly closely correlated. The sucrose lysis test is usually negative in HEMPAS.

Flow cytometric analysis of the glycosylphosphatidylinositol-linked proteins on red cells

Principle

Flow cytometry should now be considered the gold standard test for the diagnosis of PNH.[102] Patient red cells can be obtained in any of the anticoagulants described for the Ham test, though EDTA is preferred because a blood count and blood film can also be prepared from this type of sample. Samples for red cell testing will remain stable for at least a week if kept at 4 °C. Antibody clone selection is important for optimal staining and the use of anti-CD59 (clone MEM43) is strongly recommended.[103] Although CD55 and CD58 are also GPI-linked antigens on red cells, their staining profiles do not match the superior results obtained with CD59. Patient red cells are stained in a two-colour combination of antibodies using a glycophorin C antibody (CD235a) to positively identify the red cells in combination with an antibody to the GPI-linked antigen CD59 which is deficient from PNH red cells.

Reagents

- *Antibodies:* CD235a-PE:Cy5 (clone GA-R2 www.bdbiosciences.com), CD59-PE (clone MEM43 www.abnova.com).

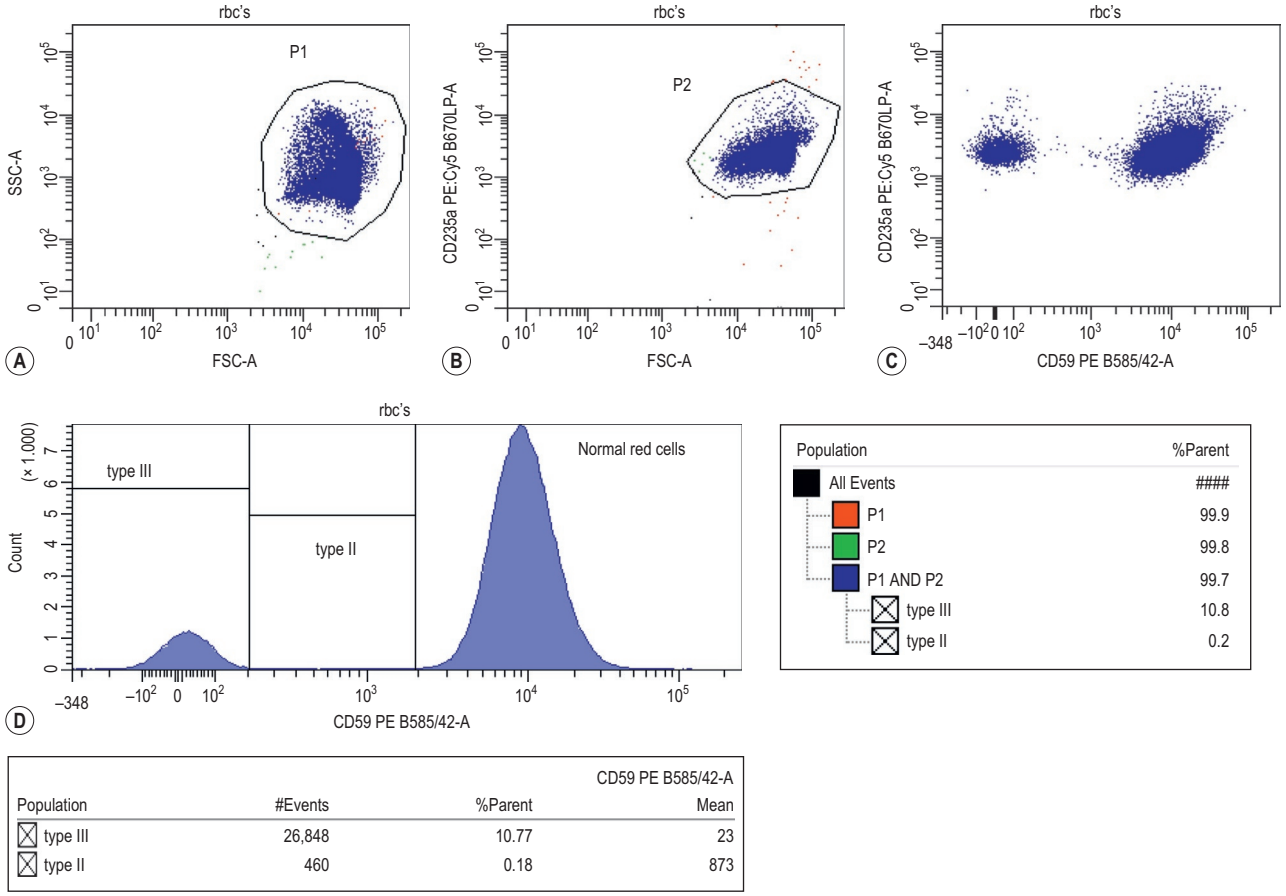
Method

The volumes of antibodies described in the method below are for guidance only, and each laboratory should establish optimal antibody titres for each reagent in the combination. For washing cells use either PBS, proprietary cell washing solutions or flow cytometry sheath fluid (FACSFlow, www.bdbiosciences.com). These solutions should not contain protein support as this promotes red cell agglutination.

1. Pipette 5 µl of a working dilution (1:400) of CD235a-PE:Cy5, 1.5 µl CD59 PE and 10 µl of FACSFlow to a round bottomed microtitre plate well. Mix the blood sample by gentle inversion and add 1.5 µl of blood to the antibody combination in the microtitre plate well. Mix on a microtitre plate mixer for 10 s, cover and incubate at 4 °C for 60 min protected from light, with gentle mixing every 15 min.
2. Add 150 µl of FACSFlow to the well then centrifuge at 2000 revolutions per minute (rpm) for 30 s. Discard the supernatant by rapid inversion of the

microtitre plate. With a clean pipette tip each time, add 150 µl of fresh FACSFlow to the red cell pellet and resuspend by pipetting up and down a few times to break up any aggregates. Repeat the centrifuging/washing stage, as above, twice more (three washes in total).

3. To a relabelled FACS tube, add 600 µl of FACSFlow. Remove 150 µl and resuspend the red cell pellet several times to break up aggregates. Transfer to a FACS tube. Just prior to acquisition, 'rack' the tube vigorously by dragging it 3 to 4 times on a metal rack to break up aggregates. The cells are now ready for data acquisition and should be processed through the flow cytometer as soon as possible after antibody staining to prevent aggregates of red cells reforming.
4. Red cells are identified on dual parameter plots of forward scatter (FSC) versus sideways scatter (SSC) with detectors set in logarithmic amplification mode, combined with CD235a versus FSC (Fig. 13-3, *A* and *B*).
5. Acquire and store 100 000 events.
6. Adjust the positions of polygonal gates P1 and P2 to capture all red cells based on FSC and SSC and CD235a positivity. These gates are combined and applied to the dot-plot of CD235a versus CD59 (Fig. 13-3, *C*) and the single histogram plot of CD59.
7. CD59 histogram (Fig. 13-3, *D*). Three population markers are set on this histogram. Type III cells (complete deficiency of GPI-antigens) can be defined using marker settings from unstained cells. Type I cells (normal expression) can be defined from processing a normal control or from the normal red cells present in the sample. Type II cells (partial GPI-deficiency) can be classified as those cells that fall between type III and type I cells. Record the percentages of type I, II and III cells.



Population	#Events	%Parent	CD59 PE B585/42-A Mean
type III	26,848	10.77	23
type II	460	0.18	873

FIGURE 13-3 Acquisition and analysis of PNH red cells by flow cytometry. In plots (A) and (B) the analysis regions P1 and P2 are adjusted to capture a pure population of red cells based on light scatter characteristics and CD235a positivity. Subsequent application of a combined analysis region P3 to a dot plot of CD235a versus CD59 (plot (C)) and the CD59 histogram (plot (D)) shows a population of PNH red cells comprising 11% of total erythrocytes.

Continued

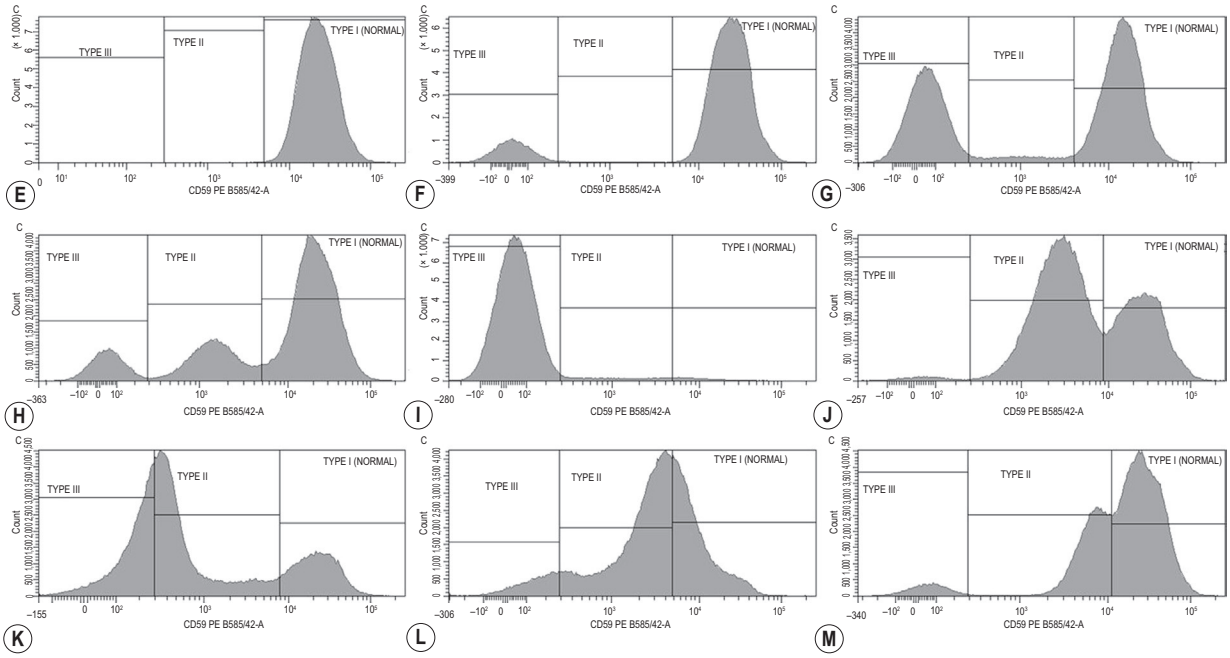


FIGURE 13-3, CONT'D (E)–(J) Representative CD59 histograms from a normal individual and eight patients with PNH. The plots illustrate the wide variety of possible CD59 profiles seen in patients with PNH. (E) A normal individual shows normal expression of CD59. (F), (G) Two patients with type III (complete GPI deficiency) populations of PNH cells and normal cells. (H) A patient with clearly distinct type III and type II (partial GPI-deficiency) PNH cells together with normal cells. (I) A patient successfully treated with complement blockade therapy who is no longer haemolysing, allowing his PNH red cell population to increase dramatically in size. (J) A large population of type II PNH cells. Patients with this profile often show little sign of haemolysis. Histograms (K)–(M) give an indication of the complex range of staining profiles seen in PNH. The red cells do not always fall into the distinct type III and type II categories, and considerable overlap can be seen between type III and type II cells as well as PNH type II cells having almost normal levels of CD59 expression.

Technical considerations and reporting of results

Report the type III and type II PNH red cell clone sizes as well as the total (type III + type II combined) PNH red cell clone size. If there is no clear separation between type II and III populations, the PNH clone can be delineated by using one gate for all cells with decreased/absent CD59 expression rather than setting arbitrary gates. Avoid reporting reactivity with each individual marker, and avoid ambiguous 'positive' and 'negative' terminology. Also avoid using the terms 'PNH-positive' or 'PNH-negative' when reporting results in flow cytometric assays. Instead use the term 'PNH clone present' or 'PNH clone absent'. Examination of red cells in the untransfused PNH patient provides the clearest definition of Type III (complete deficiency), Type II (partial deficiency) and Type I (normal expression). Typical examples of CD59 expression in patients with PNH are shown in Figure 13-2. The distributions of these populations show wide variation from patient to patient and delineation between the various types is not always clear-cut (Figure 13-3, *E–M*). Red cell analysis is important in PNH, since accurate determination of the distribution of type I, II and III cells can predict clinical phenotype. For example, patients with greater than 20% type III (complete deficiency) almost always show clinical evidence of haemolysis.

Flow cytometric analysis of glycosylphosphatidylinositol-linked proteins on neutrophils

Principle

A proportion of the patient's neutrophils have been demonstrated to be part of the PNH clone in all patients with PNH. GPI-linked antigens that are suitable for analysis include CD24, CD66 and CD157, and numerous antibodies are available that are suitable for this purpose. It is strongly recommend that the reagent FLAER (Fluorescent Aerolysin) is used for neutrophil analysis in PNH. This bacterially derived protein has high affinity binding for the GPI-anchor, and when coupled with the fluorochrome AlexaFluor488, is an ideal reagent for PNH testing, particularly when used in combination with monoclonal antibodies.[104] An EDTA blood sample is required, preferably as fresh as possible. Samples >48 h old that have not been kept under controlled conditions are almost invariably unsuitable for flow cytometry due to reduced neutrophil viability.

Method

Reagents

- *FLAER AF488* (www.protoxbiotech.com).
- *Monoclonal antibodies*: CD24PE (clone ML5, www.bdbiosciences.com); CD45PerCP:Cy5.5 (clone TÜ116, www.bdbiosciences.com) and CD15APC (clone HI98, www.bdbiosciences.com).

The volumes of antibodies described in the method below are for guidance only and each laboratory should establish optimal antibody titres for each reagent in the combination. For washing of cells, use PBS, proprietary cell washing solutions or flow cytometry sheath fluid supplemented with 0.1% BSA.

1. Pipette 5 µl of FLAER reagent, 20 µl of CD24PE, 20 µl of CD45PerCP:Cy5.5 and 10 µl of CD15 APC into a FACS tube (i.e. a tube that fits the flow cytometer). Mix the blood sample by gentle inversion and then add 100 µl of the sample directly to the antibodies and mix gently. Incubate for 15 min protected from light at room temperature.
2. Add 2 ml of a proprietary lysing reagent (e.g. FACSlyse BD Biosciences, www.bdbiosciences.com) to the blood–antibody mixture and incubate for a further 10 min with intermittent gentle mixing to ensure complete red cell lysis. Following this, cells are centrifuged and washed twice to remove excess antibody. Resuspend in 300 µl flow cytometry sheath fluid with data acquired on a flow cytometer with minimal delay.
3. The cytometer should be set up and compensated for the following fluorochromes: AF488, PE, PerCP:Cy5.5 and APC. An acquisition and analysis template should be set up as shown in Figure 13-4. Acquire up to 100 000 events.
4. Defining the neutrophil population: adjust the position of P1 to include all CD45-positive events. On the dual parameter plot of CD15 versus SSC, adjust the position of P2 to include all CD15-positive neutrophils. Finally, adjust the position of P3 in the FSC/SSC dot-plot to include all neutrophil events.
5. These analysis regions are then added together (P1 + P2 + P3) in a sequential gating strategy and applied to the dot plot of FLAER versus CD24 to identify the presence of any PNH clones (Fig. 13-4, *D*). Neutrophil PNH clones are characterised by CD24 and FLAER

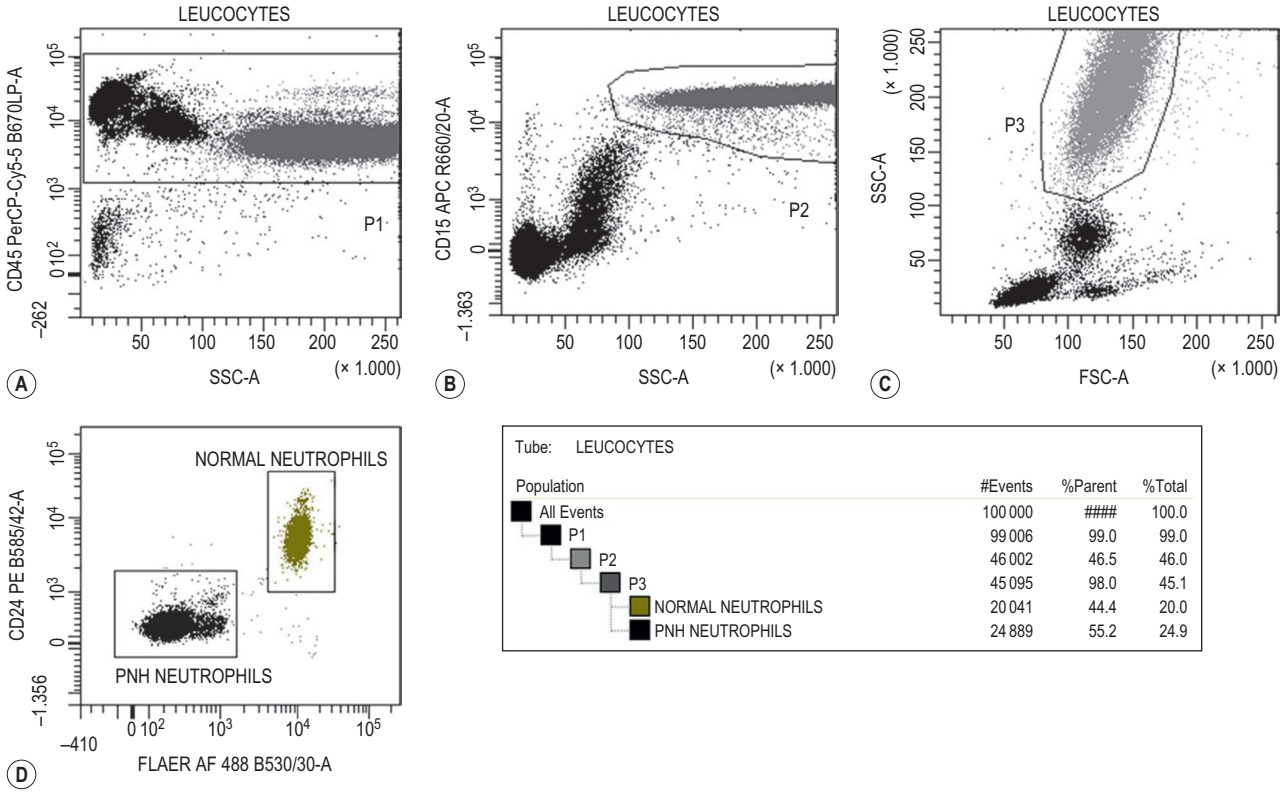

FIGURE 13-4 Acquisition and analysis of PNH neutrophils by flow cytometry. In plots (A)–(C), a sequential gating strategy is shown in order to identify neutrophils. Analysis region P1 is set around CD45-positive leucocytes and applied to plot (B) SSC v CD15. A second analysis region P2 is adjusted to capture a pure population of neutrophils. Finally, these regions are applied to an FSC v SSC plot and a third region P3 drawn around neutrophils. These combined regions are applied to a dot plot of CD24 v FLAER (D). In this example a neutrophil PNH clone is clearly visible, comprising 55.2% of total neutrophils.

(GPI) negativity. In order to determine the size of the PNH neutrophil clone an analysis region can be set directly around the PNH population.

6. Results to report: The presence and percentage size of any PNH clone. In cases where no PNH clone is detected, normal expression of GPI-linked antigens should be reported.

Technical considerations and reporting of results

The presence of a population of cells with a deficiency of more than one GPI-linked antigen is diagnostic of PNH. It is important to analyse more than one GPI-linked antigen in any antibody combination for a number of reasons. Firstly, small PNH populations are much easier to visualise on two-dimensional dot-plots. Secondly, this also allows these populations to be 'back gated' to show they share the same characteristics as normal cells and increase confidence in the results. By collecting 100 000 events, PNH clones of 0.1% can be detected using this procedure.

Although the analysis of neutrophils is more complex than for red cells, the results give a more accurate reflection of the proportion of PNH to normal haemopoiesis. Red cell analysis provides different, but complementary, information. The size of the red cell PNH clone rarely approaches that of the granulocyte PNH clone for a number of reasons. Firstly, PNH red cells will undergo *in vivo* haemolysis, but can also be significantly lower than the neutrophil PNH clone due to recurrent red cell transfusions. Despite these limitations, red cell analysis using anti-CD59 provides the clearest separation between the different types of PNH cells. Moreover, those patients with predominantly type III cells are frequently those with frank haemolytic disease. The patients with predominantly type II cells often show little signs of haemolysis, but may paradoxically show complete GPI-deficiency on their neutrophil PNH clone. Numerous patients will show mixture of type II and type III cells or partial GPI-deficiency that crosses both type II and type III populations illustrating the complex clonal nature and the multi-mutational nature of the disease.

Paroxysmal nocturnal haemoglobinuria-like red cells

By treating normal red cells with certain chemicals, it is possible to increase their complement sensitivity so that they take on many of the characteristics of PNH cells.[105] The chemicals include sulphydryl compounds such as L-cysteine, reduced glutathione, 2-aminoethyl-*iso*-thiouronium bromide (AET) and 2-mercaptobenzoic acid.[106] AET- and 2-mercaptobenzoic acid-treated cells can be used conveniently as a positive control for *in vitro* lysis tests for PNH.[107]

Preparation of AET cells

Prepare an 8 g/l solution of AET and adjust its pH to 8.0 with 5 mol/l NaOH. Collect normal blood into ACD and wash it ×2 in 9 g/l NaCl. Add 1 volume of the packed cells to 4 volumes of the AET solution in a 75 × 12 mm tube, which is then stoppered. Mix the contents gently and place the tube at 37 °C for 10–20 min; the optimal time of incubation varies between red cell samples. Then wash the cells repeatedly with large volumes of saline until the supernatant is colourless. The red cells are now ready to use.[108]

Summary of testing for paroxysmal nocturnal haemoglobinuria

The Ham test is still an important diagnostic test in PNH. If carried out with additional magnesium chloride and performed with the necessary controls, it is more sensitive than the unmodified test and remains specific for the diagnosis of PNH. The inclusion of a further test, such as the sucrose lysis test, is optional. The use of flow cytometry permits a better estimate of the size of the PNH clone and identifies the type of red cell abnormality. However, more experience and expensive equipment are required to perform flow cytometry reliably than are necessary to perform a Ham test. Flow cytometry is a useful diagnostic test in certain circumstances, especially when the patient is heavily transfused and it becomes necessary to analyse neutrophils and when following a patient after bone marrow transplantation. Flow cytometry may also be useful in the follow-up of groups of patients with aplastic anaemia because clonal evolution into PNH may be detected at an earlier stage. For laboratories already using gel technology for blood grouping and antibody screening, this technique provides a simple method for screening red cells for deficiency of GPI-linked protein.

Investigation of Variant Haemoglobins and Thalassaemias

Barbara J. Wild • Barbara J. Bain

CHAPTER OUTLINE

THE HAEMOGLOBIN MOLECULE

Human haemoglobin is formed from two pairs of globin chains each with a haem group attached. Seven different globin chains are synthesised in normal subjects; two, ε and ζ, are characteristic of the embryo and contribute to four transient embryonic haemoglobins referred to as haemoglobins Gower 1, Gower 2, Portland 1 and Portland 2. Haemoglobin F is the predominant haemoglobin of fetal life and comprises the major proportion of haemoglobin found at birth. Haemoglobin A is the major haemoglobin found in adults and children. Haemoglobins A_2 and F are found in small quantities in adult life (approximately 2–3.3% and 0.2–1.0%, respectively). The adult proportions of haemoglobins A, A_2 and F are usually attained by 6–12 months of age.

The individual chains synthesised in postnatal life are designated α, β, γ and δ. Haemoglobin A has two α chains and two β chains ($\alpha_2\beta_2$); haemoglobin F has two α chains and two γ chains ($\alpha_2\gamma_2$) and haemoglobin A_2 has two α chains and two δ chains ($\alpha_2\delta_2$). The α chain is thus common to all three types of haemoglobin molecule.

α chain synthesis is directed by two α genes, α2 and α1, on chromosome 16 and β and δ chain synthesis by single β and δ genes on chromosome 11; γ chain synthesis is directed by two genes, $^{G}\gamma$ and $^{A}\gamma$, also on chromosome 11. The globin genes are shown diagrammatically in Figure 14-1.

The four chains are associated in the form of a tetramer: the $\alpha_1\beta_1$ (and equivalent $\alpha_2\beta_2$) contact is the strongest and involves many amino acids with many interlocking side chains; the $\alpha_1\beta_2$ (and equivalent $\alpha_2\beta_1$) contact is less extensive, and the contacts between similar chains are relatively weak. The binding of a haem group within the haem pocket in each chain is vital for the oxygen-carrying capacity of the molecule and stabilises the whole molecule. If the haem attachment is weakened, the globin chains dissociate into dimers and monomers.

There are many naturally occurring, genetically determined variants of human haemoglobin (>1000)[1] and although many are harmless, some have serious clinical effects. Collectively, the clinical syndromes resulting from disorders of haemoglobin synthesis are referred to as 'haemoglobinopathies'. They can be grouped into three main categories:

1. Those resulting from a genetically determined structural variant of haemoglobin, such as haemoglobin S.
2. Those owing to failure to synthesise one or more of the globin chains of haemoglobin at a normal rate, as in the thalassaemias.
3. Those owing to failure to complete the normal neonatal switch from fetal haemoglobin (haemoglobin F) to adult haemoglobin (haemoglobin A). This category comprises a group of disorders referred to as hereditary persistence of fetal haemoglobin (HPFH).

An individual can also have a combination of two or more of these abnormalities (e.g. a variant haemoglobin can be synthesised at a reduced rate).

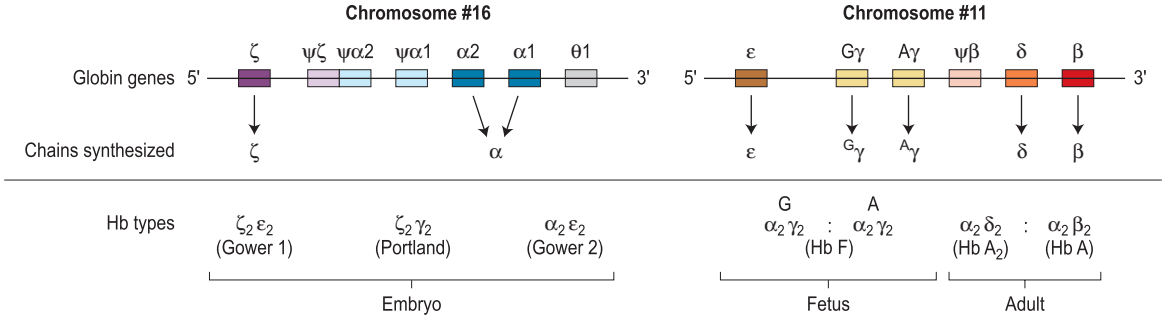

FIGURE 14-1 The α-globin gene cluster on chromosome 16 and that of the β-globin gene cluster on chromosome 11. The blue and red boxes represent functional genes; pseudogenes are shown as pale blue and pink. The α and γ globin genes are duplicated; the two α globin genes have the same product, whereas the products of the two γ globin genes are slightly different ($^{G}\gamma = \gamma$ 136Gly; $^{A}\gamma = \gamma$ 136Ala).

STRUCTURAL VARIANTS OF HAEMOGLOBIN

Alterations in the structure of haemoglobin are usually brought about by point mutations affecting one or, in some cases, two codons encoding amino acids of the globin chains. An example of such a point mutation is haemoglobin S caused by the substitution of valine for glutamic acid in position 6 of the β-globin chain ($\beta 6^{Glu \rightarrow Val}$). Less commonly, structural change is caused by shortening or lengthening of the globin chain. For example, five amino acids are deleted in the β chain of haemoglobin Gun Hill, whereas in haemoglobin Constant Spring, 31 amino acids are added to the α chain. Mutations associated with a frame shift can also lead to synthesis of a structurally abnormal haemoglobin, which may be either shorter or longer than normal. There may also be combinations of segments of β and either γ or δ chains resulting in hybrid haemoglobins; the β and δ combinations are known as the Lepore (5′δ3′β) and anti-Lepore (5′β3′δ) haemoglobins.

Many variant haemoglobins are haematologically and clinically silent because the underlying mutation causes no alteration in the function, solubility or stability of the molecule. Many of these variants are separated from their normal counterpart using electrophoresis or chromatography, but some are not and remain undetected. Some structural variants are associated with severe clinical phenotypes in the homozygous or even heterozygous state; these mutations affect the physical or chemical properties of the haemoglobin molecule, resulting in changes in haemoglobin solubility, stability or oxygen-binding properties. Some of these variants separate on electrophoresis or chromatography, whereas others do not. It is fortunate that the common haemoglobin variants that have clinical or genetic significance (e.g. haemoglobins S, C, D^{Punjab}, E and O^{Arab}) are readily detectable by electrophoretic and chromatographic techniques.

Haemoglobins with reduced solubility

Haemoglobin S

By far the most common variant haemoglobin is sickle haemoglobin or haemoglobin S. Haemoglobin S has poor solubility in the deoxygenated state and can polymerise. The red cell shows a characteristic shape change because of polymer formation and becomes distorted and rigid, the so-called sickle cell (see p. 76, Fig. 5-53). In addition, intracellular polymers lead to red cell membrane changes, generation of oxidant substances and abnormal adherence of red cells to vascular endothelium and neutrophils.

Clinical syndromes associated with common structural variants and those owing to their interaction with β thalassaemia are shown in Table 14-1.

Sickle cell disease

Sickle cell disease[2] is a collective name for a group of conditions causing clinical symptoms that result from the formation of sickled red cells. It is common in people originating from Africa, but it is also found in considerable numbers of people of Indian, Arabic and Greek descent.

The homozygous state or sickle cell anaemia (β genotype SS) causes moderate anaemia resulting largely from the reduced oxygen affinity of haemoglobin S, although there is also significant haemolysis. The main clinical disability

TABLE 14-1

CLINICAL SYNDROMES ENCOUNTERED WITH β^S AND β^C

Haemoglobin	Genotype	Name	Clinical Problems
S	β^A/β^S	Sickle cell trait	Usually none
	β^S/β^S	Sickle cell anaemia	Moderate anaemia, significant haemolysis, vaso-occlusive episodes and their consequences
C	β^A/β^C	C trait	None
	β^C/β^C	C disease	Mild haemolytic anaemia, increased incidence of gallstones
D^{Punjab}	$\beta^A/\beta^{D\ Punjab}$	D trait	None
	$\beta^D/\beta^{D\ Punjab}$	D disease	Occasional mild anaemia
O^{Arab}	$\beta^A/\beta^{O\ Arab}$	O trait	None
	$\beta^{O\ Arab}/\beta^{O\ Arab}$	O disease	Haemolytic anaemia
Interactions	β^S/β^C	Sickle cell/haemoglobin C disease	Mild anaemia, haemolysis, vaso-occlusive episodes
	$\beta^S/\beta^{D\ Punjab}$	Sickle cell/haemoglobin D disease	As for sickle cell anaemia
	$\beta^S/\beta^{O\ Arab}$	Sickle cell/haemoglobin O disease	As for sickle cell anaemia
	$\beta^S/\beta^{0\ thalassaemia}$	Sickle/β^0 thalassaemia	As for sickle cell anaemia
	$\beta^S/\beta^{+\ thalassaemia}$	Sickle/β^+ thalassaemia	Milder than sickle cell anaemia, severity being determined by the percentage of haemoglobins A and F
	$\beta^C/\beta^{thalassaemia}$	C/β thalassaemia	Mild haemolytic anaemia
	$\beta^{D\ Punjab}/\beta^{thalassaemia}$	D/β thalassaemia	Mild haemolytic anaemia
	$\beta^{O\ Arab}/\beta^{thalassaemia}$	O/β thalassaemia	Thalassaemia intermedia

arises from repeated episodes of vascular occlusion by sickled red cells resulting in acute crises and eventually in end organ damage. The clinical severity of sickle cell anaemia is extremely variable. This is partly due to the effects of inherited modifying factors, such as interaction with α thalassaemia or increased synthesis of haemoglobin F, and partly to socioeconomic conditions and other factors that influence general health.[2]

Sickle cell trait (β genotype AS), the heterozygous state, is very common, affecting millions of people worldwide. There are no associated haematological abnormalities other than occasional target cells. *In vivo* sickling occurs only at very high altitudes and when oxygen pressure is low for other reasons. Spontaneous haematuria, owing to sickling in the renal papillae, is found in about 1% of people with sickle cell trait.

Sickle cell/haemoglobin C disease is a compound heterozygous state for haemoglobins S and C. The abbreviation 'SC disease' is ambiguous and should be avoided; however, the term haemoglobin SC disease is acceptable. This compound heterozygous state usually results in a milder form of sickle cell disease.

Sickle/β thalassaemia arises as a result of inheritance of one β^S and one β thalassaemia gene. Africans and Afro-Caribbeans with this condition are often heterozygous for a mild β^+ thalassaemia allele resulting in the production of about 20% of haemoglobin A. This gives rise to a mild sickling disorder. The less common coinheritance of β^S and β^0 thalassaemia is associated with severe sickle cell disease. Interaction of haemoglobin S with haemoglobin D^{Punjab} (haemoglobin $D^{Los\ Angeles}$) or with Hb O^{Arab} gives rise to severe sickle cell disease.[2]

Haemoglobin C

Haemoglobin C is the second most common structural haemoglobin variant in people of African descent. The replacement of glutamic acid in position 6 of the β chain by lysine results in a haemoglobin molecule with a highly positive charge, decreased solubility and a tendency to crystallise. Haemoglobin C does not give a positive sickle solubility test. Heterozygotes are asymptomatic, but target cells and irregularly contracted cells may be present in blood films. Homozygotes may have mild haemolytic anaemia with numerous target cells and irregularly contracted cells (see Chapter 5, Fig. 5-49). Coinheritance of β^C and β^0 or β^+ thalassaemia results in mild or moderate haemolytic anaemia.

Other sickling haemoglobins

In addition to haemoglobin S, there are at least thirteen haemoglobins (haemoglobins $C^{Ziquinchor}$, C^{Harlem}, $C^{Ndjamena}$, $S^{Antilles}$, $S^{Cameroon}$, S^{Clichy}, $S^{Jamaica\ Plain}$, S^{Oman}, $S^{Providence}$, $S^{San\ Martin}$, $S^{South\ End}$, S^{Travis}, S^{Wake}) that have both the β6 glutamic acid to valine substitution and an additional substitution, resulting from a second point mutation, in the same β globin chain. These haemoglobins also have a positive solubility test since they are prone to polymerise but generally exhibit different electrophoretic and chromatographic properties from haemoglobin S. They have clinical significance similar – but not necessarily identical – to that of haemoglobin S (e.g. haemoglobin $S^{Antilles}$ and haemoglobin S^{Oman} are associated with an even greater propensity to sickling than haemoglobin S).

Unstable haemoglobins

Amino acid substitutions close to the haem group, or at the points of contact between globin chains, can affect protein stability and result in intracellular precipitation of globin chains. The precipitated globin chains attach to the red cell membrane giving rise to Heinz bodies, and the associated clinical syndromes were originally called the congenital Heinz body haemolytic anaemias. Changes in membrane properties may lead to haemolysis, often aggravated by oxidant drugs. There is considerable heterogeneity in the haematological and clinical effects of unstable haemoglobins. Many are almost silent and are detected only by specific tests, whereas others are more unstable, causing haemolytic anaemia in the heterozygous state. Haemoglobin Köln is the most common variant in this rare group of disorders.[3,4]

Haemoglobins with altered oxygen affinity

Haemoglobin variants with altered oxygen affinity are a rare group of variants that result in increased or reduced oxygen affinity.[5] Mutations that increase oxygen affinity are generally associated with benign lifelong erythrocytosis. This may be confused with polycythaemia vera and in the past has been inappropriately treated with cytotoxic drugs and ^{32}P.

Haemoglobin variants with decreased oxygen affinity are, with the exception of haemoglobin S, even less common and are usually associated with mild anaemia and cyanosis. However, owing to the reduced oxygen affinity, these patients are not functionally anaemic despite the reduced haemoglobin concentration (Hb). The low steady-state Hb in haemoglobin S homozygotes is, to a considerable extent, a result of its reduced oxygen affinity.

Measurement of oxygen dissociation is described on p. 251.

Haemoglobin M

The haemoglobin M group is another rare group of variants.[6] Such haemoglobins have a propensity to form methaemoglobin, generated by the oxidation of ferrous iron (Fe^{++}) in haem to ferric (Fe^{+++}) iron, which is incapable of binding oxygen. Despite marked cyanosis, there are few clinical problems. Most are associated with substitutions that disrupt the normal six-ligand state of haem iron.

Methaemoglobinaemia is also found in congenital nicotinamide adenine dinucleotide (NAD) H methaemoglobin reductase deficiency, as well as after exposure to oxidant drugs and chemicals (nitrates, nitrites, quinones, chlorates, phenacetin, dapsone and many others).

THALASSAEMIA SYNDROMES

The thalassaemia syndromes[7] are a heterogeneous group of inherited conditions characterised by defects in the synthesis of one or more of the globin chains that form the haemoglobin tetramer. The clinical syndromes associated with thalassaemia arise from the combined consequences of inadequate haemoglobin production and of unbalanced accumulation of one type of globin chain. The former causes anaemia with hypochromia and microcytosis; the latter leads to ineffective erythropoiesis and haemolysis. Clinicopathological manifestations range from completely asymptomatic microcytosis to profound anaemia that is incompatible with life and can cause death *in utero* (Table 14-2). This clinical heterogeneity arises as a result of the variable severity of the primary genetic defect in haemoglobin synthesis and the coinheritance of moderating factors, such as the capacity to synthesise increased amounts of haemoglobin F.

Thalassaemias are generally inherited as alleles of one or more of the globin genes located on either chromosome 11 (for β, γ and δ chains) or on chromosome 16 (for α chains). They are encountered in every population in the world but are most common in the Mediterranean littoral and near equatorial regions of Africa and Asia. Gene frequencies for the α and β thalassaemias on a global basis range from 1% to more than 80% in areas where malaria is endemic.[8]

β thalassaemia syndromes

Many different mutations cause β thalassaemia and related disorders.[9] These mutations can affect every step in the pathway of globin gene expression: transcription, processing of the messenger ribonucleic acid (mRNA) precursor, translation of mature mRNA and preservation of post-translational integrity of the β chain. More than 400 mutations have been described.[10] Most types of β thalassaemia are the result of point mutations affecting the globin gene, but some large deletions are also known. Certain mutations are particularly common in some communities. This helps to simplify prenatal diagnosis, which is carried out by detection or exclusion of a particular mutation in fetal deoxyribonucleic acid (DNA).

The effect of different mutations varies greatly. At one end of the spectrum are a group of rare mutations, mainly involving exon 3 of the β globin gene, which are so severe that they can produce the clinical syndrome of thalassaemia intermedia in the heterozygous state. At the other end are mild alleles that produce thalassaemia intermedia in the homozygous or compound heterozygous state and some that are so mild that they are haematologically completely silent, with normal mean cell volume (MCV), mean cell haemoglobin (MCH) and haemoglobin A_2 in the heterozygous state. In between are the great majority of β^+ and β^0 alleles, which cause β thalassaemia major in the homozygous or compound heterozygous state and in the heterozygous state give rise to a mild anaemia or Hb at the low end of the normal range, with microcytosis and a raised haemoglobin A_2.[11]

β thalassaemia major is a severe, transfusion-dependent, inherited anaemia. There is a profound defect of β chain production. Excess α chains accumulate and precipitate in the red cell precursors in the bone marrow resulting in

TABLE 14-2

CLINICAL SYNDROMES OF THALASSAEMIA

Clinically asymptomatic
Silent carriers
α^+ thalassaemia heterozygotes (some cases)
Rare forms of β thalassaemia heterozygosity
Thalassaemia minor (low MCH and MCV, with or without mild anaemia)
α^+ thalassaemia heterozygotes (some cases)
α^0 thalassaemia heterozygotes
α^+ thalassaemia homozygotes
β^0 thalassaemia trait
β^+ thalassaemia trait
Some cases of haemoglobin E/β thalassaemia
Thalassaemia intermedia (transfusion independent)*
Some β^+/β^+ thalassaemia homozygotes and compound heterozygotes
Interaction of β^0/β^0, β^0/β^+ or β^+/β^+ with α thalassaemia
Interaction of β^0/β or β^+/β with triple α
Haemoglobin H disease
α^0/haemoglobin Constant Spring thalassaemia
$\beta^0/\delta\beta$ or $\beta^+/\delta\beta$ thalassaemia compound heterozygotes
$\delta\beta/\delta\beta$ thalassaemia
Some cases of haemoglobin E/β thalassaemia and haemoglobin Lepore/β thalassaemia
Rare cases of heterozygotes for β thalassaemia mutation, particularly involving exon 3 ('dominant β thalassaemia')
Thalassaemia major (transfusion dependent)
β^0/β^0 thalassaemia
β^+/β^+ thalassaemia
β^0/β^+ thalassaemia
Some cases of β^0/haemoglobin Lepore and β^+/haemoglobin Lepore thalassaemia
Some cases of β^0/haemoglobin E and β^+/haemoglobin E thalassaemia

MCH, mean cell haemoglobin; MCV, mean cell volume.
*β thalassaemia intermedia is defined as a symptomatic condition in which regular transfusion is not essential to maintain life; however some patients have a poor quality of life and may benefit from transfusion as their condition progresses (e.g. when there is increasing splenomegaly).

ineffective erythropoiesis. The few cells that leave the marrow are laden with precipitated α chains and are rapidly removed by the reticuloendothelial system. The constant erythropoietic drive causes massive expansion of bone marrow and extramedullary erythropoiesis. If untreated, 80% of children with β thalassaemia major die within the first 5 years of life.

Heterozygotes for β thalassaemia alleles usually have either a normal Hb with microcytosis or a mild hypochromic microcytic anaemia; haemoglobin A_2 is elevated and haemoglobin F is sometimes also elevated. Laboratory features of various β thalassaemia syndromes are shown in Table 14-3.

α thalassaemia syndromes

There are four α thalassaemia syndromes:[12] α^+ thalassaemia trait, where one of the two globin genes on a single chromosome is absent or fails to function; α^0 thalassaemia trait, where a chromosome has no functional α genes; haemoglobin H disease, usually with three genes absent or defective; and haemoglobin Bart's hydrops fetalis, where all four genes are absent or severely defective. These syndromes are usually a result of deletions of one or more genes, although approximately 20% of the mutations described are nondeletional; nondeletional α thalassaemias include some where a variant haemoglobin is synthesised at a greatly reduced rate (e.g. haemoglobin Constant Spring). α^+ thalassaemia is particularly common in Africa and Southeast Asia, whereas α^0 thalassaemia is common in Southeast Asia and also occurs in certain Mediterranean countries. The laboratory features are shown in Table 14-3.

Haemoglobin Bart's hydrops fetalis occurs mainly in people from Southeast Asia but is also occasionally observed in people from Greece, Turkey and Cyprus. An affected fetus will be stillborn or will die shortly after birth. Severe anaemia and oedema are the hallmarks of this condition. Women carrying a hydropic fetus have a high incidence of complications of pregnancy. Prenatal diagnosis should be offered for women at risk of having a fetus with haemoglobin Bart's hydrops fetalis.

Haemoglobin H disease gives rise to haemolytic anaemia; rarely patients require transfusion or splenectomy.

α^0 *thalassaemia trait* is characterised by microcytosis. The Hb may be normal or slightly reduced. α^+ thalassaemia trait can be completely silent, or there may be borderline microcytosis with a slightly reduced or normal MCH. Haematologically, homozygosity for α^+ thalassaemia trait resembles heterozygosity for α^0 thalassaemia trait, but the genetic implications are very different. Both α^+ thalassaemia trait and α^0 thalassaemia trait are more difficult to diagnose than β thalassaemia trait because there is no characteristic elevation in haemoglobin A_2, and haemoglobin H inclusions may not be demonstrated. Definitive

TABLE 14-3

LABORATORY FINDINGS IN THALASSAEMIA

Phenotype	Genotype	Usual MCV	Usual MCH	Haemoglobin A_2	Haemoglobin H Inclusions
α thalassaemia					
α^+ thalassaemia heterozygosity	−α/αα	N	N	N or ↓	−
α^+ thalassaemia homozygosity	−α/−α	N or ↓	N or ↓	N or ↓	±
α^0 thalassaemia heterozygosity	− −/αα	↓	↓	N or ↓	+
Haemoglobin H disease					
Mild or moderate	− −/−α	↓	↓	N or ↓	+++
Severe	− −/α^Tα	↓	↓	N or ↓	+++
Haemoglobin Bart's hydrops fetalis (α thalassaemia major) α^0 homozygosity	− −/− −	↓	↓	−	−
β thalassaemia					
β thalassaemia trait	β^0/β or β^+/β	↓	↓	↑	−
β thalassaemia trait with normal Hb A_2	β^+/β	↓	↓	N	−
δβ thalassaemia trait	$\delta\beta^0/\beta$	↓	↓	N or ↓	−

β thalassaemia major	β^0/β^0, β^0/β^+, β^+/β^+	↓	↓	↑ or N	

MCH, mean cell haemoglobin; MCV, mean cell volume; N, normal.

diagnosis of α thalassaemia trait is more reliably made with the use of DNA techniques or globin chain biosynthesis studies.

Thalassaemic structural variants

These are abnormal haemoglobins, such as the Lepore haemoglobins, characterised by both a biosynthetic defect and an abnormal structure (Table 14-4).

Increased haemoglobin F in adult life

Haemoglobin production in man is characterised by two major switches in the haemoglobin composition of the red cells. During the first 3 months of gestation, human red cells contain embryonic haemoglobins (see p. 283), whereas during the last 6 months of gestation, red cells contain predominantly fetal haemoglobin. The major transition from fetal to adult haemoglobin synthesis occurs in the perinatal period, and by the end of the first year of life, red cells have a haemoglobin composition that usually remains constant throughout adult life. The major haemoglobin is then haemoglobin A, but there are small amounts of haemoglobins A_2 and F. Only 0.2–1.0% of total haemoglobin in adult human red cells is haemoglobin F and it is restricted to a few cells called 'F cells'. Both the number of F cells and the amount of haemoglobin F per cell can be increased in various conditions, particularly if there is rapid bone marrow regeneration.[13]

The general organisation of human globin gene clusters is shown in Figure 14-1. The products of two γ genes differ in only one amino acid: $^{G}\gamma$ has glycine in position 136, whereas $^{A}\gamma$ has alanine. In fetal red cells, the ratio of $^{G}\gamma$ to $^{A}\gamma$ is approximately 3:1; in adult red cells, it is approximately 2:3.

In recent years there has been much interest in the attempts to manipulate the fetal switch pharmacologically. If it were possible to reactivate haemoglobin F synthesis reliably beyond the perinatal period, both β thalassaemia major and sickle cell disease would be ameliorated.

Inherited abnormalities that increase haemoglobin F concentration

More than 50 mutations that increase haemoglobin F synthesis have been described.[13,14] They result in one of two phenotypes, hereditary persistence of HPFH or δβ thalassaemia; differentiation between these two phenotypes is not always simple but has clinical relevance. In general, HPFH has a higher percentage of haemoglobin F and much more balanced chain synthesis. The most common, the African type of HPFH, is associated with a high concentration of haemoglobin F (15–45%), pancellular distribution on Kleihauer staining and normal red cell indices. Mutations causing increased synthesis of haemoglobin F are mostly deletions, but some nondeletional mutations have also been described. In contrast, subjects with δβ thalassaemia have lower levels of haemoglobin F accompanied by microcytosis. The major clinical significance of these abnormalities is their interaction with β thalassaemia and haemoglobin S. Compound heterozygotes for either of these conditions and HPFH have a much milder clinical syndrome than homozygotes for haemoglobin S or β thalassaemia. Compound heterozygotes for either of these conditions and δβ thalassaemia have a condition much closer in severity to the homozygous states for HPFH or δβ thalassaemia.

Increased haemoglobin F is also found in many other haematological conditions, including inherited red cell

TABLE 14-4

THALASSAEMIC STRUCTURAL VARIANTS*

Haemoglobin	Structure	When Heterozygous	When Homozygous	In Combination with Other Haemoglobinopathies[17,18]
Lepore	Hybrid of part of δ and part of β chain owing to unequal crossover	Microcytosis, sometimes mild anaemia	Thalassaemia major or intermedia	With β thalassaemia gives thalassaemia major or intermedia
E†	$\beta^{26Glu \rightarrow Lys}$ resulting in a structural variant and a false splice site	Microcytosis, sometimes mild anaemia	Microcytosis, mild anaemia	With β thalassaemia gives thalassaemia major or intermedia
Constant Spring or Paksé	Elongated α chain owing to incorporation of 31 extra amino acids	Microcytosis, mild anaemia	Microcytosis, mild anaemia or haemoglobin H disease	With α^0 thalassaemia gives haemoglobin H disease

*Many other thalassaemic structural variants have been described but are much rarer than the three shown in this table.
†13–30% frequency in Cambodia, Thailand, Vietnam and some parts of China.

aplasia and inherited aplastic anaemia (Blackfan–Diamond syndrome and Fanconi anaemia, respectively), juvenile myelomonocytic leukaemia and some myelodysplastic syndromes. A small but significant increase in haemoglobin F may occur in the presence of erythropoietic stress (haemolysis, bleeding, recovery from acute bone marrow failure) and in pregnancy.

INVESTIGATION OF PATIENTS WITH A SUSPECTED HAEMOGLOBINOPATHY

Investigation of a person at risk of a haemoglobinopathy encompasses the confirmation or exclusion of the presence of a structural variant, thalassaemia or both. If a structural haemoglobin variant is present, it is necessary to ascertain the clinical significance of the particular variant so that the patient is appropriately managed. If it is confirmed that thalassaemia trait is present, it is not usually necessary to determine the precise mutation because the clinical significance is usually negligible. The exception to this is an antenatal patient whose partner has confirmed or suspected thalassaemia trait. If prenatal diagnosis is being considered, mutation analysis is necessary to predict fetal risk accurately and to facilitate prenatal diagnosis (see p. 134).

Because the inheritance of a haemoglobinopathy *per se* has genetic implications, it is important that genetic counselling is available for these patients.

In the majority of patients, the presence of a haemoglobinopathy can be diagnosed with sufficient accuracy for clinical purposes from knowledge of the patient's ethnic origin and clinical history (including family history) and the results of physical examination combined with relatively simple haematological tests. Initial investigations should include determination of Hb and red cell indices. A detailed examination of a well-stained blood film should be carried out. In some instances, a reticulocyte count and a search for red cell inclusions gives valuable information. Assessment of iron status by estimation of serum ferritin is sometimes necessary to exclude iron deficiency. Other important basic tests are high performance liquid chromatography (HPLC), capillary electrophoresis (CE) or cellulose acetate electrophoresis (CAE), a sickle solubility test and measurement of haemoglobin A_2 and F percentages. In the case of common haemoglobin variants and classic β thalassaemia trait, accurate data from these tests will permit a reliable diagnosis without the need for more sophisticated investigations. However, definitive diagnosis of some thalassaemia syndromes can only be obtained using DNA technology (see p. 134 and p. 135). Similarly, in particular situations, haemoglobin variants will require unequivocal identification by the use of DNA technology or protein analysis by mass spectrometry.[15] Individuals or families who require such investigation must be carefully selected on the basis of family history and on the results of the basic investigations described later in this chapter. Large-scale screening programmes are increasingly being undertaken in some countries where individual case histories and the results of other laboratory tests are not usually available. The problems of such programmes are discussed on p. 299.

The majority of errors occurring in the detection and identification of a haemoglobinopathy are the result of either failure to obtain correct laboratory data or failure to interpret data correctly. In this chapter, a sequence of investigations is proposed based on procedures that should be available in the laboratory of any major hospital. Automated HPLC has largely replaced haemoglobin electrophoresis as the initial investigative procedure in laboratories analysing large numbers of samples. Capillary electrophoresis is currently less used than HPLC. Isoelectric focusing (IEF) is, in general, used only to a limited extent, mainly for neonatal screening or in specialist laboratories, and it is only briefly described here.

Laboratory investigation of a suspected haemoglobinopathy should follow a defined protocol, which should be devised to suit individual local requirements. The data obtained from the clinical findings, blood picture and electrophoresis or HPLC will usually indicate in which direction to proceed. The investigation for a structural variant is described in the first section and that for a suspected thalassaemia syndrome in the second section of this chapter. Screening tests for thalassemia trait and haemoglobin E trait that may be especially applicable in under-resourced areas are described in Chapter 26.

LABORATORY DETECTION OF HAEMOGLOBIN VARIANTS

A proposed scheme of investigation is shown in Figure 14-2 and a list of procedures follows:[15,16]

1. Blood count and film examination (see below)
2. Collection of blood and preparation of haemolysates (see p. 291)
3. Cellulose acetate electrophoresis, Tris buffer, pH 8.5 (see p. 292)
4. Acid agarose gel electrophoresis, pH 6.0 (see p. 294)
5. Automated high performance liquid chromatography (see p. 294)
6. Capillary electrophoresis (see p. 296)
7. Isoelectric focusing (see p. 297)
8. Tests for haemoglobin S (see p. 297)
9. Detection of unstable haemoglobins (see p. 299)
10. Detection of haemoglobin Ms (see p. 300)
11. Detection of altered affinity haemoglobins (see p. 301)
12. Differentiation of common structural variants (see p. 301)

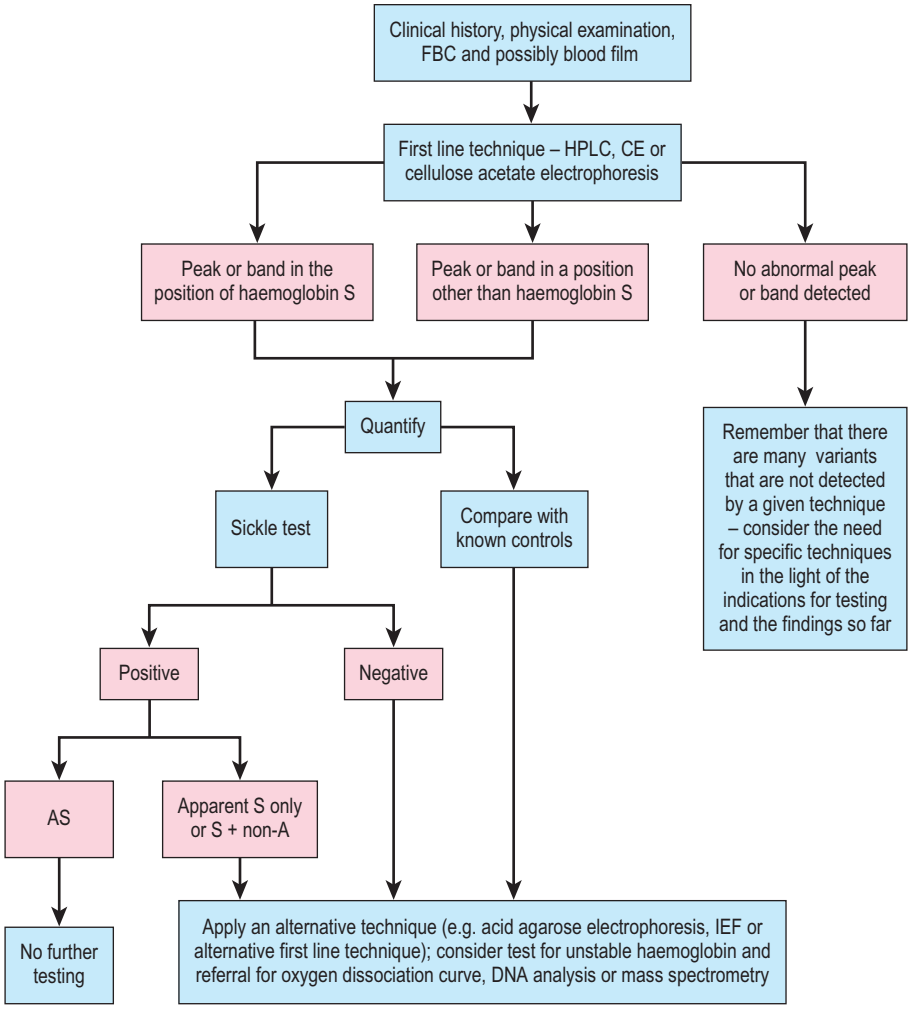

FIGURE 14-2 Suggested scheme of investigation for structural variants. CE, capillary electrophoresis; HPLC, high performance liquid chromatography; IEF, isoelectric focusing.

13. Neonatal screening (see p. 299)
14. Tests, such as zinc protoporphyrin estimation, to exclude iron deficiency as a cause of microcytosis (see Chapter 9)
15. Molecular techniques (see Chapter 8)
16. Procedures for use in under-resourced laboratories (see Chapter 26).

Globin chain electrophoresis at pH 8.0 and 6.3 and citrate agar electrophoresis at acid pH are now rarely performed. Methods can be found in previous editions of this book.

Blood count and film

The blood count, including Hb and red cell indices, provides valuable information useful in the diagnosis of both α and β thalassaemia interactions with structural variants (see Chapter 3). A film examination may reveal characteristic red cell changes such as target cells in haemoglobin C trait, sickle cells in sickle cell disease and irregularly contracted cells in the presence of haemoglobin C or an unstable haemoglobin (see Chapter 5).

Discriminant functions using various formulae have been proposed as a basis for further testing for thalassaemia,[17,18] but we do not advise their use. Although such functions and formulae do indicate whether thalassaemia or iron deficiency is more likely, they may lead to individuals who have both iron deficiency *and* thalassaemia trait not being tested promptly. Generally this is not a problem and indeed it may be preferable to keep the patient under observation until iron deficiency has been treated and then to reassess the likelihood of thalassaemia trait. However, many of the patients who require testing for thalassaemia are women who are already pregnant. In such patients the

likely delay in testing is unacceptable. Moreover, these formulae have generally not been validated for use during pregnancy. For these reasons, we advise that whenever genetic counselling might be required, testing for β thalassaemia trait should be carried out in all individuals with an MCH <27 pg and screening for α^0 thalassaemia trait should be carried out in those individuals with an MCH <25 pg who belong to an ethnic group in which α^0 thalassaemia is prevalent.[11]

Collection of blood and preparation of haemolysates

Ethylenediaminetetra-acetic acid (EDTA) is the most convenient anticoagulant because it is used for the initial full blood count and film (see Chapter 1), although samples taken into any anticoagulant are satisfactory. Cells freed from clotted blood can also be used.

Preparation of haemolysate for qualitative haemoglobin electrophoresis

See individual methods.

Preparation of haemolysate for the quantification of haemoglobins and stability tests

Preparation of haemolysate is necessary for quantification of haemoglobin A_2 or a variant haemoglobin by elution and for the quantification of haemoglobin F by alkali denaturation. It is also essential for reliable heat stability tests.

Lyse 2 volumes of washed packed cells in 1 volume of distilled water. Shake the tubes vigorously for approximately 1 min, then centrifuge at 1200 *g* (3000 rev/min on a standard bench-top centrifuge) for 30 min at 4 °C. Transfer the supernatant to a clean sample container and adjust the Hb to 100 ± 10 g/l with water. The quality of the haemolysate is much improved by the addition of carbon tetrachloride (1 volume) prior to shaking the haemolysate mixture. However, the use of organic solvents is not recommended in many countries and therefore should be omitted. Be aware that if an unstable haemoglobin is suspected, organic solvents should be avoided in haemolysate preparation.

NOTE: Whole blood samples are best stored as washed, packed cells frozen as droplets in liquid nitrogen and subsequently stored at −20 °C, −70 °C or over liquid nitrogen. Alternatively, haemolysates may also be frozen at −20 °C, −70 °C or over liquid nitrogen.

Control samples

Interpretation of migration patterns of test samples is undertaken by comparison with the migration and separation of known variant haemoglobins used as control materials. Ideally, a mixture of haemoglobins A, F, S and C should be included on each electrophoretic separation. This material can be prepared as follows:

1. The control can be made from either the combination of a sickle cell trait sample (A + S) combined with a haemoglobin C trait sample (A + C) and normal cord blood (F + A) or the combination of normal cord blood with a sample from a person with sickle cell/haemoglobin C compound heterozygosity (S + C).
2. Prepare lysates by the method given for a purified haemolysate.
3. Mix equal volumes of the lysates together and add a few drops of 0.3 mol/l KCN (20 g/l).
4. Analyse samples by electrophoresis to assess quality.
5. Aliquot and store frozen.

NOTE: Repeated freezing and thawing should be avoided. Lyophilised controls are stable for considerably longer than liquid and can be purchased from commercial sources.

Quality assurance

Because the haemoglobinopathies are inherited conditions, some of which carry considerable clinical and genetic implications, precise documentation and record-keeping are of paramount importance.[19] The use of cumulative records when reviewing a patient's data is very useful, because it of itself constitutes an aspect of quality assurance. In some situations, repeat sampling, family studies or both may be required to elucidate the nature of the abnormality in an individual.

In-house standard operating procedures should be followed carefully, particularly in this field of haematology, where a small difference in technique can make a significant difference in the results obtained and can lead to misdiagnosis. Many of the techniques described have attention drawn to specific technical details that are important for ensuring valid results.[20]

It is necessary to use reference standards and control materials in each of the analyses undertaken and in some cases to use duplicate analysis to demonstrate precision. There are international standards for haemoglobins F and A_2 (see p. 536), whereas in some countries national reference preparations are also available from national standards institutions. These are extremely valuable because the target values have been established by collaborative studies. Control materials can be prepared in-house or obtained commercially. Samples stored as whole blood at 4 °C can be used reliably for several weeks. All laboratories should confirm the normal range for their particular methods and the normal range obtained should not differ significantly from published data.

All laboratories undertaking haemoglobin analysis should participate in an appropriate proficiency testing programme (see p. 539). In the UK, the National External

Quality Assessment Service (NEQAS) provides samples for sickle solubility tests, for detection and quantification of variant haemoglobins and for quantification of haemoglobins A_2, F and S.

National and international guidelines have been published for all aspects of the investigations given here.[11,20–24]

Cellulose acetate electrophoresis at alkaline pH

Haemoglobin electrophoresis at pH 8.4–8.6 using cellulose acetate membrane is simple, reliable and rapid. It is satisfactory for the detection of most common, clinically important haemoglobin variants.[20–24]

Principle

At alkaline pH, haemoglobin is a negatively charged protein, and when subjected to electrophoresis will migrate toward the anode (+). Structural variants that have a change in the charge on the surface of the molecule at alkaline pH will separate from haemoglobin A. Haemoglobin variants that have an amino acid substitution that is internally sited may not separate, and those that have an amino acid substitution that has no effect on overall charge will not separate by electrophoresis.

Equipment

- *Electrophoresis tank and power pack.* Any horizontal electrophoresis tank that will allow a bridge gap of 7 cm. A direct current power supply capable of delivering 350 V at 50 mA is suitable for both cellulose acetate and acid agarose gels.
- *Wicks of filter or chromatography paper*
- *Blotting paper*
- *Applicators*. These are available from most manufacturers of electrophoresis equipment, but fine microcapillaries are also satisfactory.
- *Cellulose acetate membranes*. Plastic-backed membranes (7.6×6.0 cm) are recommended for ease of use and storage.
- *Staining equipment*

Reagents

- *Electrophoresis buffer.* Tris/EDTA/borate (TEB), pH 8.5. Tris-(hydroxymethyl)aminomethane (Tris), 10.2 g; EDTA (disodium salt), 0.6 g; boric acid, 3.2 g; water to 1 litre. The buffer should be stored at 4 °C and can be used up to 10 times without deterioration.
- *Wetting agent.* For example, Zip Zone Prep solution (Helena Laboratories, www.helena.com): 1 drop of Zip Zone Prep in 100 ml water
- *Fixative/stain solution.* Ponceau S (www.helena.com), 5 g; trichloroacetic acid, 7.5 g; water to 1 litre
- *Destaining solution.* 3% (v/v) acetic acid, 30 ml; water to 1 litre
- *Haemolysing reagent.* 0.5% (v/v) Triton X-100 (www.helena.com) in 100 mg/l potassium cyanide.

Method

1. Centrifuge samples at 1200 *g* for 5 min. Dilute 20 µl of the packed red cells with 150 µl of the haemolysing reagent. Mix gently and leave for at least 5 min. If purified haemolysates are used, dilute 40 µl of 100 g/l haemolysate with 150 µl of lysing reagent.
2. *With the power supply disconnected,* prepare the electrophoresis tank by placing equal amounts of TEB buffer in each of the outer buffer compartments. Wet two chamber wicks in the buffer, and place one along each divider/bridge support ensuring that they make good contact with the buffer.
3. Soak the cellulose acetate by lowering it slowly into a reservoir of buffer. Leave the cellulose acetate to soak for at least 5 min before use.
4. Fill the sample well plate with 5 µl of each diluted sample or control and cover with a 50 mm coverslip or a 'short' glass slide to prevent evaporation. Load a second sample well plate with Zip Zone Prep solution.
5. Clean the applicator tips immediately prior to use by loading with Zip Zone Prep solution and then applying them to a blotter.
6. Remove the cellulose acetate strip from the buffer and blot twice between two layers of clean blotting paper. Do not allow the cellulose acetate to dry.
7. Load the applicator by depressing the tips into the sample wells twice and apply this first loading onto some clean blotting paper. Reload the applicator and apply the samples to the cellulose acetate.
8. Place the cellulose acetate plates across the bridges, with the plastic side uppermost. Place two glass slides across the strip to maintain good contact. Electrophorese at 350 V for 25 min.
9. After 25 min electrophoresis, immediately transfer the cellulose acetate to Ponceau S and fix and stain for 5 min.
10. Remove excess stain by washing for 5 min in the first acetic acid reservoir and for 10 min in each of the remaining two. Blot once, using clean blotting paper and leave to dry.
11. Label the membranes and store in a protective plastic envelope.

Interpretation and comments

Figure 14-3 shows the relative electrophoretic mobilities of some common haemoglobin variants at pH 8.5 on cellulose acetate. Satisfactory separation of haemoglobins C, S, F, A and J is obtained (Fig. 14-4). In general, haemoglobins S, D and G migrate closely together, as do haemoglobins C, E and O^{Arab}. Differentiation between these haemoglobins can be obtained by using acid agarose gels, HPLC or IEF. There are slight differences in mobility between haemoglobins S, Lepore and D^{Punjab} and also between haemoglobins C and E. Generally, the Lepore haemoglobins and Hb D^{Punjab} migrate slightly anodal to haemoglobin S (i.e. they are slightly faster than S); haemoglobin C migrates slightly cathodal to haemoglobin E (i.e. it is slightly slower than E).

FIGURE 14-3 Schematic representation of relative mobilities of some abnormal haemoglobins. Cellulose acetate electrophoresis, pH 8.5.

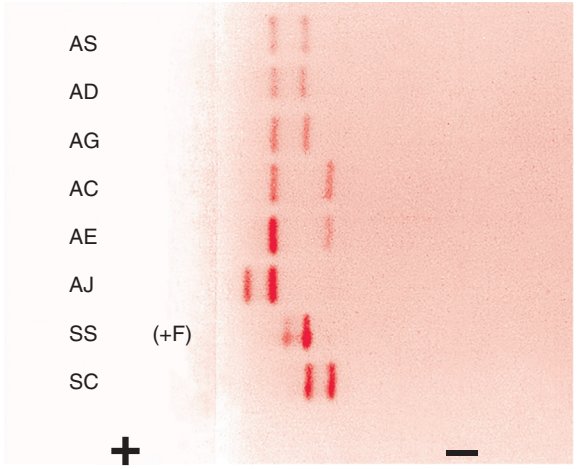

FIGURE 14-4 Relative mobilities of some abnormal haemoglobins. Cellulose acetate electrophoresis, pH 8.5.

These differences are, however, too subtle to avoid the necessity for a second confirmatory technique.

All samples showing a single band in either the S or C position should be analysed further using acid agarose gel electrophoresis, HPLC or IEF to exclude the possibility of a compound heterozygote state such as SD, SG, CE or CO^{Arab}.

The quality of separation resulting from this procedure is affected primarily by both the amount of haemoglobin applied and the positioning of the origin. Also, delays between application of the sample and commencement of the electrophoresis, delay in staining after electrophoresis or inadequate blotting of the acetate prior to application will cause poor results. This technique is sensitive enough to separate haemoglobin F from haemoglobin A and to detect haemoglobin A_2 variants as long as the strip is inspected carefully.

If an abnormal haemoglobin is present, the detection of a haemoglobin A_2 variant band in conjunction with the abnormal fraction is evidence that the variant is an α chain variant.

When an abnormal haemoglobin is found, it may be of diagnostic importance to measure the percentage of the variant; this can be done by the electrophoresis with elution procedure for haemoglobin A_2 estimation given on p. 303. Quantification of haemoglobin S is often clinically useful, both in patients with sickle cell disease who are being treated by transfusion and for the diagnosis of conditions in which haemoglobin S is co-inherited with α and β thalassaemia, as outlined in Table 14-5. Quantification of haemoglobin S can be done with HPLC, electrophoresis with elution or microcolumn chromatography.

TABLE 14-5

RESULTS OF LABORATORY INVESTIGATIONS IN INTERACTIONS OF HAEMOGLOBIN S AND α OR β THALASSAEMIA IN ADULTS

	MCV	% S	% A	% A_2	% F
AS	N	35–38	62–65	<3.5	<1
SS	N	88–93	0	<3.5	5–10
S/β^0 thalassaemia	L	88–93	0	>3.5	5–10
S/β^+ thalassaemia	L	50–93	3–30	>3.5	1–10
S/HPFH	N	65–80	0	<3.5	20–35
AS/α^+ thalassaemia	N/L	28–35	62–70	<3.5	<1

SS/α thalassaemia	N/L	88–93	0	<3.5	1–10

HPFH, hereditary persistence of fetal haemoglobin; L, low; MCV, mean cell volume; N, normal.

Agarose gel electrophoresis

Agarose gels are commercially available as for both alkaline and acid electrophoresis. They are simple to use and particularly useful in laboratories that process small numbers of samples.

Reagents and method

The manufacturer's method should be followed.

Interpretation

With alkaline systems, in general the same separation patterns are obtained as for CAE, but where individual application notes are available these should be used for reference. Because not all kits provide these, laboratories may need to build up their own data on known variants. At acid pH, the migration pattern helps to distinguish haemoglobin S from D/G and haemoglobin C from E (Fig. 14-5).

Automated high performance liquid chromatography

Automated cation-exchange HPLC[25] is being used increasingly as the initial diagnostic method in haemoglobinopathy laboratories with a high workload.[26] Both capital and consumable costs are higher than with haemoglobin electrophoresis, but labour costs are less; overall costs may be similar.[27] In comparison with haemoglobin electrophoresis, HPLC has four advantages:

1. The analysers are automated and thus require less staff time and permit processing of large batches.
2. Very small samples (5 µl) are sufficient for analysis; this is especially useful in paediatric work.
3. Quantification of normal haemoglobins (including haemoglobin A_2) and variant haemoglobins is available on every sample.
4. A provisional identification of a larger proportion of variant haemoglobins can be made.[28]

Principle

HPLC depends on the interaction of charged groups on the ion exchange material with charged groups on the haemoglobin molecule. A typical column packing is 5 µm spherical silica gel. The surface of the support is modified by carboxyl groups to have a weakly cationic charge, which allows the separation of haemoglobin molecules with different charges by ion exchange. When a haemolysate containing a mixture of haemoglobins is adsorbed onto the resin, the rate of elution of different haemoglobins is determined by the pH and ionic strength of any buffer applied to the column. With automated systems now in use, elution of the charged molecules is achieved by a continually changing salt gradient; fractions are detected as they pass through an ultraviolet/visible light detector and are recorded on an integrating computer system. Analysis of the area under these absorption peaks gives the percentage of the fraction detected. The time of elution (retention time) of any normal or variant haemoglobin present is compared with that of known haemoglobins, providing quantification of both normal haemoglobins (A, F and A_2) and many variants.

Figure 14-6 shows a schematic representation of an HPLC system and Figure 14-7 shows a chromatogram of a mixture of different haemoglobins. Systems are available from various manufacturers.

Method

The manufacturer's procedure should be followed. To prolong the life of the column it is important to follow the manufacturer's instructions with regard to the concentration of haemoglobin in the sample to be injected.

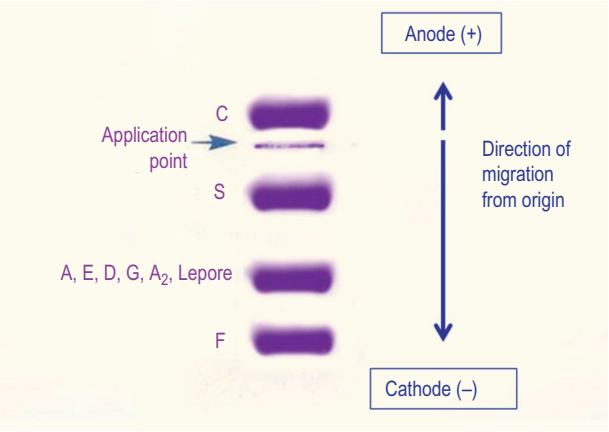

FIGURE 14-5 Schematic representation of relative mobilities of some abnormal haemoglobins. Acid agararose gel electrophoresis, pH 6.0.

*Values outside of expected ranges

Analysis comments:

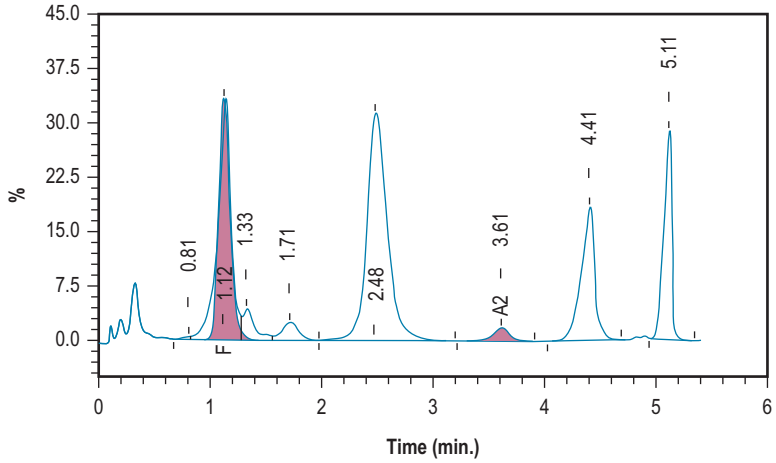

FIGURE 14-7 A mixture of haemoglobins separated by HPLC. From left to right the peaks are: injection artefact, post-translational modified haemoglobin F (double peak), haemoglobin F (pink), glycated haemoglobin A, other post-translationally modified haemoglobin A, haemoglobin A_0 (pink), haemoglobin S, post-translationally modified haemoglobin C (two very small peaks) and haemoglobin C.

Interpretation and comments

Results are generally accurate and reproducible, but as with every method of haemoglobin analysis, controls should be run with every batch. Controls are provided by manufacturers and should be used according to their instructions. If the system is being used for the detection of haemoglobin variants, elution times can be compared with those of known controls; actual times, however, are affected by the batch of buffer and column, the age of the column and the laboratory temperature. A better comparison may be obtained using the relative elution time, which is calculated by dividing the elution time of the variant with that of the main haemoglobin A fraction. It should be noted that haemoglobin A is separated into its component fractions of A_0 and A_1, and the A_1 fraction frequently subdivides into several peaks. Skill is required in interpretation of the results because various normal and abnormal haemoglobins may have the same retention time, and a glycosylated variant haemoglobin will have a different retention time from the nonglycosylated form. HPLC usually separates haemoglobins A, A_2, F, S, C, D^{Punjab} and $G^{Philadelphia}$ from each other.[27,29] However, both haemoglobin E and haemoglobin Lepore co-elute with haemoglobin A_2 (as other haemoglobins co-elute with A, S and F). The retention time of glycosylated and other derivatives of haemoglobin S can be the same as those of haemoglobins A_0 and A_2. Since derivatives of haemoglobin S co-elute with haemoglobin A_2, percentages of A_2 by this method are inaccurate in the presence of S, and therefore do not have the same significance as percentage of haemoglobin A_2 measured by alternative methods.[30] For these reasons, and because there are more than 1000 known variants, HPLC can never definitively identify any haemoglobin. It is important to analyse variants found using second-line techniques, such as a sickle solubility test, alkaline and acid electrophoresis, or iso-electric focusing.

HPLC is also applicable for the quantification of Hb A_{1c} for the monitoring of diabetes mellitus; to make optimal use of staff and equipment, this procedure is sometimes carried out in haematology laboratories. In fact, an increased glycosylated fraction is not infrequently noted when HPLC is performed for investigation of a suspected

haemoglobinopathy.[31] Unless the patient is already known to suffer from diabetes mellitus, this abnormality should be drawn to the attention of clinical staff.

Capillary electrophoresis

Principle

Capillary zone electrophoresis is an automated method in which haemoglobins are separated from each other by electrophoresis at alkaline pH within a capillary tube. The separation of normal and variant haemoglobins is similar to that of CAE at alkaline pH but because the pH is slightly different and the voltage is higher, results are not identical.[32] Haemoglobin E separates from haemoglobin A_2 and haemoglobin C shows partial separation from haemoglobin A_2. Haemoglobins C and E separate from each other and haemoglobins S and D^{Punjab} separate from each other. Typical separation is shown in Figure 14-8.

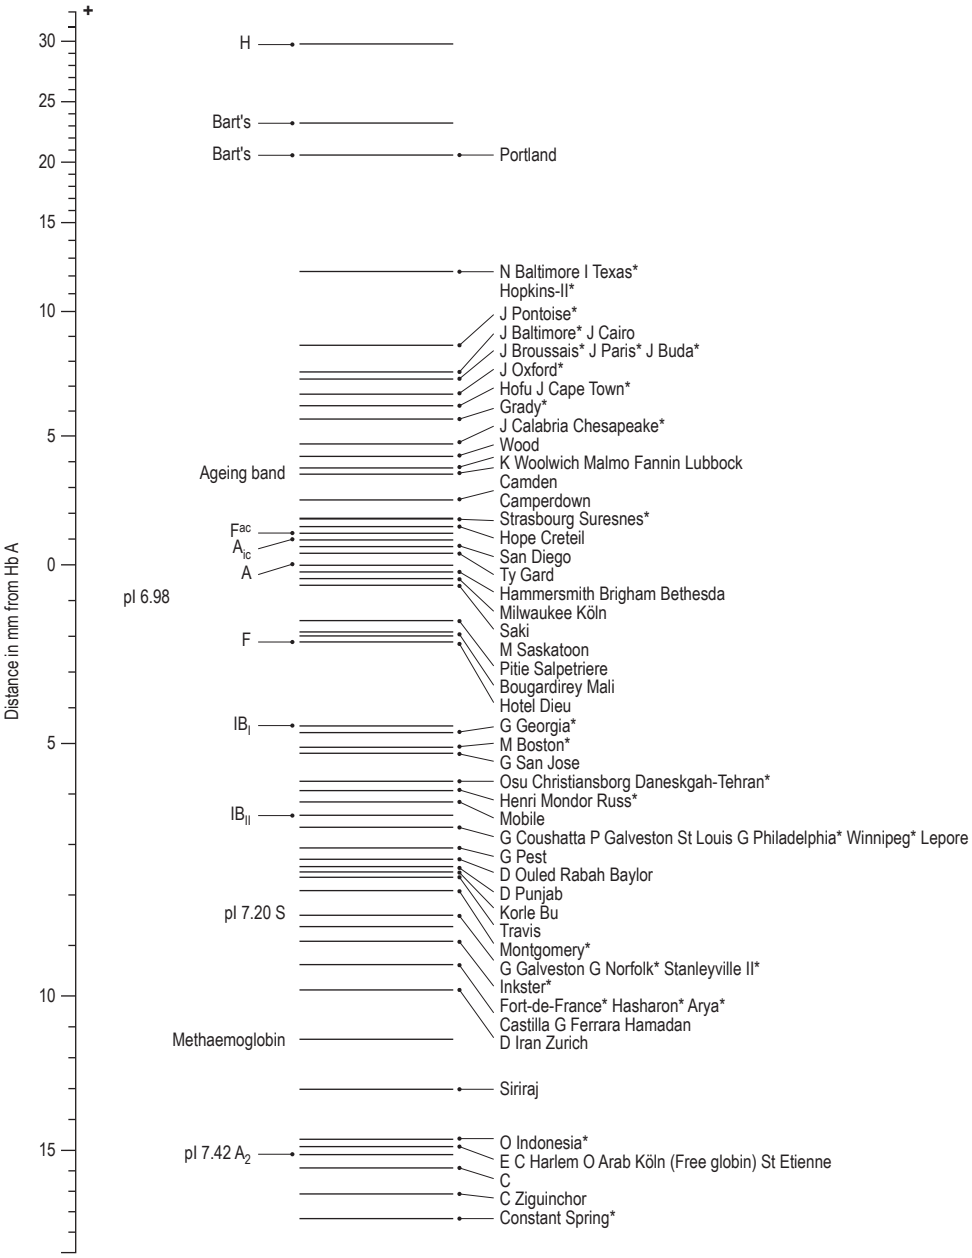

FIGURE 14-8 Schematic representation of relative mobilities of some abnormal haemoglobins. Isoelectric focusing. *NOTE* the presence of two bands for haemoglobin Bart's. The scale in mm is not linear. *Indicates α chain mutations. *(Reproduced with permission from Basset P,* et al.[34]*)*

Method

The recommendations of the instrument manufacturer should be followed. Controls are provided by manufacturers.

Interpretation and comments

Advantages of this technique include low sample volume, rapid throughput, availability of haemoglobin A_2 quantification and ease of interpretation in comparison with HPLC and IEF, since post-translationally modified haemoglobins are not separated from the parent haemoglobin. The Capillarys instruments that are mainly used for this technique have the disadvantage that the migration position of a variant haemoglobin is only determined in the presence of haemoglobins A and A_2. If either of these is absent, they must be added in order for the instrument to identify the likely nature of a variant haemoglobin. As for other methods, provisional identification must be confirmed by a second method.

Isoelectric focusing

Principle

IEF utilises a matrix containing carrier ampholytes of low molecular weight and varying isoelectric points (pIs). These molecules migrate to their respective pIs when a current is applied, resulting in a pH gradient being formed; for haemoglobin analysis, a pH gradient of 6–8 is usually used. Haemoglobin molecules migrate through the gel until they reach the point at which their individual pIs equal the corresponding pH on the gel. At this point, the charge on the haemoglobin is neutral and migration ceases. The pH gradient counteracts diffusion and the haemoglobin variant forms a discrete narrow band.[33,34]

Method

Pre-prepared plates of either polyacrylamide or agarose gel can be obtained from various manufacturers. For the exact method, the manufacturer's instructions should be followed. Controls should be included in each run. It is useful to have one control containing haemoglobins A, F, S and E and another containing A, F, D^{Punjab} and C.

Interpretation and comments

IEF is satisfactory for analysis of haemolysates, whole blood samples or dried blood spots. The use of dried blood spots is suitable for samples that have to be transported long distances and where only a few drops of blood can be obtained. Whereas IEF has the advantage that it separates more variants than cellulose acetate, it also has the disadvantage that it separates haemoglobin into its post-translational derivatives. For instance, haemoglobin F separates into F_1 (acetylated F) and F_{11}; haemoglobin A can produce five bands – A_0, A_1, A(αmet), A(βmet) and A(αβmet) – and similarly for other haemoglobins. This makes interpretation more difficult. Identification of variants is still only provisional using IEF, and second-line methods should be used for further analysis.

Figure 14-8 shows the relative isoelectric points of some common haemoglobin variants, and Figure 14-9 shows the separation obtained.

TESTS FOR HAEMOGLOBIN S

Tests to detect the presence of haemoglobin S depend on the decreased solubility of this haemoglobin at low oxygen tensions.

Sickling in whole blood

The sickling phenomenon may be demonstrated in a thin wet film of blood (sealed with a petroleum jelly/paraffin wax mixture or with nail varnish). If haemoglobin S is present, the red cells lose their smooth, round shape and become sickled. This process may take up to 12 h in haemoglobin S trait, whereas changes are apparent in homozygotes and compound heterozygotes after 1 h at 37 °C.

These changes can be hastened by the addition of a reducing agent such as sodium dithionite as follows:

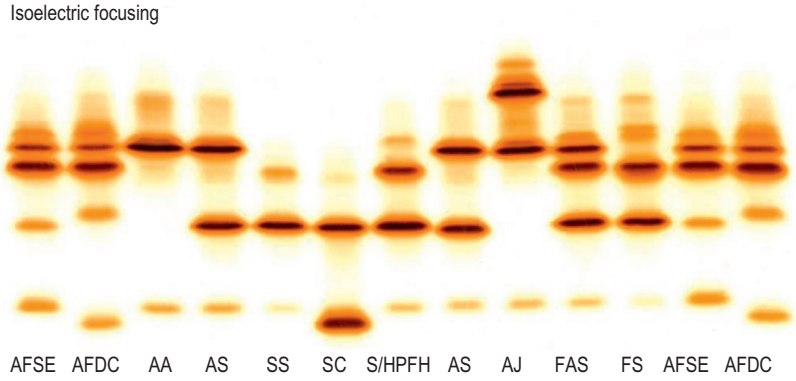

FIGURE 14-9 Relative mobilities of some abnormal haemoglobins. Isoelectric focusing. The controls are mixtures of various haemoglobins.

Reagents

- *Disodium hydrogen phosphate* (Na_2HPO_4). 0.114 mol/l (16.2 g/l)
- *Sodium dithionite* ($Na_2S_2O_4$). 0.114 mol/l (19.85 g/l). Prepare freshly just before use.
- *Working solution.* Mix 3 volumes of Na_2HPO_4 with 2 volumes of $Na_2S_2O_4$ to obtain a pH of 6.8 in the resultant solution. Use immediately.

Method

Add 5 drops of the freshly prepared reagent to 1 drop of anticoagulated blood on a slide. Seal between slide and coverslip with a petroleum jelly/paraffin wax mixture or with nail varnish. Sickling takes place almost immediately in sickle cell anaemia and should be obvious in sickle cell trait within 1 h (Fig. 14-10). A test on a positive control containing haemoglobin A plus haemoglobin S must be performed at the same time.

Haemoglobin S solubility test

Principle

Sickle cell haemoglobin is insoluble in the deoxygenated state in a high molarity phosphate buffer. The crystals that form refract light and cause the solution to be turbid.[35]

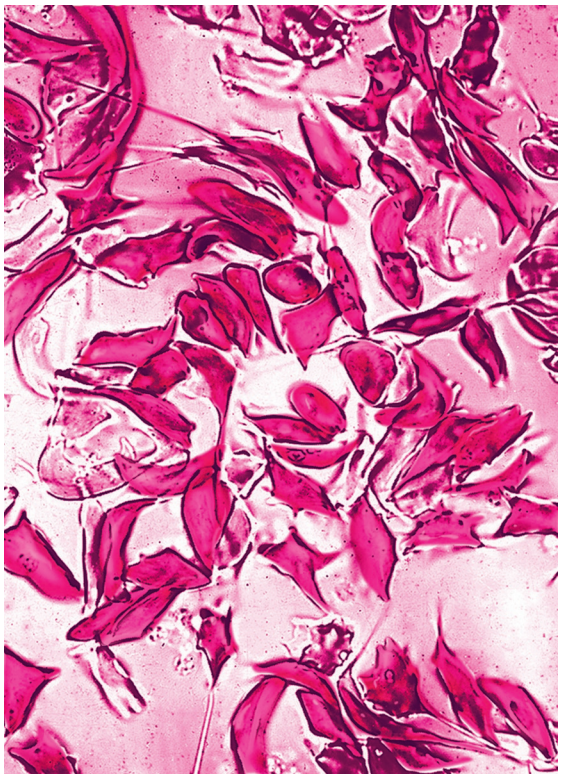

FIGURE 14-10 Photomicrograph of sickled red cells. Sickle cell anaemia. Sealed preparation of blood. Fully sickled filamentous forms predominate.

Reagents

- *Phosphate buffer.* Anhydrous dipotassium hydrogen phosphate, 215 g; anhydrous potassium dihydrogen phosphate, 169 g; sodium dithionite, 5 g; saponin, 1 g; water to 1 litre.

NOTE: Dissolve the K_2HPO_4 in water before adding the KH_2PO_4, then add the dithionite and finally the saponin. This solution is stable for 7 days. Store refrigerated.

Method

1. Pipette 2 ml of reagent into three 12 × 75 mm test tubes.
2. Allow the reagent to warm to room temperature.
3. Add 10 µl of packed cells (from EDTA-anticoagulated blood) to one tube, 10 µl of packed cells from a known sickle cell trait subject as a positive control to the second tube and 10 µl packed cells from a normal subject as a negative control to the final tube.
4. Mix well and leave to stand for 5 min.
5. NOTE: The blood reagent mixture should be light pink or red. A light orange colour indicates that the reagent has deteriorated.
6. Hold tube 2.5 cm in front of a white card with narrow black lines and read for turbidity, in comparison with the positive and negative control samples.
7. If the test appears to be positive, centrifuge at 1200 *g* for 5 min. A positive test will show a dark red band at the top, whereas the solution below will be pink or colourless.

Interpretation and comments

A positive solubility or sickling test indicates the presence of haemoglobin S and as such is useful in differentiating it from haemoglobins D and G, which migrate with haemoglobin S on CAE at alkaline pH, and similarly for the confirmation of the nature of a variant haemoglobin provisionally identified as S by HPLC or IEF. Positive results are also obtained on samples containing the rare haemoglobins that have both the haemoglobin S mutation and an additional mutation in the β chain. A positive solubility test merely indicates the presence of a sickling haemoglobin and does not differentiate between homozygotes, compound heterozygotes and heterozygotes. In an emergency, it may be necessary to decide if an individual suffers from sickle cell disease before the haemoglobin electrophoresis or HPLC results are available. In these circumstances, if the solubility test is positive, a provisional diagnosis of sickle cell trait can be made if the red cell morphology is normal on the blood film. If the blood film shows any sickle cells or numerous target cells, irrespective of the Hb, a provisional diagnosis of sickle cell disease should be made; many patients with sickle cell/haemoglobin C compound heterozygosity will have a normal Hb. Remember that the sickle test is likely to be negative in infants with sickle cell disease.

False-positive results have been reported in severe leucocytosis, in hyperproteinaemia (such as multiple myeloma) and in the presence of an unstable haemoglobin, especially after splenectomy. The use of packed cells, as described in this method, minimises the problem of false-positive results caused by hyperproteinaemia and hyperlipidaemia.

False-negative results can occur in patients with a low Hb and the use of packed cells will overcome this problem. False-negative results may also occur if old or outdated reagents are used and if the dithionite/buffer mixture is not freshly made. False-negative results are likely to be found not only in infants younger than age 6 months but also in other situations (e.g. post-transfusion) in which the haemoglobin S level is <20%.

All sickle tests, whether positive or negative, must be confirmed by electrophoresis or HPLC at the earliest opportunity.

NEONATAL (NEWBORN) SCREENING

Cord blood or a heel prick sample should be tested from all babies at risk of sickle cell disease or β thalassaemia major (i.e. where the mother has a gene for haemoglobin S, C, D^{Punjab}, E, O^{Arab}, Lepore or β or δβ thalassaemia trait and the father either has a genetic abnormality that could interact or is of unknown status). If a cord blood specimen is used, it is important that the sample is collected by venepuncture of the cleaned umbilical vein to avoid contamination with maternal blood, because even small quantities of maternal blood can cause a case of sickle cell disease to be misdiagnosed as sickle cell trait.

In areas where the frequency of haemoglobinopathies is high, universal neonatal (newborn) screening should be undertaken where possible. Universal neonatal screening for sickle cell disease is now carried out throughout the United Kingdom.[36] The screening programme is linked to the existing dried blood spot screening programme in place for phenylketonuria and congenital hypothyroidism and uses the same dried blood spot specimen. It must be emphasised that the main function of this screening is to detect sickle cell disease, although many cases of β thalassaemia major are also detected, dependent on the mutations present. Dried blood spot samples are tested using HPLC and IEF – HPLC is typically the first-line test and abnormalities are confirmed by IEF. The use of mass spectrometry is becoming increasingly popular for newborn screening. Haemoglobin eluted from dried blood spots is subjected to targeted detection of relevant haemoglobin variants. This is proving an efficient approach in newborn screening laboratories where mass spectrometers are commonly used. Haemoglobin electrophoresis is not recommended for the analysis of dried blood spots. Analysis of cord blood samples is undertaken as a clinician-led request rather than for general screening. If umbilical cord blood samples are used, they can be examined by haemoglobin electrophoresis using cellulose acetate at alkaline pH or citrate agar at acid pH,[20] or by HPLC or IEF. If any abnormality is detected, a confirmatory technique should also be undertaken.

Babies provisionally diagnosed as having SS, SC, SD^{Punjab}, SO^{Arab} or Sβ thalassaemia should be retested within 6–8 weeks of birth. After confirmation of the diagnosis, they should be followed in a paediatric clinic, immediately started on prophylactic penicillin to prevent pneumococcal infections and appropriately managed in the long term.[3] β thalassaemia major is suspected when haemoglobin A is either absent or greatly reduced at birth. Such babies are retested for confirmation. The diagnosis of β thalassaemia trait cannot be reliably made until 12 months of age unless DNA techniques are used (see p. 134).

DETECTION OF AN UNSTABLE HAEMOGLOBIN

Haemoglobin variants exhibit a wide range of instability but the clinically unstable haemoglobins can be detected by both the heat stability test and the isopropanol test.[37] However, minor degrees of instability that have little or no clinical significance may need other techniques. The unstable haemoglobins are frequently silent using electrophoretic or chromatographic techniques, and tests for haemoglobin instability are essential in the detection or exclusion of an unstable haemoglobin.

Several methods are available for the demonstration of haemoglobin instability. Samples analysed should be as fresh as possible and certainly less than 1 week old. Controls should be of the same age as the test sample; a normal cord blood sample can be used as a positive control. The isopropanol test uses chemically prepared controls.

Heat stability test

Principle

When haemoglobin in solution is heated, the hydrophobic van der Waals bonds are weakened and the stability of the molecule is decreased.[38,39] Under controlled conditions, unstable haemoglobins precipitate, whereas stable haemoglobins remain in solution.

Reagent

- *Tris-HCl buffer, pH 7.4, 0.05 M.* Tris, 6.05 g; water to 1 litre. Adjust the pH to 7.4 with concentrated HCl. (It is essential that Tris-sensitive electrodes are used.)

Method

1. Add 0.2 ml of lysate, freshly prepared by the purified haemolysate method (given on p. 291), to a tube containing 1.8 ml of buffer. The negative control is obtained from a fresh normal sample.
2. Place the tubes in a water bath at 50 °C. Examine the tubes at 60, 90 and 120 min for precipitation.

Interpretation and comments

A significantly unstable haemoglobin will have undergone marked precipitation at 60 min and profuse flocculation at 120 min. The normal control may show some (fine) precipitation at 60 min, but this should be minimal.

Isopropanol stability test

Principle

When haemoglobin is dissolved in a solvent such as isopropanol, which is less polar than water, the hydrophobic van der Waals bonds are weakened, and the stability of the molecule is decreased. Under controlled conditions, unstable haemoglobins precipitate, whereas stable haemoglobins remain in solution. This method has the advantage that it does not require a 50 °C water bath, and positive controls can be made by modification of the reagent buffer.[40]

Reagents

- *Tris-HCl buffer, pH 7.4, 0.1 mol/l.* Tris, 12.11 g; water to 1 litre. Adjust the pH to 7.4 with concentrated HCl. It is essential that Tris-sensitive electrodes are used.
- *Isopropanol buffer, 17%.* Make 17 volumes of isopropanol up to 100 volumes with tris-HCl buffer. The 17% isopropanol buffer solution may be stored in a tightly stoppered glass bottle for 3 months at 4 °C.
- *Positive controls.* These are buffers produced by adding small amounts of zinc to the standard 17% isopropanol buffer. For the strongest positive control (5+), add 0.6 mmol/l zinc acetate and for the weaker positive control (1+), add 0.1 mmol/l zinc acetate to the buffer. Samples containing haemoglobin E or haemoglobin F can also be used as weak positive controls.

Method

1. Prepare oxyhaemoglobin haemolysates from test and normal control samples as given on p. 291.
2. Pipette 2.0 ml of the standard isopropanol buffer into two tubes, followed by 2.0 ml of the 1+ and 5+ control solutions, respectively, into two further tubes.
3. Add 0.2 ml of test sample to the first tube. Add 0.2 ml normal control sample into the three remaining tubes.
4. Place the tubes in a water bath at 37 °C for 30 min. Examine the tubes at 5, 20 and 30 min for turbidity and fine flocculation.

Interpretation and comments

A normal sample will remain clear until 30 min, when a slight cloudiness may appear. Some unstable haemoglobins will show clearly observable precipitation even after 5 min incubation, whereas milder variants will not show precipitation until 20 min.

Positive results may be given by samples containing as little as 10% haemoglobin F or by samples containing increased methaemoglobin as a result of prolonged storage. If the normal sample undergoes premature precipitation, check the temperature of the water bath because it is likely to be higher than 37 °C.

False-negative results should be avoided by continuing the incubation until the normal control undergoes precipitation.

DETECTION OF HAEMOGLOBIN Ms

Methaemoglobin (Hi) has iron present in the ferric form. An inherited variant haemoglobin that undergoes oxidation to methaemoglobin more readily than haemoglobin A is referred to as haemoglobin M with an additional identifier (e.g. haemoglobin M Iwate). This is one of the causes of a very rare condition, congenital methaemoglobinaemia. The other cause of inherited methaemoglobinaemia is methaemoglobin reductase deficiency (see p. 225). Methaemoglobin levels vary, but may be as high as 40% of the total haemoglobin. Methaemoglobinaemia *per se* may also be caused by oxidant chemicals.

Methaemoglobin variants may be detected by haemoglobin electrophoresis at pH 7, but almost all can be distinguished from methaemoglobin A (Hi A) by their absorption spectra. Each methaemoglobin has its own distinct absorption spectrum. Hi A has two absorption peaks at 502 nm and 632 nm, whereas the peak absorbances for the variant haemoglobin Ms are at different wavelengths (Fig. 14-11).

Reagent

- *Potassium ferricyanide.* 0.1 mol/l.

Method

1. Lyse washed red cells from a blood sample of known haemoglobin A and of the test sample with water to give haemoglobin concentration of about 1 g/l.
2. Convert the haemoglobin to Hi by the addition of 5 µl of potassium ferricyanide solution to each ml of haemolysate.
3. Leave for 10 min at room temperature.
4. Record the spectrum of Hi A using an automatic scanning spectrometer.
5. Compare to the spectrum of Hi in the test sample.

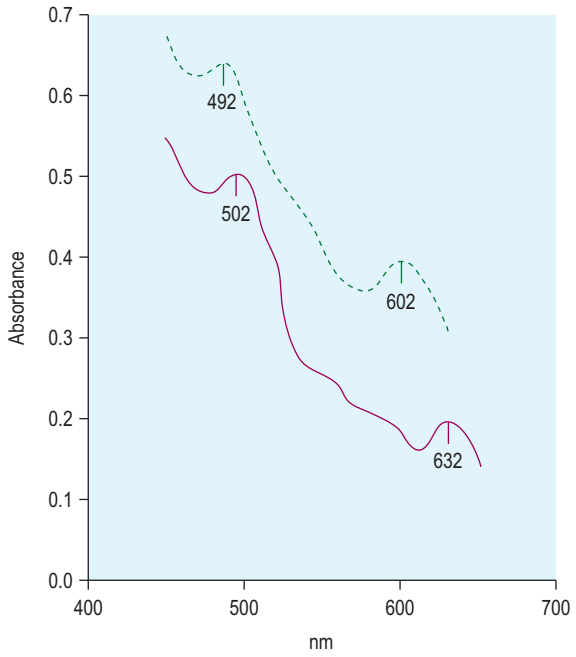

FIGURE 14-11 Absorption maxima of methaemoglobins in the range of 450 to 650 nm. Normal methaemoglobin is shown by a solid line; Hb M Saskatoon is shown by a dotted line. *(Reproduced with permission from Lehmann H, Huntsman K.* Man's haemoglobins. *2nd ed. Amsterdam: North-Holland; 1974. p. 214.)*

DETECTION OF ALTERED AFFINITY HAEMOGLOBINS

Electrophoretic and chromatographic techniques are frequently unsuccessful in separating these abnormal haemoglobins and cannot be relied on for detection because the amino acid substitution often does not involve a change in charge.

The most informative investigation is the measurement of the oxygen dissociation curve (see p. 251). The most significant finding is a decreased Hill constant ('n' value) because this can only come about by a change in the structure of the haemoglobin. The *p50* may be either increased (low affinity haemoglobin) or decreased (high affinity haemoglobin). High affinity haemoglobins result in an increase in Hb, whereas low affinity haemoglobins result in a decrease in Hb. The *p50* alone may be affected by other factors such as the high concentration of 2,3-diphosphoglycerate (2,3-DPG) (e.g. in pyruvate kinase deficiency. Aspects of this are discussed in Chapter 11.)

DIFFERENTIAL DIAGNOSIS OF COMMON HAEMOGLOBIN VARIANTS

Suggested methods for differential diagnosis are given in Table 14-6, and Figure 14-12 gives a comparison of some common variants using different techniques.

INVESTIGATION OF SUSPECTED THALASSAEMIA

A suggested scheme of investigations is shown in Figure 14-13; the methods used are listed in the following section. In addition, it should be noted that:

1. Estimates of haemoglobin A_2 between 3.4% and 3.7% need careful assessment and should be repeated.
2. Haemoglobin A_2 values in α thalassaemia trait are usually below 2.5%. Some types of β thalassaemia trait have normal haemoglobin A_2 values.

Methods for investigation of thalassaemia

1. Full blood count with red cell indices and blood film and, in selected cases, reticulocyte count
2. Haemoglobin A_2 measurement by CAE with elution (see p. 303)

TABLE 14-6

METHODS HELPFUL IN THE DIFFERENTIAL DIAGNOSIS OF COMMON STRUCTURAL VARIANTS

Initial Finding on Cellulose Acetate Electrophoresis	Most Likely Variant	Differentiation
Band in position of haemoglobin S	Haemoglobin S, D^{Punjab}, $G^{Philadelphia}$, Lepore*	Blood count, quantification, solubility test, acid agarose gel electrophoresis, IEF, HPLC
Band in position of haemoglobin C	Haemoglobin C, E, O^{Arab}	Quantification, acid agarose gel electrophoresis, IEF, HPLC
Very fast band	Hb I, H	H bodies

HPLC, high performance liquid chromatography; IEF, isoelectric focusing.
*Migrates slightly ahead of haemoglobin S

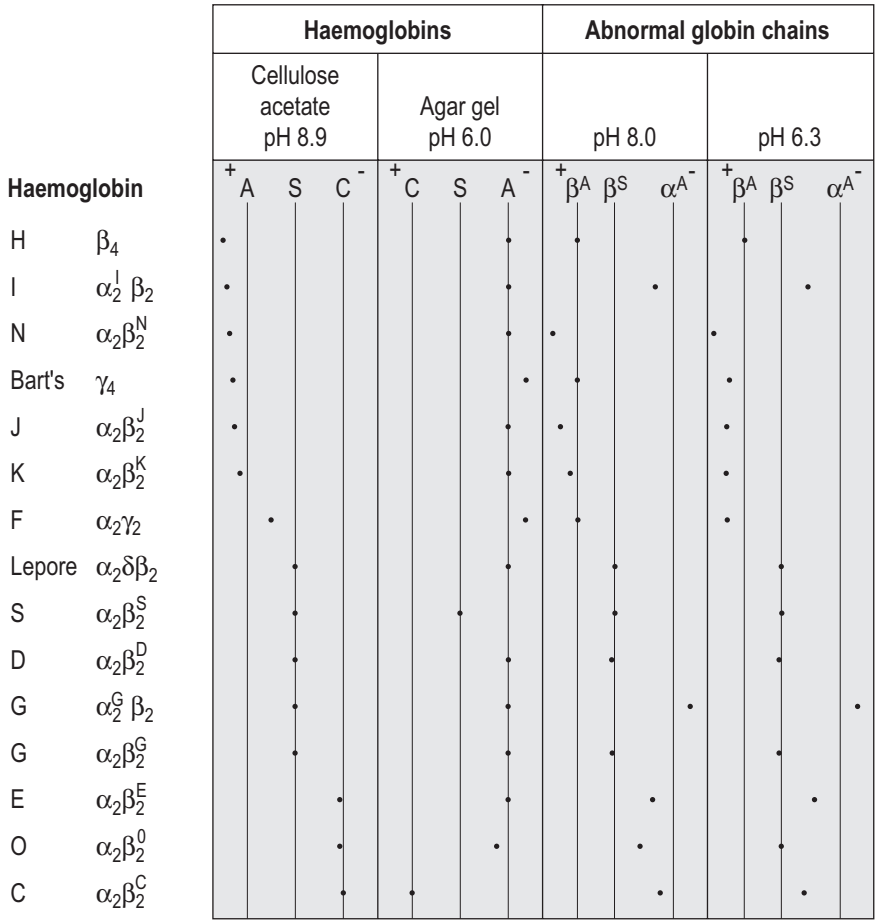

FIGURE 14-12 Comparison of the relative mobilities of some abnormal haemoglobins on capillary electrophoresis.

3. Haemoglobin A_2 measurement of microcolumn chromatography (see p. 304)
4. Automated HPLC (see p. 294)
5. CE
6. Quantification of haemoglobin F (see p. 306)
7. Assessment of the distribution of haemoglobin F (see p. 308)
8. Assessment of iron status (see p. 169)
9. Demonstration of red cell inclusion bodies (see p. 309)
10. DNA analysis (see p. 135)

Blood count and film

The blood count, including Hb and red cell indices, provides valuable information useful in the diagnosis of both α and β thalassaemia. In classic cases, there will be an elevation in the red cell count, accompanied by a decrease in MCV and MCH. The mean cell haemoglobin concentration (MCHC) and red cell distribution width (RDW) are often normal in thalassaemia trait, whereas in iron deficiency anaemia they are more likely to be abnormal. The blood film may show features such as target cells, basophilic stippling and microcytosis in the absence of hypochromia, which point to a diagnosis of thalassaemia trait. Anisochromasia, which is a feature of iron deficiency, is not usual in α and β thalassaemia trait, although it may be seen in haemoglobin H disease. Haemoglobin H disease is also characterised by marked poikilocytosis. The reticulocyte count is increased in haemoglobin H disease.

QUANTIFICATION OF HAEMOGLOBIN A_2

An increased haemoglobin A_2 level is characteristic of heterozygous β thalassaemia and its accurate measurement is required for the diagnosis or exclusion of β thalassaemia trait. Estimations may be made by elution after CAE, by chromatography – either microcolumn or HPLC, or by CE.

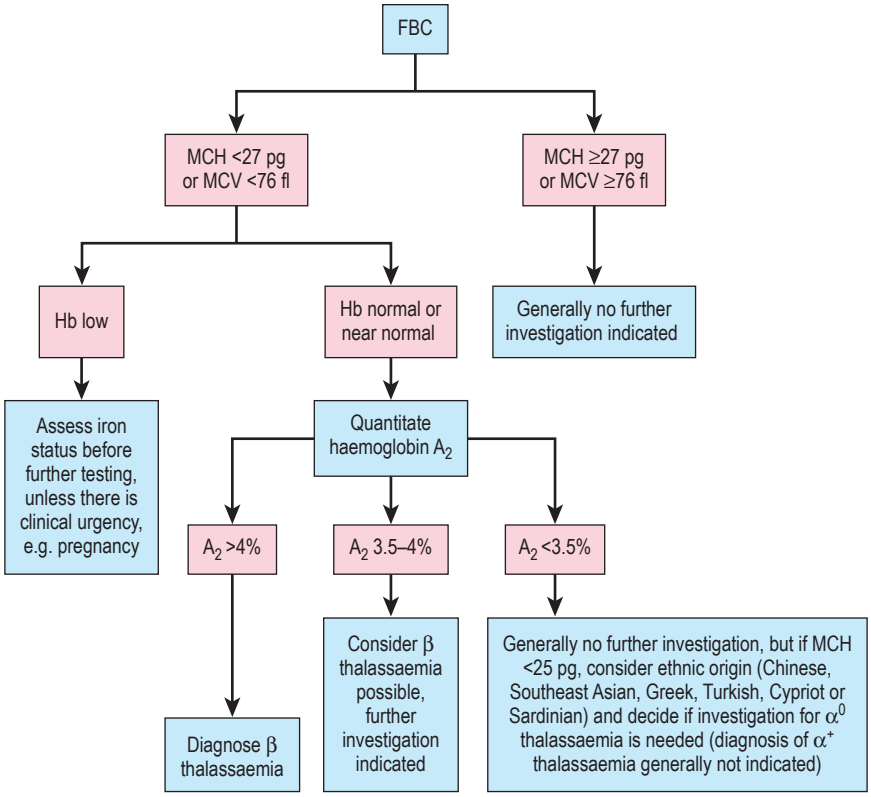

FIGURE 14-13 Suggested scheme of investigation for thalassaemia.

Measurement of haemoglobin A_2 by elution from cellulose acetate

Principle

Haemolysate is separated into its component fractions by alkaline electrophoresis on cellulose acetate membrane. The relative proportions of the separated fractions are quantified by spectrometry of the eluates of the separated fractions.[41,42]

Equipment

- *Electrophoresis tank and power pack* (see p. 292)
- *Wicks of double filter paper or chromatography paper*
- *Cellulose acetate membranes* (78 × 150 mm)

Reagent

- *TEB buffer, pH 8.5.* Tris(hydroxymethyl) methylamine, 40.8 g; disodium EDTA, 2.4 g; orthoboric acid, 12.8 g; water to 4 litres.

Method

1. Prepare a purified haemolysate from washed red cells as described on p. 291. The haemolysate may be kept at 4 °C for up to 1 week before analysis.
2. *With the power supply disconnected,* pour equal amounts of TEB buffer into both the anode and the cathode chambers. Cut lengths of filter or chromatography paper, soak them in the buffer chamber and place them along the bridge supports as wicks. Set the bridge gap to 7 cm.
3. Soak the cellulose acetate by carefully floating the cellulose acetate sheet onto the surface of the buffer, making sure that no air bubbles are trapped underneath it. When the sheet has absorbed the buffer, submerge the sheet. Leave for at least 5 min, remove and blot carefully between two sheets of blotting paper.
4. Position the cellulose acetate across the bridge supports so that the long end of the sheet is on the anodal side. Using a ruler as a guideline, apply 30 µl of lysate to each sheet 1 cm from the cathode in a single line. Leave 1 cm margin at each end of the application line.
5. Run at a constant voltage of 250 V until separation is complete. This will take approximately 60 min and there should be at least a 1 cm gap between the A and A_2 bands at the end of the run. Check the separation at 40 min, ensuring that the haemoglobin A (or fast moving variants such as haemoglobin H, J or N) do not travel onto the wicks. Check again at 5–10 min thereafter.

Samples with a variant band between the A and A_2 bands will take up to 30 min longer to obtain satisfactory separation.

6. Remove the sheet, holding it carefully at the anodal wick contact; do not place on a work surface. Cut off and discard the cellulose acetate that has been in contact with the cathodal wick. Cut a 'blank' strip of approximately 2 cm wide from the cathodal end of one sheet (do not use cellulose acetate that includes the application line). Cut out the haemoglobin A_2 section, cutting the band into pieces approximately 1 cm square directly into a clean universal container. Cut out any variant band in the same way, and finally cut out the haemoglobin A band.
7. Add 4 ml of distilled water to both the blank and haemoglobin A_2 containers and add 16 ml water to the haemoglobin A container. Variant bands are usually eluted in 8 ml of water, although this may vary.
8. Mix the eluates for 20 min and mix again by inversion just before measuring the absorbance.
9. Read the absorbance of the blank against water at 415 nm. This reading should be <0.005. Read the absorbances of the haemoglobin solutions at 415 nm against the cellulose acetate blank.

Calculation

$$\%\text{haemoglobin } A_2 = \frac{\text{Absorbance of haemoglobin } A_2 \times 100}{\text{Absorbance of haemoglobin } A_2 + (\text{Absorbance of haemoglobin A} \times 4)}$$

Interpretation and comments

For interpretation of results and normal ranges, see p. 305. Duplicate values obtained should be within 0.2%. This method is not applicable in the presence of haemoglobin C, E or O^{Arab} because they do not separate from haemoglobin A_2.

The procedure is useful for the measurement of haemoglobin variants. In these cases, the volume of water used for elution should be adjusted to the apparent quantity of the variant as judged on electrophoresis. Particular care must be taken when cutting strips on which a variant haemoglobin that moves between A and A_2 (e.g. haemoglobin S) is present, because the separation between the variant and haemoglobin A_2 is less clear.

To obtain accurate and precise results, use the same cuvette when reading the blank, haemoglobin A_2 and haemoglobin A absorbance of each sample. Read the three cuvettes in that order to minimise the effects of carryover. Some types of cellulose acetate are unsuitable for elution; this can be detected by a very high blank reading. The haemoglobin concentration of the haemolysate is important: the absorbance reading of the haemoglobin A_2 must be at least 0.1 absorbance unit, because low values will give inaccurately low haemoglobin A_2 results.

Measurement of haemoglobin A_2 by microcolumn chromatography

Principle

Microcolumn chromatography depends on the interchange of charged groups on the ion exchange cellulose with charged groups on the haemoglobin molecule. When a mixture of haemoglobins is adsorbed onto the cellulose, a particular haemoglobin component may be eluted from the column using a buffer (developer) with a specific pH and/or ionic strength, whereas other components (either a single haemoglobin or a mixture of haemoglobins) may be eluted by changing the pH or ionic strength of the developer. The separation of haemoglobin components depends on the pH and/or ionic strength of the developers used for the equilibration of the column and for the elution, the type of cellulose, the volume of the sample added, the size of the column, the gradient, flow rates and temperature. The following methods use the anion exchanger diethylaminoethyl (DEAE) cellulose (Whatman DE-52 microgranular pre-swollen), with Tris-HCl developers[43] or glycine-KCN developers.[44]

Measurement of haemoglobin A_2 by microcolumn chromatography with Tris-HCl buffers

Reagents

- *DE-52 ion exchange cellulose (Whatman)*
- *Stock buffer 1.0 mol/l Tris.* Tris, 121.1 g; water to 1 litre. It is essential that Tris-sensitive electrodes are used
- *Working buffer 1.* KCN, 200 mg; stock buffer, 100 ml; water to 2 litres; adjust to pH 8.5 with concentrated HCl
- *Working buffer 2.* KCN, 200 mg; stock buffer, 100 ml; water to 2 litres; adjust to pH 8.3 with concentrated HCl
- *Working buffer 3.* KCN, 200 mg; stock buffer, 100 ml; water to 2 litres; adjust to pH 7.0 with concentrated HCl
- *Important:* If the buffers are stored at 4 °C, they must be allowed to come to room temperature before use.[45]

Method

1. Prepare the slurry by adding 10 g of DE-52 to 200 ml of buffer 1. Mix gently and allow the cellulose to settle. Decant the supernatant and add a further 200 ml of buffer 1, mix gently for 10 min, then adjust the pH of the thoroughly suspended cellulose to 8.5 with concentrated HCl. Allow the cellulose to settle, remove the supernatant and resuspend in a further 200 ml of buffer 1. Mix gently for 10 min and ensure the pH is 8.5. Allow to settle and remove enough buffer so that the settled cellulose constitutes about half the total volume.
2. Secure short-form pipettes vertically in a support rack. Place either a 3 mm glass bead or a small piece of cotton wool in the tapered part of the pipette to act as a support for the slurry.

3. Fill the pipettes with thoroughly suspended cellulose slurry, and allow the column to pack to a height of 5–6 cm.
4. Dilute 1 drop of haemolysate (100 g/l) with 5 drops of buffer 1.
5. When the excess buffer has drained from the column, gently apply the diluted lysate to the top of the column, and allow it to be adsorbed onto the resin. Do not allow the surface of the column to dry out.
6. Apply 8 ml of buffer 2 gently to the column with a 10–15 cm length of polythene tubing attached to the top of the pipette acting as a reservoir. Collect the eluate in a 10 ml flask and make the volume up to 10 ml with buffer 2.
7. Elute the remaining haemoglobin A using 10 ml of buffer 3; collect the eluate and make the volume up to 25 ml with the remaining buffer 3.
8. Read the absorbance of the eluted haemoglobins at 415 nm in a spectrometer, using water as a blank.

Calculate the haemoglobin A_2 as follows:

$$\%\text{haemoglobin } A_2 = \frac{A^{415}\text{haemoglobin } A_2 \times 100}{A^{415}\text{haemoglobin } A_2 + \left(2.5 \times A^{415}\text{haemoglobin A}\right)}$$

Interpretation and comments

For interpretation and normal ranges, see p. 306. The technique is inappropriate in the presence of haemoglobin variants (see below). Factors affecting quality assurance include the concentration of haemoglobin applied to the column – excess haemoglobin will cause contamination of the haemoglobin A_2 fraction with haemoglobin A. An inadequate amount of haemoglobin will result in an eluate with an absorbance too low for precise measurement.

The flow rate of the column may be adjusted by altering the height of the reservoir above the column. A flow rate of 10–20 ml/h is satisfactory. Raising the reservoir increases the flow rate but broadens the haemoglobin A_2 band on the column, which will not affect quantification providing there is adequate separation. To elute the haemoglobin A_2 band, 8 ml of buffer 2 should be used; the greater part of that should elute between 4 and 6 ml.

Measurement of haemoglobin A_2 by microcolumn chromatography with glycine-potassium cyanide developers

The method described as follows is suitable for samples containing variants such as haemoglobin S. The elution of haemoglobin A_2 is dependent on the pH of the ion exchanger and on the molarity of the developer.[44]

Reagents

- *Developer A.* Glycine, 15.0 g; KCN, 0.1 g; water to 1 litre
- *Developer B.* NaCl, 9.0 g; water to 1 litre
- *DE-52 ion exchange cellulose* (*Whatman*)

Method

1. Prepare the slurry by adding 50 g of DE-52 to 250 ml of developer. Mix gently, then allow to settle and remove the supernatant. Repeat this process at least twice, then adjust the pH of the thoroughly suspended cellulose to 7.6 with 0.1 mol/l HCl. If the slurry is made too acidic, it should be discarded, because any attempt to readjust it would increase the total ionic concentration and therefore alter the elution pattern. The slurry may be stored for up to 4 weeks, but the pH should be checked and, if necessary, readjusted before use.
2. Secure short-form pipettes vertically in a support rack. Place either a 3 mm glass bead or a small piece of cotton wool in the tapered part of the pipette to act as a support for the slurry.
3. Fill the pipette with thoroughly suspended DE-52 slurry and allow the column to pack under gravity to a height of about 6 cm.
4. Check each batch of columns with haemolysate containing haemoglobins A, A_2 and S. The haemoglobin A_2 should elute in the first 3–4 ml and the haemoglobin S in the next 15–20 ml of the developer.
5. Dilute 1 drop of lysate (100 g/l) with 6 drops of water.
6. When all the excess buffer has drained from the column, gently apply the diluted lysate to the top of the column and allow it to be adsorbed onto the resin. Do not allow the surface of the column to dry out.
7. Apply developer A gently to the column with a piece of polythene tubing attached to the top of the pipette acting as a reservoir. About 3–4 ml of developer should be used to elute the haemoglobin A_2 band. Collect the eluate in a 5 ml flask and make the volume up to 5 ml with developer A.
8. Elute the remaining haemoglobin A or haemoglobin S + A, using 15–20 ml of developer B; collect the eluate and make the volume up to 25 ml with developer B. If, at any stage, the flow through the column stops, it should be discarded.
9. Read the absorbance of the eluted haemoglobins at 415 nm in a spectrometer, using water as a blank.

Calculate the haemoglobin A_2 as follows:

$$\%\text{haemoglobin } A_2 = \frac{A^{415}\text{haemoglobin } A_2 \times 100}{A^{415}\text{haemoglobin } A_2 + \left(5 \times A^{415}\text{haemoglobin A}\right)}$$

Modification for the measurement of haemoglobin S

To estimate the percentage of haemoglobin S, haemoglobin A and haemoglobin A_2, haemoglobin A_2 is eluted in the first 3–4 ml with developer A, haemoglobin S is eluted in the next 15–20 ml of the same developer A and the remaining haemoglobin A is eluted with developer B. The

eluate containing haemoglobin A_2 is diluted to 5 ml and the eluates containing haemoglobin S and the haemoglobin A are diluted to 25 ml. To ensure elution of all the haemoglobin A_2 in the first 3–4 ml and all the haemoglobin S in the next 15–20 ml, the pH of the ion exchanger may need adjustment following a test chromatogram.[44]

Interpretation and comments

Haemoglobin A_2 percentages tend to be very slightly lower using the Tris buffer system, but with either procedure there should be a distinction between normal and classic β thalassaemia trait subjects.[43] An advantage of the glycine-KCN method is that it is less sensitive to minor changes in the pH of the developer and, in addition, it can be used for samples containing haemoglobin S.

It should be noted that measurement of haemoglobin A_2 in the presence of haemoglobin S is not usually a very useful test. It is not necessary in order to distinguish sickle cell trait from sickle cell/β^+ thalassaemia and is not always reliable in distinguishing sickle cell anaemia from sickle cell/β^0 thalassaemia, because there is often interaction with α thalassaemia trait. In these circumstances, family studies can be extremely helpful.

Measurement of haemoglobin A_2 by high performance liquid chromatography

The principle of HPLC has been explained on p. 294. When this technology is used as the primary method for detecting variant haemoglobins, simultaneous quantification of haemoglobins A_2 and F means that it can replace three separate traditional methods: haemoglobin electrophoresis, quantification of haemoglobin A_2 and quantification of haemoglobin F. Each laboratory should establish its own reference range for the quantification of haemoglobin A_2 by this method, which should be similar to published ranges. Because the quantification of haemoglobin A_2 may be inaccurate in the presence of certain variant haemoglobins, such as haemoglobins E, Lepore, D^{Punjab} and S,[29,32] all chromatograms should be inspected. Inspection will also permit identification of specimens with a split A_2 band as the result of heterozygosity for a δ chain variant. If the quantity of a haemoglobin with the retention time of haemoglobin A_2 is higher than expected, an alternative technique should be applied to confirm its identity, because a peak labelled as haemoglobin A_2 can be haemoglobin E, haemoglobin Lepore or another haemoglobin that elutes with haemoglobin A_2.

Measurement of haemoglobin A_2 by capillary electrophoresis

Capillary electrophoresis is a suitable method for the quantification of haemoglobin A_2. In contrast to measurements by HPLC, there is no false elevation in the presence of adjuncts of haemoglobin S and no false reduction in the presence of haemoglobin D^{Punjab}; accurate measurement is possible in the presence of haemoglobin E.[32] Measurement may, however, be inaccurate in the presence of haemoglobin C.

INTERPRETATION OF HAEMOGLOBIN A_2 VALUES

Haemoglobin A_2 values should be interpreted in relation to a reference range established in each individual laboratory using blood samples from the local population with normal Hb and red cell indices.[11,45–48] The standard operating procedure for the relevant method should be strictly followed, and 95% reference ranges should be determined. Ranges may differ slightly but significantly between methods and between laboratories. For example, in one of our laboratories the range determined for microcolumn chromatography was 2.2–3.3%, whereas in the other it was 2.3–3.5%. We also found bias between HPLC, CE and microcolumn chromatography.[32] Technical variables affecting the range may include the use of packed cells rather than whole blood. Results obtained by HPLC analysis may be 0.1–0.2% higher than the results obtained by electrophoresis with elution. Once a reference range is determined, there is still a practical problem with borderline results, given that repeat estimates may vary by 0.1–0.2%. We recommend that haemoglobin A_2 levels of 3.4–3.7% be regarded as borderline and that the assay be repeated both on the same sample and on a fresh sample. There is also evidence that haemoglobin A_2 is elevated in patients with human immunodeficiency virus (HIV) infection, and even more so during treatment with zidovudine.[49,50]

When assays are being performed for genetic counselling, it can be useful to perform DNA analysis and also test the partner whenever borderline results are obtained.

The haemoglobin A_2 percentage should be interpreted with knowledge of the Hb and red cell indices (Table 14-7).

QUANTIFICATION OF HAEMOGLOBIN F

Haemoglobin F may be estimated by several methods based on its resistance to denaturation at alkaline pH, by HPLC or by CE. Of the alkaline denaturation methods, that of Betke *et al.*[51] is reliable for small amounts (<10–15%), whereas for levels of more than 50% and in cord blood, the method of Jonxis and Visser[52] (see previous edition for method) is preferable; however, this method is not reliable at levels of less than 10%.

TABLE 14-7

INTERPRETATION OF HAEMOGLOBIN A_2 VALUES

Haemoglobin A_2 Range (%)	Interpretation*
>7.0	Haemoglobin A_2 values of >7.0% are rare Exclude a structural variant Repeat haemoglobin A_2 estimation Rare β thalassaemia mutations
3.8–7.0	β thalassaemia trait, unstable haemoglobin
3.4–3.7	Severe iron deficiency in β thalassaemia trait Some β thalassaemia trait Additional δ chain variant with β thalassaemia trait (total A_2 must be measured) Interaction of α and β thalassaemia Rare β thalassaemia mutations Presence of haemoglobin S, making accurate measurement difficult (HPLC) Interaction of α thalassaemia and haemoglobin S Analytical error, including carryover; repeat analysis
2.0–3.3	Normal δβ thalassaemia (if haemoglobin F elevated) Rare cases of β thalassaemia trait, including coexisting β and δ thalassaemia and coexisting β and α thalassaemia α thalassaemia trait α or δ chain variant (total A_2 must be measured)
<2.0	δβ thalassaemia (if haemoglobin F elevated) α thalassaemia trait Haemoglobin H disease Additional δ chain variant present (total haemoglobin A_2 must be measured) δ thalassaemia Iron deficiency

HPLC, high performance liquid chromatography.
*In the case of HPLC, it is necessary to exclude carryover from a previous sample (e.g. containing haemoglobin E) as the cause of an elevated percentage

Modified Betke method for the estimation of haemoglobin F

Principle

To measure the percentage of haemoglobin F in a mixture of haemoglobins,[51] sodium hydroxide is added to a lysate, and, after a set time, denaturation is stopped by adding saturated ammonium sulphate. The ammonium sulphate lowers the pH and precipitates the denatured haemoglobin. After filtration, the quantity of undenatured (unprecipitated) haemoglobin is measured. The proportion of alkali-resistant (fetal) haemoglobin is then calculated as a percentage of the total amount of haemoglobin present.

Equipment

- *Filter paper.* Whatman No. 42
- *Vortex mixer*
- *Glass tubes*

Reagents

- *Cyanide solution.* Potassium cyanide, 25 mg; potassium ferricyanide, 100 mg. Dissolve in 500 ml distilled water. Store in a dark bottle.
- *Saturated ammonium sulphate solution.* Bring 1 litre of water to boil and add ammonium sulphate until the solution is saturated. Cool and equilibrate at 20 °C before use.
- *Sodium hydroxide solution, 1.2 mol/l.* Sodium hydroxide 4.8 g; distilled water to 100 ml. Prepare monthly. Equilibrate at 20 °C before use.

Method

1. Prepare a lysate as described on p. 291. The lysate may be stored at 4 °C for up to 1 week before use.
2. Add 0.25 ml lysate to 4.75 ml cyanide solution to make a solution of haemiglobincyanide (HiCN).
3. Transfer 2.8 ml of the HiCN solution to a glass test tube and allow to equilibrate at 20 °C.
4. Rapidly add 0.2 ml of 1.2 mol/l of NaOH and mix on a vortex mixer for 2–3 s.
5. After exactly 2 min, rapidly add 2 ml saturated ammonium sulphate solution and mix on a vortex mixer. Leave tubes to stand for 5–10 min at 20 °C.
6. Filter twice through the same Whatman No. 42 filter paper, using a clean test tube to collect the filtrate each time. If the filtrate is not completely clear, filter again through the same paper. This filtrate contains the alkali-resistant haemoglobin.
7. To measure the total haemoglobin, transfer 0.4 ml of the HiCN solution from step 2 into another tube and add 13.9 ml of water.
8. Read the absorbance of the alkali-resistant and total haemoglobin at 420 nm against a water blank.
9. Calculate the percentage alkali-resistant haemoglobin as follows:

$$\%\text{Alkali-resistant haemoglobin} = \frac{A^{420}\text{alkali-resistant haemoglobin}}{A^{420}\text{total haemoglobin} \times 20} \times 100$$

Interpretation and comments

Elevation of haemoglobin F has a variety of causes (see p. 288). In very exceptional situations, other abnormal haemoglobins will also exhibit resistance to alkali, giving high results. It is imperative that haemoglobin electrophoresis or HPLC is done on these samples tested for haemoglobin F to exclude the possibility of an unusual variant being present.

A normal and a raised haemoglobin F control should be tested with every batch of samples. The raised haemoglobin F control should ideally contain between 5% and 15% haemoglobin F, and this can be prepared from a mixture of cord and adult blood. Each laboratory must verify its own normal range, which should not differ significantly from published values; for adults the range is 0.2% to 1.0%.

Zago *et al.*[53] reported variability in the capacity of different batches of filter paper to absorb haemoglobin from the filtrate, which caused low results. It is necessary to equilibrate the temperature of the reagents to 20 °C and to control the reaction temperature to 20 °C to obtain accurate and reproducible results.

ASSESSMENT OF THE INTRACELLULAR DISTRIBUTION OF HAEMOGLOBIN F

Differences in the intracellular distribution of haemoglobin F are used to differentiate between heterozygotes for δβ thalassaemia and the classic African type of HPFH. In the former, it can be shown that not all red cells contain haemoglobin F (heterocellular distribution), whereas in the latter every cell contains haemoglobin F (pancellular distribution), although there is some variability in content from cell to cell. It has been suggested that a heterocellular distribution may be more apparent than real and merely reflects that high levels of haemoglobin F tend to give a more pancellular distribution than lower levels. For this reason, results should be treated with caution and not used to make a diagnosis in isolation.

Two techniques have been widely used for demonstrating intracellular haemoglobin F distribution. The most frequently used is the acid elution test of Kleihauer[54] that was originally developed for the detection of fetal red cells in the maternal circulation following transplacental haemorrhage. This method is described on p. 316. Less frequently used is the more sensitive immunofluorescence technique described in the previous edition of this book.

Interpretation of haemoglobin F values

See Table 14-8.[11,14]

ASSESSMENT OF IRON STATUS IN THALASSAEMIA

Concurrent iron deficiency makes the diagnosis of thalassaemia trait more difficult because it masks the typical blood picture and can reduce haemoglobin A_2 synthesis.[45,46,48] In β thalassaemia trait, dependent on the severity of the anaemia, the haemoglobin A_2 value may be reduced to borderline or even to normal levels (3.0–3.5%). However, in many patients with β thalassaemia trait and iron deficiency, the haemoglobin A_2 will still be raised.

TABLE 14-8

INTERPRETATION OF HAEMOGLOBIN F VALUES

Haemoglobin F Range (%)	Interpretation
0.2–1.0	Normal results
1.0–5.0	In approximately 30% of β thalassaemia traits
	Some heterozygotes for a variant haemoglobin
	Some homozygotes for a variant haemoglobin
	Some compound heterozygotes for a variant haemoglobin and β thalassaemia
	Some individuals with haematological disorders (aplastic anaemia, myelodysplastic syndromes, juvenile myelomonocytic leukaemia)
	Some pregnant women (2nd trimester)
	Sporadically in the general population, particularly in Afro-Caribbeans (representing heterozygosity for nondeletional HPFH)
5.0–20.0	Occasional cases of β thalassaemia trait
	Some homozygotes for a variant haemoglobin including some sickle cell anaemia*
	Some compound heterozygotes for a variant haemoglobin and β thalassaemia
	Some types of heterozygous HPFH or δβ thalassaemia
15.0–45.0	Heterozygous HPFH African type (usually >20%)
	Some cases of β thalassaemia intermedia
>45.0	β thalassaemia major
	Some cases of β thalassaemia intermedia
	Neonates
>95.0	Homozygous African-type (deletional) HPFH
	Some neonates (particularly if premature)

HPFH, hereditary persistence of fetal haemoglobin.
*Highest levels seen with Arab-Indian haplotype and in patients treated with hydroxycarbamide.

Whenever possible, individuals should not be investigated for the presence of thalassaemia trait if they are iron deficient. Iron stores are usually replete after 3–4 months of treatment with iron. However, if a pregnant woman is suspected of having a thalassaemia trait, it is not possible to wait for the correction of iron deficiency to establish the diagnosis. The woman and her partner should be tested without delay, with DNA analysis of globin genes being carried out if both are suspected of having thalassaemia trait (see Chapter 8, p. 135).

In addition to traditional methods for iron assessment – such as measurement of serum ferritin or serum iron plus total iron-binding capacity – estimation of zinc protoporphyrin (see p. 179) is of potential value. This test can be carried out on an EDTA sample within a haematology laboratory and is a measure of iron incorporation at the cellular level.

RED CELL INCLUSIONS

The most important red cell inclusions found in the haemoglobinopathies are haemoglobin H inclusions (precipitated β chain tetramers) found in α thalassaemia,[55] α chain inclusions found in β thalassaemia major[7,56] and Heinz bodies found in unstable haemoglobin diseases.[39,57]

Precipitated α chains are found in the cytoplasm of nucleated red cell precursors of patients with β thalassaemia major; they can be demonstrated by supravital staining of the bone marrow with methyl violet (as can Heinz bodies) and appear as irregularly shaped bodies close to the nucleus of normoblasts. After splenectomy they may also be found in the peripheral blood normoblasts and reticulocytes. Heinz bodies (insoluble denatured globin chains) form as a result of exposure to oxidant drugs or chemicals and develop spontaneously in glucose-6-phosphate dehydrogenase (G6PD) deficiency and in the unstable haemoglobin diseases. In unstable haemoglobin diseases, they are usually only seen in the peripheral blood after splenectomy but may be demonstrated in patients with an intact spleen if their blood is kept at 37 °C for 24–48 h. The use of methyl violet and of brilliant cresyl blue in the demonstration of precipitated α chain and Heinz bodies is described on p. 315.

Demonstration of haemoglobin H inclusions

Patients with α thalassaemia, who form haemoglobin H (β_4), have red cells in which multiple blue-green spherical inclusions develop on exposure to brilliant cresyl blue or New methylene blue. This is mainly a feature of haemoglobin H disease, but small numbers of similar cells may be seen in α thalassaemia trait, particularly, but not only, in α^0 thalassaemia heterozygosity. A modified method with a higher degree of specificity and a sensitivity of 94% has been proposed when haemoglobin H inclusions are used for the detection of α^0 thalassaemia.[58]

Reagent

- *Staining solution.* 1.0% brilliant cresyl blue or New methylene blue in iso-osmotic phosphate buffer pH 7.4. New batches of stain must be tested with a known positive control because the redox action of the dyes may vary from batch to batch.

Method

1. Mix 2 volumes of EDTA-anticoagulated fresh blood (within 24 h of collection) with 1 volume of staining solution.
2. Incubate at 37 °C for 2 h or at room temperature for 4 h.
3. Resuspend the cells and spread a thin blood film.
4. Examine the film, without counterstaining, as for a reticulocyte count. The inclusion bodies appear as multiple greenish blue spherical dots, like the pitted pattern of a golf ball (Fig. 14-14). They can be readily distinguished from reticulocytes, which exhibit more darkly staining, uneven reticulofilamentous material or infrequent fine dots.

Interpretation and comments

In α^+ thalassaemia trait, only a very occasional H body (1:1000 to 1:10 000) is usually seen; they are more numerous in α^0 thalassaemia (1:100 to 1:10 000) but the number of cells developing inclusions is not reliable in differentiating the various gene deletion patterns seen in α thalassaemia, and the absence of demonstrable inclusions does not preclude a diagnosis of α thalassaemia trait. In high prevalence areas where the test is done very regularly, a haemoglobin H preparation can be used for α^0 thalassaemia screening,[58] but in the UK, screening of antenatal patients is on the basis of the ethnic origin and red cell indices, proceeding to DNA analysis when precise diagnosis

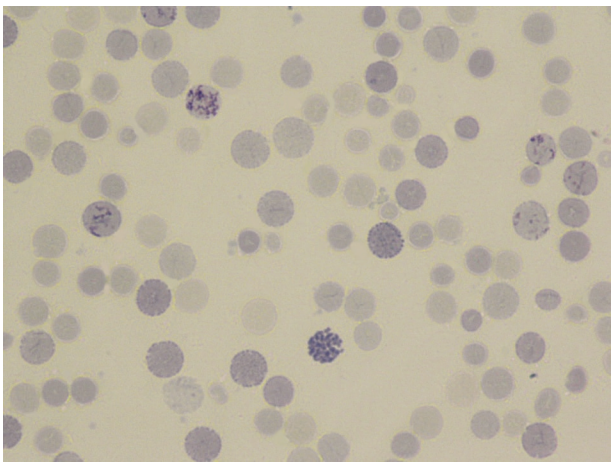

FIGURE 14-14 Denaturation of haemoglobin H by brilliant cresyl blue. Haemoglobin H disease showing an increased reticulocyte count and a number of cells with haemoglobin H inclusions – round bodies consisting of precipitated haemoglobin H.

of the type of α thalassaemia trait is required. This test is most useful in the diagnosis of haemoglobin H disease, where inclusions are usually found in 10–30% of red cells. Haemoglobin H inclusions are also detectable in patients with acquired haemoglobin H disease as a feature of a myelodysplastic syndrome.

FETAL DIAGNOSIS OF GLOBIN GENE DISORDERS

Prenatal diagnosis of globin gene disorders[59] is carried out if the fetus is at risk of thalassaemia major or a severe form of sickle cell disease such as sickle cell anaemia. DNA analysis is required, DNA being obtained from a chorionic villus sample or from cultured amniotic cells. Methods used for DNA analysis are described in Chapter 8.

When a potentially at-risk couple is detected, they will require counselling, and if a fetal diagnosis is requested, it is necessary to confirm the parental haemoglobin phenotype. The family or parental blood samples are sent to the diagnostic centre and the timing of fetal sampling is arranged.

Sample requirements

Blood samples for DNA analysis can be sent by overnight delivery without refrigeration but must be processed, at the latest, within 3 days of collection. From each parent, 10 ml of blood in EDTA or heparin is required. If restriction fragment length polymorphism (RFLP) linkage analysis is required, the following additional samples are needed: blood from either a homozygous normal or affected child, or from a heterozygous child and one set of grandparents, or, if no child is available, blood from both sets of grandparents. The samples must be carefully and clearly labelled and the family tree must be drawn. Particulars of all haematological tests must be given.

Chorionic villus samples must be dissected free of any maternal tissue and sent by urgent overnight delivery in tissue culture medium or, preferably, in a special buffer obtainable from the DNA diagnostic laboratory. Amniotic fluid samples (15–20 ml are needed) must be received within 24 h of collection. If a longer transit time is unavoidable, the amniocytes should be resuspended in tissue culture medium.

The laboratory performing DNA analysis for disorders of globin chain synthesis must be given accurate information on the precise ethnic origin of family members so that optimal use is made of the DNA available for diagnosis.

It is essential that follow-up data are obtained on all cases that have undergone fetal diagnosis. This should include tests on cord blood or heel prick sample at birth and a test at 6 months to confirm the carrier state. Whenever possible, DNA analysis of the child's globin genes should be carried out.

Erythrocyte and Leucocyte Cytochemistry

Barbara J. Bain

CHAPTER OUTLINE

ERYTHROCYTE CYTOCHEMISTRY

Siderocytes and sideroblasts

Siderocytes are red cells containing granules of non-haem iron. They were originally described by Grüneberg[1] in small numbers in the blood of normal rat, mouse and human embryos and in large numbers in mice with a congenital anaemia. The granules are formed of a water-insoluble complex of ferric iron, lipid, protein and carbohydrate. This siderotic material (or haemosiderin) reacts with potassium ferrocyanide to form a blue compound, ferriferrocyanide; this reaction is the basis of a positive Prussian blue (Perls) reaction. The material also stains with Romanowsky dyes and then appears as basophilic granules, which have been referred to as 'Pappenheimer bodies' (Fig. 15-1).[2] By contrast, ferritin, which is a water-soluble non-haem compound of iron with the protein apoferritin, is not detectable by Perls reaction. Ferritin is normally present in all cells in the body, whereas in health, haemosiderin is mainly found in macrophages in the bone marrow, liver (Kupffer cells) and spleen. When the body is overloaded with iron, as in haemochromatosis or transfusional haemosiderosis, excess iron is also found in other tissues.

Iron is transported in plasma attached to a β globulin, transferrin, and is taken up selectively by the bone marrow, where the iron–transferrin complex binds to transferrin receptors on the surface of the erythroblast; the iron is released from transferrin and enters the cell. Most of the iron is rapidly converted to haem, synthesis being partly in the cytosol and partly in the mitochondria. The non-haem residue is in the form of ferritin. Degradation of the ferritin turns some of it into haemosiderin, which can be visualised under the light microscope as golden-yellow refractile particles in phagocytic cells. When stained by Perls reaction, haemosiderin is blue.

In health, siderotic granules can normally be seen, in preparations stained by Perls reaction, in the cytoplasm of many of the erythroblasts of human bone marrow and in marrow reticulocytes.[3] However, they are not normally seen in human peripheral blood red cells. After splenectomy, siderocytes can always be found in the peripheral blood, often in large numbers. The reason for this is probably because reticulocytes, after delivery from the marrow, are normally sequestered for a time in the spleen, and there they complete haem synthesis, utilising, for this purpose, the iron stored in their cytoplasm within the siderotic

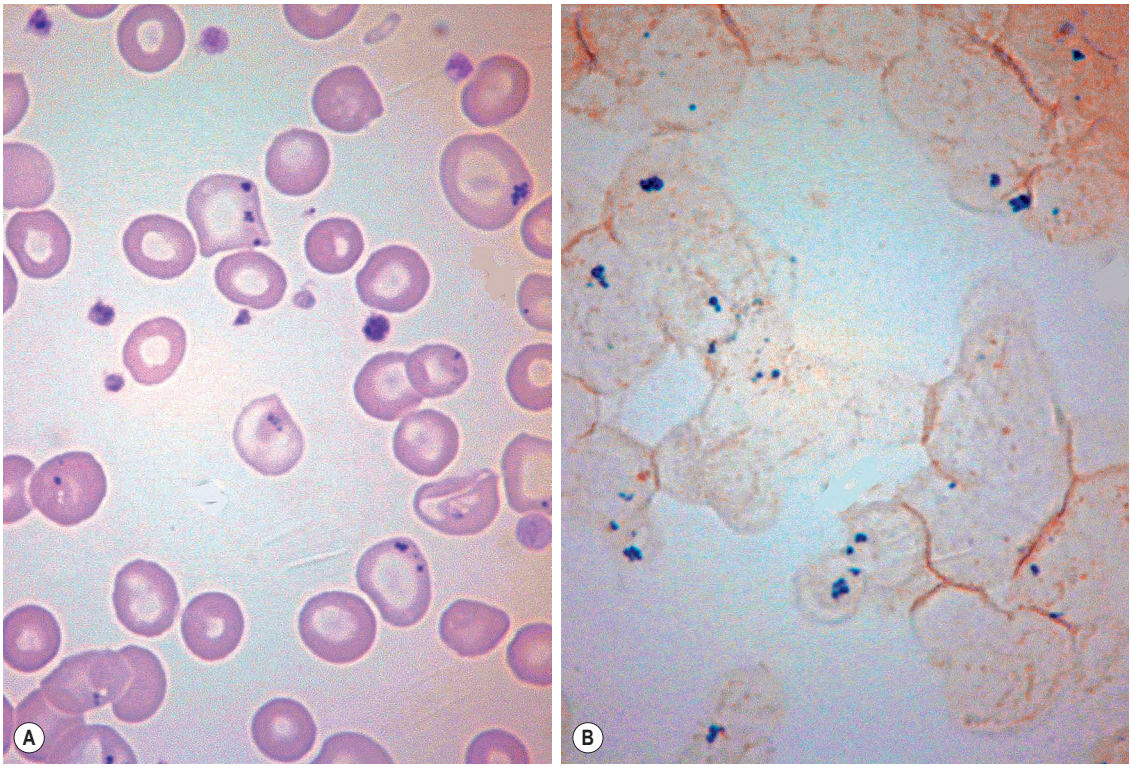

FIGURE 15-1 Siderotic granules and Pappenheimer bodies. Photomicrographs of erythrocytes in a peripheral blood film from a splenectomised patient with a myelodysplastic syndrome (refractory anaemia with ring sideroblasts) showing Pappenheimer bodies: May–Grünwald–Giemsa **(A)**; and siderotic granules: Perls reaction **(B)**.

granules. After splenectomy, this stage of reticulocyte maturation has to take place in the bloodstream, with the result that, even in an otherwise healthy person, a small percentage of siderocytes can then be found in the peripheral blood. The spleen is also probably able to remove large siderotic granules – as may be found in disease – from red cells by a process of pitting,[4] and in its absence such granules persist in the red cells throughout their lifespan.

Method for staining siderotic granules

Air dry films of peripheral blood or bone marrow and fix with methanol for 10–20 min. When they are dry, place the slides in a solution of 10 g/l potassium ferrocyanide in 0.1 mol/l HCl made by mixing equal volumes of 47 mmol/l (20 g/l) potassium ferrocyanide and 0.2 mol/l HCl immediately before use.

Leave the slides in the solution for about 10 min at about 20 °C. Wash well in running tap water for 20 min, rinse thoroughly in distilled water and then counterstain with 1 g/l aqueous neutral red or eosin for 10–15 s. Care must be taken to avoid contamination by iron that may have been present on the slides or in staining dishes. Prepare the glassware by soaking in 3 mol/l HCl before washing (see p. 564). For quality control, a positive bone marrow film should always be stained together with the test films.

Prussian blue staining can be applied to films that have previously been stained by Romanowsky dyes, even after years of storage. It is advisable to let the films stand in methanol overnight to remove most of the Romanowsky stain. The film should be checked before carrying out Perls reaction to ensure that there is no residual blue staining that could obscure Prussian blue staining. Sundberg and Bromann described a technique whereby films were stained first by a Romanowsky dye (Wright stain) and then overstained by the acid–ferrocyanide method.[5] This can give beautiful pictures, but the small blue-stained iron-containing granules tend to be masked in young erythroblasts by the general basophilia of the cell cytoplasm. Hayhoe and Quaglino described a method for combined periodic acid–Schiff (PAS) and iron staining.[6] This may be helpful in the investigation of abnormal erythropoiesis in which the erythroblasts give a positive PAS reaction (see p. 321). A rapid method has been described for demonstrating siderotic granules by staining with 1% bromochlorphenol blue for 1 min.[7] Iron-containing granules stain dark purple.

Significance of siderocytes. Siderocytes contain one or two (rarely many) small, unevenly distributed iron-containing granules that stain a Prussian blue colour.

There are normally a few very small scattered siderotic granules in about 40% of late erythroblasts.[3] They stain faintly and may be difficult to see by light microscopy. The percentage of erythroblasts recognisable as sideroblasts is increased in haemolytic and megaloblastic anaemias and in haemochromatosis and haemosiderosis, in proportion to the degree of saturation of transferrin (i.e. to the amount of iron available). A disproportionate increase in the percentage of erythroblasts that are sideroblasts occurs when the synthesis of haemoglobin is impaired, in which case the siderotic granules are both more numerous and larger than normal (Fig. 15-2). When there is a defect in haem synthesis, the granules are deposited in mitochondria and frequently appear to be arranged in a collar around the nucleus (Fig. 15-3), giving the 'ring sideroblasts' characteristic of sideroblastic anaemias. In contrast, the distribution of the granules within the cell tends to be mainly normal in conditions in which globin synthesis alone is affected (e.g. in thalassaemia) or when there is iron overload.

There are several types of sideroblastic anaemia. These include the congenital (hereditary) type, pyridoxine (vitamin B_6) deficiency (rarely), sideroblastic anaemia caused by B_6 antagonists (e.g. drugs used in antituberculosis therapy) and secondary sideroblastic anaemia in alcoholism and lead poisoning. The presence of ring sideroblasts is a defining feature of refractory anaemia with ring sideroblasts[8] and refractory cytopenia with multilineage dysplasia and ring sideroblasts, two of the World Health Organisation (WHO) categories of myelodysplastic syndrome (MDS). They may also occur in other categories of MDS. Ring sideroblasts are not uncommon in other haematological neoplasms, including primary myelofibrosis and acute myeloid leukaemia (AML), particularly erythroleukaemia and the WHO categories of therapy-related AML and AML with multilineage myelodysplasia.

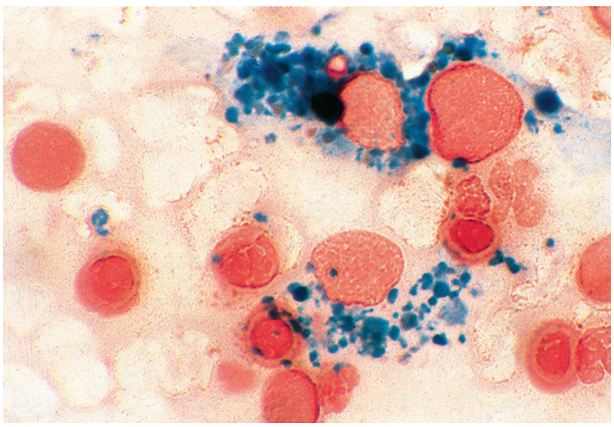

FIGURE 15-2 Pathological sideroblasts – thalassaemia. There is massive accumulation of iron-containing granules in normoblasts and also in phagocytic cells. Perls reaction.

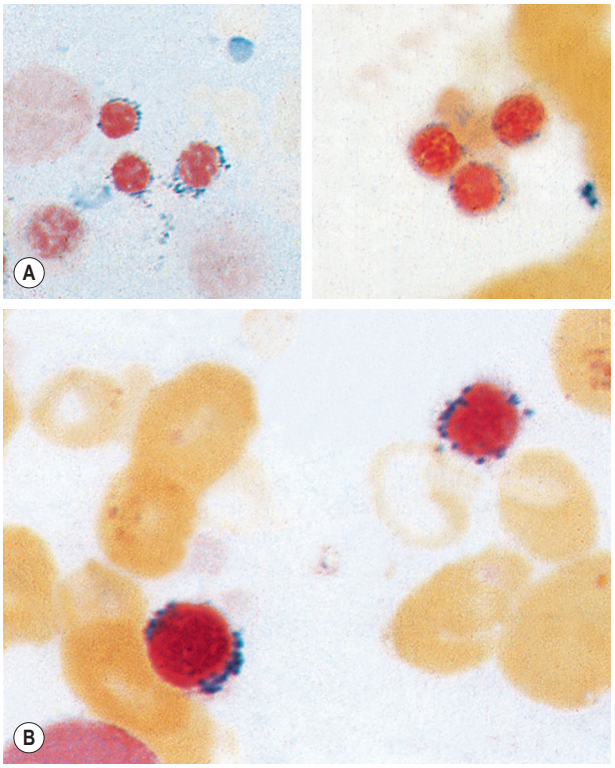

FIGURE 15-3 Pathological sideroblasts – sideroblastic anaemias. Accumulation of iron-containing granules in normoblasts, arranged characteristically around the nucleus. **A,** Hereditary congenital sideroblastic anaemia. **B,** Acquired sideroblastic anaemia, myelodysplastic syndrome (MDS). Perls reaction.

Ring sideroblasts have been defined as erythroblasts with at least five siderotic granules surrounding at least one-third of the nucleus.[9,10]

In sideroblastic anaemia as a feature of a haematological neoplasm, erythroblasts at all stages of maturity may be loaded with siderotic granules, whereas in the secondary sideroblastic anaemias and in the hereditary types, the more mature cells seem most affected.

In addition to the siderotic granules within erythroblasts, haemosiderin can normally be seen in marrow films as accumulations of small granules, lying free or in macrophages in marrow fragments.[11] The amount of haemosiderin will be markedly increased in patients with increased iron stores, whereas haemosiderin is absent in iron deficiency anaemia (Fig. 15-4). In practice, staining to demonstrate iron stores in marrow fragments and siderotic granules in erythroblasts is a simple and valuable diagnostic procedure and should be applied as a routine to marrow films from the initial bone marrow aspirate of each patient.

In chronic infections and in other examples of anaemia of chronic disease, the iron stores may be increased, with much siderotic material in macrophages but little or

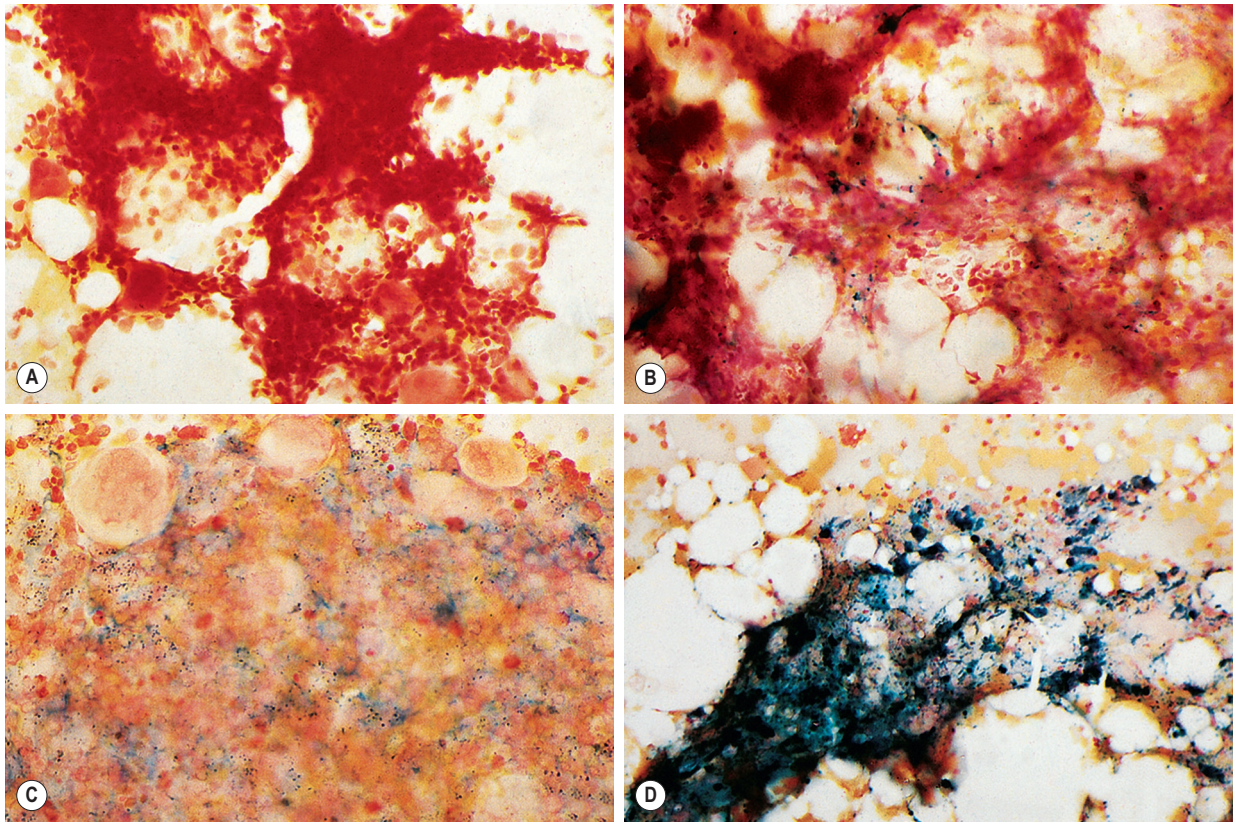

FIGURE 15-4 Prussian blue staining (Perls reaction) on aspirated bone marrow particles to demonstrate iron stores. A, Absent. **B**, Normal. **C**, Increased. **D**, Grossly increased.

none visible in erythroblasts. Markedly excessive iron in macrophages is also a feature of thalassaemia intermedia, thalassaemia major and some dyserythropoietic anaemias. Conversely, absence of iron is diagnostic of iron deficiency or iron depletion (the latter term indicating the state in which storage iron is absent but anaemia is not yet evident). One study has shown that to establish the absence of stainable iron, at least seven particles must be examined, if necessary using more than one slide for this purpose.[12]

Occasionally a Perls stain demonstrates haemosiderin in plasma cells (e.g. in copper deficiency,[13] alcoholism[14] and conditions of iron overload).

There is no cytochemical method for demonstrating ferritin.

Haemoglobin derivatives

Heinz bodies in red cells

Heinz, in 1890, was the first to describe in detail inclusions in red cells developing as the result of the action of acetylphenylhydrazine on the blood.[15] It is now known that Heinz bodies can be produced by the action on red cells of a wide range of aromatic nitro- and amino-compounds, as well as by inorganic oxidising agents such as potassium chlorate. They also occur when one or other of the globin chains of haemoglobin is unstable. In man, the finding of Heinz bodies is a sign of either chemical poisoning, drug toxicity, glucose-6-phosphate dehydrogenase (G6PD) deficiency or the presence of an unstable haemoglobin (e.g. haemoglobin Köln). When of chemical or drug origin, Heinz bodies are likely to be visible in red cells only if the patient has been splenectomised previously or when large doses of the chemical or drug have been taken. When they are due to an unstable haemoglobin, they are rarely visible in freshly withdrawn red cells except after splenectomy. They may nevertheless develop *in vitro* in the blood of patients who have not been splenectomised if the specimen is incubated for 24–48 h.[16] Heinz bodies are a late sign of oxidative damage and represent an end-product of the degradation of haemoglobin. In acute oxidant damage, the presence of Heinz bodies can be suspected from a Romanowsky-stained blood film, when they appear as small inclusions protruding from irregularly contracted cells or within an otherwise empty cell membrane.[17] Their nature can be confirmed as discussed below. Reviews dealing with Heinz bodies include those by Jacob[18] and by White.[19]

Demonstration of Heinz bodies

Unstained preparations. Heinz bodies may be seen as refractile objects in dry, unstained films, if the illumination is reduced by lowering the microscope condenser. They also can be seen by dark-ground illumination or phase-contrast microscopy. However, it is preferable to look for them in stained preparations (see below). In size they vary from 1 to 3 μm. One or more may be present in a single cell. They are usually close to the cell membrane and may cause a protrusion of the membrane; in wet preparations, they may move around within the cells in a slow Brownian movement.

The degradation product of an unstable haemoglobin (e.g. haemoglobin Köln) exhibits green fluorescence when excited by blue light at 370 nm in a fluorescence microscope.[20]

Stained preparations. Dissolve approximately 0.5 g of methyl violet in 100 ml of 9 g/l NaCl and filter. Add 1 volume of blood (in any anticoagulant) to 4 volumes of the methyl violet solution and allow the suspension to stand for about 10 min at room temperature. Then prepare films and allow them to dry or view the suspension of cells between slide and coverslip. The Heinz bodies stain an intense purple (Fig. 15-5).

Heinz bodies also stain with other basic dyes. Brilliant green stains them well, and none of the stain is taken up by the remainder of the red cell.[21] Rhodanile blue (5 g/l solution in 10 g/l NaCl) stains them rapidly[22] (i.e. within 2 min), at which time reticulocytes are only weakly stained. Compared with methyl violet, Heinz bodies stain less intensely with brilliant cresyl blue or New methylene blue. Nevertheless, they may be readily seen as pale blue bodies in a well-stained reticulocyte preparation, if the preparation is not counterstained.

If permanent preparations are required, fix the vitally stained films by exposure to formalin vapour for 5–10 min.

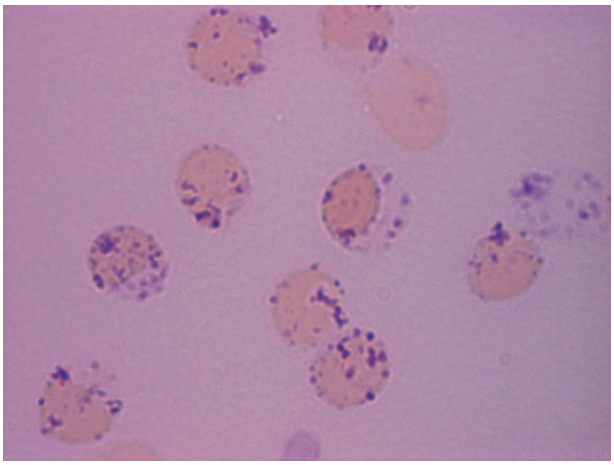

FIGURE 15-5 Glucose-6-phosphate dehydrogenase deficiency. Many of the cells contain large Heinz bodies. Stained supravitally by methyl violet. *(Courtesy of Mr David Roper.)*

Then counterstain the fixed films with 1 g/l eosin or neutral red, after thoroughly washing in water. If films are fixed in methanol, Heinz bodies are decolourised.

In β thalassaemia major, methyl violet staining of the bone marrow will demonstrate precipitated α chains. These appear as large irregular inclusions in late normoblasts, usually single and closely adhering to the nucleus. If such patients are splenectomised, inclusions are also found in reticulocytes and mature red blood cells, in the circulation as well as in the bone marrow.

Carboxyhaemoglobin and methaemoglobin

Carboxyhaemoglobin- and methaemoglobin-containing cells can be demonstrated cytochemically. These methods are described by Kleihauer and Betke.[23] They have little practical value in modern practice.

Fetal haemoglobin

An acid-elution cytochemical method that was introduced by Kleihauer *et al*.[24] is a sensitive procedure to identify individual cells containing haemoglobin F even when few are present. Their detection in the maternal circulation has provided valuable information on the pathogenesis of haemolytic disease of the newborn.

The identification of cells containing haemoglobin F depends on the fact that they resist acid elution to a greater extent than normal cells; thus, in the technique described below, they appear as isolated, darkly stained cells among a background of palely staining ghost cells. The occasional cells that stain to an intermediate degree are less easy to evaluate; some may be reticulocytes because these also resist acid elution to some extent. The following method, in which elution is carried out at pH 1.5, is recommended.[25]

Reagents

- *Fixative.* 80% ethanol
- *Elution solution.* Solution A: 7.5 g/l haematoxylin in 90% ethanol. Solution B: $FeCl_3$, 24 g; 2.5 mol/l HCl, 20 ml; doubly distilled water to 1 litre.

For use, mix well 5 volumes of A and 1 volume of B. The pH is approximately 1.5. The solution can be used for about 4 weeks; if a precipitate forms, the solution should be filtered.

- *Counterstain.* 1 g/l aqueous erythrosin or 2.5 g/l aqueous eosin.

Method. Prepare fresh air-dried films. Immediately after drying, fix the films for 5 min in 80% ethanol in a Coplin jar. Rinse the slides rapidly in water and stand them vertically on blotting paper for about 10 min to dry. Place the slides for 20 s in a Coplin jar containing the elution solution. Wash the slides thoroughly in water and finally place them in the counterstain for 2 min. Rinse in tap water and allow them to dry in the air. Films prepared (1) from a mixture of cord blood and adult blood and (2) from normal adult

blood should be stained alongside the test films as positive and negative controls, respectively. In fetomaternal haemorrhage, the maternal blood shows two populations of cells; fetal cells stain red and adult ghost cells stain pale pink (Fig. 15-6, *A*). This appearance must be distinguished from that of hereditary persistence of fetal haemoglobin, when distribution may be heterogeneous[26] (Fig. 15-6, *B*) or all cells may be uniformly red (pancellular distribution).

A number of modifications of the Kleihauer method have been proposed. In one, New methylene blue is incorporated in the buffer solution, the reaction time is prolonged and buffer is used for washing the films.[27] The advantage of this technique is that reticulocytes stain blue, whereas cells containing haemoglobin F stain pink.

An immunofluorescent staining method has been developed based on the use of a specific antibody against haemoglobin F, which does not react with haemoglobin A.[28] By using a double-labelling procedure with rhodamine-labelled antibody against γ globin and a fluorescein-labelled antibody against β globin, it is possible to detect the presence of haemoglobin F and haemoglobin A in the same cell.[29]

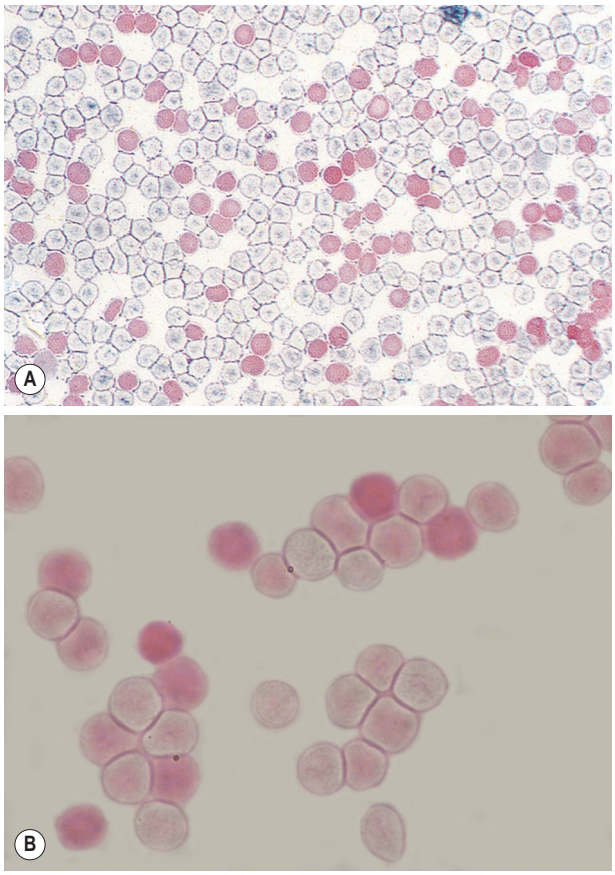

FIGURE 15-6 Cytochemical demonstration of fetal haemoglobin. Acid elution method. **A,** The preparation consists of a mixture of cord and normal adult blood. The darkly staining cells are fetal cells. **B,** This postpartum patient had hereditary persistence of fetal haemoglobin, and a heterogeneous distribution of haemoglobin F is seen.

Haemoglobin S and other haemoglobin variants

Immunodiffusion with specific antibodies has been used for the identification of haemoglobin S, haemoglobin A_2 and haemoglobin F in red cells.[30,31] An alternative method is by detection of cells after labelling the cells with fluorescein isothiocyanate (FITC).[30] By a double-labelling method similar to that described earlier, it is possible to identify haemoglobin S as well as another haemoglobin in individual cells.

LEUCOCYTE CYTOCHEMISTRY

Leucocyte cytochemistry encompasses the techniques used to identify diagnostically useful enzymes or other substances in the cytoplasm of haemopoietic cells. These techniques are particularly useful for the characterisation of immature cells in AML and the identification of maturation abnormalities in MDS and myeloproliferative neoplasms (MPN). There are many variations in the staining techniques, as discussed in the recommendations of an Expert Panel of the International Committee (now Council) for Standardisation in Haematology.[32,33] Detailed reference works discussing the theoretical and practical aspects of cytochemistry are available.[34] The use of cytochemistry to characterise lymphoproliferative disorders has been largely superseded by immunological techniques (see Chapter 16). The results of cytochemical tests should always be interpreted in relation to Romanowsky stains and immunological techniques. Control blood or marrow slides should always be stained in parallel to ensure the quality of the staining. The principal uses of cytochemistry are as follows:

1. To characterise the blast cells in acute leukaemia as myeloid (leading to a diagnosis of AML unless there is also evidence of lymphoid differentiation)
2. To demonstrate myeloperoxidase or nonspecific esterase activity and thus contribute to a diagnosis of mixed-phenotype acute leukaemia, according to the criteria of the 2008 WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues[35]
3. To identify granulocytic and monocytic components in AML
4. To identify unusual lineages occasionally involved in clonal myeloid disorders (e.g. basophils and mast cells)
5. To detect cytoplasmic abnormalities and enzyme deficiencies in myeloid disorders (e.g. myeloperoxidase-deficient neutrophils in MDS or acute leukaemia, neutrophil alkaline phosphatase-deficient neutrophils in chronic myelogenous leukaemia, CML)
6. To identify Auer rods in MDS (and thus classify a case as refractory anaemia with excess of blasts II in the WHO classification)
7. To confirm a diagnosis of hairy cell leukaemia.

It is particularly important that cytochemistry is not neglected in under-resourced countries when immunophenotyping is not readily available.

Myeloperoxidase

Myeloperoxidase (MPO) is located in the primary and secondary granules of neutrophils and their precursors, in eosinophil granules and in the azurophilic granules of monocytes. The MPO in eosinophil granules is cyanide resistant, whereas that in neutrophils and monocytes is cyanide sensitive. MPO splits H_2O_2 and in the presence of a chromogenic electron donor forms an insoluble reaction product. Various benzidine substitutes have been used, of which 3,3′-diaminobenzidine (DAB) is the preferred chromogen.[36,37] The reaction product is stable, insoluble and nondiffusible. Staining can be enhanced by immersing the slides in copper sulphate or nitrate, but this is generally not required in normal diagnostic practice. Alternative non-benzidine-based techniques use 4-chloro-1-naphthol (4CN)[38] or 3-amino-9-ethylcarbazole.[39] The former gives very crisp staining but is soluble in some mounting media and immersion oil; the latter shows some diffusibility and does not stain as strongly as DAB.

Method with 3,3′-diaminobenzidine

Reagents

- *Fixative.* Buffered formal acetone (BFA) (see p. 564)
- *Substrate.* 3,3′-DAB (Sigma D-8001, Sigma-Aldrich, UK)
- *Buffer.* Sorensen phosphate buffer, pH 7.3 (see p. 563)
- *Hydrogen peroxide* (H_2O_2, 30% w/v)
- *Counterstain.* Aqueous haematoxylin

Method

1. Fix air-dried smears for 30 s in cold BFA.
2. Rinse thoroughly in gently running tap water and air dry.
3. Incubate for 10 min in working substrate solution. Thoroughly mix 30 mg DAB in 60 ml buffer, add 120 µl H_2O_2 and mix well.
4. Counterstain with haematoxylin for 1–5 min, rinse in running tap water and air dry.

Technical considerations. MPO is not inhibited by heparin, oxalate or EDTA anticoagulants. Films should be made within 12 h of blood collection. Staining is satisfactory on films kept at room temperature for at least a week. The DAB should be stored frozen at −20 °C in 1 ml aliquots of 30 mg in 1 ml of buffer. For optimum results, it is essential to dissolve the DAB thoroughly in the buffer and to ensure the reagents in the incubation mixture are well mixed. The stain is robust and not strictly pH dependent, with identical results being obtained when using buffers ranging in pH from 7.0 to 9.0. The counterstaining time should be adjusted to the minimum time to give clear nuclear detail. Methyl green is an alternative counterstain, giving excellent contrast with the DAB reaction product, but nuclear detail is more difficult to discern.

Results and interpretation. The reaction product is brown and granular (Fig. 15-7, *A*). Red cells and erythroid precursors show diffuse brown cytoplasmic staining. The

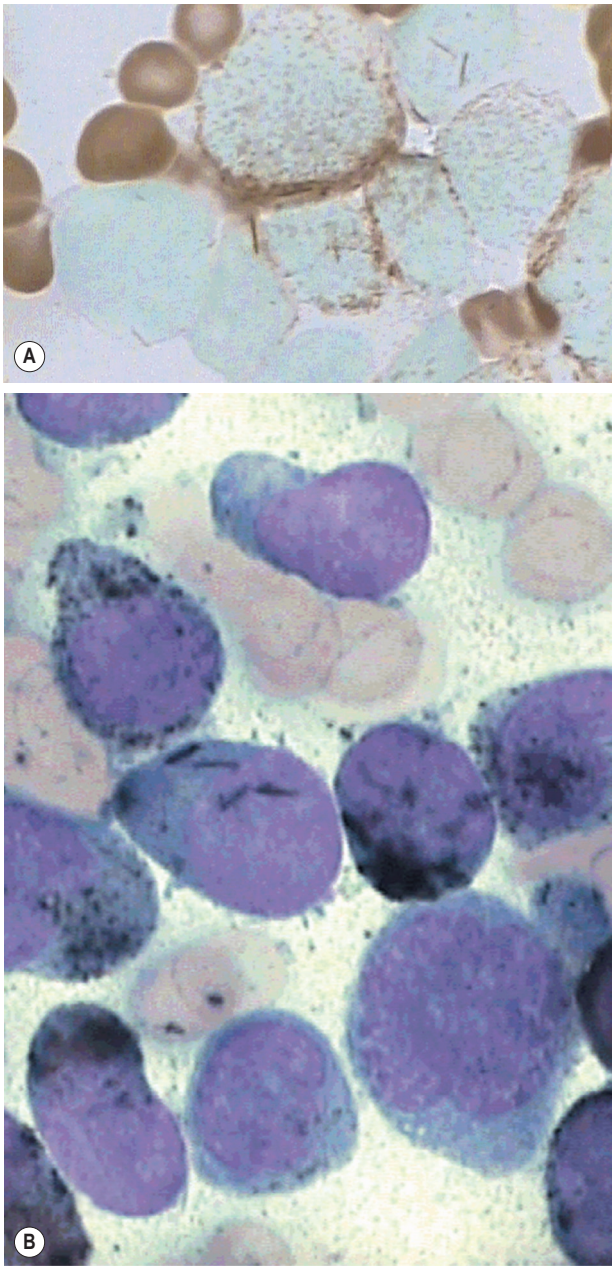

FIGURE 15-7 Bone marrow in acute myeloid leukaemia (French–American–British (FAB) M1). A, Myeloperoxidase (MPO). **B,** Sudan Black B (SBB). Myeloperoxidase staining shows Auer rods and cytoplasmic granular staining, whereas with SBB localised positive reaction in the blast cells is more definite and Auer rods are prominent.

most primitive myeloblasts are negative, with granular positivity appearing progressively as they mature toward the promyelocyte stage. The positivity may be localised to the Golgi region. Promyelocytes and myelocytes are the most strongly staining cells in the granulocyte series, with positive (primary) granules packing the cytoplasm. Metamyelocytes and neutrophils have progressively fewer positive (secondary) granules. Eosinophil granules stain strongly and the large specific eosinophil granules are easily distinguished from neutrophil granules. Eosinophil granule peroxidase is distinct biochemically and immunologically from neutrophil peroxidase. Monoblasts and monocytes may be negative or positive. When positive, the granules are smaller than in neutrophils and diffusely scattered throughout the cytoplasm. MPO activity is present in basophil granules but is not demonstrable in mature basophils by the DAB reaction described earlier.

Pathological variations. Some individuals have congenital deficiency of neutrophil MPO. All stages of the neutrophil lineage, from the myeloblast onward, are negative. In these individuals, the eosinophils stain normally. Other individuals have an MPO deficiency confined to eosinophils or monocytes. Dysplastic neutrophils may be MPO negative. Auer rods stain well with DAB and are seen more frequently on MPO staining than on Romanowsky-stained films.

Sudan Black B

Sudan Black B (SBB) is a lipophilic dye that binds irreversibly to an undefined granule component in granulocytes, eosinophils and some monocytes. It cannot be extracted from the stained granules by organic dye solvents and gives comparable information to that of MPO staining.[40] The currently used staining solution is essentially that described by Sheehan and Storey.[41]

Reagents

- *Fixative.* Vapour from 40% formaldehyde solution
- *Stain.* SBB (Sigma S-2380) 0.3 g in 100 ml absolute ethanol
- *Phenol buffer.* Dissolve 16 g crystalline phenol in 30 ml absolute ethanol. Add to 100 ml distilled water in which 0.3 g $Na_2HPO_4.12H_2O$ has been dissolved
- *Working stain solution.* Add 40 ml buffer to 60 ml SBB solution
- *Counterstain.* May–Grünwald–Giemsa or Leishman stain (see p. 52)

Method

1. Fix air-dried smears in formalin vapour as follows. Place a small square of filter paper in the bottom of a Coplin jar. Add 2 drops of 40% formalin, put on the lid and leave for 15 min to allow vaporisation. Place the slides in the Coplin jar and replace the lid. After 5–10 min, remove the slides and stand on end for 15 min to 'air wash'.
2. Immerse the slides in the working stain solution for 1 h in a Coplin jar with a lid on.
3. Transfer slides to a staining rack and immediately flood with 70% alcohol. After 30 s, tip the 70% alcohol off and flood again for 30 s. Repeat three times in total.
4. Rinse in gently running tap water and air dry.
5. Counterstain without further fixation with Leishman stain or May–Grünwald–Giemsa.

Technical considerations

Buffered formal acetone fixation for 30 s is a satisfactory alternative to formalin vapour. The working stain solution should be replaced after 4 weeks. Bone marrow films with fatty particles containing lipid-soluble SBB benefit from a 5 s swirl in xylene followed by rinsing in running tap water and air drying prior to counterstaining. The Romanowsky counterstain gives excellent cytological detail of all cells present.

Results and interpretation

The reaction product is black and granular. The results are essentially similar to those seen with MPO staining, both in normal and leukaemic cells (Fig. 15-7, *B*). MPO-negative neutrophils are also SBB negative. The only notable difference is in eosinophil granules, which have a clear core when stained with SBB. Rare cases (1% to 2%) of acute lymphoblastic leukaemia (ALL) show nongranular smudgy positivity not seen with MPO staining.[42] Basophils are generally not positive but may show bright red/purple metachromatic staining of the granules.

Neutrophil alkaline phosphatase

Alkaline phosphatase activity is found predominantly in mature neutrophils, with some activity in metamyelocytes. Although demonstrated as a granular reaction product in the cytoplasm, enzyme activity is associated with a poorly characterised intracytoplasmic membranous component distinct from primary or secondary granules.[43] Other leucocytes are generally negative, but rare cases of lymphoid malignancies show cytochemically demonstrable activity.[44] Bone marrow macrophages are positive. Early methods of demonstrating alkaline phosphatase relied on the use of glycerophosphate or other phosphomonoesters as the substrate at alkaline pH, with a final black reaction product of lead sulphide.[45] Azo-dye techniques are simpler, giving equally good results. These methods use substituted naphthols as the substrate and it is the liberated naphthol rather than phosphate that is used to combine with the azo-dye to give the final reaction product.[46–48]

Reagents

- *Fixative.* 4% formalin methanol. Add 10 ml 40% formalin to 90 ml methanol. Keep in a freezer. Discard after 2 weeks.
- *Substrate.* Naphthol AS phosphate (Sigma N-5625). Store in freezer.
- *Buffer.* 0.2 mol/l Tris buffer, pH 9.0 (see p. 564)
- *Stock substrate solution.* Dissolve 30 mg naphthol AS phosphate in 0.5 ml N,N-dimethylformamide (Sigma D-4551). Add 100 ml 0.2 mol/l Tris buffer, pH 9.1. Store in a refrigerator at 2–4 °C. The solution is stable for several months.
- *Coupling azo-dye.* Fast Blue BB salt (Sigma F-0250). Store in freezer.
- *Counterstain.* Neutral red, 0.02% aqueous solution

Method

1. Fix freshly made air-dried blood films for 30 s in cold 4% formalin methanol.
2. Rinse with tap water and air dry.
3. Prepare working substrate solution by allowing 40 ml of stock substrate solution to warm to room temperature. Add 24 mg of Fast Blue BB and mix thoroughly until dissolved. Incubate slides for 15 min.
4. Wash in tap water and air dry.
5. Counterstain for 3 min in 0.02% aqueous neutral red, rinse briefly and air dry.

Technical considerations

N,N-dimethylformamide may dissolve some types of plastic; therefore a glass tube should be used to dissolve the substrate. Blood films should be made soon after blood collection, preferably within 30 min because neutrophil alkaline phosphatase (NAP) activity decreases rapidly in EDTA-anticoagulated blood. Once spread, the blood film should be stained within 6 h. A control film with a predictably high score (e.g. from a patient with reactive neutrophilia or from a pregnant woman) should be processed together with the patient film. The technical aspects of blood film preparation and the effects of fixation on NAP activity are discussed by Kaplow.[49]

Results and interpretation

The reaction product is blue and granular. The intensity of reaction product in neutrophils varies from negative to strongly positive, with coarse granules filling the cytoplasm and overlying the nucleus (Fig. 15-8). An overall score is obtained by assessing the stain intensity in 100 consecutive neutrophils, with each neutrophil scored on a scale of 0–4 as follows:

0 – Negative, no granules
1 – Occasional granules scattered in the cytoplasm
2 – Moderate numbers of granules
3 – Numerous granules
4 – Heavy positivity with numerous coarse granules crowding the cytoplasm, frequently overlying the nucleus.

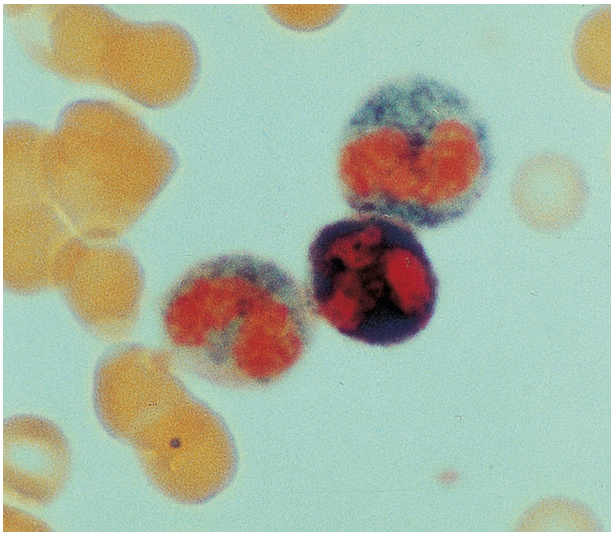

FIGURE 15-8 Neutrophil alkaline phosphatase. A strongly positive (4+) and moderately positive (3+ and 2+) intensity of reaction are shown.

The overall possible score will range between 0 and 400 (assessed on 100 neutrophils). Reported normal ranges show some variations, owing possibly in part to variations in scoring criteria and methodology: 13 to 160 (mean 61);[49] 14 to 100 (mean 46);[50] 37 to 98 (mean 68);[51] 11 to 134 (mean 48).[52] A normal range should therefore be established in each laboratory.

In normal individuals, it is rare to find any neutrophils with a score of 3, and a score of 4 should not be present. There is some physiological variation in NAP scores. Newborn babies, children and pregnant women have high scores and premenopausal women have, on average, scores one-third higher than those of men.[38] In pathological states, the most significant diagnostic use of the NAP score has been in CML but with the wider availability of cytogenetic and molecular techniques it is now rarely needed. In the chronic phase of the disease, the score is almost invariably low, usually zero. Transient increases may occur with intercurrent infection. In myeloid blast transformation or accelerated phase, the score rises. Low scores are also commonly found in paroxysmal nocturnal haemoglobinuria (PNH) and the very rare condition of hereditary hypophosphatasia. There are many causes of a raised NAP score, notably in the neutrophilia of infection, polycythaemia vera, leukaemoid reactions and Hodgkin lymphoma. A high NAP score is not useful in distinguishing between chronic neutrophilic leukaemia and a neutrophilic leukaemoid reaction to a plasma cell neoplasm since it is often high in both conditions.[53] In aplastic anaemia, the NAP score is high, but it falls if PNH supervenes.

Acid phosphatase reaction, including tartrate-resistant acid phosphatase reaction

Cytochemically demonstrable acid phosphatase is ubiquitous in haemopoietic cells. The staining intensity of different cell types is somewhat variable according to the method used. Its main diagnostic use is in the diagnosis of T-cell ALL and hairy cell leukaemia.[54,55] These diseases are more reliably diagnosed and characterised by immunophenotyping when this is available (see Chapter 16), and the unmodified acid phosphatase stain is now largely redundant. However, the tartrate-resistant acid phosphatase stain is still useful for confirmation of the diagnosis of hairy cell leukaemia, particularly when an appropriate range of monoclonal antibodies for diagnosis of this condition is not available. The pararosaniline method given in the following section, modified from Goldberg and Barka,[56] is recommended for demonstrating positivity in T lymphoid cells. Use of Fast Garnet GBC as a coupling reagent may be preferred for the demonstration of tartrate-resistant acid phosphatase activity.[32,55]

Reagents

- *Fixative.* Methanol, 10 ml; acetone, 60 ml; water, 30 ml; and citric acid, 0.63 g. Adjust to pH 5.4 with 1 mol/l NaOH before use.
- *Buffer pH 5.0.* Sodium acetate trihydrate, 19.5 g; sodium barbiturate, 29.5 g; water to 1 litre (Michaeli veronal acetate buffer)
- *Substrate solution.* 25 mg naphthol AS-BI phosphate (Sigma N-2125) dissolved in 2.5 ml N,N-dimethylformamide
- *Sodium nitrite.* 4% $NaNO_2$ aqueous solution
- *Coupling reagent*
  1. Stock pararosaniline. Dissolve 1 g pararosaniline (Sigma P-7632) in 25 ml warm 2 mol/l HCl. Filter when cool. Store at room temperature in the dark. Stable for 2 months
  2. 4% sodium nitrite solution. Dissolve 200 mg sodium nitrite in 5 ml distilled water. Stable for 1 week at 4–10 °C
  3. Hexazotised pararosaniline. Mix equal volumes of pararosaniline and 4% sodium nitrite together 2 min before use.
- *Counterstain.* 1% aqueous methyl green or aqueous haematoxylin
- *Tartaric acid L(+)* (Sigma T-1807)
- *Working solution A.* Mix 92.5 ml of buffer with 2.5 ml of substrate solution. Add 32.5 ml of distilled water and then add 4 ml of hexazotised pararosaniline. Mix well and adjust pH to 5.0 using 1 mol/l NaOH.
- *Working solution B.* Add 375 mg of crystalline L(+)-tartaric acid to 50 ml of working solution A; the final concentration is then 50 mmol/l.

Method

1. Air dry films for several hours (24 h if possible).
2. Fix for 10 min in methanol/acetone/citric acid, rinse in tap water and air dry.
3. Incubate for 1 h at 37 °C in working solutions A (acid phosphatase reaction) or incubate two films in working solutions A and B, respectively (tartrate-resistant acid phosphatase reaction).
4. Rinse in tap water and air dry.
5. Counterstain in 1% aqueous methyl green or aqueous haematoxylin for 5 min.
6. Rinse in tap water and mount wet in warmed glycerin jelly.

Results and interpretation

The reaction product is red with a mixture of granular and diffuse positivity (Fig. 15-9). In T cells, acid phosphatase is an early differentiation feature. Almost all acute and chronic T-lineage leukaemias show strong activity. In T-lineage ALL, the activity is usually highly localised (polar). Granulocytes are strongly positive. Monocytes, eosinophils and platelets show variable positivity. In the bone marrow, macrophages, plasma cells and megakaryocytes are strongly positive.

In hairy cell leukaemia the majority of leukaemic cells react equally positively in the presence and absence of tartaric acid (Fig. 15-10).

Periodic acid–Schiff reaction

Periodic acid specifically oxidises 1–2 glycol groups to produce stable dialdehydes. These dialdehydes give a red reaction product when exposed to Schiff reagent (leucobasic fuchsin). Positive reactions occur with carbohydrates, principally glycogen, but also monosaccharides, polysaccharides, glycoproteins, mucoproteins, phosphorylated sugars, inositol derivatives and cerebrosides.[57] Glycogen can be distinguished from other positively reacting substances by its sensitivity to diastase digestion. In haemopoietic cells, the main source of positive reactions is glycogen.

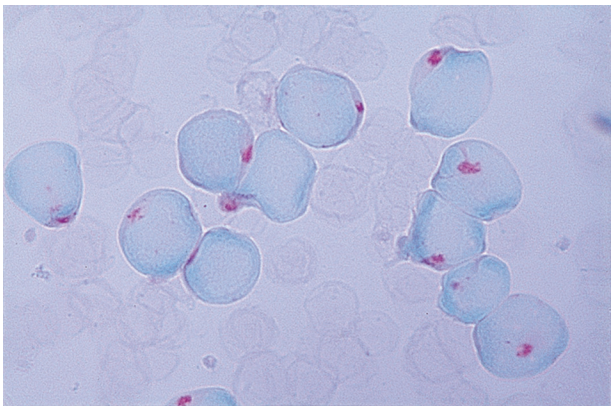

FIGURE 15-9 Acid phosphatase. T-cell acute lymphoblastic leukaemia (ALL) with intense localised staining.

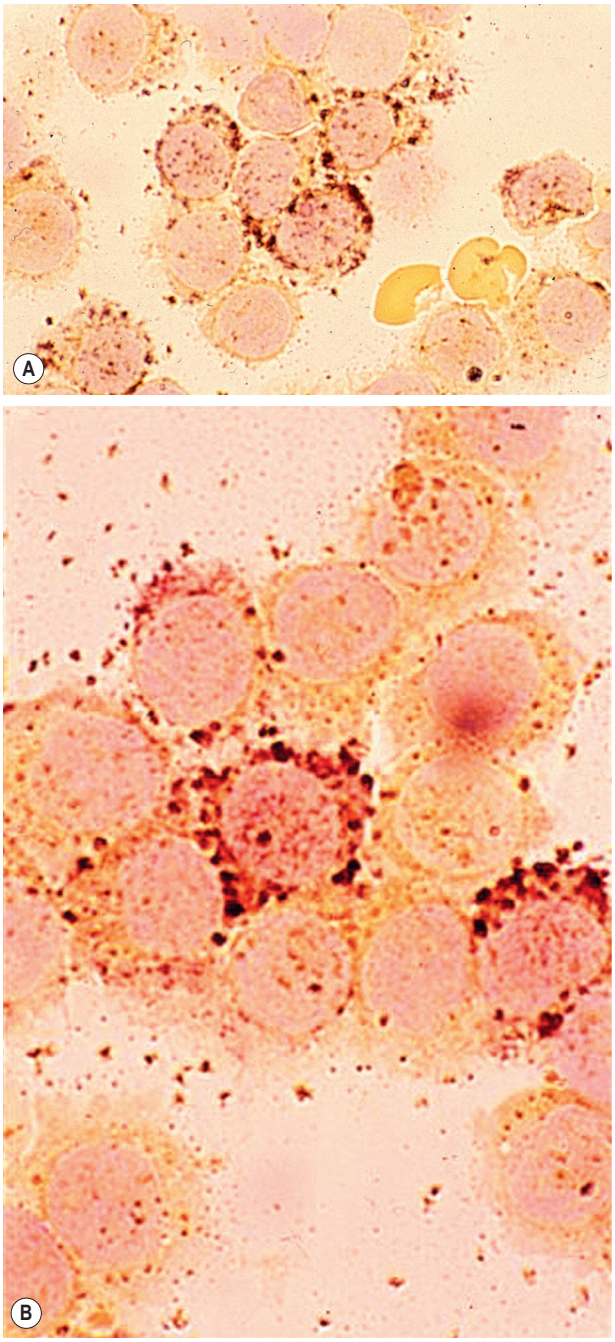

FIGURE 15-10 Acid phosphatase. Hairy cell leukaemia. **A**, Acid phosphatase. **B,** Tartrate-resistant acid phosphatase.

Reagents

- *Fixative.* Methanol
- *1% periodic acid.* $HIO_4.2H_2O$, 10 g/l in distilled water
- *Schiff reagent.* Dissolve 5 g basic fuchsin in 500 ml of hot distilled water. Filter when cool. Saturate with SO_2 gas by bubbling for 1–12 h in a fume cupboard. Shake vigorously with 2 g activated charcoal for 1 min in a conical flask in a fume cupboard and filter immediately through a large Whatman No. 1 filter into a dark bottle. The reagent is stable for 6 months at room temperature, stored in the dark
- *Counterstain.* Aqueous haematoxylin.

Method

1. Fix films for 15 min in methanol.
2. Rinse in gently running tap water and air dry.
3. If required, expose fixed control films to digestion in diastase (100 mg in 100 ml of 0.9 g/l NaCl) for 20–60 min at room temperature.
4. Flood slides with 1% periodic acid for 10 min.
5. Rinse in running tap water for 10 min and air dry.
6. Immerse in Schiff reagent for 30 min in a Coplin jar with a lid (the Schiff reagent can be returned to the stock bottle after use).
7. Rinse in running tap water for 10 min and air dry.
8. Counterstain in aqueous haematoxylin for 5–10 min.

Technical considerations

Formalin vapour (5 min), formalin/ethanol (10 ml 40% formalin/90 ml ethanol) (10 min) and buffered formal acetone (45 s) are satisfactory alternative fixatives. Previously fixed, iron-stained or Romanowsky-stained films can be overstained with the PAS reaction satisfactorily. Romanowsky-stained smears can be partly decolourised by soaking in methanol for 1 h prior to step 4. The intensity of the reaction product depends on the quality of the Schiff reagent. Normal neutrophils should always stain intensely red and deterioration of the Schiff reagent can be detected by examination of control normal films. Some methods recommend rinsing in a dilute sodium metabisulphite HCl solution ('SO_2 water') after step 6, but this is not necessary with good-quality Schiff reagent.

Results and interpretation

The reaction product is red, with intensity ranging from pink to bright red (Fig. 15-11). Cytoplasmic positivity may be diffuse or granular. Granulocyte precursors show diffuse weak positivity, with neutrophils showing intense confluent granular positivity. Eosinophil granules are negative, with diffuse cytoplasmic positivity. Basophils may be negative but often show large irregular blocks of positive material not related to the granules. Monocytes and their precursors show variable diffuse positivity with superimposed fine granules, often at the periphery of the cytoplasm. Normal erythroid precursors and red cells are negative. Megakaryocytes and platelets show variable, usually intense, diffuse positivity with superimposed fine granules, coarse granules and large blocks. Granular positivity with negative background cytoplasm is found in 10–40% of peripheral lymphocytes, with no detectable

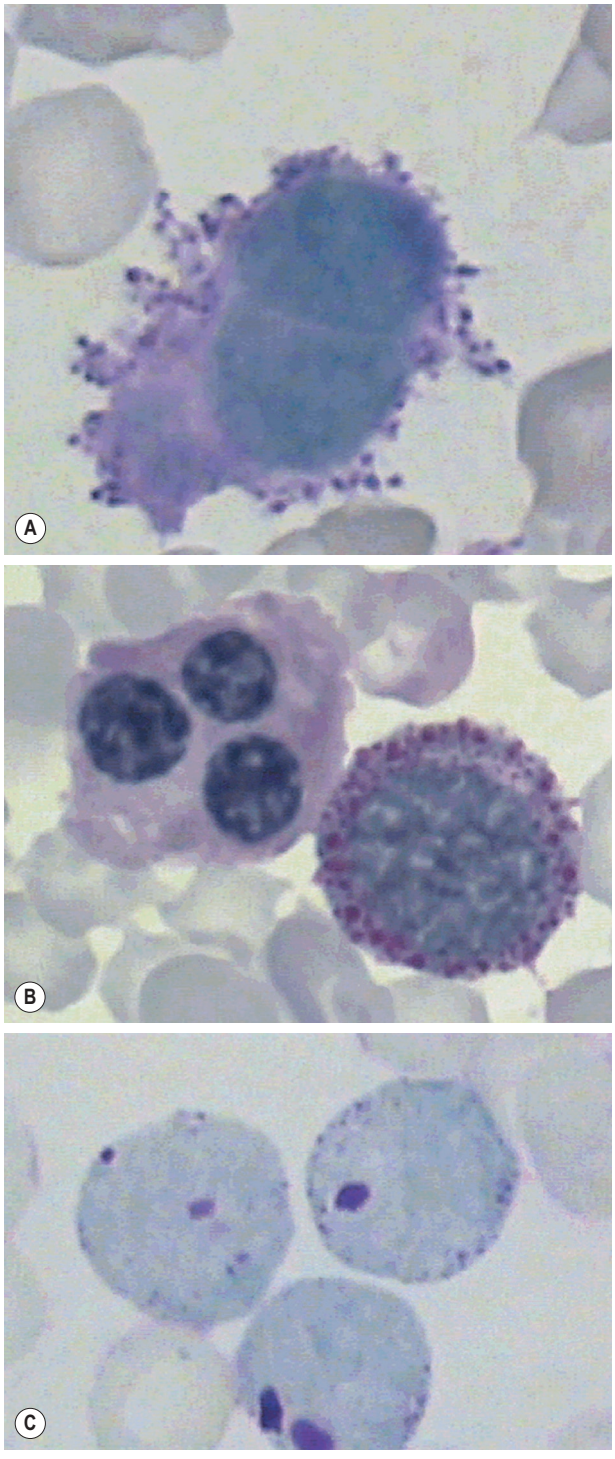

FIGURE 15-11 Periodic acid–Schiff stain. A, Dysplastic micromegakaryocytes with diffuse cytoplasmic staining and some coarse granules. **B,** Dyserythropoiesis with diffuse staining in a trinucleate normoblast and coarse granular and diffuse staining in a proerythroblast. **C,** ALL with blasts showing block positivity.

differences between T and B cells.[58,59] Lymphoblasts show variable PAS-positive cytoplasmic granules or blocks on a clear background; it is block positivity on a clear background that is most characteristic of lymphoblasts rather than myeloblasts. When immunophenotyping is available, the PAS reaction is redundant for the diagnosis of ALL. It can still be useful in AML and MDS to identify abnormal erythroblasts and dysplastic megakaryocytes and to demonstrate the cytoplasmic blush that helps to confirm a diagnosis of acute promyelocytic leukaemia (Fig. 15-12).

Esterases

Leucocyte esterases are a group of enzymes that hydrolyse acyl or chloroacyl esters of α-naphthol or naphthol AS. Li *et al*.[60] identified nine esterase isoenzymes using polyacrylamide gel electrophoresis of leucocyte extracts from normal and pathological cells. The gels were stained in parallel with cell smears. The isoenzymes fell into two groups: bands 1, 2, 7, 8 and 9 corresponded to the 'specific' esterase of neutrophils, staining specifically with naphthol AS-D chloroacetate esterase (chloroacetate esterase, CAE), whereas bands 3, 4, 5 and 6 corresponded to 'nonspecific' esterase (NSE), staining with α-naphthyl acetate esterase (ANAE) and α-naphthyl butyrate esterase (butyrate esterase, ANBE). Band 4 was best demonstrated by ANBE and band 5 by ANAE. The NSEs are inhibited by sodium fluoride (NaF). Naphthol AS acetate and naphthol AS-D acetate react with both specific and nonspecific esterases, but only the reaction with the NSEs is inhibited by NaF. The methods using parallel slides with and without NaF are not generally used anymore because it is usually more informative to perform a combination of chloroacetate esterase and one of the 'nonspecific' esterase stains on a single slide. The combined methods have the advantage of demonstrating pathological double staining of individual cells. All the esterase stains can be performed using a variety of coupling reagents, each of which gives a different coloured reaction product. The methods outlined as follows have been chosen for their simplicity and reliability.

Naphthol AS-D chloroacetate esterase

Reagents

- *Fixative.* Buffered formal acetone (see p. 564)
- *Buffer.* 66 mmol/l phosphate buffer, pH 7.4 (see p. 563)
- *Naphthol AS-D chloroacetate substrate solution.*[32] Dissolve 0.1 g of naphthol AS-D chloroacetate (Sigma N-0758) in 40 ml N,N-dimethyl-formamide (Sigma D-4254). Keep refrigerated.
- *Working substrate solution.* Add 2 ml of naphthol AS-D chloroacetate stock solution to 38 ml of 66 mmol/l

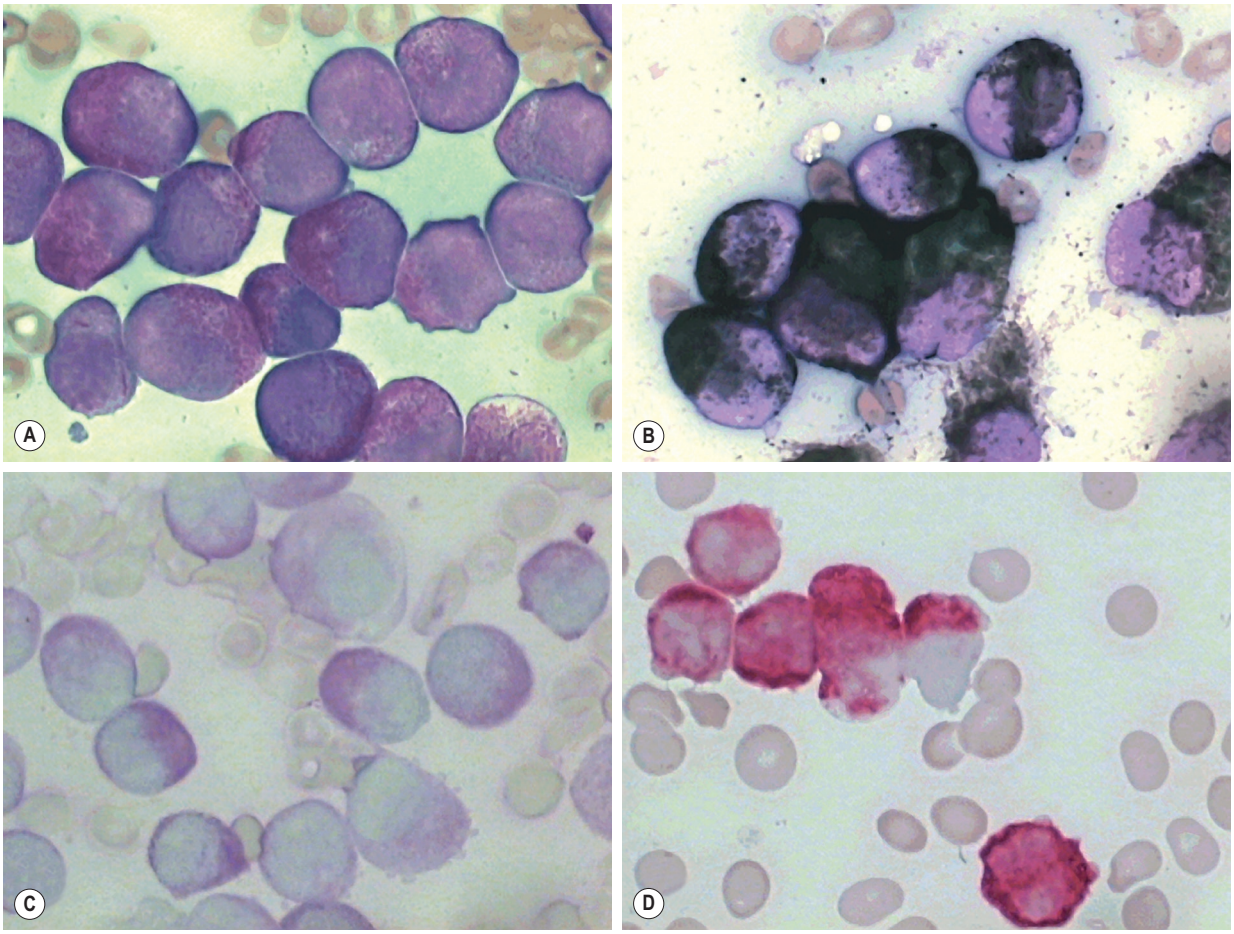

FIGURE 15-12 Acute promyelocytic leukaemia. A, May–Grünwald–Giemsa stain shows hypergranular promyelocytes with scattered Auer rods. **B,** Sudan Black B with strongly stained cytoplasm. **C,** Periodic acid–Schiff staining shows diffuse cytoplasmic blush. **D,** Chloroacetate esterase gives strong cytoplasmic staining.

phosphate buffer, pH 7.4. Mix well. Add 0.4 ml of freshly prepared hexazotised New fuchsin. Mix well.

- *Coupling reagent*
  1. Hexazotised New fuchsin. Dissolve 4 g of New fuchsin in 100 ml of 2 N HCl.
  2. Sodium nitrite solution 0.3 mol/l. Dissolve 2.1 g of sodium nitrite ($NaNO_2$) in 100 ml of water.
  3. Immediately prior to using, add 0.2 ml of the hexazotised New fuchsin to 0.4 ml sodium nitrite, mix well and leave for 1 min before adding to substrate solution.
- *Counterstain.* Aqueous haematoxylin.

Method

1. Fix air-dried smears in cold buffered formal acetone for 30 s.
2. Rinse in gently running tap water and air dry.
3. Immerse the slides in the working substrate solution in a Coplin jar for 5–10 min.
4. Rinse in running tap water and air dry.
5. Counterstain in aqueous haematoxylin for 1 min.
6. 'Blue' in running tap water for 1 min and air dry.

Technical considerations. The CAE stain is robust and reliable. A satisfactory alternative to New fuchsin is 40 mg of Fast blue BB, but it requires thorough vigorous mixing with the substrate solution. The incubation time is important because most haemopoietic cells show some scattered granular staining if the incubation is prolonged. Hydrolysis of the substrate is rapid, with staining virtually complete within 3–5 min.

Results and interpretation. The reaction product is bright red (Fig. 15-12, *D*). It is confined to cells of the neutrophil series and mast cells. Cytoplasmic CAE activity appears as myeloblasts mature to promyelocytes. Positivity in myeloblasts is rare, but promyelocytes and myelocytes stain strongly, with the reaction product filling

the cytoplasm. More mature cells stain strongly but less intensely. It is therefore useful as a marker of cytoplasmic maturation in myeloid leukaemias. In acute promyelocytic leukaemia, the cells show heavy cytoplasmic staining. The characteristic multiple Auer rods stain positively, often with a hollow core. It is rare to see CAE-positive Auer rods in other forms of AML except in cases with the t(8;21) translocation.[61]

α-naphthyl butyrate esterase

Reagents

- *Fixative.* Buffered formal acetone
- *Buffer.* 100 mmol/l phosphate buffer (Sorensen), pH 8.0
- *Substrate stock solution.* α-naphthyl butyrate (Sigma N-8125) 100 µl in 5 ml acetone. The solution should be stored at −20 °C and is stable for at least 2 months.
- *Coupling reagent.* Fast Garnet GBC (Sigma F-8761) 15 mg
- *Counterstain.* Aqueous haematoxylin.

Method

1. Fix air-dried smears in buffered formal acetone for 30 s. Rinse in gently running tap water and air dry.
2. Add the Fast Garnet GBC to 50 ml buffer and mix well.
3. Add 0.5 ml of the α-naphthyl butyrate/acetone solution and mix well.
4. Pour the incubation medium into a Coplin jar containing the fixed slides and incubate for 20–40 min.
5. Rinse thoroughly by running tap water into the Coplin jar until clear.
6. Air dry and counterstain in aqueous haematoxylin for 1–5 min.

Technical considerations. The reaction product is soluble in immersion oil and synthetic mounting media. If slides are to be looked at repeatedly, they should be mounted in an aqueous mounting medium (e.g. Apathy gum-arabic mountant or glycerin/gelatin). There may be batch-to-batch variation of the Fast Garnet GBC. Staining can be controlled by removing the control slide from the incubation medium after 20 min and examining it wet under a low-power (e.g. ×20) objective, returning it to the incubation medium while still wet. When the monocytes show as dark brown, staining is complete. Hexazotised pararosaniline is an alternative coupling reagent, which gives an insoluble brown reaction product and is suitable for mounting in synthetic mounting media.[60]

Results and interpretation. The reaction product is brown and granular (Fig. 15-13). The majority of monocytes (>80%) stain strongly, the remainder showing some weak staining. Negative monocytes are rare. Neutrophils, eosinophils, basophils and platelets are negative. B lymphocytes are negative and T lymphocytes are more variably stained. In the bone marrow, monocytes, monocyte precursors and macrophages stain strongly. α-naphthyl butyrate is more specific for identifying a monocytic component in AML than α-naphthyl acetate (see below).

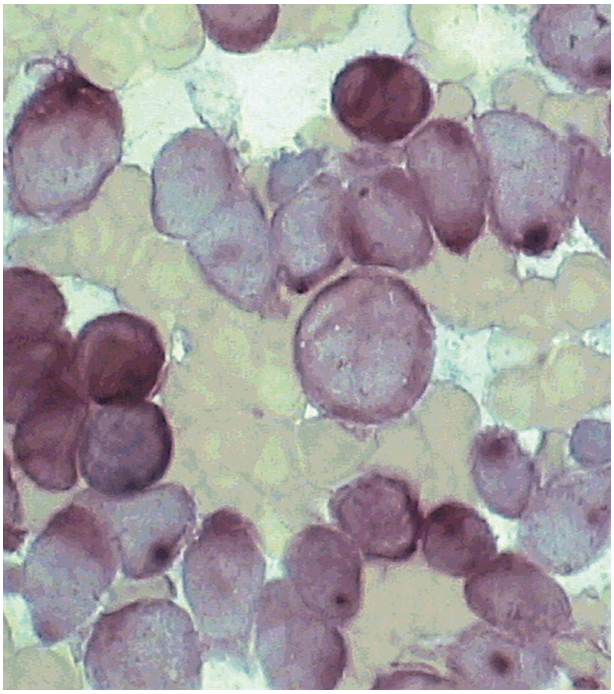

FIGURE 15-13 Nonspecific esterase. Positive *(brown)* reaction in acute monocytic leukaemia (FAB M5b).

α-naphthyl acetate esterase

Reagents

- *Fixative.* Buffered formal acetone
- *Buffer.* 66 mmol/l phosphate buffer, pH 6.3
- *Substrate solution.* Dissolve 100 mg α-naphthyl acetate (Sigma N-8505) in 5 ml ethylene monomethyl ether. Store at 4–10 °C.
- Coupling reagent
  1. Stock pararosaniline. Dissolve 1 g pararosaniline (Sigma P-7632) in 25 ml warm 2 mol/l HCl. Filter when cool. Store at room temperature in the dark. Stable for 2 months.
  2. 4% sodium nitrite solution. Dissolve 200 mg sodium nitrite in 5 ml distilled water. This solution is stable for 1 week at 4–10 °C.
  3. Hexazotised pararosaniline. Mix equal volumes of pararosaniline and 4% sodium nitrite together 1 min before use.
- *Incubation medium.* Add 2 ml of the α-naphthyl acetate solution to 38 ml of the 66 mmol/l phosphate buffer, pH 6.3, and mix well. Add 0.4 ml of freshly prepared hexazotised pararosaniline and mix well.
- *Counterstain.* Aqueous haematoxylin.

Method

1. Fix air-dried smears in cold buffered formal acetone for 30 s.
2. Rinse in running tap water and air dry.

3. Immerse the slides for 30–60 min in the incubation medium in a Coplin jar.
4. Rinse in gently running tap water in the Coplin jar until clear and air dry.
5. Counterstain in aqueous haematoxylin for 2–5 min.

Technical considerations. Fast Blue BB 80 mg can be substituted as a coupling reagent. This gives a dark green/brown granular reaction product, which is soluble in mounting media and immersion oil. The haematoxylin staining time should be adjusted to give clear nuclear detail without overstaining to obscure nucleoli and chromatin texture.

Results and interpretation. The reaction product is diffuse red/brown in colour. Normal and leukaemic monocytes stain strongly. Normal granulocytes are negative, but in MDS or AML may give positive reactions of varying intensity. Megakaryocytes stain strongly and leukaemic megakaryoblasts may show focal or diffuse positivity. Most T lymphocytes and some T lymphoblasts show focal 'dot-like' positivity, but immunophenotyping has superseded cytochemistry for identifying and subcategorising T cells. Leukaemic erythroblasts may show focal or diffuse positivity.

Sequential combined esterase stain using α-naphthyl acetate esterase and chloroacetate esterase

Reagents. As earlier for ANAE and CAE stains.

Method

1. Follow the method and steps 1–4 listed earlier for α-naphthyl acetate esterase stain, rinse in tap water and air dry.
2. Without further fixation, prepare the naphthol AS-D chloroacetate incubation medium as explained previously, substituting 10 mg Fast Blue BB (Sigma F-0250) for hexazotised New fuchsin and incubate for 10 min.
3. Rinse in tap water and counterstain with aqueous haematoxylin for 1–3 min.

Technical considerations. Fast Blue BB is relatively insoluble and the chloroacetate incubation medium should be mixed vigorously before use.

Results and interpretation. The ANAE gives a brown reaction product and the CAE gives a granular bright blue product (Fig. 15-14). Staining patterns are identical to those seen with the two stains used separately. The double-staining technique avoids the need to compare results from separate slides and reveals aberrant staining patterns. In myelomonocytic leukaemias, cells staining with both esterases may be present. In MDS and AML with dysplastic granulocytes, double staining of individual cells may be present. This may be helpful when a diagnosis of MDS is not otherwise certain, but the same abnormal pattern may be seen in nonclonal dysplastic states such as megaloblastic anaemia.

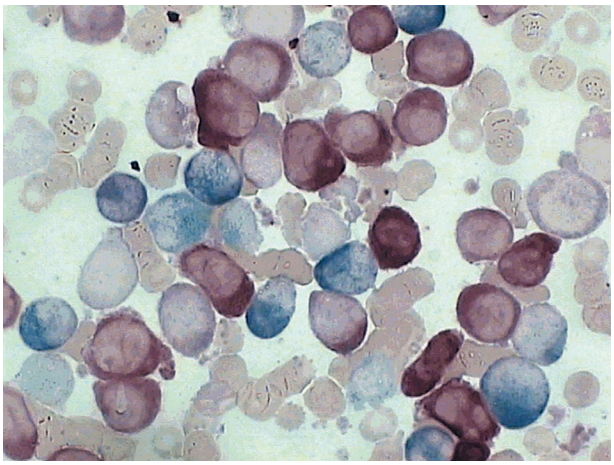

FIGURE 15-14 Combined esterase stain. Acute myelomonocytic leukaemia with almost equal numbers of chloroacetate esterase *(blue)* and nonspecific esterase *(brown)* positive cells.

Single incubation double esterase (naphthol AS-D chloroacetate and α-naphthyl butyrate)[62]

Reagents

- *Fixative.* Buffered formal acetone
- *Buffer.* 100 mmol/l phosphate buffer, pH 8.0 (Sorensen)
- *Substrates*
  1. 2.5 mg naphthol AS-D chloroacetate (Sigma N-0758) in 1 ml acetone
  2. 4 mg α-naphthyl butyrate (Sigma N-8000) in 1 ml acetone
- *Coupling reagent.* Fast Blue BB salt (Sigma F-0250)
- *Counterstain.* Aqueous haematoxylin.

Method

1. Fix air-dried smears in buffered formal acetone for 30 s.
2. Rinse in tap water and air dry.
3. Dissolve 80 mg Fast Blue BB in 50 ml phosphate buffer by vigorous mixing.
4. Add naphthol AS-D chloroacetate and mix well.
5. Add α-naphthyl butyrate and mix well.
6. Incubate slides for 10–15 min in a Coplin jar in the dark.
7. Flush the Coplin jar with running tap water until clear.
8. Air dry the slides.
9. Counterstain in aqueous haematoxylin for 1 min, rinse and air dry.

Technical considerations. Steps 4 and 5 should be carried out rapidly. Staining can be extended to 30 min if necessary to ensure maximal ANBE staining, but at longer incubation times some nonspecific granular CAE staining may occur.

Results and interpretation. The CAE reaction product is bright blue (granulocytes); the ANBE product is dark green/brown (monocytes). ANBE does not stain megakaryocytes or T cells as strongly as α-naphthyl acetate. Lam *et al*. suggest the use of hexazotised pararosaniline as coupling reagent in a single incubation combined esterase, which gives contrasting bright red and brown reaction products.[63]

In AML, the stain is useful for identifying monocytic and granulocytic components.

Toluidine blue stain

Toluidine blue staining is useful for the enumeration of basophils and mast cells. It binds strongly to the granules in these cells and is particularly useful in pathological states in which the cells may not be easily identifiable on Romanowsky stains. In AML and in CML and other MPN, basophils may be dysplastic and poorly granular, as may the mast cells in systemic mastocytosis.

Reagents

- *Toluidine blue 1% w/v in methanol.* Add 1 g of toluidine blue (BDH 34077) to 100 ml methanol and mix for 24 h on a roller or with a magnetic flea. The stain is stable indefinitely at room temperature. Keep tightly stoppered.

Method

1. Place air-dried smears on a staining rack and flood with the toluidine blue solution.
2. Incubate for 5–10 min.
3. Rinse briefly in gently running tap water until clear and air dry.

Results and interpretation

The granules of basophils and mast cells stain a bright red/purple and are discrete and distinct (Fig. 15-15). Nuclei stain blue and cells with abundant RNA may show a blue tint to the cytoplasm. Although toluidine blue is said to be specific for these granules, with >10 min incubation, the primary granules of promyelocytes are stained red/purple. However, these are smaller and finer than the mast cell or basophil granules and easily distinguished.

Toluidine blue staining does not distinguish between basophils and mast cells. This can be achieved by immunophenotyping (e.g. by identifying expression of mast cell tryptase).

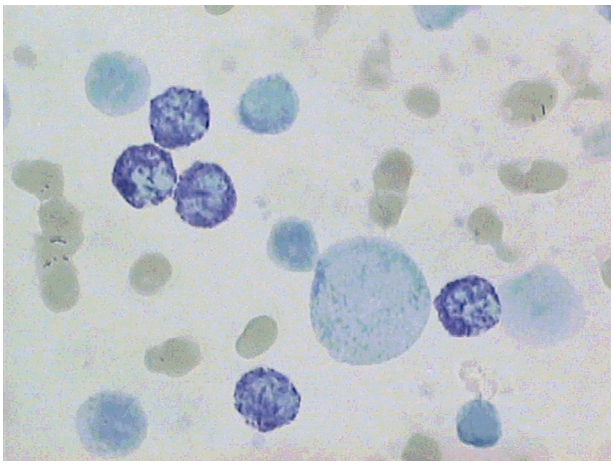

FIGURE 15-15 Toluidine blue. Chronic myelogenous leukaemia in accelerated phase. There are five strongly positive basophils.

Cytochemical reactions and leukaemia classification

Myelodysplastic syndromes and acute myeloid leukaemia

MDS is an acquired clonal preleukaemic bone marrow disorder characterised largely by a cellular or hypercellular marrow, peripheral cytopenias and variable morphological abnormalities of the haemopoietic cells. The classification system proposed by the French–American–British (FAB) cooperative group in 1982[64] was widely used for many years but is now being superseded by the WHO classification (see Chapter 23). A Perls reaction for haemosiderin is essential for the demonstration of ring sideroblasts. Other cytochemical evidence of dysplasia includes double staining of cells with chloroacetate and ANAE, the presence of SBB- or MPO-negative neutrophils and the presence of Auer rods (identified with SBB and MPO).

In AML, cytochemistry is helpful in defining monocytic cells (ANAE and ANBE), identifying Auer rods and demonstrating dysplasia (as mentioned earlier).

Acute lymphoblastic leukaemia

The modern diagnosis and classification of ALL is by cytology, followed by immunophenotyping (see Chapter 16). If immunophenotyping is not available, cytochemistry remains important. It should be noted that, on Romanowsky staining, lymphoblasts may rarely contain fine azurophilic granules. However, Auer rods are never seen and MPO and CAE are negative, whether or not fine granules are present. Occasionally granules give a weak reaction with SBB. Although not lineage specific, the pattern of any PAS positivity may be helpful.[34] In ALL, 95% of cases show positive blocks or granules of bright red PAS-positive material. This may be present in very few blasts (<1%) or the majority. The critical difference from granular or block positivity in other leukaemic cells is the glass-clear background cytoplasm in lymphoblasts. Myeloblasts, monoblasts, leukaemic erythroblasts and megakaryoblasts all show some degree of diffuse cytoplasmic positivity and occasionally block positivity is seen. Acid phosphatase staining is more likely to give focal positivity in T-lineage than B-lineage ALL, but the difference

is not clear enough to be of diagnostic certainty and focal positivity is sometimes also seen in the erythroblasts of erythroleukaemia. Esterase staining is generally unhelpful; some T-cell cases show focal positivity with ANAE, but this is not specific.

Myeloproliferative neoplasms

Although low NAP scores are typical in chronic phase CML and high scores are usually found in other MPN, the finding of a high NAP score is too nonspecific to be of diagnostic help.

Chronic lymphoproliferative disorders

Chronic lymphoproliferative disorders are now characterised by immunophenotyping (see Chapter 16). The reactions for acid hydrolases (acid phosphatase, ANAE, β-glucuronidase and β-glucosaminidase) show focal positivity in most T-cell disorders but are negative in B-cell disorders. The tartrate-resistant acid phosphatase reaction for hairy cell leukaemia is the only cytochemical stain that is sufficiently specific to still be regarded as diagnostically useful (in the absence of immunophenotyping).

ACKNOWLEDGEMENT

The major contribution of the late Dr David Swirsky to this chapter in previous editions of the book is gratefully acknowledged.

Immunophenotyping by Flow Cytometry

Ricardo Morilla • Alison M. Morilla • Elisabet Nadal-Melsió

CHAPTER OUTLINE

PRINCIPLES OF FLOW CYTOMETRIC IMMUNOPHENOTYPING

The primary methods for immunophenotyping in the haematological setting are immunocytochemistry (described in previous editions of this book) and flow cytometry.

In this chapter we shall focus on flow cytometry and its application to the diagnosis and treatment response of haematological neoplasms.

Flow cytometry is a laser-based technology, which is able to identify and quantify cell populations. Cells in suspension are manipulated into a stream of fluid where single cells are interrogated by an electronic detection system. Flow cytometry has many applications and is now routinely used in the diagnosis of haematological malignancies. It can provide quantitative data on a number of cell parameters for a large number of cells, in the region of thousands of cells per second, making it a powerful diagnostic tool.

A flow cytometer has five main components:

- Lasers providing a monochromatic light
- A flow cell with a liquid stream (sheath fluid), which carries and aligns the cells so that they pass in single file through the laser beam
- Optical systems and filters regulating the light signals
- Photomultiplier detectors (PMTs) that generate data on forward light scatter (FSC) (which provides an approximation of cell size) and side light scatter (SSC) (which relates to cell complexity), as well as converting fluorescence signals from light into electrical signals that are processed by a computer
- A computer for analysis of the signals.

Flow cytometry relies on the application of fluorescent conjugates or fluorochromes attached to a monoclonal antibody (McAb) that has specific affinity for an antigen on the cell surface, in the cytoplasm or in the nucleus. Each fluorochrome has a characteristic peak excitation and emission wavelength, and the emission spectra often overlap, requiring compensation. Consequently, the combination of fluorescent labels that can be used depends on the wavelength of the laser used to excite the fluorochromes and on the detectors available.

Immunophenotyping of haematological neoplasms by flow cytometry involves the labelling of white blood cells or their precursors with fluorescent-labelled monoclonal antibodies directed against target cellular proteins or antigens. When appropriate antibodies – usually combined as 'panels' – are chosen, the cell lineage and stage of differentiation of

leukaemic or lymphoma cells can be determined, allowing the leukaemia/lymphoma to be classified. The accurate classification of haematological neoplasms is critical for the clinician's choice of treatment and for overall prognosis.

In summary, immunophenotyping by flow cytometry facilitates:

- The identification and quantification of cell populations within a sample
- The differentiation of normal from abnormal cells
- The differentiation of reactive from neoplastic cells
- The identification of the differentiation or maturation stage of a cell population
- The quantification of tumour infiltration.

However it is the interpretation of the data provided by the described techniques which poses the greatest challenge and the reliable diagnosis of leukaemia relies on the following:

- Knowledge of physical characteristics/antigen expression on normal cells
- The ability to distinguish between different patterns of expression of antigens
- The ability to identify aberrant antigen expression
- The identification of a robust leukaemia-associated immunophenotype (LAIP).

These will be discussed in more detail in the sections below.[1]

MULTICOLOUR FLOW CYTOMETRIC IMMUNOPHENOTYPING

Flow cytometry is now a well-established technique for identifying immunophenotypic profiles in haematological neoplasms. Historically three- or four-colour antibody flow cytometry panels were used, and these panels remain of great utility. However, developments in instrumentation, namely an increase in both the number of lasers and in the availability of fluorochrome conjugates, have facilitated the design of eight- to ten-colour antibody panels. Such panels can provide data on up to 12 to 14 cellular parameters simultaneously, allowing the accurate identification and quantification of normal and abnormal cell populations in bone marrow and peripheral blood. The application of such extensive panels has provided a greater understanding of normal maturation stages in haemopoiesis and specifically the antigens expressed or down regulated at the different stages of this process. This provides a template to which abnormal cell populations can be compared. This new knowledge has increased the accuracy of diagnosis and allowed the identification of very small cell populations and subpopulations.

The advances in flow cytometry instrumentation and reagents mentioned above have facilitated the routine use of eight- to ten-colour antibody panels in the clinical laboratory setting. The use of such multicolour panels is generally what is referred to as multicolour or multiparameter flow cytometry (MFC). There are many advantages associated with the use of MFC but the corresponding pitfalls must also be considered.

Advantages of MFC:

- Increased accuracy. Using large numbers of fluorochromes is associated with an exponential increase in the information obtained from a single combination of antibodies in the same tube, permitting a more reliable identification.
- Smaller sample size. Increased number of antibodies per tube means fewer tubes and less sample needed but allows acquisition of more cellular events resulting in smaller coefficients of variation and increased data precision. This is of particular relevance to paucicellular samples such as cerebrospinal fluid (CSF) and fine needle aspirates (FNA) and also paediatric samples.
- Cost effectiveness. Less usage of repeating backbone or gating antibodies.
- Increased efficiency. Less time is required for sample processing and acquisition.
- Increased sensitivity for minimal residual disease monitoring.

Disadvantages:

- Increased complexity of compensation. Inaccurate compensation is probably the main source of erroneous data in MFC. This can be solved by applying compensation matrices but this requires expertise.
- Challenges of antibody panel validation. It is crucial to run fluorescence minus one controls for all new antibody combinations and to check for stearic hindrance between antibodies used to label antigens that are in close proximity on the cell.
- Tandem dye conjugate issues. Tandem dyes are conjugates of two fluorochromes, but this can lead to problems in resonance excitation transfer if exposed to light. Ideally a compensation matrix should be performed for each new tandem dye conjugate lot.
- Increased need for expertise in data analysis and interpretation.
- Human error associated with pipetting a high number of antibodies into a single tube. This can be overcome by preparing in-house McAb cocktails, which have been shown be stable for up to 4 weeks.[2]

Many advances have been made in addressing the issues outlined above and groups such as the EuroFlow Consortium, the Multicolour Immunophenotyping Group UK (MIG UK), European Group for the Immunological Characterization of Leukemias (EGIL), Harmonemia and others[2] have made great advances in standardising MFC protocols. Software tools such as

Kaluza (www.beckmancoulter.com) and Infinicyt (www.infinicyt.com) have been developed to aid in data analysis and interpretation (Fig. 16-1). Currently there is a move towards commercially available kits that include lyophilised or freeze-dried antibody 'cocktails' to overcome the issues associated with tandem conjugates. Some kits also include the use of standardised instrument set up facilitating the use of software analysis using libraries to compare normal with neoplastic cases[3].

Methods

Sample preparation

Flow cytometry can be performed on any sample where cells are available in suspension. Peripheral blood, bone marrow, CSF, ascitic fluid, pleural fluid and FNAs all provide such suspensions, requiring only red cell lysis and staining with appropriate antibody panels, as described below. Lymph node, spleen, liver and bone marrow trephine

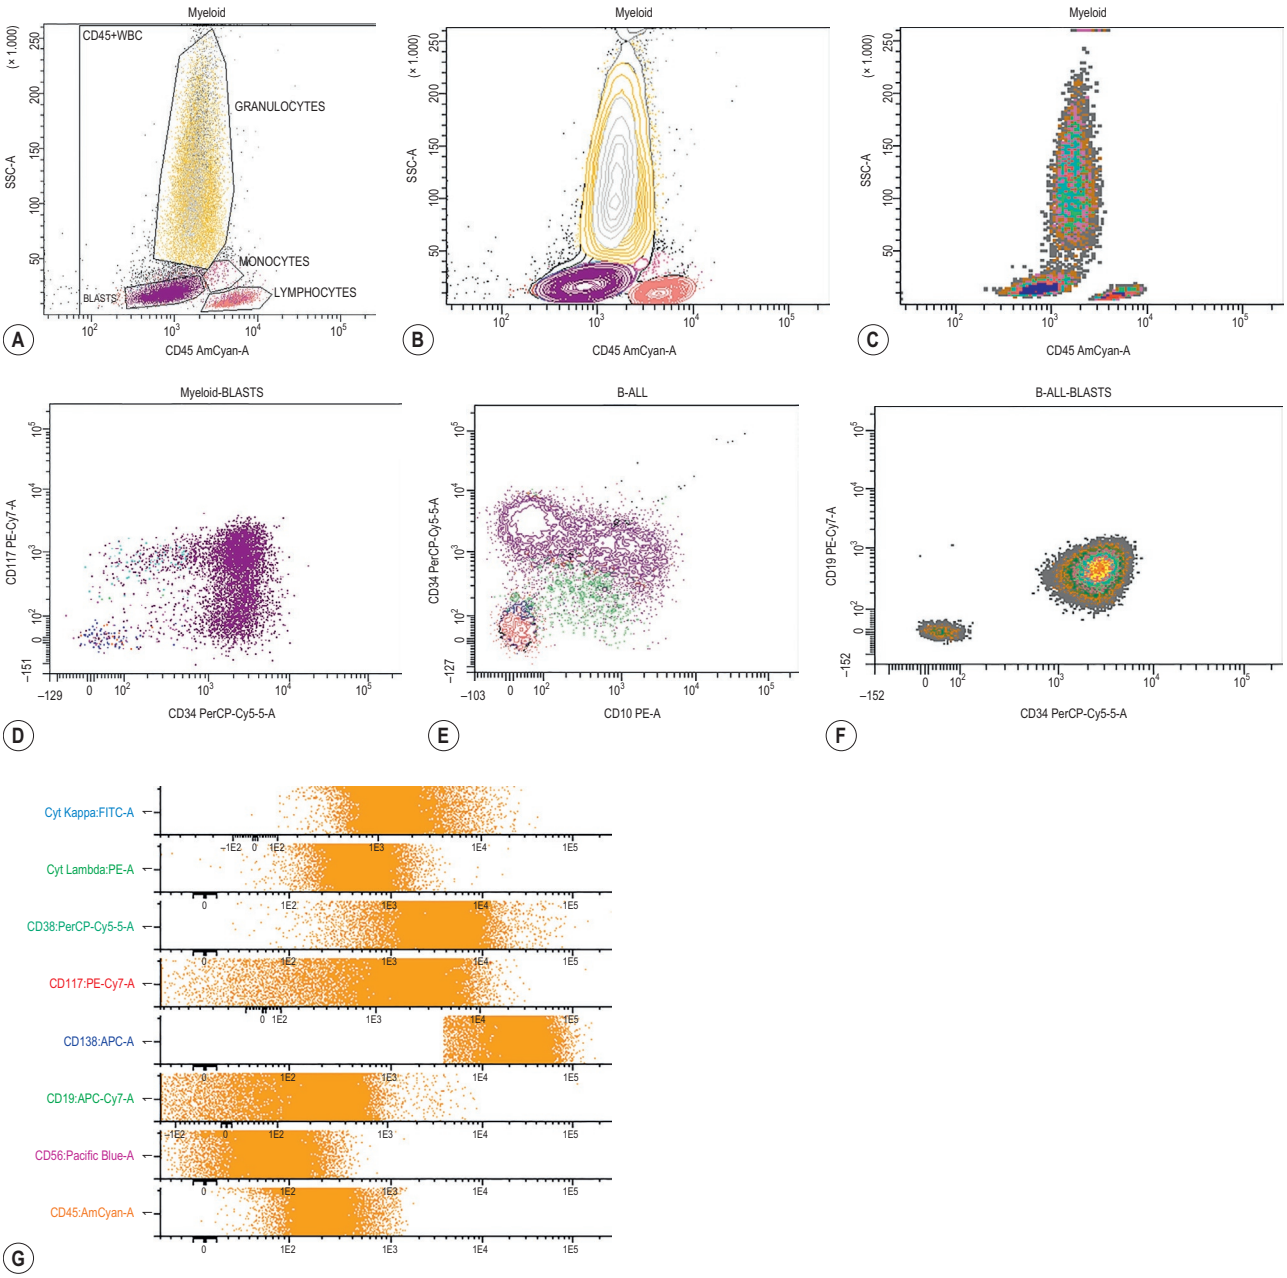

FIGURE 16-1 Data displays from different software options. A–C, Different data display options for CD45 versus SSC dot plots, contour plots and density plots. **D–F,** Different displays of different bivariate plots. **G,** A composite phenotype band diagram of a myeloma phenotype, gating on CD38+/CD138+ cells.

biopsy specimens (not in fixative) can also be processed for flow cytometry following tissue disaggregation to obtain a cell suspension.

Detection of membrane antigens

For all the methods described below the tube(s) should be clearly labelled with the name of the patient, type of specimen, laboratory number and the combination of fluorochrome-conjugated McAbs or multicolour cocktail used prior to any staining.

1. Stain–Lyse–Wash method:
   - Pipette 100 µl of the specimen into a round-bottom tube. NOTE: if the cell count of a specimen is known to be high, dilute this accordingly, aiming for a final cell concentration of 1 to 2×10^6 per tube.
   - Add the appropriate volume of McAb combination or multicolour cocktail.
   - Incubate in the dark at room temperature for 15 min.
   - Add 1 ml of ammonium chloride-based lysing solution and incubate for 10 min at room temperature in the dark.
   - Centrifuge for 5 min at 300 *g* and discard the supernatant. Repeat this step.
   - Resuspend the cells in 0.2–0.5 ml of sheath fluid solution (e.g. Isoton, www.beckmancoulter.com) and acquire data on the flow cytometer without delay.
2. Stain–Lyse–No Wash method:
   This method utilises the same procedure as the previous methodology, but after incubation with the lysing solution, the sample data are acquired on the flow cytometer. This method is ideal for samples with few cells because it minimises cell loss during the centrifugation of the washing step.
3. Lyse–Stain–Wash method (Fig. 16-2):
   This method of bulk specimen lysis is used for minimal residual disease (MRD) monitoring in order to facilitate and enrich the acquisition of leucocytes.
   - Pipette 5–10 ml of peripheral blood or bone marrow into a tube and add the same volume of ammonium chloride lysing solution, mix gently and incubate for 10 min at room temperature.
   - Centrifuge for 5 min at 300 *g*, discard supernatant after centrifugation and resuspend the cell pellet

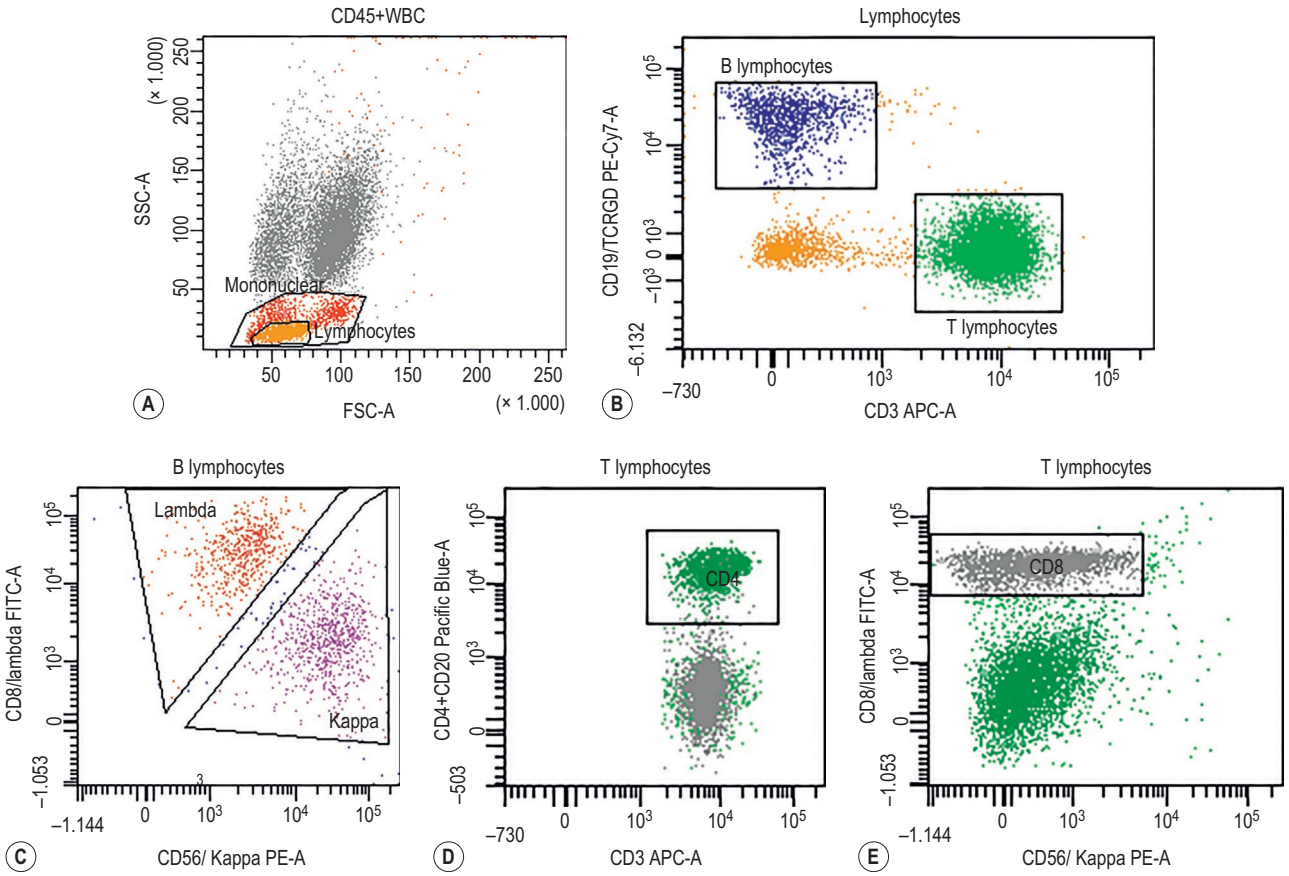

FIGURE 16-2 Normal peripheral blood flow cytometry dot plots showing a mixture of polyclonal B cells and T lymphocytes. A, Gate on FSC/SSC lymphocytes (orange). **B,** CD19-positive lymphocytes (blue) and CD3-positive lymphocytes (green). The orange population are not B or T lymphocytes, and are likely to be NK cells. **C,** Polyclonal B lymphocytes gated on CD19; some cells express kappa and some lambda. **D,** CD4-positive T cells (green, top cluster). **E,** CD8-positive T cells (grey).

in 10 ml of phosphate-buffered saline (PBS) containing sodium azide and bovine serum albumin (PBS–Azide–BSA).
- Repeat this washing procedure. If the cell pellet still contains red cells the lysing step can be repeated.
- Finally resuspend the cell pellet in 10 ml of PBS–Azide–BSA and perform a white cell count.
- Aliquot a volume of cell suspension containing 10×10^6 cells/tube.
- Add appropriate volume of McAb, and incubate in the dark.
- Repeat washing procedure and resuspend in 0.2–0.5 ml of sheath fluid.
- Acquire data on the flow cytometer without delay.

Detection of surface immunoglobulin

Lymphoproliferative disorders (LPD) of mature B cells are distinguished from their normal counterparts by identifying two main types of phenotypic abnormalities: surface immunoglobulin light chain restriction and aberrant B-cell antigen expression.

Staining for surface immunoglobulins requires some extra steps in the sample preparation. This is to avoid any nonspecific binding due either to cytophilic antibodies binding to Fc receptors (monocytes and some lymphocytes) or to the binding of antibodies to cell membranes of damaged or dying cells.

This nonspecific staining can be avoided by washing the sample with an isotonic solution prior to staining for surface immunoglobulins. Nonspecific staining can also be minimised by incubating the cells with serum prior to staining.

Finally, some B-cell LPDs such as chronic lymphocytic leukaemia (CLL) may express surface immunoglobulins very weakly and it is preferable to use polyclonal antibodies (PcAb) to detect light chain restriction in these cases (Fig. 16-3).

Two methods are suitable for detecting surface membrane immunoglobulin (SmIg) of blood and bone marrow cells, according to whether a PBS wash or a lysing procedure is used as the first step.

Method 1: wash–stain–lyse–wash

- Pipette 100 µl of the specimen into a round-bottom tube.
- Add 2 ml of PBS–Azide–BSA kept at 37 °C and centrifuge for 5 min at 300 *g*. Using a Pasteur pipette, carefully discard the supernatant.
- Repeat the procedure and resuspend the specimen in 50 µl of PBS–Azide–BSA.
- Add the appropriate McAb/PcAb combination, (e.g. anti-kappa and anti-lambda, CD19, CD45 or any multicolour cocktail).
- Incubate at room temperature in the dark for 15 min.
- Add 1 ml of ammonium chloride-based lysing solution and incubate for 10 min at room temperature.

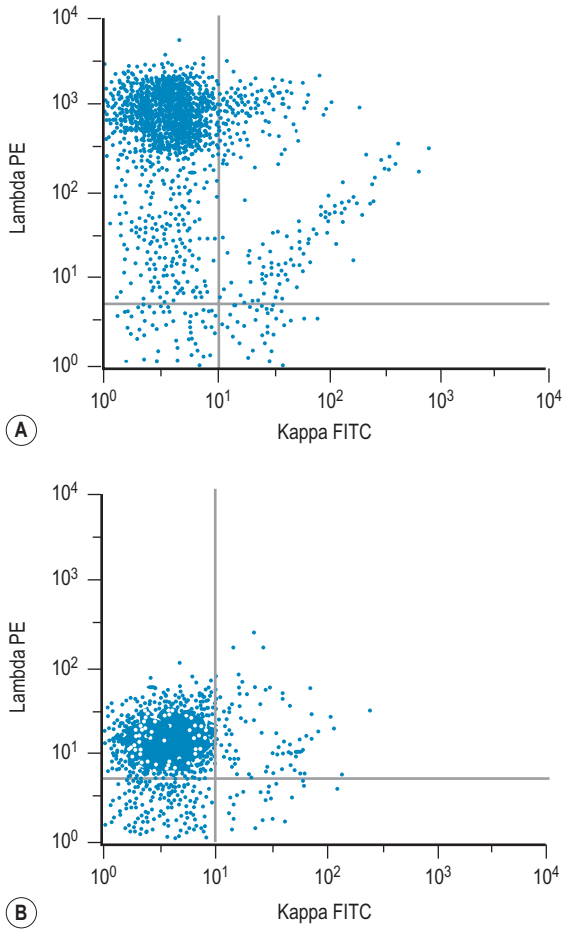

FIGURE 16-3 Surface immunoglobulin light chain staining. **A,** Dot plot showing strong expression of lambda light chain in a case of follicular lymphoma. **B,** By contrast to **(A)**, weak/dim expression of lambda light chain in a case of chronic lymphocytic leukaemia. Cells are negative with anti-kappa in both cases.

- Add 1 ml of PBS–Azide–BSA, centrifuge for 5 min at 2000 revolutions per minute (rpm), and discard the supernatant. Repeat this step.
- Resuspend cells in 0.2–0.5 ml of sheath fluid solution (e.g. Isoton).
- Acquire data on a flow cytometer without delay.

Method 2: lyse–stain–wash

- Pipette 100 µl of the specimen into a round bottomed tube.
- Add 2 ml of ammonium chloride lysing solution, incubate for 10 min at room temperature, and wash twice in PBS–Azide–BSA as above.
- Add the appropriate volume of McAb/PcAb combination, according to the manufacturer's instructions.
- Incubate in the dark for 15 min at room temperature. Add 2 ml of PBS–Azide–BSA, centrifuge for 5 min at 300 *g* and discard the supernatant. Repeat this step.
- Resuspend cells in 0.2–0.5 ml of sheath fluid (e.g. Isoton) and acquire data on a flow cytometer without delay.

Detection of intracellular antigens

This method is applied to identify antigens expressed within the cell (i.e. in the cytoplasm or nucleus); for example, intracellular immunoglobulin, myeloperoxidase (MPO), lysozyme, CD3, CD79a, BCL2, terminal deoxynucleotidyl transferase (TdT) and Ki67.

Several kits containing solutions to fix and permeabilise cells to detect cytoplasmic or nuclear antigens are commercially available. Their reliability and consistency for detecting particular nuclear and cytoplasmic (c) antigens may vary. These reagents can have some effect on the light scatter pattern as cells have a tendency to shrink after fixation[4] (Fig. 16-4).

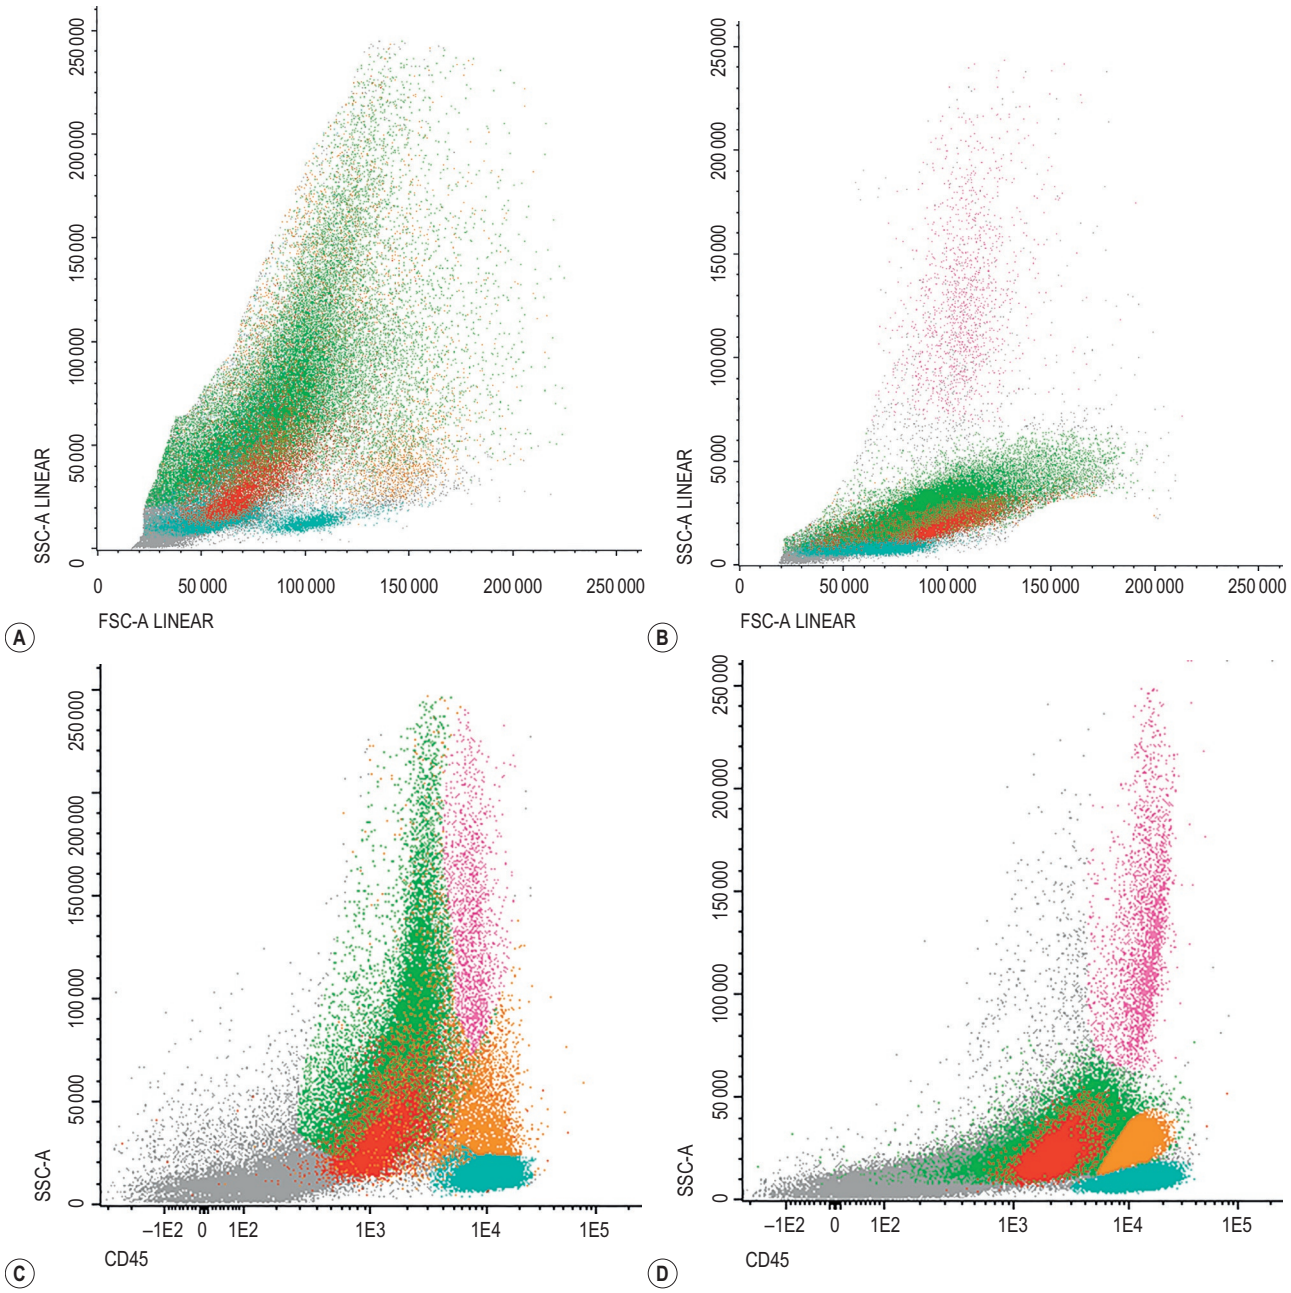

FIGURE 16-4 The effect of fixation and permeabilisation. Alteration of light scatter properties of cells after exposure to Fix-Perm. The four plots are from the same AML sample. Plots **(B, D)** show reduced SSC by most populations after the Fix-Perm process as compared to plots **(A, C)** where cells were stained for membrane markers without use of Fix-Perm. Eosinophils are shown in pink, lymphocytes in blue, monocytes in orange, neutrophils in green and blast cells in red.

The kits contain two solutions: solution A is the fixing agent based on a paraformaldehyde solution and solution B is a lysing agent based on a combination of a lysing solution and a detergent.

The methods below follow the manufacturer's kit instructions for the "Fix and Perm" kit (Invitrogen) (www.thermofisher.com).[4]

Method

- Pipette 100 µl of the specimen into a round-bottom tube.
- Add 100 µl of solution A (fixative) and incubate at room temperature for 15 min.
- Wash twice in PBS–Azide–BSA by centrifuging for 5 min at 300 *g*.
- Add 100 µl of solution B (lysing agent) and the appropriate amount of fluorochrome-conjugated McAb or antibody cocktail.
- Incubate at room temperature in the dark for 15 min.
- Wash twice in PBS–Azide–BSA, centrifuging for 5 min at 300 *g*.
- Resuspend in 0.2–0.5 ml of sheath fluid solution (e.g. Isoton).
- Acquire data on a flow cytometer without delay.

Simultaneous detection of intracellular and membrane antigens

The first step in simultaneous detection of intracellular and membrane antigens is to stain for membrane antigens followed by cytoplasmic or nuclear antigen staining (Fig. 16-5).

- Pipette 100 µl of specimen into a round-bottom tube.
- Add the appropriate fluorochrome-conjugated McAbs or cocktail to detect the membrane antigen.
- Incubate at room temperature in the dark for 15 min.
- Without washing, add 100 µl of solution A (fixative).
- Incubate at room temperature in the dark for 15 min.
- Continue with the steps described previously for intracellular antigen detection.

Acquisition and data analysis

Data acquisition: According to the 2014 British Committee for Standards in Haematology (BSCH) guidelines[2] all data files should have clear unique identification. The number of events to be acquired depends on the desired sensitivity, sample volume and cellularity.

For diagnostic LPD samples, acquisition of data representing 50 000 lymphocytes is recommended but acquisition of between 500 000 and 1×10^6 total events is required for MRD detection.

Fluidics stability should be monitored by the inclusion of a time versus fluorescence plot, and doublets should be discriminated on a FSC-H (height) versus FSC-A (area) analysis.

Data analysis: there are multiple software options available for the interpretation of FSC files. It is important to exclude debris and doublets at the beginning of the analysis. Analysis templates allow populations of interest to be identified by applying sequential gating i.e. light scatter and CD45 followed by lineage-specific antigens[5] (see Fig. 16-1).

Immunological markers in acute leukaemia

Immunophenotyping by MFC is a well-established and widely used technique for identification and characterisation of leukemic cells in acute leukaemia. According to the World Health Organisation (WHO) classification of Tumours of Haematopoietic and Lymphoid Tissues, MFC should be integrated with morphology, cytogenetics and molecular studies at presentation and follow up.[6] It is important to note that even if immunophenotyping is significantly more sensitive, specific and objective than morphological assessment, the latter remains the gold standard criterion for establishing the blast percentage both at presentation and post-treatment.

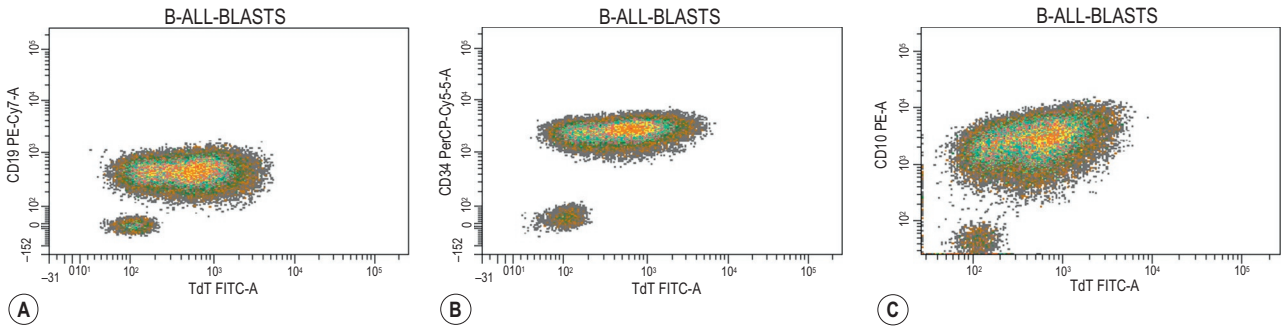

FIGURE 16-5 Simultaneous detection of intracellular and membrane markers. Density plots showing a combination of nuclear TdT with membrane CD19, CD34 and CD10 respectively (components of the common ALL phenotype).

In the diagnosis of acute leukaemia by immunophenotyping, the most commonly used approach at least in Europe is a two-step process. First a screening panel including lineage markers and immature markers (CD34/TdT, HLA-DR) allows the classification of most cases into the broad categories of myeloid (MPO positive), B cell (CD19, CD79a, cCD22) or T cell (cCD3) and, less frequently, mixed phenotype acute leukaemia (MPAL). There are numerous panels described in the literature; recently the EuroFlow Consortium has published thoroughly validated eight-colour panels for the diagnosis of haematological malignancies. Their screening tube for the categorisation of acute leukaemia – acute leukaemia orientation tube (ALOT) – includes MPO, CD34, CD19 and CD79a, CD7, cCD3 and SmCD3.

Once the lineage of the blasts has been established, a secondary panel of antibodies is necessary to define the blast differentiation and maturation stage[7] (Table 16-1).

In acute myeloid leukaemia (AML) further staining will identify mainly granulocytic and monocytic commitment and more infrequently erythroid or megakaryocytic lineage. Whilst in acute lymphoblastic leukaemia (ALL) the extended phenotyping will further sub-classify the disease on the basis of B- and T-cell differentiation or maturation stage.

This subsequent phenotyping is crucial in defining the LAIP. More than 95% of cases of ALL and over 80% of AML show an aberrant antigen expression pattern or LAIP as defined by over/under expression of markers, asynchronous antigen expression and/or cross-lineage expression. These LAIPs are extremely useful for following response to treatment and MRD levels. In the case of ALL, they normally permit the unequivocal detection of abnormal blasts amongst normal lymphoid precursors.[8] In AML, the LAIP's sensitivity and specificity will depend on how frequently the aberrancy is found in the abnormal blasts and how much it deviates from a normal myeloid maturation pattern.

TABLE 16-1

MARKERS IN ACUTE LEUKAEMIA

Panel	Markers in Acute Leukaemia
First-line screening	CD34, TdT, HLA-DR, MPO, CD19, CD79a, CD22, CD3
Second-line B ALL	CD10, cμ, CD20, CD58, CD38
Second-line T ALL	CD1a, CD2, CD3, CD4, CD5, CD7, CD8, TCR
Second-line myeloid	CD13, CD33, CD117, CD16, CD11b
Second-line monocytic	CD14, CD64, CD36, CD4, CD300e
Second-line erythroid	CD105, CD36, CD71, CD235a
Second-line megakaryocyte	CD61, CD41, CD42

TCR, T-cell receptor.

Multiparameter flow cytometry in acute lymphoblastic leukaemia

The vast majority of cases of ALL express TdT and/or CD34. For B-lineage assignment, strong expression of at least two B-cell associated markers is required (CD19, CD79a, cCD22, CD20) whereas cCD3 expression is sufficient as a T-cell lineage marker. Of note is that almost all T-ALL co-express CD7, but CD7 alone is not sufficient for T-cell lineage assignment (around 20% of AML co-express CD7).

From MFC studies performed in normal bone marrow we have learnt in detail the normal maturation pattern of the B-cell compartment.[9]

Thus a normal CD34+ early B-cell precursor acquires initially TdT, CD79a, cCD22, CD10 and CD19. Then as CD45 expression is gained, there is sequential loss of CD34/TdT, downregulation of CD10 and gain of CD20. At a later stage, cytoplasmic μ chains are expressed prior to the precursor becoming an immature B cell with SmIgM expression. The immunophenotypic classification of B-cell precursor ALL (B-ALL) is based on this physiological sequence: pro-B or early precursor ALL (blast positive for TdT, CD19, CD79a, cCD22); common ALL (positive for CD10 but not cμ); pre-B-ALL (blasts express cμ); very rarely B-ALL expresses SmIg. Abnormal precursors of B-ALLs will show a maturation arrest in one of the stages described above plus asynchronous expression of some antigens (for example co-expression of CD20 and TdT or CD22 positivity in CD10-negative blasts), over- or under-expression of certain antigens (CD58, CD38) and cross-lineage expression (usually expression of myeloid antigens such as CD66c, CD33, CD15). Over 95% of B-ALL have a phenotype that differs from that of normal B-cell precursors, and this difference allows the unequivocal identification of these blasts at relapse. Although it is recognised that, after treatment, leukaemias can exhibit an immunophenotype switch, it is still possible to discriminate between normal and abnormal B-cell precursors in most post-treatment bone marrows by identifying any deviation from normal B-cell development (Fig. 16-6).

There is also a degree of correlation between these immunological subtypes and molecular genetics and prognosis. For example the majority of B-ALL with t(1;19)(q23;p13.3) display a pre-B phenotype (CD34−, CD9+, CD19+, CD10+, cμ+); the presence of t(4;11) is associated with a pro-B phenotype and usually with CD15 cross-reactivity. A Ph-positive B-ALL in general has a common ALL phenotype with expression of CD66c and CD25.

Similarly to B-ALL, precursor T-ALL has been further classified into different subgroups that mimic normal T-cell differentiation: pro-T (positive for cCD3 and

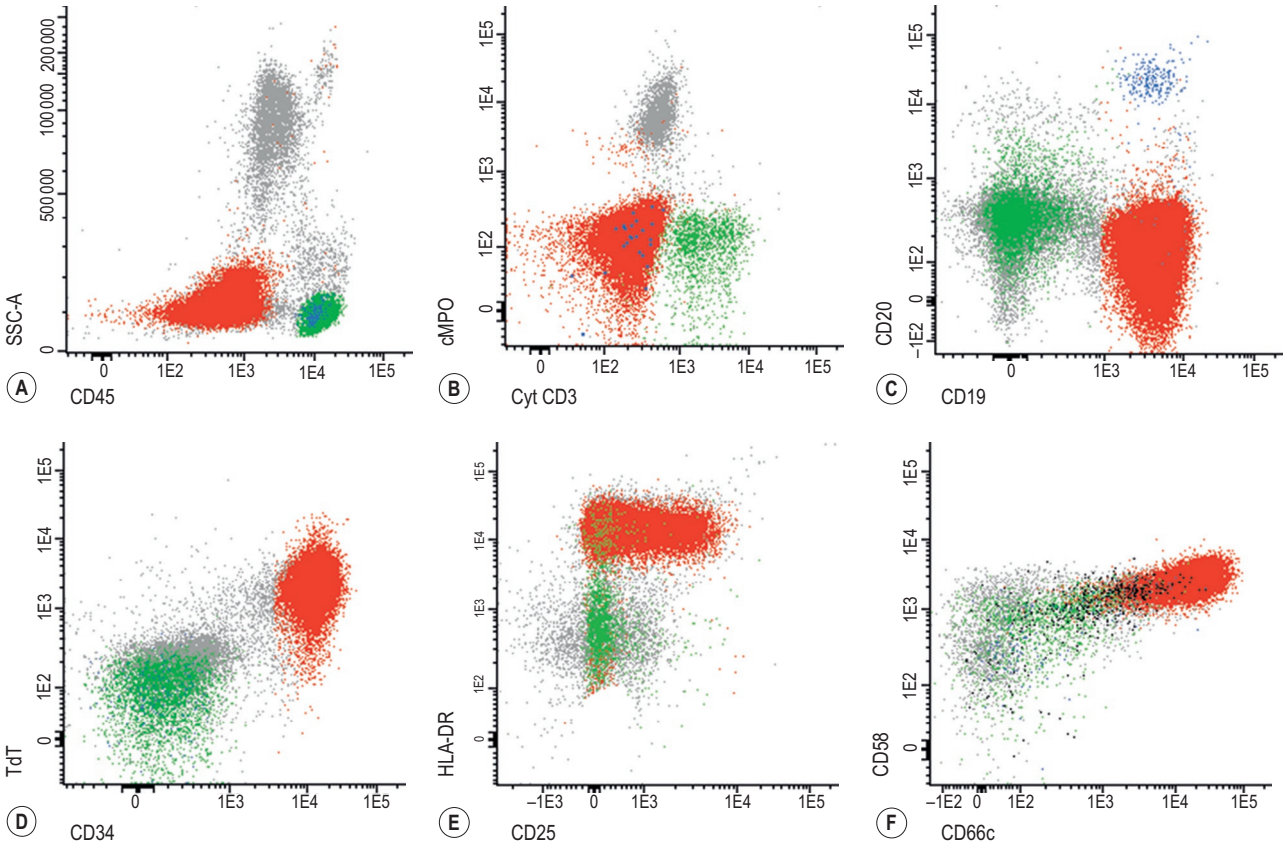

FIGURE 16-6 B-ALL phenotype with t(9;22)(q34;q11.2). Blast cells in red showing weak CD45 expression and positivity for TdT, CD34, CD19, CD10 (not shown), CD58, CD66c and CD25. Blasts are negative for CD20, cytoplasmic (c) MPO and cCD3. Residual mature lymphocytes shown in green (T cells) and blue (B cells).

CD7 with absence of other T-cell associated antigens), pre-T (additional expression of CD2 and/or CD5), cortical (CD1a positive) and mature T-ALL (sCD3+, CD4+ or CD8+).[10] More recently a new subgroup of leukaemias derived from an early T-cell progenitor (ETP) and associated with dismal outcome with standard therapy has been described.[11] These ETP-ALL characteristically lack CD1a and CD8 and show dim expression of CD5 together with expression of at least one myeloid or stem cell marker (Fig. 16-7).

In contrast to B-ALL, the association between immunophenotypic profile and genotype is not so clear, the exception being overexpression of the following oncogenes: *LYL1*, *TLX1 (HOX11)* and *TAL1* associated with a pro-T, early cortical and late cortical phenotype respectively.

Multiparameter flow cytometry in acute myeloid leukaemias

AML is a more complex and heterogeneous disease than ALL, which partly explains the less standardised approach to the immunophenotyping of this disease. In contrast to their lymphoid counterparts, myeloid leukaemias usually show more than one blastic population by MFC. Normal myeloid cells differentiate to neutrophils, monocytes, erythrocytes and megakaryocytes, and also, less often, to basophils, eosinophils, mast cells and dendritic cells. AML can show differentiation to any of these myeloid cell subsets. Most of the panels for identification of myeloid blasts include the following markers of immaturity: CD34, HLA-DR and CD117. The characteristic normal neutrophil maturation pattern of CD13 (biphasic expression), CD16 and CD11b expression is lost in AML. Acute promyelocytic leukaemia (APL) has a characteristic light scatter profile (high SCC due to the granularity) with negativity for CD34 and HLA-DR and positivity for CD117, CD33 (homogeneous) and CD13 (weak), which is similar to the promyelocyte stage except for abnormal lack of CD15 expression.

Normal monocytic differentiation includes sequential acquisition of CD4, CD64, CD36, CD14 and CD300e. AML with monocytic differentiation shows an increased monocytic compartment with a variable proportion of the cells displaying either an immature-monoblastic phenotype (CD64+ CD14−), asynchronous antigen expression (CD64+CD14−CD300e+), abnormal loss of antigens

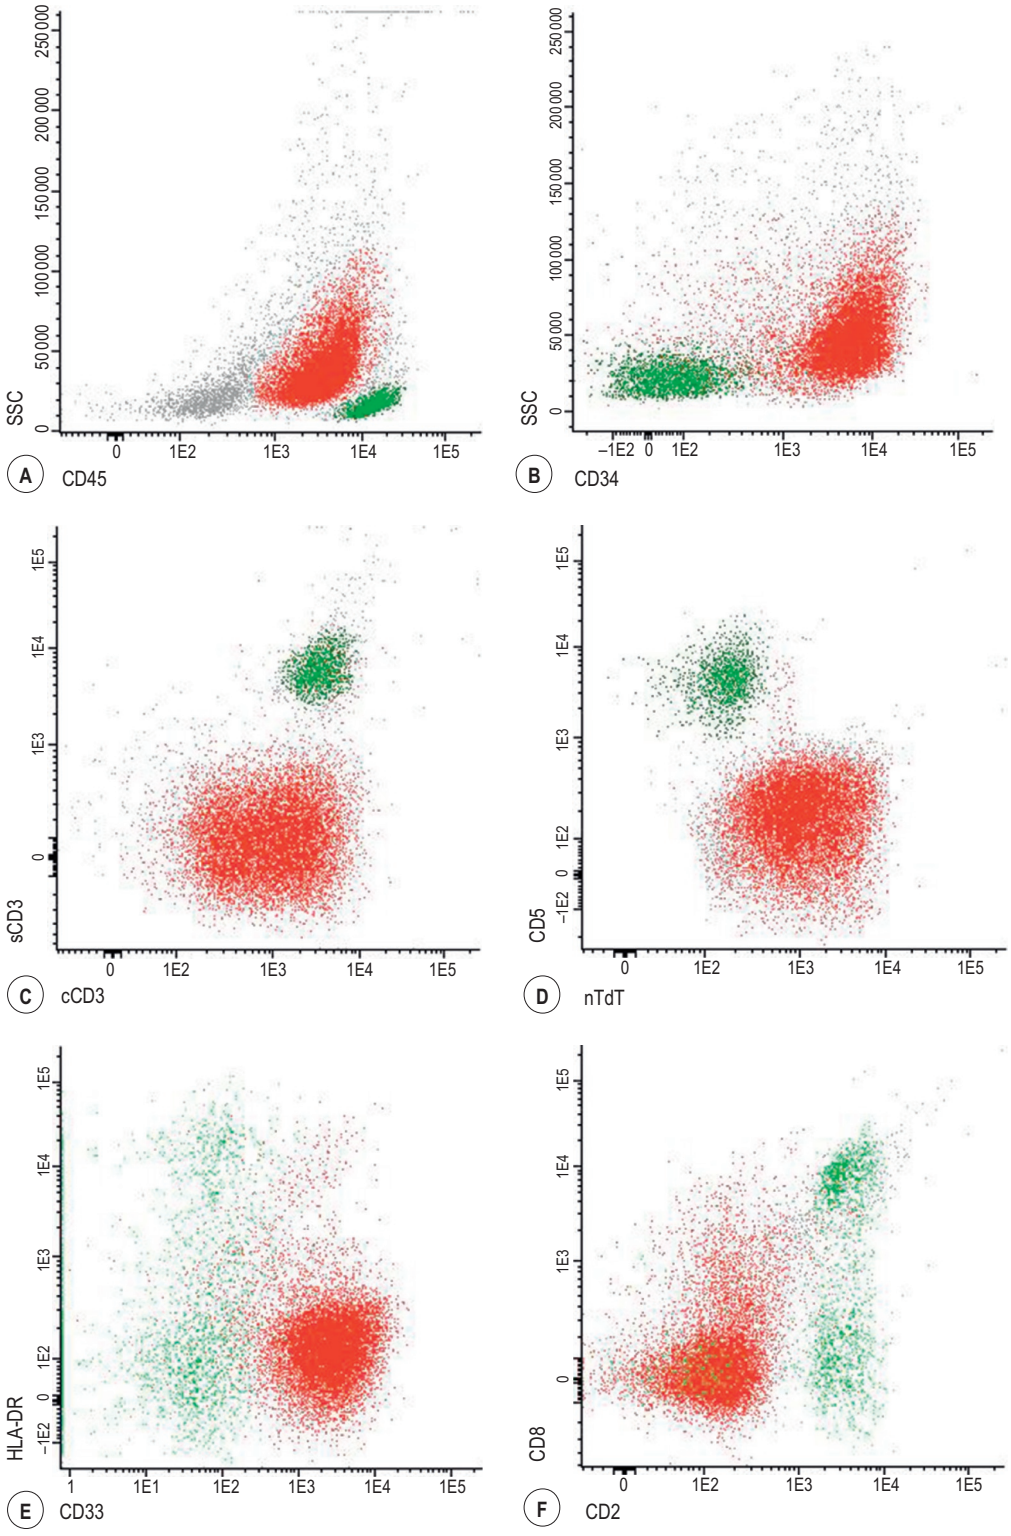

FIGURE 16-7 Early T-cell progenitor T-ALL. Blasts (red) co-express CD34, nuclear (n) TdT and cCD3, but are negative for surface membrane (Sm) CD3, CD4 (not shown) and CD8 (normal T cells in green). Leukaemic cells also express the myeloid-associated antigen, CD33.

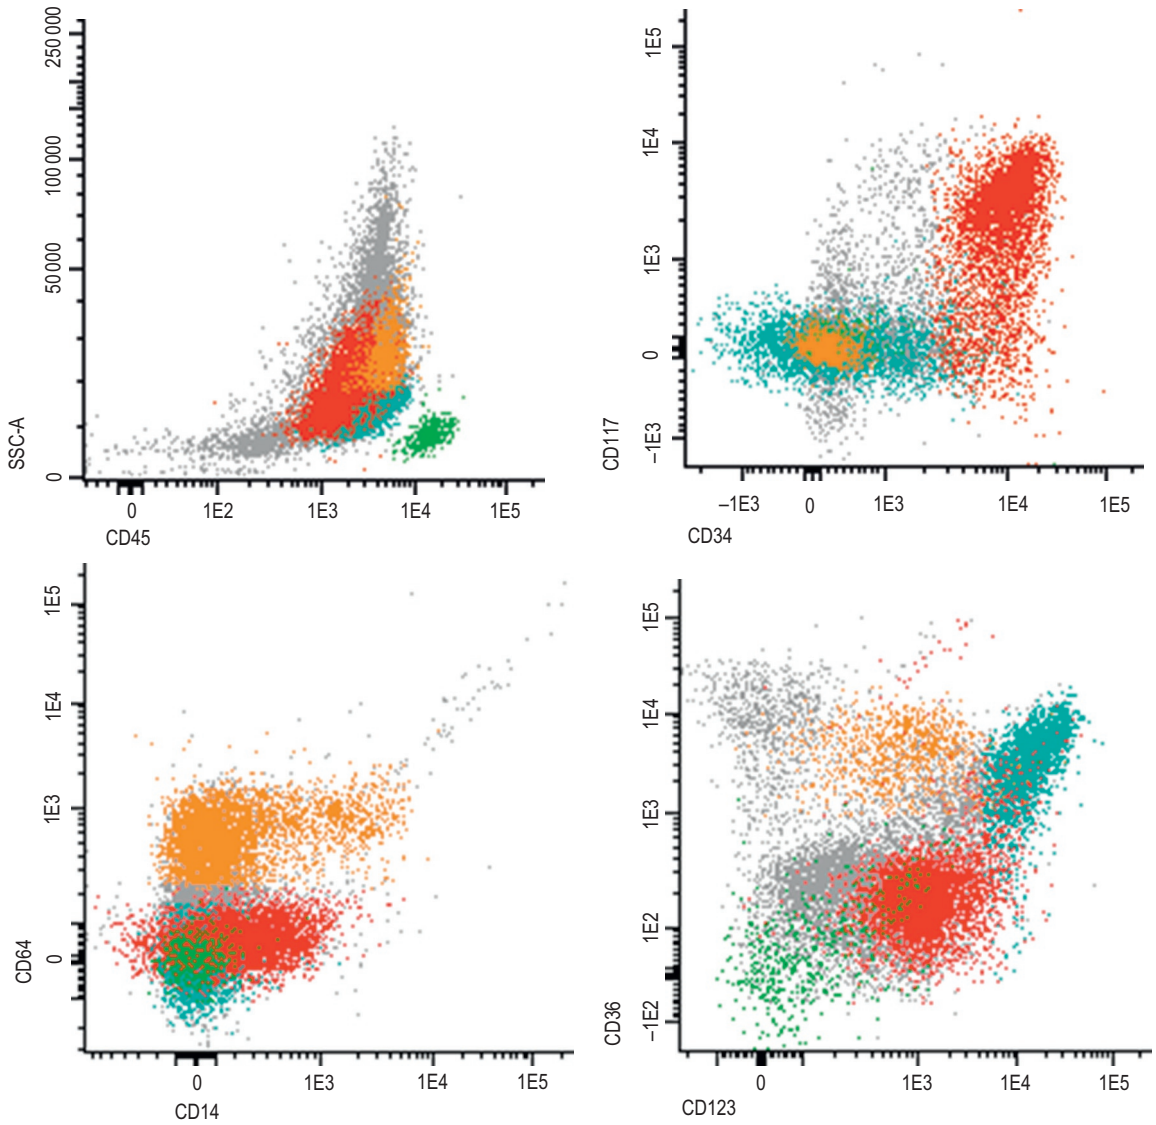

FIGURE 16-8 AML with myeloblast, monoblast and plasmacytoid dendritic cell components. Myeloblasts (red) are CD45 weak and co-express CD123 (weakly), CD34 and CD117; they are negative for CD64 and CD36 and express CD14 only weakly and partially. Monoblasts (orange) co-express CD64 and only partially CD14 and CD36. There is a third population of plasmacytoid dendritic cells (blue) which strongly co-expresses CD123 and CD36 and HLA-DR (not shown).

normally expressed by monocytes (i.e. CD13, HLA-DR) and/or cross-antigen expression (CD56 in particular) (Fig. 16-8).

Erythroid differentiation markers are expressed in this sequential order: CD105, CD36 and CD71, but none of these is specific for the lineage; CD235a (glycophorin A) is specific for the erythroid lineage but is expressed in both mature and immature erythroid cells.

For megakaryocytic differentiation, CD61, CD41 and CD42 (which recognise glycoproteins IIIa, IIb/IIIa and IX/Ib, respectively) are considered excellent markers for the detection of megakaryocytic leukaemias; these leukaemias also express CD36. Importantly, platelet adherence to blasts can cause false-positive results with the former antigens; intracellular staining can be helpful in those situations.

Normal basophils express high levels of the interleukin (IL)-3 alpha receptor (CD123) and CD203c, but neither of these is specific for the basophil lineage and abnormal immature basophils can down regulate CD123.

Although a rare entity, blastic plasmacytoid dendritic cell neoplasm has a characteristic immunophenotype (lineage markers negative, CD123 high, HLA-DR high, CD4+, CD56+). This diagnosis needs to be excluded if initial testing identifies apparently undifferentiated blasts.

As in ALL, certain AML phenotypes are highly associated with specific genotypes and therefore have prognostic implications. Some examples of this are the presence of *PML-RARA* gene transcript and the APL phenotype

described earlier and the co-expression of B-cell associated markers (CD19, CD79a) in AML with t(8;21).

Nowadays with the power of greater than six-colour MFC and availability of advanced analysis software,[8] it is possible to dissect AML and determine the lineage commitment of each blast subpopulation. This extensive and laborious approach may not be feasible in most laboratories but does have the advantage of identifying LAIPs for subsequent monitoring of MRD with high sensitivity levels, particularly applicable in those patients who lack a known molecular marker.

Multiparameter flow cytometry in mixed phenotype acute leukaemia

Immunophenotyping of acute leukaemia identifies a small proportion of cases (<5%) that show simultaneous co-expression of antigens specific for two different lineages: myeloid and lymphoid. This type of acute leukaemia in the absence of specified recurrent cytogenetic abnormalities is designated MPAL. The myeloid component in MPAL is defined exclusively by MPO positivity and/or by clear evidence of a monocytic component (CD64, CD14). The T-lymphoid component is defined by the expression of CD3, cytoplasmic or surface. Since there is no marker specific for the B-lymphoid lineage, evidence of B-lymphoid differentiation should be based on the expression of strong CD19 plus another B-cell marker (CD10, CD22 or CD79a) or weak CD19 and strong expression of two of the other specified B-cell markers (Fig. 16-9).

The WHO classification does not make a distinction between cases with co-expression of lymphoid and myeloid

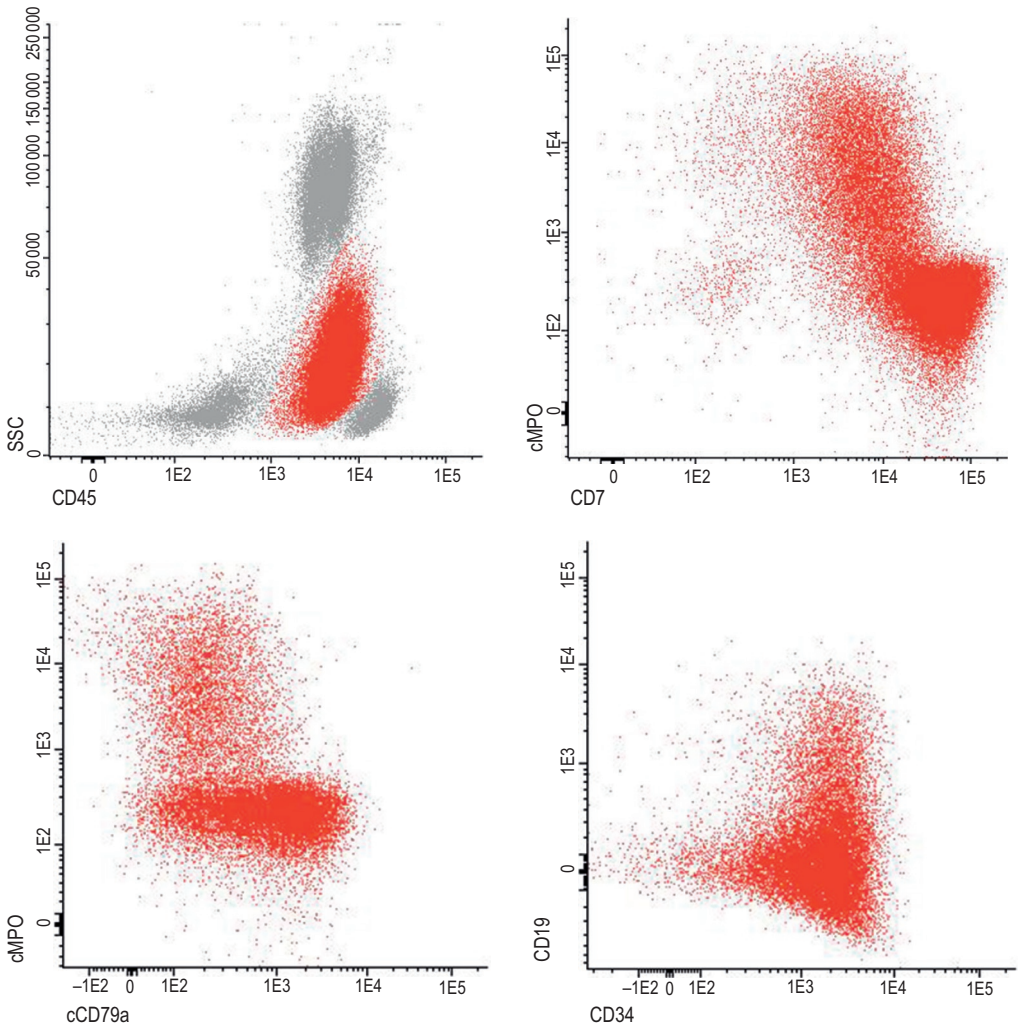

FIGURE 16-9 A case of mixed phenotype acute leukaemia. The blastic population (red) in this case co-expresses CD34 and CD7. A subset of blast cells (27%) is MPO positive with weaker expression of CD7; another subset did not express MPO and expressed intense CD7, strong CD79a and partial CD19.

antigens ('biphenotypic') from those with two separate populations ('bilineal').[6]

Immunological markers in chronic lymphoproliferative disorders

MFC immunophenotyping is an essential tool for diagnosis and screening of LPDs. It is used to effectively quantify leukaemic infiltration and to differentiate normal from abnormal phenotypes. This is achieved in the B-cell lineage by the detection of a population of abnormal lymphocytes showing light chain restriction and aberrant antigen expression.

In some cases MFC can further classify LPDs and be used to monitor treatment effectiveness.

Panels of monoclonal antibodies for screening, classification and diagnosis

Recently there has been an expansion in the availability of antibodies and fluorochromes for the screening of LPD.[12]

This development has been important in facilitating the use of a single multicolour (usually eight- or ten-colour) screening tube to differentiate abnormal from reactive or normal lymphocytes. Once an abnormal population has been identified, a secondary antibody panel(s) can be used to further classify the lymphoid population.

This new methodology does not exclude the use of panels comprised of smaller antibody combinations (three or four colours) but the use of eight to ten colours is advantageous for the rapid detection of abnormal lymphocytes at very low levels and in a cost effective manner. A minor disadvantage is the challenge of more complex data analysis.

The strategy of the multicolour screening tube is to identify and enumerate lymphocyte subsets (i.e. B cells, T cells, NK cells and plasma cells).

B-cell markers (CD19, CD20, kappa, lambda) are intended to determine the proportion of mature B cells expressing light chains either with a normal ratio or showing light chain restriction. B-cell precursors can also be identified using these combinations (SmIg−/CD20−/CD19+). The inclusion of CD5 in the panel allows for further categorisation of B-LPD

T-cell markers in the screening panel (CD3, CD4, CD8 and CD5) are designed to identify and enumerate T lymphocytes. An abnormal CD4:CD8 ratio or down regulation of CD3 or CD5 would flag a potentially abnormal T-cell population.

NK cells can be identified by the expression of CD56 by CD3/CD19-negative lymphocytes.

Plasma cells are identified by their high expression of CD38; normal plasma cells are variably positive for CD45 and CD19 and are CD20 negative. However to completely exclude an abnormal plasma cell population, a specific plasma cell tube has to be included.

If the results of this screening tube are within normal limits secondary panels are not required, and the specimen can be reported as no evidence of LPD. If an abnormal B, T or increased plasma cell population is identified, then analysis with an extended panel is performed (see Table 16-6).

Secondary B-cell panel and phenotypic profiles

The objective of performing a secondary B-cell panel is to identify phenotypic patterns that allow comparison with the phenotypes of well-characterised B-cell disorders.

The choice of antibodies for these secondary panels is directed by the morphologically suspected diagnosis and by the knowledge of both the phenotypic patterns of normal B-cell counterparts and the phenotypic aberrancies associated with specific B-cell disorders.

The EuroFlow Consortium has recently validated a secondary B-LPD panel (the so-called B-cell 1), an eight-colour panel containing the additional antibodies: CD23, CD79b, CD10, CD200 and CD43.

Combining the screening and secondary panels will help to diagnose the vast majority of B-LPDs. The antigens that are most useful in differentiating B-CLL from other B-LPDs are CD79b, CD200, CD23, CD20, CD43, CD5, FMC7 and the intensity of SmIg expression.

The results obtained for the expression of some of the antigens listed have been combined in a well-known scoring system. This scoring system can help in the diagnosis of CLL and its differentiation from other clonal B-cell disorders. The characteristic profile of CLL is that of a clonal B-cell with weak SmIg, usually IgM+, IgD±, CD5+, CD23+, FMC7− and weak or negative CD79b and CD22[13,14] (Table 16-2; Fig. 16-10).

The most common CD5-positive B-lineage non-Hodgkin lymphoma (NHL) is mantle cell lymphoma (MCL). The combination of strong expression of CD79b, CD20 and SmIg with a lack of expression of CD200[15] and CD23 is characteristic of MCL. There is a subset of clonal CD5+ B-cell disorders that currently cannot be classified as either CLL or MCL.

TABLE 16-2

SCORING SYSTEM FOR THE DIAGNOSIS OF CHRONIC LYMPHOCYTIC LEUKAEMIA (CLL)*

Marker	Points	
	1	*0*
CD5	Positive	Negative
CD23	Positive	Negative
FMC7	Negative	Positive
SmIg	Weak	Moderate/strong
CD22/CD79b	Weak/negative	Moderate/strong

*Scores for CLL range from 3 to 5, whereas in the other B-cell disorders they range from 0 to 2.

SmIg, surface membrane immunoglobulin.

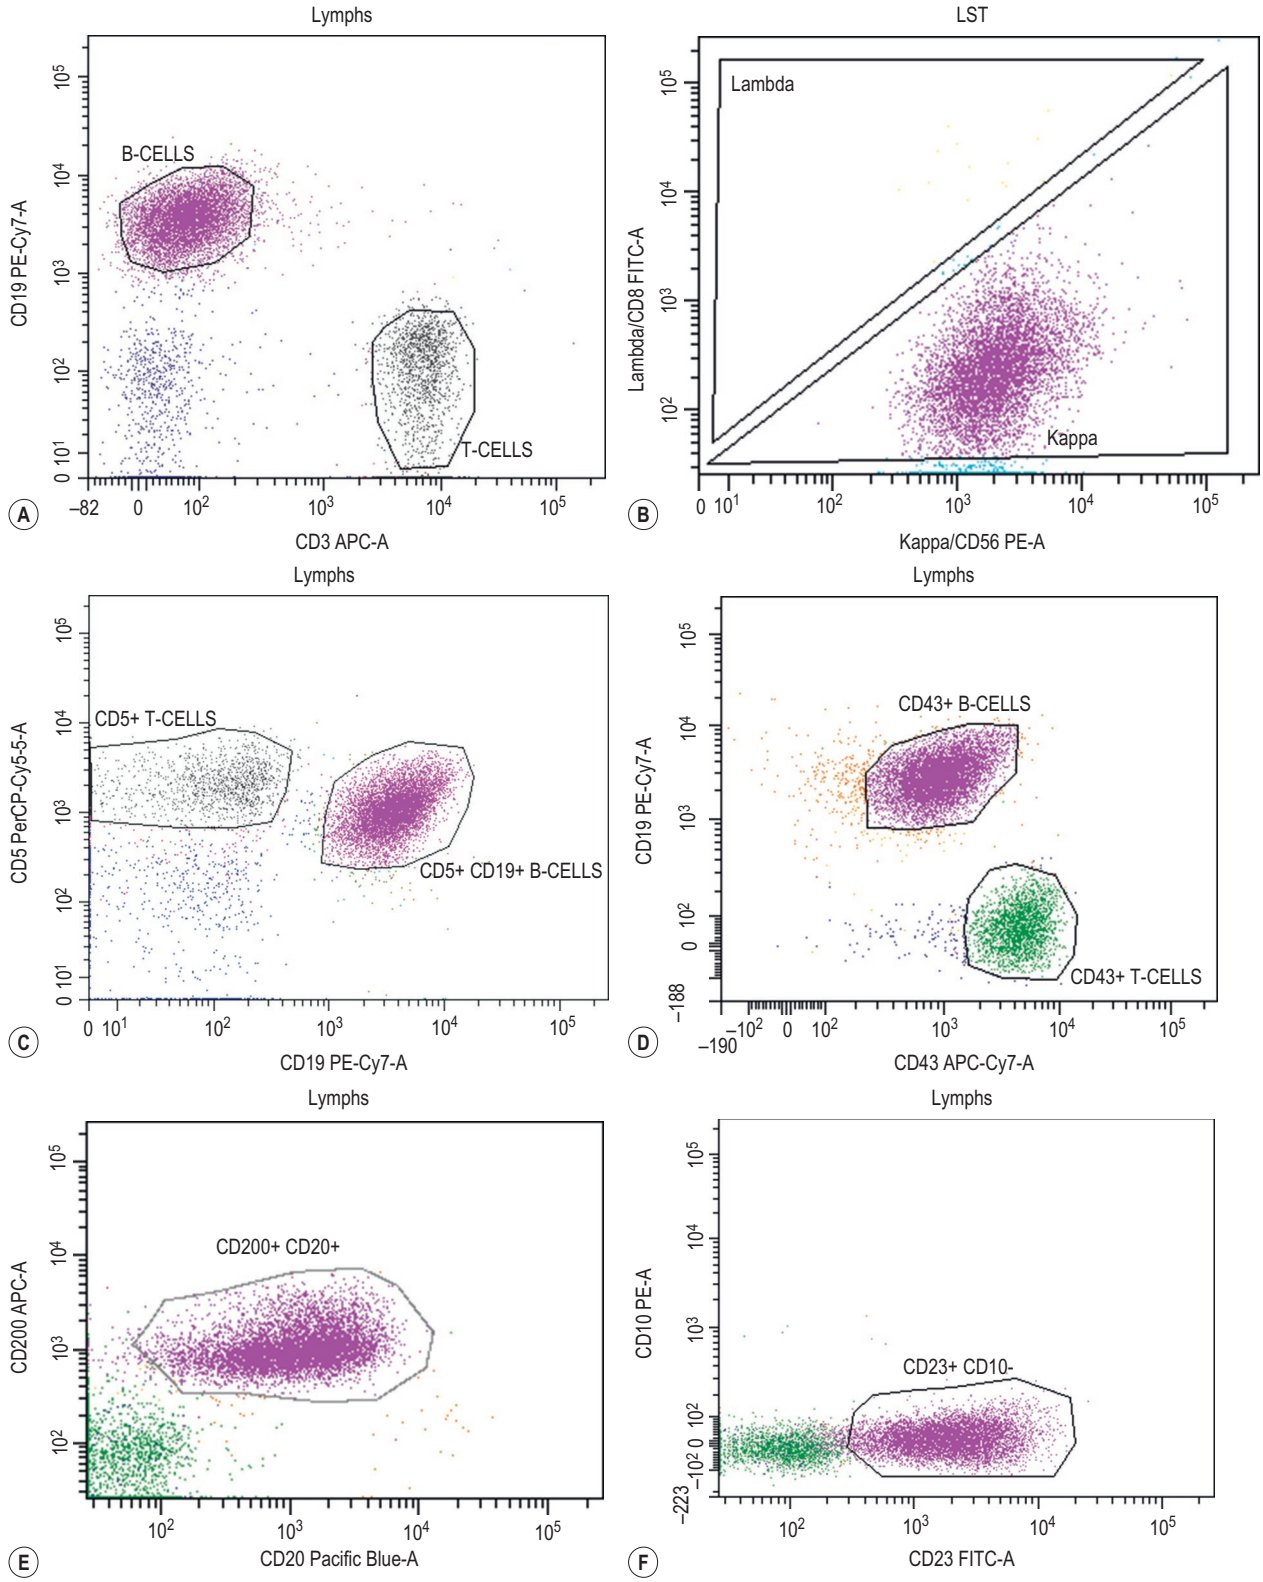

FIGURE 16-10 An example of a typical CLL phenotype. There is positivity for CD5, CD19, CD43, CD20, CD23, CD200 and kappa light chain.

TABLE 16-3

SCORING SYSTEM FOR THE DIAGNOSIS OF HAIRY CELL LEUKAEMIA (HCL)*

Marker	HCL	HCL-V	SMZL
CD123	++	–	–
CD25	++	–	+/–
CD11c	++	+/–	+/–
CD103	++	–	–

*Markers for the HCL score. HCL = 4, whereas other villous disorders score less than 4.
HCL, hairy cell leukaemia; HCL-V, hairy cell leukaemia variant; SMZL, splenic marginal zone lymphoma.

Hairy cell leukaemia (HCL) can be suspected by the presence of very strong CD19, CD200 and SmIg expression in a cell population that demonstrates high SSC (outside lymphocyte gate, occupying the monocytic gate). In this case confirmation by other markers including CD11c, CD25, CD103 and CD123 is advisable[16] (Table 16-3).

Follicular lymphoma has characteristic CD19 weak/CD20+ cells that show low SSC and are CD10+/CD43 – .

Despite the use of such comprehensive panels of antibodies, there remains a subgroup of B-LPDs – including lymphoplasmacytic lymphoma, marginal zone lymphoma and diffuse large B-cell lymphoma (all of which can be CD5 positive) – where immunophenotyping alone does not permit classification.

In general B-cell lymphomas are difficult to precisely characterise by flow cytometry, and histology and cytogenetics studies are critical for accurate diagnosis.

Secondary T-cell and NK-cell panel and phenotypic profiles

The results of the screening LPD panel may show an increased number of T cells with loss of T-cell markers or an abnormal CD4:CD8 ratio (normal 1 to 3.6). A secondary panel should include pan-T-cell antigens (CD2, CD3, CD5, CD7), activation markers (CD25 and HLA-DR), cytotoxic-related markers (CD16, CD56 and CD57), molecules associated with the T-cell receptor complex TCR αβ and TCR γδ and, in some instances, cCD3, TdT and TIA1.

Markers for helper T cells (CD4) and cytotoxic T cells (CD8) are tested at the point of screening and the predominance of one of these cell types will subclassify the clonal expansion of the T-LPD. In general the majority of T-LPD are CD4+ and TCRαβ + (Sézary syndrome, T-prolymphocytic leukaemia (T-PLL), adult T-cell leukaemia/lymphoma (ATLL), peripheral T-cell lymphoma, not otherwise specified and angioimmunoblastic T-cell lymphoma). The exception is large granular lymphocyte (LGL) leukaemia, which is mostly CD8+. In contrast, co-expression of CD4 and CD8 is almost exclusively seen in T-PLL, being found in about 25% of cases.[17] Other markers may also be differentially expressed in various T-cell malignancies. Thus, for example, there is expression of CD25 in ATLL; strong reactivity with CD7 in T-PLL; expression of granzyme B, TIA-1 or perforins in T-cell or NK-cell LGL leukaemias and TCRγδ in hepatosplenic T-cell lymphoma, and CD10 in angioimmunoblastic lymphoma.[18]

γδ hepatosplenic lymphoma is a rare entity that is double negative for CD4 and CD8 expression.

The presence of an NK population is indicated by a population negative for sCD3, CD4 and CD19 with strong expression of CD45 and with CD56+, weak or negative. This could be reactive or clonal. At present, there are no markers to reliably differentiate between different NK proliferations.[19]

In addition to the T-cell markers mentioned above, a kit with a set of McAbs that identify the various variable regions of the TCRβ in T lymphocytes is commercially available (www.beckmancoulter.com). This can be useful to demonstrate clonality of a T-cell population when molecular studies (e.g. polymerase chain reaction, PCR) are not available. A good correlation between flow cytometry and PCR has been demonstrated with flow cytometry able to predict clonality with a sensitivity of 93% and specificity of 80% (Table 16-4).

Secondary plasma cell panel

MFC offers the best approach for the differentiation of polyclonal from clonal plasma cells. A single multicolour (eight-colour) McAb/PcAb panel including CD45, CD38, CD138, CD19, CD56, CD20 and cytoplasmic kappa and lambda light chains provides a sensitive and specific method to distinguish normal from neoplastic plasma cells. Gating is based firstly on CD138 vs CD38 expression together with CD45 negativity or weak intensity and then by evaluating the expression of CD56, CD19, CD20 and cytoplasmic kappa and lambda within the total plasma cells.

Normal/reactive plasma cells are characterised by the expression of CD45, CD19, CD38 and CD138 with polyclonal expression of light chains and negativity for CD56. Neoplastic plasma cells are characterised by the expression of CD38 (weaker than normal), CD138 and CD56 with light chain restriction and in most cases lack of expression of CD45 and CD19.

MFC generally detects fewer plasma cells than seen in bone marrow aspirate films and trephine biopsy sections. This may be explained by patchy infiltration and

TABLE 16-4

IMMUNOLOGICAL MARKERS IN MATURE T-CELL DISORDERS*

Marker	T-PLL	LGL Leukaemia†	ATLL	SS	PTCL-NOS
CD3	+	++	++	++	+
CD7	++	+	−/+	+	+
CD4+, CD8−	+	−	++	++	+
CD4+, CD8+	−/+	−	−	−	+
CD4−, CD8+	−/+	++	−	−	+
CD4−, CD8−	−	−/+	−	−	+

*All are usually CD2 positive.
† A proportion of cases are CD3 negative and have a natural killer phenotype: CD56+, CD16+.
Scoring: (−), negative or positive in less than 10% of cases; (−/+), positive in 10–25% of cases; (+), positive in 25–75% of cases; and (++), positive in more than 75% of cases.
ATLL, adult T-cell leukaemia/ lymphoma; LGL, large granular lymphocyte; PTCL-NOS, peripheral T-cell lymphoma, not otherwise specified; SS, Sézary syndrome; T-PLL, T-prolymphocytic leukaemia.

TABLE 16-5

IMMUNOLOGICAL MEMBRANE MARKERS IN MATURE B-CELL DISORDERS

Disease	SmIg	CD5	CD23	FMC7	CD20	CD22	CD19	CD79b	CD200	CD10

SMZL	Strong	−/+	−/+	++	++	++	+	++	+	−
FL	Strong	−/+	−/+	++	++	++	++	++	−	++
MCL	Strong	++	−	++	++	++	+	++	−	−
DLBCL	Strong	−/+	− /+	++	++	++	++	++	−/+	−/+
MM	Negative	−	−	−	−	−	−	−	+	−/+

Scoring: (−), negative or positive in less than 10% of cases; (−/+), positive in 10–25% of cases; (+), positive in 25% to 75% of cases; and (++), positive in more than 75% of cases.
B-PLL, B-prolymphocytic leukaemia; CLL, chronic lymphocytic leukaemia; DLBCL, diffuse large B-cell lymphoma; FL, follicular lymphoma; HCL, hairy cell leukaemia; HCL-v, hairy cell leukaemia variant; MM, multiple myeloma; SmIg, surface immunoglobulin; SMZL, splenic marginal zone lymphoma.

by loss of plasma cells during sample processing for flow cytometric studies due to plasma cell adhesion[20] (Table 16-5, Table 16-6).

Minimal residual disease detection by flow cytometry

MFC is a powerful and reliable technique for assessing residual leukaemic cells following treatment. It allows the simultaneous analysis of several markers, resulting in the identification of LAIP thereby allowing leukaemic cells to be distinguished from their normal counterparts. Although PCR studies are more sensitive than MFC, not all patients have a known molecular marker that can be followed post-treatment. The level of sensitivity for flow cytometry is routinely 10^{-4} in clinical samples and has the added advantage over PCR techniques of providing information on cell viability and on the status of normal haemopoiesis in the post-treatment sample.[8,21]

The following technical issues are important to consider when performing MRD detection by flow cytometry:

- Always perform an instrument flush prior to acquisition to ensure that there is no carry-over of events from previous samples.
- Record additional parameters (FSC-height, FSC-area and time of aspiration) that can help in the exclusion of artefacts (i.e. aspirated air and doublets).
- Perform back-gating of the potential residual cells to verify the validity of the identification of such events.
- Acquire enough events to have at least 30 to 50 events in the MRD cluster.

TABLE 16-6

EXAMPLES OF STANDARDISED MULTICOLOUR PANELS[2, 7]*

The use of McAb treatments (e.g. anti-CD20, anti-CD19) should be taken into account in post-treatment samples as these will change the phenotype of normal and abnormal cells.

Many publications have demonstrated the utility of MFC in acute leukaemia follow up.[22–25]

The accuracy of residual disease detection in patients with both multiple myeloma[26,27] and CLL has been improved by the application of MFC panels, and the clinical utility of such studies has been demonstrated (Fig. 16-11).

HIV MONITORING

Accurate quantification of CD4+ T-helper lymphocytes is an integral part of the management of HIV-positive patients. The CD4 count, in conjunction with clinical features and HIV viral load, can act as a threshold to determine the commencement of treatment and is a vital component of HIV immune monitoring. It is therefore critical that CD4+ T cells are accurately enumerated.

CD4+ T cells can be easily quantified by flow cytometry using one of two methods:

1. Single platform technology (SPT) permits both percentage and absolute values of the target population to be determined using a single tube containing fluorescent microbeads.
2. Dual platform technology requires the use of a second instrument to provide white blood cell and lymphocyte counts to calculate absolute values.

Single platform methodology is recommended as measurements are derived from a single instrument hence increasing their accuracy.[28]

Antibody panels

Three- or four-colour antibody panels are used to identify T-cell subset populations. T-helper cells are positive for CD3 and CD4; T-suppressor cells are positive for CD3 and CD8. CD45 is used as a gating antibody to identify the lymphocyte population.

Three-colour panel: Two tubes containing CD3/CD4/CD45 and CD3/CD8/CD45

Four-colour panel: One tube containing CD3/CD4/CD8/CD45

A one tube/four-colour panel is economical for both time and money. However, a two tube/three-colour panel provides an additional step in internal quality control as inter-tube variability of CD3 results can help identify single tube errors.[29]

Method

- Reverse pipette 50 µl of ethylenediaminetetra-acetic acid (EDTA)–anticoagulated whole blood to a round-bottom tube containing fluorescent beads (single platform method) or a blank round-bottom tube (dual platform method).

(Accurate pipetting is essential and so reverse pipetting must be employed.)

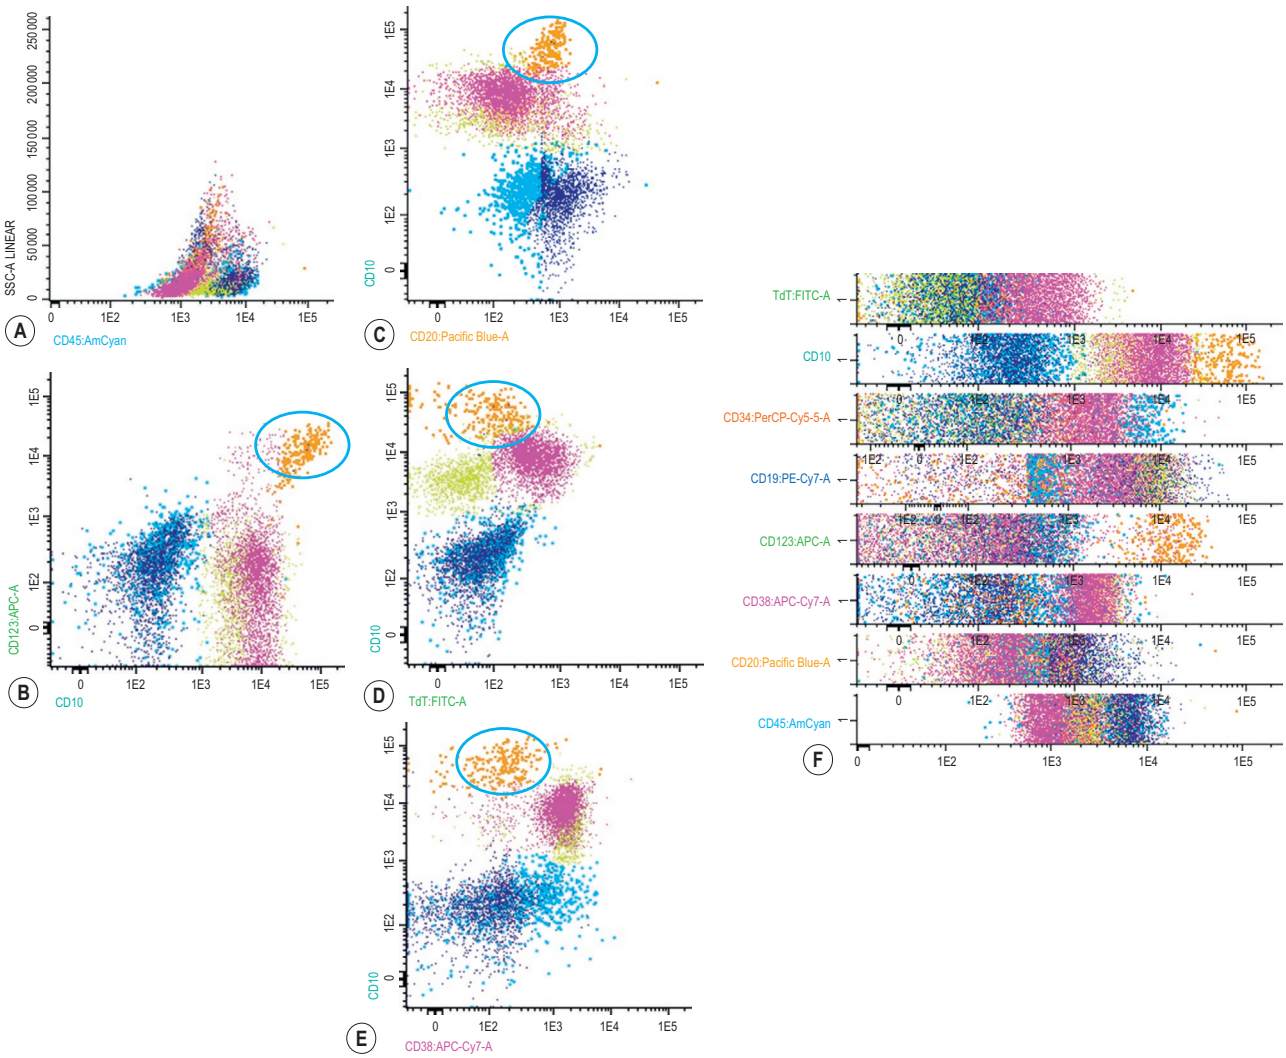

FIGURE 16-11 Multicolour plots showing 2% minimal residual disease in a case of B-ALL at day 28. (A-E) Residual blasts in amber within blue circles. **(F)** Band plot representation of composite phenotype showing residual blasts in amber.

- Add premixed fluorochrome-conjugated antibodies directed against CD3, CD4, CD8 and CD45 (commercially available).
- Incubate at room temperature for 15 min in the dark.
- Add appropriate volume of red cell lysing reagent.
- Incubate at room temperature for 15 min in the dark.
- Acquire data on a flow cytometer. Acquire 5000 lymphocyte events. Set the threshold to exclude CD45-negative events.

Data analysis

- Gate on the CD45-bright/SSC-low lymphocyte region in a CD45/SSC plot.
- Gate on the CD3+/SSC-low lymphocyte events in a CD3/SSC plot.
- Gate on the CD4+CD3+ events and CD8+CD3+ events in a plot showing lymphocyte events. Adjust the lymphocyte gate if a large proportion of CD3−CD4+ cells is present, indicating the inclusion of monocytes in the lymphocyte gate.
- Calculations:
  - Single platform and dual platform: Calculate the percentage of lymphocytes that are CD3+, CD3+CD4+ and CD3+CD8+. The sum of CD3+CD4+ and CD3+CD8+ percentages should ideally equal the total CD3+ percentage.

- Dual platform method: Multiply the percentage of lymphocytes with a CD4+CD3+ and CD8+CD3+ phenotype by the lymphocyte count obtained by a haematology analyser.
- Single platform method: Gate on the bead events and apply the data to the following equation.

$$\left(\frac{\text{Number of positive events}}{\text{Number of bead events}}\right) \times \left(\frac{\text{Total bead concentration added}}{\text{Volume of blood}}\right) = \text{Cells/}\mu\text{l}$$

Both percentage and absolute values should be reported.

Common pitfalls

Although the method for the quantification of CD4+ T cells is relatively simple, the accuracy and precision of results can be affected by minor errors. Imprecise pipetting and incorrect gating of populations can significantly affect results, so care must be taken to eliminate these errors. Comparing previous results with those of the current sample may also highlight potential inaccuracy.

Occasionally substances in the patient's plasma, such as lipids in high concentration, can interfere, resulting in poor separation between positive and negative populations on the dot plots. In these instances, a large measured volume of plasma should be removed from the sample, replaced with an equivalent volume of phosphate-buffered saline and the test repeated.

ACKNOWLEDGEMENT

The authors would like to acknowledge Kathryn Moss for her contribution to the HIV monitoring section.

Diagnostic Radioisotopes in Haematology

Kuldip S. Nijran

CHAPTER OUTLINE

Radioactive isotopes must be distinguished from nonradioactive isotopes of the same element. The radioactive forms are usually referred to as *radionuclides* or *radioisotopes*. These terms are interchangeable and in this chapter, the latter term is used.

Methods using radioisotopes have an important place in haematological diagnosis. Tests that may be undertaken in haematology departments include total blood volume (TBV), red cell survival studies and, occasionally, ferrokinetic studies.

Other investigations that may have haematological interest are more likely to be referred to a department of medical physics or nuclear medicine. Even when the tests are not carried out directly in the haematology department, it is essential for the haematologist to understand their principles and limitations and to be able to interpret the results in clinical terms. Various textbooks[1,2] provide more complete accounts of the theory and practice of nuclear medicine techniques, as does a monograph on radioisotopes in haematology by Lewis and Bayly.[3]

The main properties of the radioisotopes useful in diagnostic haematology are shown in Table 17-1. The units used to express radioactivity and the effects of radiation on the body are given in the previous edition of this book. Anyone handling radioisotopes must be aware of the potential radiation hazard. It is also important to be aware of the potential biohazard of handling blood products and administering them to patients (see Chapter 24).

TABLE 17-1

RADIOISOTOPES USED FOR DIAGNOSTIC INVESTIGATIONS IN HAEMATOLOGY

Element Isotope	Half-Life ($T_{½}$)	Energies (MeV)	Pharmaceutical	Application	Activities (MBq)	Radiation Dose (mSv)	Chest X-ray Equivalence*
^{51}Cr	27.8 days	0.320	Sodium chromate	Red cell volume	0.8	0.3	15

^{111}In	2.81 days	0.247 0.173	Indium chloride → oxine/tropolone	Red cell volume	2	1	50
				Spleen scan	5	2	100
				Platelet lifespan	4	2	100
^{99m}Tc	6 h	0.141	Pertechnetate	Red cell volume	2	0.02	1
				Spleen scan	100	1	50
				Spleen pool	100	1	

MBq, megabecquerel; 1 MBq = 10^6 Bq = approximately 27 μCi. Sv, Sievert; 10^3 mSv = 1 Sv.

*The number of chest X-rays that would expose the subject to the same amount of radiation as the radioisotopes that are listed. A simple chest X-ray has a radiation dose of 0.02 mSv, but for some radiological investigations it is far greater. For example, for intravenous urography, computed tomography (CT) scan of the chest and a large bowel barium study the effective radiation doses are 4.0, 8.0 and 9.0 mSv, respectively.

† Provided that the thyroid is blocked and the label is excreted in the urine; if not blocked, about 20% will accumulate in the thyroid, resulting in a radiation dose of 1 mSv to the thyroid.

SOURCES OF RADIOISOTOPES

Radioisotopes that emit γ-rays are particularly useful because they have the advantage of emissions that penetrate tissues well, so they can be detected at the surface of the body when they have originated within organs. The radioisotope should have as short a half-life ($T_{½}$) as is compatible with the duration of the test. A radioisotope with a very short half-life can be administered in much larger amounts than those that are likely to remain active in the body for a considerably longer time.

The longer-lived radioisotopes that are used for haematological investigations are generally available from commercial suppliers. The usual way of obtaining certain short-lived radioisotopes is by means of a radioisotope generator, in which a moderately long-lived parent radioisotope decays to produce the required short-lived isotope. In this way ^{99m}Tc ($T_{½}$ = 6 h) can be derived from ^{99}Mo ($T_{½}$ = 66 h).

RADIATION PROTECTION

The quantity of radioactivity used in diagnostic work is usually small and good laboratory practice is all that is necessary for safe working. However, before using radioisotopes, workers should be familiar with the regulations concerning radiation protection for themselves, their fellow workers and patients.[4]

The effect of radiation on the body depends on the amount of energy deposited and is expressed in grays (Gy). The unit that describes the overall effect of radiation on the body, or the 'effective dose,' is measured in sieverts (Sv) or millisieverts (mSv). The annual whole-body dose limit for somebody working with radioisotopes is in the order of 20 mSv, whereas 1 mSv is the annual limit for the general public. To put this into perspective, 1 mSv is produced by normal background radiation in about 6 months and the radiation dose from a single chest X-ray is 0.02 mSv.[5] No statutory limit of total annual radiation dose has been set for patients, but it is an important requirement that radioisotopes should be handled only in approved laboratories under the direction of a trained person who holds a certificate from the appropriate authority specifying the radioisotopes that the individual is authorised to use and the dose limits that must not be exceeded. In the UK, this authority is the Administration of Radioactive Substances Advisory Committee (ARSAC, www.gov.uk/government/organisations/administration-of-radioactive-substances-advisory-committee).[5] Radioisotopes should not be given to pregnant women unless the investigation is considered imperative; if an investigation is necessary during lactation, breast-feeding should be discontinued until radioactivity is no longer detectable in the milk. When radioisotope investigations are necessary in children, the dose relative to that for an adult should be based on body weight (Table 17-2).

TABLE 17-2

RADIOISOTOPE DOSES FOR CHILDREN AS A DECIMAL FRACTION OF THE ADULT DOSE

Weight (kg)	Fraction of Adult Dose
10	0.3
15	0.4
20	0.5
30	0.6
40	0.75
50	0.9
60	0.95
70	1.0

The laboratory (premises) using radioisotopes should be registered to store, handle and dispose of radioactive materials, and appropriate permits are obtained under the Environmental Permitting Regulations 2010.[6]

In general, the radioactive waste from radioisotopes used in haematological diagnostic procedures may be poured down a single designated laboratory sink. It should be washed down with a large quantity of running water. If the waste material exceeds the amount allowed for disposal in this way, it should be stored in a suitable place until its radioactivity has decayed sufficiently for it to be disposed of via the refuse system. All working and storage areas and disposal sinks should be clearly labelled with the internationally recognised trefoil symbol. Records should be kept of the amount of radioactive waste disposed down the drains and this should not exceed the permitted amount on the premises' registration.

Decontamination of working surfaces, walls and floors can usually be achieved by washing with a detergent such as Decon 90 (Decon Laboratories, Ltd; www.decon.co.uk). Glassware can be decontaminated by soaking in Decon 90 and plastic laboratory ware can be decontaminated by washing in dilute (e.g. 1%) nitric acid.

Protective gloves must always be worn when handling radioisotopes; any activity that does get on the hands can usually be removed by washing with soap and water or, if that fails, with a detergent solution. For each laboratory in which isotopes are used, a radiation protection supervisor (RPS) should be nominated to supervise protection procedures and to ensure that a careful record is kept of all administered radioisotopes. This RPS should work in association with the departmental safety officer (see p. 527) and must ensure that all personnel working with radioactive materials wear dosimetry badges (available from an approved dosimetry service provider, e.g. Landauer, www.landauer.co.uk), which must be checked at regular intervals.

APPARATUS FOR MEASURING RADIOACTIVITY *IN VITRO*

The radioisotopes used for most haematological tests are measured in a scintillation counter with thallium-activated sodium iodide crystals. These are available in various shapes and sizes. A 'well-type' crystal contains a cavity into which is inserted a small container or test tube holding up to 5 ml of fluid. Because the sample is almost surrounded by the crystal, counting is achieved with high efficiency. Because the geometric efficiency of a well-type counter depends on the position of the sample in relation to the crystal, it is important to use the same volume for each sample in a series. Another form of crystal detector is a solid circular cylinder, 2.5–10 cm in diameter. In this form, it is used for *in vivo* measurements and occasionally for the measurement of bulky samples (e.g. samples of faeces or 24-h urine specimens), thus avoiding the need to concentrate them to a smaller volume.

An alternative method for measuring bulky material is by using two opposed detectors in a single counting system. The sample is placed in a 450 ml waxed cardboard carton with a screw-top lid and is positioned between two counters placed above and below it with a plastic ring over the lower counter to ensure that the specimen in the carton is approximately equidistant from both crystals. The counting system is surrounded by lead and the responses of both crystals are counted together. If a single detector system is used, it is essential to homogenise the samples.

APPARATUS FOR MEASURING RADIOACTIVITY *IN VIVO*

Surface counting

Surface counting depends on shielding the crystals by means of a lead collimator to exclude as far as possible the radiation from outside a well-defined area of the body. It is thus possible to measure the radioactivity in individual organs such as the spleen and liver.

Imaging

The most widely used method for imaging is by the scintillation camera (gamma camera). It consists of a lead shielding, a large thin sodium iodide detector, an array of photomultiplier tubes, a collimator with multiple parallel holes and a system for pulse height analysis and for storage and display of the data. By scanning down the body, an image of the distribution of the label is built up and recorded. It can also be used to measure the quantity of the isotope in various organs. By rotating the scintillation camera around the body, single-photon emission computed tomography (SPECT) can be performed to produce sectional images. Positron emission tomography (PET) has augmented scintillation scanning and uses radioisotopes that are positron emitters.[7,8]

Measurement of radioactivity with a scintillation counter

Standardisation of working conditions

For each radioisotope, it is necessary to plot a spectrum of pulse height distribution and to identify a window corresponding to the energy at which the maximum number of pulses is emitted. Examples of spectra and selected settings are illustrated in Figure 17-1. The setting of the apparatus, once determined, should remain constant for many months.

Counting technique

Measurement of radioactivity. Measurements are usually carried out for a fixed time period and the results are recorded as counts per second (cps) or counts per minute (cpm). Radioactivity is subject to random but statistically predictable variation similar to that in blood cell counts (see p. 555). The accuracy of the count depends on the total number of the counts recorded as the variance (σ) of a radioactive count = $\sqrt{}$ total count.

Thus, on a count of 100 the inherent error is 10%, whereas it is 1% on a count of 10 000. Any measured activity represents the difference between the sample count and the background count, in which the errors of the two counts are cumulative. In practice, a net count of 2500 over background is adequate for the precision required for clinical studies.

Background counts should be measured alongside that of the radioactive material. If the count rate of the sample is not much above background, then the background should be counted for as long a time as the sample.

Correction for physical decay

Because physical decay is a continuous process that proceeds at an exponential rate, it is possible to correct mathematically for the loss of radioactivity and to convert any measurement back to the initial reference time. This is necessary when comparing successive observations made at different times after the administration of a radioisotope to a patient.[9]

Double radioisotope measurements

If more than one radioisotope is present in a sample, it is possible to measure the radioactivity of each radioisotope separately by one of the following techniques.

Differential decay. Differential decay is of value especially when one of the labels has a very short half-life (e.g. ^{99m}Tc, half-life 6 h). The method is to count the activity in the mixture twice – the second count being performed after the short-lived label has effectively disappeared.

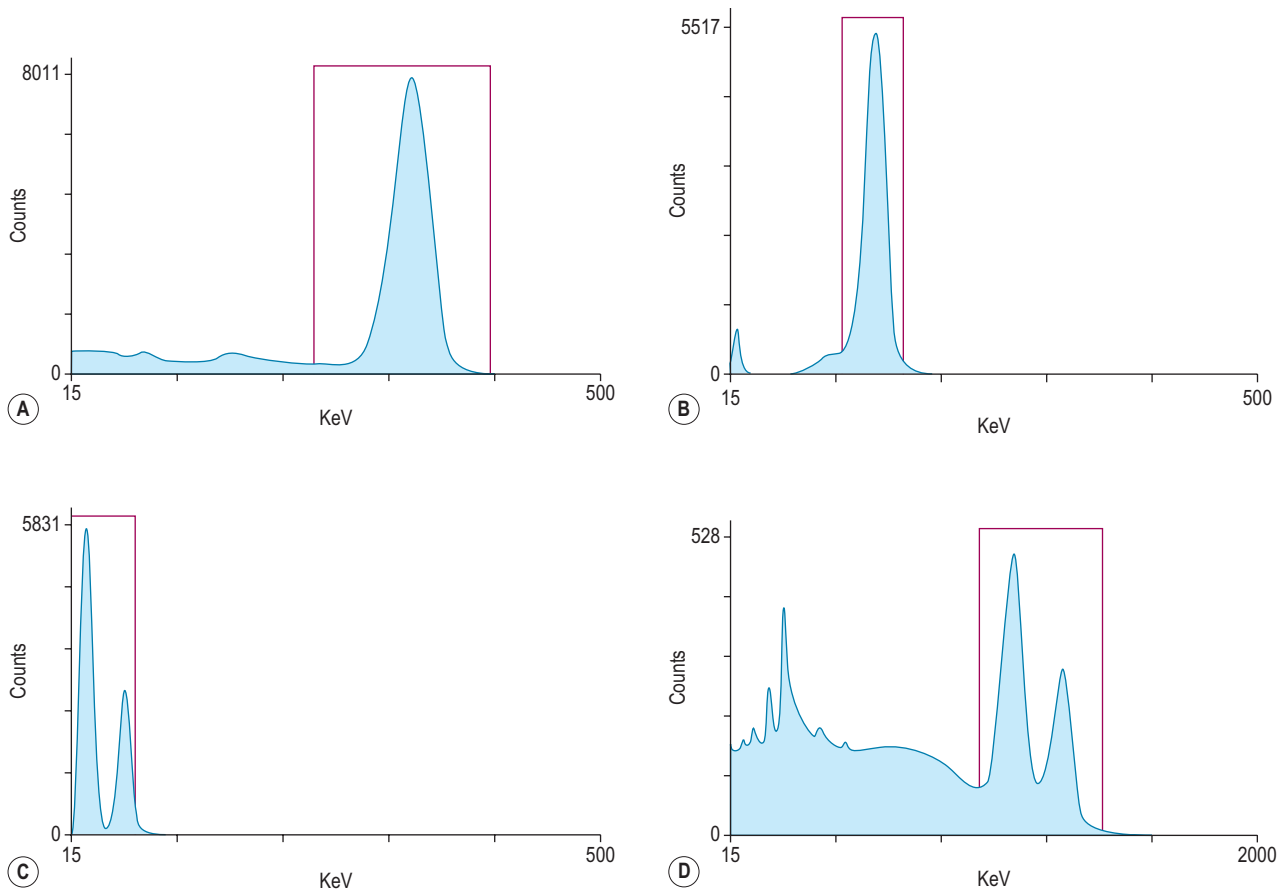

FIGURE 17-1 Spectra of radioisotopes obtained on a scintillation spectrometer. A, ^{51}Cr. **B,** ^{99m}Tc. **C,** ^{125}I. **D,** ^{59}Fe. The radioisotopes should be counted with the window set within the limits indicated by the vertical lines.

Physical separation. When the two radioisotopes produce γ rays of different energies, they can be identified by their characteristic features and separated using an energy analyser. Correction for any 'cross talk' is carried out by counting a standard (a source of known radioactivity) of each radioisotope (A and B) at both channel settings. The proportion of A (P_A) spilling over into channel B = channel B counts ÷ channel A counts from the radioisotope A standard (both corrected for background at setting for B) and the proportion of B (P_B) spilling over into channel A = channel A counts ÷ channel B counts from the radioisotope B standard at setting for A. The total counts obtained for labels A and B in their correct channels can then be corrected for the proportion of 'foreign' counts.

BLOOD VOLUME

The haemoglobin concentration (Hb), red cell count and packed cell volume or haematocrit (PCV/Hct) do not invariably reflect the total red cell volume (RCV). Whereas in most cases for practical purposes, there is adequate correlation between peripheral blood values and (total) RCV,[9] there will be a discrepancy if the plasma volume is reduced or increased disproportionately. Fluctuation in plasma volume may result in haemodilution, giving rise to pseudoanaemia, or conversely, haemoconcentration, giving rise to pseudopolycythaemia.

An increase in plasma volume occurs in pregnancy, returning to normal soon after delivery. Increased plasma volume may also be found in patients with cirrhosis, nephritis and congestive cardiac failure and when there is marked splenomegaly. Reduced plasma volume occurs with oedema, with dehydration, following the administration of diuretic drugs, in smokers and sometimes as a persistent unexplained phenomenon. It also occurs during prolonged bed rest.

In contrast to the fluctuations in plasma volume, RCV does not fluctuate to any extent if erythropoiesis is in a steady state.

Measurement of blood volume should thus be considered whenever the Hct is persistently higher than

normal; demonstration of an absolute increase in RCV is necessary to diagnose polycythaemia and to assess its severity. However, it should be noted that the discovery of a recurring *JAK2* mutation (*JAK2* V617F) in the great majority of patients with polycythaemia vera means that blood volume studies are now rarely needed for the confirmation of this diagnosis. The component parts of the TBV (i.e. red cell and plasma volume) can also be measured separately in the elucidation of obscure anaemias when the possibility of an increase in plasma volume cannot be excluded.

Measurement of blood volume

Principle

The principle is that of dilution analysis. A small volume of a readily identifiable radioisotope is injected intravenously, either bound to the red cells or to a plasma component, and its dilution is measured after time has been allowed for the injected material to become thoroughly mixed in the circulation but before significant quantities have left the circulation or become unbound. The most practical method now available is to use a small volume of the patient's red cells labelled with radioactive chromium (^{51}Cr), technetium (pertechnetate) (^{99m}Tc) or indium (^{111}In). The labelled red cells are diluted in the whole blood of the patient and from their dilution the TBV can be calculated; the RCV, too, can be deduced from knowledge of the PCV/Hct. The plasma volume can be measured directly by injecting human albumin labelled with radioactive iodine (^{125}I) that is diluted in the plasma compartment.

In contrast to measurement of RCV, plasma volume measurements are only approximations because the labelled albumin undergoes continuous slow interchange between the plasma and extravascular fluids, even during the mixing period. For this reason, it is undesirable to attempt to calculate RCV from plasma volume on the basis of the observed PCV/Hct. However, because the RCV is generally more stable, calculation of TBV from RCV is usually more reliable, provided that the difference between whole-body and venous PCV is appreciated and allowed for (see p. 356). Measurement of red cell and plasma volumes separately by direct methods is to be preferred.

Red cell volume

Radioactive chromium method

For the radioactive chromium method,[10] add approximately 10 ml of blood to 1.5 ml of sterile National Institutes of Health (NIH)-A acid–citrate–dextrose (ACD) solution (see p. 561) in a sterile bottle with a screw cap. Centrifuge at 1200–1500 *g* for 5 min. Discard the supernatant plasma and buffy coat and slowly, with continuous mixing, add to the cells 8×10^3 Bq of $Na_2^{51}CrO_4$ (www.polatom.pl or www.perkinelmer.com) per kg of body weight. The sodium chromate should be in a volume of at least 0.2 ml, being diluted in 9 g/l NaCl (saline). Allow the blood to stand for 15 min at 37 °C for labelling to take place. Wash the red cells twice in 4–5 volumes of sterile saline: for all procedures requiring sterile saline, this should be 9 g/l (0.9%) sodium chloride BP (nonpyrogenic); 12 g/l NaCl should be used when red cell osmotic fragility is greatly increased (e.g. in cases of hereditary spherocytosis).

Finally, resuspend the cells in a volume of sterile saline sufficient for an injection of about 5 ml and the preparation of a standard. Take up the appropriate volume into a syringe that is weighed before and after the injection. The volume injected is calculated from the following formula:

$$\text{Volume injected (ml)} = \frac{\text{Weight of suspension injected (g)}}{\text{Density of suspension (g/ml)}}$$

The density of the suspension = 1.0 + Hb of suspension (g/l) × 0.097/340, assuming that packed red cells have a mean cell haemoglobin concentration (MCHC) of 340 g/l and a density of 1.097 g/ml.

Inject the suspension intravenously without delay and note the time; at 10, 20 and 30 min later, collect 5–10 ml of the patient's blood and add it to the appropriate amount of K_2 ethylenediaminetetra-acetic acid (EDTA) anticoagulant. This blood should preferably be drawn from a vein other than that used for the injection. However, it is often convenient to insert a self-retaining needle; in this case, care must be taken to ensure that the isotope is well-dispersed into the bloodstream when injected by flushing through with 10 ml of sterile saline. When the mixing time is likely to be prolonged, as in splenomegaly, cardiac failure or shock, another sample should be taken 60 min after the injection.

Measure the PCV of each sample. PCV should be obtained by microhaematocrit centrifugation for 5 min or for 10 min if the PCV is more than 0.50 and correcting for trapped plasma by deducting 2% from the measurement. A more accurate measurement of the PCV can be obtained by the International Council for Standardisation in Haematology (ICSH) surrogate reference method (see p. 24).

Deliver 1 ml volumes into counting tubes and lyse with saponin; a convenient method is to add 2 drops of 2% saponin. Measure their radioactivity in a scintillation counter. Then dilute an aliquot of the original suspension that was not injected 1 in 500 in water (for use as a standard) and determine the radioactivity of a 1 ml volume. Then:

$$\text{Red cell volume (RCV) (ml)} = \frac{\text{Radioactivity of standard (cpm/ml)} \times \text{Dilution of standard} \times \text{Volume injected (ml)}}{\text{Radioactivity of post-injection sample (cpm/ml)}} \times \text{PCV (on blood sample)}$$

Technetium method

^{99m}Tc is available as sodium pertechnetate. This passes freely through the red cell membrane and will become attached to the cells only if it is present in a reduced form as it enters the cells when it binds firmly to β chains of haemoglobin. For this to occur, the red cells must be treated with a stannous (tin) compound by the following *in vivo* procedure.

Dissolve a vial of stannous reagent (stannous fluoride and sodium medronate available from Diagnostic Imaging Ltd, www.diagimaging.com or Medi-RadioPharma Co., Ltd, www.mediradiopharma.com) in 6 ml of sterile saline and inject intravenously 0.03 ml/kg body weight.

After 15 min, collect 5 ml of blood into a sterile container to which has been added 200 iu of heparin. Add 2 MBq of freshly generated ^{99m}Tc in approximately 0.2 ml of saline or 100 MBq if measurement of splenic red cell pool and scanning are also required. Allow to stand at room temperature for 5 min. Centrifuge; wash twice in cold sterile saline and resuspend in a sufficient volume of cold sterile saline for an injection of 5–10 ml. Draw 5 ml into a syringe that is weighed before and after injection and carry out subsequent procedures as for the chromium method. Because of the short half-life of ^{99m}Tc, radioactivity must be measured on the day of the test. Because 5–10% of the radioactivity is eluted from the red cells within an hour, the method is less suitable than the chromium and indium methods when delayed mixing is suspected (e.g. in splenomegaly).

Indium is available as ^{111}In chloride. The labelling procedure is simpler than with ^{99m}Tc and, because there is less elution than with technetium during the first hour,[11] it is particularly suitable for delayed sampling. For labelling blood cells, the indium is complexed with oxine[12] or tropolone.[13]

Calculating total blood volume

The TBV can be calculated by multiplying the value for RCV by 1/(whole-body PCV) (see below). Plasma volume can be calculated by subtracting RCV from TBV.

If a sample has been taken at 60 min in cases in which delayed mixing is suspected and there is a significant difference between the measurements at 10–30 min and 60 min, then the 60 min measurement should be used for calculating the RCV.

Plasma volume

^{125}I-human serum albumin method

Human serum albumin (HSA) labelled with ^{125}I or ^{131}I is available commercially (from Mallinckrodt Radiopharmacy Services, www.ucl.ac.uk/nuclear-medicine). The albumin concentration should not be less than 20 g/l. The user must ensure that the albumin is derived from plasma that has been thoroughly tested for viral infections. ^{125}I is readily distinguishable from ^{51}Cr, ^{99m}Tc and ^{111}In and this makes possible the simultaneous direct determination of RCV and plasma volume (see below). If further doses of the radioisotope are to be administered for repeat tests, it is advisable to block the thyroid by administering 30 mg of potassium iodide by mouth on the day before the test and daily for 2–3 weeks thereafter.

Withdraw approximately 20 ml of blood into a syringe containing a few drops of sterile heparin solution and transfer to a 30 ml sterile bottle with a screw cap. After centrifuging at 1200 to 1500 *g* for 5–10 min, transfer approximately 7 ml of plasma to a second sterile bottle and add 2.5×10^3 Bq of the radioisotope-labelled HSA per kg body weight (approximately 0.2 MBq in total). Inject a measured amount (e.g. 5 ml) and retain the residue for preparation of a standard.

After 10, 20 and 30 min, withdraw blood samples from a vein other than that used for the original injection (or after prior flushing through with 10 ml of sterile 9 g/l NaCl [saline] if a butterfly needle has been used) and deliver into bottles containing EDTA or heparin.

Measure the PCV (see above), centrifuge the sample and separate the plasma. Prepare a standard by diluting part of the residue of the uninjected HSA 1 in 100 in saline.

Measure the radioactivity of the plasma samples in a scintillation counter and, by extrapolation on semi-logarithmic graph paper, calculate the radioactivity of the plasma at zero time. If only a single sample is collected 10 min after the injection, the radioactivity at zero time may be approximated by multiplying by 1.015 to allow for early loss of the radioisotope from the circulation. Reliance on a single 10 min sample will lead to error if the mixing of the albumin in the plasma is delayed. After measuring the radioactivity of the standard, the plasma volume (ml) is calculated as follows:

$$\frac{\text{Radioactivity of standard (cpm/ml)} \times \text{Dilution of standard} \times \text{Volume injected (ml)}}{\text{Radioactivity of postinjection sample (cpm/ml, adjusted to zero time)}}$$

Calculating total blood volume

As has already been indicated, the TBV is frequently calculated from the RCV and PCV. Before this can be done, however, the observed PCV has to be corrected for the difference between the whole-body and venous PCV.

Whole-body and venous packed cell volume ratio. PCV measured on venous blood is not identical to the average PCV of all the blood in the body. This is mainly because the red cell:plasma ratio is less in small blood vessels (capillaries, arterioles and venules) than in large vessels. The ratio between the whole-body PCV and venous blood PCV is normally about 0.9,[10] and it is thus necessary in the calculation of TBV from measurements of RCV to multiply the observed PCV by 0.9. Thus, TBV is given by the following:

$$\text{Red cell volume} \times \frac{1}{\text{PCV} \times 0.9}$$

However, the ratio varies in individuals, especially in splenomegaly and it is better to estimate RCV and plasma volume by separate measurements than to attempt to calculate one of these from an estimate of the other.

Simultaneous measurement of red cell volume and plasma volume

Collect blood and label the red cells by one of the methods described earlier. If ^{99m}Tc is used, it is necessary first to inject stannous reagent (see p. 356). Then add ^{125}I HSA (see above) and mix it with the labelled red cell suspension. Inject an accurately measured amount and dilute the remainder 1 in 500 in water for use as a standard. Collect three blood samples at 10, 20 and 30 min, respectively, after the administration of the labelled blood and estimate the radioactivity of a measured volume of each sample and a similar volume of the standard.

When ^{99m}Tc has been used in combination with ^{125}I, count on the same day; then leave for 2 days to allow the ^{99m}Tc to decay and count again for ^{125}I activity. Because the radioactivity in the preparation from ^{125}I is much smaller than that from ^{99m}Tc, the count from the red cells is not likely to be significantly affected by interference from ^{125}I in the initial count. However, if necessary, a correction can be made by subtracting the ^{125}I counts on day 2 (corrected for decay) from the original counts to obtain a measurement of the counts owing only to the ^{99m}Tc.

When ^{51}Cr has been used in combination with ^{125}I and a multichannel counter is available, measure the radioactivity owing to the ^{51}Cr and ^{125}I at the appropriate settings for ^{51}Cr and ^{125}I.

Calculate the radioactivity owing to the red cell label in the blood from the mean of the 10-, 20- and 30-min samples and obtain that owing to ^{125}I from the value extrapolated to zero time. Calculate RCV as described on p. 355.

Plasma volume is calculated from the formula:

$$\frac{\text{Radioactivity of standard (cpm/ml)} \times \text{Dilution of standard} \times \text{Volume injected (ml)} \times (1 - \text{PCV})}{\text{Radioactivity of postinjection sample (cpm/ml, corrected to zero time)}}$$

$$\text{Total blood volume} = \text{RCV} + \text{Plasma volume}$$

Expression of results of blood volume estimations

RCV, plasma volume and TBV are usually expressed in ml/kg of body weight. Because fat is relatively avascular, relatively low values are obtained in obese subjects and the relationship between TBV and body weight varies according to body composition. Blood volume is more closely correlated with lean body mass (LBM).[14] Earlier methods for determination of LBM were not practical as a routine procedure and discounting excess fat by using an estimate of so-called 'ideal weight' is arbitrary and tends to overcorrect for the low vascularity of fat. The ICSH developed two formulae, based on body surface area, which provide normal reference values in men and women, respectively.[15] They are as follows.

Mean normal red cell mass (ml)

Men: $[1486 \times S] - 825$; ±25% includes 98% limits
Women: $[1.06 \times \text{age (years)}] + [822 \times S]$; ± 25% includes 99% limits

Mean normal plasma volume (ml)

Men: $1578 \times S$; ±25% includes 99% limits
Women: $1395 \times S$; ±25% includes 99% limits

$$S = \left[W^{0.425} \times H^{0.725} \times 0.007184 \right]$$

where S = surface area (m^2), W = weight (kg), H = height (cm).

However, the problem of establishing the LBM has been overcome to some extent because there are now instruments that are simple to use for estimating body composition by the different response of fat and other tissues to electrical impedance (body composition monitor, Tanita Corporation, www.tanita.com).[14,16]

Thus, RCV can now be obtained by a direct measurement that discounts the effect of fat. The graph in Figure 17-2 shows the normalisation of the RCV in ml/kg LBM.[14] It is obtained as follows: on arithmetic graph paper with % fat on the horizontal (x) axis and RCV in ml/kg total body weight on the vertical (y) axis, plot the intercepts of the following:

Fat 20% with RCV 29 ml; Fat 50% with RCV 19 ml
Join these two points and extend the line to the right and left.

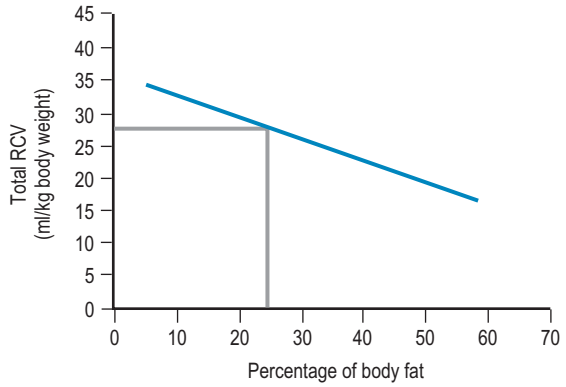

FIGURE 17-2 Normalisation of red cell volume in ml/kg lean body mass. This example shows a patient with 25% body fat; from the slope of the graph the normalised red cell volume for that person should be 28 ml/kg body weight. A measurement of more than 120% of this value (i.e. 33.6 ml) would indicate polycythaemia. See text for definition of the sloped line.

When the % fat is known in any individual (male or female), draw a line vertically from this reading on the *x* axis to the slope and where this line intersects the slope draw a horizontal line to the *y* axis. The reading of this line on the *y* axis is the normalised RCV for that individual. When the measured RCV is >120% of this figure, it is equivalent to 43 ml/kg LBM and a diagnosis of polycythaemia can be made with confidence in men or women.

Range in health

The TBV is 250–350 ml at birth. After infancy, the volume increases gradually until adult life when the RCV in men is 30 ± 5 ml (2 standard deviations [SD])/kg and in women it is 25 ± 5 ml (2SD)/kg. Plasma volume (for men and women) is 40–50 ml/kg; TBV is 60–80 ml/kg.

As a rule, the TBV remains remarkably constant in an individual and rapid adjustments take place within a few hours after blood transfusion or intravenous infusion. In pregnancy, both the plasma volume and TBV increase. The plasma volume increases especially in the first trimester and the total volume increases later; by full term the plasma volume will have increased by about 40% and TBV will have increased by 32% or even more. The blood volume returns to normal within a week postpartum.[17]

Bed rest causes a reduction in plasma volume and muscular exercise and changes in posture cause transient fluctuations. In practice, the patient should always be allowed to rest in a recumbent position for 15 min before measuring the blood volume.

Splenic red cell volume

The red cell content of the normal spleen (the red cell 'pool') is <5% of the total RCV (i.e. <100–120 ml in an adult). In splenomegaly, the pool is increased (e.g. by perhaps as much as 5–10 times in primary myelofibrosis, in polycythaemia vera and in hairy cell leukaemia and other lymphoproliferative disorders).[18] An increase in the volume of the splenic red cell pool may itself be a cause of anaemia; measurement of the pool may be useful in investigating the anaemia in these conditions. It is also useful in determining the cause of erythrocytosis because the expanded pool in polycythaemia vera contrasts with that in secondary polycythaemia, which is normal.[19]

An approximate estimate of the splenic RCV can be obtained from the difference between the RCV calculated from the measurement of the blood sample that has been collected 2–3 min after the injection of labelled cells and that measured after mixing has been completed (i.e. after a delay of 20 min). The splenic RCV can be estimated more accurately by quantitative scanning, following injection of viable red cells labelled with ^{99m}Tc.[20] The blood volume is measured in the usual way using 100 MBq of ^{99m}Tc. The splenic area is scanned 20 min after the injection or after 60 min when there is splenomegaly. To delineate the spleen more precisely, it may be necessary to carry out a second scan after an injection of heat-damaged labelled red cells (see p. 362). From the radioactivity in the spleen, relative to that in a standard, and with knowledge of the total RCV, the proportion of the total RCV contained in the spleen can be calculated. This technique has also been used for demonstrating localised accumulation of blood in haemangiomas in the liver,[21] telangiectasia and other vascular abnormalities.[22]

FERROKINETICS

Whereas much can be learned about the rate and efficiency of erythropoiesis from the red cell count and reticulocyte counts, studies of iron metabolism and measurement of red cell lifespan with radioactive isotopes may provide useful additional information. However such analysis is now rarely used and the reader is therefore referred to the previous edition of this book for further information. (^{59}Fe is not available at present from the former supplier, Amersham plc, but has been available from POLATOM, www.polatom.pl).

ESTIMATION OF THE LIFESPAN OF RED CELLS *IN VIVO*

There is extensive literature on the survival of red cells in haemolytic anaemias using radioisotope labelling of red cells (see review by Bentley and Miller[23]). Although now undertaken less frequently than in the past, measurement of red cell survival can still provide important data in cases of anaemia in which increased haemolysis is suspected but not clearly demonstrated by other tests. In the usual procedure, a population of circulating red cells of all ages is labelled ('random labelling'). Cohort labelling of red cells is no longer used.

Radioactive chromium (^{51}Cr) method

Radioactive chromium (^{51}Cr) is a γ-ray emitter with a half-life of 27.8 days. As a red cell label, it is used in the form of hexavalent sodium chromate. After passing through the surface membrane of the red cells, it is reduced to the trivalent form that binds to protein, preferentially to the β-globin chains of haemoglobin.[24] In this form, it is not reutilised or transferred to other cells in the circulation.

The main disadvantage of ^{51}Cr is that it gradually elutes from red cells as they circulate; there may be, too, an increased loss over the first 1–3 days and uncertainty as to how much has been lost makes it impossible to measure red cell lifespan accurately. Chromium, whether radioactive or nonradioactive, is toxic to red cells, probably by its oxidising actions; it inhibits glycolysis in red cells

when present at a concentration of 10 µg/ml or more[25] and blocks glutathione reductase activity at a concentration exceeding 5 µg/ml.[26] Blood should thus not be exposed to >2 µg of chromium per ml of packed red cells.

$Na_2^{51}CrO_4$ is available commercially (www.polatom.pl) at a specific activity of about 15–20 GBq/mg Cr. For administration, the stock solution usually must be dissolved in 9 g/l NaCl (saline) (see below). ACD must not be used as a diluent because this reduces the chromate to the cationic chromic form.

Care must be taken to avoid lysis when the red cells are washed; it may be necessary, especially if the red cells are spherocytic, to use a slightly hypertonic solution (e.g. 12 g/l NaCl). This should certainly be used if an osmotic fragility test has demonstrated lysis in 9 g/l NaCl. In patients whose plasma contains high-titre, high-thermal-amplitude cold agglutinins, the blood must be collected in a warmed syringe and delivered into ACD solution previously warmed to 37 °C; the labelling and washing in saline should be carried out in a 'warm room' at 37 °C.

Method

The technique of labelling red cells is the same as for TBV measurement (see p. 355).[27] To ensure as little damage to red cells as possible, with subsequent minimal early loss and later elution, it is important to maintain the blood at an optimal pH. This can be achieved by adding 10 volumes of blood to 1.5 volumes of NIH-A ACD solution (see p. 561).

For a red cell survival study, 0.02 MBq per kg body weight (an average total dose of *c*2 MBq) is recommended. If this is to be combined with a spleen scan or pool measurement, a higher dose (4 MBq) should be used, bearing in mind that <2 µg of chromium should be added per ml of packed red cells.

After injection, allow the labelled cells to circulate in the recipient for 10 min (or for 60 min in patients with cardiac failure or splenomegaly, in whom mixing may be delayed). Then collect a sample of blood from a vein other than that used for the injection (or after washing the needle through with saline if a butterfly needle is used) and mix with EDTA as anticoagulant. The radioactivity in this sample provides a baseline for subsequent observations. Retain part of the labelled cell suspension that was not injected into the patient to serve as a standard. This enables the blood volume to be calculated if required.

Take further 4–5 ml blood samples from the patient 24 h later (day 1) and subsequently at intervals, the frequency of the samples depending on the rate of red cell destruction: in general, three specimens between day 2 and day 7 and then two specimens per week for the duration of the study. Measurements should be continued until at least half the radioactivity has disappeared from the circulation.

Measure the Hb or PCV in a part of each sample; then lyse the samples with saponin, mix well and deliver 1 ml into counting tubes, if possible in duplicate.

Measurement of radioactivity

Estimate the percentage survival (of ^{51}Cr) on any day (t) by comparing the radioactivity of the sample taken on that day with that of the day 0 sample (i.e. the sample withdrawn 10 (or 60) min after the injection of the labelled cells). Thus ^{51}Cr survival on day t (%) is given by the following:

$$\frac{\text{cpm/ml of blood on day t}}{\text{cpm/ml blood on day 0}} \times 100$$

No adjustment is necessary for the physical decay of the isotope, provided that the samples and the standard are counted within a few minutes of each other.

Carry out the measurements in any high-quality scintillation counter, at least 2500 counts being recorded to achieve a precision within ±2%.

Processing of radioactivity measurements

Before the data can be analysed and interpreted, factors, other than physical decay, that are involved in the disappearance of radioactivity from the circulation have to be considered. There are two processes: ^{51}Cr-labelled cells are lost from the circulation by lysis, phagocytosis or haemorrhage and, in addition, ^{51}Cr is eluted from intact red cells that still circulate.

Elution

The rate of elution differs to a small extent from one individual to another. It is thought to vary to a greater extent between different diseases, especially when the red cell lifespan is considerably reduced. However in such cases, elution and variation in the rate of elution become unimportant. The rate of elution is also influenced by technique, especially by the anticoagulant solution into which the blood is collected prior to labelling. With the NIH-A ACD solution, the rate of elution is about 1% per day.[27]

Early loss

Sometimes, in addition to the elution that occurs continuously and at a relatively low and constant rate, up to 10% of the ^{51}Cr is lost within the first 24 h. The cause of this major early loss is obscure and several components may be involved. If this major loss does not continue beyond the first 2 days, it is often looked on as an artefact, in the sense that it does not denote an increased rate of lysis *in vivo,* and it can be ignored by replotting the figures as described on p. 361. This procedure is acceptable, at least for clinical studies, but it does not take into account the possibility that a small proportion of red cells are present that lyse rapidly. It is common practice to calculate the $T_{50}Cr$ (i.e. the time taken for the concentration of ^{51}Cr in the blood to fall to 50% of its initial value) after correcting the data for physical decay but not for elution. T_{50} is used rather than ($T_{½}$) because the elimination of the label is

not a constant exponential fraction of the original amount. The chief objection to the use of T_{50}Cr is that it may be misleading without additional information on the pattern of the survival curve. Moreover, the mean red cell lifespan cannot be directly derived from it. With the technique described earlier, the mean value of T_{50} in normal subjects is 30 days, with a range of 25–33 days (Table 17-3).

Correction for elution

When haemolysis is marked, elution is of minor importance and can be ignored. When haemolysis is not greatly increased, it is essential to correct for elution. This can be done by multiplying the measured survival by the factors given in Table 17-3.

Survival curves

Normal red cell survival (corrected for elution) will be in the range shown in Figure 17-3. When survival is reduced, a survival curve should be drawn and from this the mean red cell lifespan can be derived.

TABLE 17-3

NORMAL RANGE FOR ^{51}CR SURVIVAL CURVES WITH CORRECTION FOR ELUTION

Day	% ^{51}Cr (Corrected for Decay; Not Corrected for Elution)	Elution Correction Factors*
1	93–98	1.03
2	89–97	1.05
3	86–95	1.06
4	83–93	1.07
5	80–92	1.08
6	78–90	1.10
7	77–88	1.11
8	76–86	1.12
9	74–84	1.13
10	72–83	1.14
11	70–81	1.16
12	68–79	1.17
13	67–78	1.18
14	65–77	1.19

35	39–47	1.53
40	34–42	1.60

*To correct for elution, multiply the % ^{51}Cr by the elution factor for the particular day.

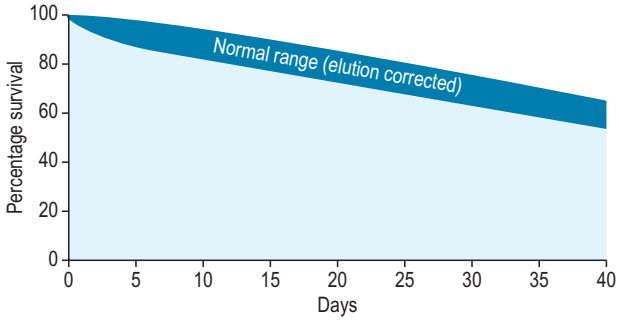

FIGURE 17-3 **^{51}Cr red cell survival.** The filled area shows the normal range.

Plot the % radioactivity figures or count rates per ml of whole blood (corrected for physical decay and for elution) on arithmetic and semi-logarithmic graph paper and attempt to fit straight lines passing through the data points.

1. If a straight line can be fitted to the arithmetic plot, the mean red cell lifespan is given by the point in time at which the line or its extension cuts the abscissa (Fig. 17-4).
2. As a rule, however, a straight line is better fitted to the semi-logarithmic plot; the mean red cell lifespan can be read as the exponential e^{-1} (that is, the time when 37% of the cells are still surviving, Fig. 17-5) or calculated by multiplying the half-time of the fitted line by the reciprocal of the natural log of 2 (0.693) (i.e. multiplying by 1.44).

A computer programmed curve-fitting procedure is more precise but is not likely to improve overall accuracy of the results for clinical purposes.

Interpretation of survival curves

In the autoimmune haemolytic anaemias, the slope of elimination is usually markedly curvilinear when the data are plotted on arithmetic graph paper. Red cell destruction is typically random and the curve of elimination is thus

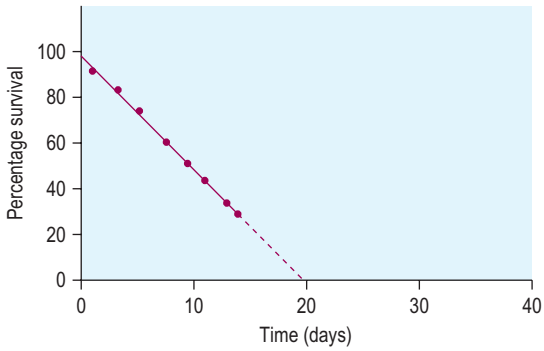

FIGURE 17-4 **^{51}Cr red cell survival curve.** Patient with hereditary spherocytosis. The results give a straight line when plotted on arithmetic graph paper. The mean cell lifespan is indicated by the point at which its extension cuts the abscissa (20 days).

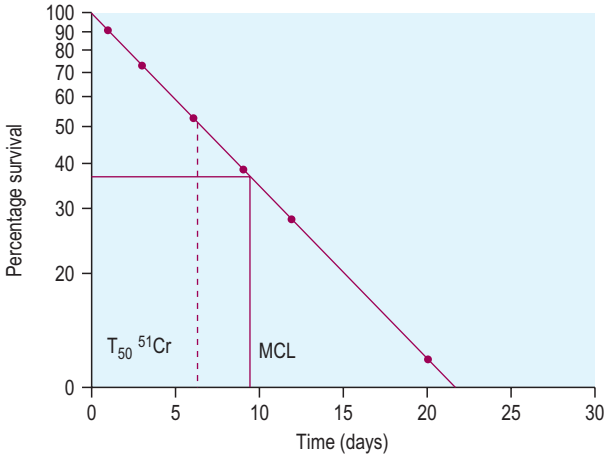

FIGURE 17-5 **^{51}Cr red cell survival curve.** Patient with autoimmune haemolytic anaemia. The results have been plotted on semi-logarithmic graph paper and the mean cell lifespan was read as the time when 37% of the cells were still surviving (9–10 days). The T_{50}Cr was 6–7 days. MCL, mean cell lifespan.

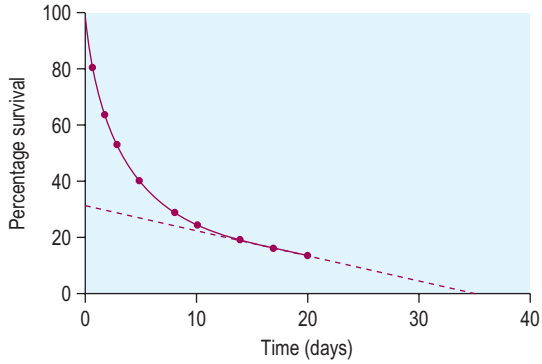

FIGURE 17-6 **^{51}Cr red cell survival curve showing a 'double population'.** By plotting the data on semilogarithmic graph paper as described in Figure 17-7, the mean cell lifespan (MCL) of the entire cell population was deduced as 5 days. When plotted on arithmetic graph paper, by extrapolation of the less steep slope to the ordinate it was calculated that approximately 30% of the red cells belonged to one population, and by extrapolation of the same slope to the abscissa the MCL of this population was calculated as 35 days. The lifespan of the remaining 70% of cells was calculated to be 3.6 days (see text for formula). The T_{50}Cr was 3–4 days.

exponential and the data give a straight line when plotted on semi-logarithmic graph paper.

In some cases of haemolytic anaemia (possibly only when there are intra-corpuscular defects), the survival curve appears to consist of two components, an initial steep slope followed by a much less steeply falling slope. This suggests the presence of cells of widely varying lifespan. This type of 'double population' curve is seen in paroxysmal nocturnal haemoglobinuria, in sickle cell anaemia, in some cases of hereditary enzyme-deficiency haemolytic anaemia and when the labelled cells consist of a mixture of transfused normal cells and short-lived patient's cells. The mean cell lifespan of the entire cell population can be deduced by plotting the points on semi-logarithmic graph paper, as described earlier. The proportion of cells belonging to the longer-lived population can be estimated by plotting the data on arithmetic graph paper and extrapolating the less steep slope back to the ordinate; the lifespan of this population can be estimated by extending the same slope to the abscissa (Fig. 17-6). The lifespan of the short-lived cells can be deduced from the formula:

$$\text{MCLs} = \frac{\%S}{\frac{100}{\text{MCL}_T} - \frac{\%L}{\text{MCL}_L}}$$

where S = short-lived population, L = longer-lived population, T = entire cell population and MCL = mean cell lifespan.

Correction for early loss

The simplest method is to ignore the early loss by taking as 100% the radioactivity still present at the end of 24–48 h. Alternatively, the following method can be used; it has the advantage that the slope of the survival curve is not altered. Plot the data on arithmetic graph paper, extrapolate the line of the slope beyond the initial steep part back to the ordinate and take the point of intersection as 100%; then calibrate the ordinate scale accordingly.

Blood volume changes

There is no need to correct the measurements of radioactivity per ml of whole blood for alterations in PCV provided that the total blood volume remains constant throughout the study. However, if it is suspected that the TBV is changing (e.g. in patients suffering from haemorrhage or being transfused), serial determinations of TBV should be carried out and the observed radioactivity should be multiplied by the observed TBV and divided by the initial TBV. In practice, if a patient receives a blood transfusion during a survival study, it can, as a general rule, be assumed that the TBV will have returned to its pre-transfusion level within 24–48 h.

Correction of survival data for blood loss

When there is a relatively constant loss of blood during a red cell survival study, the true mean red cell lifespan (MCL) can be obtained by the following equation:

$$\text{True MCL} = \frac{\text{Ta} \times \text{RCV}}{\text{RCV} - (\text{Ta} \times \text{L})}$$

where Ta = apparent MCL (days), RCV = red cell volume (ml) and L = mean rate of loss of red cells (ml/day).

Normal red cell lifespan

The mean red cell lifespan in health is usually taken as 120 days.

Determination of sites of red cell destruction using ^{51}Cr

Because ^{51}Cr is a γ-ray emitter, the sites of destruction of red cells, with special reference to the spleen and liver, can be determined by *in vivo* surface counting using a shielded scintillation counter placed, respectively, over the heart, spleen and liver. This procedure is laborious, but occasionally it provides clinically useful information on the role of the spleen in various types of haemolytic anaemia, especially by predicting response to splenectomy.[28]

COMPATIBILITY TESTING

The behaviour of labelled donor cells in a recipient can provide information on the compatibility or otherwise of donor blood when the results of serology are not clear. This test is now rarely performed and for details the reader is referred to the previous edition of this book.

VISUALISATION OF THE SPLEEN BY SCINTILLATION SCANNING

Anatomical features of organs, including the spleen, are usually studied in radiology or nuclear medicine departments by means of magnetic resonance imaging (MRI), computed tomography imaging (CT scans) or ultrasound imaging. Imaging of radioisotope-labelled red cells provides an alternative functional method. If red blood cells labelled with ^{99m}Tc are heat damaged, they will be selectively removed by the spleen. ^{99m}Tc-labelled colloid is also removed from the circulation by the spleen, but this is not as specific because it is also taken up by reticuloendothelial cells in the liver and elsewhere. The rate of uptake of the isotope by the spleen is a measure of its function (see below). Imaging by scintillation scanning is usually started about 1 h after the injection of the damaged cells, but it can be performed up to 3–4 h later. Accumulation of radioactivity within the spleen after administration of heat-damaged labelled cells thus provides a means of demonstrating spleen size and position, whether splenic function is absent or reduced and whether splenunculi are present. Satisfactory scans can also be obtained with ^{51}Cr or ^{111}In.

Method

With ^{99m}Tc as the label, carry out pre-tinning *in vivo* by an injection of a stannous compound as described on p. 356. Then collect 5–10 ml of blood into a sterile bottle containing 100 iu of heparin. Wash twice in sterile 9 g/l NaCl (saline), centrifuging at 1200–1500 *g* for 5–10 min. Transfer 2 ml of the packed red cells to a 30 ml glass bottle with a screw cap; heat the bottle in a water bath at a constant temperature of 49.5–50 °C for exactly 20 min with occasional gentle mixing. Wash the cells in saline until the supernatant is free from haemoglobin and discard the final supernatant. Label with 40 MBq of ^{99m}Tc by the method described on p. 356. After it has stood for 5 min, wash twice in saline. Resuspend in about 10 ml of saline and inject as soon as possible. After about 1 h carry out a gamma camera scan.[29]

Spleen function

Information on splenic activity may be obtained by measuring the rate of clearance of heat-damaged labelled red cells from the circulation. A blood sample is taken exactly 3 min after the midpoint of the injection and further samples are collected at 5-min intervals for 30 min, at 45 min and finally at 60 min. The radioactivity in each sample is measured and expressed as a percentage of the radioactivity in the 3-min sample. The results are plotted on semi-logarithmic graph paper, the 3-min sample being taken as 100% radioactivity. For consistent results, a carefully standardised technique is necessary to ensure that the red cells are damaged to the same extent.

The disappearance curve is, as a rule, exponential (Fig. 17-7). The initial slope reflects the splenic blood flow; the rate of blood flow is calculated as the reciprocal of the time taken for the radioactivity to fall to half the 3-min value

$$\left(\text{i.e.}\,\frac{0.693}{T_{½}}\right),$$

where 0.693 is the natural log of 2.

When the spleen is functioning normally, the $T_{½}$ is 5–15 min and fractional splenic blood flow is 0.05–0.14 ml/min (i.e. 5–14% of the circulating blood per min). The clearance rate is considerably prolonged in some

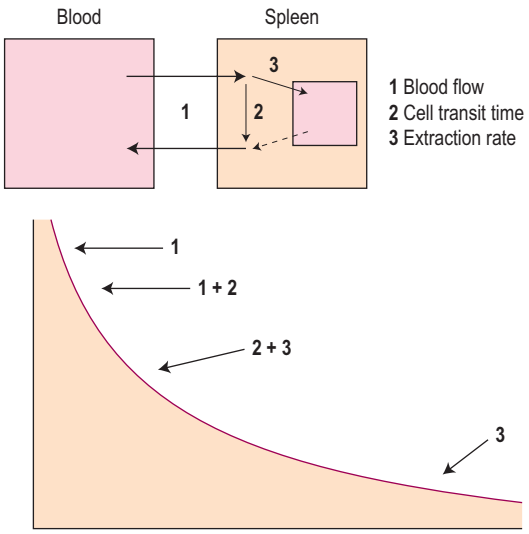

FIGURE 17-7 Curve of disappearance of heat-damaged red cells from the circulation. The curve shows the sequence of blood flow, transient pooling, sequestration and irreversible trapping of cells.

patients with thrombocythaemia and in other conditions associated with splenic atrophy such as sickle cell anaemia, coeliac disease and dermatitis herpetiformis.[18] It thus provides some indication of spleen function. However, the disappearance curve is a complex of at least two components. The first (mentioned earlier) reflects the splenic blood flow and the second component mainly measures cell trapping, the consequence of both transient sequestration and phagocytosis with irreversible extraction of the cells from circulation.[30,31] Measurement of phagocytosis alone is obtained more reliably with immunoglobulin G (IgG) (anti-D)-coated red cells.[32]

LEUCOCYTE IMAGING

The main diagnostic value of ^{111}In-labelled granulocyte scintigraphy is to localise specific sites of infection and abscesses and, in investigation of patients with fever of unknown origin, to rule out an infectious cause for the fever.[33] For this it is necessary to prepare a granulocyte concentrate separated from other leucocytes (see p. 58). This is then labelled with ^{111}In in a procedure similar to that for labelling platelets (see p. 363)[34] and administered. The sites of granulocyte accumulation are shown by gamma camera scan.

MISCELLANEOUS IMAGING

In addition to the radioisotopes discussed earlier, there are other radioisotopes that can be used to provide information in haematological disorders. For example, ^{18}F-FDG (fluorine-18 fluorodeoxyglucose), a tracer of glucose metabolism, with PET scanning can be useful in the assessment of tumour metabolism.[35,36] The information generated can assist in clinical staging of patients with malignancies, including lymphomas. Malignant tissue shows enhanced uptake of this tracer and this information can be used to monitor progress of patients receiving chemotherapy. Similarly, other more mainstream radiological investigations can be useful in the management of haematological diseases. For example, MRI can assist in monitoring the progress of patients with lymphoma and myeloma. In the management of patients with iron overload, MRI scans (by specified imaging method T2) can provide important information on liver and cardiac iron that can be used to optimise iron chelation regimens.[37]

MEASUREMENT OF BLOOD LOSS FROM THE GASTROINTESTINAL TRACT

The ^{51}Cr method of red cell labelling can be used to quantitate blood lost into the gastrointestinal tract because ^{51}Cr is neither excreted nor more than minimally reabsorbed. Accordingly when the blood contains ^{51}Cr-labelled red cells, faecal radioactivity is at a very low level unless bleeding has taken place somewhere within the gastrointestinal tract. Measurement of the faecal radioactivity then gives a reliable indication of the extent of the blood loss.

Method

Label the patient's own blood with approximately 4 MBq of ^{51}Cr, as described on p. 355. On each day of the test, collect the faeces in plastic or waxed cardboard cartons. Prepare a standard by adding a measured volume (3–5 ml) of the patient's blood, collected on each day, to approximately 100 ml of water in a similar carton. Compare the radioactivity of the faecal samples and the corresponding daily standard in a large-volume counting system (see p. 353). Then:

$$\text{Volume of blood in faeces (in ml)} = \frac{\text{cpm/24 hour faeces collection}}{\text{cpm/ml standard}}$$

Blood loss from any other source (e.g. surgical operation or menstruation) can be measured in a similar way by counting swabs, dressings and so on placed in a carton. It is not, however, possible to measure blood or haemoglobin loss in the urine (haematuria or haemoglobinuria) by this method because free ^{51}Cr is normally excreted in the urine.

An imaging procedure has also been described in which blood is labelled with ^{99m}Tc and a large-field scintillation scan is performed after 60–90 min and, if necessary, again at intervals for 24 h.[38]

MEASUREMENT OF PLATELET LIFESPAN

Principle

The procedure for measuring platelet lifespan is broadly similar to that for red cell survival (see p. 358). A method using ^{111}In-labelled platelets was recommended by ICSH.[39] A modification of this method especially for use with low platelet counts[40] is described in the following.

Method

Collect 51 ml of blood into 9 ml of NIH-A ACD (see p. 561); a proportionately lower amount is required if the platelet count is normal or high. Distribute the blood equally into three 30 ml polystyrene tubes, each containing 2 ml of 60 g/l hydroxyethyl starch (Hetastarch Novaplus, www.novaplus.com). Mix and immediately centrifuge at 150 *g* for 10 min. Transfer the supernatant platelet-rich plasma into clean centrifuge tubes and add ACD, 1 volume to 10 volumes of the platelet-rich plasma. If necessary, centrifuge again at 150 *g* for 5 min to remove residual red cells.[40]

Centrifuge the platelet-rich plasma at 640 *g* for 10 min to obtain platelet pellets. Carefully remove the supernatant plasma but do not discard. Add 1 ml of this platelet-poor plasma to the platelet pellets, gently tap the tubes to resuspend and pool the contents.

Prepare a solution of tropolone, 4.4 mmol/l (0.54 mg/ml) in HEPES-saline buffer, pH 7.6 (see p. 563). Mix 0.1 ml with 8 MBq (250 μCi) of ^{111}InCl in <50 μl of 40 mmol/l HCl. Add the platelet suspension with gentle mixing and leave at room temperature for 5 min. Then add 5 ml of platelet-poor plasma. Centrifuge at 640 *g* for 10 min. Remove the supernatant and resuspend the platelet pellet in 5 ml of platelet-poor plasma. Take up the platelet suspension into a 10 ml plastic syringe.

Add 0.5 ml of the platelet suspension to 100 ml of water in a volumetric flask as a standard. Weigh the syringe, inject the platelets into the patient through a butterfly needle and reweigh.

$$\text{Volume injected} = \text{Wt}\,(\text{g}) \times 1 / 1.015$$

where 1.015 is the specific gravity of plasma.

Collect 5 ml blood samples in EDTA at 45 min and at 2, 3 and 4 h after injection and then daily for up to 10 days.

Measure the PCV/Hct and centrifuge part of each sample at 1500 *g* for 10 min to obtain cell-free plasma.

Lyse part of the whole blood sample with 2% saponin and measure the radioactivity in 1 ml sample of whole blood, plasma and diluted standard.

From radioactivity in 1 ml of whole-blood sample subtract the radioactivity in 1 ml of plasma, corrected for the true volume of plasma in 1 ml of whole blood (i.e. 1-PCV/Hct).

Calculation of platelet recovery at each sampling time

$$\frac{\text{cpm/ml blood sample (corrected for plasma activity)} \times \text{Total BV}\,(\text{ml})}{\text{cpm/ml standard} \times \text{dilution of standard} \times \text{volume injected}}$$

NOTE: If total blood volume is not measured, an approximate estimate can be obtained from the subject's height and weight.[41]

Analysis of data

Plot the percentage survival against time on arithmetic graph paper and estimate the survival time as for red cell survival (see p. 360).

By this method, normal platelet lifespan is 8–10 days, but the validity of the analysis is based on the assumption that the blood volume is constant and the pattern of disappearance of platelets from the circulation remains constant during the course of the study.

Platelet survival in disease

In autoimmune ('idiopathic') thrombocytopenia purpura, platelet lifespan is considerably reduced. It is also shortened in consumption coagulopathies and in thrombotic thrombocytopenic purpura. In thrombocytopenia resulting from defective production of platelets, the lifespan should be normal, provided that platelets are not being lost by bleeding during the course of the study. In thrombocytopenia resulting from splenomegaly, the recovery of injected labelled platelets is low, but their survival is usually almost normal. By quantitative scanning with ^{111}In, it is possible to measure the splenic platelet pool and to distinguish the relative importance of pooling and destruction of platelets in the spleen.[42–44] The splenic platelet pool is normally about 30% of the total platelet population and it is thought that each platelet spends one-third of its lifespan in the spleen. The size of the pool is increased in splenomegaly, resulting in thrombocytopenia but not necessarily in a reduced mean platelet lifespan.

Investigation of Haemostasis

Michael A. Laffan • Richard A. Manning

CHAPTER OUTLINE

COMPONENTS OF NORMAL HAEMOSTASIS

The haemostatic mechanisms have several important functions: (1) to maintain blood in a fluid state while it remains circulating within the vascular system; (2) to arrest bleeding at the site of injury or blood loss by formation of a haemostatic plug; (3) to limit this process to the vicinity of the damage and (4) to ensure the eventual removal of the plug whilst healing is completed. Normal physiology thus constitutes a delicate balance between these conflicting tendencies, and a deficiency or exaggeration of any one may lead to either thrombosis or haemorrhage. There are at least five different components involved: blood vessels, platelets, plasma coagulation factors and their inhibitors and the fibrinolytic system. In this chapter a brief review of normal haemostasis is presented followed by a discussion on the general principles of basic tests used to investigate haemostasis and bleeding disorders.

The blood vessel

General structure of the blood vessel

The blood vessel wall has three layers: intima, media and adventitia. The intima consists of endothelium and subendothelial connective tissue and is separated from the media by the elastic lamina interna. Endothelial cells form a continuous monolayer lining all blood vessels. The structure and the function of the endothelial cells vary according to their location in the vascular tree, but in their resting state they all share three important characteristics: they are 'nonthrombogenic' (i.e. they promote maintenance of blood in its fluid state), they play an active role in supplying nutrients to the sub-endothelial structures and they act as a barrier to cells, macromolecules and particulate matter circulating in the bloodstream. The permeability of the endothelium may vary under different conditions to allow various molecules and cells to pass.

Endothelial cell function

The luminal surface of the endothelial cell[1] is covered by the glycocalyx, a proteoglycan coat. It contains heparan sulphate and other glycosaminoglycans, which are capable of activating antithrombin, an important inhibitor of coagulation enzymes. Tissue factor pathway inhibitor (TFPI) is present on endothelial cell surfaces, mostly in a truncated form covalently linked to a glycophosphoinositol (GPI) anchor (TFPIbeta) although some full length TFPI (TFPIalpha) is also present and noncovalently bound. Endothelial cells express a number of coagulation-active proteins that play an important regulatory role, such as thrombomodulin and the endothelial protein C (PC) receptor. Thrombin diffusing away from the site of injury is rapidly bound to thrombomodulin which can then activate PC bound to the endothelial protein C receptor (EPCR) and a carboxypeptidase which inhibits fibrinolysis (discussed later). Thrombin also stimulates the endothelial cell to produce tissue

plasminogen activator (tPA). The endothelium can also synthesise protein S, the cofactor for PC. Finally, endothelium produces von Willebrand factor (VWF) which is essential for platelet adhesion to the subendothelium and stabilises factor VIII (FVIII) within the circulation. VWF is both stored in specific granules called Weibel Palade bodies and secreted constitutively, partly into the circulation and partly toward the subendothelium where it binds directly to collagen and other matrix proteins. The expression of these and other important molecules such as adhesion molecules and their receptors are modulated by inflammatory cytokines. The lipid bilayer membrane also contains adenosine diphosphatase (ADPase), an enzyme that degrades adenosine diphosphate (ADP), which is a potent platelet agonist (see p. 401). Many of the surface proteins are found localised in the specialised lipid rafts and invaginations called caveolae which may provide an important level of regulation.[2]

The endothelial cell participates in vasoregulation by producing and metabolising numerous vaso-active substances. On one hand it metabolises and inactivates vasoactive peptides such as bradykinin, on the other hand, it can also generate angiotensin II, a local vasoconstrictor, from circulating angiotensin I. Under appropriate stimulation the endothelial cell can produce vasodilators such as nitric oxide (NO) and prostacyclin or vasoconstrictors such as endothelin and thromboxane. These substances have their principal vasoregulatory effect via the smooth muscle but also have some effect on platelets.

The subendothelium consists of connective tissues composed of collagen (principally types I, III and VI), elastic tissues, proteoglycans and noncollagenous glycoproteins, including fibronectin and VWF. After vessel wall damage has occurred, these components are exposed and are then responsible for platelet adherence. At low shear platelets can bind to collagen but in practice this appears to be largely mediated by VWF binding to collagen. VWF bound to collagen undergoes a conformational change and platelets are captured via their surface membrane glycoprotein Ib binding to VWF. Platelet activation follows, and a conformational change in glycoprotein IIbIIIa allows further, more secure, binding to VWF via this receptor as well as to fibrinogen.[3]

Vasoconstriction

Vessels with muscular coats contract following injury thus helping to arrest blood loss. Although not all coagulation reactions are enhanced by reduced flow, this probably assists in the formation of a stable fibrin plug by allowing activated factors to accumulate to critical concentrations. Vasoconstriction[1,4] also occurs in the microcirculation in vessels without smooth muscle cells. Endothelial cells themselves can produce vasoconstrictors such as angiotensin II. In addition, activated platelets produce thromboxane A_2 (TXA_2), which is a potent vasoconstrictor.

Platelets

Platelets[5] are small fragments of cytoplasm derived from megakaryocytes. On average they are 1.5 to 3.5 μm in diameter but may be larger in some disease states. They do not contain a nucleus and are bounded by a typical lipid bilayer membrane. Beneath the outer membrane lies the marginal band of microtubules, which maintain the shape of the platelet and depolymerise when aggregation begins. The central cytoplasm is dominated by the three types of platelet granules: the δ (dense) granules, α granules and lysosomal granules. The contents of these various granules are detailed in Table 18-1. Finally there exist the dense tubular system and the canalicular membrane system; the latter communicates with the exterior.

The platelet membrane is the site of interaction with the plasma environment and with the damaged vessel wall. It consists of phospholipids, cholesterol, glycolipids and at least nine glycoproteins (GP), named GPI to GPIX. The membrane phospholipids are asymmetrically distributed, with sphingomyelin and phosphatidylcholine predominating in the outer leaflet and phosphatidylethanolamine, -inositol and -serine in the inner leaflet. After platelet activation, phosphatidylserine is exposed on the outer membrane surface to support assembly of coagulation factor complexes.

The contractile system of the platelet consists of the dense microtubular system and the circumferential microfilaments, which maintain the disc shape. Actin is the main constituent of the contractile system, but myosin and a regulatory calcium-binding protein, calmodulin, are also present.

TABLE 18-1

SOME CONTENTS OF PLATELET GRANULES

Dense (δ) Granules	α Granules	Lysosomal Vesicles
ATP	PF4	Galactosidases
ADP	VWF	Fucosidases
Calcium	β-thromboglobulin	Hexosaminidase
Serotonin	Fibrinogen	Glucuronidase
Pyrophosphate	Factor V	Cathepsin
P selectin (CD62)	Thrombospondin	Glycohydrolases
Transforming growth factor-beta (1)	Fibronectin	+ others
	PDGF	
	PAI-1	
Catecholamines (epinephrine/ norepinephrine)	Histidine-rich glycoprotein	
	α_2 Macroglobulin	
GDP/GTP	Plasmin inhibitor	
	P selectin (CD62)	

ADP, adenosine 5′-diphosphate; ATP, adenosine 5′-triphosphate; GDP, guanosine 5′-diphosphate; GTP, guanosine 5′-triphosphate; PAI-1, plasminogen activator inhibitor-1; PDGF, platelet-derived growth factor; PF4, platelet factor 4; VWF, von Willebrand factor.

Platelet function in the haemostatic process

The main steps in platelet functions are adhesion, activation with shape change and aggregation.[6] When the vessel wall is damaged, the subendothelial structures, including basement membrane, collagen and microfibrils, are exposed. VWF binds to collagen and microfibrils and then captures platelets via initial binding to platelet GPIb, resulting in an initial monolayer of adherent platelets. Binding via GPIb initiates activation of the platelet via a G-protein mechanism. Once activated, platelets immediately change shape from a disc to a sphere with numerous projecting pseudopods. After adhesion of a single layer of platelets to the exposed subendothelium, platelets stick to one another to form aggregates. Fibrinogen, fibronectin, further VWF released from platelets and the glycoprotein IbIX and IIbIIIa complexes are essential at this stage to increase the cell-to-cell contact and facilitate aggregation. Positive feedback is provided by platelet release of ADP, 5-hydroxytryptamine (5HT) and thromboxane. In areas of nonlinear blood flow, such as may occur at the site of an injury, locally damaged red cells release ADP, which further activates platelets.

Platelet aggregation

Platelet aggregation may occur by at least two independent but closely linked pathways. The first pathway involves arachidonic acid metabolism. Activation of phospholipase enzymes (PLA_2) releases free arachidonic acid from membrane phospholipids (phosphatidyl choline). About 50% of free arachidonic acid is converted by a lipo-oxygenase enzyme to a series of products including leucotrienes, which are important chemoattractants of white cells. The remaining 50% of arachidonic acid is converted by the enzyme cyclooxygenase into labile cyclic endoperoxides, most of which are in turn converted by thromboxane synthetase into TXA_2. TXA_2 has profound biological effects, causing secondary platelet granule release and local vasoconstriction, as well as further local platelet aggregation via the second pathway below. It exerts these effects by raising intracellular cytoplasmic free calcium concentration and binding to specific granule receptors. TXA_2 is very labile with a half-life of less than 1 min before it is degraded into the inactive thromboxane B_2 (TXB_2) and malonyldialdehyde.

The second pathway of activation and aggregation can proceed completely independently from the first one: various platelet agonists, including thrombin, ADP, TXA_2 and collagen, bind to receptors and via a G-protein mechanism, activate phospholipase C. This generates diacylglycerol and inositol triphosphate, which in turn activate protein kinase C and elevate intracellular calcium, respectively. Calcium is released from the dense tubular system to form complexes with calmodulin. This complex and the free calcium act as coenzymes for the release reaction, for the activation of different regulatory proteins and of actin and myosin and the contractile system and also for the liberation of arachidonic acid from membrane phospholipids and the generation of TXA_2.

The aggregating platelets join together into loose reversible aggregates, but after the release reaction of the platelet granules, larger, firmer aggregates form. Changes in the platelet membrane configuration now occur; 'flip-flop' rearrangement of the surface brings the negatively charged phosphatidyl-serine and -inositol on to the outer leaflet, thus generating platelet factor 3 (procoagulant) activity. At the same time specific receptors for various coagulation factors are exposed on the platelet surface and help coordinate the assembly of the enzymatic complexes of the coagulation system. Local generation of thrombin will then further activate platelets.

The resting endothelium helps maintain platelets in a nonactivated state by secreting prostacyclin and NO. Prostacyclin released locally binds to specific platelet membrane receptors and then activates the membrane-bound adenylate cyclase (producing cyclic adenosine monophosphate, or cAMP). cAMP inhibits platelet aggregation by inhibiting arachidonic acid metabolism and the release of free cytoplasmic calcium ions.

Thus platelets have several roles in haemostasis:

1. Adhesion and aggregation forming the primary haemostatic plug
2. Clot retraction
3. Release of platelet activating and procoagulant molecules
4. Provision of a procoagulant surface for the reactions of the coagulation system.

Blood coagulation

The chief product of the coagulation pathways is thrombin, which cleaves fibrinogen to produce fibrin and thus the fibrin clot.[7] This clot is further strengthened by the crosslinking action of factor XIII (FXIII), which is also activated by thrombin with fibrin acting as a cofactor. The two commonly used coagulation tests, the activated partial thromboplastin time (APTT) and the prothrombin time (PT), have defined two pathways of coagulation activation: the intrinsic and extrinsic paths, respectively. However, this bears only a limited relationship to the way coagulation is activated *in vivo*. For example, deficiencies of factor XII (FXII) or FVIII both produce marked prolongation of the APTT, but only deficiency of the latter is associated with a haemorrhagic tendency. Moreover, there is considerable evidence that activation of factor IX (FIX) (intrinsic pathway) by activated factor VII (FVIIa) (extrinsic pathway) is crucial to establishing coagulation after an initial stimulus has been provided by FVIIa-tissue factor (TF) activation of factor X (FX). See Figure 18-1.

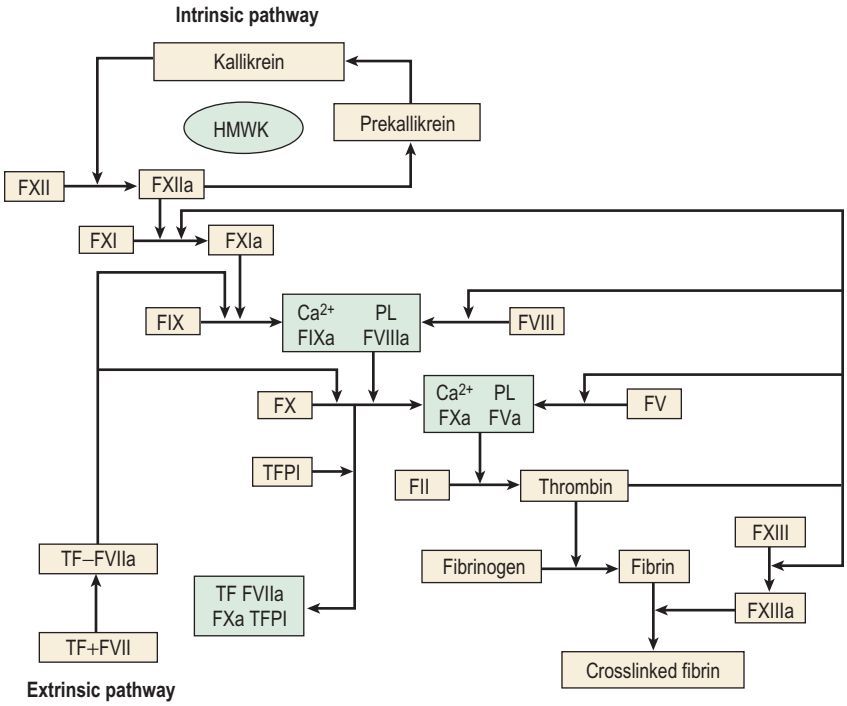

FIGURE 18-1 Schematic representation of the coagulation network. The arrows all indicate procoagulant activating actions except for the initial damping effect of TFPI. Other inhibitory factors and clot limiting mechanisms are not shown. HMWK, high molecular weight kininogen; PL, phospholipid; TFPI, tissue factor pathway inhibitor.

TABLE 18-2

THE COAGULATION FACTORS

				Concentration in Plasma	
No.	**Factor**	**RMM (Daltons)**	**Half-Life**	**µg/ml**	**nmol/l**
I	Fibrinogen	340 000	90 h	$1.5–4 \times 10^6$	–
II	Prothrombin	70 000	60 h	100–150	1400
V	–	330 000	12–36 h	5–10	20
VII	–	48 000	6 h	0.5	10
VIII	–	200 000	12 h	0.2	0.7
VWF	–	800 000–140 000 000	10–24* h	10	–
IX	–	57 000	24 h	4	90
X	–	58 000	40 h	10	170
XI	–	158 000	60 h	6	30
XII	–	80 000	48–52 h	30	375
Prekallikrein	–	85 000	48 h	40	450
HMWK	–	120 000	6.5 days	80	700
XIII	–	32 000	3–5 days	30 (A + B)	900 (tetramer)

h, hours; HMWK, high molecular weight kininogen; RMM, relative molecular mass (molecular weight); VWF, von Willebrand factor.
*The half-life of VWF varies according to the ABO blood group being shortest in O, longest in AB and intermediate in A and B.

Investigation of the coagulation system centres on the coagulation factors, but the activity of these proteins is also greatly dependent on specific surface receptors and phospholipids largely presented on the surface of platelets and also by activated endothelium. The necessity for calcium in many of these reactions is frequently used to control their activity *in vitro*. The various factors are described in the following sections, as far as possible in their functional groups; their properties are detailed in Table 18-2.

The contact activation system

The contact activation system[8] comprises FXII (Hageman factor) high molecular weight kininogen (HMWK) (Fitzgerald factor) and prekallikrein/kallikrein (Fletcher factor). As mentioned earlier, these factors are not essential for haemostasis *in vivo*. Their important activities are to activate the fibrinolytic system, to activate the complement system and to generate vasoactive peptides: in particular, bradykinin is released from HMWK by prekallikrein or FXIIa cleavage. Kallikrein and FXIIa also function as chemoattractants for neutrophils. The contact activation system also has some inhibitory effect on thrombin activation of platelets and prevents cell binding to endothelium. Recent animal evidence implicates the contact system in platelet-dependent thrombosis although a role in humans is not yet established.[9]

When bound to a negatively charged surface *in vitro*, FXII and prekallikrein are able to reciprocally activate one another by limited proteolysis, but the initiating event is not clear. It may be that a conformational change in FXII on binding results in limited autoactivation that triggers the process. HMWK acts as a (zinc-dependent) cofactor by facilitating the attachment of prekallikrein and factor XI (FXI), with which it circulates in a complex, to the negatively charged surface. There are numerous candidates for the physiological surface on which this takes place, including collagen and polyphosphate. The contact system can also activate fibrinolysis by a number of mechanisms: plasminogen cleavage, urokinase plasminogen activator (uPA) activation and tPA release. Most importantly from the laboratory point of view, the contact activation system generates FXIIa, which is able to activate FXI, thus initiating the coagulation cascade of the intrinsic pathway.

Tissue factor

TF is the cofactor for the extrinsic pathway and the physiological initiator of coagulation. It is a transmembrane protein and constitutively present in many tissues outside the vasculature and on the surface of activated monocytes and, under some conditions, endothelial cells. FVIIa binds to TF in the presence of calcium ions and then becomes enzymatically active. Small amounts of FVIIa are present in the circulation but have virtually no enzymic activity unless bound to TF. The FVIIa-TF complex can activate both FX and FIX and therefore two routes to thrombin production are stimulated. FXa subsequently binds to TFPI and then to FVIIa to form an inactive quaternary (Xa-TF-VIIa-TFPI) complex. This mechanism therefore functions to shut off the extrinsic pathway after an initial stimulus to coagulation has been provided.

The vitamin K-dependent coagulation factors are the serine proteases factors II, VII, IX and X. However the anticoagulant proteins – S, C and Z – are also vitamin K dependent. Each of these proteins contains a number of glutamic acid residues at its amino terminus that are γ-carboxylated by a vitamin K-dependent mechanism. This results in a novel amino acid, γ-carboxyglutamic acid, which by binding calcium promotes a conformational change in the protein allowing it to bind to negatively charged phospholipid. Because this binding is crucial for coordinating the interaction of the various factors, the proteins produced in the absence of vitamin K (PIVKAs) that are not γ carboxylated are essentially functionless. The vitamin K-dependent factors are zymogens which require cleavage, sometimes with release of a small peptide (activation peptide) to become functional. Measurement of these activation peptides has been used as a means of assessing coagulation activation.[10]

Cofactors

Factors VIII and V are the two most labile of the coagulation factors, and they are rapidly lost from stored blood or heated plasma. They share considerable structural homology and are cofactors for the serine proteases FIXa and FXa, respectively. They both require proteolytic activation by factor IIa or Xa to function. FVIII circulates in combination with VWF, which is present in the form of large multimers of a basic 200 kD monomer. One function of VWF is to stabilise FVIII and protect it from degradation. In the absence of VWF, the survival of FVIII in the circulation is extremely short (<2 h instead of the normal 8–12 h). VWF may also serve to deliver FVIII to platelets adherent to a site of vascular injury. Once FVIII has been cleaved and activated by thrombin it no longer binds to VWF.

Fibrinogen

Fibrinogen[11] is a large dimeric protein, each half consisting of three polypeptides named Aα, Bβ and γ held together by 12 disulphide bonds. The two monomers are joined together by a further three disulphide bonds. A variant γ chain denoted γ′ is produced by a variation in messenger RNA splicing. In the process a platelet binding site is lost and high-affinity binding sites for FXIII and thrombin are gained. The γ′ variant constitutes approximately 10% of plasma fibrinogen. A less common (<2%) α chain variant 'γE' is also produced by splice variation. Fibrinogen is also found in platelets, but the bulk of this is derived not from synthesis by megakaryocytes but from glycoprotein IIbIIIa-mediated endocytosis of plasma fibrinogen, which is then stored in alpha granules. Fibrin is formed from fibrinogen by thrombin cleavage releasing the A and B peptides. This results in fibrin monomers that then associate and precipitate forming a polymer that is the visible clot. The central E domain exposed by thrombin cleavage binds with a complementary region on the outer or D domain of another monomer. The monomers thus assemble into a staggered overlapping two-stranded fibril. More complex interactions subsequently lead to branched and thickened fibre formation making a complex mesh that binds and stabilises the primary platelet plug.

Factor XIII

The initial fibrin clot is held together by noncovalent interactions and can be deformed and resolubilised. FXIII, which is also activated by thrombin, is able to covalently crosslink these fibrin monomers. FXIII is a transglutaminase that joins a glutamine residue on one chain to a lysine on an adjacent chain. This loss of resolubility is the basis of the screening test for FXIII deficiency.

Inhibitors of coagulation

A number of mechanisms exist to ensure that the production of the fibrin clot is limited to the site of injury and the clot is not allowed to propagate indefinitely.[12,13] First there are a number of proteins that bind to and inactivate the enzymes of the coagulation cascade. Probably the first of these to become active is TFPI, which rapidly quenches the FVIIa-TF complex that initiates coagulation. It does this by combining first with FXa so that further propagation of coagulation is dependent on the small amount of thrombin that has been generated during initiation being sufficient to activate the intrinsic pathway.

The principal physiological inactivator of thrombin is antithrombin (AT, formerly ATIII), which belongs to the serpin group of proteins. This binds to factor IIa forming an inactive thrombin–antithrombin complex (TAT), which is subsequently cleared from the circulation by the liver. This process is greatly enhanced by the presence of heparin or vessel wall heparan. AT is responsible for approximately 60% of thrombin-inactivating capacity in the plasma; the remainder is provided by heparin cofactor II and less specific inhibitors such as α2 macroglobulin. AT is also capable of inactivating factors X, IX, XI and XII but to lesser degrees than thrombin.

As thrombin diffuses away from the area of damage it binds to thrombomodulin on the surface of endothelial cells. Although remaining available for binding to AT, thrombin bound to thrombomodulin no longer cleaves fibrinogen. It now has a greatly enhanced preference for PC as a substrate. PC is presented to the thrombin–thrombomodulin complex by EPCR and when activated by thrombin cleavage acts to limit and arrest coagulation by inactivating factors Va and VIIIa. This action is further enhanced by its cofactor, protein S, which does not require prior activation. The role of EPCR is particularly important in larger vessels, where the effective concentration of thrombomodulin is low. PC is subsequently inactivated by its own specific inhibitor.

The fibrinolytic system

The deposition of fibrin and its removal are regulated by the fibrinolytic system.[14] Although this is a complex multicomponent system with many activators and inhibitors, it centres on the fibrinogen- and fibrin-cleaving enzyme, plasmin. Plasmin circulates in its inactive precursor form, plasminogen, which is activated by proteolytic cleavage. The principal plasminogen activator (PA) in humans is tissue plasminogen activator, which is another serine protease. tPA and plasminogen are both able to bind to fibrin via the amino acid lysine. Binding to fibrin brings tPA and plasminogen into close proximity so that the rate of plasminogen activation is markedly increased and thus plasmin is generated preferentially at its site of action and not free in plasma. The second important physiological PA in humans is urokinase (uPA). This single-chain molecule (scuPA or pro-urokinase) is activated by plasmin or kallikrein to a two-chain derivative (tcuPA), which is not fibrin-specific in its action. However, the extent to which this is important *in vivo* is not clear, and the identification of cell surface receptors for uPA suggests that its primary role may be extravascular. The contact activation system also appears to generate some plasminogen activation via FXIIa and bradykinin-stimulated release of tPA. The cleavage products released by the action of plasmin on fibrin are of diagnostic use and are discussed later in this chapter. The activation of plasmin on fibrin is restricted by the action of a carboxypeptidase, which removes the amino terminal lysine residues to which plasminogen and tPA bind. This carboxypeptidase is activated by thrombomodulin-bound thrombin and is referred to as thrombin-activated fibrinolysis inhibitor (TAFI).

Plasminogen activator inhibitor-1 (PAI-1) is a potent inhibitor of tPA, produced by endothelial cells, hepatocytes, platelets and placenta. Levels in plasma are highly variable. It is a member of the serpin family and is active against tPA and tcuPA. A second inhibitor, PAI-2, has also been identified, originally from human placenta, but its role and importance are not yet established.

The main physiological inhibitor of plasmin in plasma is plasmin inhibitor (α2-antiplasmin), which inhibits plasmin function by forming a 1:1 complex (plasmin–antiplasmin complex, PAP). This reaction in free solution is extremely rapid but depends on the availability of free lysine-binding sites on the plasmin. Thus, fibrin-bound plasmin in the clot is not accessible to the inhibitor. Deficiencies of the fibrinolytic system are rare but have sometimes been associated with a tendency to thrombosis or haemorrhage.

GENERAL APPROACH TO INVESTIGATION OF HAEMOSTASIS

This section begins with some general points regarding the clinical and laboratory approach to the investigation of haemostasis. Following this, the basic or first-line

screening tests of haemostasis are described. These tests are generally used as the first step in investigation of an acutely bleeding patient, a person with a suspected bleeding tendency or as a precaution before an invasive procedure is carried out. They have the virtue that they are easily performed, and the patterns of abnormalities obtained point clearly to the appropriate next set of investigations. However these tests examine only a portion of the haemostatic mechanism and have limited sensitivity for the presence of significant bleeding diatheses such as von Willebrand disease (VWD) or disorders of platelets or vessels. Hence a normal 'clotting screen' should not be taken to mean that haemostasis is normal.[15]

Clinical approach

The investigation of a suspected bleeding tendency may begin from three different points:

1. *Investigating a clinically suspected bleeding tendency.* The investigation properly begins with the bleeding history, which may suggest an acquired or congenital disorder of primary or secondary haemostasis. If the bleeding history or family history is significant, appropriate specific tests and assays should be performed, notwithstanding the results of screening tests such as the PT and APTT. Considerable effort has been put into defining those aspects of clinical history that predict a significant bleeding disorder, and bleeding state questionnaires are now available.[16]
2. *Following up an abnormal first-line test.* The abnormalities already detected will determine the appropriate further investigations and are described below.
3. *Investigation of acute haemostatic failure.* This is often required in the context of an acutely ill or postoperative patient. Investigations are therefore directed toward detecting disseminated intra-vascular coagulation (DIC) or a previously undetected coagulation defect (congenital or acquired). The availability of a normal premorbid coagulation screen and further questioning to determine a bleeding history can be extremely useful in this respect.

In all cases, comprehensive clinical evaluation – including the patient's history, the family history and the family tree, as well as the details of the site, frequency and character of haemorrhagic manifestations – should be considered in conjunction with laboratory results to avoid misinterpretation. The results of the screening investigations, taken in conjunction with clinical information, usually point to the appropriate additional procedure.

Principles of laboratory analysis

As noted above the tests of coagulation performed in the laboratory are imperfect attempts to mimic *in vitro* processes that normally occur *in vivo*. More detailed investigations of coagulation proteins also require caution in their interpretation depending on the type of assay performed. These can be divided into four principal categories described below.[17]

Immunological

Immunological tests rely on the recognition of the protein in question by polyclonal or monoclonal antibodies. The antibody is coupled to a system that quantifies the extent of binding. Polyclonal antibodies lack specificity but provide relatively high sensitivity, whereas monoclonal antibodies are highly specific but produce relatively low levels of antigen binding. Immunological assays are often easy to perform, convenient for large batches and can be bought as kits with standardised controls. The obvious drawback of these assays is that they may tell you nothing about the functional capacity of the antigen detected. If possible they should always be carried out in parallel with a functional assay.

The antibody may be bound to a plate but to facilitate automation it is now often bound to microparticles. Antibody binding may then be quantified by some form of luminescence (e.g. chemiluminescence) using a secondary antibody or by changes in turbidity when particles are cross linked (immunoturbidimetric assay). Artefacts in these assays may arise from the presence of rheumatoid factor or other auto-antibodies.

Assays using chromogenic peptide substrates (amidolytic assays)

The serine proteases of the coagulation cascade have narrow substrate specificities and it is possible to synthesise a short peptide specific for each enzyme that has a dye (*p*-nitroaniline, *p*-NA) attached to the terminal amino acid.[18] When the synthetic peptide reacts with the specific enzyme, the dye is released and the rate of its release or the total amount released can be measured photometrically. This gives a measure of the enzyme activity present. Chromogenic substrate assays can be classified into direct and indirect assays. Direct assays can be further subclassified into primary assays, in which a substrate specific for the enzyme to be measured is used, and secondary assays, in which the enzyme or proenzyme measured is used to activate a second protease for which a specific substrate is available. Specific substrates are available for many coagulation enzymes. However, the substrate specificity is not absolute and most kits include inhibitors of other enzymes capable of cleaving the substrate to improve specificity. Indirect assays are used to measure naturally occurring inhibitors and some platelet factors.

The measurement of amidolytic activity is not the same as the measurement of biological activity in a coagulation assay and in some cases may not accurately reflect this. This is particularly important when dealing with the molecular variants of various coagulation factors for which a functional assay may be required. The assays can be

automated, carried out in a microtitre plate or in a tube when a spectrophotometer is used to measure the intensity of the colour development.

Coagulation assays

Coagulation assays are functional bioassays and rely on comparison with a control or standard preparation with a known level of activity. In the one-stage system optimal amounts of all the clotting factors are present except the one to be determined, which should be as near to absent as possible. The principles of bioassay, its standardisation and its limitations are considered in detail on page 386.

Coagulation assay techniques are also used in mixing tests to identify a missing factor in an emergency or to identify and quantify an inhibitor or anticoagulant. The advantage of this type of assay is that it most closely approximates the activity *in vivo* of the factor in question. However, they can be technically difficult to perform and their susceptibility to interference from other plasma components has a detrimental effect on their accuracy and precision.

Fluorescence resonance energy transfer

Fluorescence resonance energy transfer (FRET) describes the distance-dependent transfer of energy from one molecule (the donor) to a second molecule (the acceptor). The transfer of energy leads to a reduction in the donor fluorescence and increase in the acceptor fluorescence. Thus a FRET assay can be used for a function that results in separation of the two molecules. For example, FRET assays for ADAMTS13 involve a chemically modified fragment of the VWF A2 domain spanning the ADAMTS13 cleavage site.

Other assays

Other assays include measurement of coagulation factors using snake venoms, assay of ristocetin cofactor and the amide-release assay for FXIII transglutaminase activity. DNA analysis is sometimes helpful in coagulation and is described in Chapter 8.

NOTES ON EQUIPMENT

Water baths

A 37 °C water bath is required for manual coagulation tests, incubation steps and the rapid thawing of frozen specimens. Water baths should be set at 37 °C and monitored using a certified thermometer to ensure it varies by no more than ± 0.5 °C. Slight variation in temperature will markedly affect the speed of clotting reactions. A water bath with plastic or glass sides is preferable, and cross-illumination helps to determine the exact time of formation and appearance of the fibrin clot. Check that the temperature is 37 °C before and during use. Distilled water should be used to fill the water bath and maintain the water level. Records must be kept.

Refrigerators and freezers

Ensure that the temperature does not move out of the acceptable range of 4° ± 2 °C for refrigerators and −20° ± 2 °C or −80 ± 2 °C (as applicable) for freezers, rechecking during the day. Records must be kept. Freezers should maintain a constant temperature and so should not auto-defrost.

Centrifuges

Check to ensure each machine is clean before and after use. Also do a visual inspection of rotors, buckets and liners for corrosion and cracks. Thorough maintenance records should be kept.

Reagents and buffers

Attention must be paid to the age and condition of solutions. This is particularly important with the calcium chloride solution. Whenever a solution is prepared it should be correctly labelled and dated. Buffers should be inspected for bacterial growth before use: contamination with microorganisms can cause errors and assay failures as a result of the release of enzymes and other active biological substances into solution. Azide may be added as a preservative to some buffers but should not be used in reagents for platelet studies or enzyme-linked immunosorbent assay (ELISA) substrates. Chromogenic substrates should be reconstituted with sterile distilled water; contamination with bacterial enzymes may cause pNA release and yellow discolouration of the reagent. Records of batch numbers, in use dates and expiry dates should be kept.

Plastic and glass tubes

For clotting tests, 75 × 10 mm glass rimless test tubes should be used. Plastic tubes should be used for sample dilutions, storage and reagent preparation.

Pipettes

A range of graduated glass (certified Class A) and automatic pipettes must be obtained. The latter should be accurate and durable. Fluids should not be drawn into the pipette barrels and acids should not be pipetted with instruments containing metal piston assemblies, which may become pitted or corroded. Attention to technique is vital because contamination of reagents with used pipette tips may occur, there may be errors of volume as a result of fluid on the exterior of the pipette tip, or the manner of addition of a reagent may alter the results obtained. The amount of fluid drawn into the tip should be inspected visually with each pipetting procedure. Records of pipette accuracy and precision should be kept.

Stopwatches and clocks

Stopclocks are useful for timing incubation periods of several minutes or more, but stopwatches that can be held in the hand and controlled rapidly should be used for measuring clotting times and for short incubations. At least four stopwatches are needed unless an automated coagulometer is used.

Automated coagulation analysers

A wide variety of automated and semi-automated coagulation analysers are available. The choice of analyser depends on predicted workload, repertoire and cost implications. Evaluation of laboratory equipment for coagulation testing is detailed in previous editions of this book and now in Chapter 24.

PRE-ANALYTICAL VARIABLES INCLUDING SAMPLE COLLECTION

Many misleading results in blood coagulation arise not from errors in testing but from carelessness in the pre-analytical phase.

When blood is withdrawn from a vessel, changes begin to take place in the components of blood coagulation. Some occur almost immediately, such as platelet activation and the initiation of the clotting mechanism dependent on surface contact.

It is essential to take precautions at this early stage to prevent, or at least minimise, *in vitro* changes by conforming to recommended criteria during collection and storage. These criteria, as described below, have been established by the Clinical and Laboratory Standards Institute (CLSI).

Collection of venous blood

Venous blood samples should be obtained whenever possible, even from the neonate. Capillary blood tests require modification of techniques, experienced operators and locally established normal ranges; they are not an easy alternative to tests on venous blood. Patients requiring venepuncture should be relaxed and in warm surroundings. Excessive stress and vigorous exercise cause changes in blood clotting and fibrinolysis. Stress and exercise will increase FVIII, VWF and fibrinolysis.

Whenever possible, venous samples should be collected without a pressure cuff, allowing the blood to enter the syringe by continuous free flow or by the negative pressure from an evacuated tube (see p. 2). Venous occlusion causes haemoconcentration, increase of fibrinolytic activity, platelet release reaction and activation of some clotting factors. In the majority of patients, however, light pressure using a tourniquet is required; this should be applied for the shortest possible time (e.g. less than 1 min). The venepuncture must be 'clean'; blood samples from an indwelling line or catheter should not be used for tests of haemostasis because they are prone to dilution and heparin contamination. If there is no other source of blood then the line must be flushed thoroughly before sampling and the results scrutinised for possible artefacts.

To minimise the effects of contact activation, good-quality plastic or polypropylene syringes should be used. If glass blood containers are used, they should be evenly and adequately coated with silicone.

The blood is thoroughly mixed with the anticoagulant by inverting the container several times. The samples should be brought to the laboratory as soon as possible. If urgent fibrinolysis tests are contemplated, the blood samples should be kept on crushed ice until delivered to the laboratory. Assays of tPA and of PA1-1 antigen are preferably performed on samples taken into trisodium citrate to prevent continued tPA-PA1-1 binding (see p. 562).

If an evacuated tube system is used for collecting samples for different tests, the coagulation sample should be the second or third tube obtained.

Blood sample anticoagulation

The most commonly used anticoagulant for coagulation samples is trisodium citrate. A 32 g/1 (0.109 M) solution (p. 562) is recommended. Other anticoagulants, including oxalate, heparin and ethylenediaminetetra-acetic acid (EDTA) are unacceptable. The labile factors (factors V and VIII) are unstable in oxalate, whereas heparin and EDTA directly inhibit the coagulation process and interfere with end-point determinations. Additional benefits of trisodium citrate are that the calcium ion is neutralised more rapidly in citrate, and APTT tests are more sensitive to the presence of heparin.

For routine blood coagulation testing, 9 volumes of blood are added to 1 volume of anticoagulant (i.e. 0.5 ml of anticoagulant for a 5 ml specimen). When the haematocrit is abnormal due to either severe anaemia or polycythaemia, the blood:citrate ratio should be adjusted. For a 5 ml specimen (total), the amount of citrate should be as follows:

Haematocrit	*Citrate (ml)*
0.20	0.70
0.25	0.65
0.30	0.61
0.55	0.39
0.60	0.35
0.65	0.30
0.70	0.26

Time of sample collection

The time of day when the sample is collected can be an important factor in the interpretation of results. Fibrinolytic activity follows a definite circadian pattern with a trough at around 6 a.m.

The timing of the collection of the blood sample in relation to drug administration should also be taken into consideration (e.g. after subcutaneous heparin therapy, direct acting anticoagulants and desmopressin).

The timing following administration of factor concentrate samples is very important. The following times are recommended.

FVIII: at 15 min
FIX: at 30 min

Transportation to the laboratory

An efficient and regular collection service is necessary. It is important that samples are delivered as quickly as possible to prevent deterioration of the labile clotting factors such as factors V and VIII. Automated systems can facilitate rapid delivery, but should be avoided when platelet function tests are to be performed because the associated trauma may affect results.

Centrifugation: preparation of platelet-poor plasma

Most routine coagulation investigations are performed on platelet-poor plasma (PPP), which is prepared by centrifugation at 2000*g* for 15 min at 4 °C (approximately 4000 rev/min in a standard bench cooling centrifuge). The sample should be kept at room temperature if it is to be used for PT tests, lupus anticoagulant (LAC) or factor VII assays and it should be kept at 4 °C for other assays. The testing should preferably be completed within 2 h of collection. Care must be taken not to disturb the buffy coat layer when removing the PPP.

Samples for platelet function testing, LAC and the activated PC resistance (APCR) test should not be centrifuged at 4 °C. These samples should be prepared by centrifugation at room temperature to prevent activation of platelets and release of platelet contents such as phospholipid and factor V. For LAC testing and APCR it is very important that the number of platelets and the amount of platelet debris in the samples is minimised. The platelet count should be below 10×10^9/l. This is best achieved by double centrifugation. Filtration of the plasma through a 0.2 μm filter is not recommended because it may create microparticles.

Storage of plasma and sample thawing

Some tests such as the PT and APTT are carried out on fresh samples. Certain coagulation assays, unless urgently required, can be performed in batches at a later date on deep frozen plasma. Storage of small aliquots of samples in liquid nitrogen (−196 °C) is the optimum, although samples may be frozen at −40 °C or −80 °C for several weeks without significant loss of most haemostatic activities. Gentle but thorough mixing of samples is essential after thawing and before testing. Once thawed the sample should never be refrozen. Samples should be thawed at 37 °C to avoid forming cryoprecipitate.

Some common 'technical' errors

A false abnormality of the clotting time may occur in the following situations:

1. Faulty collection of the sample, resulting in it undergoing partial clotting
2. Underfilling or overfilling of the bottle or high or low haematocrit causing an incorrect volume of citrate in relation to the volume of plasma
3. An unsuitable anticoagulant, such as EDTA, used in collecting the sample
4. Collection of blood through a line that has been in contact with heparin or used for concentrate infusion
5. Contamination of the kaolin/platelet substitute reagent with a trace of thromboplastin
6. Delay in sample analysis
7. Use of inaccurate pipettes (documentation of pipette calibration is essential)
8. Machine malfunction
9. Incorrect water bath temperature
10. Calcium chloride at incorrect concentration or not freshly prepared.

CALIBRATION AND QUALITY CONTROL

Reference standard (calibrator)

International (World Health Organisation, WHO) and national standards are available for a number of coagulation factors (see p. 536). For diagnostic tests it is necessary to test a calibrated normal reference preparation alongside the patients' plasmas.

Because the concentration of some coagulation factors may vary as much as fourfold in different normal plasma samples, it is inadvisable to use plasma from any one person to represent 100% clotting activity. It is recommended that a calibrated reference plasma be routinely used with each assay. If this is not possible, then a locally prepared normal pool can be used, provided it is itself calibrated against a reference preparation. If it is necessary to use an uncalibrated plasma pool then the larger the number of donors, the closer the pool clotting activity will be to 100% or 1 iu/ml. A suggested minimum for a normal pool is 20 donors.

Calibration of standard pools and suggested calibration procedure

Whenever possible, the normal pool should be calibrated against a reference material already calibrated against the international standard. The reference material may be a national standard (e.g. National Institute for Biological Standards and Control, www.nibsc.org) or a commercial standard. In the absence of reference materials, the laboratory should obtain as large a normal pool as possible and assign it a value of 1 iu/ml.

The most important principle of calibration is repetition to minimise possible errors at each stage. It is necessary to carry out at least four independent assays and preferably six. An independent assay is an assay for which a new ampoule of standard is opened, or if a freeze-dried standard is not available, for which a new set of dilutions are prepared from frozen previous reference plasma. Each

plasma must be tested in duplicate; two replicate assays should be carried out each day and the procedure should be repeated on at least 4 days (four independent assays). Whenever possible more than one operator should be involved.

Comparison should always be made with the previous normal pool. The potency of the new normal pool is calculated for each replicate assay on each day and an overall mean value is calculated. This calibration also enables an assessment of the precision of the method used.

Control plasma

Controls are included alongside patient samples in a batch of tests. Inclusion of both normal and abnormal controls will enable detection of nonlinearity in the standard curve. Whereas a reference standard (calibrator) is used for accuracy, controls are used for precision. Precision control, the recording of the day-to-day variation in control values, is an important procedure in laboratory coagulation. Participation in an external assessment scheme (see p. 539) is also important to ensure inter-laboratory harmonisation. The use of lyophilised reference standard and control plasmas has become widespread, whereas locally calibrated standard pools are used especially in under-resourced laboratories. The results of participation in external quality-control schemes require careful attention. The large number of different reagents, substrate plasmas, reference preparations and analysers available makes comparison of like with like difficult. Ideally all combinations should give similar results, but this is often not the case and the results should be used to carefully choose the combination to be used.

A control must be stable and homogeneous; the exact potency is not important, although the approximate value should be known to select preparations at the upper and lower limit of the normal reference range. Third party controls with assigned values should be used.

Fresh control blood is required for procedures such as platelet aggregation and should be obtained from 'normal' healthy subjects. Fresh controls should be prepared in exactly the same way as the patient sample.

Variability of coagulation assays

Within a laboratory, variability is most commonly the result of a dilution error, differences in the composition of reagents, failure to take the time trend into account and differences in experience and technique between operators.

Variability between laboratories is much higher. Apart from the factors described for the within-laboratory variability, there is the major effect of differences in methods and in the composition of reagents. Comparability between laboratories improves if standardised reagents and techniques are used.

The unavoidable variability associated with coagulation assays makes the use of reliable reference materials imperative.

PERFORMANCE OF COAGULATION TESTS

Handling of samples and reagents

All plasma samples should be kept in plastic or siliconised glass tubes and placed on melting ice or at 4 °C until used, except when cold activation of factor VII and platelets is to be avoided, in which case the plasma is kept at room temperature. All pipetting should be performed using disposable plastic pipettes or autodiluter pipette tips. Manual clotting tests are performed at 37 °C in new round-bottom glass tubes of standard size (10 or 12 mm external diameter). Ideally, all glassware should be disposable. If the tubes have to be reused, scrupulous cleaning using chromic acid and a detergent such as 2% Decon 90 (Decon Laboratories Ltd, www.decon.co.uk) is essential.

Eliminating a time trend

The potential instability of biological reagents used in tests of haemostasis makes it desirable to arrange results so as to reduce time-related errors. Thus, if there is a significant length of time between the test with the patient's plasma and the test with the control sample, any difference may be the result of the deterioration of one or more of the reagents or of the plasma itself rather than a true defect or deficiency. In the simplest case, if there are two samples A and B, the readings should be carried out in the order A_1, B_1, B_2, A_2. Additional specimens are allowed for by inserting further letters into the design.

Assay monitoring and end-point detection

Manual methods

Detecting clot formation as the end-point depends to some extent on the rate of its formation: the shorter the clotting time the more opaque is the clot and the easier it is to detect. A slowly forming clot may appear as mere fibrin wisps, which are difficult to detect by eye or machine. In manual work, the observer must try to adopt a uniform convention in selecting the moment in clot formation that will be accepted as the end-point. It is also important to ensure that the tube can be watched with its lower part under the water or while being quickly dipped in and out so as to avoid cooling and a slowing down of the clot formation. Bubbles also make the determination of the end-point difficult.

Manual clotting techniques are still used in WHO calibration schemes and therefore should be viewed as an

essential skill despite the ever-increasing reliance on automation. End-point detection by analysers sometimes fails and dubious or inconsistent results or samples which fail to record a clotting time should be checked manually.

In instrumental work, the coagulometer must be shown to detect long clotting times reliably and reproducibly. The various coagulometers available have different means of detecting the end-point, which may make comparison of results difficult. Some commonly used techniques follow.

Electromechanical

Impedance, steel ball, rotating cuvette. The sample cuvette rotates and a steel ball remains stationary in a magnetic field until the formation of fibrin strands around the ball produces movement (e.g. Amelung KC4, www.tcoag.com). This is detected by a change in the magnetic field and the coagulation time is recorded.

Impedance, steel ball, rotating steel ball. A steel ball rotates under the influence of a magnet until the formation of fibrin strands around the ball stops it rotating (e.g. Axis Shield Group Thrombotrack www.axis-shield.com). This is detected by a sensor and the coagulation time is recorded.

Photo-optical analysis

Scattered light detection for clotting assays. The increasing turbidity during the formation of a fibrin clot is measured as an increase in scattered light intensity when exposed to light at a wavelength of 660 nm.

Transmitted light detection for chromogenic assays (405 nm, 575 nm, 800 nm). Colour production leads to a change in light absorbance, which is detected as a change in transmitted light. The change in absorbance per minute is calculated (Δ optical density (OD)/min). Various wavelengths can be used, such as 405 nm, 575 nm and 800 nm.

Transmitted light detection for immunoassays (405 nm, 575 nm, 800 nm). The change in light absorbance caused by the antigen–antibody reaction is detected as the change in transmitted light. The change in absorbance per minute is calculated (Δ OD/min). Some analysers detect light transmittance at multiple wavelengths between 395 and 710 nm.

Nephelometry (IL ACL analysers). Nephelometry is the determination of the intensity of light scatter using a detector placed at right angles to the incident light path and detecting light of the same wavelength as the incident light. The technique is particularly useful in measuring complexes of antigen and antibody produced by immunoprecipitation.

Photo-optical end point determination and analyses. Using the techniques above, a number of methods can be used to define the change in optical transmission that corresponds to the endpoint of the reaction.

Percentage detection method

After initiating the clotting reaction, the transmitted light is monitored and a baseline value (bH) is determined for the reaction (bH = 0%) (Fig. 18-2). The reaction is then monitored until the clotting reaction is completed (dH = 100%). The time to an arbitrarily set end point, usually 50%, is then determined. At this point the H value usually shows the greatest rate of change and the fibrin monomer polymerisation reaction rate is high. Detection based on this principle enables coagulation analysis to be more accurate at low fibrinogen concentrations in samples with low scatter and those samples for which the initial scatter is higher than usual, such as lipaemic and haemolysed samples.

Rate method

After the start of the reaction the change in absorbance is monitored (Fig. 18-3). After a predetermined time the final absorbance measurement is made. The rate of the absorbance increase per minute between these two time point measurements is calculated. The calculated rate of change in absorbance (Δ OD/min) is used to construct a standard curve (i.e. there is no end-point *per se*). This

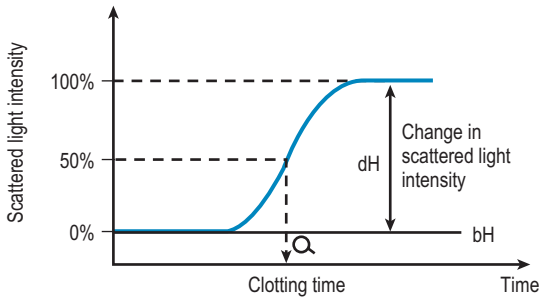

FIGURE 18-2 Endpoint determination: percentage detection method. *(Reproduced by permission of Sysmex UK Ltd.)*

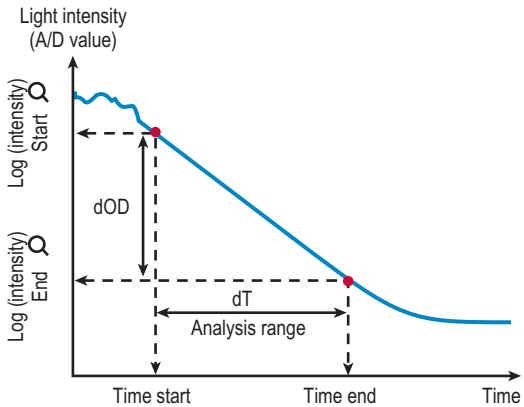

FIGURE 18-3 Analysis of reaction: rate method. This is used for chromogenic assays. *(Reproduced by permission of Sysmex UK Ltd.)*

method is used for activity measurement such as in chromogenic substrate assays. It is important that the rate is measured on a linear portion of the curve.

VLin integral method

The VLin integral method evaluates the absorbance per minute of an immunological reaction (Fig. 18-4). This is monitored and mathematical analysis is used to determine the peak rate of change (maximum velocity). The VLin integral evaluation method is used for immunological assays including those for D-dimer and VWF antigen. Using this method allows increased sensitivity, extended measuring range, reduced measurement time and improved antigen excess reliability when measuring an immunological reaction.

Analysis time over

The 'Analysis Time Over' check is used to detect whether the reaction end-point is correct and an endpoint has been reached (Fig. 18-5). If the sample reaction end angle is greater than the permitted angle at the maximum detection time, the result will be flagged with an 'Analysis Time Over' error. The situation occurs when testing samples with prolonged clotting times and a satisfactory end point has not been reached by the end of the time allotted for analysis. When this occurs the following checks should be performed:

1. Check the sample for possible anticoagulant contamination, haemolysis, lipaemia, hyperbilirubinaemia or turbidity.
2. Verify delivery of sample and reagent.
3. Set the 'Maximum Reading Time' to a longer time and reanalyse the sample.
4. If reanalysis of the sample results in a numerical value without an error flag, the result can be reported.
5. If reanalysis gives an 'Analysis Time Over' message again, the sample may not be capable of forming a firm clot. In these situations the clotting time must be checked manually.

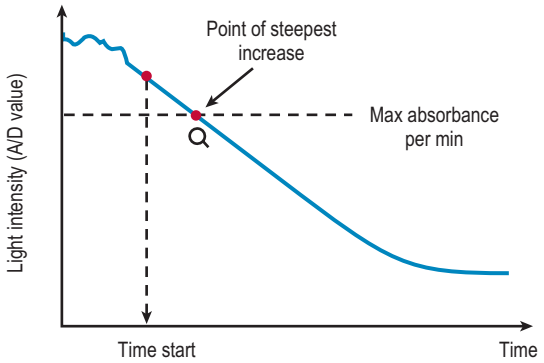

FIGURE 18-4 Analysis of reaction: VLin integral method. This is used for immunological assays. *(Reproduced by permission of Sysmex UK Ltd.)*

Turbidity level over

If the dH exceeds the detection capacity of the analogue to digital converter, the result will not be reported and it may be suspected that the sample plasma is turbid or lipaemic (Fig. 18-6). When this occurs the following checks should be performed:

1. Check the sample for turbidity, lipaemia, haemolysis or hyperbilirubinaemia.
2. Verify delivery of sample and reagent.
3. For a fibrinogen assay, dilute the sample with Owren veronal buffer and reanalyse.
4. If reanalysis of the sample results in a numerical value without an error flag, the result can be reported.
5. Clotting tests such as PT, APTT and thrombin time (TT) must be performed manually.

Clot signatures: normal and abnormal activated partial thromboplastin time clot waveforms

On some analysers the clot waveform can be generated from the monitoring of light transmission or absorbance during the PT or APTT (Fig. 18-7). This has been used to assess procoagulant activity and to detect DIC but is not in routine practice.[19]

Commonly used reagents

Some reagents are common to the majority of first-line tests. They are described here, whereas the reagents specific for one particular test or assay are described with the relevant test.

$CaCl_2$. The working solution is best prepared from a commercial molar solution. Small volumes of 0.025 mol/l concentration should be prepared frequently and stored for short periods to avoid proliferation of microorganisms. Prewarmed $CaCl_2$ should always be discarded at the end of the working day. Commercial solutions are available.

Barbitone buffer

- 50 ml sodium diethyl barbiturate ($C_8H_{11}O_3N_2Na$) 0.2 M (41.2 g/l)
- Add 32.5 ml hydrochloric acid (HCl) 0.2M
- Make up to 200 ml with water (pharmacy grade distilled water www.baxterhealthcare.co.uk) and correct pH to 7.4 with HCl.

Barbitone buffered saline, pH 7.4

- NaCl 5.67 g
- Barbitone buffer, pH 7.4, 1 litre
- Before use, dilute with an equal volume of 9 g/l NaCl.

pH 7.3–7.4 is recommended for most clotting tests.

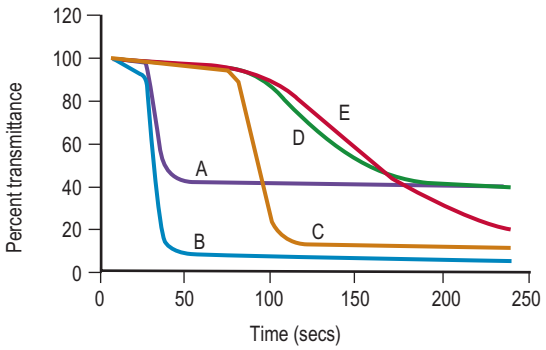

FIGURE 18-7 Clot signatures: normal and abnormal activated partial thromboplastin time (APTT) clot waveforms. A, Normal specimen; APTT = 29 s, fibrinogen concentration = 2.89 g/l. **B,** Biphasic response in a suspected disseminated intravascular coagulation (DIC) specimen with normal APTT (28.5 s) and elevated fibrinogen (6.74 g/l). **C,** Patient treated with heparin (0.52 anti-Xa u/ml); prolonged APTT (81.2 s) and elevated fibrinogen concentration (5.54 g/l). **D,** FVIII-deficient specimen (<1%), with prolonged APTT (84.1 s) and slightly reduced fibrinogen concentration (1.56 g/l). **E,** FIX-deficient specimen (<1%) with prolonged APTT (83.4 s) and normal fibrinogen concentration (2.94 g/l). *(Reproduced by permission of bioMérieux.)*

Glyoxaline buffer. Dissolve 2.72 g of glyoxaline (imidazole) and 4.68 g of NaCl in 650 ml of water. Add 148.8 ml of 0.1 mol/l HCl and adjust the pH to 7.4. Adjust the volume to 1 litre with water.

Owren veronal buffer

- Sodium acetate: 3.89 g
- Barbitone sodium: 5.89 g
- Sodium chloride: 6.8 g
- Dissolve the salts in 800 ml of water.
- Add 21.5 ml of 1 mol/l HCl, then make up to 1 litre with water, mix and check that the pH is 7.4.

Alternatively the solutions can be purchased commercially (www.sigmaaldrich.com).

Factor-deficient plasmas

Plasmas deficient in specific factors are required for many bioassays. They may be obtained from individuals with congenital deficiency of the factor, but frequently these patients will have been treated with plasma concentrates and there is a danger of infection. Many laboratories now use commercial plasmas rendered deficient in the factor by immunodepletion and then lyophilised. However, it is important to establish that these are completely deficient. Once reconstituted, lyophilised plasmas should be gently mixed and left to stand for 20 min before use. If an automated coagulation analyser is used, the factor-deficient plasma should be placed in position 10 min prior to testing.

THE 'CLOTTING SCREEN'

Basic tests of coagulation are often performed with no specific diagnosis in mind and in the absence of any clinical indication of a haemostatic disorder. There may be numerous reasons for this and the tests performed may give clues to diagnosis or may detect an unsuspected hazard that increases the risk of postoperative bleeding. Equally, they may produce false-positive abnormalities that cause concern and confusion and delay procedures.[15] The choice and extent of tests performed in this screening process will vary between hospitals.

Prothrombin time

Principle

The prothrombin time measures the clotting time of recalcified plasma in the presence of an optimal concentration of tissue extract (thromboplastin) and indicates the overall efficiency of the extrinsic clotting system. Although originally thought to measure prothrombin, the test also depends on factors V, VII and X and on the fibrinogen concentration of the plasma.

Reagents

Patient and control plasma samples. Platelet-poor plasma from the patient and control is obtained as described on p. 375. Note that plasma stored at 4 °C may have a shortened PT as a result of factor VII activation in the cold.

Thromboplastin. Thromboplastins were originally tissue extracts obtained from different species and different organs containing tissue factor and phospholipid. Because of the potential hazard of viral and other infections from handling human brain, it should no longer be used as a source of thromboplastin. A laboratory method for a rabbit brain preparation, of use in under-resourced laboratories, is described on page 556 and in previous editions.

Recombinant thromboplastins are manufactured using recombinant human tissue factor produced in *Escherichia coli* and synthetic phospholipids, which do not contain any other clotting factors. Therefore they are highly sensitive to factor deficiencies and oral anticoagulant-treated patient plasma samples and have an International Sensitivity Index (ISI) close to 1.

Each preparation has a different sensitivity to clotting factor deficiencies and defects, in particular the defect induced by oral anticoagulants. For control of oral anticoagulation a preparation calibrated against the International Reference Thromboplastin should be used (see Chapter 20).

$CaCl_2$. 0.025 mol/l.

Method

Deliver 0.1 ml of plasma into a glass tube placed in a water bath and add 0.1 ml of thromboplastin. Wait 1–3 min to allow the mixture to warm. Then add 0.1 ml of warmed $CaCl_2$ and start the stopwatch. Mix the contents of the tube and record the end-point. Carry out the test in duplicate on the patient's plasma and the control plasma. When a number of samples are to be tested as a batch, the samples and controls must be suitably staggered to eliminate time bias. Some thromboplastins contain calcium chloride, in which case 0.2 ml of thromboplastin-Ca is added to 0.1 ml plasma and timing is started immediately.

Expression of results

The results are expressed as the mean of the duplicate readings in seconds or as the ratio of the mean patient's plasma time to the mean normal control plasma time. The control plasma is obtained from 20 normal men and women (the latter not pregnant and not taking oral contraceptives) and the logarithmic mean normal PT (LMNPT) is calculated. For further details and a discussion of the importance of the PT in oral anticoagulant control, when results may be reported as an International Normalised Ratio (INR), see Chapter 20.

Normal values

Normal values depend on the thromboplastin used, the exact technique and whether visual or instrumental end-point reading is used. With most rabbit thromboplastins the normal range of the PT is between 11 and 16 sec; for recombinant human thromboplastin it is somewhat shorter (10–12 sec). Each laboratory should establish its own normal range.

Interpretation

The common causes of a prolonged PT are as follows:

1. Administration of oral anticoagulant drugs (vitamin K antagonists)
2. The presence of a direct acting inhibitor of factor Xa
3. Liver disease, particularly obstructive jaundice
4. Vitamin K deficiency
5. Disseminated intravascular coagulation
6. Rarely, a previously undiagnosed factor VII, X, V or prothrombin deficiency or defect.

Note: With prothrombin, FX or factor V deficiency the APTT will also be prolonged.

Activated partial thromboplastin time

Specific variations of the APTT test are known as the partial thromboplastin time with kaolin (PTTK) and the kaolin cephalin clotting time (KCCT), reflecting the methods used to perform the test.

Principle

The test measures the clotting time of plasma after the activation of contact factors and the addition of phospholipid and $CaCl_2$ but without added tissue thromboplastin and so indicates the overall efficiency of the intrinsic pathway. The plasma is first preincubated for a set period with a contact activator such as kaolin, silica or ellagic acid. During this phase of the test, FXIIa is produced, which cleaves FXI to FXIa, but coagulation does not proceed beyond this point in the absence of calcium. After recalcification, FXIa activates FIX and coagulation follows. A standardised phospholipid is provided to allow the test to be performed on PPP. The test depends not only on the contact factors and on factors VIII and IX, but also on the reactions with factors X, V, prothrombin and fibrinogen. It is also sensitive to the presence of circulating anticoagulants (inhibitors) and heparin.

Reagents

PPP. From the patient and a control, stored as described on p. 376.

Kaolin. 5 g/l (laboratory grade) in barbitone buffered saline, pH 7.4 (p. 380). Add a few glass beads to aid resuspension. The suspension is stable at room temperature. Other insoluble surface active substances such as silica, celite or ellagic acid can also be used.

Phospholipid. Many reagents are available; these contain different phospholipids.

When choosing a reagent for the APTT, it is important to establish that the activator–phospholipid-incubation time combination is sensitive to deficiencies of factors VIII, IX and XI at concentrations of 0.35–0.4 iu/ml. Combinations that do not produce a prolonged clotting time at these levels are too insensitive. The system should also be responsive to unfractionated heparin over the therapeutic range of approximately 0.3–0.7 anti-Xa iu/ml. In addition, some laboratories will wish the system to be sensitive to the presence of lupus anticoagulants.

$CaCl_2$. 0.025 mol/l.

Method

Mix equal volumes of the phospholipid reagent and the kaolin suspension and leave in a glass tube in the water bath at 37 °C. Place 0.1 ml of plasma into a second glass tube. Add 0.2 ml of the kaolin–phospholipid solution to the plasma, mix the contents and start the stopwatch simultaneously. Leave at 37 °C for 10 min with occasional shaking. At exactly 10 min add 0.1 ml of prewarmed $CaCl_2$ and start a second stopwatch. Record the time taken for the mixture to clot. Repeat the test at least once on both the patient's plasma and the control plasma. It is possible to do four tests at 2-min intervals if sufficient stopwatches are available.

Expression of results

Express the results as the mean of the paired clotting times.

Normal range

The normal range is typically 26 to 40 s. The actual times depend on the reagents used and the duration of the preincubation period, which varies in manufacturers' recommendations for different reagents. Laboratories can choose appropriate conditions to achieve the sensitivity they require. Each laboratory should calculate its own normal range.

Interpretation

The common causes of a prolonged APTT are as follows:

1. Disseminated intravascular coagulation
2. Liver disease
3. Massive transfusion with plasma-depleted red blood cells
4. Administration of or contamination with heparin or other anticoagulants
5. A nonspecific circulating anticoagulant (such as an LAC)
6. The presence of a direct acting anticoagulant drug (e.g. anti-IIa or anti-Xa agents)
7. Deficiency of a coagulation factor other than factor VII

The APTT is also moderately prolonged in patients taking oral anticoagulant drugs and in the presence of vitamin K deficiency. Occasionally, a patient with previously undiagnosed haemophilia or another congenital coagulation disorder presents with an isolated prolonged APTT. If the patient's APTT is abnormally long, mixing tests, an inhibitor screen and factor assays should be considered (see below).

Thrombin time

Principle

Thrombin is added to plasma and the clotting time is measured. The TT is affected by the concentration and function of fibrinogen and by the presence of inhibitory substances. The clotting time and the appearance of the clot are both informative.

Reagents

PPP. From the patient and a control.

Thrombin solution. A commercial bovine thrombin is used. It is stored frozen as a 50 National Institutes of Health (NIH) unit solution, and it is freshly diluted in barbitone buffered saline in a plastic tube so as to give a clotting time of normal plasma of 15 s (usually approximately 7–8 NIH thrombin units per ml). Shorter times with normal plasma may fail to detect mild abnormalities.

Method

Add 100 µl thrombin solution to 200 µl of control plasma in a glass tube at 37 °C and start the stopwatch. Measure the clotting time and observe the nature of the clot (e.g. whether transparent or opaque, firm or wispy). Repeat the procedure with two tubes containing the patient's plasma in duplicate and then with a second sample of control plasma.

Expression of results

The results are expressed as the mean of the duplicate clotting times in seconds for the control and the test plasma.

Normal range

A patient's TT should be within 2 s of the control (i.e. 15 to 19 s). Times of 20 s and longer are definitely abnormal.

Interpretation of results

The common causes of prolonged TT are as follows:

1. Hypofibrinogenaemia as found in DIC and, more rarely, in a congenital deficiency
2. Dysfibrinogenaemia, either inherited or acquired, in liver disease or in neonates
3. Extreme prolongation of the TT is nearly always a result of thrombin inhibition; typically unfractionated heparin but also oral or parenteral direct thrombin inhibitors. If a thrombin inhibitor is suspected, a reptilase time test can be carried out (see p. 386) or the test can be repeated after the addition of heparinase. Low molecular weight heparin (LMWH) produces only a slight prolongation at therapeutic levels
4. Raised concentrations of fibrin degradation products (FDP), as encountered in DIC or liver disease

5. Hypoalbuminaemia[20]
6. Paraproteinaemia.

Shortening of the TT occurs in conditions of coagulation activation.

A transparent bulky clot is found if fibrin polymerization is abnormal, as is the case in liver disease and some congenital dysfibrinogenaemias.

A gross elevation of the plasma fibrinogen concentration may also prolong the TT. Correction can be obtained by diluting the patient's plasma with saline (see p. 386).

Measurement of fibrinogen concentration

Numerous methods of determining fibrinogen concentration have been devised including clotting, immunological, physical and nephelometric techniques, and all tend to give slightly different results, presumably because of the heterogeneous nature of plasma fibrinogen.[21] Automated analysers can estimate fibrinogen concentration from the coagulation changes during the PT (PT-derived fibrinogen). This is simple, inexpensive and widely used but is not recommended because it is inaccurate (overestimates fibrinogen) in some disease states and in patients who are anticoagulated.[22] Guidelines on fibrinogen assays have been published and recommend the Clauss technique for routine laboratory use.[23]

Fibrinogen assay (Clauss technique)

Principle

Diluted plasma is clotted with a strong thrombin solution; the plasma must be diluted to give a low level of any inhibitors (e.g. FDPs and heparin). A strong thrombin solution must be used so that the clotting time over a wide range is independent of the thrombin concentration.[24]

Reagents

- *Calibration plasma.* With a known level of fibrinogen calibrated against an International Reference Standard
- *PPP.* From the patient and a control
- *Thrombin solution.* Freshly reconstituted to 100 NIH u per ml in 9 g/l NaCl
- *Owren veronal buffer,* pH 7.4. See p. 380.

Method

A calibration curve is prepared each time the batch of thrombin reagent is changed or there is a drift in control results; this is used to calculate the results of unknown plasma samples.

Make dilutions of the calibration plasma in veronal buffer to give a range of fibrinogen concentrations (1 in 5, 1 in 10, 1 in 20 and 1 in 40). Part (0.2 ml) of each dilution is warmed to 37 °C, 0.1 ml of thrombin solution is added and the clotting time is measured. Each test should be performed in duplicate. Plot the clotting time in seconds against the fibrinogen concentration in g/l on log/log graph paper. The 1 in 10 concentration is considered to be 100% and there should be a straight line connection between clotting times of 5 and 50 s. Make a 1 in 10 dilution of each patient's sample and clot 0.2 ml of the dilution with 0.1 ml of thrombin.

The fibrinogen level can be read directly off the graph if the clotting time is between 5 and 50 s. However, outside this time range a different assay dilution and arithmetical correction of the result will be required (i.e. if the fibrinogen level is low and a 1 in 5 dilution is required, divide answer by 2; for a 1 in 20 dilution multiply answer by 2).

The clot formed in this method may be 'wispy' as a result of the plasma being diluted and end-point detection may be easier with optical or mechanical automated equipment. These have been assessed with available substrates and give reasonably consistent results.[25] The high concentration of thrombin used raises the risk of carry over into subsequent tests.

Normal range

The normal range is approximately 1.8 to 3.6 g/l.

Interpretation

The Clauss fibrinogen assay is usually low in inherited dysfibrinogenaemia but is insensitive to heparin unless the level is very high (>0.8 u/ml). High levels of FDPs (>190 µg/ml), may also interfere with the assay.[26] Because the chronometric Clauss assay is a functional assay it will generally give a relevant indication of fibrinogen function in plasma. When an inherited disorder of fibrinogen is suspected, a physicochemical estimation should be obtained (e.g. clot weight estimate of fibrinogen or total clottable fibrinogen or an immunological assay; see page 392). If a dysfibrinogenaemia is present, it will reveal a discrepancy between the (functional) Clauss assay and the physical amount of fibrinogen present.

Platelet count

Before considering further investigation of a suspected bleeding disorder always check the platelet count and the blood film (for size and staining characteristics of platelets).

Interpretation of first-line tests

The pattern of abnormalities obtained using the first-line tests described earlier often gives an indication of the underlying defect and determines the appropriate further tests required to define it. The patterns are outlined in Table 18-3 with suggestions for further testing.

TABLE 18-3

FIRST-LINE TESTS USED IN INVESTIGATING ACUTE HAEMOSTATIC FAILURE

	PT	APTT	Fibrinogen	Platelets	Condition	Second-Line Investigation
1.	N	N	N	N	Normal haemostasis Disorder of platelet function Factor XIII deficiency Mild/masked coagulation factor deficiency Mild von Willebrand disease LMWH or direct acting inhibitor Anatomical or surgical lesion Disorder of vascular haemostasis Disorder of fibrinolysis	Specific factor assays including FXIII Platelet function (or screening such as PFA-100) VWF assay (or screening such as PFA-100) Anti-Xa assay Assays of fibrinolytic factors
2.	Long	N	N	N	Factor VII deficiency Mild liver impairment or vitamin K deficiency Early oral anticoagulation (primarily factor VII reduction) Lupus anticoagulant (with some reagents) Mild factor II, V or X deficiency	Mixing test for correction of PT Specific factor assays beginning with factor VII Test for lupus anticoagulant Liver function tests, trial of vitamin K
3.	N	Long	N	N	Factor VIII, IX, XI, XII, prekallikrein or HMWK deficiency FVIII deficiency secondary to VWD Circulating anticoagulant, e.g. lupus anticoagulant Heparin or direct acting anticoagulant Mild factor II, V or X deficiency	Mixing test for correction Specific factor assays VWF assays if factor VIII low Anti-Xa assay, anti-IIa assay Test for lupus anticoagulant
4.	Long	Long	N or Abnormal	N	Vitamin K deficiency Anticoagulants (warfarin, direct acting, heparins) Factor V, X or II deficiency Multiple factor deficiency, e.g. liver failure Combined factor V + VIII deficiency Fibrinogen deficiency/disorder Inhibition of fibrin polymerisation Hyperfibrinolysis	Mixing tests for correction Specific factor assays Thrombin time Anti-Xa assay, anti-IIa assay Liver function tests, trial of vitamin K D-dimer assay
5.	N	N	N	Low	Thrombocytopenia	Blood count and film
6.	Long	Long	N or Abnormal	Low	Massive transfusion Liver disease Disseminated intravascular coagulation	D-dimer assay Liver function tests

HMWK, high molecular weight kininogen; N, normal.

The choice of second-line investigation will be determined partly by the pattern and degree of abnormality detected in the screening tests but also by the clinical circumstance and history, including use of anticoagulant therapy. Unfortunately it has become apparent that significant anticoagulant effects from LMWH and the direct acting inhibitors of Xa and thrombin may be accompanied by little or no abnormality of the screening tests in some circumstances. When drug ingestion has not been excluded, specific assays may be necessary to exclude their presence.

SECOND-LINE INVESTIGATIONS

Correction tests using the prothrombin time or activated partial thromboplastin time

Principle

Prolongation of the PT or APTT can be investigated with simple correction tests by mixing the patient's plasma with normal plasma. Correction indicates a possible factor deficiency,

whereas failure to correct suggests the presence of an inhibitor, but interpretation should be cautious (see below).

Reagents

Plasmas for correction. Normal plasma contains all the coagulation factors; therefore mixing tests with normal plasma will identify the presence of an inhibitor or a factor deficiency. In previous editions the use of aged and adsorbed plasma is described, but these correction reagents may give misleading results if not used with great care. It is better to proceed directly to specific factor assays if appropriate factor-deficient plasmas are available.

- *PPP.* From the patient and a control
- *Other reagents.* As described on p. 380.

Method

Perform a PT and/or APTT on control, patient and a 50:50 (0.05 ml of each) mixture of the control and patient plasma. Perform all the tests in duplicate using a balanced order to avoid time bias. Note that mixing experiments to detect FVIII inhibitors may require incubation for 2 h before analysis (see p. 390).

Interpretation

If the prolongation is the result of a deficiency of a clotting factor, the PT or APTT of the mixture should return to within a few seconds of normal. It is then necessary to identify the specific factor(s) that are deficient.

If the APTT is prolonged and normal plasma fails to correct the APTT, an inhibitor should be suspected. An inhibitor screen and tests for an LAC should be performed paying attention to the following:

1. Some inhibitors (usually anti-FVIII antibodies) are time dependent in their action and testing immediately after mixing may show correction, whereas testing after 2 h of incubation reveals an inhibitory effect.
2. The use of a 50:50 mix has high sensitivity but lower specificity for factor deficiency because some lupus-like anticoagulants are relatively weak and may be overcome by dilution in normal plasma. Some laboratories prefer a 25:75 or 20:80 mix of normal and test plasma for this reason. However the increased sensitivity to lupus anticoagulants is at the cost of reduced specificity because sensitivity to factor deficiency is reduced. Thus confusion with factor deficiency is possible and should be resolved by performing relevant factor assays paying close attention to linearity (parallelism) of the assay. For details of testing for inhibitors, see p. 389.
3. When the test is only slightly prolonged it may be difficult to detect correction accurately and specific factor and inhibitor tests should be performed from the outset.

Correction tests using the thrombin time

Principle

The tests use certain physicochemical properties of reagents to bind to inhibitors or abnormal molecules and normalise the prolonged TT. Protamine sulphate has a net positive charge and interacts with heparin, as well as binding to FDP, neutralising the inhibitory effects of both. Toluidine blue is also a charged reagent that will neutralise heparin but has no effect on FDP. It is interesting that toluidine blue normalises the TT in some dysfibrinogenaemias, probably by interacting with the excess of sialic acid attached to the fibrinogen molecules. Mixing with serum or albumin solution will correct the prolongation of the TT resulting from hypoalbuminaemia.

Reagents

- *Patient's and control plasma.*
- *Protamine sulphate.* 1% and 10% in 9 g/l NaCl
- *Toluidine blue.* 0.05 g in 100 ml of 9 g/l NaCl
- *Bovine thrombin.* As described under thrombin time.

Method

Perform the test as described for TT, adding 0.1 ml of saline to the controls and replacing in the test with protamine sulphate or toluidine blue solution. Also perform a TT on a 50:50 mixture of control and test plasma.

Interpretation

See Table 18-4.

TABLE 18-4

INTERPRETATION OF CORRECTION TESTS USING THE THROMBIN TIME (TT)

TT of Test Plasma Corrected with				
Saline	**Normal Plasma**	**Protamine Sulphate**	**Toluidine Blue**	**Interpretation**
No	Yes	No	No	Deficiency
No	Variable	No	Yes	Dysfibrinogenaemia of liver disease
No	Variable	Yes	No	High concentration of FDP

FDP, fibrin degradation product.
It is essential to exclude the possibility of heparin contamination.

Comment

The end-point may be difficult to see in samples with a low fibrinogen content in the presence of toluidine blue owing to the dark colour of the reagent. Grossly elevated fibrinogen concentrations or the presence of a paraprotein can cause a prolonged time not corrected by either protamine or toluidine blue. Diluting the test plasma in saline will shorten the TT.

Reptilase (batroxobin) or ancrod time

Reptilase, a purified enzyme from the snake *Bothrops atrox* and ancrod (Arvin), a similar enzyme from the snake *Agkistrodon rhodostoma,* may be used to replace thrombin in the TT test.[27]

The venoms are reconstituted as directed by the manufacturers, and the test is performed exactly as described for the TT. The snake venoms are not inhibited by heparin or direct thrombin inhibitors. The clotting times will, however, remain prolonged in the presence of raised FDP or abnormal or reduced fibrinogen or hypoalbuminaemia.

INVESTIGATION OF A BLEEDING DISORDER RESULTING FROM A COAGULATION FACTOR DEFICIENCY OR DEFECT

When the screening tests indicate that an individual has a coagulation defect, the plasma concentration of the coagulation factors should be assayed. Such assays establish the diagnosis of the deficiency or defect and they assess its severity; they also can be used to monitor replacement therapy and to detect the carrier state in affected families.

An individual may have a congenital deficiency of a coagulation factor because of impaired synthesis or because a variant of the molecule that is deficient in clotting activity is synthesised. In both instances the results of assays based on coagulation tests will be subnormal, but when a variant molecule is being produced, the result of an immunological assay may be normal or near normal.

General principles of parallel line bioassays of coagulation factors

Guidelines on performance of laboratory coagulation assays have been published by the British Committee for Standards in Haematology (BCSH).[28] If two materials containing the same coagulation factor are assayed in a specific assay system in a range of dilutions and the clotting times are plotted against the plasma concentration on linear graph paper, curved dose-response lines are obtained. If the plot is redrawn on double-log paper, a sigmoid curve with a straight middle section is obtained (Fig. 18-8), although in some cases (e.g. FVIII) semi-log paper is required. If the dilutions of the test and standard materials are chosen carefully, it should be possible to draw two straight parallel lines. The horizontal distance between the two lines represents the difference in potency ('strength' or concentration) of the factor assayed. The assay is based on the assumption that both test and control behave like simple dilutions of each other. This assumption has

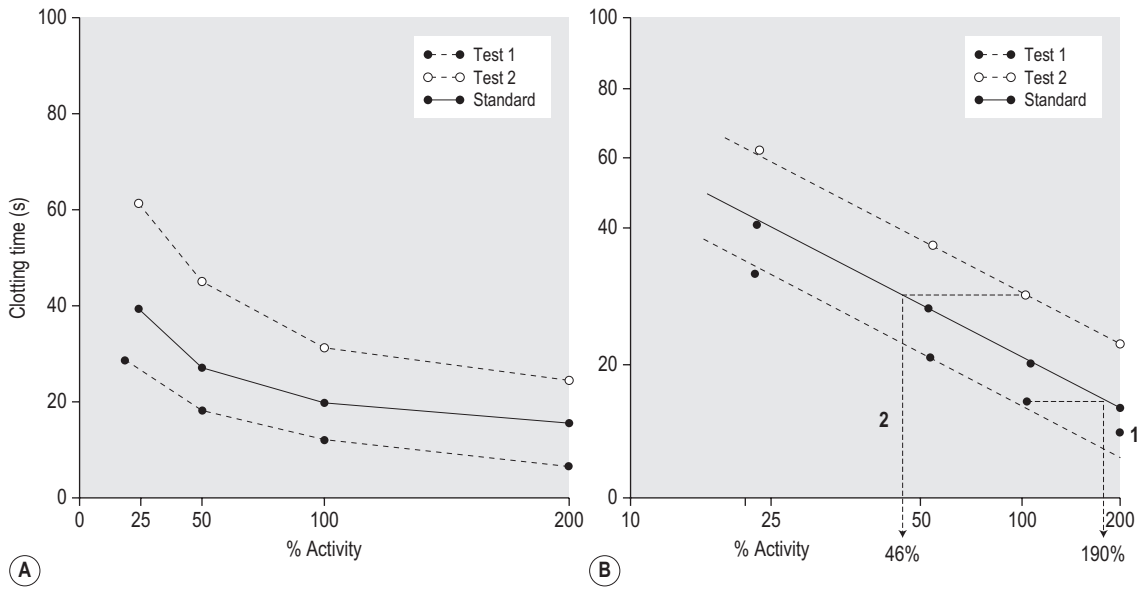

FIGURE 18-8 Parallel line bioassay of factor VII. A, Clotting times with 1 in 5, 1 in 10, 1 in 20 and 1 in 40 dilutions of test and standard plasma plotted on linear graph paper. **B,** The same data plotted on double-log paper. Three parallel straight lines are obtained. The horizontal shift of the test line represents the difference in potency. The 1 in 10 dilution of the standard plasma is assigned a potency of 1.00 iu/ml. The % figures of the test samples can therefore be converted to iu/ml. In this case, test 1 has a potency of 0.190 iu/ml and test 2 has a potency of 0.46 iu/ml.

caused some problems when assaying samples containing FVIII or IX concentrates (see below).

When setting up and performing a parallel line assay, a number of measures must be taken to ensure that the assay is valid and reliable.

1. *Dilution range.* This should be chosen so that the coagulation times lie on the linear portion of the sigmoid curve. For example, when assaying FVIII by a one-stage assay, dilutions giving times between 60 and 100 s are chosen if the blank clotting time is more than 120 s. (The blank consists of a mixture of buffer and substrate or deficient plasma, which provides all factors except the one to be measured.)
2. *Number of dilutions.* At least three dilutions of the standard and the test are assayed to give the best graphic or mathematical solution.
3. *Responses.* Dilutions of the test sample should be chosen so that the clotting times fall within the range obtained for the standard. If it transpires that the test result falls outside this range, the standard curve should not be extrapolated but the dilutions of the test and/or the standard must be adjusted.
4. *Duplicates and replicates.* Duplicates are obtained from the same dilution of the sample and sometimes by subsampling from the same incubation mixture. Replicates are true repeats involving a fresh dilution and fresh reagents. Normally, coagulation times are measured on duplicates. Replicates are sometimes used for particularly difficult assays.
5. *Temporal drift.* This has already been discussed. Duplicates in a coagulation assay should always be tested in a balanced order (e.g. ABCCBA).

Automated factor assays

Factor assay results are dependent on obtaining parallel lines for the test and reference plasmas. Many automated coagulation analysers will give an assay result obtained from a single dilution, assuming that this condition is met. However, this is not always true, and it is recommended that at least three dilutions are measured. As well as establishing validity (each set of results should be similar unless there is an inhibitor present), this improves the accuracy of the result.

Assays based on the prothrombin time

The investigation of an isolated prolonged PT includes a one-stage factor VII assay. If a reduced concentration of factor VII is found, further tests may include immunoassays of factor VII and, when possible, a family study.

One-stage assay of factor VII

Principle. The assay of factor VII is based on the PT. The assay compares the ability of dilutions of the patient's plasma and of a standard plasma to correct the PT of a substrate plasma. It is easily adapted to assay prothrombin, FV or FX.

Reagents

- *PPP from the patient.*
- *Standard/reference plasma.* See p. 376
- *Factor VII-deficient plasma.* Commercial or from a patient with known severe deficiency.
- *Barbitone buffered saline*. See p. 380.
- *Thromboplastin*. It is recommended that a recombinant human thromboplastin is used for the assay of human FVII to avoid effects of interspecies differences. The thromboplastin should be reconstituted according to the manufacturer's instructions and may have sufficient Ca for the assay. Warm sufficient thromboplastin for the assay to 37 °C.
- *$CaCl_2$.* 0.025 mol/l (if not present in the thromboplastin preparation).

Method. Prepare 1 in 5, 1 in 10, 1 in 20 and 1 in 40 dilutions of the standard and test plasma in buffered saline. Transfer 0.1 ml of each dilution to a glass tube and add to it 0.1 ml of deficient (substrate) plasma. Mix and allow to warm to 37 °C. Add 0.1 ml of dilute thromboplastin and start the stopwatch. Record the clotting time. If the thromboplastin does not contain calcium, start the stopwatch after adding 0.1 ml of $CaCl_2$. A blank must be included with every assay and all tests must be carried out in duplicate and in balanced order.

Calculation of results. Plot the clotting times of the test and standard against the concentration of factor VII on log/log graph paper. Read the concentration as shown in Figure 18-8.

Interpretation. The FVII level should be compared to the normal range, but the minimum necessary for normal haemostasis is probably 0.2 iu/ml or lower.[29,30] The concentration measured may vary according to the thromboplastin used in the assay, so human thromboplastin is preferable. Some FVII variants give abnormal results with animal thromboplastin but have normal function with human.

Assays based on the activated partial thromboplastin time

An APTT-based assay (e.g. for FVIII) may be indicated after obtaining correction of a prolonged APTT by mixing with another plasma. An assay for FVIII is described, but this is easily adapted to FIX, FXI or contact factor assays by substituting the relevant factor-deficient plasma.

One-stage assay of factor VIII

Principle. The one-stage assay for FVIII is based on the APTT according to the bioassay principle described earlier.[17,31]

Reagents and equipment

- *PPP.* From the patient.

- *Standard/reference plasma.* See page 376.
- *FVIII-deficient plasma (substrate plasma).* If using a commercial plasma, the reagent should be reconstituted according to the manufacturer's instructions. If a haemophiliac donor is used, his FVIII concentration should be <0.01 iu/ml and his plasma should be free of inhibitors. The plasma should be stored in suitable volumes (e.g. 2 ml) at −20 °C or lower until used. All samples obtained from patients must be considered potentially infective. Patient samples should be tested for antibodies to human immunodeficiency virus (HIV) and hepatitis C virus and for hepatitis B surface (HBs) antigen.
- *Barbitone buffered saline.* See page 380.
- *Reagents for APTT.*
- *Plastic tubes.* To avoid contact activation while preparing samples.
- *Ice bath.*

Method. Place the APTT reagent and $CaCl_2$ at 37 °C and the patient's, standard and substrate plasma in the ice bath until used.

Make 1 in 10 dilutions of the test and standard plasma in buffered saline in plastic tubes in the ice bath. Using 0.2 ml volumes, make doubling dilutions in buffered saline to obtain 1 in 20 and 1 in 40 dilutions. Place 0.1 ml of the three dilutions (1 in 10, 1 in 20 and 1 in 40) in glass tubes. If the test plasma is suspected of having a very low FVIII content, make 1 in 5, 10 and 20 dilutions of the test instead.

Add to each dilution 0.1 ml of freshly reconstituted or thawed substrate plasma and warm up at 37 °C. Perform APTTs according to the laboratory protocol following a balanced order of duplicates.

The dilutions should be tested at 2-min intervals on the master watch, ending with a blank consisting of 0.1 ml of buffered saline and 0.1 ml of substrate plasma.

Calculation of results. Plot the clotting times of the test and standard against the concentration of FVIII on semi-log paper. Read the concentration as shown in Figure 18-8. It is important to obtain straight and parallel lines if the result is to be accurate. The reasons for nonparallelism and curvature are as follows:

1. Technical error: Repeat the assay with fresh dilutions.
2. Activation of the plasma by poor collection: A new sample should be collected.
3. A low concentration of FVIII in the test plasma giving rise to nonparallel lines: Stronger concentration of plasma should be prepared and tested.
4. The presence of an inhibitor: The tests described on p. 389 should be carried out.

Some automated coagulometers produce computed values using mathematical formulae. If the standard plasma is calibrated in terms of international units, the result can be expressed in iu/ml. For example, if the standard plasma has a FVIII concentration of 0.65 iu/ml and the test is shown to have 20% of the activity of the standard, the test plasma will have a FVIII concentration of 0.13 iu/ml (20% of 0.65 iu/ml).

Normal range. The normal range is 0.45 to 1.58 iu/ml.

Interpretation. Some clinically normal people have FVIII concentrations of 0.35–0.50 iu/ml. Values below 0.30 iu/ml are unequivocally abnormal; values below 0.50 iu/ml are significant in potential carriers of haemophilia (heterozygotes).

A reduced FVIII concentration is found in the following:

1. Haemophilia A
2. Some carriers of haemophilia A (heterozygotes)
3. VWD of all types, to varying degrees
4. Congenital combined deficiency of factors VIII and V (rare)
5. Disseminated intravascular coagulation
6. Acquired haemophilia (anti-FVIII antibodies).

Further tests in haemophilia A

Reduction in FVIII secondary to VWD should be excluded by measuring VWF antigen (VWF:Ag) and VWF ristocetin cofactor (VWF:RCo) (described later), and the patient's family history should be investigated. A low FVIII with normal VWF:Ag and VWF:RCo may also result from the Normandy type of VWD (type 2 N), which should be suspected when there is not a clear sex-linked family history and which can be confirmed by a VWF-FVIII-binding assay or genetic analysis.[32]

Two-stage and chromogenic assays for factor VIII

The one-stage FVIII assay is sensitive to preactivation of coagulation factors in the patient sample. The two-stage and chromogenic assays circumvent this problem by allowing sufficient time for activation of all the available FVIII and for generation of FXa which is then assayed in a separate step. In the chromogenic assay, Xa is measured using a chromogenic substrate; in the two-stage assay it is measured by a clotting end-point. In general these have proved too cumbersome (two stage) or expensive (chromogenic) for widespread use and preactivation is rarely a significant problem. However, a clinically significant discrepancy between the two types of assay has been reported in many cases of mild haemophilia. In these cases mutations destabilising the interaction between the A domains result in a one-stage assay result that is higher than that obtained by two stage. Most significantly, the patient's clinical bleeding tendency is more in keeping with the two-stage assay result.[33,34] The reverse phenomenon can also occur but is not associated with bleeding.[35] The chromogenic assay has also found utility in avoiding some of the problems encountered assaying FVIII concentrates, including novel modified FVIII molecules and is the reference method for

the European Pharmacopoeia. Consequently FVIII concentrates in Europe are labelled in units as measured by the chromogenic assay.

Chromogenic factor IX assays

Commercial chromogenic assays are available for measuring FIX but have not established a specific role to date (www.siemens.com). However they may prove to be important in assaying modified FIX molecules. FIX is activated to FIXa which in turn proportionally activates FX to FXa. The FXa activity is then measured using a chromogenic substrate.

Monitoring replacement therapy in coagulation factor defects and deficiencies

Estimations of FVIII levels in patients with haemophilia treated with FVIII concentrates often yield discrepant results. This is primarily because the FVIII concentrate (diluted in haemophilic plasma) is compared with a plasma standard. In general two-stage or chromogenic assays indicate greater potency than one-stage assays in this situation. In some cases the difference is sufficient to warrant the use of a product-specific reference preparation available from the manufacturer. It is recommended that this is used in conjunction with a chromogenic assay, but this may not be necessary.[36,37] In most other cases the clinical experience of using results from one-stage assays remains valid.

Assays of FVIII concentrates are fraught with difficulty and a detailed discussion is beyond the scope of this chapter.[38] The difficulties arise from several problems. First, the concentrate potency may be assigned using either a one-stage assay (as in the United States) or the chromogenic assay (as in Europe). Second, many concentrates, even when diluted in haemophilic plasma, behave differently in one-stage and chromogenic assays. As a result there are separate WHO standards for FVIII measurement: a plasma standard for measurement of FVIII in plasma samples and a concentrate standard for measurement of FVIII in concentrates. This is based on the principle of assaying like against like, although there are so many different concentrates with different characteristics that this is difficult to truly achieve and all must eventually be calibrated against a single plasma pool.

INVESTIGATION OF A PATIENT WITH A CIRCULATING ANTICOAGULANT (INHIBITOR)

Circulating anticoagulants or acquired inhibitors of coagulation factors are immunoglobulins arising either in congenitally deficient individuals as a result of the administration of the missing factor or in previously haemostatically normal subjects as a part of an autoimmune process. Usually, an inhibitor is suspected when a prolonged clotting test does not correct after mixing 50:50 with normal plasma or if an apparent factor deficiency does not fit with a patient's clinical history.

The most common anticoagulant in haemostatically normal people is the LAC, but despite the prolongation of clotting tests *in vitro,* this anticoagulant predisposes to thrombosis and its diagnosis and investigation therefore are considered on p. 411. Of the anticoagulants that cause a bleeding tendency, antibodies to FVIII are most common, either in haemophiliacs or as autoantibodies in previously normal individuals. Patients with haemophilia usually develop antibodies with simple kinetics; this inhibitor reacts rapidly with FVIII in a linear fashion and the antigen–antibody complex has no FVIII activity. Antibodies in nonhaemophilic individuals or patients with mild/moderate haemophilia usually have complex kinetics: inactivation of FVIII progresses slowly towards an equilibrium in which the plasma may display some residual FVIII activity even though there is an excess of antibody. Addition of further FVIII results in the same residual (equilibrium) FVIII activity. This distinction is not absolute, and either type of antibody may occasionally be found in the other patient group.

Inhibitors directed against other coagulation factors are rare, but an acquired form of VWD may arise in this way, usually from a paraprotein. Hypoprothrombinaemia owing to autoantibodies is a rare complication of systemic lupus erythematosus and is also seen as a transient post-viral phenomenon in children.[39,40] Only the FVIII inhibitor assays are described in detail in this section; the principles can be adapted to other factors with appropriate changes.

Confusion may arise in the presence of inhibitors if different clotting factors are assayed. For instance, if a patient's plasma contains an inhibitor directed against FVIII and the FIX level in that plasma is assayed using FIX deficient plasma, the clotting times in the FIX assay may be prolonged. This may lead to the mistaken conclusion that the patient has FIX deficiency, particularly if a single dilution of test plasma is used. Clotting factors should always be assayed at multiple dilutions. If the inhibitor is specifically directed against one clotting factor, that factor will appear to be equally deficient at all dilutions of the patient's plasma. The assayed level of other clotting factors will increase with increasing dilution as the inhibitor is diluted out.

Circulating inhibitor (anticoagulant) screen based on the activated partial thromboplastin time

Principle

Circulating anticoagulants or inhibitors affecting the APTT may act immediately or be time dependent. Normal plasma mixed with a plasma containing an immediately

acting inhibitor will have little or no effect on the prolonged clotting time. In contrast, if normal plasma is added to a plasma containing a time-dependent inhibitor, the clotting time of the latter will be substantially shortened. However, after 1–2 h, correction will be abolished and the clotting time will become long again. To detect both types of inhibition, normal plasma and test plasma samples are tested immediately after mixing and also after incubation together at 37 °C for 120 min.

Reagents

- *Normal plasma.* Commercial lyophilised normal plasma or a plasma pool from 20 donors as described on p. 376.
- *PPP.* From the patient
- *Reagents for the APTT.* (See p. 381.)

Method

Prepare 3 plastic tubes as follows: place 0.5 ml of normal plasma in a first tube, 0.5 ml of the patient's plasma in a second tube and a mixture of 0.25 ml of normal and 0.25 ml of patient's plasma in a third tube. Incubate the tubes for 120 min at 37 °C and then place all 3 tubes in an ice bath or on crushed ice. Next, make a 50:50 mixture of the contents of tubes 1 and 2 into a fourth tube, which serves to check for the presence of an immediate inhibitor. Perform APTTs in duplicate on all four tubes.

Results and interpretation

See Table 18-5. Note that the incubation period results in a prolongation of the normal plasma APTT.

Method for detecting inhibitors in patients with haemophilia

A simple inhibitor screen has been reported to be more sensitive than a Bethesda assay (see below) in monitoring for the development of inhibitors in haemophilia A and B. Add 0.4 ml patient plasma (or factor deficient control plasma) to 0.1 ml of 5 iu/ml FVIII or IX concentrate, giving a final concentration of 1 iu/ml. Mix gently and incubate at 37 °C for 60 min for haemophilia A patients and 10 min for haemophilia B patients. Perform appropriate factor assays for the patient and control sample; if the factor level in the patient sample is less than 90% of the control sample the inhibitor screen is positive.[41]

Quantification of factor VIII inhibitors

Principle

FVIII inhibitors are usually time dependent. Thus if FVIII is added to plasma containing an inhibitor and the mixture is incubated, FVIII will be progressively neutralised. If the amount of FVIII added and the duration of incubation are standardised, the strength of the inhibitor can be measured in units according to how much of the added FVIII is destroyed.

In the Bethesda method, the unit is defined as the amount of inhibitor that will neutralise 50% of 1 unit of FVIII in normal plasma after 2 h of incubation at 37 °C.

Dilutions of test plasma are incubated with an equal volume of the normal plasma pool at 37 °C. The normal plasma pool is taken to represent 1 unit of FVIII. Dilutions of a control normal plasma containing no inhibitor are treated in the same way. An equal volume of normal plasma mixed with buffer is taken to represent the 100% value.

At the end of the incubation period the residual FVIII is assayed and the inhibitor strength is calculated from a standard graph of residual FVIII activity versus inhibitor units.

Inhibitor assay modifications

The Bethesda assay and its Nijmegen modification give similar results at high levels of FVIII inhibition. Reports have shown that shifts in pH and protein concentrations will lead to changes in FVIII stability and inactivation. FVIII inactivation increases with pH and reduced protein concentration. This can result in false-positive results using the unmodified Bethesda method. The Nijmegen modification prevents these discrepancies by buffering the normal plasma with 0.1 M imidazole buffer at pH 7.4 and using immunodepleted

TABLE 18-5

INTERPRETATION OF THE INHIBITOR SCREEN BASED ON THE ACTIVATED PARTIAL THROMBOPLASTIN TIME

Tube	Content	Clotting Time		
1	Normal plasma	Normal	Normal	Normal
2	Patient's plasma	Long	Long	Long
3	50:50 mixture, patient: normal; incubated 2 h	Normal	Long	Long
4	50:50 mixture, patient: normal; no incubation	Normal	Long	Normal
Interpretation		Deficiency	Immediately acting inhibitor	Time-dependent inhibitor

FVIII-deficient plasma in the control mixture and for diluting the test plasma instead of the glyoxaline buffer.[42,43] The assay can also be modified to use FVIII concentrate (Oxford method), porcine FVIII concentrate or by increasing the incubation time to 4 h (new Oxford method).

In congenital haemophilia, testing for inhibitors is most likely to be successful after a washout period without FVIII infusions. If the sample is likely to contain some residual FVIII or the patient has mild or moderate haemophilia, then this may interfere with accurate quantification of the inhibitor. The FVIII can be removed by heating the sample to 58 °C for 90 min.

Reagents

- *Glyoxaline buffer.* See p. 380.
- *Kaolin.* 5 mg/ml and platelet substitute. Phospholipid or preferred APTT reagent.
- *FVIII C-deficient plasma.*
- *Standard plasma.* Normal plasma pool.

Method

1. Pipette into each of a series of plastic tubes 0.2 ml of normal pool plasma.
2. To the first tube add 0.2 ml of glyoxaline buffer. This mixture will be taken to have a FVIII level of 100%.
3. Make a series of dilutions of the patient plasma in glyoxaline buffer and add 0.2 ml of each to one of the remaining 0.2 ml normal plasma aliquots. If the patient has not been tested before, a range of dilutions should be set up ranging from undiluted plasma to a 1 in 50 dilution. If the approximate titre is known then this can be used to guide dilution.
4. Cap, mix and incubate all the tubes for 2 h at 37 °C. Then immerse all the tubes in an ice bath. Perform FVIII assays on all the incubation mixtures.

Calculation of results

Record the residual FVIII percentage for each mixture assuming the assay value of the control mixture to be 100%. (Although this has been diluted 1 in 2, so has the test plasma so the calculation of Bethesda units is valid). The lowest dilution of test plasma that gives a residual FVIII percentage close to 50% (between 30% and 60%) is used for calculating the strength of the inhibitor. The inhibitor titre is calculated as shown with examples in Table 18-6 and Figure 18-9 using a standard graph.

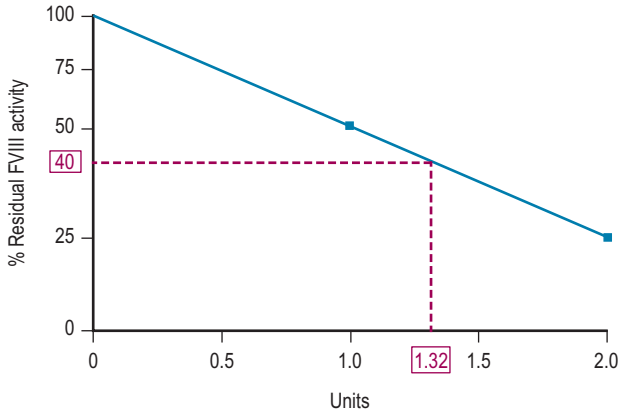

FIGURE 18-9 Plot used for determination of inhibitor level in Bethesda units. Note that the *y* axis is a logarithmic scale. One Bu results in 50% residual factor VIII activity after incubation with normal plasma for 2 h. The example shows a sample in which residual activity was 40% and the corresponding number of Bu is 1.32. This figure should then be multiplied by the dilution of the sample to obtain the Bu potency of the original test plasma.

TABLE 18-6

EXAMPLE OF THE CALCULATION OF BETHESDA UNITS (Bu) IN THREE PLASMA SAMPLES

Patient	Plasma Dilution	% Residual VIII	Calculation Bu × Dilution	Inhibitor in Bu
A	Undiluted	61	0.70 × 1	=0.07
B	1 in 5	33	1.60 × 5	=8.0
	1 in 10	55	0.85 × 10	=8.5
	1 in 15	68	0.55 × 15	=8.3
C	1 in 5	40	1.30 × 5	=6.5
	1 in 10	55	0.85 × 10	=8.5
	1 in 15	61	0.70 × 15	=10.5
	1 in 20	65	0.60 × 20	=12

Patient A has a mild inhibitor, patient B an inhibitor with simple kinetics and patient C an inhibitor with complex kinetics. All values are chosen for the percent residual FVIII activity close to 50%. The units for the calculation are read from Figure 18-9 using the % residual VIII. NOTE. In patients B and C the results should be reported as 8.5 Bethesda units (Bu); in C, the calculated level of inhibitor may continue to rise with increasing dilution.

(Modified from Kasper CK, Ewing NP. The haemophilias: measurement of inhibitor to FVIII C (and IX C). Methods in Haematology *1982;5:39).*

Interpretation

If the residual FVIII activity is between 80% and 100%, the plasma sample does not contain an inhibitor. If the residual activity is less than 60%, the plasma unequivocally contains an inhibitor. Values between 60% and 80% are borderline, and repeated testing on additional samples is needed before the diagnosis can be established.

Tests for other inhibitors

FIX inhibitors can be measured in a system identical to that described earlier. Because FIX inhibitors act immediately, there is no need for prolonged incubation; the mixtures can be assayed after 5 min at 37 °C. The activity of an inhibitor against porcine FVIII can be measured by substituting porcine FVIII concentrate, appropriately diluted in FVIII deficient plasma, for normal plasma.

INVESTIGATION OF A PATIENT WITH SUSPECTED AFIBRINOGENAEMIA, HYPOFIBRINOGENAEMIA OR DYSFIBRINOGENAEMIA

A patient suspected of afibrinogenaemia, hypofibrinogenaemia or dysfibrinogenaemia usually has a prolonged APTT, PT and TT. The prolongation of the PT is usually less marked than that of the APTT and TT. There may be either a history of bleeding or of recurrent thrombotic events but many patients (*c.* 50%) are asymptomatic. It is important that a physical estimation of fibrinogen (such as the clot weight) is obtained as well as a function-based assay (e.g. Clauss).[44]

Fibrinogen estimation (dry clot weight)

Principle

Fibrinogen in plasma is converted into fibrin by clotting with thrombin and calcium. The resulting clot is weighed. This may include other proteins and FDPs but is simpler than the total clottable protein method used for the international standard[45] and provides a useful comparison for the Clauss.

Reagents

- *Platelet-poor plasma (PPP).*
- *$CaCl_2$.* 0.025 mol/l
- *Bovine thrombin.* 50 NIH u/ml.

Method

Pipette 1 ml of plasma into a 12 × 75 mm glass tube and warm to 37 °C. Place a wooden applicator or swab stick in the tube, add 0.1 ml of $CaCl_2$ and 0.9 ml of thrombin and mix. Incubate for 15 min at 37 °C.

Gently wind the fibrin clot onto the stick, squeezing out the serum. Wash the clot in a tube containing at first 9 g/l NaCl, then water. Blot the clot carefully with filter paper, remove the fibrin from the stick and put into acetone for 5–10 min. Dry the clot in a hot air oven or over a hot lamp for 30 min. Allow it to cool and then weigh it.

Results

The fibrinogen level is expressed as g/l (i.e. the weight of fibrin obtained from 1 ml of plasma × 1000).

Normal range

Normal range is 1.5 to 4.0 g/l.

Further investigations

Whenever a congenital fibrinogen abnormality is suspected, DIC, liver disease and hyperfibrinolysis must be excluded; FDP should not be in excess and there should be no evidence of the consumption of other coagulation factors and platelets (see p. 405). Immunological or chemical determination of fibrinogen concentration is the next step in investigation. In dysfibrinogenaemias there is often a normal or even raised plasma fibrinogen concentration using these methods, although the functional assays indicate a deficiency. Hepatic or neonatal dysfibrinogenaemia is not associated with an increased risk of bleeding. In hereditary dysfibrinogenaemia it is not usually possible to predict the phenotype from the laboratory results. In this circumstance, DNA analysis is recommended to detect the mutation responsible allowing comparison with reported phenotypes. Family studies may also be helpful as dysfibrinogenaemia is usually autosomal dominant in inheritance.

DEFECTS OF PRIMARY HAEMOSTASIS

Investigation of the vascular disorders of haemostasis

Vascular disorders of haemostasis are those that arise as a result of a defect or deficiency of the vessel wall. This may result from one of the inherited disorders of collagen or from an acquired disorder such as amyloidosis or scurvy.

In general, the tests of coagulation available in the laboratory will be of little help in elucidating such defects. The only test of possible use is the bleeding time. Tests of capillary resistance are of little value. A careful clinical history and physical examination are most likely to provide the basis for diagnosis. Particular attention should be paid to previous scars, associated signs of the inherited syndromes and evidence of systemic disease. In some cases a tissue biopsy may be useful, but confirmation of the diagnosis requires analysis of collagen from cultured fibroblasts or DNA analysis of the relevant candidate genes.[46]

Bleeding time

A standard incision is made on the volar surface of the forearm and the time the incision bleeds is measured. Cessation of bleeding is dependent on an adequate number of platelets, the ability of the platelets to adhere to the subendothelium directly and via adhesion molecules such as VWF and fibrinogen, and the ability of the platelets to aggregate. However the test has poor sensitivity for disorders such as VWD, is a poor predictor of bleeding risk and is poorly reproducible. Consequently it is now rarely performed and readers are referred to previous editions for details.

Laboratory tests of platelet–von Willebrand factor function

The PFA-100 system

The *in vitro* system for measuring platelet–VWF function PFA-100 (Dade Behring) was introduced as a substitute for the bleeding time. The instrument aspirates a citrated whole blood sample under constant vacuum from the sample reservoir through a capillary and a microscopic aperture cut into a membrane. The membrane is coated with collagen and either epinephrine or ADP. It therefore attempts to reproduce under high shear rates VWF binding and platelet attachment, activation and aggregation, which slowly build a stable platelet plug at the aperture. The time required to obtain full occlusion of the aperture is reported as the 'closure time'. Collagen/epinephrine is the primary screening cartridge and the collagen/ADP is used to identify possible aspirin use. Studies have shown this system to be sensitive to platelet adherence and aggregation abnormalities and to be dependent on normal VWF, glycoprotein Ib and glycoprotein IIbIIIa levels but not on plasma fibrinogen or fibrin generation.[47]

The PFA-100 system may reflect VWF function better than the bleeding time, but it is not sensitive to vascular-collagen disorders.[48,49] Studies have shown that many patients with minor platelet disorders such as secretion defects are not detected by the PFA-100.[50] A modification, the PFA-200, is available to monitor anti-platelet therapy with P2Y12 inhibitors (Sysmex, www.sysmex.co.uk).

INVESTIGATION OF SUSPECTED VON WILLEBRAND DISEASE

A diagnosis of VWD should be considered in individuals with a relevant history or family history of bleeding, particularly of the mucosal type. Although a prolonged APTT in screening tests is suggestive, this is normal in many patients with VWD and specific assays must be performed.[51,52] Preliminary screening with a test such as the PFA-100 may be useful in excluding borderline cases. All relevant activities (FVIII concentration, VWF:Ag concentration, collagen binding activity [VWF:CB] and VWF:RCo) should be measured. When interpreting the results, the very wide range of VWF levels in the normal population and the effect of the ABO blood group should be borne in mind. It is apparent that many individuals with levels down to 30% of normal do not have any significant bleeding tendency and caution should be exercised in diagnosing VWD on the basis of moderately low VWF levels alone.[51]

Thus if an abnormality is detected it should be considered in relation to the clinical history. When a discrepancy between antigen and function is found (i.e. function is <60% of the antigen) multimer analysis of the plasma should be performed. In normal plasma, each multimer of VWF (a large molecule consisting of 2 to more than 20 subunits of VWF) is seen to be composed of a 'triplet', a dark central band sandwiched between two lighter bands; high molecular weight multimers predominate. In VWD, the multimer analysis may be superficially normal, there may be no VWF:Ag detectable, the high-molecular-weight forms necessary for normal platelet adhesion may be lacking, or the triplet pattern may be abnormal. On the basis of these results VWD can usually be classified as shown in Table 18-7 although some remain unclassifiable.[51,52]

Enzyme-linked immunosorbent assay for von Willebrand factor antigen

Principle

ELISA involves coating a special microtitre plate with a primary antibody to VWF:Ag. A suitable dilution of the test plasma is added to the wells, allowing the VWF:Ag to bind to the primary antibody. After removal of excess antigen by washing the plate, a second antibody, conjugated to an enzyme, usually peroxidase and called the 'tag' antibody, is added and this binds to the VWF:Ag already bound to the plate. On addition of a specific substrate, a colour change occurs. After the reaction has been stopped with acid, the OD of each well can be measured using an electronic plate reader; the OD is directly proportional to the amount of VWF:Ag present in the test plasma.

Reagents

- *0.05 M Carbonate buffer.* 1.59 g Na_2CO_3, 2.93 g $NaHCO_3$, 0.2 g NaN_3 in 1 litre of distilled water (pH 9.6).
- *0.01 M Phosphate buffered saline.* 0.39 g $NaH_2PO_4.2H_2O$, 2.68 g $Na_2HPO_4.12H_2O$, 8.47 g NaCl in 1 litre distilled water (pH 7.2).
- *0.1 M Citrate phosphate buffer.* 8.8 g citric acid, 24.0 g $Na_2HPO_4.12H_2O$ in 1 litre distilled water (pH 5.0).
- *Anti VWF:Ag antiserum.*
- *Anti VWF:Ag conjugated with peroxidase.*
- *Platelet-poor (100%) calibration plasma.*
- *PPP (tests and control).*
- *1,2-o-Phenylenediamine dihydrochloride (orthophenylenediamine, OPD).*
- *1 M Sulphuric acid.*
- *Hydrogen peroxide 20 vol.*
- *Tween 20.*

TABLE 18-7

CLASSIFICATION OF VON WILLEBRAND DISEASE

Type	Description	Factor VIII	VWF:Ag	VWF:RCo	Comments	Inheritance
1	Partial quantitative deficiency of VWF	L/N	L	L	Includes VWF mutations causing rapid VWF clearance (e.g. VWF Vicenza) and requires function:antigen ratio >0.6	Mostly autosomal dominant inheritance when VWF <0.3 iu/ml. Mutations of *VWF* in kindreds with levels >0.3 iu/ml show variable penetrance.
2A	Decreased VWF-dependent platelet adhesion with selective deficiency of high-molecular-weight multimers	L/N	L/N	L	Some controversy exists regarding classification of VWF mutations associated with subtle reductions in HMW multimers. Function:Ag ratio <0.6	Mostly autosomal dominant
2B	Increased affinity for platelet GPIb	L/N	L	L/N	Should be distinguished from platelet type pseudo-VWD (PT-VWD), using either platelet agglutination tests or genetic testing. Cases with normal VWF multimer and platelet count have been described.	Autosomal dominant
2 M	Decreased VWF-dependent platelet adhesion without selective deficiency of HMW multimers	N	N	L	This also includes defects of VWF collagen binding. May be combined quantitative/qualitative defect. Function:Ag ratio <0.6	Autosomal dominant
2 N	Markedly decreased binding affinity for FVIII	L	N	N	Should be distinguished from mild haemophilia A	Reduced VWF:FVIII binding defects are often identified in a compound heterozygote state with a VWF null allele rather than classic homozygous form
3	Virtually complete deficiency of VWF	L	L	L	Corresponds to <0.03 iu/ml in most assays	Autosomal recessive, frequent null VWF alleles. Bleeding symptoms occur in 26–48% of obligate carriers

L, low; N, normal; RCo, ristocetin cofactor; VWF, von Willebrand factor.

NOTE: Following reports of VWD in which the only abnormality is a defect in collagen binding, it has been suggested that the 2 M category be extended to include these patients.[51] VWD is extremely varied and recessive forms of type 1 and type 2 are occasionally encountered.

Method

Dilute the antihuman-VWF:Ag 1:500 in 0.05 M carbonate buffer (i.e. 40 µl antibody in 20 ml buffer) and add 100 µl to each well of the microtitre plate. Incubate for 1 h at room temperature in a moist chamber. Discard antibody and wash 3 times by immersion in a trough of phosphate buffered saline (PBS) with 0.5 ml/l Tween (VWR, www.vwr.com) for 2 min, followed by inversion onto absorbent paper.

Prepare dilutions of the 100% standard 1 in 10, 1 in 20, 1 in 40 and 1 in 60 in PBS with 1 ml/l Tween. Dilute patient's and control plasmas 1 in 10, 1 in 20 and 1 in 40 in the same way and add 100 µl of each dilution in duplicate to the wells of the microtitre plate. Incubate for 1 h as before and repeat washing.

Dilute the antihuman-VWF:Ag-peroxidase conjugate 1:500 in 1 ml/l PBS-Tween (i.e. 40 µl antibody in 20 ml buffer) and add 100 µl to each well. Incubate for 1 h.

Wash twice in 0.5 ml/l PBS Tween and once in 0.1 M citrate phosphate buffer.

Dissolve 40 mg of substrate (OPD) in 15 ml citrate phosphate buffer. Add 10 µl of 20 volume hydrogen peroxide to the substrate solution immediately before use and then add 100 µl to each well.

When the yellow colour has reached an intensity at which a mid-yellow ring is clearly visible in the bottom of the wells, stop the reaction by the addition of 150 µl of 1 M sulphuric acid. Read the optical density across the plate at 492 nm using a microtitre plate reader. Plot the standard curve on log-linear graph paper. VWF:Ag levels are obtained by reading from the reference curve.

Normal range

The normal range is approximately 0.50 to 2.0 iu/ml.

Interpretation

The results must be interpreted in conjunction with the results of FVIII assay and the ristocetin cofactor assay (see Table 18-7). VWF:Ag can also be measured by an immunoelectrophoretic assay. The Laurell rocket method for this is described in the 7th edition of this book.

von Willebrand factor antigen immunoturbidimetric assay

Latex microparticles, coated with antibodies specific for VWF, are incubated with plasma; an antigen–antibody reaction occurs resulting in agglutination of the latex microparticles. Agglutination of the microparticles leads to an increase in turbidity and hence absorbance, which is measured photometrically. Using a standard curve, the VWF concentration can be calculated (Instrumentation Laboratories, www.instrumentationlaboratory.com; Stago, www.stago.com; Siemens, www.healthcare.siemens.com). Falsely elevated results may be obtained in the presence of rheumatoid factor or in acquired von Willebrand syndrome.

Normal range

The normal range is approximately 0.50 to 2.00 iu/ml.

Interpretation

The results must be interpreted in conjunction with the results of the FVIII and ristocetin cofactor assays (see Table 18-7).

Ristocetin cofactor assay

Principle

Washed platelets do not 'agglutinate' in the presence of ristocetin unless normal plasma is added as a source of VWF. 'Agglutination' follows a dose-response curve dependent on the amount of plasma/VWF added.[53] Freshly washed platelets or formalin-fixed platelets can be used in the assay. Fixed platelets take longer to prepare but are not susceptible to aggregation (as distinct from 'agglutination') with ristocetin and they can be stored so that they are available for emergency use. Freshly washed platelets are quicker to prepare and retain a functional platelet membrane, but they cannot be retained for later use. Commercial lyophilised, fixed, washed platelet preparations are available. Once reconstituted these preparations are stable for several weeks and should enhance assay standardisation.

Assay using fresh platelets

Reagents

- *K_2EDTA*. 0.134 mol/l
- *Citrate–saline*. One volume of 31.1 g/l trisodium citrate + 9 volumes of 9 g/l NaCl
- *EDTA–citrate–saline*. One volume of 0.134 mol/l K_2EDTA + 9 volumes of citrate–saline.

Method

Collect 40–60 ml of normal blood into a one-tenth volume of EDTA–saline in flat-bottom plastic universal containers. Do not use conical-bottom containers. Centrifuge at 150–200 *g* at room temperature (about 20 °C) for 15 min.

Pipette, using a plastic pipette, the platelet-rich plasma (PRP) into a plastic container. Mark the level of plasma on the tube. Centrifuge at 1500–2000 *g* to obtain a platelet button.

Discard the PPP. Resuspend the platelet button in a 2 ml volume of EDTA–citrate–saline by gently squeezing the liquid up and down a pipette until a smooth suspension is formed. Add EDTA–citrate–saline to the 20 ml mark.

Centrifuge at 1500–2000 *g* for 15 min. Discard the supernatant. Resuspend in EDTA–citrate–saline and leave at room temperature for 20 min to elute the ristocetin cofactor from the platelets.

Centrifuge again, discard the supernatant and resuspend in EDTA–citrate–saline two more times to a total of four washes.

Centrifuge at 1500–2000 *g* for 15 min. Discard the supernatant and resuspend in citrate–saline using a volume slightly under the original plasma volume (marked on the container). Centrifuge at 800 *g* for 5 min to remove platelet clumps, white cells and red cells.

Remove the platelet-rich supernatant carefully. Perform a platelet count and dilute the platelet-rich suspension with citrate–saline until the platelet count is about 200×10^9/l.

Leave the platelets at room temperature for 30–45 min to allow the platelets to recover from the trauma of washing and centrifugation.

Reagents for assay

- *Citrate–saline.*
- *Ristocetin.* 100 mg/ml. Stored frozen in 1 ml volumes.
- *Plasma standard.*
- *PPP.* From the patient(s).

Assay method

Confirm that the washed platelets do not 'agglutinate' with ristocetin in the absence of added plasma. Deliver 0.5 ml of citrate–saline into an aggregometer cuvette and 0.4 ml of the platelet suspension + 0.1 ml of citrate–saline into another cuvette. Place in the warming block and leave it there for 3 min to warm. Add 5 µl of ristocetin and record at 1 cm/min for 2 min. The absorbance resulting from citrate–saline alone is taken to represent 100% agglutination and that resulting from platelets alone represents zero (%) agglutination (blank). The absorbance resulting from the platelet suspension must not exceed 5 divisions on the chart paper. If it is greater, the platelets must be washed again and the procedure must be repeated. The reading of this blank must be repeated every hour.

All plasma samples and ristocetin should be kept in an ice bath.

Standard curve

A standard curve is obtained by making doubling dilutions, 1 in 2 to 1 in 32 in citrate–saline, of the standard plasma (donor pool, commercial reference plasma or other reference materials). Frozen plasma standards may be preferred because lyophilisation can result in pH changes that affect lyophilised platelets. The absorbance resulting from a mixture of 0.4 ml of citrate–saline and 0.1 ml of plasma dilution is taken to represent 100% agglutination, and that resulting from the mixture of 0.4 ml of platelet suspension and 0.1 ml of plasma dilution represents zero (0%) agglutination.

Add 5 µl of ristocetin to the cuvette containing the mixture giving zero agglutination and record the agglutination for 2 min. Test each dilution of the standard plasma in a similar way.

The patient's plasma is tested at two dilutions, depending on the expected concentration of VWF in the plasma. Both dilutions should give agglutination within the range of that of the standard curve.

Reset 100% and zero aggregation for each patient.

A reading of the platelet blank should be repeated at hourly intervals. If the reading differs from the original, the difference must be subtracted from the results of subsequent tests.

Results

Measure 'agglutination' at 1 or 2 min depending on the strength of agglutination. All responses must be compared on the same time scale and not read at maximum agglutination.

Plot the standard curve on semi-log paper with agglutination on the linear scale and the concentration of VWF in iu/ml on the log scale (Fig. 18-10). For assay purposes, assign the 1 in 2 dilution of standard plasma a value of 0.50 iu/ml. (Each batch of standard is precalibrated and may not necessarily be 1.0 iu/ml.)

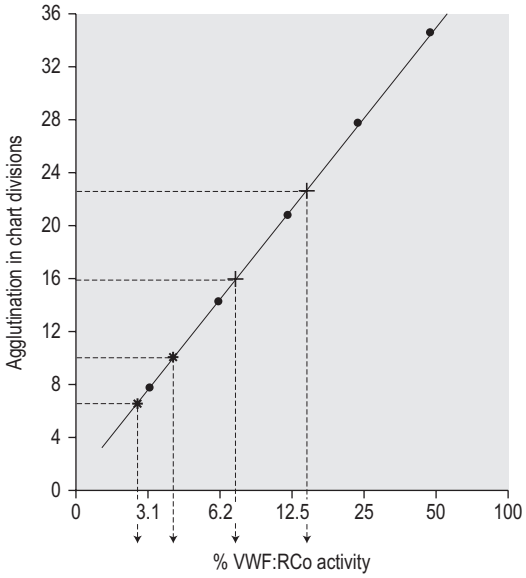

FIGURE 18-10 Ristocetin cofactor assay. The standard curve is plotted on semi-log paper. Each test plasma is assayed in two dilutions. Plasma 1 (+) produced the following readings: 1 in 4 dilution: 16 divisions of the chart paper = 7% (four times (dilution factor) = 28%); 1 in 2 dilutions: 22 divisions = 13% (twice dilution factor = 26%). The mean of the two readings is 27%. Plasma 2 (*) gave the following results: 1 in 2 dilution: 7 divisions = 2.5% (twice dilution factor = 5%). 1 in 4 dilution: 5 divisions (not shown). This result was similar to the blank, and the plasma was next tested undiluted, giving a reading of 10 divisions = 4%. The mean is 4.5% (very low). If the reference plasma is taken to have a potency of 1.0 iu/ml then the % figures can be converted to iu/ml (e.g. 26% becomes 0.26 iu/ml).

Read the patient's VWF concentration directly off the standard curve, correct for the dilution factor and average the two results from the different dilutions.

Normal range

The normal range is approximately 0.50 to 2.00 iu/ml.

Interpretation

The VWF concentration measured by ristocetin cofactor assay should be interpreted in conjunction with other FVIII and VWF:Ag assays, as shown in Table 18-7.

Assay using formalin-fixed platelets

Reagents

- *Sodium citrate solution.* 32 g/l trisodium sodium citrate ($Na_3C6H_5O_7.2H_2O$).
- *K_2 EDTA.* 0.134 mol/l.
- *2% formalin (40% formaldehyde).* In 9 g/l NaCl.
- *0.05% sodium azide.* In 9 g/l NaCl.

Method

Suitable preparations can be obtained from citrated blood in a blood donation bag, from a normal individual or from a therapeutic venesection carried out on a patient with a normal or high platelet count. Acid–citrate–dextrose or citrate–phosphate–dextrose solution from the donor bag is ejected through the taking needle and replaced by the equivalent volume of sodium citrate. Collect *c*. 500 ml of blood.

Centrifuge the blood at 300*g* for 15 min at room temperature. Separate the PRP and add 9 volumes of PRP to 1 volume of EDTA solution. Incubate for 1 h at 37 °C to reverse the effect of ADP released during the preparation. Add an equal volume of 2% formalin and leave at 4 °C for 1 h. Centrifuge at 200*g* for 10 min at 4 °C. Decant the supernatant and recentrifuge it at 250*g* for 20 min at 4 °C. Discard the supernatant and resuspend the platelet sediment in chilled (4 °C) 9 g/l NaCl. Wash the platelets twice more. After the final wash, resuspend the platelets in the sodium azide solution. Adjust the platelet count to $300–500 \times 10^9$/l. The suspension is stable for 1 month at 4 °C.

Fixed platelets are also available commercially.

Reagents for assay

- *Buffer for plasma dilutions*. Barbitone buffer, pH 7.4, containing 40 mg/ml of bovine serum albumin (p. 380).
- *Ristocetin, plasma standard and patient's PPP*. As described in the previous assay.

Assay method

Follow the method described for washed fresh platelets. Prepare all plasma dilutions in the albumin-containing buffer.

Results, interpretation and normal range are as described for the washed platelet assay.

Automated assays of von Willebrand factor platelet-binding function

Because the conventional VWF:RCo assay is laborious and is notoriously imprecise (CV 20–30%) and insensitive (lower limit of detection 0.1–0.2 iu/ml), a number of modified and novel assays suitable for automation have been devised. However these do not all measure VWF:RCo and a new nomenclature has been suggested to clarify what has been assessed.[54]

1. *VWF:RCo*. This represents the original ristocetin cofactor assay using VWF, platelets and ristocetin. The assay may be automated, using lyophilised platelets and ristocetin with agglutination being measured on an automated analyser.
2. *VWF:GPIbR (ristocetin-triggered GPIb-binding assays)*. In these assays only the GPIb molecule is used rather than entire platelets. For automation, the GPIb is captured on latex beads or magnetic particles and binding of patient VWF is triggered by ristocetin. The binding is detected either by change in turbidity or by an anti-VWF antibody with chemiluminescent detection system.
3. *VWF:GPIbM (gain of function GPIb binding)*. It is possible to engineer a GPIb molecule containing mutations that allow binding to VWF in the absence of ristocetin. This is immobilised on latex beads. Incubation with the patient sample results in aggregation of the beads and the change in turbidity is recorded. It has the advantage of not detecting mutations in the ristocetin binding site which can lead to an incorrect diagnosis of VWD.[55]
4. *VWF:Ab (antibody binding to VWF)*. These assays utilise an antibody which binds to a region of the A1 domain responsible for binding to GPIb. Although easy to perform and accurate for normal VWF, this type of assay has failed to detect certain forms of type 2A VWD.

All these assays have some benefits and advantages but it is not yet entirely clear how they will perform in practice for the very wide range of VWF variants encountered.

Collagen-binding assay (ELISA)

The ELISA-based VWF collagen binding assay (VWF:CB) was developed as an alternative to VWF:RCo as a measure of VWF functional activity. It has the advantage over VWF:RCo of using an ELISA-based system, giving greater precision. Clearly, because it measures a different ligand-binding property to ristocetin, it should be seen as a complementary rather than alternative assay of VWF function. Indeed, some cases of VWD have reduced VWF:RCo but normal VWF:CB and vice versa. The assay conditions have been adjusted to make the result sensitive to the presence of high-molecular-weight multimers of VWF and thus to its functional activity *in vivo*.

The collagen-binding assay ELISA method is based on the ability of VWF to bind collagen. The source of collagen is an important variable and wells of the ELISA test strips are coated with human collagen type III although type I and type I/III mixtures have also been used.[56] After incubation with the test plasma, the amount of VWF bound is detected using an anti-VWF peroxidase-conjugated antibody. Antibody-peroxidase binding is quantified in the usual way and the intensity of the colour generated is directly proportional to the VWF:CB concentration. Using a reference curve, the VWF:CB is quantified.

Collagen-binding assay kits are commercially available, and assay details can be found in the manufacturer's instructions. They may vary with manufacturer and even from batch to batch of the same kit. Particular attention should be paid to the shelf life of the kits.

Multimeric analysis of von Willebrand factor

Analysis of the multimeric structure of VWF is a highly specialised technique requiring considerable laboratory expertise and resource.[57,58] Although it is recommended

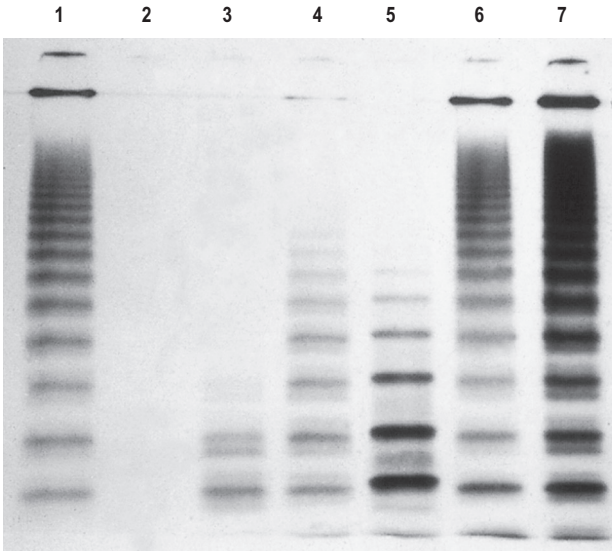

FIGURE 18-11 Autoradiograph of the electrophoretic analysis of von Willebrand factor (VWD) multimer patterns. The largest multimers appear at the top of the gel. The normal pattern with numerous large multimers and a triplet pattern visible in the smaller multimers are shown in lane 7. Lanes 1 and 6 are compatible with type 1 VWD in which there is a generalised decrease in multimer numbers but the normal triplet pattern is retained. In lane 2 there is virtually no VWF detected, indicating type 3 VWD. Lanes 3 and 5 show both abnormality of VWF amount and multimer pattern, indicating type 2A. In lane 4 there is a selective loss of the large multimers typical of type 2B VWD.

for the classification of VWD types and has proved useful in understanding VWF structure and function, it is not essential for practical management of VWD. A technique for performing multimer analysis is given in the previous edition of this book and an illustration of the results obtained with interpretation in Figure 18-11. The principal diagnostic question is whether the high molecular weight forms are present or not and this can usually be deduced by comparing VWF:RCo with VWF:CB.[56]

INVESTIGATION OF A SUSPECTED DISORDER OF PLATELET FUNCTION, INHERITED OR ACQUIRED

(For investigation assays of VWD, see p. 393; for diagnosis of thrombocytopenia, see pp. 554.)

Abnormalities of platelet function lead to signs and symptoms characteristic of defects of primary haemostasis: bleeding into the mucous membranes, epistaxes, menorrhagia and cutaneous ecchymoses. The patient may also suffer from abnormal intraoperative or postoperative bleeding and oozing from small cuts or wounds.

Laboratory investigation of platelets and platelet function

The peripheral blood platelet count and, for some laboratories, PFA-100 are first-line tests of platelet function. However, some disorders of platelet function are not detected by these tests. Additional information may be obtained by inspecting a fresh blood film, which may show abnormalities of platelet size or morphology that may be of diagnostic importance.[59,60] Neutrophils should also be examined for cytoplasmic inclusions indicative of *MYH9*-related disorders.

If the screening procedures or clinical history suggest a disorder of primary haemostasis and VWF function is normal, further tests should be organised.[61] Drugs and certain foods (Table 18-8) may affect platelet function tests and the patient must be asked to refrain from taking such substances for at least 7 days before the test.

The usual sequence of investigation is shown in Figure 18-12. Platelet function tests can be divided into six main groups (Table 18-9): adhesion tests, aggregation tests, assessment of the granular content, assessment of the

TABLE 18-8

SUBSTANCES THAT COMMONLY AFFECT PLATELET FUNCTION[60]

Agents that Affect Prostanoids Synthesis
Aspirin
Nonsteroidal anti-inflammatory drugs
Corticosteroids
Agents that Bind to Platelet Receptors and Membranes
α-antagonists
β-blockers
Antihistamines
Tricyclic antidepressants
Local anaesthetics
Ticlopidine
Clopidogrel
IIb/IIIa blocking agents
Selective serotonin reuptake inhibitors (SSRIs)
Antibiotics
Penicillin
Cephalosporins
Agents that Increase Cyclic Adenosine Monophosphate (cAMP) Levels
Dipyridamole
Aminophylline
Prostanoids
Others
Heparin
Chondroitin sulphate and glucosamine
Dextran
Ethanol
Clofibrate
Phenothiazine
Garlic

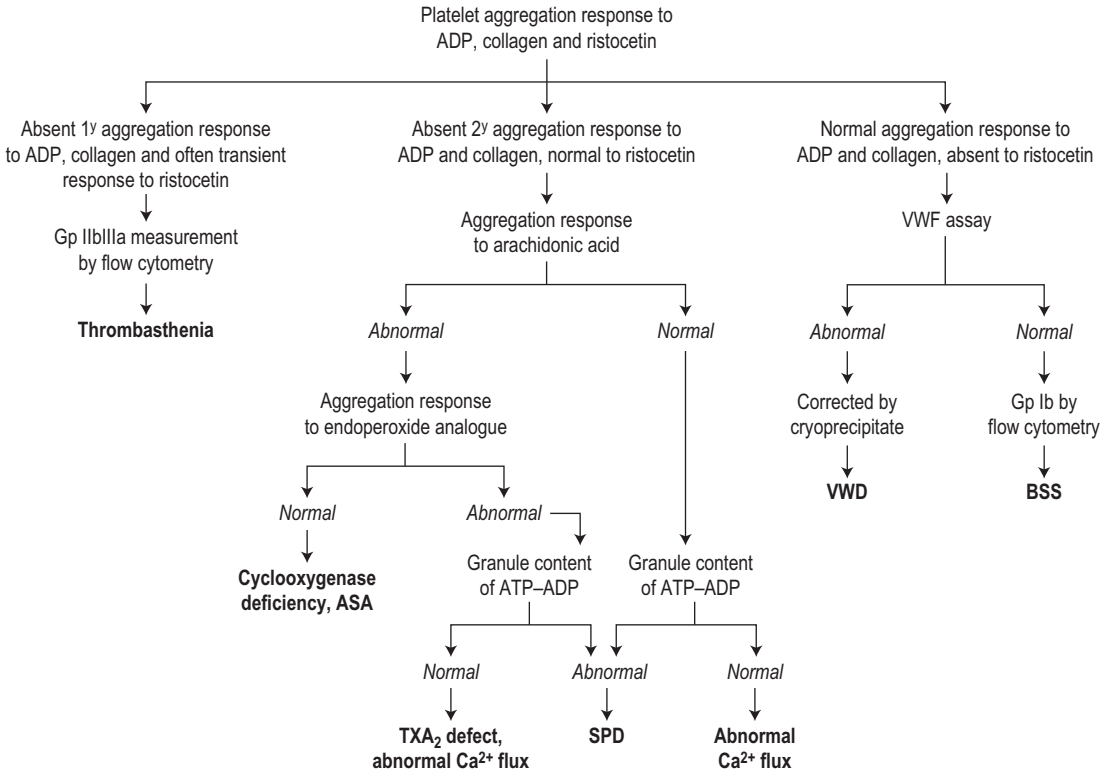

FIGURE 18-12 Flowchart for investigation of suspected platelet dysfunction. ASA, effect of aspirin ingestion; BSS, Bernard–Soulier syndrome; Responses mimicking BSS and Thrombasthenia can be caused by coating of platelets by autoantibodies in autoimmune 'idiopathic' thrombocytopenic purpura; SPD, storage pool defect; VWD, von Willebrand disease.

release reaction, investigation of the prostaglandin pathways and tests of platelet coagulant activity. Expression of platelet glycoproteins can be assessed by flow cytometry, although this does not necessarily correlate with functional activity.

The *granular content* of the platelets can be assessed by electron microscopy or by measuring the substances released. Adenine nucleotide and serotonin release from the dense granules are best measured by a specialist laboratory.

If the initial aggregation studies suggest a defect in the prostaglandin pathways, TXB_2 can be estimated quantitatively by radioimmune assay. Highly specific assays of various steps in arachidonic acid metabolism are also available but are outside the scope of a routine laboratory.

Platelet coagulant activity – the completion of the membrane 'flip-flop' – can be indirectly measured using the prothrombin consumption index. This test is rarely performed now but is abnormal in Scott syndrome, a rare bleeding disorder; it was described in the 7th edition of this book. Alternatively, phosphatidylserine exposure can be directly assessed by flow cytometry.

Platelet aggregation

Principle

The light absorbance of PRP decreases as platelets aggregate. The amount and the rate of fall are dependent on platelet reactivity to the added agonist, provided that other variables, such as temperature, platelet count and mixing speed, are controlled. The absorbance changes are monitored on a chart recorder.

Reagents

Test and control platelet-rich plasma. The patient and control subject should not be ingesting any drugs, beverages or foods that may affect aggregation for at least the preceding 10 days (see Table 18-8) and preferably should have fasted overnight because the presence of chylomicra may also disturb the aggregation patterns. Collect 20 ml of venous blood with minimal venous occlusion and add to a one-tenth volume of trisodium citrate (see p. 562) contained in a plastic or siliconised container. The blood should not be chilled because cold activates the platelets. PRP is obtained by centrifuging at room temperature (*c.* 20 °C) for 10–15 min at 150–200 *g*. Carefully remove the PRP, avoiding contamination with red cells or buffy coat and place in

a stoppered plastic tube. Store at room temperature until tested. This is stable for about 3 h. It is important to test all samples after a similar interval of time (say 1 h) and to store them at the same temperature to minimise variation.

Test and control platelet-poor plasma. Centrifuge the remaining blood at 2000 *g* for 20 min to obtain PPP.

Use of platelet-rich plasma. A platelet count is performed on the PRP. Adjustment of the platelet count in the PRP is not recommended because this inhibits platelet activation.[61] PRP should always be stored in tightly stoppered tubes that are filled nearly to the top to avoid changes in pH, which also affect platelet aggregation and tests of nucleotide release.

Aggregating agents. The five aggregating agents listed in the following sections should be sufficient for the diagnosis of most functional disorders. One study recommended a minimal screening panel of 1.25 μg ml^{-1} collagen, 6 μM epinephrine, 1.6 mM arachidonic acid and 1.0 μM U44619 (endoperoxide analogue).[62] This combination had high specificity but relatively poor sensitivity and should be coupled with additional tests such as nucleotide release. For research purposes and when investigating unusual kindreds, other agonists listed in Table 18-9 may also be used.

Adenosine 5-diphosphate. The anhydrous sodium salt of ADP is used. Prepare a stock solution by dissolving 4.93 mg of the trisodium salt or 4.71 mg of the disodium salt in 10 ml of 9 g/l NaCl, pH 6.8. This makes a 1 mmol/l solution. Store in 0.5 ml volumes at −40 °C until use; they remain stable for up to 3 months at this temperature. Once thawed, the solution must be used within 3 h and then discarded. For aggregation testing, prepare 100, 50, 25, 10 and 5 μmol/l solutions.

Collagen 1 mg/ml. A 1 mg/ml stock solution of collagen (Sigma, www.sigmaaldrich.com; Helena, www.helenabiosciences.com) is diluted before use in the buffer supplied with the collagen or in 5% dextrose to obtain concentrations of 10 and 40 μg/l. When diluted 1 in 10 in PRP (see below), the final concentrations will be 1 and 4 μg/ml.

Ristocetin sulphate (American Biochemical & Pharmaceuticals Ltd., www.abpcorp.com). Each vial of ristocetin sulphate contains 100 mg of ristocetin and should be stored at 4 °C until dissolved; 8 ml of 9 g/l NaCl are added to each vial to obtain a 12.5 mg/ml solution. Store at −40 °C in 0.5 ml volumes until used. Ristocetin may be refrozen after use. It should never be used in concentrations of greater than 1.4 mg/ml because protein precipitation may occur in plasma and give rise to false results.

Arachidonic acid. Arachidonic acid is Na-salt, 99% pure. Dissolve the contents of a 10 mg vial in 1.5 ml of sterile water by gentle mixing to give a 20 mmol/l stock solution. This may be frozen in 0.5 ml volumes at −20 °C for later use. Prepare a working solution by making doubling dilutions of the stock in saline to give 5 and 10 mmol/l solutions.

Adrenaline (epinephrine). Dissolve 1-epinephrine bitartrate, 3.33 mg, in 10 ml of water to prepare a 1 mmol/l stock solution. Store in 0.5 ml volumes at −40 °C. Solutions of 20 and 200 μmol/l are prepared for use in barbitone buffered saline, pH 7.4.

NOTE: All aggregation reagents should be kept on ice until used.

Method

Centrifugation may cause cellular release of ADP and platelet refractoriness to aggregation, and the actual aggregation test should not be started within 30 min of preparing the PRP. However, the tests should be completed within 3 h and whenever possible within 2 h of preparing the PRP. Platelets left standing at room temperature (*c.* 20 °C) become increasingly reactive to adrenaline and in some cases to collagen; the rate of change increases after 3 h.

Switch on the aggregometer 30 min before the tests are to be performed to allow the heating block to warm up to 37 °C. Set the stirring speed to 900 rpm. Pipette the appropriate volume of PRP (this varies depending on the make of the aggregometer used) into a plastic tube or cuvette. Place the tube in the heating block. After 1 min insert the stirrer into the plasma. Set the transmission to 0 on the chart recorder. Replace with a cuvette containing PPP and set the transmission to 100%. Repeat this procedure until no further adjustments are needed and the pen traverses most of the width of the chart paper in response to the difference in absorbance between the PRP and PPP.

Allow the PRP to warm up to 37 °C for 2 min and then add 1 in 10 volumes of the agonist. Record the change in transmission until the response reaches a plateau or for 3 min (whichever is sooner). Repeat this procedure for each agonist. The starting amount for each agonist is the lowest concentration prepared as described earlier. If no release is obtained, increase the concentration until a satisfactory response is obtained.

Interpretation

Normal and abnormal platelet aggregation curves are shown in Figures 18-13 and 18-14.

Adenosine 5-diphosphate. Low concentrations of ADP (0.5 to 2.5 μmol/l) cause primary or reversible aggregation. First, ADP binds to a membrane receptor and releases Ca^{2+} ions. A reversible complex with extracellular fibrinogen forms and the platelets undergo a shape change reflected by a slight increase in absorbance. After this, the bound fibrinogen adds to the cell-to-cell contact and reversible aggregation occurs. At very low concentrations of ADP, platelets may disaggregate after the first phase. In the presence of higher concentrations of ADP an irreversible secondary wave aggregation is associated with the release of dense and α granules as a result of activation of the arachidonic acid pathway. If only high doses of ADP are used, defects in the primary wave will be missed.

Collagen. The aggregation response to collagen is preceded by a short 'lag' phase lasting between 10 and 60 s. The duration of the lag phase is inversely proportional to the concentration of collagen used and to the responsiveness of the platelets tested. This phase is succeeded by a single wave of aggregation resulting from the activation of the arachidonic acid pathway and the release of the granules. Higher doses of collagen (>2 μg/ml) cause a sudden increase in intraplatelet calcium concentration and this may bring about the release reaction without activating the prostaglandin pathway. Collagen responses should therefore always be measured using 1 and 4 μg/ml concentrations.

Ristocetin. Ristocetin reacts with VWF and the membrane receptor to induce platelets to clump together ('agglutination'). It does not activate any of the three aggregation pathways and does not initially cause granule

Blue, high-dose arachidonic acid 0.5 mg/ml; orange, low-dose arachidonic acid 0.25 mg/ml.

release. The response is assessed on the basis of the angle of the initial slope. The platelet response to 1.2 mg/ml is initially studied. Concentrations above 1.4 mg/ml may cause nonspecific platelet 'agglutination' as a result of an interaction between ristocetin and fibrinogen and protein precipitation.

Arachidonic acid. Arachidonic acid induces TXA_2 generation and granule release even if there is a defect of agonist binding to the surface membrane or of the phospholipase-induced release of endogenous arachidonate. If steps further along the pathway are impaired, such as absence or inhibition of cyclooxygenase (e.g. aspirin effect), arachidonic acid will not produce normal aggregation.

Adrenaline (epinephrine). No shape change precedes aggregation, but the response thereafter resembles the ADP response. Such a response is usually obtained with concentrations of 2–10 µmol/ml. Some clinically normal people have severely reduced responses to epinephrine.

Calculation of results

Results can be expressed in one of three ways:[59,60]

1. As a percentage decrease in absorbance measured at 3 min after the addition of an agonist (see Fig. 18-13) or the percentage of maximum aggregation. This does not provide any information on the shape of the curve.
2. By the initial slope of the aggregation tracing (see Fig. 18-13). This indicates the rate of aggregation but does not show whether secondary aggregation has occurred.
3. By the minimum amount of agonist required to induce a secondary response.

Normal range

The platelets of normal subjects usually produce a single reversible primary wave with 1 µmol/l ADP or less, biphasic aggregation with ADP at 2.5 µmol/l and a single irreversible wave at 5 or 10 µmol/l. A single-phase response is observed after a lag phase lasting not more than 1 min with 1 and 4 µg/ml of collagen. A single phase or biphasic response is seen with 1.2 mg/ml of ristocetin and after 50 and 100 µmol/l of arachidonic acid. Normal ranges have been compiled for the common agonists.[63] Interpretation can be difficult but reduced maximal aggregation with two or more agonists is highly indicative of a bleeding disorder. Biphasic aggregation is observed with 2–10 µmol/l of epinephrine. A response to a low concentration of ristocetin (0.5–0.7 mg/ml) is abnormal and is a feature of type 2B VWD (see below).

Interpretation and technical artefacts

The volumes of PRP used will depend on the aggregometer and cuvette used. The smaller the cuvette, the more responses can be tested with a given volume of PRP, but the poorer the optical quality (because of a shorter light path) and the more likely the influence of factors such as debris or air bubbles.

Care should be taken to exclude red cells and granulocytes from PRP because these will interfere with the light transmittance and cause reduced response heights, which can be mistaken for abnormal aggregation. In diseases such as thalassaemia, where there may be red cell fragments and membranes, these may be removed by further centrifugation of PRP at 150 *g* for 2 min or after settling has occurred.

If cryoglobulins are present, they may cause changes in transmittance that resemble the appearance of spontaneous aggregation. Warming the PRP to 37 °C for 5 min allows aggregation to be tested in the normal way.

Lipaemic plasma may cause problems in adjusting the aggregometer, and the responses may be compressed owing to the small difference in transmitted light between PRP and PPP. Care should be taken in the interpretation of results from such samples.

The pattern of responses in various disorders of platelet function is shown in Table 18-10. For a discussion of hyperaggregability, see p. 421.

Some common technical problems associated with platelet aggregation are described in Table 18-11.

Further investigation of platelet function

If an abnormal aggregation pattern is observed, it is advisable to check the assessment on at least one further occasion. If the aggregation tests are persistently abnormal and the patient is not taking any drugs or substances known to interfere with platelet function, the following tests should be done (see also Table 18-10):

1. If thrombasthenia or the Bernard–Soulier syndrome is suspected, an analysis of membrane glycoproteins is necessary, most conveniently by flow cytometry.
2. If a release abnormality is suspected, additional agonists, including synthetic endoperoxide analogues and calcium ionophores, should be used in testing for aggregation. Release products can be measured directly or concurrently with aggregation in a lumi-aggregometer. In addition, the total adenine nucleotide content of the platelets or the amount released after maximal stimulation should be measured using a firefly bioluminescence technique; see lumi-aggregometry below.[64]

Note that many other defects, such as found in oculocutaneous albinism, Chédiak–Higashi syndrome and grey platelet syndrome, have also been described.

TABLE 18-11

TECHNICAL FACTORS THAT MAY INFLUENCE PLATELET AGGREGATION TESTS

Centrifugation. At room temperature, *not* at 4 °C. Should be sufficient to remove red cells and white cells but not the largest platelets. Residual red cells in the PRP may cause apparently incomplete aggregation.
Time. For 30 min after the preparation of the PRP, platelets are refractory to the effect of agonists. Progressive increase in reactiveness occurs thereafter; more marked from 2 h onward.
Platelet count. Slow and weak aggregation observed with platelet counts below 150 or over 400×10^9/l.
pH. <7.7 inhibits aggregation; pH >8.0 enhances aggregation.
Mixing speed. <800 rpm or >1200 rpm slows aggregation.
Haematocrit. >0.55 is associated with less aggregation, especially in the secondary phase owing to the increased concentration of citrate in PRP. It may also be difficult to obtain enough PPP. Centrifuging twice may help.
Temperature. <35 °C causes decreased aggregation except to low-dose ADP, which may be enhanced.
Dirty cuvette. May cause spontaneous platelet aggregation or interfere with the optics of the system.
Air bubbles in the cuvette. Cause large, irregular oscillations, even before the addition of agonists.
No stir bar. No response to any agonist obtained.

PPP, platelet-poor plasma; PRP, platelet-rich plasma.

3. When possible, electron microscopic studies of platelet ultrastructure should be carried out.
4. FVIII, VWF:Ag and ristocetin cofactor assay should be carried out on all patients investigated for an abnormality of platelet function who show abnormal ristocetin 'agglutination' or in whom all platelet function tests are normal.

Platelet lumi-aggregometry

The Chrono-log aggregometers (Chrono-log Corporation, www.chronolog.com) measure platelet function using electrical impedance in whole blood, or optical density in platelet-rich plasma, with simultaneous measurement of adenosine 5′-triphosphate (ATP) release by luminescence.

Whole blood aggregation measures platelet function in anticoagulated blood without the need to isolate them from other blood components. Without the necessity for centrifugation, the entire platelet population is tested, and labile factors in the blood (e.g. prostacyclin and TXA_2) that may influence platelet function are preserved.

Results of impedance aggregation tests are quantified by:

1. Ohms of aggregation at a given time in the test
2. Slope, or rate of the reaction, in ohms change per minute
3. Maximum extent of aggregation, in ohms.

The increase in impedance is directly proportional to the mass of the platelet aggregate. Impedance aggregation in blood is not dependent on optical characteristics of the sample so tests can be performed on lipaemic and thrombocytopenic samples. The method is also useful in situations where sample volume is critical, such as in children.

ATP secreted by dense granules is measured by a visible light range luminescence technique in either PRP or whole blood. The lumi-aggregometer measures secretion by a sensitive luminescent (firefly luciferin-luciferase) assay for extracellular ATP in combination with the simultaneous measurement of aggregation. Luminescence measurement of ATP secretion provides unequivocal evidence of normal or impaired (as in secretion defects and storage pool deficiency) dense granule release.

Multiplate whole blood aggregation

The Multiplate system is a whole blood impedance platelet aggregometer that may be useful for the rapid management of platelet function and bleeding complications in surgical procedures and the monitoring of anti-platelet therapy (Roche, www.roche.co.uk).

ASSAYS OF FACTOR XIII ACTIVITY

Clot solubility test

Principle

Fibrin clots formed in the presence of FXIII and thrombin are stable (as a result of crosslinking) for at least 1 h in 5 mol/l urea, whereas clots formed in the absence of FXIII dissolve rapidly. Quality assurance surveys in the United Kingdom have shown that the solubility test for XIII is more sensitive when the sample is clotted with thrombin rather than calcium. Thrombin preparations containing calcium should not be used. The use of 5 M urea as described here will detect FXIII deficiency of less than 0.05 iu/ml. One study suggested that deficiency of <0.1 iu/ml could be detected by using 2% acetic acid as the lysing solution.[65]

Reagents

- *PPP.* From the patient and a control subject.
- *Thrombin.* 10 NIH unit solution.
- *Urea.* 5 mol/l in 9 g/l NaCl.

Method

In duplicate, 0.2 ml patient plasma is mixed with 0.2 ml 10 NIH unit thrombin solution in a glass test tube and incubated at 37 °C for 20 min. Set up a normal plasma control in the same way; EDTA-plasma can be included as a negative control. Each tube is filled with approximately 3 ml of urea solution, carefully dislodging the clot, and is

left undisturbed at 37 °C for 24 h. Inspect each tube for the presence of a clot at regular intervals.

Interpretation

The control clot, if normal, shows no sign of dissolving after 24 h. However, in the absence of FXIII, the clot will have dissolved. The test is reported as normal if the clot is present and abnormal if the clot is absent. The clot solubility test has poor sensitivity and may only detect levels below approximately 0.05 iu/ml. The relationship between FXIII level and adequate haemostasis is uncertain, but there is some evidence that levels of 0.05–0.4 iu/ml may also be associated with bleeding. In suspected cases photometric and ELISA assays of FXIII are available for quantification.[66] The introduction of these assays into routine practice may clarify the significance of intermediate levels of FXIII activity.

Amide release assay for factor XIII

FXIII in plasma is converted by thrombin into FXIIIa (a transglutaminase); this is accelerated by the formation of fibrin by thrombin. The fibrin produced is prevented from clotting by an aggregation-inhibiting peptide and is held in solution. FXIIIa cross links a specific peptide substrate to glycine ethyl ester and releases ammonia. Released ammonia is then determined in a simultaneous reaction utilising nicotinamide adenine dinucleotide (NAD) H. The decrease in NADH is measured at 340 nm and is proportional to the FXIII activity of the sample. However, there are some ammonia-producing and NADH-consuming reactions independent of FXIIIa that can lead to an overestimation of FXIII activity. Whilst these overestimations do not cause a problem in the normal FXIII range they can give misleading information in the severe forms of FXIII deficiency and thus influence replacement therapy. For this reason a plasma blanking procedure is recommended, in which FXIIIa is inhibited by iodoacetamide (an alkylating agent), to eliminate potential overestimation.

FXIII assays are commercially available (Siemens, www.siemens.co.uk; Sysmex, www.sysmex.co.uk).

DISSEMINATED INTRAVASCULAR COAGULATION

The term DIC encompasses a wide range of clinical phenomena of varying degrees of severity. It is also sometimes referred to as consumptive coagulopathy because its characteristic feature is excessive and widespread activation of the coagulation mechanism with consequent consumption of clotting factors and inhibitors with loss of the normal regulatory mechanisms. In acutely ill patients this usually results in defibrination and a haemorrhagic diathesis. In some situations, however, the activation may be less marked and partially compensated resulting in a tendency to thrombosis. This latter phenomenon is typical of the coagulation activation seen in association with malignancy and may be associated with slightly shortened clotting times.

The diagnosis of acute DIC can generally be made from abnormalities of the basic first-line screening tests described earlier occurring in an appropriate clinical context. Characteristically, the PT, APTT and TT are all prolonged and the fibrinogen level is markedly reduced. In association with the consumption of clotting factors responsible for these abnormalities there is also a fall in platelet count also resulting from consumption. As DIC develops, a decrease in the platelet count is an early sign, and hypofibrinogenaemia may be relatively late. This distinguishes it from dilutional coagulopathy in which the reverse is usually the case. Concomitantly there is activation of the fibrinolytic system and an increase in circulating fibrin(ogen) degradation products. These abnormalities form the basis for the diagnosis of DIC. Diagnostic guidelines are available but are most useful in clinical trials rather than routine practice.[67] More elaborate tests are not usually performed but can demonstrate reductions in individual clotting factors, antithrombin and antiplasmin and increased levels of thrombin–antithrombin and plasmin–antiplasmin complexes and of activation peptides such as prothrombin F1 + 2. Some analysers provide a waveform analysis that can detect early stages of DIC (see p. 380).[68]

Detection of fibrinogen/fibrin degradation products using a latex agglutination method

Principle

A suspension of latex particles is sensitised with specific antibodies to the purified FDP fragments D and E. The suspension is mixed on a glass slide with a dilution of the serum to be tested. Agglutination indicates the presence of FDP in the sample. By testing different dilutions of the unknown sample, a semiquantitative assay can be performed.[69]

Reagents

- *Venous blood.* Collected into a special tube (provided with the kit) containing the antifibrinolytic agent and thrombin.
- *Test Kit.* (Oxoid Ltd, www.oxoid.com/uk).
- *Positive and negative controls.* Provided by the manufacturer.
- *Glycine buffer.* Part of the kit.

Method

Allow the tube with blood to stand at 37 °C until clot retraction commences. Then centrifuge the tube and withdraw the serum for testing. It is important that the

fibrinogen in the sample is completely clotted or this will be detected by the test. This may be a problem in the presence of heparin or a dysfibrinogenaemia or high levels of FDPs. Addition of a few drops of 100 u (NIH)/ml thrombin will enhance clotting in these cases.

Make 1 in 5 and 1 in 20 dilutions of serum in glycine buffer. Mix 1 drop of each serum dilution with 1 drop of latex suspension on a glass slide. Rock the slide gently for 2 min while looking for macroscopic agglutination. If a positive reaction is observed in the higher dilution, make doubling dilutions from the 1 in 20 dilution until macroscopic agglutination can no longer be seen.

Interpretation

Agglutination with a 1 in 5 dilution of serum indicates a concentration of FDP in excess of 10 μg/ml; agglutination in a 1 in 20 dilution indicates FDP in excess of 40 μg/ml.

Normal range

Healthy subjects have an FDP concentration of less than 10 μg/ml. Concentrations between 10 and 40 μg/ml are found in a variety of conditions including acute venous thromboembolism, acute myocardial infarction, severe pneumonia and after major surgery. High levels are seen in systemic fibrinolysis associated with DIC and thrombolytic therapy with streptokinase.

Screening tests for fibrin monomers

Principle

When thrombin acts on fibrinogen, some of the monomers do not polymerise but give rise to soluble complexes with plasma fibrinogen and FDP. These complexes can be associated *in vitro* by ethanol or protamine sulphate. It is now rarely used but described in previous editions of this book.

Detection of crosslinked fibrin D-dimers using a latex agglutination method

Principle

The latex agglutination method used to detect crosslinked fibrin D-dimers is identical to the test previously described for FDP, but in this case the latex beads are coated with a monoclonal antibody directed specifically against fibrin D-dimer in human plasma or serum. Because there is no reaction with fibrinogen, the need for serum is eliminated and measurements can be performed on plasma samples.

Reagents

Several manufacturers market kits for the measurement of D-dimers. These usually contain the latex suspension, dilution buffer and positive and negative controls.

Method

The manufacturer's protocol should be followed. Undiluted plasma is mixed with one drop of latex suspension on a glass slide and the slide is gently rocked for the length of time recommended in the kit. If macroscopic agglutination is observed, dilutions of the plasma are made until agglutination can no longer be seen.

Interpretation

Agglutination with the undiluted plasma indicates a concentration of D-dimers in excess of 200 mg/l. The D-dimer level can be quantified by multiplying the reciprocal of the highest dilution showing a positive result by 200 to give a value in mg/l. D-dimers are also reported as fibrin equivalent units which are twice the D-dimer value.

Normal range

Plasma levels in normal subjects are <200 mg/l. There has been much study of D-dimer assays as a useful way of excluding thrombosis, but there is naturally a compromise between sensitivity and specificity, especially when a rapid turnaround time is required. The lack of an international standard and the poor correlation between kits mean that the use of kits for this purpose should be validated individually. A number of kits using ELISA methods for the detection of D-dimers are now available; these have greater sensitivity but the tests are more cumbersome to perform. Latex tests using automated analysers provide a suitable combination of speed and sensitivity and have now been incorporated into clinical guidelines.[70,71]

INVESTIGATION OF CARRIERS OF A CONGENITAL COAGULATION DEFICIENCY OR DEFECT

Carrier detection is important in genetic counselling, and antenatal diagnosis may enable heterozygotes to consider termination of pregnancy with a severely affected foetus and may optimise management of the pregnancy and delivery. The information of value in carrier detection is derived from family studies, phenotype investigations and determination of genotype.

Family studies

Haemophilia A and B (FVIII and FIX deficiency) are inherited by X-linked genes. This means that all the sons of a person with haemophilia will be normal and all of his daughters will be carriers. The children of a carrier have a 0.5 chance of being affected if they are sons and a 0.5 chance of being carriers if they are daughters. The other coagulation factor defects are inherited as autosomal traits. Heterozygotes possess approximately half the

normal concentration of the coagulation factor and are generally not affected clinically; only homozygotes have a significant bleeding tendency. FXI is an exception to this where heterozygotes sometimes bleed excessively after trauma or surgery. The most common form of VWD (type 1) is inherited as an autosomal dominant trait.

A detailed family study is important in all coagulation factor defects to establish the true nature of the defect and its severity. Patients often describe any familial bleeding tendency as haemophilia and it is therefore essential to prove the exact defect in every new patient and family. In inbred kindreds, the likelihood of homozygotes emerging is increased.

Phenotype investigation

Theoretically one might expect the concentration of the affected coagulation factor in the heterozygote or carrier to be roughly half that of normal. However, in the case of FVIII and FIX, this is complicated by the phenomenon of X chromosome inactivation (XCI). Women possess two X chromosomes, but in each cell only one of these two is used and the other is largely inactivated. In each cell the choice of which X is active is essentially random and varies over a normal distribution. Thus, in carriers of haemophilia A or B, the level of FVIII or IX also varies over roughly a normal distribution depending on the proportions of the normal and affected Xs that are used. As a result, some carriers may have an entirely normal level of FVIII or FIX and others may be significantly deficient.[72] This chromosome inactivation is sometimes referred to as Lyonisation after Mary Lyon, by whom it was first described.

In the case of FVIII, the level of VWF has sometimes been found to be useful. The ratio of VIII to VWF:Ag is reduced in most carriers and can be used in conjunction with the family history to determine a probability that the subject is a carrier. These estimations are further complicated by the fact that FVIII behaves as an acute-phase reactant and may be elevated by a number of intercurrent factors including pregnancy, stress and exercise.

When a detailed family study has been carried out it may be possible to establish the statistical chance of inheriting a coagulation defect. For a review, see Graham *et al*.[73]

Genotype assignment

The advent of molecular biology and the cloning of many of the genes for coagulation factors, especially FVIII and FIX, have revolutionised the approach to carrier determination. The discovery of genetic polymorphisms, some of which are multi-allelic, within the coagulation factor genes, has meant that in most families the affected gene can be tracked and the carrier state can be determined with a high degree of probability. Increasingly, the genetic defect itself can be identified, resulting in unequivocal genotypic assignment in every member of a family. This must now be regarded as the standard of care, removing the ambiguity and uncertainty of preceding methods.

The techniques required for these analyses are described in Chapter 21. Best practice guidelines for genetic analyses in haemophilia and VWD can be found at www.acgs.uk.com/committees/quality-committee/best-practice-guidelines. Although the options for affected families increase, approximately one-third of cases arise with no preceding family history.

Investigation of a Thrombotic Tendency

Michael A. Laffan • Richard A. Manning

CHAPTER OUTLINE

INTRODUCTION TO THROMBOPHILIA

Investigations to identify an acquired or inherited thrombotic tendency are most frequently carried out in patients who develop venous or arterial thrombosis at a young age, in those who have a strong family history of such events or have thrombosis at an unusual site and in individuals of all ages with recurrent episodes of thromboembolism. In recent years the utility of these tests, as judged by their ability to alter management, has come under scrutiny.[1] In most cases the results of individual assays have a limited effect on decisions made on the basis of clinical history alone. This is partly because they are initiated in patients who have already had a thrombosis and have thus demonstrated their thrombotic tendency. Nonetheless there is still a need to identify those individuals whose risk of further thrombosis is sufficiently high to warrant long-term anticoagulation, and attention has turned to global tests of thrombotic potential and combinations of single traits as well as details of the clinical history. It should be remembered that many thromboses are almost entirely the result of circumstantial factors; these include trauma, fractures, surgery and an acute-phase inflammatory response. Further investigation of coagulation is often unnecessary in these circumstances. The investigations described here are most commonly instituted in venous thrombosis, but some unexplained arterial events, especially

in young people or when paradoxical embolism is suspected, are also investigated. In general, the contribution of the inherited abnormalities of plasma coagulation factors is less evident for arterial than venous thrombosis because the aetiology is dominated by atherosclerosis.

In this chapter the investigations to detect an acquired thrombotic tendency are presented first, followed by a simplified battery of tests needed to establish the diagnosis of the more important inherited 'thrombophilias'. Measurement of this small number of factors does not provide a complete assessment of the coagulation system, and the failure to detect one of the traits described does not indicate that the individual does not have an increased risk of thrombosis. An acquired thrombotic tendency is common and occurs in many conditions, but the aetiology is usually complex, multifactorial and not easily identifiable by a single laboratory test. The large number of traits identified, often with a small associated relative risk, makes their individual utility equally small. Until the interactions of these numerous factors are more completely understood, the clinical history remains a dominant factor in clinical management. The British Committee for Standards in Haematology has published guidelines on the investigation of inherited thrombophilia.[1]

Pre-analytical factors

Testing during the acute phase of a thrombotic event is not recommended since acute inflammatory effects, comorbidities and consumptive effects can lead to misleading results. There is no evidence that the acute management of thrombosis requires alteration on the basis of these measurements, so they are best deferred until the patient's condition is stable. The only exception is the development of purpura fulminans in children. Similarly the effects of anticoagulant therapy, pregnancy and oestrogen therapy on these tests should be borne in mind and avoided if possible.

TESTS FOR THE PRESENCE OF A LUPUS ANTICOAGULANT

The lupus anticoagulant (LAC) is an acquired auto-antibody found both in association with other autoimmune disorders and in otherwise healthy individuals.[2] LACs are immunoglobulins that bind to certain phospholipid-bound proteins. The effective sequestration of phospholipid can then cause prolongation of phospholipid-dependent coagulation tests such as the prothrombin time (PT) or the activated partial thromboplastin time (APTT). The name 'anticoagulant' is misleading because despite the *in vitro* effects, patients do not have a bleeding tendency. Instead, there is a clear association with recurrent venous thromboembolism, stroke and other arterial events and, in women, with recurrent abortions, fetal loss and other complications of pregnancy.[3] Therefore tests for the presence of an LAC should be carried out in all individuals with unexplained venous or arterial thrombosis and also in women with recurrent early or late pregnancy loss.[4] Antibodies of this class are members of a larger group called antiphospholipid or anticardiolipin antibodies (although not precisely the same, these terms are often used interchangeably). Tests for LAC are usually performed in parallel with tests for the presence of antiphospholipid antibodies. In general the latter are not performed by haematology laboratories and are therefore not described here. Serological tests for antiphospholipid antibodies are not yet standardised and agreement between laboratories is poor. A large number of target proteins have been described but the most important – and for which there is clear evidence of a pathogenetic effect – is β2 glycoprotein I.[5] Prothrombin is another target for which there is weaker evidence of pathogenicity but which frequently contributes to the LAC effect. Increasingly, tests specifically for anti-β2 glycoprotein I antibodies are performed and possible mechanisms for their prothrombotic activity are being elucidated.[6,7]

The presence of an LAC may be detected by the clotting screen and, depending on the reagents and methods used as well as on the potency and avidity of the antibody, the PT, APTT or both may be prolonged. However these tests may well be normal and, if clinically suspected, specific tests should always be performed.[4]

Patients with an LAC may show other abnormalities, including thrombocytopenia, a positive direct antiglobulin test and a positive antinuclear antibody test. Although prothrombin is a frequent target for antiphospholipid antibodies these are only rarely sufficient to inhibit or deplete prothrombin activity. Such patients may have a bleeding tendency. Guidelines on investigations for LACs have been published[4,8] and recommend the following tests:

1. Dilute Russell's viper venom time (DRVVT) in conjunction with the platelet neutralisation test.
2. An APTT test that has a low concentration of phospholipid and uses silica as an activator, thus making it sensitive to the presence of LAC.

There are a large number of additional tests that have in the past been successfully used for the detection of LAC, several of which are no longer recommended due to poor reproducibility, technical problems and lack of standardisation.[4] The kaolin clotting time (KCT) and the dilute thromboplastin inhibition test are retained here because they are still widely used and thought to have some advantages by some authors. Although no single test is sufficiently sensitive to detect all LAC, readers are counselled against performing an excessive (more than two) number of tests because a large number of false positives will be obtained. The most recent guidelines for the optimal performance of testing for LAC have been well laid out and are summarised in Table 19-1.[4]

Sample preparation

It is essential that all the samples of plasma tested for an LAC are as free of platelets as possible. This is achieved by further centrifugation of plasma at 2500 *g* for 10 min.

TABLE 19-1

RECOMMENDATIONS FROM THE ISTH ON THE PERFORMANCE OF TESTS FOR LUPUS ANTICOAGULANT (LAC)[4,8]

(A) Blood Collection

1. Blood collection before the start of any anticoagulant drug or a sufficient period after its discontinuation
2. Fresh venous blood in 0.109 M sodium citrate 9:1
3. Double centrifugation
4. Quickly frozen plasma is required if LAC testing is postponed
5. Frozen plasma must be thawed at 37 °C.

(B) Choice of the Test

1. Two tests based on different principles
2. DRVVT should be the first test considered
3. The second test should be a sensitive activated partial thromboplastin time (low phospholipids and silica as activator)
4. LAC should be considered as positive if one of the two tests gives a positive result.

(C) Mixing Test

1. Pooled normal plasma (PNP) for mixing studies should ideally be prepared in house. Adequate commercial lyophilized or frozen PNP can alternatively be used
2. A 1:1 proportion of patient:PNP shall be used, without pre-incubation within 30 min
3. LAC cannot be conclusively determined if the thrombin time of the test plasma is significantly prolonged.

(D) Confirmatory Test

1. Confirmatory test(s) must be performed by increasing the concentration of phospholipid content of the screening test(s)
2. Bilayer or hexagonal (II) phase phospholipid should be used to increase the concentration of PL.

(E) Expression of Results

1. Results should be expressed as ratio of patient-to-PNP for all procedures (screening, mixing and confirmation).

(F) Transmission of Results

1. A report with an explanation of the results should be given.

A platelet count of less than 10×10^9/l should be achieved. The plasma is centrifuged at room temperature to avoid platelet activation because the presence of platelet microvesicles can also invalidate the test. After separation, the plasma should be frozen at −70 °C as soon as possible to prevent deterioration. Prior to testing, the frozen sample should be rapidly warmed to 37 °C in a water bath.

Dilute Russell's viper venom time

Principle

Russell's viper venom (RVV) activates factor X leading to a fibrin clot in the presence of factor V, prothrombin, phospholipid and calcium ions. An LAC prolongs the clotting time by binding to the phospholipid and preventing the action of RVV. Dilution of the venom and phospholipid makes it particularly sensitive for detecting an LAC.[9] Because RVV activates factor X directly, defects of the contact system and factor VIII, IX and XI deficiencies do not influence the test. The DRVVT should be combined with a platelet/phospholipid neutralisation procedure to add specificity, and this is incorporated into several commercial kits.

Reagents

- *Platelet-poor plasma.* From the patient and a control (depleted of platelets by a second centrifugation) (p. 376).
- *Glyoxaline buffer.* 0.05 mol/l, pH 7.4 (p. 380).
- *RVV (Stago, www.stago.com).* Stock solution: 1 mg/ml in saline. For working solution dilute approximately 1 in 200 in buffer. The working solution is stable at 4 °C for several hours.
- *Phospholipid.* Platelet substitute; also available commercially (e.g. Bell and Alton platelet substitute, www.diagen.co.uk).
- *$CaCl_2$.* 0.025 mol/l (p. 380).

Reagent preparation

The RVV concentration is adjusted to give a clotting time of 30–35 s when 0.1 ml of RVV is added to the mixture of 0.1 ml of normal plasma and 0.1 ml of undiluted phospholipid. The test is then repeated using doubling dilutions of phospholipid reagent. The last dilution of phospholipid, before the clotting time is prolonged by 2 s or more, is selected for the test (thus giving a clotting time of 35–37 s).

Method

Place 0.1 ml of pooled normal plasma and 0.1 ml of dilute phospholipid reagent in a glass tube at 37 °C. Add 0.1 ml of dilute RVV and, after warming for 30 s, add 0.1 ml of $CaCl_2$. Record the clotting time. Repeat the sequence using the test plasma.

Interpretation

International guidelines suggest that the 99th centile (2.3 standard deviations for normally distributed data) should be used as a cut-off for definition of a prolonged DRVVT. UK guidelines point out that accurate determination of this limit may require >120 normal samples, but that if established normal ranges are available this may be possible with a smaller number of 20–60 samples.[8,10]

Prolongation of the DRVVT may indicate the presence of an LAC but could also arise from an abnormality of factors II, V or X or fibrinogen or the presence of some other inhibitor. The presence of an inhibitor can be confirmed by testing a mixture of equal volumes of the patient's and control plasma, whereas phospholipid dependence can be confirmed by using the platelet neutralisation test described below. Mixing with normal plasma corrects an abnormal DRVVT caused by a factor deficiency or defect, but should not do so in the presence of an LAC, although the effect of dilution may overcome a weak inhibitor.

The platelet or phospholipid neutralisation procedure shortens the clotting time in the DRVVT test when this is prolonged due to an LAC (see below).

Platelet neutralisation test

Principle

When an excess of phospholipid, originally in the form of lysed platelets, is added to clotting tests, the tests become insensitive to the presence of an LAC. This appears to be a result of the ability of the platelets/phospholipid to adsorb the LAC. Platelet neutralisation reagents are available commercially and are usually provided in DRVVT kits. Commercial reagents are preferred for consistency but a method for preparation is provided below. To utilise this property of platelets, they must be washed to remove contaminating plasma proteins and activated or 'fractured' to expose their coagulation factor binding sites.

Reagents for preparation of platelet neutralisation reagent

- *Acid–citrate–dextrose (ACD) anticoagulant solution* (p. 561) pH 5.4, is required for washed platelets. For use, 6 parts of blood is added to 1 part of this anticoagulant.
- *Na_2EDTA.* 0.1 mol/l in saline.
- *Calcium-free Tyrode's buffer.* Dissolve 8 g NaCl, 0.2 g KCl, 0.625 g Na_2HPO_4, 0.415 g $MgCl_2$ and 1.0 g $NaHCO_2$ in 1 litre of water. Adjust pH if necessary to 6.5 with 1 mol/l HCl.

Method

Collect normal blood into ACD and centrifuge at 270 *g* for 10 min. Pipette the supernatant platelet-rich plasma (PRP) into a plastic container, and centrifuge again to obtain more PRP, which is added to the first lot. Dilute the PRP with an equal volume of the calcium-free buffer, and add one-tenth volume of ethylenediaminetetra-acetic acid (EDTA) to give a final concentration of 0.01 mol/l. Centrifuge the mixture in a conical or round-bottom tube at 2000 *g* for 10 min, and discard the supernatant. Gently resuspend the platelet pellet in buffer and 0.01 mol/l EDTA. Centrifuge again, discard the supernatant and resuspend the pellet in buffer alone. Then centrifuge the platelets a third time and resuspend the pellet in buffer without EDTA to give a platelet count of at least 400×10^9/l. The washed platelets may be stored below −20 °C in volumes of 1–2 ml. Before use, they must be activated by thawing and refreezing 3–4 times.

Use the washed platelets or the commercial reagent in the DRVVT test or in the APTT in place of the usual phospholipid reagent. First, determine a suitable dilution by testing a range of doubling dilutions in the test system with control plasma. A suitable dilution gives a similar clotting time to that obtained using control plasma and the phospholipid reagent.

Interpretation

The addition of platelets or a commercial 'confirm' phospholipid reagent to the DRVVT system corrects the clotting time when prolongation is caused by an LAC. It does not correct the time when the prolongation is due to a factor deficiency or an inhibitor directed against a specific coagulation factor. However, the ability of different batches of platelets to perform this correction is variable and may vary further with storage. Accordingly, each time the test is performed a plasma sample known to contain an LAC should be tested in parallel to establish the efficacy of the platelets. Many commercial kits are now available for performing the tests described above.

Each batch of tests should be performed in parallel with a pooled normal plasma control. The DRVVT of commercial normal plasmas should be close to the mid-point of locally derived normal ranges. The degree of correction produced by addition of excess phospholipid must take into account the normal plasma result and ideally the extent to which it is affected by the addition of excess phospholipid. One survey of reagents found that the best discriminator of positivity was by using a normalised correction ratio (CR) of DRVVT clotting times as follows:

$$CR = \frac{\left(\frac{P_D}{N_D}\right) - \left(\frac{P_C}{N_C}\right)}{\frac{P_D}{N_D}}$$

where P is patient's clotting time and N is the clotting time of normal plasma, D represents the detection procedure and C represents the confirmation (platelet/phospholipid neutralisation) procedure. A correction of >10% is regarded as positive, but care should be taken to establish a local normal range. Other calculations are sometimes used, such as a detection ratio/control ratio $((P_D/N_D)/(P_C/N_C)$, a simple ratio of P_D/P_C or percentage correction: $((P_D - P_C)/P_D) \times 100\%$.[4]

False-positive results may be obtained in patients receiving intravenous heparin, although some reagents contain heparin-neutralising agents. Interpretation may be difficult in patients receiving oral anticoagulants; this can sometimes be overcome by performing the test on a 50:50 mix with normal plasma, in which case a positive result is reliable but a negative one cannot be taken to exclude an LAC. Testing for LAC should be avoided in patients with an international normalised ratio (INR) >3.0 and in patients receiving directly acting oral anticoagulants because the results are not reliable.

Interpretation of tests for lupus anticoagulant

Detailed instructions for the interpretation of LAC testing have been published. No single test detects all lupus-like anticoagulants and, if suspected clinically, two specific

tests should be performed before concluding that an LAC is not present.[4,8,11] Conversely, a single positive test should be repeated 12 weeks later because a transient positive may arise as the result of intercurrent illness or medication. It is crucial to distinguish LAC from specific anti-factor VIII antibodies, which are more typically time dependent but may have some immediate effect as well. Specific factor assays can be useful in discrimination but note that the LAC may result in nonparallelism and spuriously low results. Similarly, some weak LACs are neutralised by 50:50 mixing with normal plasma and sometimes exhibit a time-dependent effect. Some transient non-specific coagulation inhibitors are not detected by tests for LAC.

Kaolin clotting time

Principle

When the APTT is performed in the absence of platelet substitute reagent, it is particularly sensitive to an LAC. If the test is performed on a range of mixtures of normal and patient's plasma, different patterns of response are obtained, indicating the presence of LAC, deficiency of one or more of the coagulation factors or the 'lupus cofactor' effect.[12]

There are commercially available kits based on the KCT such as Kaoclot. These show high sensitivity to LACs but are not suitable for testing patients receiving heparin (Haemochrom Diagnostica GmbH, www.haemochrom.de/en).

Reagents

- *Kaolin* (www.sysmex.co.uk or www.siemens.co.uk). 20 mg/ml in Tris buffer, pH 7.4. This may need to be reduced to 5 mg/ml in some automated analysers (see p. 381).
- *Normal platelet-poor plasma.* Depleted of platelets by second centrifugation.
- *Patient's plasma.* Also platelet depleted.
- *$CaCl_2$.* 0.025 mol/l.

Method

Mix normal and patient plasma in plastic tubes in the following ratios of normal to patient's plasma: 10:0, 9:1, 8:2, 5:5, 2:8, 1:9 and 0:10. Pipette 0.2 ml of each mixture into a glass tube at 37 °C. Add 0.1 ml of kaolin and incubate for 3 min, then add 0.2 ml of $CaCl_2$ and record the clotting time.

Results

Plot the clotting times against the proportion of normal to patient's plasma on linear graph paper as shown in Figure 19-1.

Interpretation

The pattern obtained for each patient must be critically assessed. A convex pattern (Pattern 1) indicates a positive result, whereas a concave pattern (Pattern 4) indicates a negative result. Pattern 2 indicates a coagulation factor deficiency and an LAC. Pattern 3 is found in plasma which contains an LAC but is also deficient in a cofactor necessary for the full inhibitory effect. The initial rate of slope is important because a steep slope indicates a positive result. This allows the test to be simplified so that only the tests of 100% normal and of 80% normal/20% test plasmas need be performed. The slope can be calculated using the ratio of KCT at 20% test plasma and KCT at 100% normal control plasma (N). For a positive result, the ratio at this point should be 1.2 or greater.

Thus,

$$\frac{\mathrm{KCT}(80\%\mathrm{N}:20\%\mathrm{Test})}{\mathrm{KCT}(100\%\mathrm{N})} \geq 1.2$$

A control KCT of <60 s may indicate contamination of the control plasma with phospholipid.

Dilute thromboplastin inhibition test

Principle

When the thromboplastin used for the PT is diluted, the PT becomes prolonged. At a certain point (usually 1:50–1:500 dilution) the concentration of phospholipid is low enough for the test to become sensitive to phospholipid-binding antibodies, and when an LAC is present the ratio of the test plasma to normal plasma clotting time increases. This test is now considered more useful because some thromboplastin reagents (e.g. Dade Innovin, www.siemens.co.uk) are more sensitive to LACs. However, it should be noted that diluting thromboplastin makes the system sensitive to low levels of factor VIII, such as are encountered in mild haemophilia and acquired haemophilia, and low levels of factor V or factor VII. Care should be taken that these disorders are not confused with the presence of an LAC. In one study, the test was determined to be positive when the dilute PT ratio (test/mean normal) using Innovin at 1:200 dilution was greater than 1.15.[13]

Other acquired thrombophilic states. There are numerous other disorders that are associated with an increased risk of thrombosis but which are not usually diagnosed using coagulation-based tests. Appropriate tests for some of these such as myeloproliferative neoplasms and paroxysmal nocturnal haemoglobinuria are found elsewhere in this book. Heparin-induced thrombocytopenia is a powerful acquired thrombotic state, and this is considered in Chapter 20.

One of the most important factors precipitating thrombosis is malignancy. The value of extensive testing for possible malignancy in patients with thrombosis remains contentious, but current UK guidelines recommend considering computed tomography (CT) scanning in patients over 40 years old with otherwise unprecipitated

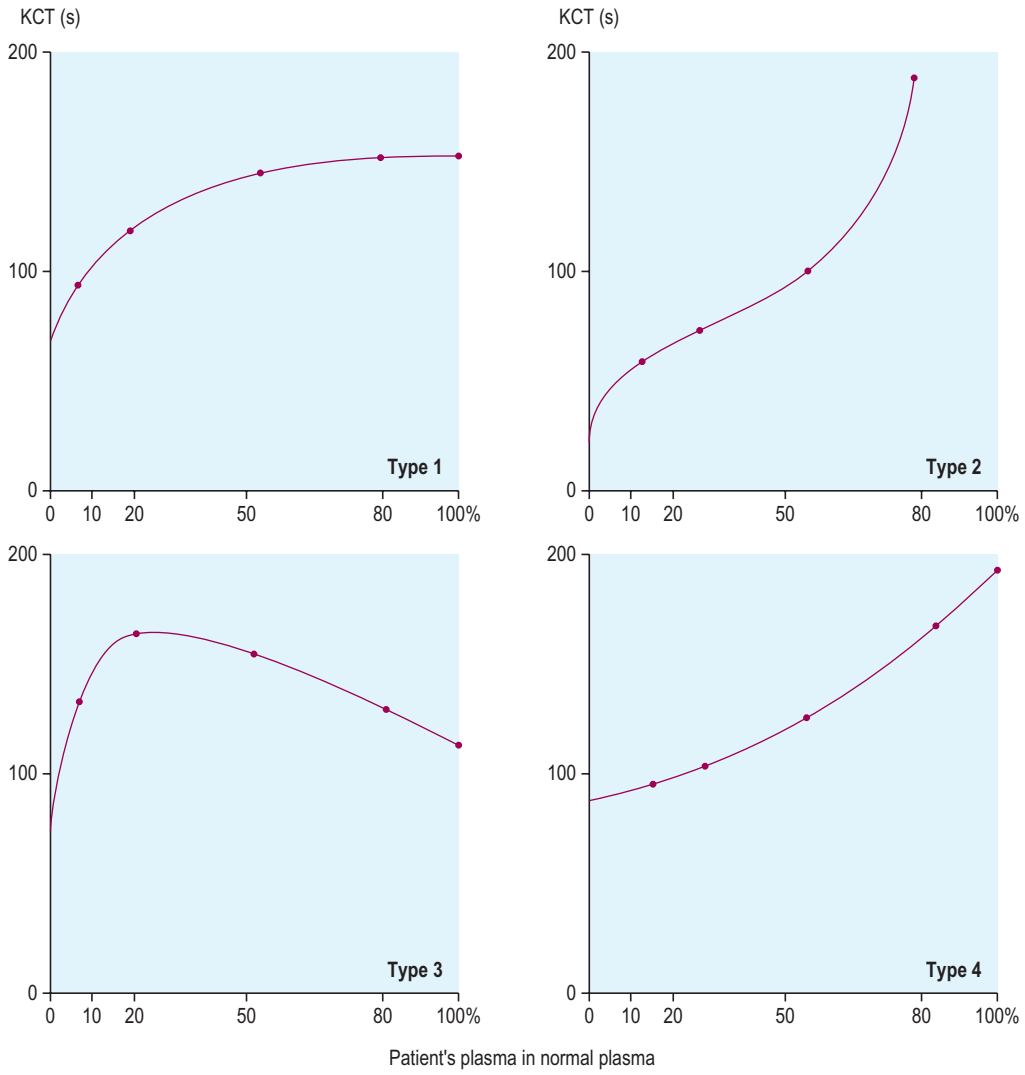

FIGURE 19-1 **Curves obtained using the kaolin clotting time (KCT) to test for the presence of a lupus anticoagulant (see text).**

thromboembolism.[14] Unfortunately, even when tests have been effective in detecting occult malignancy it is not clear there is any improvement in outcome.[15,16]

INVESTIGATION OF INHERITED THROMBOTIC STATES

Testing for thrombotic syndromes remains frequent despite doubts about its clinical utility.[1] Prior to testing for thrombophilia consideration should be given to the likely benefits, including alteration in management, that can be achieved. This requires a carefully taken history, noting in particular the circumstances of any previous thrombotic event, a family history of thrombosis and identification of any co-existing disorders. The relevant tests are described below. DNA analysis for factor V Leiden and the prothrombin gene G20210A polymorphisms are described in Chapter 8. Extensive testing for genetic traits with minor impact on thrombotic risk is not recommended.

Antithrombin

Antithrombin[17] (AT, previously known as antithrombin III) is the major physiological inhibitor of thrombin and factors IXa, Xa and XIa. AT deficiency is found in approximately 2% of cases of thrombosis and may be acquired or congenital. Various methods are available for measuring either functional activity or antigenic quantity of AT. The functional methods are based on the reaction with thrombin or factor Xa and can be coagulation based or chromogenic assays. A chromogenic assay is described below.

Antithrombin measurement using a chromogenic assay

Principle. In the presence of heparin, AT reacts rapidly to inactivate thrombin by forming a 1:1 complex. The chromogenic AT assay is a two-step procedure. In the first step the plasma sample is incubated with a fixed quantity of thrombin and heparin. In the second step the residual thrombin is measured spectrometrically by its action on a synthetic chromogenic substrate, which results in the release of para nitro-aniline (pNA) dye. The use of bovine thrombin avoids interference in the assay by heparin cofactor II. AT activity can also be assayed as its Xa-neutralising capacity with an appropriate chromogenic substrate. In this case either human or bovine Xa can be used.

The assays thus measure heparin cofactor activity rather than progressive AT activity (which is measured in the absence of heparin) and may therefore also detect AT variants with altered heparin binding.

Method. Carry out the procedure on dilutions of a standard plasma to construct a standard graph. Then test dilutions of the test plasma in an identical manner and read the results directly from the standard graph.

The reagents provided and details of the method vary among manufacturers and should be closely followed. There may also be variation between different batches of the same reagent.

Normal range. The normal range is generally between 0.75 and 1.25 iu/ml. Some manufacturers suggest a slightly narrower range (e.g. 0.8 to 1.20 iu/ml). Repeated freezing and thawing of samples, as well as storage at or above −20 °C, results in a reduction in AT concentration.

Interpretation. In an inherited deficiency, the AT concentration is usually <0.7 iu/ml. Most cases are heterozygotes for null mutations (type I deficiency) and have levels of approximately 50% of normal. Be aware that numerous type 2 variants have been described affecting the reactive site or the heparin-binding site or having pleiotropic effects, sometimes resulting in assay results that are close to normal. The clinical significance of heterozygous heparin-binding site mutations is probably low. Further tests such as AT antigen assay, crossed immunoelectrophoresis or mutation analysis may be required to identify variant molecules.[18,19] A low level of AT may be acquired as a result of active thrombosis, liver disease, heparin therapy, nephrotic syndrome or asparaginase therapy; very low values are sometimes encountered in fulminant disseminated intravascular coagulation (DIC) or liver failure. Normal newborns have a lower AT concentration (0.60–0.80 iu/ml) than adults. In neonates who are congenitally deficient, very low values (0.30 iu/ml and lower) may be found. Oral anticoagulant therapy may increase the AT concentration by approximately 0.1 iu/ml in cases of congenital deficiency.

Antithrombin antigen determination

AT antigen can be assessed using various methods such as enzyme-linked immunosorbent assay (ELISA), immunoelectrophoresis assay and latex agglutination (nephelometry). The principles on which these tests are based are described in Chapter 18.

Protein C assay

Protein C (PC)[20,21] is a vitamin K-dependent protein. After activation by thrombin, which is accelerated in the presence of thrombomodulin on the vascular endothelium, PC complexes with phospholipids and protein S (PS) to degrade factors Va and VIIIa. Inherited heterozygous PC deficiency is found in 2–4% of first-episode thromboses and 5–7% of all recurrent thromboembolic episodes in young adults.[22–24] The importance of the PC–PS system is evidenced by the catastrophic syndrome of purpura fulminans in neonates with homozygous PC or PS deficiency.[25] Acquired PC deficiency is found in association with vitamin K deficiency including therapy with vitamin K antagonists. A low plasma concentration is also found in DIC, sepsis (especially meningococcal septicaemia), liver disease, sickle cell disease and in the early postoperative period.

PC can be measured using a chromogenic assay, a coagulation assay or an antigenic method.[26]

Measurement of functional protein C by the protac method

Principle. In the presence of a specific snake venom activator, PC is converted into its active form. This allows the activation to be carried out in whole plasma without separation of PC. Activated PC is measured by its action on a specific chromogenic substrate (e.g. S-2366, CBS 65.25, www.chromogenix.com). The reaction is stopped by the addition of 50% acetic acid and the *p*-nitro-alanine produced is measured in a spectrometer at 405 nm.

Reagents

- *Platelet-poor plasma.* Standard and test samples are centrifuged at 1500–2000 *g* for 15 min. After centrifugation, plasma can be stored indefinitely at −40 °C or below.
- *Protac.* This is an activator derived from the venom of *Agkistrodon contortrix contortrix* (Southern copperhead snake). It is obtained commercially (www.pentapharm.com); each vial contains lyophilised powder, which is reconstituted and stored according to the manufacturer's instructions.
- *Specific chromogenic substrate.* Reconstituted and stored according to the manufacturer's instructions.
- *Barbitone buffered saline.* See p. 380.
- *Acetic acid.* 50%.

Method. Construct the standard curve according to the instructions using a calibrated reference plasma.

The assay is carried out by a two-step method. In the first step plasma and activator are incubated for an exact period of time. In the second step the specific chromogenic substrate is added, and the reaction is stopped with acetic acid again at a precise point in time. Read the amount of the dye produced at 405 nm against a blank obtained as follows: acetic acid, activator and chromogenic substrate are first mixed, then activated standard or patient's plasma is added to the mixture and the absorbance measured. Plot the PC activity against the corresponding absorbance on linear graph paper.

Normal range. The normal range is 0.70 to 1.40 iu/ml.

Further investigation for protein C deficiency

If inherited PC deficiency is suspected, an immunological assay may also be carried out with an ELISA-based kit which will distinguish between type 1 and type 2 deficiencies. The amidolytic assay described here does not detect the rare type 2 PC deficiency due to mutations in the Gla domain, although they can be detected by a coagulation-based assay.[26] The specificity of the chromogenic substrate is limited and is augmented by the inclusion of substances that inhibit other enzymes capable of cleaving the substrate. In some circumstances this can fail and spuriously high PC activities can be obtained, which may obscure PC deficiency. This effect can be detected by assaying a chromogenic blank to which the PC activator has not been added.[27] PC activity and antigen are reduced in patients taking oral vitamin K antagonists and the chromogenic assay will overestimate the functional activity *in vivo*. It is also important to exclude vitamin K deficiency and liver disease by assaying other vitamin K-dependent factors. Family studies should be carried out whenever possible.

Clotting-based protein C assay

Principle. PC clotting assays use a modified APTT reagent incorporating a PC activator derived from the Southern copperhead snake venom, PC-deficient plasma and calcium chloride. The modified APTT reagent thus activates both PC and the factors of the intrinsic pathway. The clotting time of normal plasma is long (>100 s), whereas that of PC-deficient plasma is normal (approximately 30 s). The degree of prolongation of the clotting time when patient plasma is mixed with PC-deficient plasma is proportional to the concentration of PC in the patient plasma.

Unlike chromogenic PC assays, PC clotting assays are sensitive to functional PC defects in calcium or phospholipid binding (mutations in the Gla domain) or in cofactor binding. However, they are also sensitive to anticoagulants, factor V Leiden, LACs, elevated FVIII levels and protein S concentration. A functional PC activity assay can also be performed using the DRVVT, which may be less sensitive to these effects.[28]

Protein C antigen

PC antigen can be measured using a conventional ELISA. Commercial kits are available (www.pathwaydiagnostics.com).

Protein S assay

Protein S is a vitamin K-dependent protein that acts as a cofactor for activated PC (APC) and also for tissue factor pathway inhibitor (TFPI). It is similar to the serine proteases of the coagulation system in having a Gla domain and four EGF domains; however, instead of a protease domain it has a large terminal domain closely homologous to sex hormone-binding globulin (SHBG). In plasma, 60% of PS is bound to C4b-binding protein (C4bBP) via the SHBG which blocks its APC and TFPI cofactor activities; the remaining 40% is free and has full function. Functional assays of PS are based on the capacity of PS to augment the prolongation of a clotting test time by APC, although this does not measure all its anticoagulant activity.[29] Measurement of the total and free PS antigen is possible using an enzyme-linked immunosorbent assay. Free PS is considered the most reliable measure and to have the closest association with thrombotic risk.[30] Type II PS mutations leading to reduced function but normal antigen are very rare. Free PS can be distinguished from total or bound PS by using a separation procedure or by using a specific antibody.

Enzyme-linked immunosorbent assay of free and total protein S

Details of methods for this assay can be found in previous editions of this book. Commercial kits are available (www.helena-biosciences.com or www.hartbio.co.uk).

Automated assays using an immunoturbidimetric method and an antibody specific for free PS are now available (Diagnostica-Stago, www.stago-us.com or www.sysmex.co.uk or www.uk.werfen.com).[31–33]

Protein S functional assay

Principle. Functional PS can be assessed using coagulation-based assays activated by different means (e.g. Staclot, www.stago-us.com). The general principle is that dilutions of normal and test plasmas are mixed with PS-deficient plasma. Activation of these mixtures can then be achieved by a reagent containing factor Xa, APC and phospholipid. After a 5 min activation time, clot formation is initiated by the addition of calcium chloride. Under these conditions, the prolongation of the clotting time is directly proportional to the concentration of PS in the patient plasma. The use of factor Xa as the activator minimises the potential interference by high levels of factor VIII.

A PS function assay may also be based on the PT, in which case the effect of factor VIII is again bypassed. The PT-based PS assay uses PS-depleted plasma activated by

Protac (see above), thus providing activated PC. The PT is increased by the APC–PS-mediated destruction of factor Va, which occurs in the presence of PS supplied by the test and control plasmas. The PT is measured using bovine thromboplastin, and prolongation is proportional to PS activity.

These tests are performed according to the manufacturer's instructions, and many tests can be automated.

Because the assays are subject to interference by other plasma factors, it is recommended that the test plasma be assayed at two different dilutions to ensure parallelism with the standard curve.

Interpretation of protein S functional and antigenic assays

PS deficiency has been classified into three subtypes according to the pattern of results obtained in functional and antigenic assays (Table 19-2). Studies have suggested that the type I and type III patterns are both the result of the same genetic defect and that the difference may be the result of an age-related increase in C4bBP.[34,35]

Although an estimate of PS functional activity would be ideal for diagnosing PS deficiency, the functional PS assays available are problematic. Like other functional assays they are prone to confounding by other factors: factor V Leiden (FVL), LAC and levels of other coagulation factors. Fortunately type II PS defects appear to be extremely rare; many previously diagnosed cases proved to be due to FVL. Thus measurement of free PS antigen has proved to be most reliable and is the preferred method for detecting PS deficiency.

Low levels of PS may be an acquired phenomenon during pregnancy, oral anticoagulation, nephrotic syndrome, use of oral contraceptives, systemic lupus erythematosus, human immunodeficiency virus (HIV) infection and liver disease. Catastrophically low levels have been reported in children after varicella infection owing to auto-antibody production.[36] Some studies have found that the normal range for premenopausal women is significantly lower, suggesting that age and sex-specific reference ranges should be applied, but these differences have not always been found to be significant. The effects of hormonal therapy and artefactual reduction in PS have been described above.[37,38] Although C4bBP is elevated during an acute-phase reaction, the PS-binding β chain does not increase, and as a result free PS does not decrease.[39]

TABLE 19-2

CLASSIFICATION OF PS DEFICIENCY

Category	Total PS	Free PS	Functional PS
Type I	Low	Low	Low
Type II	Normal	Normal	Low
Type III	Normal	Low	Low

Activated protein C resistance

In 1993 Dahlback *et al.* described an inherited tendency to thrombosis characterised by a defective plasma response to activated PC. This became known as activated PC resistance (APCR) and was subsequently shown in >90% of cases to result from a polymorphism encoding the amino acid change Arg506Glu, subsequently named factor V Leiden.[40,41] This mutation destroys a cleavage site for APC, which greatly slows APC inactivation of Va. It also blocks the conversion by APC of factor V into factor Vi, which acts a cofactor for APC degradation of factor VIIIa. APCR is found in approximately 20% of patients with a first episode of venous thrombosis.

Principle

When APC is added to plasma and an APTT is performed, there is normally a prolongation of the clotting time as a result of factor V and factor VIII degradation.[42] The original detection of this phenomenon was by means of a modified APTT, but it can also be detected using modifications of the PT, DRVVT and Xa clotting time. These tests vary somewhat in their sensitivity and specificity for the FVL mutation, which is generally improved by mixing the test plasma with factor V-deficient plasma. This reduces the effect of other factors such as factor VIII and prothrombin, which can alter estimation of APCR and restores the sensitivity of the test in patients who are taking oral anticoagulants. However, the test remains sensitive to interference by LACs. Commercial kits are available for these tests (e.g www.chromogenix.com).

Expression of results

APCR was originally reported as a simple ratio of clotting times with and without APC. The result can be normalised by expressing this as a ratio of the same result obtained with normal plasma, that is:

$$\text{Normalised APCR} = \frac{T + APC}{T - APC} \div \frac{N + APC}{N - APC}$$

when T = test and N = normal.

The use of a normalised ratio improves day-to-day precision and may also improve accuracy. However, it is extremely important that the pooled normal plasma does not contain FVL because very small amounts (2.5%) markedly affect the response to APC. A normal range should be established locally, and its relationship to the presence of FVL should be determined.

Interpretation

The Leiden thrombophilia survey estimated the relative risk of thrombosis for APCR to be approximately 7. Studies using DNA analysis alone have generally found slightly lower relative risks.[43,44] Most testing strategies have been directed toward producing tests that have a

high sensitivity and specificity for FVL to avoid the need for DNA analysis. It seems that 'acquired APCR' or APCR resulting from other causes represents a prothrombotic state even in the absence of FVL,[45] as does the presence of acquired APCR in prothrombotic states such as pregnancy. These are not (except LACs) detected after mixing with factor V-deficient plasma. Some laboratories use a combination of plasma and DNA testing to assess patients' status but increasingly DNA analysis alone is performed and this can be combined with analysis of the prothrombin gene (below). (See also Chapter 8).

Increased prothrombin, factor VIII and other factors

A later finding from the Leiden thrombophilia survey was that elevated levels of prothrombin were significantly associated with thrombosis.[46] Most elevated levels were associated with a mutation in the 3′ untranslated region of the gene (G20210A). The mutation is detected by a simple polymerase chain reaction-based test (see p. 136). Subsequently, other factors, including factor VIII, factor IX and factor XI, have been shown to have an association with thrombosis when elevated.[24,47]

Heparin cofactor II assay

There is no clear evidence that heparin cofactor II (HCII) deficiency is more prevalent in patients with thrombosis than in the normal population; consequently, testing is not recommended as part of thrombophilia investigation. A method for measuring HCII is described in previous editions of this book.

FIBRINOLYTIC SYSTEM

Investigation of suspected dysfibrinogenaemia

Congenital dysfibrinogenaemia, which may be associated with thrombosis, should be suspected in individuals with a prolonged thrombin time and a slightly or moderately reduced fibrinogen concentration in plasma. The presence of a dysfibrinogen is proved when a significant (usually twofold) discrepancy is found between the Clauss and clot weight assays. For details of investigation see p. 383.

Investigation of the fibrinolytic system: general considerations

The investigation of fibrinolysis has an uncertain place in haemostasis. It seems well-established that uncontrolled fibrinolytic capacity as a result of plasmin inhibitor or plasminogen activator inhibitor (PAI-1) deficiency can lead to a haemorrhagic tendency, although these are rare.[48,49] Conversely it has been difficult to demonstrate that an impaired fibrinolytic capacity results in a tendency to venous thrombosis. This may be attributed in part to the poor reproducibility of global tests such as euglobulin clot lysis or fibrin plate lysis, but it has not been resolved by use of either specific assays or genetic polymorphic markers. More recently a plasma clot lysis time has been developed which has been shown to detect a reduced fibrinolytic potential associated with an increased risk of first and recurrent thrombosis.[50,51] Moreover, this defect was associated with levels of thrombin-activatable fibrinolysis inhibitor (TAFI), PAI-1, plasminogen and tissue plasminogen activator (tPA) although for the latter two the association was lost after adjusting for other variables. This test is not yet in routine clinical use. High levels of tPA were shown to be predictive of myocardial infarction in the ECAT (European Concerted Action on Thrombosis and Disabilities) study, but it is possible that this unexpected association can be interpreted as demonstrating an abnormality of endothelial function rather than a problem with fibrinolysis *per se*.

Fibrinolysis shows considerable diurnal variation as well as interference from plasma lipids and stress. It is therefore generally recommended that these tests be performed in the morning after an overnight fast, after a period of no smoking and after the subject has lain resting for ≥15 min (the plasma half-life of tPA is approximately 5 min). Great care is required in obtaining and handling samples for the assays described later.[52] Tests for fibrin and fibrinogen degradation products are described in Chapter 18.

Investigation of fibrinolysis

The 'fibrinolytic potential' of plasma is measured as the combined effect of plasminogen activators and inhibitors. The euglobulin lysis time and fibrin plate lysis have been used to give a global assessment of fibrinolytic potential, sometimes augmented by venous occlusion or administration of desmopressin (1-deamino-8-D-arginine vasopressin). However these tests are laborious, technically difficult and of uncertain clinical significance. They are now rarely performed and have been largely supplanted by assays of individual components of the fibrinolytic system. Instructions for their performance can be found in previous editions. For rapid assessment of fibrinolytic activity, a viscoelastic test such as thromboelastography or ROTEM can be performed (www.rotem.de/en).

Investigation of suspected plasminogen defect or deficiency

Inherited plasminogen defect or deficiency may be found in 2–3% of unexplained thromboses in young people. However, there is no good evidence that deficiency is associated with an increased risk of thrombosis. The most consistent clinical findings appear to be

ligneous conjunctivitis and adhesions at other sites.[53,54] Measurement should be carried out using a functional assay based on full transformation of plasminogen into plasmin by activators. Such assays can be caseinolytic, fibrin substrate or chromogenic.

Chromogenic assay for plasminogen

Principle. In this two-step amidolytic assay, plasminogen is first complexed with excess streptokinase. In the second step, the plasmin-like activity of the streptokinase–plasminogen complex is measured by its effect on a plasmin-specific peptide (e.g. S-2251). The amount of the dye released is proportional to the amount of plasminogen available in the sample for complexing with streptokinase. The streptokinase–plasminogen complex is not significantly inhibited by the plasma plasmin inhibitors. An excess of plasminogen-free fibrinogen can be added to maximise the activity and avoid confounding by the presence of fibrin degradation products (FDPs).

Reagents and method. Details can be found in the manufacturer's instructions (www.siemens.co.uk or www.sysmex.co.uk).

Normal range. The normal range is usually approximately 0.75 to 1.60 iu/ml.

Interpretation. Plasminogen concentration is reduced in the newborn, in patients with cirrhosis, in DIC and during and after thrombolytic therapy, but the assay is less reliable in these circumstances when fibrinogen/fibrin degradation products may augment plasmin activity. A high concentration of fibrinogen can also augment plasmin activity and make the assay less reliable. Plasminogen is an acute-phase reactant, and an increased concentration is found in infection, trauma, myocardial infarction and malignant disease. Hereditary plasminogen deficiency is most commonly due to a type I deficiency and so an antigenic test is usually sufficient. If suspicion remains high then a functional assay will be required.

Tissue plasminogen activator amidolytic assay

Principle

Different amidolytic assays for tPA have been described.[55,56] One method relies on the activation of purified plasminogen to plasmin in the presence of fibrinogen fragments, which stimulate the tPA activity in the test plasma. The generated plasmin is measured using a specific chromogenic substrate. In the second method, tPA is captured on specific antibodies bound to a solid-phase matrix such as a microtitre plate; the various plasma inhibitors of tPA and plasmin are washed away, plasminogen is added together with a stimulator of tPA activity and the plasmin produced is measured with a chromogenic substrate.[57] Alternatively, chromogenic substrates specific for tPA may be used, but there are specificity problems especially in plasma assays.

Interpretation

tPA is secreted into plasma in its active form but rapidly complexes with its principal inhibitor, PAI-1. The amount of active tPA in the plasma is the result of this equilibrium and represents only a small fraction of the total (antigenic) tPA. This process continues after blood sampling unless blood is taken into an appropriate acidic anticoagulant (see above). tPA levels are elevated by exercise and endothelial activation as well as in cirrhosis. The presence of heparin will augment tPA activity and lead to a misleadingly high estimate of activity.[58] Deficiency of tPA in mice produces a number of effects on repair, angiogenesis, cell migration and tissue organisation, but a deficiency state in humans has not been described.[59–61]

tPA can also be measured by ELISA using monoclonal antibodies on microtitre plates, although this closely parallels the PAI-1 concentration and says little about the proportion of free, active tPA.

Plasminogen activator inhibitor activity assay

Principle

Plasma antiplasminogen activator activity is almost entirely due to PAI-1. A fixed amount of tPA is added in excess to undiluted plasma and part of it rapidly complexes with PAI-1. Plasminogen in plasma is then activated to plasmin by the residual, uncomplexed tPA. The amount of plasmin formed is directly proportional to the residual tPA activity and inversely proportional to the PAI activity of the sample. The amount of plasmin generated is measured using a plasmin-specific substrate (e.g. Spectrolyse, www.sekisuidiagnostics.com).

An alternative method uses urokinase plasminogen activator (uPA) bound to a microtitre plate to capture functionally active PAI-1. The amount of PAI-1 bound is then measured using an anti-PAI-1 antibody and a secondary peroxidase-conjugated antibody (e.g. Molecular Innovations, www.mol-innov.com).

Reagents are available in kit form, and the manufacturer's instructions must be closely followed. The normal range, in particular the lower limit, is not clearly defined and many normal subjects have levels below the assay's lower limit of detection.[62,63]

The time of sampling must be standardised to allow valid comparisons. Early morning (7:00 a.m.) samples have much greater levels of activity than those taken later in the day. Rapid sample processing is extremely important because PAI leaks from platelets in sampled blood and PAI-1 in plasma rapidly converts to a latent (inactive) form.

Plasminogen activator inhibitor antigen assay

Principle

Antigenic measurement of PAI-1 can be performed using commercially available ELISA or immunoturbidimetric assays (Chromogenix, www.chromogenix.com). These are specific for PAI-1 and do not detect PAI-2 which is produced by the placenta.

Specimen collection

Blood should be collected into CTAD tubes or Diatube H (Stago, www.stago-us.com) and immediately cooled on ice; CTAD is a buffered tri-sodium citrate solution containing theophylline, adenosine and dipyridamole. Vacutainer coagulation tubes with CTAD (Becton-Dickinson, www.bd.com) samples can be stored on ice for up to 7 h in the collection tubes. If the sample is not tested immediately, it should be separated and frozen as soon as possible.

Normal range

The normal range is usually 11 to 69 ng/ml.

α_2 plasmin inhibitor (α_2 antiplasmin) amidolytic assay

α_2 plasmin inhibitor is synthesised primarily in the liver but also in megakaryocytes. Circulating α_2 antiplasmin is therefore present in plasma and in the alpha-granules of platelets. During clot formation antiplasmin is covalently bound to fibrin by the action of FXIIIa which facilitates its inhibition of plasmin.

Principle

Plasma dilutions are incubated with excess plasmin, a proportion of which are inhibited by antiplasmins. The residual, uninhibited plasmin is measured using a specific chromogenic substrate. Plasmin inhibitor is the major circulating inhibitor of plasmin and forms complexes much more rapidly than other inhibitors; if the reaction times are short, the assay effectively measures plasmin inhibitor only.

Different commercial kits are available containing all the necessary reagents (e.g. Berichrom Alpha 2 Antiplasmin kit, www.sysmex.co.uk or www.siemens.co.uk). The manufacturer's instructions should be carefully followed. Care is required when aliquoting the plasmin solution, which has a high viscosity because of its glycerol content. Note that plasmin bound to α_2 macroglobulin may escape inhibition, thus underestimating inhibitor activity. Aprotinin will inhibit plasmin and lead to an overestimation of antiplasmin concentration.

An alternative method uses plasmin bound to a microtitre plate to capture functionally active α_2 antiplasmin which is then quantified using an anti-$\alpha_2$antiplasmin antibody (e.g. www.oxfordbiomed.com or www.cellsciences.com).

The usual normal range is between 0.80 and 1.20 iu/ml. Congenital plasmin inhibitor deficiency is associated with a severe bleeding tendency. A reduced concentration is also found in liver disease, in DIC and during thrombolytic therapy. Plasmin inhibitor increases with age and is higher in Caucasians than in Africans.

PLATELET 'HYPERREACTIVITY' AND ACTIVATION

Platelets may be more reactive than normal as a consequence of *in vivo* activation by thrombin or non-endothelial surfaces, such as prosthetic valves or Dacron grafts. This can sometimes be detected by a lowered threshold (increased sensitivity) for aggregating agents. Because there is considerable variation in response to aggregating agents in normal people, the attempts to show significance of platelet hyper-aggregability are rarely successful and the results are frequently inconsistent. Spontaneous aggregation of platelets in the blood can also be demonstrated.

Platelets that have formed a part of a platelet thrombus and have been released into the circulation may show a measurable decrease in their ability to aggregate because of a loss of some granule content. The released contents can be measured in plasma; the α granule proteins, β thromboglobulin and platelet factor 4 are the constituents most commonly measured. Overall the problems with these tests make them of doubtful utility; they are described in previous editions of this book.

Several genetic polymorphisms have been reported to affect the reactivity of platelet glycoproteins and P selectin. Although they may be important in population studies, their clinical significance for individual patients remains unclear.[64,65]

Platelet activation: flow cytometry

The problems associated with previous tests of platelet activation have been circumvented to some extent by the application of flow-cytometric analysis of platelets in whole blood samples.

Principle

The activation of platelets is associated with the appearance of new antigenic determinants on the platelet surface. Some of these are molecules present in platelet granules brought to the surface during degranulation (e.g. CD62p, CD63, LAMP-1 and CD40L), and others are new conformations of existing molecules (e.g. the ligand-induced binding site on GpIIbIIIa). These can be detected using fluorescein-conjugated antibodies, and the degree of expression can be quantified by flow cytometry even in the presence of thrombocytopenia. Samples may need to be collected into inhibitors of

TABLE 19-3

INDICATORS OF PLATELET ACTIVATION DETECTABLE BY FLOW CYTOMETRY

Name	CD Designation	Comment
Gplb, IX, V	CD42	Decreases
GpIIbIIIa	CD41	Increases
Phosphatidyl serine	–	Increases Detected by Annexin V or lactadherin binding
Lysosomal	CD63	Indicates lysosomal degranulation
Integral membrane protein (gp53, granulophysin)		
P-selection	CD62	Indicates α granule release, subsequently cleaved and measurable in plasma
Fibrinogen	–	Surface-bound fibrinogen increases
IIbIIIa activation	–	Conformation change in IIbIIIa produced by activation, detected by PAC-1 antibody

platelet activation such as PGE_1. Numerous alternative surface molecules can be investigated (Table 19-3). These tests have not entered routine laboratory practice but are proving increasingly useful in research.[66,67] An alternative approach is offered by the PFA-100 (see p. 393) in which short closure times may be indicative of platelet hyperreactivity and/or hyperreactive von Willebrand factor species.

HOMOCYSTEINE

Following the observation that patients with homocystinuria have venous and arterial thromboses with accelerated vascular damage, there was considerable interest in patients with less marked elevation of plasma homocysteine (hyperhomocysteinaemia). This has been shown to have an association with arterial and venous thrombosis but the assay has little clinical utility and dietary interventions have been ineffective.[68,69] Previously, homocysteine was measured by high-performance liquid chromatography or mass spectroscopy, but an ELISA-based assay is available that allows it to fit more easily into coagulation laboratory practice. To standardise study results, homocysteine is measured either while fasting or after a methionine load. Rapid processing of samples is required because homocysteine quickly leaches out of red blood cells.

MARKERS OF COAGULATION ACTIVATION

Numerous commercial kits are available for measuring molecules produced by coagulation activation.

Principle

The activation of many proteins active in coagulation is mediated by proteolytic cleavage with the release of small peptides – activation peptides. The most frequently measured of these is prothrombin fragment 1+2, which is released when prothrombin is converted to thrombin. It has an appreciable half-life of approximately 45 min, which allows a measurable concentration to accumulate in plasma and provides an indication of the rate at which thrombin is being generated.

An alternative is to measure the concentration of thrombin–antithrombin complexes (TAT), which provides similar information. Plasmin–antiplasmin complexes provide corresponding information about fibrinolysis. These can all be measured using commercially available ELISA kits but are not used routinely and are not required for normal diagnostic work. Other tests such as fibrinopeptide A require exceptional care and the use of special anticoagulants to prevent *in vitro* activation of the sample.

A plasmin cleavage product of cross-linked fibrin, D-dimer (see p. 405), is another measure of activity in the coagulation system. In combination with a pre-test probability score, D-dimer has proven utility in excluding venous thrombosis (www.nice.org.uk/guidance/cg144). Several studies have shown that elevated levels of D-dimer measured after oral anticoagulants have been discontinued are an indicator of future risk of thrombosis. This is the only measure of coagulation activation to have entered clinical practice

GLOBAL ASSAYS OF COAGULATION

As a response to the failure of reductive approaches to identify assays that reliably predict thrombosis or thrombotic risk, some workers have moved in the opposite direction and devised global assays that assess the overall coagulation potential of a blood or plasma sample. These tests include the endogenous thrombin potential (ETP) and viscoelastic techniques. The latter have received approval for the management of haemorrhage but their ability to assess thrombotic risk is less well described.[70] There is some evidence that increased ETP can predict patients at increased risk of first or recurrent thrombosis.[71] However, neither of these techniques is in routine diagnostic use. Some manufacturers have developed kits for global assessment of the PC-PS pathway.

Laboratory Control of Anticoagulant, Thrombolytic and Antiplatelet Therapy

Michael A. Laffan, Richard A. Manning

CHAPTER OUTLINE

Anticoagulant and antithrombotic therapy is given to prevent formation or propagation of thrombi. Anticoagulant drugs, unlike fibrinolytic agents, have little if any effect on an already-formed thrombus. There are five main classes of drugs that require consideration:

1. Coumarins and indanediones, which are orally active and act by interfering with the γ-carboxylation step in the synthesis of the vitamin K-dependent factors (see p. 371).
2. Heparin, heparinoids (low molecular weight and synthetic compounds) and the heparin pentasaccharide (fondaparinux), which have a complex action on haemostasis, the main effect being the potentiation and acceleration of the effect of antithrombin.
3. Direct thrombin and Xa inhibitors. These include derivatives of hirudin (natural or recombinant), and a number of orally active synthetic compounds which are now entering clinical use.
4. Antiplatelet drugs such as aspirin, nonsteroidal anti-inflammatory drugs, dipyridamole, inhibitors of the $P2Y_{12}$ adenosine diphosphate (ADP) receptor and inhibitors of glycoprotein IIb/IIIa function, some of which are antibodies. Novel agents targeting other platelet receptors and functions are also in development.

5. Thrombolytic agents including streptokinase, urokinase and tPA as well as a number of recombinant tPA derivatives with modified properties.

ORAL ANTICOAGULANT TREATMENT USING VITAMIN K ANTAGONISTS

It has not yet proved possible to produce a therapeutic reduction in thrombotic tendency without increasing the risk of haemorrhage. The purpose of laboratory control is to maintain a level of hypocoagulability that effectively minimises the combined risks of haemorrhage and thrombosis: the therapeutic range. This range will be different for different patients and individual responses to oral anticoagulant treatment with vitamin K antagonists[1] are extremely variable, so must be regularly and frequently controlled by using laboratory tests to ensure that the anticoagulant effect remains within the therapeutic range.

Selection of patients

Before starting oral anticoagulant treatment it is advisable to perform the first line coagulation screen: a prothrombin time (PT), an activated partial thromboplastin time (APTT) and a platelet count. Any abnormality of these tests must be investigated because a contraindication to the use of oral anticoagulants may be revealed and an abnormality will confound their use for controlling anticoagulant effect. History and clinical examination should be assessed to ensure that no local or general haemorrhagic diathesis exists.

Methods used for the laboratory control of oral anticoagulant treatment

The one-stage PT of Quick is the most commonly used test. Originally, lack of standardisation of the thromboplastin preparations and methods of expressing the PT results led to great discrepancies in the reported results and hence also in anticoagulant dosage. The use of the International Sensitivity Index (ISI), to assess the sensitivity of any given thromboplastin, and the International Normalised Ratio (INR), to report the results, has minimised these difficulties and greatly improved uniformity of anticoagulation throughout the world.

Chromogenic substrate assays of factors X, VII or II have been used for the control of anticoagulant treatment and might be necessary when baseline tests are abnormal. Although it is possible to use such a single factor measurement, it must be remembered that the PT measures the effect of three vitamin K-dependent factors (factors VII, X and II) and is also affected by the presence of PIVKAs (proteins induced by vitamin K absence or antagonism), which are the acarboxy forms of vitamin K-dependent factors. It thus gives a better assessment of the situation *in vivo:* in addition data on the appropriate individual factor levels corresponding to a given INR are limited.[2,3]

The Thrombotest of Owren and the prothrombin and proconvertin (P&P) method of Owren and Aas were used in the past, but they are no longer recommended for oral anticoagulant control. Historically, standardisation of oral anticoagulant therapy was carried out following the procedure described below. It is now possible to simplify this by using local procedures which are discussed afterwards.

Standardisation of oral anticoagulant treatment

1. A thromboplastin is chosen, and its ISI is determined by comparison with a reference thromboplastin.
2. The log mean normal PT is determined for that thromboplastin.
3. PTs are performed on patient samples, and the results are converted to an INR.

World Health Organisation (WHO) Reference Preparations are available from the National Institute for Biological Standards and Control (NIBSC) (www.nibsc.org). Certified preparations calibrated against the WHO material are available from the Institute for Reference Materials and Measurements (IRMM) (https://ec.europa.eu/jrc/institutes/irmm/) and from commercial suppliers (see p. 535). All the reference preparations have been calibrated, now sometimes indirectly, against a primary WHO reference of human brain thromboplastin, which was established in 1967.[4,5]

The following terms are used in the calibration procedure described below:

International Sensitivity Index (ISI).[6] This is the slope of the calibration line obtained when the PTs obtained with the reference preparation are plotted on the vertical axis of log-log paper and the PTs obtained by the test thromboplastin are plotted on the horizontal axis. The same normal and anticoagulated patient plasma samples are used for both sets of results.

International Normalised Ratio (INR). This is the PT ratio for a sample, which, by calculation, would have been obtained had the original primary, human reference thromboplastin been used to perform the PT. Its calculation is shown below.

Calibration of thromboplastins

Principle

The test thromboplastin should be calibrated against a reference thromboplastin of the same species (rabbit vs. rabbit, bovine vs. bovine) although reference plasmas from different species must at some stage be compared with each other. All reference preparations are calibrated in terms of the primary material of human origin and have an ISI which is assigned after a collaborative study involving many laboratories from different countries.[4]

Reagents

- *Normal citrated plasma.* From 20 healthy donors.
- *Anticoagulated plasma.* From 60 patients stabilised on oral anticoagulant treatment for at least 6 weeks.
  The tests need not all be done at the same time; they may be carried out on freshly collected samples on successive days.
- *Reference and test thromboplastins.*
- *$CaCl_2$.* 0.025 mol/l.

Method

Carry out PT tests as described on p. 380. Test each plasma in duplicate with each of the two thromboplastins in the following order with minimum delay between tests:

	Reference Thromboplastin	*Test Thromboplastin*
Plasma 1	Test 1	Test 2
	Test 4	Test 3
Plasma 2	Test 5	Test 6
	Test 8	Test 7, etc.

Record the mean PT for each plasma. If there is a discrepancy of more than 10% in the clotting times between duplicates, repeat the test on that plasma.

Calibration

Plot the PTs on log-log graph paper, with results using the reference preparation (y) on the vertical axis and results with the test thromboplastin (x) on the horizontal axis (Fig. 20-1). If using arithmetical paper, plot the logarithms of the PTs (Fig. 20-2). The relationship between the two thromboplastins is determined by the slope of the line (b).

An estimate of the slope can be obtained as shown in Figures 20-1 and 20-2; this can then be used to obtain the ISI of the test thromboplastin. Alternatively the slope can be calculated using a computer or online system to apply simple linear regression. This has been shown to be sufficiently accurate compared to the orthogonal regression that is theoretically preferable.[7] A procedure for manual calculation of the slope is given in previous editions of this book.

Whenever possible, however, to obtain a reliable measurement, the following more complicated calculation should be used instead.

Calculation of international sensitivity index

The natural logarithms of the PTs obtained using the reference thromboplastin and the test thromboplastin are called y_i and x_i, respectively, where $i = 1,2,3\ldots N$ for N pairs of results.

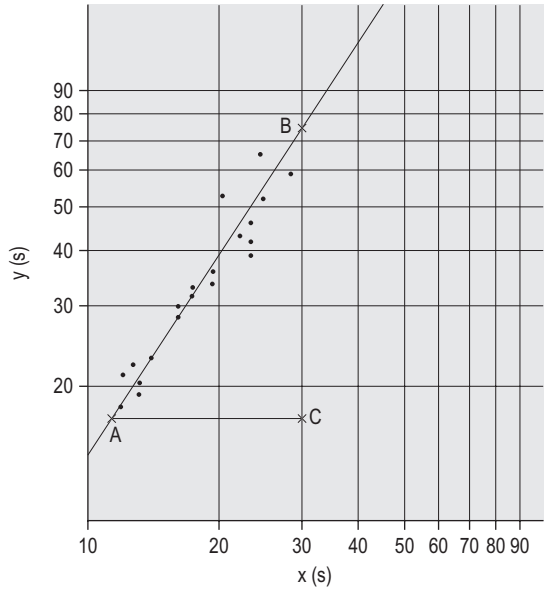

FIGURE 20-1 Calibration of thromboplastin. The PTs (in seconds) with the test thromboplastin are plotted on the horizontal axis (x) and with the reference thromboplastin on the vertical axis (y) on double log graph paper. The best-fit line is drawn by eye, and the slope is obtained as follows: points (A) and (B) are marked on the line just below the lowest recorded PT and just above the longest recorded PT, respectively. A horizontal line drawn from (A) and vertical line from (B) meet at point (C). The lengths of the lines are measured accurately in mm. The slope $b = \frac{[\text{B to C}]}{[\text{A to C}]}$. In this example B to C = 55 mm, A to C = 35 mm, $b = 55/35 = 1.57$. The ISI of the reference thromboplastin was 1.11. Therefore the ISI of the test thromboplastin = $1.11 \times 1.57 = 1.74$.

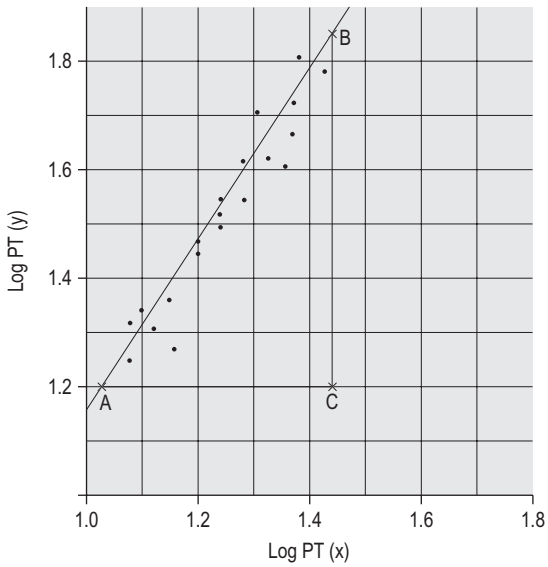

FIGURE 20-2 Calibration of thromboplastin. The PTs (in seconds) are converted to their logarithms which are plotted on arithmetical graph paper. The slope is calculated as in Figure 20-1. In this example, A to C = 42 mm, B to C = 65 mm, $b = 65/42 = 1.54$. Therefore ISI = $1.11 \times 1.54 = 1.71$.

The following designations are then made:

x_0 and y_0 are the arithmetical means of the N values of x_i and y_i, respectively.
Q_1 and Q_2 are the sums of the squares of $(x_i - x_0)$ and $(y_i - y_0)$, respectively.
P is the sum of their products $\Sigma(x_i - x_0)(y_i - y_0)$

$$E = (Q_2 - Q_1)^2 + 4P^2$$

$$\text{And } b = \frac{Q_2 - Q_1 + E^{1/2}}{2P}$$

where b is the slope of the graph. The ISI of the preparation under test (ISI_t) is then given by the following:

$$ISI_t = ISI_{IRP} \times b$$

where IRP stands for International Reference Preparation.

Local calibration of thromboplastins and direct INR determination

Although the ISI system has been very effective in standardising anticoagulant control and improving agreement between laboratories, it is not perfect. One reason is that the ISI of a thromboplastin may vary according to the technique or coagulometer used and even with different models of the same instrument. To circumvent this, a system of local calibration using plasmas with a certified INR is now recommended.[8]

In the method called 'local calibration' the manufacturer supplies a set of plasmas representing a range of INRs with an assigned PT using a reference thromboplastin. The laboratory then measures the PTs of these samples locally and they are plotted against the assigned PT on a log/log plot and an orthogonal regression line is calculated to give the ISI as with the standard method above. It has been shown that use of a linear regression, which is easier to calculate, is also acceptable.[7]

A simpler method is direct INR determination. In this system, a set of plasmas with an assigned INR are tested with the local thromboplastin-machine combination. These results are then plotted on log-log paper against the assigned INR. The INR for subsequent patient samples can then be read off the graph using the locally measured PT. Thus the PT is converted directly into an INR without the need for measurement of the ISI: this has been described as 'direct INR determination'. The accuracy of the system relies on the ability of the supplier to validate the INR for the (usually) lyophilised plasma on the system to be used by the laboratory.[8] For this method it is recommended that a minimum set of one normal and three abnormal plasmas are used to reduce imprecision. The plasmas may be lyophilised or frozen and from anticoagulated patients or artificially factor-depleted but should span a range of INRs from 1.5 to 4.5.

Geometric mean normal prothrombin time

If the INR is to be calculated using the PT and the determined ISI then the geometric mean normal PT (GMNPT) for each batch of thromboplastin must be determined by testing 20 normal samples or blood donors. An equal number of males and females should be tested. The GMNPT is the logarithmic mean normal PT (i.e. $e^{(\Sigma \ln PT)/N}$).

Calibration audits

External quality-assurance surveys (e.g. United Kingdom National Quality Assessment Service, UK NEQAS, see p. 539) will reflect differences relating to thromboplastin-machine combinations but not differences in blood sampling techniques (i.e. capillary and venous blood sampling). This can be a problem when capillary blood sampling is used in an outpatient setting, whereas venous samples are taken for inpatient anticoagulant monitoring. Regular internal audits comparing results from a range of patients whose blood has been sampled by both capillary and venous techniques will provide information not provided by NEQAS surveys.

Determination of the international normalised ratio

If a local calibration scheme is not used then it is essential to use a thromboplastin the ISI of which has been determined either by the commercial supplier or (preferably) according to a local, regional or national procedure. The PT result can then be expressed as an INR. Using the INR/ISI system, the patient's INR should be the same in any laboratory in the world. To ensure safety and uniformity of anticoagulation, the results should be reported as an INR, either alone or in parallel with the locally accepted method of reporting. The INR is calculated as follows:

$$INR = (\text{PT patient} / \text{GMNPT})^{ISI}$$

For example, a PT ratio of 2.5 using a thromboplastin with ISI of 1.4 can be calculated from the formula to be $2.5^{1.4} = 3.61$, which is either read from a logarithmic table or determined on an electronic calculator.

Capillary reagents

Reagents are commercially available for monitoring the INR using samples of capillary blood. These are usually a mixture of thromboplastin, calcium, and adsorbed plasma so that when whole blood is added the reagent measures the overall clotting activity; it is sensitive to deficiency of factors II, VII and X. The reagents have an ISI assigned to them in the same way as individual thromboplastins, and the INR is calculated from the PT ratio. These reagents are frequently used in anticoagulant clinics, when a large number of INRs need to be performed rapidly, and in point-of-care testing.

Point-of-care testing

There are now schemes for monitoring INR using point-of-care devices outside the hospital clinic. These require selection and standardisation of appropriate analysers and a quality-control programme that includes participation in an external quality assessment scheme.[9] There should be an established procedure for checking any problems of instrument performance and for referring to the specialist centre patients who are difficult to control.[10,11]

Self-management of warfarin treatment may also be an effective point-of-care procedure for selected patients. They should first attend two or more training sessions on the use and quality control of the appropriate analyser, interpretation of INR, adjustment of warfarin dosage and guidance on when it is necessary to be seen at the specialist clinic.[10,11]

Therapeutic range and choice of thromboplastin

Several authorities have now published recommended therapeutic targets denoting the appropriate degree of anticoagulation in different clinical circumstances.[1,9] These are largely based on controlled clinical trials but to some extent also represent a consensus on practice that has emerged over many years.

The choice of thromboplastin largely determines the accuracy with which anticoagulant control can be maintained. If the ISI of the thromboplastin is high, then a small change in PT represents a large change in the degree of anticoagulation. This affects the precision of the analysis, and the coefficient of variation for the test increases with the ISI. Moreover, the target prothrombin ratio range becomes very small for any given range of INR. This is illustrated in Figure 20-3. For these reasons it is strongly recommended that a thromboplastin with a low ISI (i.e. close to 1) is used.

Management of overanticoagulation

The approach to management of a patient whose INR exceeds the therapeutic range with or without bleeding is shown in Table 20-1 and guidelines have been published.[9,12]

HEPARIN TREATMENT

The anticoagulant action of heparin is primarily a result of its ability to bind to antithrombin (AT), thereby accelerating and enhancing the latter's rate of inhibition of the major coagulation enzymes (i.e., factors IIa and Xa and to lesser extents IXa, XIa and XIIa). The two main effects of heparin, the antithrombin and the anti-Xa effects, are differentially dependent on the size of the heparin molecule. The basic minimum sequence needed to promote anticoagulant activity has been identified as a pentasaccharide unit. Of the molecules containing this pentasaccharide, those comprising fewer than 18 saccharide units and of molecular weight less than 5000 Da can only augment the inhibitory activity of AT against Xa. In contrast, longer chains can augment anti-IIa activity as well by formation of a tertiary complex bridging AT and thrombin molecules.

Hence low molecular weight heparins (LMWH), which have an average molecular mass of 5000 Da, have a ratio of anti-Xa to antithrombin effect of 2–5 compared to that of unfractionated heparin (UFH), which is defined as having a ratio of 1. However, all heparin preparations are heterogeneous mixtures of molecules with different molecular weight, many of which do not contain the crucial pentasaccharide sequence. Heparin also produces some anticoagulant effect by promoting the release of tissue factor pathway inhibitor (TFPI) from the endothelium (see p. 372) which will not be present in plasma 'spiked' with heparin.

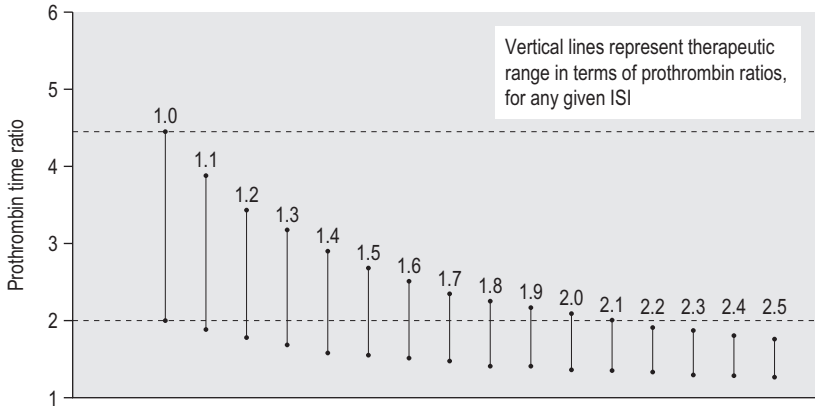

FIGURE 20-3 The ratios obtained with thromboplastins with given ISI values equivalent to INR therapeutic range of 2.0–4.5. *(Slightly modified with permission from Poller L. Oral anticoagulant therapy. In: Bloom AL, Thomas DP, editors.* Haemostasis and thrombosis. *2nd ed. Edinburgh: Churchill Livingstone; 1987.)*

TABLE 20-1

RECOMMENDATIONS FOR MANAGEMENT OF BLEEDING AND EXCESSIVE ANTICOAGULATION

INR 3.0–6.0 (target INR 2.5) INR 4.0–6.0 (target INR 3.5)	1. Reduce warfarin dose or stop 2. Restart warfarin when INR <5.0
INR >6.0–8.0 (No bleeding or minor bleeding)	1. Stop warfarin 2. Restart when INR <5.0
INR >8.0 (No bleeding or minor bleeding)	1. Stop warfarin 2. Restart warfarin when INR <5.0 3. If other risk factors for bleeding give 0.5–2.5 mg of vitamin K (oral or IV)
Major bleeding	1. Stop warfarin 2. Give PCC 25-50 u/kg or FFP 15 ml/kg only if PCC not available 3. Give 5 mg of vitamin K (oral or IV)

FFP, fresh-frozen plasma; INR, International Normalised Ratio; IV, intravenous; PCC, prothrombin complex concentrate.

Selection of patients

It is advisable to perform the first line tests of haemostasis as described in Chapter 18 before starting treatment. In the presence of a reduced platelet count or deranged coagulation, heparin may be contraindicated or, if used, the dose may need to be reduced.

Laboratory control of heparin treatment[13]

The pharmacokinetics of heparins are extremely complicated, partly because of the variation in molecule size. Large molecules are cleared by a rapid saturable cellular mechanism and bind to numerous acute-phase proteins such as von Willebrand factor and fibronectin. Smaller molecules are cleared by a nonsaturable renal route and bind less to plasma proteins. As a result, therapeutic doses of UFH result in a variable degree of anticoagulation and require close monitoring (Table 20-2). The dose-response relationship is much more predictable for the LMWHs, and most trials have not monitored therapy with these agents, which are simply given on a 'units per kg' dosing regimen. Thus the approach to monitoring heparin therapy varies according to the type of heparin used and the clinical circumstance.

Prophylactic therapy with either UFH or LMWH is given by subcutaneous injection and is usually not monitored. However, LMWH may be monitored in some circumstances when it is expected that pharmacokinetics may be altered, such as in renal failure, at extremes of weight and when the risk of bleeding or thrombosis is thought to be particularly high. A blood sample is taken 4 h after subcutaneous injection to detect the effect of the peak heparin level. Some authors have also measured the effect at the trough prior to injection.

Therapeutic treatment with UFH is usually given by continuous intravenous infusion and monitored using the APTT, which is repeated 6 h after every dose change and at least once a day. Rarely, therapeutic UFH is given twice daily by subcutaneous injection, in which case samples for testing can be taken at the midpoint between injections. Alternatively, a study showed that twice daily subcutaneous UFH could be safe and effective using a weight-adjusted

TABLE 20-2

TESTS USED IN THE LABORATORY CONTROL OF HEPARIN TREATMENT

Test	Advantages	Disadvantages
Whole blood clotting time	Simple, inexpensive, no equipment needed	Time consuming, can only be carried out at the bedside, one at a time, insensitive to <0.4 iu/ml anti-Xa and to LMW heparins
APTT	Simple, many tests can be carried out in parallel	Not all reagents sensitive to heparin, insensitive to <0.2 iu/ml anti-Xa and to LMW heparins, affected by variables other than heparin
TT	Simple, many tests can be carried out in parallel	Variable sensitivity to UFH and LMW heparins. Steep dose-response relationship.
Protamine neutralisation	Sensitive to all concentrations	Time consuming and insensitive to LMW heparins
Anti-Xa assays	Sensitive to all concentrations and to LMW heparins	Expensive if commercial kits used; time consuming if home-made reagents used. Not clear that anti-Xa is the clinically relevant measure.

APTT, activated partial thromboplastin time; LMW, low molecular weight; TT, thrombin time; UFH, unfractionated heparin.

dose regimen without monitoring.[14] In all cases, if heparin resistance is suspected, an anti-Xa assay must be performed.

LMWHs have relatively little effect on the APTT, and if monitoring is required, a specific heparin assay must be used. In general, unless stated otherwise, this is measured as anti-Xa activity. International standards for UFH and for LMWH are now available (www.nibsc.org) and the assay results are reported in iu/ml.

It is important to note that therapeutic levels of LMWH may be present without producing prolongation of the PT or APTT. The dose-response curve of the thrombin time (TT) is too steep to make it useful for monitoring heparin therapy. However, it is very sensitive to the presence of UFH and is a useful laboratory indicator of its presence.

Activated partial thromboplastin time for heparin monitoring

Principle

The APTT is the most widely used test for monitoring unfractionated heparin therapy. It is very sensitive to heparin but has a number of short-comings. First, different APTT reagents have different sensitivities to heparin. It is important to establish that the reagent in use has a linear relationship between clotting times and heparin concentration in the therapeutic range (0.3–0.7 anti-Xa u/ml). This is illustrated in Figure 20-4. The result is expressed as a ratio referred to as the APTTR:

$$\text{APTTR} = \text{APTTtest} / \text{APTTcontrol}.$$

The second shortcoming of the APTT in the control of heparin treatment is that the APTT is affected by a number of variables not related to heparin. The most important of these are fibrinogen and factor VIII concentration and the presence of fibrinogen/fibrin degradation products (FDP). When these factors are abnormal, there may be dissociation of the APTT and heparin level causing 'apparent heparin resistance'. In these circumstances a heparin assay must be performed. Last, the use of the APTT may be rendered invalid by the presence of inhibitors (including a lupus anticoagulant), factor deficiency (including liver disease) or the effect of other coagulation-active drugs. In severely ill patients a significant prolongation of the APTT may arise from disseminated intravascular coagulation (DIC) or haemodilution, giving a misleading impression of heparin effect. It has not proved possible to develop for APTT reagents a calibration system equivalent to the ISI employed for thromboplastins in the PT. Overall the APTT has the advantage of simplicity, speed and wide availability but in many situations an anti-Xa assay is preferable.[15]

Reagents and method

The reagents and method for the APTT are described on p. 381.

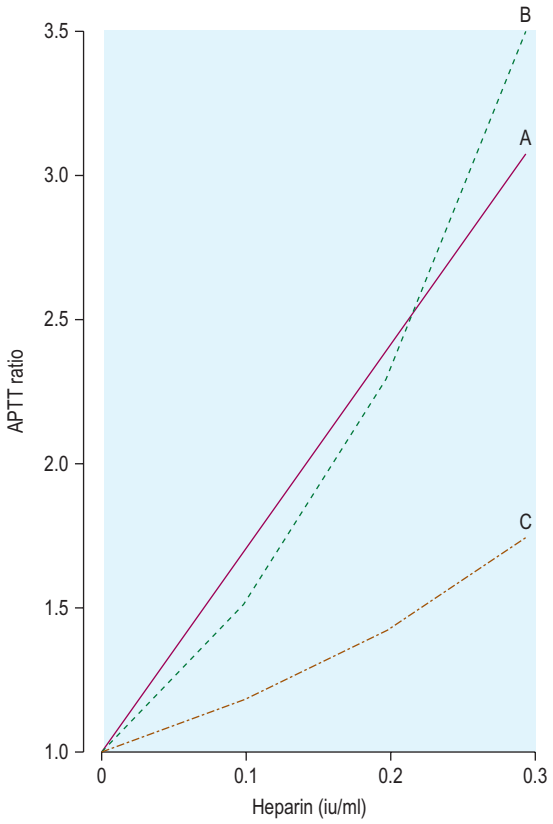

FIGURE 20-4 APTT response to heparin added to plasma *in vitro*. APTT response expressed as ratio (APTT of heparinised plasma/APTT of plasma without heparin). Three different reagents and methods shown. *(Slightly modified with permission from Thomson JM, editor.* Blood coagulation and haemostasis. A practical guide. *Edinburgh: Churchill Livingstone; 1985.)*

Therapeutic range

The therapeutic range for heparin is 0.3–0.7 iu/ml by anti-Xa assay and 0.2–0.4 iu/ml by protamine titration. However the basis for this widely utilised recommendation is weak.[15] The prolongation of the APTT achieved with these concentrations varies between reagents and according to the coagulometer used. The results may be expressed as clotting time in seconds or as a ratio. For the majority of sensitive reagents, ratios of 1.5–3.0 cover the therapeutic range, but can deviate widely from this and must be determined for each reagent and ideally, each batch of reagent. It is important that samples from patients treated with heparin are used for calibration because these give significantly different results from those obtained when normal plasma is 'spiked' with heparin. Regression analysis is used to determine the therapeutic range and a better fit may be obtained using logarithmically transformed APTT values. Plasma from samples for heparin monitoring should be separated within 2 h because heparin activity is lost with time.

Near-patient heparin monitoring

The whole blood activated clotting time (ACT) is routinely used to assess heparin effects during cardiac surgery and is useful for the high heparin concentrations used.[16] However, like the APTT, the ACT is not a specific assay for heparin and may be influenced by several other factors such as hypothermia, factor deficiency, haemodilution and platelet dysfunction. For these reasons the ACT may be misleading with regard to the proper administration of heparin and protamine.

Principle

The ACT is determined by using one of several different contact system activators, such as kaolin or celite (diatomaceous earth activator) to which a sample of whole blood is added, and a method of end-point detection such as optical or electromagnetic. No additional phospholipid is added. A number of commercial devices are available suitable for use in operating theatres. The ACT is thus primarily a system with little laboratory involvement.

Anti-Xa assay for heparin

Principle

Plasma anti-Xa activity as a result of antithrombin is enhanced by the addition of heparin, and either a coagulation or amidolytic (chromogenic) assay of Xa activity can be adapted to measure this effect. A standard curve is constructed by adding varying amounts of heparin to a normal plasma pool, which provides the source of the antithrombin. A known amount of Xa is added and after incubation, the amount of Xa remaining is assayed by chromogenic or coagulation-based assay. A number of commercial kits, based on clotting or chromogenic substrate methods, are in use but although they give linear and reproducible responses, studies have shown considerable variation between kits.[17] A standard curve should be constructed that is appropriate for the level of heparin expected. Some but not all assays add an exogenous source of antithrombin to the test sample which can improve the detection of infused heparin but it is not clear how important this is in patients with low antithrombin levels.[18]

Chromogenic method

The assay is performed as instructed with the kit. The concentration of heparin is read off a standard curve constructed according to the manufacturer's instructions.

Clotting method

Principle

The anti-Xa activity of antithrombin is enhanced by the addition of heparin. The inhibition of factor Xa induced by heparin is measured in a modified factor-Xa assay.

Reagents

- *Pooled normal plasma.* From 20 normal donors or commercial source.
- *Patient's plasma.* Citrated platelet-poor plasma (PPP) should be collected 4 h after subcutaneous injection of LMWH, 6 h after subcutaneous injection of UFH and 6 h after a dose change of UFH infusion; it should be tested as soon as possible after collection and kept at 4°C or on crushed ice until tested.
- *Buffer.* Trisodium citrate 30 vol, glyoxaline buffer (p. 562) 150 volumes, and 20% bovine albumin 1 volume.
- *Commercially prepared artificial factor X-deficient plasma.* Reconstitute according to instructions.
- *Platelet substitute.* Mix equal volumes of factor X deficient plasma and platelet substitute. This is the working reagent and is kept at 37°C.
- *Factor Xa.* Reconstitute as instructed by the manufacturer. Dilute further in the buffer to give a 1 in 100 dilution. Keep on crushed ice until used.
- *Heparin.* 1000 iu/ml or as supplied by the manufacturer. Dilute in 9 g/l NaCl to 10 iu/ml. Ideally, the same batch of heparin as the patient is receiving should be used.
- *$CaCl_2$.* 0.025 mol/l.

Method. A standard curve is constructed as shown in Table 20-3. Add 0.05 ml of each dilution to 0.45 ml of the normal plasma pool. This will give final concentrations of heparin from 0.05 to 0.30 iu/ml in 0.05 iu steps.

Pipette 0.3 ml of diluted factor Xa into a large glass tube at 37°C.

Add 0.1 ml of the first standard dilution. Start the stopwatch. At 1 min and 30 s exactly transfer duplicate 0.1 ml

TABLE 20-3

PREPARATION OF A STANDARD CURVE FOR AN ANTI-Xa ASSAY

	Tube					
Reagent	**1**	**2**	**3**	**4**	**5**	**6**
Heparin (10 iu/ml) (ml)	0.05	0.10	0.15	0.20	0.25	0.30
Saline (ml)	0.95	0.90	0.85	0.80	0.75	0.70
Concentration of heparin (iu/ml)	0.5	1.0	1.5	2.0	2.5	3.0
Final concentration of heparin after addition to normal plasma pool	0.05	0.10	0.15	0.20	0.25	0.30

volumes of the mixture into two tubes each containing 0.1 ml of prewarmed $CaCl_2$.

At 2 min after subsampling add 0.2 ml of the mixture of factor X deficient plasma and platelet substitute, start the stopwatch, mix and record the clotting time.

Repeat for each dilution of standard. The patient's sample is tested undiluted in pooled normal plasma if the clotting time is longer than the times used to construct the standard curve.

Calculation

Plot the clotting times against the heparin concentration on log-linear graph paper, with the clotting times on the linear axis. The concentration of heparin in the patient's sample can be read directly from the standard curve. It is multiplied by the dilution factor if necessary.

Protamine neutralisation test

Principle

This test is an extension of the TT, varying amounts of protamine sulphate being added to the plasma before the addition of thrombin. When all the heparin present in plasma has been neutralised, the clotting time should become normal. The concentration of heparin in the plasma can be calculated from the amount of protamine sulphate required to produce this effect. The protamine neutralisation test was used mainly to calculate the dose of protamine sulphate needed to neutralise circulating heparin after cardiopulmonary surgery or haemodialysis, but is now performed infrequently. It can also be used to control treatment or to calculate the dose of protamine to be administered if the patient needs rapid reversal of heparinisation.

Reagents

- *Protamine sulphate.*
  Dilute 5 ml of protamine sulphate (10 mg/ml) 1 in 20 with barbitone buffer (p. 380), pH 7.4 to give 100 ml of a stock solution containing 500 μg/ml. Then make working solutions to cover the range of 0–500 μg/ml in 50 μg steps from the stock solution by dilution with buffer. The solutions keep indefinitely at 4°C.
- *Thrombin.*
  Dilute thrombin in barbitone buffer to a concentration of about 20 National Institutes of Health (NIH) u/ml. Adjust the concentration so that 0.1 ml of thrombin solution clots 0.2 ml of normal plasma at 37°C in 10 ± 1 s. Keep the thrombin in a plastic tube in melting ice during the assay.
- *Plasma.*
  Citrated PPP from the patient.

Method

Place 0.2 ml of test plasma and 20 μl of barbitone buffer in a glass tube kept in a water bath at 37°C. Allow the mixture to warm and then add 0.1 ml of thrombin. Record the clotting time. If this is approximately 10 s, there is no demonstrable heparin in the plasma. If the TT is prolonged, repeat the test using 20 μl of the 500 μg/ml protamine solution instead of buffer. Repeat the test if necessary, until a concentration of protamine is found that gives a clotting time of near to 10 s.

Calculation

If 20 μl of 150 μg/ml protamine sulphate produces a normal TT (whereas the clotting time is prolonged with 100 μg/ml protamine), then 15 μg of protamine is sufficient to neutralise the heparin in 1 ml of the plasma. Assuming that 1 mg of protamine can neutralise 100 iu of heparin, the plasma therefore contains heparin at a concentration of 1.5 u/ml.

In the previous example, for *in vivo* neutralisation of heparin by protamine sulphate, assuming a total blood volume of 75 ml per kg body weight, the required dose of protamine in mg would be as follows:

$$\frac{15 \times 75 \times \text{body weight} \times (1 - \text{Hct})}{1000}$$

Heparin-induced thrombocytopenia

Most patients receiving unfractionated heparin experience a small and immediate drop in their platelet count. This has been referred to as type 1 heparin-induced thrombocytopenia (HIT) and is completely harmless. It is thought to arise as a result of heparin binding to platelets. The term HIT is now more generally used to describe a second more serious thrombocytopenia (type II HIT) seen in approximately 5% of patients receiving UFH, which is the result of development of antibodies against heparin–platelet factor 4 (PF4) complexes. The antigen-antibody complexes bind to and activate platelets via the FCRγII, resulting in accelerated clearance and a highly prothrombotic state. Type II HIT develops 5–12 days after starting heparin therapy and causes a decrease in platelets to <50% of pre-heparin value and usually between 20 and 50×10^9/l. The process of activation sometimes results in arterial, or more frequently venous, platelet thrombus formation, and skin necrosis has also been reported. This syndrome of heparin-induced thrombocytopenia and thrombosis (HITT) has a high mortality risk. Heparin must be stopped immediately, and alternative immediate-acting anticoagulation must be instituted.[19]

The diagnosis of HITT is primarily clinical, and there is no test that can be performed with sufficient speed, sensitivity and specificity to positively guide the primary decision to stop heparin. The decision to perform laboratory tests and the interpretation of the results should always be performed after consideration of the clinical likelihood or pretest probability. A simple scoring scheme (the 4 Ts system) has been devised and tested for this purpose (Table 20-4).[20–22]

TABLE 20-4

PRE-TEST CLINICAL SCORING SYSTEM TO ASSESS THE LIKELIHOOD OF HEPARIN-INDUCED THROMBOCYTOPENIA

Score	2	1	0
Thrombocytopenia	>50% platelet count fall to nadir $>20\times10^9$/l	30–50% platelet count fall, or nadir $10–19\times10^9$/l	30% platelet count fall, or nadir $<10\times10^9$/l
Time of platelet fall (or other sequelae)*	Days 5–10, or day 1 with recent heparin (previous 30 days)	Day 10 or later, or timing unclear; or day 1 with less recent heparin (previous 31–100 days)	Day 4 or earlier (but no recent heparin)
Thrombosis	Proven new thrombosis, skin necrosis or acute systemic reaction after intravenous UFH bolus	Progressive or recurrent thrombosis; erythematous skin lesions; suspected thrombosis (not proven)	None
Other explanation equally plausible	None evident	Possible	Definite

HIT, heparin-induced thrombocytopenia; UFH, unfractionated heparin.
HIT probability score: 6–8 indicates high likelihood of HIT; 4–5, HIT possible but further testing required; and 0–3, low probability of HIT and no further testing is indicated.
*First day of heparin exposure is counted as day 0. Sequelae such as thrombosis or skin necrosis.

Antibody tests to detect the presence of PF4-heparin dependent antibodies have sufficient sensitivity to reliably exclude the diagnosis whilst lacking the specificity to positively identify it; although judicious choice of a cut off can help considerably and achieve sensitivity of 100% with specificity of >90%.[23] Confirmatory tests may also include functional tests in which platelet activation stimulated by antigen-antibody complexes is detected. The principal example of a functional test is the serotonin release assay,[24] but this is too cumbersome and inconvenient for routine use. Alternatives are heparin-induced platelet aggregation and flow cytometry-based tests. The simplest for routine use is a modified platelet aggregation test as described in the following section.[25,26]

Heparin-induced thrombocytopenia: detection by platelet aggregation

Addition of heparin to the patient's PPP results in heparin/PF4 complexes that are bound by the pathological antibody. The antibody-heparin/PF4 complexes then bind to and activate the platelets. Platelet activation is detected as aggregation.

Principle

Blood is centrifuged gently to obtain platelet rich plasma (PRP), which is stirred in a cuvette at 37°C, between a light source and a photocell.

Reagents

- *Normal control platelet rich plasma (PRP)*
  Preferably blood group O or the same group as the patient should be used. For method of preparation see page 399. A platelet count is performed on the PRP. The number of platelets will influence aggregation response if the count falls outside a range of $200–400\times10^9$/l. If necessary the PRP is adjusted to give a platelet count of 300×10^9/l by diluting with control platelet poor plasma (PPP).
  Patient and normal control PPP is obtained by centrifuging at 2000 *g* for 20 min. Check that the platelet count is zero.
- *Heparin*
  A sample of the type (batch identical) of heparin previously given to the patient is required. The heparin is diluted to give working concentrations of 10 and 20 iu/ml (final concentration of 1.0 and 2.0 iu/ml).

Method

Following the scheme shown in Table 20-5, four aggregation cuvettes are set up. Add 300 µl of normal PRP to each cuvette. Then add 200 µl of the appropriate patient or control PPP with a magnetic stir bar. Set the 100% baselines with the normal control PPP and the 0% baselines with PRP and PPP. Set the stir rate at 1200 revolutions per minute (rpm). Observe the baselines for 1 min. Initiate aggregation by the addition of 50 µl of either heparin or saline. Observe aggregation for a minimum of 15 min.

Interpretation

1. If aggregation (>20%) is observed in cuvette 4 with a final heparin concentration of 1.0 and 2.0 iu/ml, the test is repeated using normal platelets, patient plasma and a final heparin concentration of 0.2 iu/ml.
2. Aggregation observed in cuvette 4 only, with subsequent demonstration of heparin-induced aggregation at a final concentration of 0.2 iu/ml, is considered positive for heparin-induced platelet aggregation.
3. A confirmatory step can be performed by repeating the test using a much higher final concentration of heparin (10 to 100 iu/ml). Inhibition of aggregation is suggestive of heparin-induced platelet aggregation.

TABLE 20-5

THE COMBINATIONS OF PLATELETS, PLASMA AND HEPARIN REQUIRED TO TEST FOR HEPARIN-INDUCED THROMBOCYTOPENIA

	Cuvette 1	Cuvette 2	Cuvette 3	Cuvette 4
Normal control PRP	300 µl	300 µl	300 µl	300 µl
Patient PPP	None	200 µl	None	200 µl
Normal control PPP	200 µl	None	200 µl	None
Heparin (10 or 20 iu/ml)	None	None	50 µl	50 µl
Saline (0.85%)	50 µl	50 µl	None	None

PRP, platelet-rich plasma; PPP, platelet-poor plasma.

4. Aggregation observed in cuvettes 1, 2 or 3 indicates that the reaction may be a result of something other than heparin-induced platelet aggregation and the test is repeated using different normal donor platelets and control PPP.

With experience, subjective assessment of aggregation responses is usually sufficient for clinical interpretation. A positive test result is shown in Figure 20-5. The total amount of aggregation seen may be reported.

Interpretation

See platelet aggregation (p. 401).

	Black	Green	Red	Blue
Normal control PRP	300 µl	300 µl	300 µl	300 µl
Patient PPP	None	200 µl	None	200 µl
Normal control PPP	200 µl	None	200 µl	None
Heparin (10 or 20 iu/ml)	None	None	50 µl	50 µl
Saline (0.85%)	50 µl	50 µl	None	None

FIGURE 20-5 The combinations of platelets, plasma and heparin required to test for heparin-induced thrombocytopenia. The aggregation traces show that platelet aggregation occurs only when the patient plasma is exposed to heparin (blue trace).

Reported studies using platelet aggregation tests indicate they have a high specificity for HIT (>90%). However the sensitivity of the test is more variable and although it is >80% on some occasions[26] it is frequently much nearer to 50–60% and therefore cannot reliably exclude HIT. The literature suggests that test sensitivity can be improved by the use of the patient's own platelets, platelets from selected donors known to be reactive in the assay, or washed platelets.[27] The reactivity of the donor platelets can be established by using a known positive sample. Test specificity is enhanced by including neutralisation of the reaction by a high dose of heparin but this is not always observed.

Immunological tests for heparin–PF4 antibodies

Several commercial kits are available for detection of antibodies directed against the heparin–platelet factor 4 complex. These include enzyme immunoassays; 'PF4 enhanced' (GTI Diagnostics, www.immucor.com) and 'Zymutest HIA' (Hyphen BioMed, www.hit-assay.com), an immunofiltration kit, PIFA heparin/PF4 Rapid Assay (Akers Biosciences, www.akersbio.com) and a particle gel immunoassay. The first two of these have reported high sensitivity (>90%) for the presence of antibodies and although they lack specificity, have reasonable utility. The test performance can be improved by using the optical density (OD) to assign a probability of a true positive result.[28] The immunofiltration assay did not perform so well in one study but subsequent reports were more encouraging.[29,30] These tests are performed according to the manufacturers' instructions.

DIRECT ACTING ORAL ANTI-IIa AND ANTI-Xa AGENTS

A number of orally active direct inhibitors of IIa and Xa have now entered clinical use. The implications for laboratory practice are unclear because clinical trials have been carried out without monitoring of anticoagulant effect. However it is likely that some measurement, or at least detection, of their effect will be required in some circumstances such as bleeding or renal failure.[31] Anti-Xa activity can be measured as described for heparin but using dilutions of a reference preparation of the drug to generate the standard curve instead of heparin. The results can then be reported in ng/ml. It is essential to ensure that a range of concentrations is used, which spans the range of expected plasma concentrations, and that the assay shows a linear response across this range.[31] In one study the presence of exogenous antithrombin appeared to result in overestimation of rivaroxaban concentration.[32]

Anti-IIa activity can be measured in a number of ways. Specific anti-IIa assays using chromogenic substrates are available commercially. Anti-IIa activity can

also be measured using the ecarin clotting time (ECT). This test has previously been employed to measure high levels of hirudin because the ECT has a linear relationship with hirudin concentration over a greater range than the APTT.[33] Concentration of thrombin inhibitors can also be measured using a modified thrombin time: the Hemoclot kit (www.hyphen-biomed.com) is a suitable example.[34]

Ecarin clotting time

Ecarin is a snake venom (*Echis carinatus*) that directly activates prothrombin to meizothrombin.[33] This action is not dependent on phospholipid membranes and so is not impaired by the presence of lupus anticoagulant or by inadequate prothrombin carboxylation due to warfarin therapy. The activity of meizothrombin is not inhibited by heparin-antithrombin and can be detected by a clotting or chromogenic assay.

Reagents

- *Ecarin solution:* reconstituted according to manufacturer's instructions and diluted to 4 u/ml with buffer.
- *Buffer:* HEPES buffered saline (0.2 M) containing 0.025 M calcium chloride.
- *Patient PPP.*

Warm the reagents to 37°C.

Add 50 µl of ecarin reagent to 100 µl of PPP and record clotting time.

The clotting time for normal plasma is approximately 50 s. A standard curve can be created using appropriate dilutions of the thrombin inhibitor in question added to normal plasma. Commercial ecarin activity tests using chromogenic substrates for meizothrombin are also available.

THROMBOLYTIC THERAPY

The thrombolytic agents currently in use are principally streptokinase and recombinant tissue type plasminogen activator (rtPA). Tenecteplase and reteplase are genetically modified forms of tPA.

Streptokinase

Streptokinase is a purified fraction of the filtrate from cultures of *Streptokinase haemolyticus*. Streptokinase interacts with plasminogen or plasmin to form a plasminogen activator in plasma. The activator complex in turn cleaves a bond in the plasminogen molecule to give rise to free plasmin. Streptokinase therefore results in systemic fibrinogenolysis as well as lysis of fibrin clot. Streptokinase is a foreign protein and induces antibody production in humans, limiting a course of treatment to 3–5 days. It is recommended that 2 years should elapse before repeated administrations of streptokinase. It also cross-reacts with anti-streptococcal antibodies, which may cause resistance to therapy, although this is usually overcome with large doses.

Tissue-type plasminogen activator

The tissue-type plasminogen activator is a single- or double-chain polypeptide obtained by recombinant techniques or from tissue cultures. Plasminogen and tPA both have a high affinity for fibrin, which acts as a cofactor bringing the two molecules together and greatly accelerating plasmin formation. tPA thus causes less systemic fibrinogenolysis than any of the previously mentioned agents, although some decrease in circulating fibrinogen does occur, particularly with prolonged administration. It induces a thrombolytic state of longer duration than either streptokinase or urokinase infusion.

Selection of patients

Thrombolytic treatment carries a serious risk of bleeding, and thrombolytic agents should not be given to individuals after surgery or trauma or who are at a high risk of bleeding. In addition, each patient should have haemostatic function and platelet count measured before treatment is started.

Laboratory control of thrombolytic therapy

Many laboratory tests are abnormal during thrombolytic therapy, but a useful procedure for monitoring is not available. In practice, thrombolytic therapy is given rapidly according to protocol, with no time or need for adjustment of dosage. During thrombolytic therapy all screening tests of coagulation are prolonged, reflecting the hyperplasminaemic state with the reduction in the fibrinogen concentration and the presence of FDP. The prolongation is most marked with streptokinase and streptokinase-plasminogen complex; it is less marked with urokinase and least with tPA. The fibrinogen concentration commonly decreases to below 0.05 g/l, and the FDP concentration may increase to more than 1000 ng/l.[35] Factor V is also very susceptible to plasmin cleavage and its plasma concentration may also fall significantly.

Plasma fibrinogen

Depending on duration of therapy and the specific plasminogen activator used, there is a variable decrease in fibrinogen. The fibrinogen should be measured by a method dependent on clottable fibrinogen (e.g. Clauss technique, p. 383). The PT-derived fibrinogen is likely to be unreliable. Fibrin(ogen) degradation products will be elevated, but this is unlikely to be helpful.

Investigation of a patient who bleeds while taking thrombolytic agents or immediately afterward

Haemorrhage is an inevitable risk associated with fibrinolytic therapy and may occur despite normal coagulation tests. When severe, bleeding will necessitate cessation of fibrinolysis and administration of tranexamic acid to limit further activity. Coagulation tests may guide replacement therapy with plasma, fibrinogen concentrate or cryoprecipitate.[12,35]

ANTIPLATELET THERAPY

Many drugs inhibit platelet function *in vitro*, but only a few have antiplatelet activity in acceptable doses. Each category of drugs has a different pharmacological action and requires different methods to demonstrate its effect on platelets. Antiplatelet agents are used in primary and secondary prevention of arterial thrombosis especially following insertion stents. Haematology laboratories are only rarely asked to monitor these aspects of antiplatelet therapy and monitoring has not been shown to be of clinical benefit.

Interest has been revived in the observation that some patients do not respond to aspirin. 'Aspirin resistance' is poorly defined and sometimes apparent resistance may be merely the result of a failure to take the medication. Otherwise this term may refer either to a failure to inhibit platelet aggregation, a failure to suppress thromboxane A_2 production or occurrence of a thrombotic event despite aspirin therapy. The first may be detected by platelet function analysers such as the PFA100 (see p. 393) or by platelet aggregation responses; the second may be detected by serum thromboxane B_2 (TXB_2) levels or the metabolite 11-dehydro TXB_2 in the urine. A similar 'resistance' has been identified in patients taking clopidogrel, which blocks the platelet $P2Y_{12}$ receptor. The effect of clopidogrel can be detected by demonstrating a reduced response to ADP in a modification of the standard platelet light transmission aggregometry (see p. 399). In addition a number of commercial assays are available to monitor antiplatelet therapy or to detect resistance. The PFA100 is sensitive to aspirin but not clopidogrel effect. Monitoring antiplatelet therapy has not reached routine hospital practice: first because the clinical utility of these assessments and the appropriate responses are not established[36–38] and second because a series of new antiplatelet agents with more reliable dose-response characteristics have been introduced.

Blood Cell Antigens and Antibodies: Erythrocytes, Platelets and Neutrophils

Fiona A.M. Regan

CHAPTER OUTLINE

ERYTHROCYTES

Red cell antigens

Since Landsteiner's discovery in 1901, that human blood groups existed, a vast body of serological, genetic and biochemical data on red cell (blood group) antigens has been accumulated. More recently, the biological functions of some of these antigens have been appreciated.

A total of 30 blood group systems have been described (Table 21-1). Each system is a series of red cell antigens, determined either by a single genetic locus or by very closely linked loci. In addition to the blood group systems, there are six 'collections' of antigens (e.g. Cost), which bring together other genetically, biochemically or serologically related sets of antigens and a separate series of low-frequency (e.g. Rd) and high-frequency (e.g. Vel) antigens, which do not fit into any system or collection. A numerical catalogue of red cell antigens is being maintained by an International Society of Blood Transfusion (ISBT) Working Party.[1]

Apart from those of the ABO system, most of these antigens were detected by antibodies stimulated by transfusion or pregnancy.

Alternative forms of a gene coding for red cell antigens at a particular locus are called alleles and individuals may inherit identical or non-identical alleles. Most blood group genes have been assigned to specific chromosomes (e.g. ABO system on chromosome 9, Rh system on chromosome 1). The term genotype is used for the sum of the inherited alleles of a particular gene (e.g. AA, AO) and most red cell genes are expressed as codominant antigens (i.e. both alleles are expressed in the heterozygote). The phenotype refers to the recognisable product of the alleles and there are many racial differences in the frequencies of red cell phenotypes, as shown in Table 21-2.

Red cell antigens are determined either by carbohydrate structures or protein structures. Carbohydrate-defined antigens are indirect gene products (e.g. ABO, Lewis, P). The genes code for an intermediate product, usually an enzyme that creates the antigenic specificity

TABLE 21-1

BLOOD GROUP SYSTEMS RECOGNISED BY THE ISBT WORKING PARTY

ISBT No.	System Name	System Symbol	Epitope	Chromosome
001	ABO	ABO	Carbohydrate (*N*-acetyl-D-galactosamine, galactose). A, B and H antigens mainly elicit IgM antibody reactions, although anti-H is very rare, see the Hh antigen system (Bombay phenotype, ISBT 018)	9
002	MNS	MNS	GPA/GPB (glycophorins A and B). Main antigens M, N, S, s	4
003	P	P_1	Glycolipid. Antigen P1	22
004	Rh	RH	Protein. C, c, D, E, e antigens (there is no 'd' antigen; lowercase 'd' indicates the absence of D)	1
005	Lutheran	LU	Protein (member of the immunoglobulin superfamily). Set of 21 antigens	19
006	Kell	KEL	Glycoprotein. Antibodies to K_1 can cause haemolytic disease of the newborn (anti-Kell), which can be severe	7
007	Lewis	LE	Carbohydrate (fucose residue). Main antigens Le^a and Le^b – associated with tissue ABH antigen secretion	19
008	Duffy	FY	Protein (chemokine receptor). Main antigens Fy^a and Fy^b. Individuals lacking Duffy antigens altogether are immune to malaria caused by *Plasmodium vivax* and *Plasmodium knowlesi*	1
009	Kidd	JK	Protein (urea transporter). Main antigens Jk^a and Jk^b	18
010	Diego	DI	Glycoprotein (band 3, AE1 or anion exchange). Positive blood is found only among North-Central and East Asians and Native Americans	17
011	Yt or Cartwright	YT	Protein (acetylcholinesterase)	7
012	XG	XG	Glycoprotein	X
013	Scianna	SC	Glycoprotein	1
014	Dombrock	DO	Glycoprotein (fixed to cell membrane by GPI)	12
015	Colton	CO	Aquaporin 1. Main antigens Co(a) and Co(b)	7
016	Landsteiner-Wiener	LW	Protein (member of the immunoglobulin superfamily)	19
017	Chido/Rogers	CH/RG	C4a C4b (complement fractions)	6
018	Hh/Bombay	H	Carbohydrate (fucose residue)	19
019	Kx	XK	Glycoprotein	X
020	Gerbich	GE	GPC/GPD (glycophorins C and D)	2
021	Cromer	CROM	Glycoprotein (DAF, decay accelerating factor or CD55, regulates complement fractions C3 and C5, attached to the membrane by GPI)	1
022	Knops	KN	Glycoprotein (CR1 or CD35, immune complex receptor)	1
023	Indian	IN	Glycoprotein (CD44 adhesion function)	11
024	Ok	OK	Glycoprotein (CD147)	19
025	Raph	MER2	Transmembrane glycoprotein	11
026	JMH	JMH	Protein (fixed to cell membrane by GPI)	6
027	Ii	I	Branched (I)/unbranched (i) polysaccharide	6
028	Globoside	GLOB	Glycolipid. Antigen P	3
029	GIL	GIL	Aquaporin 3	9
030	Rh-associated glycoprotein	RHAG	Rh-associated glycoprotein	6

GPI, glycosylphosphatidylinositol; IgM, immunoglobulin M; ISBT, International Society of Blood Transfusion.

by transferring sugar molecules onto a protein or lipid. Protein-defined antigens are direct gene products and the specificity is determined by the inherited amino acid sequence and/or the conformation of the protein. Proteins carrying red cell antigens are inserted into the membrane in one of three ways: single pass, multipass or linked to glycosyl phosphatidylinositol (GPI-linked). Only a few red cell antigens are erythroid-specific (Rh, LW, Kell and MNSs), the remainder being expressed in many other tissues. The structure and functions of the membrane proteins and glycoproteins carrying blood group antigens have been reviewed by Daniels.[2] An illustration of the

TABLE 21-2

FREQUENCIES OF RED CELL PHENOTYPES IN US BLACK AND WHITE POPULATIONS

System	Phenotype	US Black Population (%)	US White Population (%)
ABO	O	49	43.7
	A	26	41.7
	B	20.5	10.6
	AB	4.5	4
Lewis	Le (a−b−)	28.5	6
Rh	Dce	47.8	2.1
	DCcEe	4.2	13.4
	dce	5.6	14.6
	DCe	2.6	18.9
MNSs	S−s+	68.1	45
	S+s+	24.5	44
	S+s−	5.9	11
	S−s−	1.5	Rare
Duffy	Fy (a−b−)	63.7	Rare
	Fy (a−b+)	18.8	34
	Fy (a+b+)	2	44
	Fy (a+b−)	15.5	17
Kidd	Jk (a+b−)	50	27.5
	Jk (a+b+)	41.4	49.4
	Jk (a−b+)	8.6	23.1

putative functions of molecules containing blood group antigens is provided in Table 21-3.

However, the main clinical importance of a blood group system depends on the capacity of alloantibodies (directed against the antigens not possessed by the individual) to cause destruction of transfused red cells or to cross the placenta and give rise to haemolytic disease in the fetus or newborn. This in turn depends on the frequency of the antigens and the alloantibodies and the characteristics of the latter: thermal range, immunoglobulin class and ability to fix complement. On these criteria, the ABO and Rh systems are of major clinical importance. Anti-A and anti-B are naturally occurring and are capable of causing severe intravascular haemolysis after an incompatible transfusion. The RhD antigen is the most immunogenic red cell antigen after A and B, being capable of stimulating anti-D production after transfusion or pregnancy in the majority of RhD-negative individuals.

ABO system

Discovery of the ABO system by Landsteiner marked the beginning of safe blood transfusion. The ABO antigens, although most important in relation to transfusion, are also expressed on most endothelial and epithelial membranes and are important histocompatibility antigens.[3] Transplantation of ABO-incompatible solid organs increases the potential for hyperacute graft rejection, although ABO-incompatible renal transplantation can be successfully carried out with plasmapheresis in addition to immunosuppression of the recipient.[4] Major ABO-incompatible stem cell transplants (e.g. group A stem cells into a group O recipient) will provoke haemolysis, unless the donation is depleted of red cells.

ABO antigens and encoding genes. There are four main blood groups: A, B, AB and O (Table 21-4). In the British Caucasian population, the frequency of group A is 42%, B 9%, AB 3% and O 46%, but there is racial variation

TABLE 21-3

PUTATIVE FUNCTIONS OF MOLECULES EXPRESSING BLOOD GROUP ANTIGENS

Class	Blood Group System	Structure	Function
Transporter/channel	Kidd	Multipass GP	Urea transporter
	Colton	Aquaporin 1	
		Multipass GP	Water channel
	Diego	Band 3, multipass GP	Anion exchanger
Receptors	Duffy	DARC, multipass GP	Chemokine (*Plasmodium vivax* receptor)
	Indian	Single-pass GP	Hyaluronate receptor
Complement pathway	Chido/Rogers	Complement absorbed	Complement component onto red cells
	Cromer	DAF	Complement regulator
	Knops	Complement receptor 1	Complement regulator
Adhesion	LW	IgSF	Binds CD11/CD18 Integrins
Molecule	Lutheran	IgSF	Laminin receptor
Enzyme	Yt	GPI-linked GP Acetylcholinesterase	Unknown on red cells
	Kell	Single-pass GP	Endopeptidase
Structural protein	Gerbich	Glycophorins C and D Single-pass GP	Attachment to membrane skeleton

DAF, decay accelerating factor (CD55); DARC, Duffy antigen receptor for chemokines; GP, glycoprotein; GPI, glycosylphosphatidylinositol; IgSF, immunoglobulin superfamily.

TABLE 21-4

ABO BLOOD GROUP SYSTEM

Blood Group	Subgroup	Antigens on Red Cells	Antibodies in Plasma
A	A_1	A + A_1	Anti-B
	A_2	A	(Anti-A_1)*
B	–	B	Anti-A, Anti-A_1
AB	A_1B	A + A_1 + B	None
	A_2B	A + B	(Anti-A_1)*
O	–	(H)†	Anti-A
			Anti-A_1
			Anti-B
			Anti-A,B‡

*Anti-A_1 found in 1–2% of A_2 subjects and 25–30% of A_2B subjects.
†The amount of H antigen is influenced by the ABO group; O cells contain most H and A_1B cells least. Anti-H may be found in occasional A_1 and A,B subjects (see text).
‡Crossreactivity with both A and B cells.

in these frequencies.[5] The epitopes of ABO antigens are determined by carbohydrates (sugars), which are linked either to polypeptides (forming glycoproteins) or to lipids (glycolipids).

The expression of ABO antigens is controlled by three separate genetic loci: *ABO* located on chromosome 9 and *FUT1* (*H*) and *FUT2* (*Se*), both of which are located on chromosome 19. The genes from each locus are inherited in pairs as Mendelian codominants. Each gene codes for a different enzyme (glycosyltransferase), which attaches specific monosaccharides onto precursor disaccharide chains (Table 21-5). There are four types of disaccharide chains known to occur on red cells, on other tissues and in secretions. The Type 1 disaccharide chain is found in plasma and secretions and is the substrate for the *FUT2* (*Se*) gene, whereas Types 2, 3 and 4 chains are only found on red cells and are the substrate for the *FUT1* (*H*) gene. It is likely that the *O* and *B* genes arose by mutation of the *A* gene. The *O* gene does not encode a functional enzyme; group O individuals commonly have a deletion at nucleotide 261 (the *O1* allele), which results in a frame-shift and premature termination of the translated polypeptide and the production of an enzyme with no catalytic activity. The *B* gene differs from *A* by seven nucleotide substitutions, four of which lead to a different amino acid being encoded.[6] The expression of A and B antigens is dependent on the *H* and *Se* genes, which both give rise to glycosyltransferases that add L-fucose, producing the H antigen. The presence of an *A* or *B* gene (or both) results in the production of further glycosyltransferases, which convert H substance into A and B antigens by the terminal addition of *N*-acetyl-D-galactosamine and D-galactose, respectively (Fig. 21-1). Because the *O* gene produces an inactive transferase, H substance persists unchanged on group O cells. In the extremely rare Oh Bombay phenotype, the individual is homozygous for the inactive *h* allele of *FUT1* and hence cannot form the H precursor of the A and B antigen. Their red cells type as group O, but their plasma contains anti-H in addition to anti-A, anti-B and anti-A,B, which are all active at 37 °C. As a consequence, individuals with an Oh Bombay phenotype can only be safely transfused with other Oh red cells.

Serologists have defined two common subgroups of the A antigen. Approximately 20% of group A and group AB individuals belong to group A_2 and group A_2B, respectively, the remainder belonging to group A_1 and group A_1B. These subgroups arise as a result of inheritance of either the A^1 or A^2 alleles. The A_2 transferase is less efficient in transferring *N*-acetyl-D-galactosamine to available H antigen sites and cannot utilise Types 3 and 4 disaccharide chains. As a consequence, A_2 red cells have fewer A antigen sites than A_1 cells and the plasma of group

TABLE 21-5

GLYCOSYLTRANSFERASES PRODUCED BY GENES ENCODING ANTIGENS WITHIN THE ABO, H AND LEWIS BLOOD GROUP SYSTEMS

Gene	Allele	Transferase
FUT1	H	α-2-L-fucosyltransferase
	h	None
ABO	A	α-3-*N*-acetyl-D-galactosaminyltransferase
	B	α-3-D-galactosyltransferase
	O	None
FUT2	Se	α-2-L-fucosyltransferase
	se	None
FUT3	Le	α-3/4-L-fucosyltransferase
	le	None

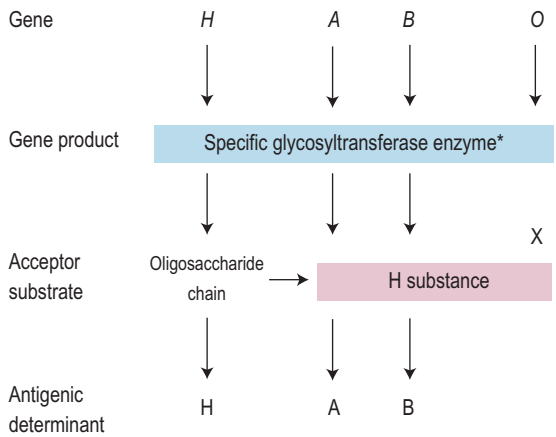

FIGURE 21-1 Pathways from HAB blood group genes to antigens. *Glycosyltransferase H transfers L-fucose; A transfers *N*-acetyl-D-galactosamine; B transfers D-galactose; O is inactive.

A_2 and group A_2B individuals may also contain anti-A_1. The distinction between these subgroups can be made using the lectin *Dolichos biflorus,* which only reacts with A_1 cells. The H antigen content of red cells depends on the ABO group and, when assessed by agglutination reactions with anti-H, the strength of reaction tends to be graded $O > A_2 > A_2B > B > A_1 > A_1B$. Other subgroups of A are occasionally found (e.g. A_3, A_x), resulting from mutant forms of the glycosyltransferases produced by the A gene that are less efficient at transferring *N*-acetyl-D-galactosamine onto H substance.[6]

The A, B and H antigens are detectable early in fetal life but are not fully developed on the red cells at birth. The number of antigen sites reaches 'adult' level at around 1 year of age and remains constant until old age, when a slight reduction may occur.

Secretors and non-secretors. The ability to secrete A, B and H substances in a water-soluble form is controlled by *FUT2* (dominant allele *Se*). In a Caucasian population, about 80% are secretors (genotype *SeSe* or *Sese*) and 20% are nonsecretors (genotype *sese*) (Table 21-6). Secretors have H substance in the saliva and other body fluids together with A substances, B substances or both, depending on their blood group. Only traces of these substances are present in the secretions of nonsecretors, although the antigens are expressed normally on their red cells and other tissues.

An individual's secretor status can be determined by testing for ABH substance in saliva (see p. 457).

ABO antigens and disease. Rarely group A individuals acquire a B antigen from a bacterial infection that results in the release of a deacetylase enzyme. This converts *N*-acetyl-D-galactosamine into α-galactosamine, which is similar to galactose, the immunodominant sugar of group B, thereby sometimes causing the red cells to appear to be group AB. In the original reported cases, five out of seven of the patients had carcinoma of the gastrointestinal tract. Case reports attest to the danger of individuals with an acquired B antigen being transfused with AB red cells, resulting in a fatal haemolytic transfusion reaction following the production of hyperimmune anti-B.[7]

The inheritance of ABH antigens is also known to be weakly associated with predisposition to certain diseases. Group A individuals have 1.2 times the risk of developing carcinoma of the stomach than group O or B; group O individuals have 1.4 times more risk of developing peptic ulcer than non-group O individuals; and nonsecretors of ABH have 1.5 times the risk of developing peptic ulcer than secretors.[8] The ABO group also affects plasma von Willebrand factor (VWF) and factor VIII levels; group O healthy individuals have levels around 25% lower than those of other ABO groups.[9] ABO blood group appears to mediate its effect by accelerating clearance of VWF but the mechanism is not yet clear.[10] ABH antigens are also frequently more weakly expressed on the red cells of persons with leukaemia.

TABLE 21-6

SECRETOR STATUS IN THE CAUCASIAN POPULATION

Genes	Blood Group of Red Cells	ABH Substance Present in Saliva	Incidence (%)
Secretor *SeSe* or *Sese* (*FUT2* gene)	A	A+H	80
	B	B+H	
	AB	A+B+H	
	O	H	
Nonsecretors *sese* (*FUT2* gene)	A, B, AB or O	None	20

ABO antibodies

Anti-A and Anti-B. ABO antibodies, in the absence of the corresponding antigens, appear during the first few months after birth, probably as a result of exposure to ABH antigen-like substances in the diet or the environment (i.e. they are 'naturally occurring') (Table 21-4). This allows for reverse (serum/plasma) grouping as a means of confirming the red cell phenotype. The antibodies are a potential cause of dangerous haemolytic transfusion reactions if transfusions are given without regard to ABO compatibility. Anti-A and anti-B are always, to some extent, immunoglobulin (Ig) M. Although they react best at low temperatures, they are nevertheless potentially lytic at 37 °C. Hyperimmune anti-A and anti-B occur less frequently, usually in response to transfusion or pregnancy, but they may also be formed following the injection of some toxoids and vaccines. They are predominantly of IgG class and are usually produced by group O and sometimes by group A_2 individuals. Hyperimmune IgG anti-A and/or anti-B from group O or group A_2 mothers may cross the placenta and cause haemolytic disease of the newborn (HDN). These antibodies react over a wide thermal range and are more effective haemolysins than the naturally occurring antibodies. Group O donors should always be screened for high-titre anti-A and anti-B antibodies, which may cause haemolysis when group O platelets or plasma are transfused to recipients with A and B phenotypes.

Plasma-containing blood components from such high-titre universal donors should be reserved for group O recipients.

Anti-A_1 and anti-H. Anti-A_1 reacts only with A_1 and A_1B cells and is occasionally found in the serum of group A_2 individuals (1–8%) and not uncommonly in the serum

of group A_2B subjects (25–50%). However, anti-A_1 normally acts as a cold agglutinin and is very rarely reactive at 37 °C, when it is only capable of limited red cell destruction. There have been a few reports of red cell haemolysis ascribed to anti-A_1, which some authors have questioned because, although the antibodies reacted only with A_1 red cells, no attempts were made to absorb them with A_2 cells, which would have revealed their anti-A specificity.

Anti-H reacts most strongly with group O and A_2 red cells and also normally acts as a cold agglutinin (autoantibody). A notable, but rare, exception is the anti-H allo-antibody that occurs in the Oh Bombay phenotype, which is an IgM antibody and causes lysis at 37 °C (Table 21-4) so that Oh Bombay phenotype blood is required for transfusion.

Lewis system

Lewis antigens and encoding genes. The Lewis antigens (Le^a and Le^b) are located on soluble glycosphingolipids found in saliva and plasma and are secondarily absorbed into the red cell membranes from the plasma.

The Le gene at the *FUT3* (*LE*) locus is located on chromosome 19 and codes for a fucosyltransferase, which acts on an adjacent sugar molecule to that acted on by the *Se* gene. Where *Se* and *Le* are present, the Le^b antigen is produced; where *Le* but not *Se* is present, Le^a is produced; and where *Le* is not present, neither Le^a nor Le^b is produced. After transfusion of red cells, donor red cells convert to the Lewis type of the recipient owing to the continuous exchange of glycosphingolipids between the plasma and red cell membrane.

Neonates have the phenotype Le(a−b−) because low levels of the fucosyltransferase are produced in the first 2 months of life.

Lewis antibodies. Lewis antibodies are naturally occurring and are usually IgM and complement binding. *In vitro,* their reactivity is enhanced with the use of enzyme-treated red cells, when lysis may occur. However, only rare examples of anti-Le^a that are strictly reactive at 37 °C have given rise to haemolytic transfusion reactions and there is no good evidence that anti-Le^b has ever caused a haemolytic episode. Explanations for the relative lack of clinical significance include their thermal range, neutralisation by Lewis antigens in the plasma of transfused blood and the gradual elution of Lewis antigens from the donor red cells. Consequently, it is acceptable to provide red cells for transfusion that have not been typed as negative for the relevant Lewis antigen but are compatible with the recipient plasma when the compatibility test is performed strictly at 37 °C.

Lewis antibodies have not been implicated in haemolytic disease of the fetus or newborn. The role of Lewis in influencing the outcome of renal transplants is unclear.

The P system and globoside collection

Antigens. The P_1 antigen of the P1PK system and the P and P^k antigens of the globoside (P) collection are related but nonallelic. The relevant genes are at 3q26.1 for P (*B3GALT3*) and at 22q13.2 (*A4GALT*) for P_1 and P^k. All antigens are derived from the precursor, lactosyl ceramide dihexoside. Carbohydrate products related to the P system are widely distributed in nature.

Expression of P_1 varies considerably between individuals. One in 100 000 individuals is p (negative for P_1 and P_2) and is resistant to parvovirus B19 infection.

Antibodies. Anti-P_1 is a common naturally occurring antibody of no clinical significance and in its presence P_1-positive red cells for transfusion can be provided that are crossmatch compatible at 37 °C. Allo-anti-P is also a naturally occurring antibody found in individuals with the rare P^k phenotype. Auto-anti-P is the specificity attributed to the Donath–Landsteiner antibody; it is a potent biphasic haemolysin, responsible for paroxysmal cold haemoglobinuria.

Anti-PP_1P^k is a naturally occurring high-titre IgM or IgG antibody and it is found only in individuals with the rare p phenotype. It is reactive at 37 °C and is capable of causing intravascular haemolysis and HDN. It is also associated with spontaneous miscarriage in early pregnancy.

Rh system

The Rh system, formerly known as the Rhesus system, was so named because the original antibody that was raised by injecting red cells of rhesus monkeys into rabbits and guinea pigs reacted with most human red cells. Although the original antibody (now called anti-LW) was subsequently shown to be different from anti-D, the Rh terminology has been retained for the human blood group system. The clinical importance of this system is that individuals who are D negative are often stimulated to make anti-D if transfused with D-positive blood or, in the case of pregnant women, if exposed to D-positive fetal red cells that have crossed the placenta.

Rh antigens and encoding genes. This is a very complex system. At its simplest, it is convenient to classify individuals as D positive or D negative, depending on the presence of the D antigen. This is largely a preventive measure, to avoid transfusing a D-negative recipient with the cells expressing the D antigen, which is the most immunogenic red cell antigen after A and B. At a more comprehensive level, it is convenient to consider the Rh system as a gene complex that gives rise to various combinations of three alternative antigens – C or c, D or d and E or e – as originally suggested by Fisher. The *d* gene was thought to be amorphic without any corresponding antigen on the red cell. Subsequently it was confirmed that the *RH* locus is on chromosome 1 and comprises two highly homologous, very closely linked genes, *RHD* and

RHCE, each with 10 exons. Each gene codes for a separate transmembrane protein with 417 residues and 12 putative transmembrane domains. The D and CE proteins differ at 35 residues. The *RHCE* gene has four main alleles; *CE, Ce, ce* and *cE*. Positions 103 and 226 on the CE polypeptide, situated in the external loops, determine the C/c (serine/proline) and E/e (proline/alanine) polymorphisms, respectively. This concept of D and CcEe genes linked closely and transmitted together is consistent with the Fisher nomenclature.

In Caucasian D-negative individuals, the *RHD* gene is deleted, whereas in black and other populations, single-point mutations, partial deletions or recombinations have been described. In individuals with a weak D antigen (D^u), there is a quantitative reduction in D antigen sites, believed to arise from an uncharacterised transcriptional defect. These individuals do not make anti-D antibodies following a D antigen challenge. Partial D individuals lack one or more epitopes of the D antigen, defined using panels of monoclonal reagents. D^{VI} is perhaps the most important partial D phenotype because such individuals not infrequently make anti-D. Partial D phenotypes arise from DNA exchanges between *RHD* and *RHCE* genes and from other rearrangements. RhD variants types 1–3 may be distinguished serologically, but red cell genotyping may better distinguish RhD variants of types 4 onwards. Comprehensive reviews of this system have been provided by Avent and Reid[11] and Daniels *et al.*[12]

The Rh haplotypes are named either by the component antigens (e.g. DCe, dce) or by a single shorthand symbol (e.g. R^1 = DCe, r = dce). Thus a person may inherit *DCe* (R^1) from one parent and *dce* (r) from the other and have the genotype *DCe/dce* (R^1r). The haplotypes in order of frequency and the corresponding shorthand notation are given in Table 21-7.[13] Although two other nomenclatures are also used to describe the Rh system, namely, Wiener's Rh-Hr terminology and Rosenfield's numeric notation, the CDE nomenclature, derived from Fisher's original theory, is recommended by a World Health Organisation Expert Committee[14] in the interest of simplicity and uniformity. The Rh antigens are defined by corresponding antisera, with the exception of 'anti-d', which does not exist. Consequently, the distinction between homozygous *DD* and the heterozygous *Dd* cannot be made by direct serological testing but may be resolved by informative family studies. It is still routine practice to predict the genotype from the phenotype on the basis of probability tables for the various Rh genotypes in the population (Table 21-7). However, in women with immune anti-D and a history of an infant affected by HDN, *RH* DNA typing is used in prenatal testing for the fetal D status to decide on the clinical management of the pregnancy, e.g. the need for monitoring for fetal anaemia using middle cerebral artery Doppler ultrasound. Suitable sources include amniotic fluid (amniocytes) and trophoblastic cells (chorionic villi) or after 15 weeks' gestation, maternal blood can be used because it contains fetal DNA.[15,16] In practice, multiplex polymerase chain reaction (PCR) is used, with more than two primer sets, to detect the different molecular bases for D-negative phenotypes in non-Caucasians. *RH* DNA typing also has applications in paternity testing and forensic medicine. There are racial differences in the distribution of Rh antigens, e.g. D negativity is more common in Caucasians (approximately 15%), whereas R^o (*Dce*) is found in approximately 48% of black Americans but is uncommon (approximately 2%) in Caucasians. The Rh antigens are present only on red cells and are a structural part of the cell membrane. Complete absence of Rh antigens (Rh-null phenotype) may be associated with a congenital haemolytic anaemia with spherocytes and stomatocytes in the blood film, increased osmotic fragility and increased cation transport. This phenotype arises either as a result of homozygosity for silent alleles at the *RH* locus (the amorph type) or more commonly by homozygosity for an autosomal suppressor gene (X), genetically independent of the *RH* locus (the regulator type). Rh antigens are well-developed before birth and can be demonstrated on the red cells of very early fetuses.

TABLE 21-7

APPROXIMATE FREQUENCIES OF COMMON HAPLOTYPES IN SELECTED POPULATIONS[13]

Haplotype	Approximate Frequencies	
	English	Nigerian
DCe R^1	0.421	0.060
dce r	0.389	0.203
DcE R^2	0.141	0.115
Dce R^0	0.026	0.591
dcE r''	0.012	0
dCe r'	0.010	0.031

Antibodies. Fisher's nomenclature is convenient when applied to Rh antibodies, and antibodies directed against all Rh antigens, except d, have been described: anti-D, anti-C, anti-c, anti-E and anti-e. Rh antigens are restricted to red cells and Rh antibodies result from previous alloimmunisation by previous pregnancy or transfusion, except for some naturally occurring forms of anti-E and anti-C^W. Immune Rh antibodies are predominantly IgG (IgG_1 and/or IgG_3), but may have an IgM component. They react optimally at 37 °C, they do not bind complement and their detection is often enhanced by the use of enzyme-treated red cells. Haemolysis, when it occurs, is therefore extravascular and predominantly in the spleen.

Anti-D is clinically the most important antibody; it may cause haemolytic transfusion reactions and was a common

cause of fetal death resulting from haemolytic disease of the newborn before the introduction of anti-D prophylaxis. Anti-D is accompanied by anti-C in 30% of cases and anti-E in 2% cases. Primary immunisation following a transfusion of D-positive cells becomes apparent within 2–5 months, but it may not be detectable following exposure to a small dose of D-positive cells in pregnancy. However, a second exposure to D-positive cells in a subsequent pregnancy will provoke a prompt anamnestic or secondary immune response.

Of the non-D Rh antibodies, anti-c is most commonly found and can also give rise to severe haemolytic disease of the fetus and newborn. Anti-E is less common, whereas anti-C is rare in the absence of anti-D.

Kell and Kx systems

Antigens and encoding genes. A total of 34 antigens have been identified (K1–K34), but three very closely linked sets of alleles are clinically important: *K* (KEL1) and *k* (KEL2); Kp^a (KEL3), Kp^b (KEL4) and Kp^c (KEL21); and Js^a (KEL6) and Js^b (KEL7). These antigens are encoded by alleles at the *KEL* locus on chromosome 7, but their production also depends on genes at the *KX* locus on the X chromosome. The K antigen is present in 9% of the English population. The Kp^b antigen has a high frequency in Caucasians; the Js^b antigen is universal in Caucasians and almost universal in black populations.

The Kell protein is a single-pass glycoprotein and is believed to be complexed by a disulphide bridge to the Kx protein, which is multipass with 10 putative transmembrane domains. It has considerable sequence homology to other neutral endopeptidases.

In the McLeod phenotype, red cells lack Kx and there is a marked decrease in all Kell antigens, an acanthocytic morphology and compensated haemolysis. The McLeod syndrome is X-linked with slow progression of cardiomyopathy, skeletal muscle wasting and neurological defects.

Kell antibodies. Immune anti-K is the most common antibody found outside the ABO and Rh systems. It is commonly IgG_1 and occasionally complement binding. Other immune antibodies directed against Kell antigens are less common. The presence of some of these antibodies, such as anti-k, anti-Kp^b and anti-Js^b, may cause considerable difficulties in the selection of antigen-negative units for transfusion.

Duffy system

Duffy antigens and encoding genes. The Duffy (Fy) locus is on chromosome 1 (*ACKR1* gene) and encodes a multipass protein with seven or nine putative transmembrane domains.

The locus has the following alleles: Fy^a, Fy^b, which code for the codominant Fy^a and Fy^b antigens, respectively; Fy^x, which is responsible for a weak Fy^b antigen; and *Fy*, which is responsible when homozygous for the Fy(a−b−) phenotype in black populations. This *Fy* gene is identical to the Fy^b gene in its structural region but has a mutation in the promoter region, resulting in the lack of production of red cell Duffy glycoprotein.

The Fy glycoprotein (also known as Duffy antigen receptor for chemokines, DARC) is a receptor for the CC and CXC classes of proinflammatory chemokines and is expressed on vascular endothelial cells and Purkinje cells in the cerebellum, but its precise role as a potential scavenger of excess chemokines is unknown. The Fy glycoprotein is also a receptor for *Plasmodium vivax*.

Duffy antibodies. Anti-Fy^a is much more common than anti-Fy^b and all other Duffy antibodies are rare apart from anti-Fy^3 (to both Fy^a and Fy^b), which occurs in some African/Afro-Caribbean patients, in whom Fy(a−b−) antigen status is common. They are predominantly IgG_1 and are sometimes complement binding.

Kidd (JK) system

Kidd antigens and encoding genes. Genes at the *HUT 11*(*JK*) locus on chromosome 18 (*SLC14A1* gene) encode a multipass protein, which carries the Kidd antigens and functions as the human erythroid urea transporter. The codominant alleles, Jk^a and Jk^b, represent a polymorphism of *SLC14A1*, which differs by a single amino acid substitution at position 280 (Asp/Asn).

The Jk(a−b−) phenotype is very rare and is caused by homozygous inheritance of the silent allele, *Jk*, at the *JK* (*SLC14A1*) locus or by inheritance of the dominant inhibitor gene *In* (*Jk*) unlinked to the *JK* locus. These Jk(a−b−) cells are resistant to lysis by solutions of urea and have a selective defect in urea transport.

Kidd antibodies. Anti-Jk^a is more common than anti-Jk^b; both are usually IgG. Kidd antibodies are usually complement binding, which is thought to be because most of them contain an IgG_3 fraction. Anti-Jk3 is produced by individuals of the rare Jk(a−b−) phenotype.

Kidd antibodies can be difficult to detect because they often show dosage (may only react with cells showing homozygous expressions of Jk^a or Jk^b), they fall to undetectable levels in plasma and they are often present in mixtures of alloantibodies. A previous history of antibodies is therefore important, to avoid a post-transfusion haemolytic reaction, due to an anamnestic response by an antibody that was below the level of detection before transfusion.

MNSs system

MNSs antigens and encoding genes. *GYPA* and *GYPB* are closely linked genes on chromosome 4 and encode glycophorin A (GPA) and glycophorin B (GPB), respectively. Both GPA and GPB are single-pass membrane sialoglycoproteins. *M* and *N* are alleles of *GYPA* (encoding the M and N antigens on GPA) and *S* and s are alleles of *GYPB*

(encoding the S and s antigens on GPB). Many rare variants have been described owing to gene deletions, mutations and segmental exchanges.

The U antigen is found on the red cells of Caucasians and 99% of black populations. U-negative individuals are, with rare exceptions, S−s− and lack GPB or have an altered form of GPB.

MNSs antibodies. Anti-M is a relatively common antibody that may be IgM or IgG. Rare examples are reactive at 37 °C when they can give rise to haemolytic transfusion reactions. Anti-M very rarely gives rise to HDN.

Anti-N is uncommon and of no clinical significance.

Anti-S and anti-s are usually IgG; both have, rarely, been implicated in haemolytic transfusion reactions and HDN.

Anti-U is a rare immune antibody, usually containing an IgG_1 component. It has been known to cause fatal haemolytic transfusion reactions and occasionally severe HDN.

Other blood group systems

Lutheran system. The antigens in the Lutheran system are not well-developed at birth and as a consequence there are no documented cases of clinically significant haemolytic disease of the newborn owing to Lutheran antibodies.

Anti-Lu^a is uncommon and rarely of clinical significance. Anti-Lu^b has caused extravascular haemolysis.

Yt (Cartwright) system. The antigens Yt^a and Yt^b are found on GPI-linked acetylcholinesterase. Some examples of anti-Yt^a have caused accelerated red cell destruction.

Colton system. The antigens in the Colton system, Co^a and Co^b, are carried on the water-transport protein, channel-forming integral protein (CHIP-1). Anti-Co^a and the rarer anti-Co^b are both sometimes clinically significant.

Dombrock system. The antigens in the Dombrock system include Do^a and Do^b and also include the high-incidence antigens Gy^a, Hy and Jo^a. Antibodies of this system are usually weak, but all should be considered as potentially significant.

Clinical significance of red cell alloantibodies

The significance of the alloantibodies described, with respect to the nature of the haemolytic transfusion reaction they produce, is provided in Table 21-8. The majority of haemolytic transfusion reactions, however, are the result of ABO incompatibility.[17]

Mollison *et al.*[18] analysed the significance of blood group antigens other than those of the ABO system and D by looking at the prevalence of transfusion-induced red cell alloantibodies, excluding anti-D, -CD and -DE (Table 21-9). Rh antibodies, mainly anti-c or anti-E, accounted for 53% of the total and anti-K and anti-Fy^a accounted for a further 38%, leaving only about 9% for all other specificities. A similar distribution of the different red cell antibodies was found in a smaller group of patients who experienced immediate haemolytic transfusion reactions (HTR). However, the figures for delayed HTR showed a striking increase in the relative frequency of Jk antibodies, which reflects the outlined characteristics of Jk antibodies.

TABLE 21-8

ANTIBODY SPECIFICITIES RELATED TO THE MECHANISM OF IMMUNE HAEMOLYTIC DESTRUCTION

Blood Group System	Intravascular Haemolysis	Extravascular Haemolysis
ABO,H	A, B, H	
Rh		All
Kell	K	K, k, Kp^a, Kp^b, Js^a, Js^b
Kidd	Jk^a	Jk^a, Jk^b, Jk^3
Duffy		Fy^a, Fy^b
MNS		M, S, s, U
Lutheran		Lu^b
Lewis	Le^a	
Cartwright		Yt^a
Colton		Co^a, Co^b
Dombrock		Do^a, Do^b

Haemolytic disease of the fetus and newborn has not been associated with antibodies directed against Lewis antigens and only very mild disease is produced by anti-Lu^a and anti-Lu^b. With these exceptions, all other IgG antibodies directed against antigens in the systems mentioned should be considered capable of causing haemolysis in this setting.

The significance of the many other blood group antigens not referred to in the text is summarised in Table 21-10. However, it should be noted that the antibodies listed are usually wholly or predominantly IgG and would be detectable in routine pretransfusion testing using the indirect antiglobulin test (IAT).

It is difficult to find suitable blood for transfusion to a patient whose plasma contains an antibody, such as anti-Vel, which has a specificity for a high-frequency antigen and which can cause severe haemolytic transfusion reactions. In addition to using blood from a frozen blood bank and calling up rare phenotype donors, autologous blood could be considered for planned elective procedures and if necessary, the compatibility of red cells from close relatives (particularly siblings) can be investigated, if no allogeneic blood is available. However, blood from first degree relatives would need to be irradiated, to prevent transfusion-associated graft-versus-host disease. Antibodies such as anti-Kn^a are commonly found and not clinically important, but their presence may cause delay in the provision of blood until their specificity has been determined.

TABLE 21-9

RELATIVE FREQUENCY OF IMMUNE RED CELL ALLOANTIBODIES*

Patient Group	No. Studied	Blood Group Alloantibodies (% of Total)				
		Rh†	K	Fy	Jk	Other
Transfused (some pregnant)	5228	53.1	28.1	10.2	4.0	4.7
Immediate HTR‡	142	42.2	30.3	18.3	8.5	0.7
Delayed HTR‡	82	34.2	14.6	15.9	32.9	2.4

HTR, haemolytic transfusion reaction.
*Excluding antibodies of ABO, Lewis, P systems and anti-M and anti-N.
† Excluding anti-D (or -CD or -DE); almost all were anti-c or anti-E.
‡ Haemolytic transfusion reaction.

TABLE 21-10

'MINOR' BLOOD GROUP ANTIGENS

Antigen	Antigen Frequency (%) Caucasians	Associated HTR	Associated HDN	Comments
Di^a	0	Yes	Yes	Part of DI system. Di^a
Di^b	100	Yes	Yes	More common in American Indians and North-Central and East Asians
Wr^a	<0.1	Yes	Yes	
Xg^a	65 (males); 88 (females)	Rarely	Rarely	Xg^a only antigen in system
Sc1	>99.9	No	No	3 antigens in SC system
Sc2	<0.1	No	Mild	
Ge2	100	Some	No	7 antigens in GE system
Ge3	>99.9	Some	No	
Cr^a	100	Some	No	10 antigens in CR system
Ch1	96	No	No	9 antigens in CH/RG systems, reside on chromosome 4
Rg1	98	No	No	Reside on C4
Kn^a	98	No	No	Belong to KN system of 5 antigens
McC^a	98	No	No	
Yk^a	92	No	No	
In^a	0.1	Yes	No	In^a has incidence of 4% in Asian Indians
In^b	99	Yes	No	Asian Indians
LW^a	100	Some	Mild	–
JMH	>99.9	No	No	One of 901 series* of high-incidence antigens
Vel	>99.9	Yes	No	One of 901 series*; complement binding
Bg^a	approx. 15	No	No	Corresponds to HLA-B7, detectable on red cells

HDN, haemolytic disease of the newborn; HTR, haemolytic transfusion reaction.
*901 series refers to 11 red cell antigens with a frequency of >99%, based on ISBT terminology.[1]

Mechanisms of immune destruction of red cells

Immune-mediated haemolysis of red cells depends on the following:[19]

1. The immunoglobulin class of the antibody (for all practical purposes, antibodies directed against red cell antigens are either IgM or IgG or both).
2. The ability of the antibody to bind complement.
3. Interaction with the reticuloendothelial system (mononuclear phagocytic system). The most important phagocyte participating in immune haemolysis is the macrophage, predominantly in the spleen.
4. The mechanism of immune haemolysis also determines the site of haemolysis:
   a. *Intravascular haemolysis* owing to sequential binding of complement components (C1 to C9) and the formation of the membrane attack complex (MAC; $C5b678(9)_n$). This is characteristic of IgM

antibodies, but some IgG antibodies can also act as haemolysins. Red cells are usually destroyed by intravascular complement lysis in ABO incompatible transfusion reactions (see p. 488). Most other alloimmune red cell destruction is extravascular and mediated by the mononuclear-phagocytic system.
Red cell autoantibodies may also cause intravascular lysis, especially the IgG autoantibody of paroxysmal cold haemoglobinuria (PCH) (see p. 257) and some autoantibodies found in cold haemagglutinin disease (CHAD) (see p. 257). Complement-mediated intravascular lysis can also occur in drug-induced immune haemolysis (see p. 268).

b. *Extravascular haemolysis* by the mononuclear phagocytic system is characteristic of IgG antibodies and occurs predominantly in the spleen. This is caused by non-complement-binding IgG antibodies or those that bind sublytic amounts of complement. Macrophages have Fcγ receptors for cell-bound IgG and sensitised red cells may be wholly phagocytosed or lose part of the membrane and return to the circulation as microspherocytes. Spherocytes are less deformable and more readily trapped in the spleen than normal red cells; this shortens their lifespan. In addition to Fc receptor-mediated phagocytosis, antibody-dependent cell-mediated cytotoxicity (ADCC) may also contribute to cell damage during the close contact with splenic macrophages. Red cells are destroyed external to the monocyte membrane by lysosomal enzymes secreted by the monocyte.[20]

5. Complement components may enhance red cell destruction. Complement activation by some IgM and most IgG antibodies may be incomplete and the red cell then escapes intravascular lysis. The activation of complement stops at the C3 stage and, in these circumstances, complement can be detected on the red cell by the antiglobulin test using appropriate anticomplement reagents. The first activation product of C3 is membrane-bound C3b, which is constantly being broken down to C3bi. Red cells with these components on their surface adhere to phagocytes (monocytes, macrophages and neutrophils), which have complement receptors, CR1 (CD35) and CR3 (CD 11b/CD 18). These sensitised cells are rapidly sequestered in the liver because of its bulk of phagocytic cells (Kupffer cells) and high blood flow, but no engulfment occurs. When C3bi is cleaved, leaving only C3dg on the cell surface, the cells tagged with 'inactive' C3dg return to the circulation, as in chronic cold haemagglutinin disease. However, when IgG is also present on the cell surface, C3b enhances phagocytosis and under these circumstances both liver and spleen are important sites of extravascular haemolysis. Hence, C3b and C3bi augment macrophage-mediated clearance of IgG-coated cells and antibodies binding sublytic amounts of complement (e.g. Duffy and Kidd antibodies) often cause more rapid destruction and more marked symptoms than noncomplement binding antibodies (e.g. Rh antibodies).

Macrophage activity is an important component of cell destruction and further study of cellular interactions at this stage of immune haemolysis may provide an explanation for the differing severity of haemolysis in patients with apparently similar antibodies. *In vitro* macrophage (monocyte) assays have been used sometimes to supplement conventional serological techniques to assess this aspect of immune haemolysis.[21]

Factors that may affect the interaction between sensitised cells and macrophages include the following:

1. *IgG subclass.* IgG_1 and IgG_3 antibodies have a higher binding affinity for mononuclear Fcγ receptors than IgG_2 and IgG_4 antibodies.
2. *Antigen density.* This affects the number of antibody molecules bound to the cell surface.
3. *Fluid-phase IgG.* Serum IgG concentration is a determinant of Fc-dependent mononuclear-phagocytic function. Normal levels of IgG block the adherence of sensitised red cells to monocyte Fc receptors (particularly FcγR1) *in vitro.* Haemoconcentration within the splenic sinusoids is probably a major factor in minimising this effect *in vivo,* which may explain why the spleen is about 100 times more efficient at removing IgG-sensitised cells than the liver despite the greater macrophage mass and higher blood flow of the latter organ.
4. The initial effect of high-dose intravenous IgG is to cause blockade of macrophage FcγR. This reduces the immune clearance of antibody-coated cells and has particular application in the management of autoimmune thrombocytopenia and post-transfusion purpura.
5. *Regulation of macrophage activity.* Cytokines are known to be important in the upregulation of macrophage receptors. Interferon gamma enhances macrophage phagocytic activity by increasing the expression of FcγRI *in vitro* and *in vivo* and also activates FcγII without increasing the number of these receptors.[22]

Interleukin-6 also enhances FcγRII activation and increased activity of the CR1 receptor occurs through the action of T-cell cytokines and through chemotactic agents released in the inflammatory response.[23] The increased levels of proinflammatory cytokines and other biological mediators and their effects on the activity of the monocyte phagocytic system have been monitored in patients with systemic inflammatory response syndrome.[24] It is therefore possible that release of cytokines during viral and bacterial infections could, at least in part, trigger some episodes of autoimmune cell destruction.

The rate of immune destruction is therefore determined by antigen and antibody characteristics and the level of activation of the monocyte phagocytic system.

Antigen–antibody reactions

The red cell is a convenient marker for serological reactions. Agglutination or lysis (owing to complement action) is a visible indication (endpoint) of an antigen–antibody reaction. The reaction occurs in two stages: in the first stage the antibody binds to the red cell antigen (sensitisation) and the second stage involves agglutination (or lysis) of the sensitised cells.

The *first stage* (i.e. association of antibody with antigen – sensitisation) is reversible and the strength of binding (equilibrium constant) depends on the 'exactness of fit' between antigen and antibody. This is influenced by the following:

1. *Temperature.* Cold antibodies (usually IgM) generally bind best to the red cell at a low temperature (e.g. 4 °C), whereas warm antibodies (usually IgG) bind most efficiently at body temperature (i.e. 37 °C).
2. *pH.* There is relatively little change in antibody binding over the pH range 5.5–8.5, but to ensure comparable results, it is preferable to buffer the saline in which serum or cells are diluted to a fixed pH, usually 7.0. Some antibody elution techniques depend on altering the pH to <4 or to >10.
3. *Ionic strength of the medium.* Low ionic strength increases the rate of antibody binding. This is the basis of antibody detection tests using low ionic strength saline (LISS).

The *second stage* depends on various laboratory manipulations to promote agglutination or lysis of sensitised cells. The cell surface is negatively charged (mainly owing to sialic acid residues), which keeps individual cells apart; the minimum distance between red cells suspended in saline is about 18 nm. Agglutination is brought about by antibody crosslinking between cells. The span between antigen-binding sites on IgM molecules (30 nm) is sufficient to allow IgM antibodies to bridge between saline-suspended red cells (after settling) and so cause agglutination. IgG molecules have a shorter span (15 nm) and are usually unable to agglutinate sensitised red cells suspended in saline; notwithstanding this, heavy IgG sensitisation owing to high-antigen density lowers intercellular repulsive forces and is able to promote agglutination in saline (e.g. IgG anti-A, anti-B). The agglutination of red cells coated by either IgM or IgG antibodies is enhanced by centrifugation. However, it is standard procedure to promote agglutination of IgG-sensitised red cells by the following:

1. Reducing intercellular distance by pretreatment of red cells with protease enzymes (e.g. papain or bromelin), which reduce the surface charge of red cells (see p. 451)
2. Adding polymers (e.g. albumin), although the mechanism by which albumin or other water-soluble polymers enhance agglutination is uncertain
3. Bridging between sensitised cells with an antiglobulin reagent in the antiglobulin test (see p. 453).

Some complement-binding antibodies (especially IgM) can cause lysis *in vitro* (without noticeable agglutination), which can be enhanced by the addition of fresh serum as a source of complement. However, complement activation may only proceed to the C3 stage; in these circumstances cell-bound C3 can be detected by the antiglobulin test using an appropriate anticomplement reagent (see p. 453).

General points of serological technique

Serum versus plasma

Serum is preferred to plasma for the detection of red cell alloantibodies. Nevertheless, plasma is being used increasingly for convenience in microplate technology and in automated systems.

When plasma is used, complement is inactivated by the ethylenediaminetetra-acetic acid (EDTA) anticoagulant. This is relevant for the detection of some complement-binding antibodies (e.g. of Kidd specificity) that may be missed or give only weak reactions with anti-IgG in the routine antiglobulin test but can be readily detected by anticomplement (see p. 453). It is therefore essential, before using plasma, to optimise the sensitivity of techniques for detecting weak IgG antibodies and to validate the procedure (see p. 453). For example, in antibody screening, increased sensitivity can be achieved by using panel cells with homozygous expression of selected antigens (see p. 480).

Red cell suspensions

Normal ionic strength saline. A 2–3% suspension of washed red cells in phosphate buffered saline (PBS), pH 7.0, is generally recommended. Cells suspended in normal ionic strength saline (NISS) are routinely used for antibody titrations, but their use in routine pretransfusion testing has declined over the last decade as observations from external quality assessment exercises have demonstrated that laboratories using NISS have a significantly lower detection rate of antibodies than those using other technologies.[25]

Low ionic strength saline. It is known that the rate of association of antibodies with red cell antigens is enhanced by lowering the ionic strength of the medium in which the reactions take place. Hence, a major advantage of LISS is that the incubation period in the IAT (see p. 480) can be shortened while maintaining or increasing sensitivity to the majority of red cell antibodies. The LISS solution can be made up in the laboratory (see p. 562) or purchased commercially.

There was historical reluctance to use low ionic strength media in routine laboratory work for two reasons: first, nonspecific agglutination may occur when NaCl concentrations <2 g/l (0.03 mol/l) are used and second, complement components are bound to the red cells at low ionic strengths.

To avoid false-positive results, the following rules should be followed:

a. Red cells resuspended in LISS should be incubated with serum or plasma in equal volumes: 2 volumes of cells to 2 volumes of serum are recommended to ensure the optimal molarity in the test of the order of 0.09 mol. Doubling the serum to cell ratio (by halving the cell concentration from 3% to 1.5%) will enhance the detection of some antibodies (e.g. anti-K) that might otherwise be missed.[26]
b. The red cells should be washed in saline twice and then once in LISS before suspending in LISS at 1.5–2% cell suspension.
c. The working solution of LISS should be freshly made and kept at room temperature.
d. Centrifugation force and time should be optimal to give maximum sensitivity with freedom from false-positive or false-negative reactions (see p. 454).

False-positive reactions may still infrequently occur with some sera/plasmas. If plasma is used, subsequent serological work may be performed using NISS; if serum is used, anti-IgG should replace the polyspecific antiglobulin reagent.

Reagent red cells

Red cells of selected phenotypes are required for ABO and RhD grouping, Rh phenotyping and antibody screening and identification (see Chapter 20). Such cells are available commercially or from blood transfusion centres.

Use of enzyme-treated cells

Enzyme-treated red cells are useful reagents in the detection and investigation of autoantibodies and alloantibodies. Papain and bromelin are currently used for this purpose. Enzyme treatment is known to increase the avidity of both IgM and IgG antibodies. Some red cell antigens, however, may be inactivated by enzyme treatment (e.g. M, N, S, Fy^b).

The most sensitive techniques are those using washed enzyme-pretreated red cells (two-stage), which should match the performance of the spin-tube LISS antiglobulin test (see p. 454). One-stage mixtures and papain inhibitor techniques are relatively insensitive and are not recommended. An ISBT/International Council for Standardisation in Haematology (ICSH) protease enzyme standard and an agreed method for its use are available.

Methods for the preparation of papain solution (Low's method and the two-stage method) and for preparation of bromelin solution have been described.[27–29]

Agglutination of red cells by antibody: a basic method

Agglutination tests are usually carried out in tubes, microtitre plates or using column agglutination (gel) technology, centrifugation or sedimentation. Rarely slide tests are used for emergency ABO and D grouping (see p. 475). For microplate tests, see p. 476.

Tube tests. Add 1 volume of a 2% red cell suspension to 2–3 volumes of plasma in a disposable plastic tube. Mix well and leave undisturbed for the appropriate time (see below).

Tubes. For agglutination tests, use medium-sized (75 × 10 or 12 mm) disposable plastic tubes. Similar tubes should be used for lysis tests when it is essential to have a relatively deep layer of serum to look through, if small amounts of lysis are to be detected. The level of the fluid must rise much higher than the concave bottom of the tubes.

Glass tubes should always be used if the contents are to be heated to 50 °C or higher or if organic solvents are being used. Glass tubes, however, are difficult to clean satisfactorily, particularly small-bore tubes and cleaning methods such as those given on p. 564 should be followed carefully.

Temperature and time of exposure of red cells to antibody. In blood group serology, tube tests are generally done at 37 °C, room temperature or both. There is some advantage in using a 20 °C waterbath rather than relying on 'room temperature', which in different countries and seasons may vary from 15 °C (or less) to 30 °C (or more).

Sedimentation tube tests are usually read after 1–2 h have elapsed. Strong agglutination will, however, be obvious much sooner than this. In spin-tube tests, agglutination can be read after only 5–10 min incubation if the cell–plasma mixture is centrifuged.

Slide tests. These are used rarely in a few parts of the world. Because of evaporation, slide tests must be read within about 5 min. Reagents that produce strong agglutination within 1–2 min are normally used for rapid ABO and RhD grouping. Because the results are read macroscopically, strong cell suspensions should be used (35–45% cells in their own serum or plasma).

Reading results of tube tests. Only the strongest complete (C) grade of agglutination seems to be able to withstand a shake procedure without some degree of disruption, which may downgrade the strength of reaction. The British Committee for Standards in Haematology (BCSH) Blood Transfusion Task Force has therefore recommended the following reading procedure.[30]

Microscopic reading. It is essential that a careful and standardised technique be followed. Lift the tube carefully from its rack without disturbing the button of sedimented cells. Holding the tube vertically, introduce a straight-tipped Pasteur pipette. Carefully draw up a column of supernatant about 1 cm in length and then, without introducing an air bubble, draw up a 1–2 mm column of red cells by placing the tip of the pipette in the button of red cells. Gently expel the supernatant and cells onto a slide

over an area of about 2 × 1 cm. It is important not to overload the suspension with cells and the method described earlier achieves this.

A scheme of scoring the results is given in Table 21-11.

Macroscopic reading. A gentle agitation tip-and-roll 'macroscopic' method is recommended. It is possible to read agglutination tests macroscopically with the aid of a hand reading glass or concave mirror, but it is then difficult to distinguish reactions weaker than + (microscopic reading) from the normal slight granular appearance of unagglutinated red cells in suspension. Macroscopic reading thus gives lower titration values than does microscopic reading, but the former is recommended. Follow the system of scoring in Table 21-11.

TABLE 21-11

SCORING OF RESULTS IN RED CELL AGGLUTINATION TESTS

Symbol	Agglutination Score*	Description
4+ or C (complete)	12	Cell button remains in one clump, macroscopically visible
3+	10	Cell button dislodges into several large clumps, macroscopically visible
2+	8	Cell button dislodges into many small clumps, macroscopically visible
1+	5	Cell button dislodges into finely granular clumps, macroscopically just visible
(+) or w (weak)	3	Cell button dislodges into fine granules, only visible microscopically†
-	0	Negative result – all cells free and evenly distributed

*Titration scores are the summation of the agglutination scores at each dilution.

† May be further classified depending on the number of cells in the clumps (e.g. clumps of 12–20 cells [score 3]; 8–10 cells [score 2]; 4–6 cells [score 1]). This is the minimum agglutination that should be considered positive.

A good idea of the presence or absence of agglutination can often be obtained by inspection of the deposit of sedimented cells: a perfectly smooth round button suggests no agglutination, whereas agglutination is shown by varying degrees of irregularity, 'graininess', or dispersion of the deposit (Fig. 21-2).

Demonstration of lysis

Many blood-group antibodies lyse red cells under suitable conditions in the presence of complement. This is particularly true of anti-A and anti-B, anti-P, anti-Le^a and Le^b, anti-PP_1P^k (anti-Tj^a) and certain autoantibodies (see p. 266). If it is necessary to add fresh complement, this should be mixed with the serum being tested before the addition of red cells. Otherwise, agglutination occurs and could block complement access. Lysis should be looked for at the end of the incubation period before the tubes are centrifuged, if the cells have sedimented sufficiently; lysis may be scored semiquantitatively after centrifuging the suspensions and comparing the colour of the supernatant with that of the control.

If the occurrence of lysis is of interest, then the final volume of the cell–serum suspension has to be greater than is required for the reading of agglutination. Tubes (75 × 10 or 12 mm) should be used and the level of the cell–serum suspension must rise much higher than the concave bottom of the tubes.

In testing for lytic activity, a high concentration of complement may be required. Therefore, in contrast to tests for agglutination, it is advantageous to use a stronger red cell suspension (*c.* 5%).

Lysis tests are usually carried out at 37 °C, but with cold antibodies a lower temperature (e.g. 20 °C or 30 °C) would be appropriate, depending on the upper thermal range of activity of the antibody or, in the case of the Donath–Landsteiner antibody, 0 °C followed by 37 °C (see p. 267).

With certain antibodies the pH of the cell–serum suspension affects the occurrence of lysis. In these, optimal pH is 6.5–6.8.

Controls. It is necessary to be sure that any lysis observed is not artefactual (i.e. that lysis is brought about by the serum under test and not by the serum added as a source of complement) and that the added complement

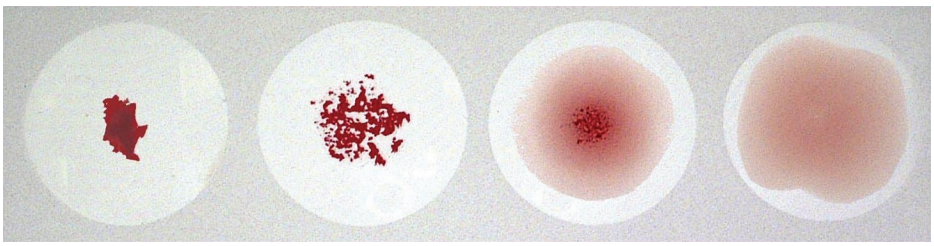

FIGURE 21-2 Macroscopic appearances of agglutination in round-bottom tubes or hollow tiles. Agglutination is shown by various degrees of 'graininess'; in the absence of agglutination, the sedimented cells appear as a smooth round button, as on the extreme right.

is potent. A complement control (no test serum) is thus necessary, as is a control using a serum known to contain a lytic antibody.

In lysis tests, great care should be taken to deliver the cell suspension directly into the serum. If the cell suspension comes into contact with the side of the tube and starts to dry, this in itself will lead to lysis.

Antiglobulin test

The antiglobulin test (Coombs test) was introduced by Coombs and colleagues in 1945[31] as a method for detecting 'incomplete' Rh antibodies (i.e. IgG antibodies capable of sensitising red cells but incapable of causing agglutination of the same cells suspended in saline), as opposed to 'complete' IgM antibodies, which do agglutinate saline-suspended red cells.

Direct and indirect antiglobulin tests can be carried out. In the *direct* antiglobulin test (DAT), the patient's cells, after careful washing, are tested for sensitisation that has occurred *in vivo;* in the *indirect* antiglobulin test (IAT), normal red cells are incubated with a serum suspected of containing an antibody and subsequently tested, after washing, for *in vitro*-bound antibody.

The antiglobulin test is probably the most important test in the serologist's repertoire. The DAT is used to demonstrate *in vivo* attachment of antibodies to red cells, as in autoimmune haemolytic anaemia (see p. 255), alloimmune HDN (see p. 491) and alloimmune haemolysis following an incompatible transfusion (see p. 488). The IAT has wide application in blood transfusion serology, including antibody screening and identification and crossmatching.

Antiglobulin reagents

Polyspecific (broad-spectrum) reagents. The majority of red cell antibodies are non-complement-binding IgG; anti-IgG is therefore an essential component of any polyspecific reagent. Anti-IgA is not required because IgG antibodies of the same specificity almost always occur in the presence of IgA antibodies. Anti-IgM is also not required because clinically significant IgM alloantibodies that do not cause agglutination in saline are much more easily detected by the complement they bind.

Anticomplement has also traditionally been considered essential – namely, anti-C3c and anti-C3d. However, if plasma is used, only anti-IgG is necessary because EDTA prevents complement activation. In addition, it seems that most, if not all, antibodies detected by the C3-anti-C3 reaction in NISS can be detected with anti-IgG in polybrene, polyethylene glycol (PEG) and LISS. Laboratories using techniques other than NISS have adopted the use of anti-IgG alone, supported by changes to guidelines from the AABB (previously American Association of Blood Banks) in 1990 and from the BCSH in 1996. Nevertheless, the BCSH guidelines stress the importance of having screening cells with homozygous expression of Jk^a before deciding to use anti-IgG rather than a polyspecific antiglobulin reagent. Anti-C3 will certainly be required for DATs for the diagnosis of autoimmune haemolytic anaemia.

Monospecific reagents. Monospecific reagents can be prepared against the heavy chains of IgG, IgM and IgA and are referred to as anti-γ, anti-μ and anti-α; antibodies against IgG subclasses are also available. Specific antibodies against the complement components C4 and C3 and C3 breakdown products can be prepared as mentioned earlier.

The main clinical application of these monospecific reagents is to define the immunochemical characteristics of antibodies. This is relevant to the mechanisms of *in vivo* cell destruction and, in the case of IgG, the subclasses have different biological properties (see p. 449).

Quality control of antiglobulin reagents

This is not commonly done in UK hospital laboratories, as they use commercial antiglobulin reagents. The quality control of antiglobulin reagents must always be carried out using the exact technique by which they are to be used. All reagents should be used according to the manufacturer's instructions, unless appropriately standardised for other methods.

An ISBT/ICSH freeze-dried reference reagent is available for evaluating either polyspecific antihuman globulin reagents or those containing their separate monospecific components.[32] The validation of a new antiglobulin reagent should assess the following qualities of the reagent:

1. *Specificity.* The reagent should only agglutinate red cells sensitised with antibodies and/or coated with significant levels of complement components
2. *Potency of anti-IgG by serological titration*
3. *Specificity and potency of anticomplement antibodies.* A polyspecific reagent should contain anti-C3c and anti-C3d at controlled levels to avoid false-positive reactions or a suitable potent monoclonal anti-C3d (e.g. BRIC-8). It should contain little or no anti-C4. The assessment of these qualities requires red cells specifically coated with C3b, C3bi, C3d and C4. Details of the procedures recommended for the preparation of such cells have been published by an ISBT/ICSH Working Party.[33]

It is appreciated that some hospital blood banks worldwide will be unable to evaluate an antiglobulin reagent as comprehensively as outlined earlier. They should, however, carry out the following minimum assessment of all new antiglobulin reagents:

1. Test the antiglobulin reagent for freedom from false-positive results by simulated crossmatch tests:
   a. Test for excess anti-C3d by incubating fresh serum at 37 °C by NISS or LISS tests with 6 ABO-compatible

cells from CPD-A1 donor unit segments (10–30 days old). This is a critical test for false-positive results owing to C3d uptake by stored red blood cells, which is further augmented by incubation with fresh serum.

b. Tests for contaminating red cell antibodies (against washed A_1, B and O cells) must be negative.

Only proceed further if the antiglobulin reagent passes the previously listed tests.

1. Compare the antiglobulin reagent with the current reagent using a selection of weak antibodies. These antibodies may be selected from those encountered in routine work or can be obtained from a transfusion centre or reference laboratory. Store such antibodies in small volumes at 4 °C for repeated tests.
2. Dilute a weak IgG anti-D (0.8 iu/ml), as used for routine antiglobulin test controls, from undiluted (neat) to 1 in 16 and sensitise R_1r red cells with each dilution of anti-D. These sensitised cells (washed four times) should then be tested with neat to 1 in 8 dilutions of the antiglobulin reagents. The antiglobulin reagent should not show prozones by immediate spin tests using 2 volumes of antiglobulin per test. The potency of the test antiglobulin should at least match the current antiglobulin reagent.

The ISBT/ICSH antiglobulin reference reagent can be used to calibrate an 'in-house' antiglobulin reagent for use as a routine standard.

The quality control of Ig class- and subclass-specific antiglobulin reagents, although following the previously listed general principles, is more complex. Details of the appropriate techniques are beyond the scope of this chapter; the reader should consult the review by Engelfriet *et al*.[34]

Recommended antiglobulin test procedure

A spin-tube technique is recommended for the routine antiglobulin test; the procedure described here is based on BCSH *Guidelines for Compatibility Testing in Hospital Blood Banks*.[30,35] Reliable performance depends on the correct procedure at each stage of the test and appropriate quality-control measures.

The test is preferably carried out in glass tubes (75 × 10 or 12 mm), as plastic tubes may adsorb IgG, which could neutralise anti-IgG of the antiglobulin reagent.

1. *Sensitise red cells* (not relevant to the direct test) by using the following serum:cell ratios:
   a. For NISS, use at least 2 volumes of serum (preferably 4) and 1 volume of a 3% suspension of red cells washed (3 times) and suspended in PBS or 0.15 mol/l NaCl (see p. 562).
   b. For LISS, use 2 volumes of serum and 2 volumes of a 1.5% suspension of red cells washed twice in PBS or 0.15 mol/l NaCl and washed once in LISS and then suspended in LISS (see p. 562).
   c. For commercial low ionic-strength additive solutions, the manufacturer's instructions must be followed.
   d. Because the volume of 'a drop' varies according to the type of pipette or dropper bottle, a measured or known drop volume should be used to ensure that appropriate serum:cell ratios are maintained.
   e. Mix the reactants by shaking, then incubate at 37 °C, preferably in a waterbath, for a minimum period of 15 min for LISS tests and 45 min for NISS tests.
2. *Wash the test cells* four times with a minimum of 3 ml of saline per wash. Vigorous injection of saline is necessary to resuspend the cells and achieve adequate mixing. As much of the supernatant as possible should be removed after each wash to achieve maximum dilution of residual serum.
3. *Add 2 volumes of a suitable antiglobulin reagent* to each test tube and centrifuge without delay after thorough mixing. The combinations of centrifugal force (RCF) and time for spin-tube tests are as follows:

RCF (*g*)	100	200–220	500	1000
Time (s)	60	25–30	15	8–10

4. *Read agglutination* as previously described (see p. 451).
5. *Quality control of the test* should be monitored by the following:
   a. An IgG anti-D diluted to give 1+ or 2+ reactions with RhD-positive (R_1r) cells as a *positive control.*
   b. An inert group AB serum with the same RhD-positive cells as a *negative control;* this is not essential because most tests are negative.
   c. The addition of sensitised cells to all negative tests. This is widely used to detect neutralisation of the antiglobulin reagent owing to incomplete removal of serum by the wash step. The value of this test as a control depends on the strength of reaction of the sensitised cells. Appropriate control cells sensitised with IgG anti-D should give a 3+ reaction when tested directly with the antiglobulin reagent and should still be positive (if the reagent is potent) when added to negative tests but downgraded (1+ or 2+) owing to the 'pooled-cell' effect of the non-sensitised cells. The reaction will, of course, be negative if the antiglobulin has been neutralised by residual serum.
   d. The production of satisfactory antiglobulin control cells can be achieved by limiting the level of anti-D sensitisation to that which gives a negative test in the presence of 1 in 1000 parts serum in saline.[30]

e. The suitability of the antiglobulin control cells can be checked as follows:
   i. Prepare two tubes (10×75 mm) with 1 volume of 3% unsensitised cells; wash four times.
   ii. Add 2 volumes of antiglobulin to each of the tubes, mix well, spin and read the tubes to confirm the tests are negative.
   iii. Add 1 volume of 1 in 1000 serum in saline to one tube and 1 volume of saline as a control to the other tube. Mix and incubate for 1 min at room temperature.
   iv. Add 1 volume of control cells to each tube, mix, spin and read the tests.

The test containing 1 in 1000 serum in saline should be negative and the control tube should give at least 2+ reaction. A negative reaction with the control tube suggests a washing deficiency and demands corrective action. If an automated cell-washing centrifuge is used, the washing efficiency should be checked.[30,36]

Alternative technology for antibody detection by the antiglobulin test

Alternative techniques, now commonly in use, have a simpler reading phase than the manually read spin-tube IAT. These are of two main types: solid-phase red cell adherence methods[37] and column agglutination techniques. A well-performed spin-tube IAT, as described earlier, is the standard against which any new system should be compared.

Solid-phase red cell adherence methods involve systems in which known red cells, which may also be sensitised, are immobilised on a solid matrix. In the method referenced, ABO and D typing plates are prepared by immobilising A_1-, B- and D-positive red cells to chemically modified U-bottom strips. The cells are then exposed to the appropriate antibody and the sensitised red cell monolayers are then dried. The unknown test cells are added and the plates are centrifuged after incubation. In a positive reaction, the cells spread over the surface of the well because they have adhered to the bound antibody. In a negative reaction, there is no adherence and the cells form a small button in the centre of the well when the plates are centrifuged.

For reverse typing and antibody screening, A_1, B and O screening cell monolayers are prepared and dried. The test serum is added and, if antibodies to any of the immobilised antigens are present, they attach to the monolayer. The tests are read by the addition of A_1B cells that are coated with anti-IgG.

Solid-phase methods are highly suited for automated reading by passing a light beam through the well at a point at which it will not be interrupted by the button of cells in a negative test but will be dispersed by the layer of red cells spread across the well in a positive test.

With *column agglutination techniques* very small volumes of serum and cells are mixed in a reservoir at the top of a narrow column that contains either a Dextran gel (DiaMed, www.diamed.com) or glass beads (BioVue, Ortho Clinical Diagnostics, www.orthoclinical.com).[38] The columns with the integral reservoirs are supplied in card or cassette form, respectively. After a suitable incubation period, the cards/cassettes containing the tests are spun in a centrifuge in which the axis of the column is strictly in line with the centrifugal force. The red cells, but not the medium in which they are suspended, enter the column. Agglutinated red cells are trapped at the top of the column and unagglutinated red cells form a pellet at the bottom of the column (see Fig. 22-4, see p. 477).

The columns can also contain an antiglobulin reagent for performing DATs or IATs. Because, during centrifugation, the red cells but not the suspending fluid pass through the gel, the red cells do not have to be washed before coming into contact with the antiglobulin reagent. The columns can also include an antibody (e.g. anti-D) for cell typing. Antigen-positive cells are agglutinated and trapped in the upper portion of the column.

The advantages of column agglutination technology are as follows:

1. Ease of use and reading and can theoretically be performed by relatively unskilled staff.
2. There is less chance of aerosol contamination from infected samples because there is no cell washing before an IAT.
3. The cards can be kept for up to 24 h, enabling the results to be reviewed by experienced staff.
4. Ease of automation and positive sample identification.

However, the technology is relatively expensive and its performance does not always compare favourably with the standard LISS-IAT in experienced hands.

Assessment of individual worker performance

It is recommended that all staff (including 'on-call' staff who do not routinely work in the blood bank) should be assessed at regular intervals. A procedure based on 'blind' replicate antiglobulin tests may be used for this purpose.[30,39]

The procedure is as follows:

1. A low-titre (8–16) IgG anti-D, as used for the control of the antiglobulin test, should be titrated against OR_1r or pooled O RhD-positive cells to find the dilution of anti-D that gives 1+ or 2+ sensitised cells (most workers use around 0.3 iu/ml). A standard BCSH-NIBSC anti-D reference reagent[40] is available for this purpose (available from National Institute for Biological Standards and Controls, NIBSC, www.nibsc.org).
2. A batch of sensitised cells is prepared (e.g. by incubating 16 ml of the selected anti-D dilution with 8 ml of 3% washed OR_1 red cells at 37 °C for 45 min).
3. Twelve tubes are labelled for blind tests by another person. One volume of 3% 1+ or 2+ sensitised cells and 2 volumes

of group AB inert serum (to simulate the volumes of serum used in routine tests) are placed in 9 random tubes and then 1 volume of unsensitised cells + 2 volumes of group-AB inert serum are placed in the remaining tubes. The positions of the various tests are recorded.
4. The cells are washed thoroughly four times, antiglobulin is added and the tubes are spun and read.
5. The number of false-negative (and false-positive) results are recorded for each worker and analysed in relation to reading and/or washing technique. It is advisable to give immediate tuition to any workers with washing or reading test faults, followed by further blind replicate trials to demonstrate improvement in procedure and to restore confidence.

Titration of antibodies

A method for preparing primary dilutions of serum and subsequent antibody titration is illustrated in Figure 21-3.

External quality assessment exercises have demonstrated the wide range of titres reported for a single sample, reflecting the differing sensitivities of technologies in use and have also highlighted the lack of reproducibility.[41] The following points are taken from an addendum to the BCSH guidelines.[42]

Preparation of serial dilutions of patient's or other sera

1. All dilutions and titrations should be made using calibrated pipettes and a separate tip for each step.
2. The diluent should be buffered saline, pH 7.0, for agglutination tests; for lysis tests undiluted ABO-compatible fresh normal human serum should be acidified so that the pH of the cell–serum mixture is *c.* 6.8. The normal serum serves as a source of complement.
3. Tube sizes and assay volumes should be chosen to permit thorough mixing of the dilutions.
4. When assaying high-titre samples, an initial dilution should be made to reduce the number of doubling serial transfers to less than 10. A sufficient range of dilutions should be chosen to ensure that two negative results can be observed.
5. The endpoint should be macroscopic and well-defined. The use of visual comparator aids should be considered where possible.
6. Wherever possible, each sample should be tested in parallel with the previous sample.
7. Titrations should be repeated if there is more than a one-tube difference in the titres obtained from sequential samples.

Addition of red cell suspensions to dilutions of serum. It is conventional to add 1 volume of red cell suspension to 1 volume of serum or serum dilution. This means that each antibody dilution, and hence the 'final' titre, will be twice that of the original serum dilution. Because red cell antigen expression varies with the source and age of the sample, wherever possible, the same cell sample should be used.

ABO titration for renal transplant recipients. ABO incompatible (ABOi) renal transplants are assessed according to risk based on the relevant anti-A and/or anti-B titres, but the methodology for titre measurement has been variable both within countries and internationally. This has made comparisons of titre thresholds for transplant and outcome data of transplant programmes, difficult to assess. Variation in titre results could potentially lead to some patients (with erroneously low titres) being transplanted inappropriately, while others with erroneously high titres

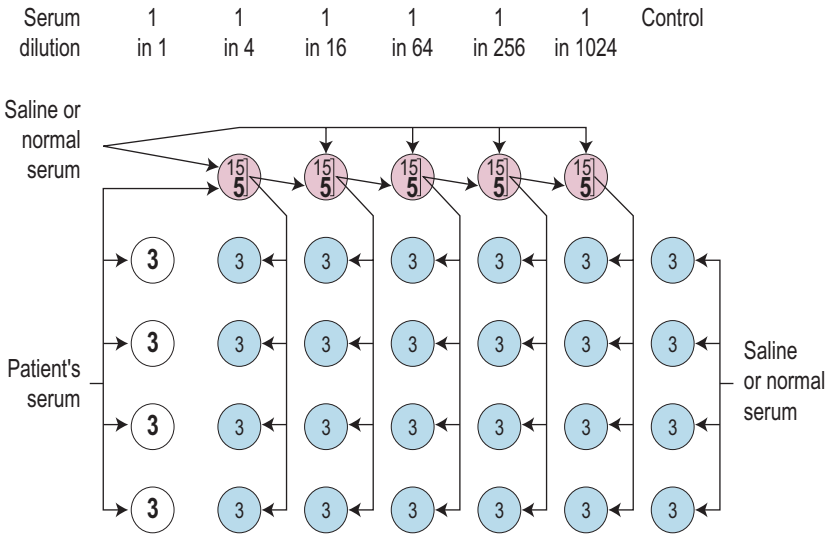

FIGURE 21-3 Diagram illustrating method of preparing four sets of four-fold dilutions of a serum. The large circles at the top represent the large tubes in which the primary dilutions are made; the smaller circles represent the tubes in which the titrations are carried out. The figures represent drops or volumes. The patient's neat serum is indicated by the bold type.

are rejected for transplant or subjected to excessive treatment pretransplant, to lower these titres. The UK National External Quality Assessment Service (NEQAS) demonstrated that titre results showed significant variation across UK laboratories, which could be reduced in part by using a standardised method[43] (see Table 21-12).

Test for ABH substance secretion

In the majority of the population, substances with the appropriate A, B and H antigenic activity are distributed widely in saliva and all body fluids, controlled by a regulator secretor gene (*Se*), which is inherited independently of *ABH* genes. Only about 20% of people are nonsecretors. Although rarely used, an individual's secretor status can be determined by testing saliva. The method is given in the previous edition.

Red cell genotyping

Over the past 20 years the molecular bases of almost all the major blood group antigens have been determined. This research has enabled development of DNA-based methods for determining blood group genotype, except for ABO genotyping, which remains unreliable as an alternative to serological methods. Red cell genotyping is not yet in widespread use in place of serological provision of compatible blood for patients, but is increasingly used in situations when serological techniques prove difficult, e.g. phenotyping of a recently transfused patient or in a patient with autoimmune haemolytic anaemia[44,45] and in detection of Rh variants (mainly in Afro-Caribbean patients), which can be associated with allo-antibody formation, which sometimes cause clinically significant haemolysis, though antibodies may disappear with time and may not recur on subsequent exposure to the corresponding antigen.[46] Large-scale donor genotyping, using high throughput, automated systems, would most likely be carried out with DNA arrays or gene chips, but this technology is not in widespread use at present, due to the relatively high cost of extended red cell genotyping of all donors, when only a minority of patients have allo-antibodies or require extended matching of red cells. However, targeted genotyping of a proportion of donors is increasingly used, to provide for patients with multiple antibodies or antibodies to high frequency antigens, especially patients with sickle cell disease. Many red cell genotyping systems are available: with high or low throughput capacity; shorter or longer turnaround times (some with results within 2 h); some covering a more extensive range of genotypes than others (e.g. beyond Rh, Kell, Fy, Jk, MNSs – some may cover Rh variants, Js, Do as well as genotyping for haemoglobin S and human platelet antigens – HPA).

Discrepancies between genotyping and phenotyping results may occur:

Phenotype +/ Genotype –
False + phenotype due to transfusion or stem cell transplantation.
False + phenotype due to IgG sensitisation of red cells.
Phenotype –/ Genotype +
'False +' genotype due to nonexpression/weak expression of gene products.
Serological reagent may be deficient (false – phenotype).
Management: For patients, default to antigen-negative blood if possible, until the discrepancy is resolved.

TABLE 21-12

UNIFIED METHOD USED FOR EQA PILOT FOR ABO TITRES

Preparation of reagents and endpoint reading:
1. Prepare dilutions of plasma in saline (PBS or NaCl) using a doubling dilution method. Make the dilutions with a minimum volume of 200 µl, using an automatic pipette. Use a new tip to dispense each dilution.
2. Prepare a 0.8–1% red cell suspension in CellStab (www.bio-rad.com); use ID-diluent 2 (www.diamed.com) if CellStab is not available.
   Read the endpoint of the titration as the last *weak* reaction.

LISS indirect antiglobulin test (IAT) using DiaMed IgG or polyspecific cards
a) Add 50 µl of cells suspended in CellStab or ID-diluent 2 to each microtube
b) Add 25 µl of each plasma dilution to the corresponding microtube
c) Incubate at 37 °C for 15 min
d) Centrifuge 10 min in DiaMed centrifuge

Direct agglutination at room temperature (DRT) using DiaMed NaCl cards
a) Add 50 µl of cells suspended in CellStab or ID-diluent 2 to each microtube
b) Add 50 µl of each plasma dilution to the corresponding microtube
c) Incubate at room temperature for 15 min
d) Centrifuge 10 min in DiaMed centrifuge

PLATELET AND NEUTROPHILS

Platelet and neutrophil alloantigen systems

Platelet and neutrophil alloantigens may be exclusive to each cell type (cell-specific) or shared with other cells. The currently recognised human platelet antigens (HPA) and human neutrophil antigens (HNA) are shown in Tables 21-13 to 21-15.[47–49] The historical nomenclature for granulocyte antigens used the letter N to indicate neutrophil specificity and this has been retained, although it is recognised that many studies used granulocytes rather than pure neutrophils and many 'neutrophil-specific' antibodies can also target neutrophil precursors. In the HPA

HPA-6b		2.4		4.8	4.0

HPA, human platelet antigen.

nomenclature, HPA-1, -2, -3, -4 and -5 were designated as separate diallelic alloantigen systems. The high-frequency allele of a system was designated with the letter 'a' and the low-frequency allele was designated with the letter 'b'. However, this system is difficult to reconcile with recent molecular genetic knowledge, which suggests that each new base change does not constitute a new diallelic alloantigen system but rather defines a single allele that expresses a single new epitope. Currently, nine different glycoprotein (Gp)IIIa alleles have been found in the human gene pool,[50] four allelic variants have been described for GpIa and GpIIb and two allelic variants have been found for the GpIbα and GpIbβ subunits[50] (a database of human platelet antigens is available at: www.ebi.ac.uk/ipd/hpa).[51] Of the shared antigens, the human leucocyte antigen (HLA) system is the most important clinically;

TABLE 21-15

THE HUMAN NEUTROPHIL ANTIGEN SYSTEMS

Antigen System	Antigen Phenotype	Location	Acronym	Caucasian Frequency (%)
HNA-1	HNA-1a	FcγRIIIb	NA1	58
	HNA-1b	FcγRIIIb	NA2	88
	HNA-1c	FcγRIIIb	SH	5
HNA-2	HNA-2a	gp50-64	NB1	97
HNA-3	HNA-3a	gp70-95	5b	97
HNA-4	HNA-4a	CD11b	MART	99
HNA-5	HNA-5a	CD11a	OND	96

HNA, human neutrophil antigen.

only class 1 antigens (HLA-A, -B and to a lesser extent -C) are expressed on platelets and granulocytes. ABH antigens are also expressed on platelets (in part absorbed from the plasma) but cannot be demonstrated on granulocytes.

Clinical significance of platelet and neutrophil antibodies

Platelet and neutrophil antibodies may be classified on the basis of the antigenic stimulus (e.g. allo-, auto- and drug-induced antibodies).

Alloantibodies

Alloimmunisation to platelet and neutrophil antigens is most commonly a result of transfusion or pregnancy. The associated clinical problems depend on the specificity of the antibody, which determines the target cell involved. Cell-specific alloantibodies are associated with well-defined clinical conditions, which are summarised in Tables 21-16 and 21-17.[52–55]

Alloimmune fetal and neonatal thrombocytopenia are commonly caused by anti-HPA-1a and less frequently by anti-HPA-5b. The chance of HPA-1a alloimmunisation is strongly associated with maternal HLA class-II DRB3*0101 (DR52a) type.[56] Fathers should be offered HPA genotyping and, if heterozygous, with a severely affected previous child, fetal HPA grouping should be considered in the first trimester of the next pregnancy using amniocyte DNA. Potential strategies for routine antenatal screening and the acceptability and cost-effectiveness of such a programme are discussed in several publications.[57,58]

TABLE 21-16

CLINICAL SIGNIFICANCE OF PLATELET-SPECIFIC ALLOANTIBODIES AND OTHER ALLOANTIBODIES RECOGNISING ANTIGENS ON PLATELETS[52]

1. Neonatal alloimmune thrombocytopenia
2. Post-transfusion purpura
3. Refractoriness to platelet transfusion; usually as a result of human leucocyte antigen antibodies.

TABLE 21-17

CLINICAL SIGNIFICANCE OF NEUTROPHIL-SPECIFIC ALLOANTIBODIES AND OTHER ALLOANTIBODIES RECOGNISING ANTIGENS ON NEUTROPHILS[55]

1. Neonatal alloimmune neutropenia
2. Febrile reactions following transfusion (HLA antibodies also involved)
3. Transfusion-related acute lung injury (TRALI) (transfusion of high-titre antibody)
4. Poor survival and function of transfused neutrophils (HLA antibodies also involved)
5. Autoimmune neutropenia – some autoantibodies have allospecificity for HNA system antigens.

HLA, human leucocyte antigen; HNA, human neutrophil antigen.

Post-transfusion purpura is most commonly caused by anti-HPA-1a but can be associated with HPA antibodies with other specificities against HPA-1b, HPA-2b, HPA-3a, HPA-3b, HPA-4a and HPA-5b.[59]

Immunological refractoriness to platelet transfusions is usually the result of anti-HLA antibodies. However, in multi-transfused patients with HLA immunisation, up to 25% may also have anti-HPA antibodies.[60,61]

Isoantibodies

Rarely, after blood transfusion or pregnancy, patients with type I Glanzmann disease make antibodies that react with GpIIb/IIIa not present on their own platelets but present on normal platelets (i.e. isotypic determinants).[62–65] Similarly, patients with Bernard–Soulier syndrome may make antibodies against isotypic determinants on GpIb/V/IX not present on their own platelets.[66] This may present a serious clinical problem because no functional compatible donor platelets can be found to treat severe bleeding episodes.

Autoantibodies

Autoimmune thrombocytopenia may be idiopathic or secondary in association with other conditions. Demonstration of a platelet autoantibody is not required; even with the most suitable techniques now available, platelet autoantibodies remain elusive in a variable proportion (10–20%) of patients. The autoreactive antibodies target epitopes on certain glycoproteins. In 30–40% of patients these are directed against epitopes on the αIIbβ3 integrin heterodimer, platelet glycoprotein GpIIbIIIa (CD41) and in 30–40% against the von Willebrand receptor or complex GpIbα/GPIbβ/IX (CD42).[67–70]

In the diagnosis of autoimmune thrombocytopenia it is important to consider and exclude three other immunological conditions:

1. *Post-transfusion purpura (PTP).* A blood transfusion within 2 weeks will suggest this possibility, although it is very rare in the UK since leucodepletion of blood components was introduced.[16,59]
2. *Drug-induced immune thrombocytopenia.* A drug history is essential. Heparin-induced thrombocytopenia (HIT) is the most frequent drug-induced thrombocytopenia. The diagnosis can be supported by the demonstration of antibodies to the heparin/platelet factor 4 (PF4) complex by ELISA (enzyme-linked immunosorbent assay).[71]
3. *Pseudothrombocytopenia.* The patient has an EDTA-dependent platelet antibody that is active only *in vitro*. The antibody (IgG and/or IgM) reacts with hidden (cryptic) antigens on platelet GpIIbIIIa, which are exposed owing to conformational changes in the complex caused by the removal of Ca^{2+} by EDTA.[72] The antibody causes platelet agglutination in the EDTA blood sample associated with large platelet clumps on the blood film or platelet satellitism around neutrophils, both of which lead to a falsely low platelet count. To overcome this, blood should be taken into a tube containing citrate instead of EDTA, with a correction being made for dilution.

Autoimmune neutropenia may be idiopathic or secondary. Idiopathic autoimmune neutropenia is more common in infants than in adults, in whom it is usually associated with other disorders that have in common a postulated imbalance of the immune system.[73] However, it is the least well-studied of the autoimmune cytopenias because it is rare and performing granulocyte assays is difficult, lengthy, labour-intensive and expensive.

Neutrophil autoantibodies (which are usually IgG) are unusual in that they often have well-defined specificity for alloantigens, especially NA1 or NA2.[74] These autoantibodies may suppress granulocyte precursors in the bone marrow and cause more severe neutropenia. The investigation of suspected autoimmune neutropenia should, when possible, include granulocyte immunology and studies of colony growth (e.g. colony-forming units–granulocyte-macrophage, CFU-GM) to identify any suppression of bone marrow precursors, as a result of interaction with autoantibodies.

Drug-induced antibodies

Drug-induced antibodies may cause selective haemolytic anaemia (see p. 268), thrombocytopenia or neutropenia or various combinations of these in the same patient.[75,76]

A drug may cause an immune cytopenia by stimulating production of either an *autoantibody* (which reacts directly with the target cell independently of the drug itself) or a *drug-dependent antibody* (which destroys the target cell by reacting with a drug–membrane complex on the target cell).[77] Laboratory tests may demonstrate both types of antibody in some patients.[78]

Demonstration of platelet and neutrophil antibodies

No single method will detect all types of platelet and neutrophil antibodies equally well. In practice, it is useful to have a basic screening method that will detect most commonly occurring antibodies, both cell-bound (direct test) and in serum (indirect test), and to supplement this with other selected methods for demonstrating particular properties of an antibody and for measuring the amount of cell-bound antibody.

Alloantibodies

Reports of national and international workshops make it possible to formulate guidelines for *platelet immunological tests*. The basic procedure for demonstrating platelet alloantibodies should include the following:

1. *A platelet test for platelet-reactive antibodies.* The ISBT/ICSH Working Party on Platelet Serology[79] recommended the platelet suspension immunofluorescence test[80] as the standard for assessment of other platelet antibody techniques.
2. It is important to combine a sensitive binding assay, such as the platelet immunofluorescence test (PIFT), with an antigen-capture method, such as the monoclonal antibody immobilisation of platelet antigens (MAIPA),[81] to increase the chance of detecting weak antibodies or those that react with relatively few antigen sites.
3. *A lymphocyte test for detecting HLA antibodies.* Because HLA antibodies also react with platelets, a lymphocyte cytotoxicity and/or ELISA assay should be included in the basic antibody screening procedure.
4. *Tests to differentiate platelet-specific from HLA antibodies.* The MAIPA technique using appropriate monoclonal antibodies is particularly useful for resolving mixtures of platelet-reactive antibodies (see p. 465). The chloroquine-'stripping' technique to inactivate HLA Class I

molecules on platelets[52] is also helpful in this respect (see p. 465). Conventional serological techniques (e.g. differential reactions with a panel of normal lymphocytes and platelets; differential absorption of HLA antibodies) can also be used to differentiate cell-specific and HLA antibodies, but these are less suitable for rapid screening than the chloroquine-'stripping' technique.

Further characterisation of platelet-specific antibodies will require referral to a reference laboratory. Identification of allospecificity should be carried out as for red cell antibodies by reaction with a selected genotyped panel of group O platelets, preferably with reference to the patient's platelet genotype.

An important consideration in platelet serology is the occasional occurrence of antibodies against hidden (cryptic) antigens of the GpIIbIIIa complex, which are exposed by EDTA and paraformaldehyde (PFA) fixation.[82] These antibodies, which are only active *in vitro,* are unpredictable but when suspected can be avoided by using unfixed test platelets from citrated blood.

The detection and identification of granulocyte alloantibodies should be left to experienced reference laboratories, but should follow a similar schedule with the use of monoclonal antibody immobilisation of granulocyte antigens (MAIGA)[83,84] or adsorption of the sera with pooled platelets to differentiate between granulocyte-specific and HLA antibodies.

Autoantibodies

The detection of autoantibodies and drug-induced antibodies requires special consideration.

It can be misleading, when looking for platelet (or neutrophil) autoantibodies, only to test the patient's serum against normal platelets (or neutrophils) because positive reactions may result from the presence of alloantibodies (e.g. HLA or cell-specific) induced by previous transfusion or pregnancy. It is important to show that an autoantibody in the patient's serum reacts with the patient's own cells. Ideally a DAT (e.g. PIFT) should be performed, before treatment is given, to detect antibody bound *in vivo.* Where a severe cytopenia exists, it may not be possible to harvest enough cells for the test; nevertheless, serum samples should be stored at −20 °C and tested retrospectively against the patient's cells when the peripheral platelet (or neutrophil) count has increased in response to treatment.

A major interest in platelet autoimmunity has been the quantitative measurement of platelet-associated immunoglobulins as an indication of *in vivo* sensitisation. A criticism of these quantitative methods is that they detect not only platelet autoantibody but also Ig nonspecifically trapped or bound to platelets and platelet fragments[85] and are therefore generally nonspecific in the diagnosis of autoimmune thrombocytopenia.[86] It is now customary to use the direct PIFT,[87,88] using flow cytometry. The patient's platelets are incubated with isotype-specific fluorescein-isothiocyanate (FITC)-labelled conjugates (anti-IgG, anti-IgM and anti-IgA) and the test is reported as positive when the fluorescence intensity is > mean + 2SD when compared with the results obtained with pooled (10 or more) normal donor platelet suspensions. In a study of 75 patients with autoimmune thrombocytopenic purpura, using microscopy rather than flow cytometry, von dem Borne and colleagues[89] found a weak positive (± to +) direct PIFT in 60% of patients and strong reactions (++ to ++++) in only 26% of patients. In the same study, the indirect PIFT was positive with the patient's serum in 66% of cases who had a positive direct PIFT and it was positive with an ether eluate of the patient's platelets in 94% of the same cases. Although these results may be a reflection of the relative insensitivity of the method, they may result from a low-affinity antibody that is easily eluted during the assay procedure[85] or indicate an alternative immune mechanism for thrombocytopenia in some cases.

The Ig class of platelet autoantibodies is similar in idiopathic and secondary autoimmune thrombocytopenia; mostly it is IgG (92%), but often (also) IgM (42%) and sometimes (also) IgA (9%).[89] All IgG subclasses occur, but IgG_1 and/or IgG_3 are the most frequent.

A combination of the granulocyte immunofluorescence test (GIFT)[90] and the granulocyte agglutination test (GAT)[91] provides the most effective means of granulocyte (neutrophil) antibody detection. However, immune complexes and aggregates in a patient's serum can still cause false-positive results. This can cause a problem with sera from adult patients with secondary autoimmune neutropenia, which should also be investigated for immune complexes (e.g. Clq-enzyme-linked immunosorbent assay). The granulocyte chemiluminescence test (GCLT)[92] is relatively insensitive to the presence of immune complexes when inactivated serum is used, but it is unable to detect antibodies of the IgM class. Several reviews provide an appraisal of the techniques available for detecting granulocyte-specific antibodies and antigens,[93,94] including a recent review of investigations for transfusion-related acute lung injury (TRALI).[95]

Drug-induced antibodies

The serological investigation of drug-induced immune thrombocytopenia (or neutropenia) follows the same pattern as for haemolytic anaemia (see p. 268), with the exception that it is not always possible to collect enough cells to test at the nadir of thrombocytopenia or neutropenia. The following blood samples are therefore necessary:

1. *Acute-phase blood sample when the cell count is at the nadir.* If there are too few cells to test for cell-bound antibody and complement at this time, it is necessary to test the acute-phase serum against the patient's cells during remission. These tests will demonstrate the immune basis of the cytopenia.
2. If the patient's acute-phase serum is tested against *normal* donor cells, it is essential to take account of

positive reactions owing to HLA or cell-specific alloantibody in the patient's serum. Furthermore, negative results with normal donor cells may be the result of absence of the antigen for the particular drug-dependent antibody (e.g. owing to genetic restriction of the antigen concerned).[96]

3. *Subsequent samples after stopping the drug.* Ideally, sampling should be done when the drug has been eliminated and the antibody is still detectable. Tests using this sample with and without the drug in the assay system are necessary to demonstrate the part played by the drug in causing the immune cytopenia. The drug may be added directly to the assay system (and included in the wash solution) or the cells may be pretreated with the drug. For some drugs, a metabolite and not the native drug is the appropriate antigen for testing; in these cases an *'ex vivo'* drug antigen from urine or plasma may be used.[97]

Methods of demonstrating antibodies

The basic immunofluorescent antiglobulin method and the MAIPA assay will be described in detail. Only brief mention will be made of other methods.

The immunofluorescent antiglobulin methods

The immunofluorescent antiglobulin methods are based on the conventional antiglobulin technique (see p. 453) and are suitable for platelet,[80] granulocyte[90] and lymphocyte[98] serology. The PIFT and GIFT are described in detail in this chapter.

These tests can either be read by direct examination of a cell suspension using fluorescence microscopy or by flow cytometry. These tests can detect allo-, auto- and drug-induced antibodies and, by using appropriate monospecific antiglobulin reagents, can determine the Ig class and subclass of the antibody and cell-bound complement components. Both tests can be used with chloroquine-treated cells to differentiate cell-specific from HLA antibodies.[99]

Patient's and screening panel cells

Platelets and granulocytes are prepared from venous blood taken into 5% (w/v) K_2EDTA in water (9 volumes blood:1 volume anticoagulant).

Screening panel cells should be obtained from group O donors for platelet serology to avoid positive reactions owing to anti-A and anti-B, but this is not necessary for granulocyte serology because A and B antigens cannot be demonstrated on granulocytes. If a patient's serum must be tested with ABO-incompatible platelets, anti-A and/or anti-B can be absorbed with corresponding red cells or A or B substance.

The best results are obtained with the freshest cell preparations, but some delay is tolerable (see later). Neutrophils are more susceptible to storage damage than platelets; cells should be fixed (see later) on the day of collection, but serology may be delayed to the following day. Platelets are more resilient and an anticoagulated blood sample may be satisfactory for testing for up to 2 days at ambient temperature (*c.* 20 °C). Once fixed, platelets may be kept for 3–4 days at 4 °C before serological testing. For longer storage, platelet-rich plasma may be kept at −40 °C for at least 2 months; however, there is some membrane damage after recovery of frozen platelets, which causes increased background fluorescence that may limit the sensitivity of the test.[100,101] For longer-term storage a cryoprotectant (e.g. DMSO) may be used.[101]

Patient's serum

Serum from clotted venous blood should be heated at 56 °C for 30 min to inactivate complement and stored in 1–2 ml volumes at −40 °C (to avoid repeated thawing of a stock).

Control sera

Negative control serum is prepared from a pool of 10 sera from group AB male donors who have never been transfused. *Positive control* sera containing platelet-specific antibodies (e.g. anti-HPA-1a), granulocyte-specific antibodies or multispecific HLA antibodies should be obtained from reference centres.

Eluate from patient's sensitised cells

Elution is important to confirm the antibody nature of cell-bound immunoglobulin and to determine the specificity of antibodies. This applies especially when no antibody is demonstrable in the patient's serum, which often occurs in patients with autoimmune thrombocytopenia and neutropenia.

Elution by lowering the pH of the medium, by ether (or DMSO) and by heating to 56 °C, has been used.[102] For routine platelet serology, ether elution for platelet autoantibodies or heating to 56 °C for platelet-specific alloantibodies could be used.

Heat eluate

Incubate platelets or granulocytes suspended in 0.5 ml of 0.2% bovine serum albumin (BSA) in PBS for 60 min at 56 °C. Centrifuge and remove the supernatant that contains the eluted antibody.

Platelet preparation

1. Prepare platelet-rich plasma (PRP) by centrifugation of anticoagulated blood (200 *g*, 10 min).
2. Wash the platelets three times (2500 *g*, 5 min) in PBS/EDTA buffer (8.37 g of Na_2 EDTA dissolved in 2.5 l of PBS, pH 7.2); resuspend the platelets thoroughly each time.
3. Fix the platelets in 3 ml of 1% paraformaldehyde solution for 5 min at room temperature. A stock solution

of PFA is prepared by dissolving 4 g of PFA (BDH Chemicals, www.labdepotinc.com) in 100 ml of PBS by heating to 70 °C with occasional mixing. Add 1 mol/l NaOH dropwise with continuous mixing until the solution clears. This 4% stock solution may be stored at 4 °C protected from light for several months. Prepare a 1% PFA working solution by adding 1 volume of the 4% PFA stock solution to 3 volumes of PBS and by correcting the pH if necessary to 7.2–7.4 with 1 mol/l HCl.

4. Wash the platelets twice as before and resuspend in PBS/EDTA buffer at a concentration of 250–500 × 10^9/l for use in the PIFT.

Granulocyte preparation

1. Mix anticoagulated blood or blood retained from platelet preparation after removal of PRP (and made up to its original volume with PBS) with 2 ml of Dextran solution per 10 ml of blood (Dextran 150 injection BP in 5% dextrose). Incubate this mixture at 37 °C for 30 min at an angle of about 45° to accelerate red cell sedimentation and then remove the leucocyte-rich supernatant (LRS).
2. Granulocytes can be separated by double-density sedimentation (Fig. 21-4). The LRS is underlayered with 2 ml of lymphocyte separating medium (LSM) (LSM = Ficoll-Hypaque sp gr 1.077), which is then underlayered with 2 ml of mono-poly resolving medium (MPRM) (MPRM = Ficoll-Hypaque sp gr 1.114) (LSM and MPRM supplied by Flow Labs Ltd, www.himedialabs.com). The density gradient tube is then centrifuged at 2500 *g* for 5 min. Granulocytes form an opaque layer at the LSM/MPRM interface from which they are harvested by careful pipetting (microscopic examination shows that the cells from this layer are predominantly neutrophil polymorphs). Lymphocytes can similarly be harvested from the plasma/LSM interface (e.g. for use in the lymphocyte immunofluorescence test or LIFT).[98]
3. Wash the granulocytes three times at 400 *g* for 5 min in PBS/BSA buffer (PBS pH 7.2 with 0.2% BSA).
4. Fix the granulocytes in 3 ml of 1% PFA for 5 min at room temperature.
5. Wash the granulocytes twice as before and resuspend in PBS/BSA buffer at a concentration of about 10 × 10^9/l for use in the GIFT.

Platelet and granulocyte immunofluorescence tests

The serological methods for testing platelets and granulocytes in the suspension immunofluorescence test are similar, except that platelets are washed throughout in PBS/EDTA buffer and granulocytes are washed in PBS/BSA buffer. A flow diagram of the PIFT is shown in Figure 21-5.

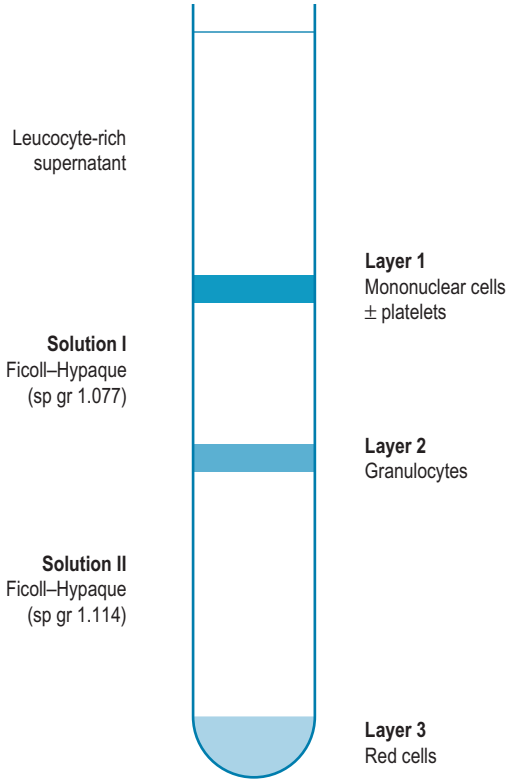

FIGURE 21-4 A diagram showing double-density separation of lymphocytes and granulocytes. A leucocyte-rich supernatant is underlayered with Ficoll–Hypaque with a specific gravity of 1.077 (Solution I) and 1.114 (Solution II) and then centrifuged at 2500 *g* for 5 min. Lymphocytes concentrate in layer 1; granulocytes concentrate in layer 2.

FITC-labelled antiglobulin reagents are used as follows: anti-Ig (polyspecific), anti-IgG, anti-IgM and anti-C3. $F(ab)_2$ fragments of these reagents should be used to minimise nonspecific membrane fluorescence owing to Fc receptor binding, which is a particular problem with granulocytes. The optimal dilution for each reagent should be determined by chequer-board titration. Centrifuge the FITC conjugates at 2500 *g* for 10 min before use to remove fluorescent debris and reduce background fluorescence.

Positive and negative controls (as described earlier) should be included with each batch of tests.

Indirect test

1. In plastic precipitin tubes (50 × 7 mm), mix 0.1 ml of serum and 0.1 ml of the appropriate cell suspension, as prepared earlier. (The method can also be adapted for use with microtitre plates, which has the advantage of using smaller volumes.)
2. Incubate for 30 min at 37 °C (for IgG and C3 tests) and at room temperature (for IgM tests). For C3 tests *only*, sediment cells (1000 *g*, 5 min), remove the supernatant

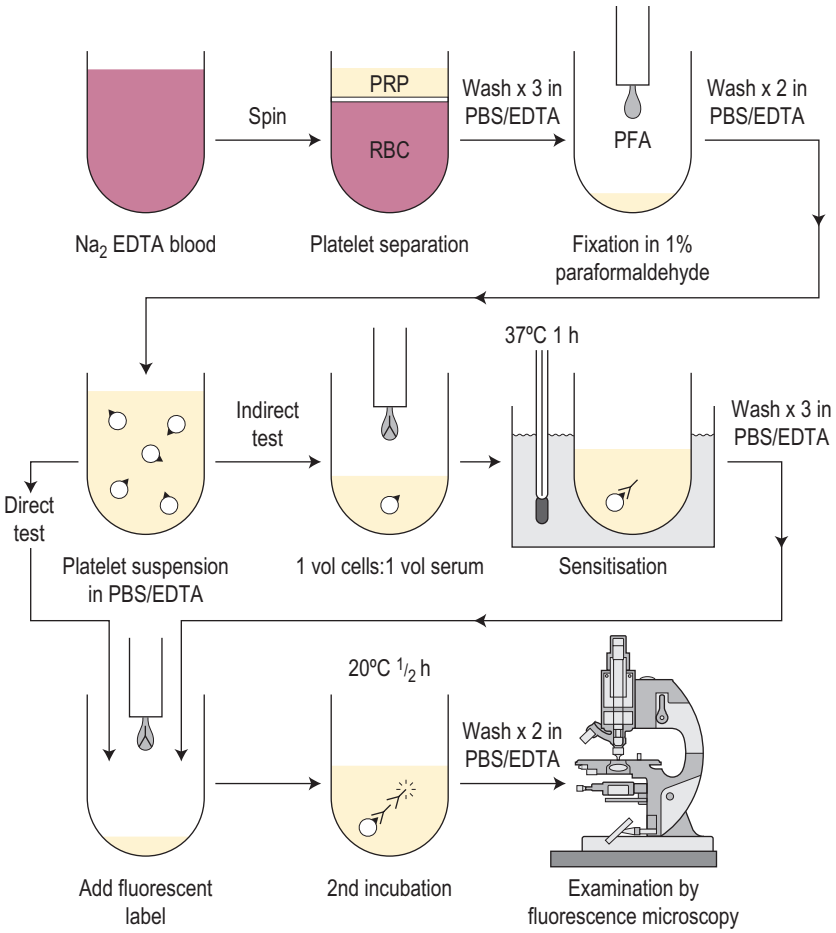

FIGURE 21-5 Platelet immunofluorescence test. PBS, phosphate buffered saline; PFA, paraformaldehyde; PRP, platelet-rich plasma; RBC, red blood cells.

and resuspend the cell button in 0.1 ml of freshly thawed human serum as a source of complement. Incubate for 30 min at 37 °C.

3. Wash the cells three times at 1000 *g*, for 5 min with appropriate buffer – PBS/EDTA for platelets, PBS/BSA for granulocytes; decant the final supernatant. This and subsequent steps are common for both the *indirect* test (i.e. patient's serum with donor cells) and the *direct* test (i.e. patient's own cells to detect *in vivo* sensitisation).
4. Add the fluorescent antiglobulin reagent (0.1 ml of the appropriate dilution determined by chequer-board titration), mix with the cell button and leave at room temperature for 30 min in the dark.
5. Wash twice as before and remove the supernatant.
6. Mix 0.5 ml of glycerol – PBS (3 volumes glycerol:1 volume PBS) with the cell button and mount on a glass slide under a coverslip.
7. Examine microscopically using ×40 objective and epifluorescent ultraviolet illumination.

Scoring results

Reactions in the PIFT and GIFT may be scored on a scale from negative (−) through graded positives from + to + + + +. Although subjective, this method of scoring in experienced hands can produce semiquantitative results in the PIFT.[103]

In general, normal platelets and granulocytes incubated with AB serum do not fluoresce after incubation with an appropriately diluted FITC antiglobulin reagent. Sometimes the negative control may show weak fluorescence (up to ++ on some cells); in these cases, the test result is classified as positive only if it is clearly stronger than the negative control (AB serum). Stronger fluorescence in the negative control should raise doubts about the performance of the test.

Use of flow cytometry

With simplification of flow cytometers and improved software, more platelet reference laboratories are using them for primary analysis in PIFT because sensitivity

is improved. Nevertheless, platelets are more difficult to work with flow cytometrically than leucocytes and erythrocytes and particular attention has to be paid to prevent aggregation and to ensure single cell suspensions. Presence of platelet particles and debris may also cause confusion. The technical considerations of applying flow cytometry to platelet work have been the subject of several reviews.[87,88]

Chloroquine treatment of platelets and granulocytes

Platelets for chloroquine treatment should be prepared from fresh blood or blood stored overnight at 4 °C; granulocytes are suitable only if freshly prepared.[52,104] An important consideration is the extent of chloroquine-induced cell membrane damage, which is minimal with fresh cells.

1. Cells are prepared as already described. Two-thirds of the cells are treated with chloroquine; the remaining one-third are not treated. After washing and before PFA fixation, the cell button is incubated with 4–5 ml of chloroquine diphosphate in PBS (200 mg/ml, pH adjusted to 5.0 with 1 mol/l NaOH) for 2 h at room temperature with occasional mixing or overnight at 4 °C without mixing, if this is more convenient for the laboratory routine.
2. Wash three times in the appropriate buffer and fix in 1% PFA as previously described. Cell clumping during washing may be a problem after chloroquine treatment, especially with granulocytes; cell clumps should be dispersed by repeated gentle aspiration with a Pasteur pipette. The final cell suspension for serological testing should be prepared as previously described.

When reading the test by fluorescence microscopy, it is important to recognise and allow for any fluorescence owing to chloroquine-induced cell damage, which is more likely to occur with granulocytes than platelets. Damaged cells are easily recognised by bright homogeneous fluorescence. Such cells should be excluded from assessment; only cells showing obvious punctuate fluorescence should be considered positive.

Chloroquine-treated cells were tested initially in the fluorescent antiglobulin method, but they may also be used in enzyme and radionuclide-labelled antigen methods.

Interpretation of results with chloroquine-treated cells

Typical results with HLA- and cell-specific antibodies are shown in Table 21-18. If a serum that has been shown to contain HLA antibodies by a lymphocytotoxicity test (LCT) and/or LIFT gives equal or stronger reactions with chloroquine-treated cells than with untreated cells, then a cell-specific antibody is also present. The Second Canadian Workshop on Platelet Serology[100] concluded that a weaker reaction with chloroquine-treated platelets should be interpreted with caution; this could indicate residual HLA reactivity, especially in the presence of high-titre multispecific HLA antibodies. If a platelet-specific antibody is nevertheless still suspected, other methods should be used to confirm this (e.g. MAIPA using appropriate monoclonal antibodies for capture; see later).

Similar caution should be observed in interpreting the GIFT results with chloroquine-treated cells.

MAIPA assay

The principle of the MAIPA assay is shown in Figure 21-6. The test is based on the use of monoclonal antibodies, such as anti-GpIIbIIIa, anti-GpIbIX, anti-GpIaIIa and anti-HLA class I, to 'capture' specific platelet membrane glycoproteins. The availability of appropriate monoclonal antibodies has led to the wider clinical application of this method.[81] The same principle can be used with granulocytes, depending on the availability of appropriate monoclonal antibodies.[81,105]

The following assay protocol was developed from the original method described by Kiefel.[81,106]

1. Prepare platelets as for the PIFT (see p. 463), except that paraformaldehyde fixation is omitted.
2. Resuspend a pellet of $50–100 \times 10^6$ platelets in 30 µl of human serum or plasma to be tested and incubate at 37 °C for 30 min in a U-well microplate.
3. Wash platelets twice in PBS/EDTA buffer (8.37 g of Na_2EDTA in 2.5 l of phosphate buffered saline, see p. 563). Resuspend the platelets in 30 µl of mouse monoclonal antibody (anti-GpIIbIIIa, IaIIa, IbIX or HLA at 20 µg/ml) and incubate at 37 °C for 30 min.

TABLE 21-18

PLATELET AND GRANULOCYTE ANTIBODY REACTIONS USING CELLS PREPARED WITH AND WITHOUT CHLOROQUINE TREATMENT

Sera	Untreated Cells		Chloroquine-Treated Cells	
	Platelets	Granulocytes	Platelets	Granulocytes
Negative	–	–	–	–
Multispecific HLA antibodies	+++	++	–	–
Granulocyte-specific antibody	–	++	–	+++
Platelet-specific antibody	+++	–	+++	–

HLA, human leucocyte antigen.

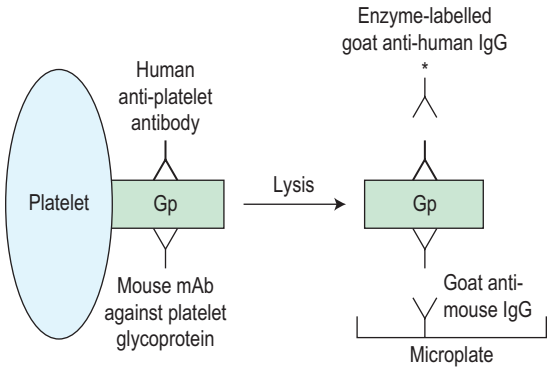

FIGURE 21-6 Monoclonal antibody immobilisation of platelet antigens (MAIPA): principle of the method. Gp, platelet membrane glycoprotein; IgG, immunoglobulin G; mAb, monoclonal antibody.

4. Wash platelets twice in PBS/EDTA buffer, lyse by the addition of 100 µl of Tris buffered saline (TBS) containing 0.5% Nonidet P-40 and leave at 4 °C for 30 min.
5. Transfer the platelet lysate to a 2 ml conical tube and centrifuge at 11 600 *g* for 30 min at 4 °C to remove particulate matter.
6. Dilute 60 µl of the resulting supernatant with 180 µl of TBS wash buffer (0.5% Nonidet P-40, 0.05% Tween 20 and 0.5 mmol $CaCl_2$). Transfer 100 µl of diluted platelet lysate, in duplicate, to a flat-well microplate previously coated with goat antimouse IgG.* Leave at 4 °C for 90 min.
7. Wash the microplate well four times with 200 µl of TBS wash buffer and then add 100 µl of alkaline phosphatase-labelled antihuman IgG (Jackson ImmunoResearch, www.jacksonimmuno.com) diluted 1:4000 in TBS wash buffer.
8. Leave at 4 °C for a further 90 min, then wash the wells four times with TBS wash buffer and add 100 µl of substrate solution (1 mg/ml *p*-nitrophenyl phosphate in diethanolamine buffer, pH 9.8) to each well.
9. Measure the resulting colour change at 30 min using a dual-wavelength spectrometer, e.g. FLUOstar Omega, which is a multimode microplate reader (www.bmglabtech.com).

Express results as the mean absorbance at 405 nm of duplicate tests minus the mean of eight blanks containing TBS wash buffer instead of platelet lysate.

Use pooled AB serum as a negative control.

Other methods

Several other methods have been developed for the detection of platelet antibodies.

Solid-phase red cell adherence (SPRCA) techniques (some commercially available) evolved as alternatives to the microscopic reading initially required for the PIFT. These assays combine traditional red cell serology technology with platelet serology. Platelets are captured on microtitre wells; test antibodies are applied; and, after washing and addition of antihuman globulin, platelet or HLA alloantibody binding is detected using tanned sheep red cells[107] or anti-D sensitised RhD-positive red cells.[108] SPRCA are robust, sensitive tests that lend themselves to automation and the chloroquine treatment of platelets can be used effectively to screen out HLA antibodies.

GTI PakPlus is a platelet antibody kit based on an ELISA principle (Quest Biomedical, www.immucor.com). Microwells coated with platelet glycoproteins or HLA class I antigens are incubated with test serum. After incubation, followed by washing to remove unbound proteins, any antibody bound to the microwell is detected using an alkaline-phosphatase-conjugated antihuman globulin reagent (anti-immunoglobulin or anti-IgG) and the appropriate substrate. Results are considered positive when the ratio of the mean absorbance of the test sample to that of the normal control sera is ≥2.0.[109]

With respect to testing for granulocyte antibodies when working with the GIFT or GAT, elucidation of the alloantibody requires panels of typed granulocytes, which cannot be preserved for more than a few hours. A technique has been reported that uses extracted granulocyte antigens coated onto U-well Terasaki plates and a micromixed passive haemagglutination test.[110] Patient's serum and appropriate controls (sera known to contain granulocyte-specific antibodies, monoclonal antibodies, such as anti-CD16 and anti-NA1 and sera from normal donors) are added to the wells and, following incubation and washing, indicator blood cells are added (sheep red blood cells coated with antihuman IgG and antimouse IgG).

Molecular genotyping of platelet alloantigens

The application of DNA technology for platelet genotyping is based on the knowledge that the platelet antigen systems are the result of single DNA base changes, which lead to single amino acid substitutions in the platelet membrane glycoproteins (Table 21-13).

Molecular genotyping involves amplification of the relevant segments of genomic DNA from any nucleated cell by PCR in combination with sequence-specific primers[111] or by allele-specific restriction enzyme analysis[112] or allele-specific oligonucleotide dot blot hybridisation.[113]

Of the variety of PCR-based techniques available, the PCR with sequence-specific primers (PCR-SSP) is still the most widely used in the UK for the determination of HPA 1 to 5. Molecular genotyping has now been accepted as an essential part of confirming the specificity assigned to

*The microplate is prepared by adding to each well 100 µl of goat antimouse IgG (Sera-Lab, www.seralab.co.uk) at 3 µg/ml in carbonate coating buffer, pH 9.6. Leave the plate to stand overnight at 4 °C. Next morning, wash the plate four times with TBS wash buffer. Leave the last wash supernatant for 30 min to 'block' nonspecific protein adsorption to the plastic and then decant.

platelet alloantibodies, as well as allowing the investigation of patients with severe thrombocytopenia and making possible the determination of the fetal platelet genotype in early pregnancy to assess the risk of alloimmune thrombocytopenia.

Laboratory Aspects of Blood Transfusion

Megan Rowley • Carol Cantwell • Clare Milkins

CHAPTER OUTLINE

Safe and effective blood transfusion requires the combined efforts of blood transfusion services, biomedical scientists and clinicians to ensure the highest standards are applied to all the systems in a complex process from 'vein to vein'. This chapter provides a description of the laboratory framework required to provide the right blood components to the right patients at the right time. The increased awareness of what can go wrong with blood transfusion comes from national haemovigilance schemes[1] including the Serious Hazards of Transfusion (SHOT) UK scheme,[2] which was started in 1996. SHOT, a confidential reporting scheme for serious adverse reactions and events relating to transfusion, analyses reaction-specific questionnaires and makes a detailed root cause analysis

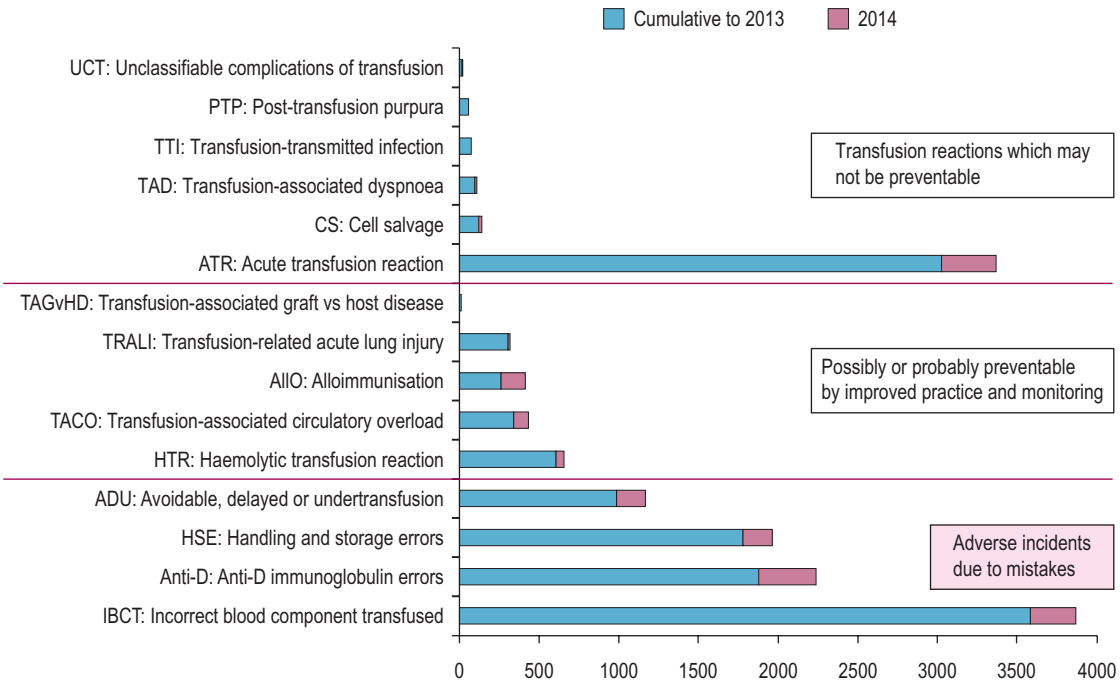

FIGURE 22-1 Cumulative data from SHOT (Serious Hazards of Transfusion) 1996/7–2014[2] showing distribution of errors, according to the main reporting categories, a total of 14 822 completed case reports. *With permission from Serious Hazards of Transfusion (SHOT). Annual Reports 1996–2014. Available at: www.shotuk.org.*

of errors. The data, learning points and recommendations provided in an annual report have informed both national bodies and local transfusion services of measures to introduce in order to reduce risk (Fig. 22-1). It is clear that multiple errors can contribute to a single adverse event and that many of these are outside the control of the transfusion laboratory.

Within the laboratory setting, the application of strict protocols for sample labelling and testing, robust laboratory procedures, reliable documentation, frequent staff training and competency assessment should be used. Recognising that a high proportion of wrong blood errors arise in the laboratory, the UK Transfusion Collaborative, comprised of representatives of the professional bodies involved in UK transfusion practice, produced some recommendations about training, competency, staffing levels and automated systems in 2009 and these were upgraded to best practice standards in 2014.[3]

This chapter is concerned with the testing of patient samples prior to the provision of appropriate compatible blood components including identification of red cell antibodies. It also covers compatibility testing, investigation of transfusion reactions and the testing required in other special situations including the antenatal and postnatal settings. National professional bodies such as the British Committee for Standards in Haematology (BCSH)[4] issue technical and clinical guidance to transfusion laboratories, and these have been referenced where appropriate.

In the UK there is a regulatory framework governing hospital transfusion laboratory practice which was implemented after the publication of two European Union Directives: 2002/98/EC and 2004/33/EC.[5] In the UK these are the Blood Safety and Quality Regulations 2005 (BSQR, Statutory Instruments 2005/50, 2005/1098 and 2006/2013) and they set standards for quality and safety of human blood and blood components in hospital 'blood banks' (hospital transfusion laboratories) as well as 'blood establishments' (the UK Blood Services).[6] 'Blood banks' are regulated in their roles of storing, distributing and performing compatibility tests on blood and blood components for use in hospitals. The implications for hospital transfusion practice are the requirement for 'vein to vein' traceability of blood components, the importance of maintaining the 'cold chain' for all therapeutic blood components, the need to store transfusion records for 30 years and the requirement for a quality management system. UK laboratories have to assess their compliance by completing and submitting an annual compliance report to the competent authority, which is the Medicines and Healthcare products Regulatory Agency (MHRA).[7] The MHRA carries out laboratory inspections of a proportion of 'blood banks' to assess compliance with these regulations.

Three UK Government Health Service Circulars entitled "Better Blood Transfusion" were published in 1998, 2002 and 2007, promoting a team approach to

blood transfusion safety and good transfusion practice through a structure of Hospital Transfusion Committees and Hospital Transfusion Teams.[8] The European Union Optimal Use of Blood Project produced a resource for anyone who is working to improve the clinical transfusion process, and this covers laboratory and clinical practice.[9] The World Health Organisation (WHO) also provides resources to support blood transfusion safety.[10]

TECHNOLOGY AND AUTOMATION IN BLOOD TRANSFUSION LABORATORIES

Important changes have taken place in the blood transfusion laboratory in the last 10–15 years, as outlined in the previous edition of this book. As a result, transfusion laboratory practice is safer, largely as a result of the implementation of new technologies for testing, the introduction of automated systems to replace manual systems and the widespread use of information technology (IT) systems to support transfusion laboratory practice.

Barcoded labels on blood components, reagents, patient samples and equipment are now commonplace, and these result in safer transfer of information, free from the transcription errors associated with manual methods. It is estimated that in the UK, 97% of routine group and screens are undertaken using full automation.[11]

Column agglutination (CAT) and solid-phase technology can be used on automated machines, and CAT can also be used by manual techniques. In UK hospital transfusion laboratories these technologies have replaced tube techniques and liquid-phase microplates for antibody screening and crossmatching.[11]

The currently available CAT systems include Ortho BioVue (www.orthoclinical.com), which comprises a six-well cassette containing a glass microbead matrix, ID Bio-Rad cards utilising Sephadex gel matrix, also with six wells, and an eight-well Sephadex gel matrix card from Grifols (www.grifols.com). Each offers a wide range of profiles and reagent systems. Other similar formulations produced by different commercial companies are available outside of the UK.

The currently available solid-phase systems are Immucor Capture-R (www.immucor.com) and Bio-Rad Solidscreen II (www.bio-rad.com). The Immucor system utilises a range of red cell antigens that have adhered to the surface of a U-shaped microplate well. Sensitised red cells are then used as a marker. The Bio-Rad Solidscreen II is a solid-phase method for antibody screening and identification. The wells of the microplates are coated with protein A so that the reaction results in a solid-phase cell layer bound to the plate.

Individual laboratories need to make careful and informed decisions when selecting reagents for pretransfusion testing. It is vital that any abbreviated testing in an automated or semiautomated system is carefully evaluated for the risks that could ensue if important controls were omitted when using this technology for blood grouping.[12]

Laboratory information management systems (LIMS) store patient details and results of laboratory tests, allowing timely and accurate access to important information. In the transfusion department, IT systems have a much broader use, and the updated BCSH guidelines for the specification and use of IT systems in blood transfusion practice (2015) reflect this.[13] Where possible, using bi-directional or unidirectional interfaces to automated blood grouping analysers, IT systems are used to eliminate errors that can arise when a manual step is employed, including in interpretation of test results.

Computer algorithms support the 'electronic issue' of blood to patients with a negative antibody screen without the need to perform an antiglobulin crossmatch, and in the UK in 2014, 53% of laboratories were using this system for some or all of their patients (Fig. 22-2). The use of automation for all aspects of compatibility testing is now recommended practice and recognised as safer than manual techniques.[3] Automation brings several or all of the discrete activities of compatibility testing into a single-platform process. It provides various levels of increased security over manual testing and may provide justification for abbreviated pretransfusion testing (e.g. stopping duplicate D typing or reverse ABO grouping in the presence of a valid historical group). A risk assessment must be made and documented prior to any abbreviation of an established procedure, with consideration being given to the presence or absence of key functions in the automated equipment. The BCSH guidelines for

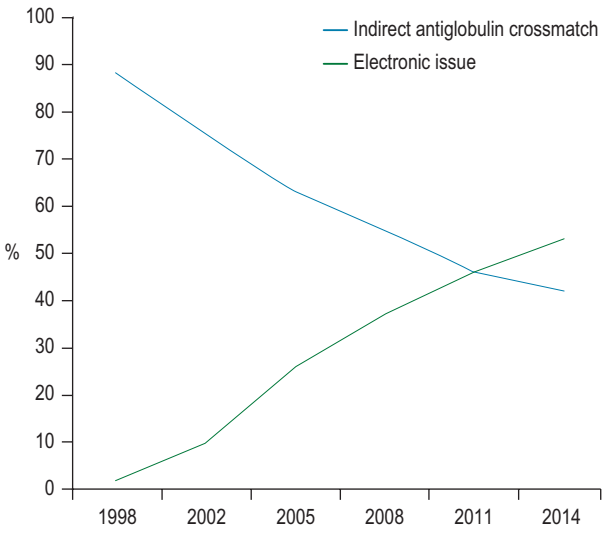

FIGURE 22-2 Change in proportion of UK laboratories issuing blood electronically 1998–2014.[11] *Data from UK NEQAS surveys indicating the increased use of electronic issue rather than compatibility testing in UK transfusion laboratories.*

pretransfusion compatibility procedures[12] and guidance from the MHRA[14] give a list of factors to be taken into consideration. The reader is advised to consult these prior to implementing automated or semiautomated systems.

PRETRANSFUSION COMPATIBILITY SYSTEMS

The process of providing blood for transfusion involves many steps, all of which have to be reliably completed. These include the following:

- Blood samples have to be taken from the correct patient and labelled at the bedside in a single uninterrupted procedure. The sample must be identified by four core patient identifiers handwritten on the sample label: the correctly spelled first name and last name, the exact date of birth and an accurate unique patient number (ideally the NHS number or equivalent, but a hospital medical records number is acceptable).[15] The sample should be dated and signed by the person taking the sample. The laboratory should have a policy for rejecting badly labelled samples. In a UK national comparative audit of collection and labelling of samples sent for pretransfusion testing, 2.99% were rejected.[16] The hospitals participating in this audit showed considerable variation in the content and application of sample acceptance policies. UK guidelines recommend that preprinted 'addressograph' labels are not accepted on blood samples for pretransfusion compatibility testing, because acceptance increases the risk of 'wrong blood in tube' (WBIT). In an international study from the Biomedical Excellence for Safer Transfusion (BEST) collaborative,[17] it was estimated that these miscollected samples occurred at a median rate of 0.5 per 1000, with a great variation worldwide in the reported frequency of mislabelled samples, probably resulting from variation in sample acceptance policies. Labels printed at the bedside using barcoded patient wristband and hand-held scanners are acceptable.[15] Unless secure electronic patient identification systems are in place, it is recommended that a second sample collected at a different time is taken for confirmation of the ABO group of a first-time patient prior to transfusion, as long as this does not impede the delivery of urgent red cells or other components.[12]
- A request for testing or issue of blood components can be made electronically, in writing or exceptionally in an urgent situation, by phone. In addition to the previously outlined four core patient identifiers, the request should include clear information about the source of the request and the location of the patient. Clinical details should include the justification for the request, such as the indication for transfusion. Previous transfusion history and any special considerations for the selection of blood components are also needed. Specific requirements could include antigen-negative red cells if the patient has a clinically significant antibody, extended matched red cells in a patient with a haemoglobinopathy or irradiated cellular blood components for certain groups of immunosuppressed patients. The use of 'order-comms' or computerised provider order entry (CPOE) systems can improve the accuracy and completeness of transfusion requests as well as being of use to challenge requests that do not comply with the hospital's transfusion policy.[18]
- An ABO and D group of the patient sample must be accurately performed.
- An antibody screen of the patient's plasma (or mother's plasma in the case of a neonate) should be able to detect any red cell antibodies of potential clinical significance. In the event of a positive red cell antibody screen, antibody identification should be undertaken to assist the selection of compatible blood.
- There should be a check of existing transfusion records to compare current and historical results. When LIMS are upgraded or replaced, results of previous ABO and D groups, antibody identification and specific requirements on the legacy system should preferably be migrated to the new LIMS, but alternatively should be accessible in real-time to support the correct selection of blood components for issue to named patients.[13]
- The appropriate blood component should be selected and issued to a named patient using a serological crossmatch or electronic issue.
- Traceable documentation should exist to ensure that the results of laboratory compatibility procedures are available at the patient's bedside to allow a check before transfusing the blood component. This should include a blood bag compatibility label (Fig. 22-3) and may include a compatibility form. The patient must be identified with an identification wristband containing the four core identifiers, and the blood component should be prescribed on a drug or fluid administration chart.[15] In some countries, an additional bedside check of the patient's blood group is undertaken prior to commencing the transfusion.

FIGURE 22-3 A unit of red cells showing the compatibility label.

Documentation of the transfusion process

All stages of the transfusion process must be clearly documented, and these records must be kept. In addition to guidance from the UK Royal College of Pathologists on the retention of pathological records and specimens,[19] the BSQR 2005 regulations stipulate that the records must be accessible for 30 years.[6] This allows any blood component to be traced from the donor to the recipient should information come to light about any potential infective risks to the recipient.

Computer records are easier to search than paper records, but LIMS are likely to become obsolete and be replaced several times within this mandatory 30-year period, so provision must be made to store historical data in an accessible format when procuring a replacement computer system.[13] Patient-held records are useful for patients who are treated in more than one institution, particularly if they have red cell antibodies and require phenotyped blood or if they have special requirements because of their underlying disease or its treatment. Credit card-sized records with corresponding patient information leaflets are issued by some transfusion centres to patients with red cell antibodies, and similar cards exist for patients who require irradiated cellular blood components.[20]

Blood samples and their storage requirements

Depending on laboratory practice, blood transfusion tests use a clotted (serum) sample or ethylenediaminetetraacetic acid (EDTA)-anticoagulated blood (plasma). Most laboratories using automated systems will use a plasma sample because it is difficult to make a cell suspension from a clotted sample. An incompletely clotted blood sample may contain small fibrin clots that trap red cells into aggregates that could resemble agglutinates that could be falsely interpreted as a positive reaction in an automated system. When plasma is used, complement is inactivated by the EDTA, which may result in complement-binding antibodies (e.g. of Kidd specificity) being missed or giving weak reactions by the indirect antiglobulin test (IAT). In serum samples the presence of complement can cause lysis. If laboratory staff are accustomed to recognising agglutination as an indicator of a positive reaction they may fail to interpret the lysed red cells as an equally valid positive reaction. Therefore, when using serum for blood grouping and compatibility testing, any red cells in the test system should be washed and resuspended in saline that contains EDTA (see later). In addition, false-negative reactions may occur in immediate spin crossmatching with potent ABO antibodies, where rapid complement fixation causes a prozone effect (bound C1 inhibits agglutination). EDTA saline is not necessary when using plasma.

Throughout this chapter, for the sake of brevity, the term 'plasma' is used, as the majority of UK laboratories are automated and therefore plasma samples are required. If serum samples are specifically required, this will be indicated in the text.

On being received in the laboratory, the details on the request form must be checked against the blood sample. Each blood sample must be labelled with a unique sample number. Barcode labels offer the advantage of positive sample identification and reduce the number of transcription errors. Samples inadequately or inaccurately labelled should NOT be used for pretransfusion testing.[12]

Great care must be taken to select and identify the sample prior to any testing. Transposition of samples in the laboratory can lead to an incorrect blood group being assigned to a patient, with serious consequences, including ABO incompatible transfusions.

Whole blood samples should be tested as soon as possible because they will deteriorate over time. Problems associated with storage include lysis of the red cells, bacterial contamination, decrease in potency of antibodies (particularly immunoglobulin (Ig) M antibodies) and loss of complement in serum samples. To ensure that the specimen used for compatibility testing is representative of a patient's current immune status, serological studies should be performed using blood collected no more than 3 days in advance of the actual transfusion when the patient has been transfused or has been pregnant within the preceding 3 months, or when such information is uncertain or unavailable. The BCSH guidelines from which this advice is taken[12] are summarised in Table 22-1.

Where possible, the primary sample should be used for testing. If samples are separated, the plasma must be clearly and accurately identified. It is important to have a system to ensure that the correctly identified sample has been retrieved from the storage location. If repeated testing on a sample is anticipated, storing separate small aliquots reduces the risk of sample deterioration, which occurs with repeated thawing/freezing of larger samples. If separated samples are stored for later serological testing or electronic issue, care must be taken to ensure that the patient has not been transfused in the interim. So although antibodies are probably stable for up to 6 months, it is safer to obtain another sample after 3 months.

It has been recommended that samples should be retained for at least 3 days post-transfusion for investigation of acute transfusion reactions and where feasible stored for 7–14 days post-transfusion to enable investigation of delayed transfusion reaction.[12,19]

TABLE 22-1

WORKING LIMITS FOR USE OF STORED WHOLE BLOOD AND PLASMA FOR PRETRANSFUSION TESTING OF SAMPLES USED FOR COMPATIBILITY TESTING[12]

	Sample Type		
Patient Type	Whole Blood at Room Temperature	Whole Blood at 2–8 °C	Plasma at −30 °C
Patient transfused or pregnant within last 3 months	Up to 48 h	Up to 3 days*	Not applicable
Patient not transfused or pregnant in last 3 months	Up to 48 h	Up to 7 days	Up to 3 months

*This is the time between the sample being taken and the subsequent transfusion.

QUALITY ASSURANCE IN THE TRANSFUSION LABORATORY

Test systems used for pretransfusion testing are important because errors can and do lead to patient morbidity and mortality. Chapter 25 covers the general aspects of a laboratory quality assurance system, and specific guidance for transfusion laboratories can be found in the BCSH guidelines for validation and qualification[21] as well as the guidelines for pretransfusion compatibility procedures in blood transfusion laboratories.[12]

The quality management system for a hospital transfusion laboratory should include the following:

- **Quality control:** The appropriate use of internal quality controls and participation in external quality assessment exercises where available.
- **Validation:** Automated equipment and computer systems should be validated to ensure that they function as specified and back up procedures should be in place to cover the failure of automated equipment and computers.
- **Policies and procedures:** There should be standard operating procedures (SOPs) available which cover all aspects of the laboratory work, and these must be reviewed and updated regularly.
- **Reagents, calibrators and control materials:** They should correspond to the specification given in the Guidelines for the Blood Transfusion Services[22] and should be used in accordance with the manufacturer's instructions. As they are included under the In-vitro Diagnostics (IVD) Medical Devices Directive they must be CE (Conformité Européenne) marked (www.gov.uk/ce-marking).
- **Preventative maintenance:** The regular checking and maintenance of all laboratory equipment must be documented.
- **Training and competency testing:** Laboratory tasks should only be undertaken by appropriately trained staff, and there should be a documented programme for training laboratory staff, which covers all SOPs in use and which fulfils the documented requirements of the laboratory. There must be a documented programme for assessing staff proficiency, which should include details of the action limits for retraining.
- **Quality incidents and exceptions:** There should be a system in place for documenting and reviewing all incidents of noncompliance with procedures. A programme of independent audits should be conducted to assess compliance with documented 'in-house' procedures.

ABO AND RhD GROUPING

Fully automated systems should be used where possible to reduce the risks of interpretation and transcription errors. ABO and RhD (D) grouping must be performed by a validated technique with appropriate controls. Before use, all new batches of grouping reagents should be checked for reliability by the techniques used in the laboratory. Grouping reagents should be stored according to the manufacturer's instructions.

ABO grouping

ABO grouping is the single most important serological test performed in compatibility testing; consequently, it is imperative that the sensitivity and security of the test system is not compromised. The fact that anti-A and anti-B are naturally occurring antibodies allows the patient's plasma to be tested against known A and B cells in a 'reverse' group. This is an excellent built-in check. Fully automated analysers linked to secure LIMS have the ability to prevent erroneous ABO grouping due to errors in either transcription or interpretation, with the consequence that some laboratories now omit the reverse group when testing samples for which a historical group is available.[12] This should only be considered following a careful risk assessment and taking into account that the first sample taken may have been from the wrong patient. This has been estimated to be in the order of 1:2000 samples.[17] A full group should therefore be performed on all samples from first-time patients, with the exception of those from neonates since red cell antibodies are not usually produced within the first 4 months of life,[23] and any reactions found in the reverse group are therefore likely to arise from maternal ABO antibodies. Any

discrepancy between the forward and reverse groups should be investigated further, and any repeat tests should be undertaken using cells taken from the original sample rather than from a prepared cell suspension.

Reagents for ABO grouping

Monoclonal anti-A and anti-B reagents have replaced polyclonal reagents in routine grouping tests. A_1 and B cells are used for reverse grouping; group O cells or an 'auto control' may be included to ensure that reactions with A and B cells are not a result of the presence of cold autoantibodies. A diluent control should be included where recommended by the manufacturer.

D grouping

D grouping is usually undertaken at the same time as ABO grouping for convenience and to minimise clerical errors that may arise through repeated handling of patients' samples. In the absence of secure automation, testing should be undertaken in duplicate, as there is no counterpart of the 'reverse' grouping of ABO testing.

Reagents for D grouping

Monoclonal reagents do not have the problem of possible contamination with antibodies of unwanted specificities, as was the case with polyclonal reagents. With secure automation, a single IgM monoclonal anti-D reagent that does not detect DVI (see below) may be used. If secure automation is not in use, each sample should be tested in duplicate with either the same anti-D reagent or with two different IgM monoclonal anti-D reagents.

DVI is the partial D with the fewest epitopes; therefore of all the D variants, DVI individuals are those most likely to form anti-D, and a case of severe haemolytic disease of the fetus and newborn (HDFN) has been described.[24] The use of anti-CDE reagents has led to the misinterpretation of r′ and r″ cells as D positive in UK National External Quality Assessment Service (NEQAS) exercises, and because they are of no value in routine patient typing, their use is not recommended.[11,12] Monoclonal anti-D reagents will allow detection of all but the weakest examples of weak D, negating the need to use more sensitive techniques to check the D status of apparent D negatives. However, monoclonal anti-D reagents vary widely in their ability to detect both partial and weak D, so it is helpful to use two of a similar affinity to reduce the number of discrepancies due to the detection of weak D.[12]

Some anti-D reagents have high levels of potentiator (e.g. polyethylene glycol, PEG) and should be used with caution; a diluent control is essential to demonstrate that the diluent does not promote agglutination of the test red cells as may happen if the patient's cells are coated *in vivo* with IgG; any positive reaction seen with the control, however weak, invalidates the test result. Anti-D reagents are provided by many manufacturers, and those responsible for selection and purchase should make themselves aware of the content, specificity and potentiation of the chosen reagent.

Methods

There are several techniques available for routine ABO and D grouping, including both manual tube and slide tests and liquid-phase and solid-phase microplates and columns that can be used in both manual and automated settings. Care should be taken to use the appropriate reagent, because not all reagents have been validated by the manufacturer for all techniques.

The techniques are described above (in the section on **Technology and Automation in Blood Transfusion Laboratories, p. 472**) and also in more detail in Chapter 21. Molecular techniques for ABO blood grouping are not in routine use because serology is superior, being quicker, cheaper and accurate. ABO genotyping can be helpful to investigate anomalous ABO groups and is in use in organ transplantation where red cells from the donor are not available as well as in forensic practice and paternity testing.[25,26]

Tube and slide tests. Spin-tube tests may be used for urgent testing, where small numbers of tests are performed at once. Slide or tile techniques are widely used in under-resourced countries for ABO and D grouping. Immediate spin tests may be used in an emergency, whereas routine tests are usually left for 15 min at room temperature (about 20 °C) before centrifugation for 1 min at 150 *g*. Equal volumes (1 or 2 drops from either a commercial reagent dropper or a Pasteur pipette) of liquid reagent or plasma and 2% cell suspensions are used. The patient's red cells (diluted in phosphate buffered saline, PBS) should be tested against monoclonal anti-A and anti-B grouping reagents. The patient's plasma should be tested against A_1 and B reagent red cells (reverse grouping). In addition, the plasma should be tested against either the patient's own cells or group O cells (i.e. a negative control) to exclude reactions with A and B cells as a result of cold agglutinins other than anti-A or anti-B in the patient's sample. Mix the suspensions by tapping the tubes and leave them undisturbed for 15 min. Agglutination should be read as described on p. 451.

Slide method. In an emergency, rapid ABO grouping may be carried out on slides or tiles. The method is satisfactory if potent grouping reagents are used. An immediate spin-tube test is preferable.

Liquid-phase microplate methods. Liquid-phase microplate technology provides a relatively inexpensive and secure method for batch testing when semiautomation is utilised for dispensing and reading, but it is no longer the grouping technique of choice in the UK. In 2015 a UK NEQAS survey showed that <1% of responding laboratories were using liquid phase microplates for manual grouping, down from 41% in a similar survey in 2002.[11]

FIGURE 22-4 Column agglutination technology showing ABO/D blood group.

Column agglutination techniques. Column agglutination techniques are now the commonest method for grouping in the UK (85% of laboratories who responded to a UK NEQAS survey in 2014), especially where automated systems are in place. There are several different profiles to choose from, and some cards/cassettes include monoclonal antibodies to other blood group antigens (e.g. K). The manufacturer's instructions should always be followed. An example is shown in Figure 22-4, and more details can be found in Chapter 21.

Solid-phase techniques. ABO/D grouping using solid-phase techniques would usually be part of a fully automated system, and testing should be in accordance with the manufacturer's instructions. Bio-Rad Erytype (www.bio-rad.com) employs a standard agglutination technique for blood grouping performed in a microtitre plate. The reagents for the forward group are dried onto the wells. Uncoated empty wells are used with standard reagent red cells for a reverse group.

Controls for ABO and D grouping

Positive and negative controls should be included with every test or batch of manual tests. In fully automated systems, the controls should be set up at least twice in a 24-h period. The timings should take account of the length of time that reagents have been kept on the analyser. Controls should be run at start-up and when changing reagent lot numbers. Control samples should be loaded in the same way as the test samples. Where controls do not give the expected reactions, investigations should be undertaken to determine the cause of the problem and also to confirm the validity of all tests undertaken subsequent to the most recent valid control results.

Causes of discrepancies in ABO/D grouping

False-positive reactions

Rouleaux. Rouleaux may occur in various clinical conditions, where the ratio of normal albumin to globulin is altered in plasma (e.g. in multiple myeloma) and in the presence of plasma substitutes such as dextrans. The stacking of red cells on top of one another in columns may be misinterpreted as weak agglutination by inexperienced workers. Rouleaux will usually disperse on a slide if a drop of saline is added; alternatively, the reverse grouping can be repeated using plasma diluted 1 in 2 or 1 in 4 with saline.

Cold autoagglutination and cold reacting alloantibodies. Cold autoantibodies (usually anti-I) that are reactive at room temperature may lead to autoagglutination in the cell group (ABO and D) and panagglutination in the reverse group, causing a grouping anomaly (p. 262). The tests should be repeated using cells washed in warm saline and plasma prewarmed to 37 °C. An auto control should be included.

Cold reacting alloantibodies (e.g. anti-P_1) may cause agglutination of reverse grouping cells, and if this is suspected, reverse grouping should be repeated using prewarmed plasma or grouping cells that lack the implicated antigen.

T-activation/polyagglutination. Polyagglutination[27] describes agglutination of red cells by all or most normal adult sera but not by the patient's own serum. This is the result of IgM antibodies reacting with an antigen on the red cells, which is usually hidden but can be exposed by enzyme activity. The most common form is T-activation, which occurs when the bacterial enzyme neuraminidase cleaves *N*-acetyl neuraminic acid from the red cell membrane, exposing the T antigen.

This used to be a problem when grouping with polyclonal reagents, which contain anti-T, but tests using monoclonal reagents are not affected by this phenomenon.

Acquired B. This arises in group A_1 patients where the expected reaction with anti-A is noted but an *additional* weak reaction with anti-B occurs. The blood group appears to be 'AB' but with anti-B in the reverse group. This discrepancy between the forward and reverse grouping may be overlooked if the patient's own anti-B is weak or if the reverse group is omitted.

The acquired B antigen is usually caused by a bacterial deacetylase enzyme acting on A_1 red cells and producing a B-like substance. Some anti-B reagents react strongly with the acquired B antigen (e.g. those derived from the ES4 clone).[28] Such anti-B reagents are rare but should be avoided in routine blood grouping.

Potentiators. Red cells may be coated with IgG as a result of *in vivo* sensitisation. The use of potentiated

techniques, such as the antiglobulin test for D typing, or of potentiated reagents for ABO or D typing, may result in a false-positive reaction; the latter would also result in a positive reaction with the diluent control, but UK NEQAS data have shown that some laboratories fail to include an appropriate control or fail to understand the significance of a positive control.[29] For this reason, use of potentiated techniques or reagents for blood grouping is not advised.

***In vitro* bacterial contamination.** *In vitro* bacterial contamination of reagents, patients' red cells or reverse grouping cells may cause false-positive agglutination.

False-negative reactions

Failure to add reagents. The most likely cause of a false-negative grouping result is failure to add the reagent or test plasma. For this reason, in liquid-phase tube and plate tests, the serum or plasma should always be added first to the reaction chamber, and a visual check should be made before red cells are added. The use of colour-coded reagents for ABO grouping is helpful in this respect. Automated systems have liquid level sensors resulting in an alert indicating failure to add reagent or test plasma.

Loss of potency. Inappropriate storage or freezing and thawing may cause a loss of potency of blood grouping reagents. The regular use of controls will alert the user to this problem.

Failure to identify lysis. In the presence of complement, anti-A and anti-B may cause *in vitro* lysis of reagent red cells. If lysis is not recognised as a positive reaction, falsely negative results may be recorded in reverse grouping tests. To avoid this, reverse grouping cells should be resuspended in EDTA saline, where serum rather than plasma is used.

Mixed-field appearance. This describes a dual population of agglutinated and nonagglutinated red cells, which may be observed in both ABO and D grouping. It is important to recognise this as a mixed-field picture and not to confuse it with weak agglutination. The most likely cause of a mixed-field picture is the transfusion (either deliberate or accidental) of nonidentical ABO or D red cells. Investigation will be required to determine the actual blood group of the patient, who may have been transfused in an emergency or at a different establishment or who may have received an intrauterine transfusion. A mixed-field ABO group may be the first indication of a previous ABO-incompatible transfusion.

An ABO- or D-incompatible haemopoietic stem cell transplant will result in a mixed-field picture until total engraftment has occurred; the mixed-field picture may subsequently reappear if the graft is failing. Rarely, a dual population of cells is permanent and results from a weak subgroup of A (A_3) or a blood group chimaerism.

Interpretation of a dual population of red cells will depend on the technique used. In a tube, microscopic reading will reveal strong agglutinates in a background sea of free cells. In CAT cards/cassettes there will be a line of agglutinated cells at the top of the column, with the nonagglutinated cells travelling through to the bottom of the column (Fig. 22-5). In liquid-phase techniques, if the reaction grade is not a strong positive or an obvious negative then the reaction requires further investigation, which may include microscopic examination. In a solid-phase technique a mixed field is seen as a dual population of cells, with the agglutination being surrounded by free cells. Automated systems should be set up to detect mixed-field pictures, and this should be used in conjunction with local policies.

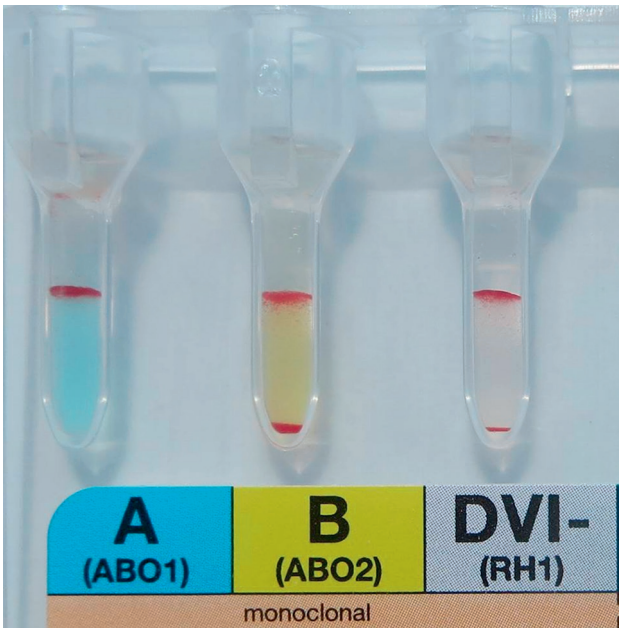

FIGURE 22-5 Column agglutination technology showing mixed field/dual population.

D variant phenotypes. Most people are either D positive or D negative, but a minority have a variant D type, historically categorised as weak or partial D. People with a partial D antigen can make anti-D to the epitope(s) of the D antigen which they lack, when sensitised to D-positive red cells by transfusion or pregnancy. Historically, those classified as weak D, with fewer D antigen sites per red cell, but no missing epitopes, were considered unable to make anti-D, and could therefore be treated as D positive. There are two problems with using this concept to decide on whether to treat a patient as D positive or D negative: firstly, it is not always possible to distinguish serologically between weak and partial D, as many partial D antigens are also phenotypically weak; secondly, there have been many reports of patients with a variant defined as weak D having made anti-D. Daniels has suggested replacing the terms weak and partial D with a single term of D variant.[30]

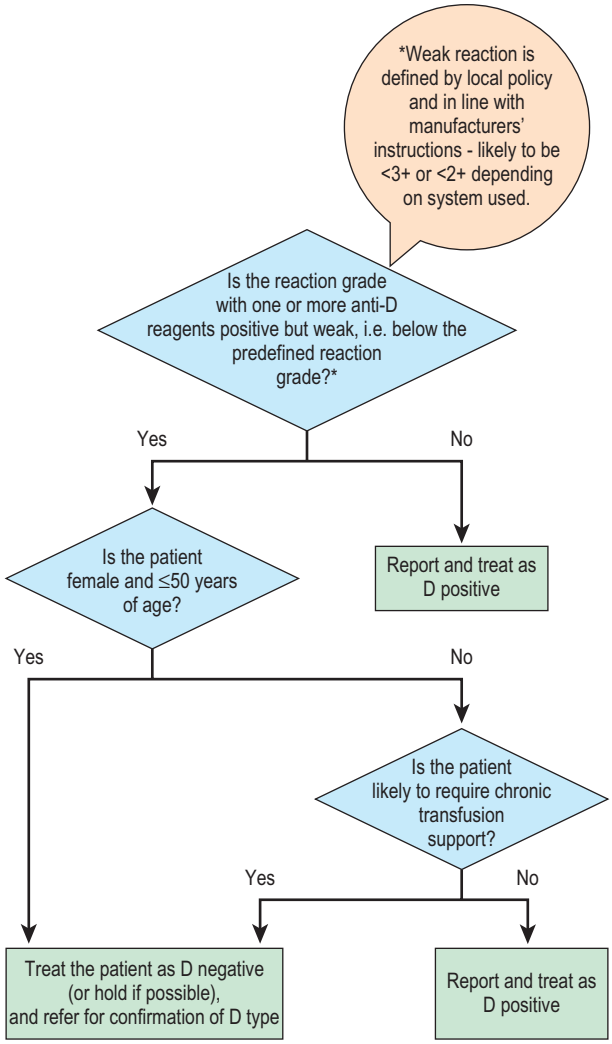

FIGURE 22-6 Algorithm of the reporting of D typing anomalies and selection of red cells. *With permission from British Committee for Standards in Haematology, Milkins C, Berryman J, Cantwell C, et al. Guidelines for pretransfusion compatibility procedures in blood transfusion laboratories.* Transfus Med *2013:**23**;3–35.*

In the previous edition it was recommended that a weak reaction with a single anti-D reagent should be investigated with a second anti-D reagent before assigning a result of D positive. However, in the UK, a new patient-based algorithm has been recommended (Fig. 22-6), whereby following a weak reaction with anti-D, samples from children, from women of child-bearing potential and from any patient likely to be transfusion dependent, should be investigated to determine the specificity of the D variant, with the patient being treated as D negative in the meantime. All other patients can be reported as D positive, without further investigation.[12] Weak D types 1, 2 and 3 are the most common weak D types in a Caucasian population and rarely, if ever, make anti-D. Types 1 and 2 can be distinguished from other D variants using a panel of monoclonal antibodies, and such patients can be regarded as D positive. Identification of type 3 requires molecular testing, so if this is unavailable or not cost effective, a practical guide is to regard vulnerable patients (see above) other than those confirmed as types 1 and 2 as D negative. If in doubt, it is safer to call the patient D negative. This will be of no clinical consequence because it is safe to transfuse D negative blood to a patient who is D positive, and a pregnant woman who is D positive and her unborn child would be unlikely to be harmed by the injection of prophylactic anti-D Ig.

It is essential to be able to distinguish between a weak reaction and a mixed-field reaction because the latter may be the result of a patient having been transfused with blood of a different D type.

Because DVI lacks the most epitopes, such individuals are likely to make anti-D when challenged by transfusion or pregnancy. For this reason, current advice about choice of D-typing reagents is that anti-D reagents for routine grouping of patients' samples should not detect DVI.[12] There is little evidence to suggest that a DVI donor would elicit an immune response in a recipient who is D negative; however, weak D positive and partial D donors, including DVI donors, should be classified as D positive.[30] There are some important ethnic differences in the frequency of different Rh haplotypes, as shown in Table 22-2.

TABLE 22-2

APPROXIMATE FREQUENCIES OF COMMON Rh HAPLOTYPES IN SELECTED POPULATIONS[64]

Haplotype	Approximate Frequencies		
	English	Nigerian	Chinese
DCe R^1	0.421	0.060	0.730
dce r	0.389	0.203	0.023
DcE R^2	0.141	0.115	0.187
Dce R^0	0.026	0.591	0.033
dcE r″	0.012	0	0
dCe r′	0.010	0.031	0.019

ANTIBODY SCREENING

Antibody screening is usually undertaken at the same time as blood grouping and in advance of selecting blood for transfusion. Antibody screening may be more reliable and sensitive than crossmatching against donor cells because some antibodies react more strongly with red cells with homozygous expression (double dose) of the relevant antigen than with those with heterozygous expression (single dose) – most notably anti-Jk^a/Jk^b but also anti-Fy^a, -Fy^b, -S and -s. Screening cells can be selected to reflect this, whereas the zygosity of donors is usually unknown and some will be heterozygous. Red cells for antibody

screening are preserved in diluents shown to minimise loss of blood group antigens during storage. In addition, reagent red cells are easier to standardise than donor cells and there is potentially less opportunity for procedural error, particularly in automated systems.

Clinically significant antibodies are those that are capable of causing haemolytic transfusion reactions or haemolytic disease of the fetus and newborn (HDFN). With few exceptions, clinically significant antibodies are those that are reactive in the IAT at 37 °C; however, it is not possible to predict serologically which of these antibodies will definitely be of clinical significance, so the term 'of potential clinical significance' is often used.

Red cell reagents

The patient's plasma should be tested against at least two individual screening cells, used individually, not pooled. The screening cells should be group O and encompass the common antigens of the population.

In the UK, the following antigens should be expressed as a minimum: C, c, D, E, e, K, k, Fy^a, Fy^b, Jk^a, Jk^b, S, s, M, N, P_1, Le^a and Le^b; one cell should be R_2R_2 and another R_1R_1 or $R_1^wR_1$. The following phenotypes should also be represented in the screening set: Jk(a+b−), Jk(a−b+), S+s−, S−s+, Fy(a+b−) and Fy(a−b+) (Table 22-3). These recommendations for homozygosity are based on UK data regarding the incidence of delayed haemolytic transfusion reactions, the need for high sensitivity in the detection of Kidd antibodies and the poorer performance of column agglutination techniques in the detection of some examples of Kidd antibodies using heterozygous cells.[12,22] The requirement for the expression of C^w and Kp^a antigens on screening cells has been the cause of much debate, but in the UK and the USA detection of anti-C^w or anti-Kp^a is not a requirement even in the absence of an antiglobulin crossmatch.[12,21] This is because these are low-frequency antigens and the antibodies rarely cause delayed haemolytic transfusion reactions or severe HDFN.

TABLE 22-3

EXPRESSION OF RED CELL ANTIGENS ON SCREENING CELLS[12,22]

Blood Group System	Antigen	Homozygous Cells Recommended
Rh	C	Yes (R_1R_1 or $R_1^wR_1$)
	c	Yes (R_2R_2)
	D	Yes (R_1R_1 and R_2R_2)
	E	Yes (R_2R_2)
	e	Yes (R_1R_1 or $R_1^wR_1$)
Kell	K	No*
	k	No
Duffy	Fy^a	Yes
	Fy^b	Yes
Kidd	Jk^a	Yes
	Jk^b	Yes
MNSs	M	No
	N	No
	S	Yes
	s	Yes
Lewis	Le^a	No
	Le^b	No
P	P1	No

*Although desirable, KK cells are unlikely to be available.

Methods

Antibody screening should always be carried out by an IAT as the primary method. Additional methods (e.g. two-stage enzyme or Polybrene) may also be used but are inferior for the detection of some clinically significant antibodies and should not be used alone. A large retrospective study showed that the vast majority of antibodies reactive only by enzyme technique are of no clinical significance.[31] In Issitt's study of 10 000 recently transfused patients, only one anti-c, initially unreactive by IAT, caused a delayed haemolytic transfusion reaction.[32] There has been one SHOT report (1998–1999) of an enzyme-only anti-E that became detectable by IAT 7 days following the transfusion, causing a delayed haemolytic transfusion reaction and subsequent death of the patient due to renal failure.[2]

For liquid-phase techniques, BCSH guidelines[12] recommend the use of red cells suspended in low ionic strength saline (LISS), rather than in standard normal ionic strength saline (NISS), because LISS increases the speed and sensitivity of detection of many potentially clinically significant antibodies (see Chapter 21). There are conflicting reports about whether sensitivity can also be improved by adding PEG.[33]

Indirect antiglobulin techniques

Column agglutination

In many countries, including the UK, column agglutination is now more commonly used than traditional tube or liquid-phase microplate techniques, because it has been shown to be at least as sensitive as a standard LISS spin-tube technique,[34,35] it is simpler to perform because it requires no washing phase, it uses small volumes of plasma and reagents, it has a more objective reading phase and it is easy to automate. The antihuman globulin (AHG) incorporated in the matrix is available as either a polyspecific or anti-IgG reagent. Red cell concentrations and volumes can be critical and it is important to follow manufacturers' instructions at all times.

Column agglutination crossmatching tests have been shown to be less sensitive than standard tube techniques in the detection of weak ABO antibodies such as anti-A with A_2B cells[36] and Kidd antibodies with heterozygous red cells.[37] It has been suggested that these failures may be

the result of shear forces occurring during centrifugation, which cause weak agglutinates to be disrupted, especially when the antigen density is low.[37]

Solid-phase systems

Solid-phase techniques (e.g. Immucor Capture-R and Bio-Rad Solidscreen II) are also becoming more popular because they have been shown to have a high level of sensitivity, and they also lend themselves to full automation. In 2014, 11% of UK laboratories were routinely using solid phase for antibody screening.[11]

Liquid-phase techniques – tubes and microplates

Tube techniques are still used for antibody screening in some parts of the world. With LISS-suspension techniques it is important to maintain a high serum:cell ratio, without affecting the ionic strength. Equal volumes of serum and 1.5–2% cells suspended in LISS will result in a serum:cell ratio of >60:1, ensuring optimal sensitivity. Reagents should be incubated for 15–20 min at 37 °C, and the cells then should be washed in PBS. After AHG is added, the red cells should be examined using a careful 'tip and roll' procedure to prevent disruption of weak agglutinates. Reading aids such a light box or concave mirror may also be used with this technique.

Liquid-phase microplate technology has never achieved a huge popularity for antibody screening because it is relatively difficult to introduce and standardise, and it cannot be automated. Because it is becoming increasingly difficult to obtain AHG reagents standardised for use in microplates, no method is detailed here.

Controls for antibody screening

A weak anti-D should be used on a regular basis to ensure the efficacy of the whole procedure, although the exact frequency will depend on work patterns as described in the blood grouping section. Additional weak controls are also recommended to confirm the sensitivity of the procedure and the integrity of the red cell antigens throughout their shelf life; anti-Fy^a and/or anti-S are good examples because Fy and S antigens are protease labile and may deteriorate more quickly on reagent cells than the D antigen, and their use will also ensure that enzyme-treated cells have not been used by mistake. Consideration should also be given to selecting controls that demonstrate that the correct screening cell has been added to the batch of tests. Anti-S can be used as a control following the use of bleach to clean automated blood grouping analysers to check no cleaning fluid remains; the S antigen is very sensitive to Clorox bleach (www.clorox.com).

The use of red cells weakly sensitised with anti-D is essential to control the washing phase of every negative liquid-phase test because inadequate washing may result in complete or partial neutralisation of AHG by unbound globulin. Any test that does not give a positive reaction at the expected strength following addition of these cells (and subsequent centrifugation) indicates insufficient free anti-IgG and should be repeated. The washing phase of solid-phase systems is difficult to control and it may be necessary to add a weak control to every column to ensure that every probe has dispensed wash solution during each wash cycle.

ANTIBODY IDENTIFICATION

When an antibody is detected in the antibody screen, its specificity should be determined, and its likely clinical significance should be assessed before blood is selected for transfusion or relevant advice is given during pregnancy. It is essential to use a systematic approach to antibody identification to ensure that all specificities of potential clinical significance are identified. It may be tempting to match a reaction pattern immediately and look no further, but this is likely to result in additional specificities being missed.

Principles

As a starting point, the test plasma should be tested against an identification panel of reagent red cells by the technique with which it was detected in the screen. The next section on reagents outlines the minimum requirements for the panel. Inclusion of an autoantibody test is helpful in distinguishing between an autoantibody, an antibody directed against a high-frequency antigen and a complex mixture of alloantibodies. The positive and negative reactions should be compared with the panel profile in conjunction with the screening results.

Each antibody specificity should be considered in turn, and its presence should be systematically excluded by identifying antigen-positive cells that have given negative reactions. Wherever possible a negative reaction should be obtained with a red cell with homozygous expression of the relevant antigen. For example, if a negative reaction has been recorded against a Jk(a+b−) cell, then the presence of anti-Jk^a can be excluded, but if the only negative reactions are against Jk(a+b+) cells, then anti-Jk^a cannot immediately be safely excluded. This will leave a list of potential specificities that should be considered by matching the positive reactions to the antigen-positive cells to determine if any are definitely present. Once this process is complete with the initial screen and identification panel, further cells and techniques may need to be used to complete the exclusion process. For example, where anti-S has been identified as being present, an enzyme-treated panel may be required to exclude the presence of anti-E, if all of the E-positive cells were also S positive, or a K+S− cell may need to be selected to exclude the presence of anti-K. The more specificities present, the more complicated the process, and where resources are limited, samples may need to be sent to a reference centre to elucidate all specificities. If the reagents are available, phenotyping the patient's red cells early on in the process will allow exclusion of specificities for which the patient is antigen positive.

The specificity of an antibody should only be assigned when it is reactive with at least two examples of reagent red cells carrying the antigen and nonreactive with at least two examples of reagent red cells lacking the antigen. This is because a single positive reaction could occur if the panel cell unexpectedly expressed a low-frequency antigen and a single negative reaction could occur if the panel cell lacked a high-frequency antigen.

Phenotyping

When an antibody has been identified, the patient's own red cells should be phenotyped for the relevant antigen. If the patient's red cells are negative for the antigen, this confirms that the patient is capable of making an antibody of that particular specificity. If the patient's red cells are positive for the antigen this suggests one of the following:

1. The antibody is an autoantibody, in which case the direct antiglobulin test (DAT) should be positive.
2. The patient has been transfused recently and the reagent is detecting transfused cells rather than the patient's own cells. Care should be taken to look for a mixed-field reaction. Evidence of a delayed transfusion reaction should be sought.
3. The initial antibody identification result is incorrect.
4. The patient's red cells are Ig-coated with a positive DAT. Care should be taken, particularly when using reagents potentiated with PEG, to recognise this to prevent reporting a false-positive result.

Extended phenotyping can be helpful where a mixture of antibodies is present because it allows the exclusion of antibodies specific for antigens for which the patient is positive, reducing the number of additional reagent cells required.

Additional panels/techniques

The chances of identifying antibodies when two specificities are present are significantly improved by using a two-stage enzyme technique, if at least one of the relevant antigens is affected by enzymes. For example, Rh antibodies are enhanced by proteolytic enzymes in routine use, whereas M, N, S, Fy^a and Fy^b antigens are destroyed. Similarly, two different panels of reagent cells provide an increased chance of excluding further specificities where a mixture of two antibodies has been identified.

Direct agglutination at room temperature or 4 °C may be helpful to distinguish between an antibody of potential clinical significance and a cold reacting antibody; again this is particularly useful where a mixture of antibodies is present. Weak examples of Kidd antibodies are often enhanced by the use of an IAT using enzyme-treated cells, and this can be particularly helpful where the antibody is only reacting against homozygous cells by the IAT.

Reagents

An identification panel should consist of red cells from at least eight group O donors, although 10 is more common in commercial panels and allows easier elucidation of antibody mixtures. To be functional, the panel must permit confident identification of the most commonly encountered, clinically significant antibodies. The UK guidelines[12] can be summarised as follows:

1. For each of the commonly encountered clinically significant red cell antibodies, there should be at least two examples of phenotypes lacking, and at least two examples of phenotypes expressing, the corresponding antigen.
2. There should be at least one example of each of the phenotypes R_1R_1 and $R_1^wR_1$. Between them, these two samples should express the antigens K, k, Fy^a, Fy^b, Jk^a, Jk^b, M, N, S and s.
3. There should be at least one example of each of the phenotypes R_2R_2, r′r and r″r and at least two examples of the phenotype rr.
4. The following phenotypes should be expressed in those samples lacking both D and C antigens: K+, K−, Jk(a+b−), Jk(a−b+), S+s−, S−s+, Fy(a+b−) and Fy(a−b+). The panel should be able to resolve as many likely antibody mixtures as possible.

Antibody cards

Delayed haemolytic transfusion reactions can occur when antibodies have not been detected in the current antibody screen or have been *incorrectly* identified.[1] It has been suggested that antibody cards, produced either by the hospital or the reference centre, be carried by the patient for presentation on admission to hospital. To be effective, such cards have to be accompanied by patient information leaflets, explaining the significance of the antibodies and preferably handed personally to the patient by someone with a clear understanding of blood transfusion practice. There are potential pitfalls with this suggestion, not least that the level of proficiency in identifying antibodies and appreciating their clinical significance varies between establishments. A better long-term approach may be to have a national database of patients who have been identified as having clinically significant antibodies.

SELECTION AND TRANSFUSION OF RED CELLS

Once the blood group of a patient has been established and any antibodies have been identified, a set of procedures is required to select units of red cells that are appropriate for transfusion. These include selecting ABO/D-compatible units, which will also need to be negative for antigens to which the recipient has clinically significant alloantibodies (Table 22-4). It is also important that consideration is given to certain clinical criteria dictating specific requirements

TABLE 22-4

RECOMMENDATIONS FOR THE SELECTION OF BLOOD FOR A PATIENT WITH RED CELL ANTIBODIES

System	Antibody	Recommendation
ABO	Anti-A_1	IAT crossmatch compatible at 37 °C
Rh	Anti-D, -C, -c, -E, -e	Antigen negative*

IAT, indirect antiglobulin test.
*Antigen negative and crossmatch compatible.
† These recommendations apply when the antibody is present as a sole specificity. If present in combination, antigen-negative blood may be provided by the blood centre to prevent wastage of phenotyped units.

(e.g. the requirement for irradiated or washed red cells). Selection according to these criteria depends on good clinical information, accurate ABO and D typing and a sensitive antibody screen.

Some patients are identified as definitely needing transfusion of blood, but others may be undergoing surgery where blood is crossmatched to 'stand by'. Audits have shown that blood is often crossmatched but not transfused. The transfusion ratio, or crossmatch index, can be used to assess how well blood stocks are managed. One option is to perform a blood group and antibody screen on a patient and then save the sample, only crossmatching blood if certain pre-agreed transfusion triggers are met. Local policy should define a maximum surgical blood ordering schedule, indicating which surgical procedures can be 'group and screen/group and save' and how many units of blood need to be crossmatched for procedures with a high likelihood of intraoperative transfusion. The decision as to whether blood is crossmatched in advance may relate to local factors, including the proximity of the blood transfusion laboratory to the operating theatre (or other location where blood is to be transfused) and the time it takes to provide compatible blood following a request.

Once the appropriate red cells have been selected, compatibility needs to be ensured. This is usually referred to as crossmatching, which may include an IAT to check for incompatibility as a result of IgG antibodies and ABO antibodies or an immediate spin test to check for ABO incompatibility only. Instead of a serological test, an assessment of ABO compatibility may be based on a 'computer check', usually referred to as 'electronic issue'. Some transfusion laboratories, where surgery takes place in a different hospital, have extended electronic issue to the selection of compatible units, as dictated by the transfusion laboratory, from a remote issue refrigerator.[38]

The purpose of crossmatching blood is to prevent the transfusion of incompatible red cells and a subsequent haemolytic transfusion reaction. The different types of crossmatch are outlined in the following paragraphs. Whichever crossmatch technique is chosen, it should be clear that all patients with known red cell antibodies of potential clinical significance, even if currently undetectable, should have an indirect antiglobulin crossmatch and are not suitable for electronic issue.[12,13]

CROSSMATCHING

Indirect antiglobulin crossmatch

The IAT crossmatch is used to detect both ABO and non-ABO incompatibility between recipient plasma and individual donor red cells. The IAT crossmatch is the default technique to be used in the absence of functioning validated IT or when electronic issue is contraindicated.

Methods for IAT crossmatching are the same as those used for antibody screening. Crossmatching may be less

effective than antibody screening at detecting incompatibility as a result of IgG antibodies. This is partly because the cells may only show heterozygous expression of an antigen to which the patient has an antibody, potentially leading to weaker or negative reactions, and also because the cell suspensions and other techniques (e.g. cutting pigtails from donations, labelling tubes, washing cells) are less likely to be standardised and present more opportunity for transposition errors than the screening processes.

An IAT crossmatch should always be performed if the patient has red cell antibodies of likely clinical significance, even if currently undetectable. The reasons for this are as follows:

1. It acts as a double check that the donation has been correctly phenotyped and labelled as negative for the corresponding antigen(s)
2. It ensures serological compatibility even if the identification of the antibody(ies) is incorrect or incomplete
3. It allows detection of antibodies to low-frequency antigens not present on the screening cells, which may be more likely to be present in a patient who is clearly a 'responder' and which may be masked by other alloantibodies.

Other circumstances in which an IAT crossmatch should be performed include the following:

1. The patient has had an ABO-incompatible solid organ transplant and is being transfused within 3 months of the transplant. This is necessary to detect IgG antibodies that may be produced by passenger lymphocytes in the transplanted organ.[39]
2. The patient has an alloantibody of low clinical significance detectable in the routine antibody screen, such as anti-C^w.
3. The patient has cold-reacting antibodies. In this case blood may be issued if compatible in the antiglobulin crossmatch performed strictly at 37 °C, without the need for antigen-negative blood.

Saline spin crossmatch

The saline spin test has previously been called the 'immediate spin' crossmatch. The reason for the change in nomenclature is because the previous name gave the incorrect impression that the test was centrifuged as soon as recipient plasma and donor cells were mixed together. The saline spin crossmatch is used to detect ABO incompatibility between recipient plasma and individual donor red cells. It is not a suitable test to use for detection of ABO incompatibility if the recipient reverse blood group reveals a very weak anti-A or anti-B. The saline spin crossmatch may be used in conjunction with an antiglobulin crossmatch.

There is evidence of poor standardisation of this technique,[40] but its sensitivity can be optimised using 2 volumes of plasma with 1 volume of 2–3% cells, incubating at room temperature for 2–5 minutes, centrifuging at 100 *g* for 1 minute, then reading using tip and roll technique.

False-negative results in the saline spin crossmatch

Incompatibilities between A_2B donor cells and group B patient sera are not consistently detected with this technique.[41] Of more concern is the potential failure of agglutination with potent ABO antibodies[42,43] on account of rapid complement fixation with bound C1 interfering with agglutination if using serum. Red blood cells must therefore be suspended in saline containing EDTA.

False-positive results in the saline spin crossmatch

Cold-reacting antibodies, other than anti-A and anti-B, may cause agglutination in the saline spin crossmatch. This has the potential to cause delays to transfusion while further procedures are used to rule out ABO incompatibility.

Electronic issue

Electronic issue is the selection and issue of red cells where the compatibility is determined by the LIMS. There is no testing of recipient plasma against donor red cells. There were initial concerns regarding the likelihood of failing to identify antibodies against low-frequency antigens in the antibody screen that would then lead to an incompatible transfusion. Garratty[31] summarised observations indicating that the likelihood of missing a clinically significant antibody is approximately 1 in 10 615 crossmatches if the IAT component is omitted and antibody detection relies on a sensitive antibody screen alone. Moreover, the usual outcome of transfusion if an antibody is present but undetected by the antibody screen is limited to shortened red cell survival.

Initially, in order for electronic issue to occur, certain patient-specific criteria, such as the patient having been grouped twice, had to be met. However, since the 2013 BCSH guidelines there are significant additional best practice requirements that should also be met by UK laboratories in order for them to carry out electronic issue.[13]

BCSH guidelines[13] and AABB (previously American Association of Blood Banks) standards[44] require that there be concordant determinations of the patient's ABO and D type either on two separate samples, at least one of which must be a current sample, or on one current sample tested twice, depending on the security present in the system. In addition, there must be no clinically significant antibodies detected and no record of any having been detected previously. The AABB recommends that the group of donor units is rechecked, but the BCSH accepts written verification by the supplying transfusion service of the accuracy of the donor unit label. It is strongly recommended by the BCSH that ABO and D grouping procedures are automated with positive sample identification (e.g. barcodes) and electronic transfer of results from the analyser

to the transfusion laboratory computer, whereas the AABB does not have such a requirement. Ideally, computer algorithms should direct the procedure, only allowing issue if all the criteria are fulfilled. For example, issue of red cells for transfusion will be prevented if only one ABO and D group is on file or if the previous and current groups do not agree. Any manually controlled part of this process increases the risk of error. Electronic issue, based on fully validated systems, has been in place in several countries for some time and has proved to be clinically safe, providing the recommendations are rigidly adhered to.

EMERGENCY BLOOD ISSUE

In clinical emergencies where immediate red cell support is required, there may not be time for full compatibility testing. Either rapid techniques and/or abbreviated testing are employed or group O red cells are issued. There must be a documented procedure for dealing with emergencies. Local policies on this should be formally risk-assessed and adequate training should be given to staff, particularly those providing the service out of routine laboratory hours. Out-of-hours staff should be included in internal proficiency testing as well as external quality assessment exercises designed to test emergency tests and techniques.[3,12]

The transfusion laboratory should be involved in the development of emergency procedures within the hospital, including massive haemorrhage protocols (MHP) and the major incident plan. All staff should receive regular training and should take part in emergency practice drills. Clear and effective communication is key to the success of provision of blood components in an emergency, and the transfusion laboratory needs to be fully informed about the current status of the patient or patients, so as to provide an efficient and timely service.[45]

Rapid ABO and D typing

In an emergency, a sample should be obtained prior to transfusion, and the patient's ABO and D type should be determined as rapidly as possible using the techniques already described. Tube and slide tests are most convenient.

Confirmation

A reverse group, a repeat cell group or a saline spin crossmatch should be carried out on the sample before issuing group-specific blood. The ABO and D group must always be confirmed by a further test on a second aliquot from the sample. If an inadequately labelled sample is provided, group O units should be issued until a further sample can be tested.

Selection of units

Some hospitals provide one or two units of O D-negative red cells for use by clinicians pending the availability of ABO- and D-specific compatible red cells. Because of the relatively short supply of O D-negative red cells (only 8% of Caucasian blood donors are O D-negative in the UK) the English National Blood Transfusion Committee has issued guidance to hospitals about the restrictions on the use of O D-negative red cells in patients of another blood group.[46]

Compatibility testing

Group-specific red cells can be issued following a saline spin crossmatch to check for ABO incompatibility, or a LISS antiglobulin crossmatch and antibody screen can be done if more time is available. If no matching procedure is performed, the red cell units must be group-checked unless the supplier has indicated confidence in the validity of the donor unit labelling. Units issued following abbreviated testing must be labelled as such (e.g. 'Selected for patient…but not crossmatched'). Cells from the donor units should be removed before issuing the units to enable retrospective crossmatch, although a crossmatch is only necessary if the antibody screen is subsequently found to be positive.

Antibody screening

Good practice requires a simultaneous crossmatch and antibody identification if the antibody screen is positive. If group-specific units have been issued without an IAT crossmatch, an antibody screen must be performed as soon as possible. If the antibody screen is negative, it is not necessary to carry out a retrospective crossmatch. It is not acceptable to perform a crossmatch and not carry out an antibody screen. If the antibody screen is found to be positive, then contact the clinicians responsible for the patient to discuss how to proceed regarding the issue of potentially incompatible blood. Always follow agreed local procedure. Any untransfused incompatible units should be withdrawn from issue as soon as possible.

Major or massive haemorrhage

Major haemorrhage is a clinical diagnosis based on actual or suspected blood loss and physiological signs of haemodynamic instability such as a low blood pressure, tachycardia and failure to respond to a fluid challenge. The definition of major or massive haemorrhage based on the volume of blood lost (or transfused) is either (1) more than one blood volume lost within 24 h, (2) loss of 50% of the patient's blood volume within 3 h or (3) blood loss of 150 ml/minute. However, this is largely retrospective and not at all helpful at the point when the emergency is declared.[45]

The pre-agreed major haemorrhage protocol triggers the transfusion laboratory to issue emergency blood and blood components according to a 'foundation formula' without the need for approval of, or discussion with, a haematologist.[46] Where full patient identification is not available or labelled patient samples provided do not meet the minimum acceptance criteria it may be safer

to give group O blood, recognising that the supply of O D-negative blood is limited.[47]

Blood components and tranexamic acid in major haemorrhage

There is convincing evidence from the CRASH 2 study that two 1 g doses of tranexamic acid (TXA) given to trauma victims with major haemorrhage improves survival if the first dose is given within 3 h of the event.[48,49] There is some evidence for using TXA in major surgical bleeding,[50] but ongoing trials of TXA in major obstetric haemorrhage and gastrointestinal (GI) bleeding are yet to report.

It has been increasingly recognised that patients with hypotensive shock and/or large volume red cell replacement develop a coagulopathy and that early replacement with fresh frozen plasma (FFP), cryoprecipitate and platelets can improve outcome. The international consensus statement[51] for blood component replacement in major haemorrhage associated with trauma is that the early use of a locally agreed 'foundation formula' (e.g. 1 FFP:1 red cell unit or 1 FFP:1.5 red cell units) is advisable in the first instance and in advance of the availability of the results of laboratory tests.[45] Ongoing management of the patient can be guided by the results of the initial full blood count and coagulation screen combined with frequent re-evaluation of both the laboratory tests and the clinical state. The choice of blood component replacement should be tailored to the cause of the massive haemorrhage. The 'foundation formula' approach may not be applicable to obstetric haemorrhage where early use of cryoprecipitate should be considered and GI bleeding where a more restrictive approach has been advocated.[45]

COMPATIBILITY TESTING IN SPECIAL TRANSFUSION SITUATIONS

Neonates and infants in first 4 months of life[52]

Fetal and neonatal blood grouping differs from adult grouping because fetal/neonatal ABO antigens may be poorly expressed, the corresponding ABO red cells antibodies are not usually developed and maternal IgG ABO antibodies may be detectable in the fetal/neonatal plasma. For these reasons the in-built laboratory double-check for ABO blood grouping (forward group confirmed by reverse group) cannot be used.

In the UK, blood components for infants under 1 year of age have a particular specification with additional safety features.[22]

Investigations on the maternal sample

ABO, D group and antibody screen should be performed. If the antibody screen is positive, identification of the antibody specificity/ies is required. A maternal sample is preferred for antibody testing because it is easier to obtain a large sample from the mother, which in turn helps prevent iatrogenic anaemia in the neonate due to sample collection; also if maternal antibody has bound to fetal cells *in vivo*, the resulting lower concentration of antibody in neonatal plasma could lead to a false-negative antibody screen if using neonatal plasma.

Investigations on the infant sample

ABO and D group (cell group only) of the infant's blood should be verified on two separate samples (unless electronic patient identification is in place), one of which can be a cord blood sample. Prior transfusion can affect blood group interpretation, so any transfusion history needs to be taken into account when interpreting the group. Antibody screen of the infant's plasma should be performed if the mother's sample is not available. Identification of the antibody specificity/ies is required if the antibody screen is positive.

Direct antiglobulin test

If the DAT is positive or any red cell antibodies are detected in the maternal or infant serum, the diagnosis of HDN should be considered (see section on haemolytic disease of the newborn).

Selection of blood and other components

Many laboratories issue group O D-negative red cells for neonatal top-up and exchange transfusions. If using group-specific red cells, the group of the red cell unit should be ABO and D identical or an alternative compatible ABO group, taking into account the infant's blood group and maternal blood group (i.e. presence of maternal anti-A and/or anti-B) (Table 22-5).

Plasma components should be selected to match the neonatal group where possible (Table 22-6). Group O FFP should be given only to group O infants. It may be necessary

TABLE 22-5

CHOICE OF ABO GROUP FOR RED CELL COMPONENTS FOR ADMINISTRATION TO NEONATES AND INFANTS YOUNGER THAN AGE 4 MONTHS[52]

TABLE 22-6

CHOICE OF ABO GROUP FOR PLATELET AND FFP FOR ADMINISTRATION TO NEONATES AND INFANTS YOUNGER THAN AGE 4 MONTHS[52]

Neonatal/Infant ABO Group	ABO Group of Blood Component to be Transfused	
	Platelets	*FFP*
O	O	O
A	A	A or AB
B	B* or A or O†	B or AB
AB	AB* or A	AB

*Group B or AB platelets may not be available.
†Group O platelets must be negative for high-titre anti-A and anti-B if they are to be transfused to recipients who are not group O.

to give group O platelets to non-group O infants, and these should be negative for high-titre anti-A and anti-B. There have been reports of haemolysis of group A infants' red cells when given group O platelets.[52] Current production methods for FFP result in minimal red cell stroma, which is not antigenic; therefore plasma components do not need to be D compatible.

If there are no maternal antibodies, the neonatal DAT is negative and group O red cells are issued, there is no need for a crossmatch. Repeat antibody screens are not necessary if repeat transfusions are required within the first 4 months of life, because formation of red cell antibodies is rare in infants younger than 4 months of age.[52]

In the case of HDN (non-ABO or ABO), an indirect antiglobulin crossmatch is required, using either maternal or neonatal plasma, against red cell units that are antigen negative for the maternal red cell antibody/ies. For neonates and infants, red cells for exchange transfusion should be <5 days old, negative for cytomegalovirus virus (CMV) antibodies, plasma reduced (or washed), haemoglobin S negative, leucodepleted, K negative and irradiated.[22,52]

Intrauterine (fetal) transfusion

Intrauterine (fetal) transfusions are carried out in specialised fetal medicine units. In addition to the stipulations listed earlier for selection of blood for infants and neonates, blood for intrauterine transfusions should also be leucodepleted, K negative and irradiated to prevent transfusion-associated graft-versus-host disease and should be transfused within 24 h of irradiation.[22,52] When providing red cells for intrauterine transfusion, an antiglobulin crossmatch should be performed using maternal plasma. Intrauterine transfusion can result in fetomaternal haemorrhage (FMH) and hence sensitisation to new antigens, so antibody identification and quantification or titration must be performed on all maternal samples. Maternal samples should be collected less than 72 h prior to the planned transfusion. Red cells selected should be group O D-negative (except where maternal anti-c is present, then provide D-positive, c-negative) and K-negative (except where maternal anti-k (cellano) is present, then provide k-negative). Further selection of phenotyped blood will depend on the maternal red cell antibody profile.

It is essential for maternity units, associated neonatal units and the blood transfusion laboratory to have information about previous intrauterine transfusion because it will influence the selection of appropriate blood components if transfusion is required after delivery (see above). This is particularly important when the clinical care takes place in different institutions that are serviced by different transfusion departments. There should be local policies in place to ensure that neonatal and maternal transfusion history, including any history of fetal transfusions, is made available to the blood transfusion laboratory.

Patients receiving transfusions at short intervals

Patients who are acutely ill, particularly those on intensive care units and those undergoing intensive chemotherapy for a haematological malignancy, may require frequent blood transfusions.

There is no need for daily samples to test for the development of alloantibodies, but an antibody screen at least every 72 h is recommended as being practical and safe.

Chronic transfusion programmes

Examples of patients in whom a decision has been made that regular transfusions are required to sustain life and maintain health include those with β thalassaemia major, some patients with sickle cell anaemia, and congenital or acquired bone marrow failure, including myelodysplastic syndromes. It is important to establish a treatment plan for each patient with clear triggers for transfusion and regular checks for the adverse effects of transfusion such as alloimmunisation and iron overload. The risk of developing alloantibodies to red cell antigens of transfused blood influences the timing of blood samples (Table 22-1). If a less rigorous approach is considered for patients in whom repeated transfusions have not led to alloantibody formation, a mutual documented decision should be made by the clinician and the transfusion department after careful consideration of the risks.[12]

Prior to commencing a transfusion programme a pretransfusion Rh phenotype allows matching for D, C, c, E and e. Where patients have already been transfused, red cell genotyping can be used as an alternative to phenotyping. Additionally, patients with haemoglobinopathies should have an extended red cell phenotype before they are first transfused to include the antigens K, Jk^a, Jk^b, Fy^a, Fy^b, M, N, S and s. This is useful when subsequently identifying alloantibodies.

Provision of red cells with a 'matched extended phenotype' meaning matched for Rh and K is undertaken by units treating haemoglobinopathies, but the degree of matching depends on local resources and should not impede the delivery of effective transfusion support.[53–55] Some ethnic groups commonly have the phenotype cDe (R_o) and D-positive blood that is negative for C and E may be difficult to find, particularly if there are other red cell antibodies. In this situation D-negative (cde/cde) blood is selected.[53]

A high incidence of red cell alloantibodies has been reported in patients with sickle cell disease, and the many reports of alloimmunisation and haemolytic transfusion reactions received by SHOT are now highlighted in a separate chapter of the SHOT annual report.[2] However, there is insufficient evidence to make the above recommendation for other patients who are being chronically transfused.

Allogeneic haemopoietic stem cell transplantation

An allogeneic haemopoietic stem cell transplant may introduce a new blood group. The recipient/donor pairs have different ABO and D groups in about 15–20% of sibling stem cell transplants, and this is more common in unrelated donor transplants. If there is a major ABO mismatch and isoagglutinins persist in the recipient's plasma, engraftment may result in a positive DAT when substantial numbers of donor red cells start to enter the circulation and some haemolysis may occur.

A minor ABO mismatch is when the donor has antibodies to the recipient's red cells (e.g. donor O, recipient A). A major ABO mismatch is when the recipient has antibodies to the donor red cells (e.g. donor A, recipient O). A major plus minor ABO mismatch is when there are antibodies to recipient and donor red cells (e.g. donor A, recipient B).

When there is a recipient/donor mismatch, group O red cells (in additive solution or high-titre negative) should be selected. Postengraftment, when ABO antibodies to the donor ABO type are undetectable and the DAT is negative, the donor group can be selected. When there is a D mismatch, D-negative components should be used.[12]

From the time of conditioning therapy, throughout the period of immunosuppression and until immune reconstitution, all cellular blood components should be irradiated to prevent transfusion-associated graft-versus-host disease. The stem cell processing laboratory will ensure that products for infusion in the allogeneic setting do not contain significant numbers/amounts of red cells/plasma if there is the potential for a haemolytic transfusion reaction.

INVESTIGATION OF A TRANSFUSION REACTION

Adverse events related to transfusion can be acute (within 24 h) or delayed[56] (Table 22-7). Transfusion laboratories should be informed immediately of a suspected transfusion reaction, being ideally placed to coordinate investigation, to communicate with clinicians and transfusion services and to advise on appropriate choice of blood components for subsequent transfusions. Serious adverse reactions and events should be reported to the Hospital Transfusion Team and confidentially to the national haemovigilance scheme. Acute transfusion reactions are easier to attribute to the transfusion than delayed reactions, although in patients who are already very ill, they can go undiagnosed. The symptoms and signs of acute transfusion reactions are similar regardless of the cause, so treatment and investigation of potential causes is, by necessity, simultaneous. It is easier to distinguish between the causes of delayed transfusion reactions, but it may be more difficult to recognise their relationship to the transfusion episode because of the delay in onset. The following scheme outlines the role of the laboratory in investigation and management of transfusion reactions, and a very useful algorithm can be found in the *Handbook of Transfusion Medicine*.[57]

TABLE 22-7

TYPES OF TRANSFUSION REACTION

Acute Transfusion Reactions	Delayed Transfusion Reactions
Acute haemolytic reaction	Delayed haemolytic reaction
Anaphylaxis	Transfusion-transmitted infection
Bacterial contamination	Transfusion-associated graft-versus-host disease
Transfusion-associated acute lung injury	Post-transfusion purpura
Transfusion-associated circulatory overload	Iron overload
Allergic reaction	Immunosuppression
Febrile nonhaemolytic transfusion reaction	

Acute transfusion reactions

Acute life-threatening transfusion reactions can result from the following:

1. Acute intravascular haemolysis as a result of ABO incompatibility. Acute intravascular haemolysis can occur, although rarely, as a result of other red cell antibodies that activate complement through to the membrane attack complex (e.g. anti-Vel and anti-PP_1P^k).
2. Anaphylaxis and severe acute allergic reactions: These reactions are more commonly associated with blood components containing large amounts of plasma where the recipient has been presensitised to an allergen in the donor plasma. Recipients with IgA deficiency can develop antibodies to IgA present in plasma-containing blood components.

3. Severe extravascular haemolysis. This may happen where a strong antibody, which does not bind complement, or only binds it to the C3 stage, is missed in pretransfusion testing and causes rapid extravascular clearance of incompatible transfused red cells. These reactions are usually less severe than those caused by ABO incompatibilities.
4. Transfusion of a bacterially contaminated blood component. This causes sudden collapse after transfusion of red cells or platelets but not usually frozen components. If contamination is suspected, the blood centre must be informed immediately so that other components from the same donor can be traced and withdrawn if not already transfused. Because of the recognition that bacterial contamination is more likely with platelets that are stored at room temperature, measures have been successfully introduced to reduce this risk. In the UK platelets are screened for bacteria prior to release using a BacT/ALERT system, and some countries use pathogen inactivation systems for platelets.
5. Transfusion-associated acute lung injury (TRALI). This is an acute respiratory disorder, with one mechanism being passive transfer of antibodies in the plasma of the donor unit that react with the recipient's white blood cells, resulting in noncardiogenic interstitial pulmonary oedema. It is rarer in countries where male-only FFP is manufactured.
6. Transfusion-associated circulatory overload (TACO). The onset of breathlessness within 6 h of transfusion due to pulmonary oedema resulting from fluid overload due to excessive volume or rate of transfusion.

Although rare, the onset of an acute transfusion reaction is usually very dramatic and the patient is acutely ill. Treatment is aimed at resuscitating the patient and elucidating the cause to try to prevent any further incidents (Table 22-8). In addition, there are unpleasant but not life-threatening reactions that may occur during transfusion. They include the following:

- Allergic reactions – the patient may experience mild urticaria or itching caused by a reaction to plasma proteins in the donor unit.
- Febrile nonhaemolytic transfusion reactions – antibodies in the recipient react to donor white cells and cause an increase in temperature of no more than 1 °C; alternatively, cytokines released from white cells in the donor units can cause a similar reaction. These conditions usually settle on slowing the transfusion and administration of antipyretics and antihistamines. They do not require detailed investigation. They are less common where cellular blood components are leucodepleted.

Acute intravascular haemolysis

Transfused red cells react with the patient's own anti-A or anti-B, and the red cells are destroyed in the circulation, causing collapse, renal failure and disseminated intravascular coagulation. Transfusion of ABO-incompatible cells usually results from an identification error. This can occur at the point of blood sampling and labelling (wrong blood in tube), laboratory testing (technical error), blood unit labelling and collection from the blood refrigerator or inadequate bedside checking (administrative error). If red cells are mistakenly transfused to the wrong patient, there is approximately a 1 in 3 chance that ABO incompatibility will occur. The reaction is most severe if group A blood is transfused to a patient who is group O, and only a small volume of red cells is required to cause this reaction. Prompt action in recognising this acute emergency and stopping the transfusion may lead to a better outcome because the severity depends on the volume of blood transfused. If an acute transfusion reaction is suspected, the laboratory must be informed immediately and the unit of blood and giving set must be returned to the laboratory with blood and urine samples from the patient (Table 22-8).

Documentation check. The patient's identification wristband and the compatibility label attached to the blood unit should be checked again at the bedside. Any discrepancies must be notified to the transfusion laboratory

TABLE 22-8

IMMEDIATE INVESTIGATIONS IN THE CASE OF AN ACUTE TRANSFUSION REACTION

Check for Haemolysis

Perform visual examination of patient's plasma and urine (plasma and urine haemoglobin can be checked but this is not essential).

Blood film may show spherocytosis.

Bilirubin and lactate dehydrogenase (LDH) levels will be raised.

Check for Incompatibility

Check the documentation and the patient's identity.

Repeat ABO group of patient on pretransfusion and post-transfusion samples and of the donor unit(s).

Screen the patient for red cell antibodies pretransfusion and post-transfusion.

Repeat crossmatch with pretransfusion and post-transfusion samples.

Direct antiglobulin test (DAT) on pretransfusion and post-transfusion samples.

Eluate from patient's red cells.

Check for Disseminated Intravascular Coagulation

Perform blood count and film, coagulation screen and fibrin degradation products (or D-dimers).

Check for Renal Dysfunction

Check blood urea, creatinine and electrolytes.

Check for Bacterial Infection

Take blood cultures from the patient and donor unit including immediate Gram stain.

Immunological Investigations

Check immunoglobulin A (IgA) levels and anti-IgA antibodies.

immediately, and the transfusion should not go ahead until the discrepancy has been resolved. If the wrong blood has been administered, the units intended for that patient must be withdrawn from issue to prevent the converse error occurring with the corresponding patient who may have the same or a similar name.

Serological investigations. Serological investigations have a two-fold purpose: (1) to check for any laboratory errors in the pretransfusion sample group and compatibility check and (2) to repeat the group and compatibility tests with the post-transfusion sample to see if the pretransfusion sample was from the correct patient.

Tests for haemolysis. Not all acute transfusion reactions are the result of haemolysis, therefore haematological and biochemical tests as well as visual inspection of the plasma and urine are required. Further tests may be required to manage the resuscitation of the patient and direct the use of blood components to treat disseminated intravascular coagulation.

Microbiological tests. If the cause of the acute transfusion reaction is suspected to be contamination, blood cultures should be taken from the unit and the patient. Blood centres issue guidance for the investigation of potentially contaminated units and often will carry out this investigation themselves.

Delayed haemolytic transfusion reaction

A delayed haemolytic transfusion reaction occurs when the recipient has been immunised to a red cell antigen by a previous transfusion or during pregnancy but the antibody is present at low or undetectable levels and may have been missed by the antibody screen. A secondary immune response is mounted to the incompatible antigen that has been transfused. The IgG- and/or complement-coated red cells are destroyed in the spleen and/or liver. Kidd antibodies are often implicated in delayed transfusion reactions because they are difficult to detect (often displaying a dosage effect), fall rapidly to undetectable levels and are frequently present in combination with other antibodies.

Haematological investigation

The following suggest a delayed haemolytic transfusion reaction:

- Haemoglobin concentration falls more rapidly than would be expected after a red cell transfusion.
- Increase in haemoglobin concentration is less than expected for the number of units transfused.
- Blood film shows spherocytosis.
- DAT is positive.
- Unconjugated bilirubin is raised.

Serological investigation

Full serological investigation is warranted only when there is clinical or laboratory-based evidence of haemolysis. Ideally the pretransfusion sample should be available to test in addition to a post-transfusion sample. This is not always possible or practicable because of the delay between the time of the transfusion and the investigation unless samples are routinely saved on all patients who are transfused. The units transfused will not usually be available for retesting. In the UK the National Blood Services can provide phenotypes of many units and this information can help in the investigation of a delayed transfusion reaction. The following tests should be carried out, preferably using different or more sensitive techniques:

- Confirm the ABO and D group of the patient on a pretransfusion and post-transfusion sample.
- Perform a DAT on well-mixed pretransfusion and post-transfusion patient samples, preferably on washed red cells. In the event of a positive DAT, elution of the antibody may aid identification or confirm specificities in cases of non-ABO incompatibility. Consideration should be given to performing an eluate even if the DAT is negative. Sometimes the causative antibody is only detectable in the eluate.[1]
- Screen the pretransfusion and post-transfusion samples for red cell antibodies and identify any antibodies. The immediate post-transfusion sample may have no detectable red cell antibodies, although they may be eluted from the patient's red cells if the DAT is positive. It is also possible to have a delayed haemolytic transfusion reaction with a negative DAT because the antibody-coated red cells have been removed from the circulation. If the immediate post-transfusion investigation is inconclusive, repeat the tests 10 days later to allow antibody levels to increase.
- If no antibodies are detectable by any technique and no other cause of the haemolysis has been identified, advice should be sought from a haematologist or reference laboratory. Consideration should be given to using more sensitive techniques such as enzyme IAT, the use of panel containing rare red cell antigens or genotyping the patient's red cells.

ANTENATAL SEROLOGY AND HAEMOLYTIC DISEASE OF THE FETUS AND NEWBORN

Maternal ABO and D grouping and red cell antibody screening must be done early in pregnancy as a routine. This is the basis for the prevention, detection and, with antibody titration or quantification, the management of haemolytic disease of the fetus and newborn (HDFN).

Haemolytic disease of the fetus and newborn

Haemolytic disease of the fetus and newborn occurs when a maternal alloantibody to fetal antigens crosses the placenta and causes haemolysis of fetal red cells or suppression of fetal red cell progenitors, the latter occurring with antibodies within the Kell system.[58,59]

IgG is the only immunoglobulin that crosses the placenta, so only red cell antibodies of this class are a potential cause of HDFN. Anti-D causes the most severe form of HDFN, but the success of prophylaxis with anti-D immunoglobulin (anti-D Ig) for potentially sensitising events in pregnancy and after delivery of a D-positive baby reduced the number of cases, and routine antenatal anti-D prophylaxis (RAADP) has reduced it even further. The relative proportion of HDFN due to other IgG red cell antibodies has thus increased.[60] Although HDFN resulting from anti-D is the most severe form of the disease, anti-c can give rise to significant haemolysis *in utero,* sufficient in some cases to result in intrauterine death and therefore to warrant intervention in pregnancy. Anti-K has a different mode of action but can also result in a severely affected fetus.[58,59] Other IgG antibodies (e.g. anti-E, anti-Ce, anti-Fy^a and anti-Jk^a) uncommonly give rise to fetal haemolysis of sufficient severity to merit antenatal intervention. HDN as a result of ABO antibodies can also occur and is described later. For a detailed discussion of the investigation and management of HDFN, the reader is referred to the 2004 review by Kumar and O'Brien,[61] and the 2014 Royal College of Obstetricians and Gynaecologists guidelines.[62]

Antenatal serology

ABO and D grouping and antibody screening

Maternal ABO and D grouping as well as antibody screening and identification are performed early in pregnancy (i.e. when first seen and 'booked in') and then at 28 weeks' gestation. All pregnant women, whether D positive or D negative, should be screened for red cell antibodies.[63] Further testing depends on the specificity of any antibodies detected, whether they are capable of causing HDFN and the obstetric history.

Antibody titration and quantitation

Serial measurements of IgG antibodies capable of causing HDFN are used to manage sensitised pregnancies. The technique for antibody titration uses doubling dilutions and is described in detail in Chapter 21. In many laboratories, tube techniques have been replaced by CAT. It is recommended that the technique chosen for titration should be validated against the National Institute for Biological Standards Control anti-D standard, which can also be used as an internal control.[63] Antibody titrations in pregnancy should be performed in parallel with the previous sample.

Antibody quantitation

Automated quantification is considered to be a more accurate predictor of when to proceed to more active investigation of the fetus but is only available for anti-D and anti-c. Results in international units (iu) or μg per ml are used as part of clinical algorithms to proceed to the next step of fetal investigation.[62]

Follow-up antibody screening

Protocols for antenatal screening and follow-up vary from country to country. In the United Kingdom, the following is recommended by the BCSH:[63]

1. All pregnant women have ABO and D grouping and an antibody screen in early pregnancy when 'booked-in' and at 28 weeks' gestation. If the antibody screen at 28 weeks is negative, no further routine testing is required.
2. Pregnant women with anti-D, antibodies to Kell-related antigens or anti-c should be tested monthly to 28 weeks and then every 2 weeks to delivery. The tests should include antibody quantification or titration as well as testing for additional red cell antibodies.
3. Pregnant women with other red cell antibodies should have a titration done when booked in and again at 28 weeks.
4. All pregnant women with a previous history of HDFN or those who have a significant increase in anti-D, antibodies to Kell-related antigens or anti-c should be referred to a specialist fetal medicine unit for further assessment of the need for antenatal intervention.
5. Pregnant women who have red cell antibodies of other specificities, capable of giving rise to HDFN and which demonstrate a significant increase in titre over the course of the pregnancy, should have their condition discussed with their obstetrician. It is now appreciated that an increasing titre rather than an individual level is more predictive of an affected fetus.

Prediction of fetal blood group

Partner testing

The father's blood group phenotype should be determined in all cases where the mother has a red cell alloantibody capable of causing HDFN. If the father's red cells lack the corresponding antigen, the baby is not at risk. However, caution is advised because the assumed father may not be the biological father of the fetus. It is useful to predict whether the partner of a woman who is D negative and who has immune anti-D is homozygous or heterozygous for the D antigen. This helps to forecast the chances of having a baby affected by anti-D HDFN.

The zygosity of the D gene is usually predicted from the results of tests with anti-c, anti-C, anti-e and anti-E and from the likelihood of the homozygous or heterozygous

association with these antigens (see Table 22-2).[64] These data have been compiled for different racial groups. It is important, therefore, to tell the specialist laboratory the ethnic origin of the patient. The genetic basis for the common D types is now known, therefore DNA typing provides a better alternative for predicting the potential for HDFN.[65]

Testing fetal DNA in the maternal circulation

It is now possible to detect fetal DNA in the maternal circulation and, using DNA amplification techniques (see Chapter 8), to obtain D, c, E and K types on these cells. This has proved to be accurate at predicting the D type and, in the UK, testing is available at the beginning of the second trimester.[65] This may replace more invasive tests and supplement partner typing. It can be especially helpful if the father is absent or unknown.

Fetal blood sampling

Using ultrasound guidance, it is possible to take a sample of fetal blood for blood grouping, but this carries some risks. Contamination by maternal blood can hinder analysis of the sample obtained, leading to false-negative results. In addition, the procedure itself can lead to FMH and hence further sensitisation to fetal antigens. There is also a risk of miscarriage.[61]

Antenatal assessment of the severity of haemolytic disease of the fetus and newborn

There has been considerable change in antenatal assessment of the severity of HDFN with noninvasive techniques being routinely used to assess the degree of fetal anaemia, with fetal blood sampling and, if necessary, intrauterine transfusion only being considered in cases suspected of having severe anaemia but before development of hydropic changes on the ultrasound scan.[61]

Assessment of fetal anaemia

In a mother with increasing antibody levels and a fetus suspected or known to carry the red cell antigen against which the antibody is directed, an assessment of the severity of haemolysis is required. Traditionally this was done using amniocentesis to measure the optical density of the amniotic fluid (Lilley's lines) using spectrophotometry.

This, however, is an indirect measurement, whereas direct fetal blood sampling by ultrasound-guided cordocentesis provides not only direct diagnostic information but can be followed by direct intravascular transfusion of the fetus. However, both of these procedures carry the risk of miscarriage and further FMH. It is now common practice for fetal medicine units to offer noninvasive tests to determine fetal anaemia; middle cerebral artery Doppler studies have been very useful in this regard.[66] The incidence and severity of HDFN is declining, and the increasingly specialised management of severely affected pregnancies has meant that these women are now being referred early in pregnancy to fetal medicine units who specialise in dealing with this condition, thus decreasing the involvement of the routine transfusion laboratory in any but the early stages.

Tests on maternal and cord blood at delivery

In all pregnancies with red cell antibodies, blood samples should be collected at delivery to establish the phenotype of the baby and detect the presence and extent of haemolytic anaemia. The cord blood sample should be tested for ABO and D group, phenotype for the red cell antigen against which the antibody is directed, DAT and haemoglobin and bilirubin concentrations. The mother's sample should be tested to confirm the known antibody and screen for any new red cell antibodies.

There should be a local protocol for these procedures, especially noting the importance of correctly labelling fetal and maternal samples to avoid misidentification.

Anti-D immunoglobulin prophylaxis

This is given to prevent HDFN due to anti-D. Correct identification of D-negative women in early pregnancy offers the chance to give intramuscular anti-D Ig to prevent sensitisation to the D antigen at times during the pregnancy when significant FMH is likely to occur, known as 'potentially sensitising events'.[67] Accuracy in D grouping is particularly important because women who are D negative, erroneously grouped as D positive, risk not receiving prophylactic anti-D Ig (or being transfused with D-positive cells). The SHOT scheme has a reporting category for anti-D errors which includes any adverse event relating to the prescription, administration or omission of anti-D Ig that has the potential to cause harm to the mother or fetus immediately or in the future (Fig. 22-6).[2]

Anti-D prophylaxis

Anti-D Ig should be given routinely as soon as possible after delivery (but always within 72 h) to women who are D negative who deliver babies that are D positive. It should also be given at times during pregnancy when sensitisation could occur, such as during medical or surgical therapeutic termination of pregnancy, chorionic villus sampling, amniocentesis and following any abdominal trauma. It should also be given for episodes of vaginal bleeding where the pregnancy remains viable.[67] At delivery and for potentially sensitising events after 20 weeks' gestation, it is necessary to screen for FMH using an acid elution method and estimate the degree of FMH if fetal cells are seen. The BCSH guidelines recommend confirming any FMH >2 ml by flow cytometry so that additional anti-D Ig can be given if the standard dose in use is not sufficient for the estimated bleed.[68]

It takes 125 iu of anti-D Ig to remove a bleed of 1.0 ml fetal cells and preparations containing 250 iu, 500 iu and 1500 iu are in routine prophylactic use.

Because of the risk of silent FMH in pregnancy, routine antenatal anti-D prophylaxis is being offered to women in some countries. In the UK, this has been the subject of an appraisal by the National Institute for Health and Clinical Excellence,[69] which recommends that anti-D Ig should be given either as a single 1500 iu dose at 28 weeks or in two 500 iu doses at 28 and 34 weeks in addition to the postnatal dose and doses to cover any potentially sensitising events during pregnancy. Women can decline RAADP, e.g. if they know the baby's father is D negative or if they do not want any further pregnancies. The typing of fetal DNA in the maternal circulation may be used in the future to select women with fetuses that are D positive who would benefit from this additional prophylaxis, but at the moment, it is not universally offered.[70]

It is important to take the 28-week sample for blood group and antibody screen *before* administration of anti-D Ig to ensure the maternal antibody screen correctly reflects the maternal antibody status. If anti-D is detected it is important to establish whether prophylactic anti-D has already been given resulting in passive acquisition of anti-D. In the absence of a clear history of anti-D Ig administration it is difficult to distinguish passively acquired from low-level maternal anti-D using serological techniques alone. The consequence of misinterpreting passively acquired anti-D as a maternal immune response is that anti-D prophylaxis may be omitted, leaving the women unprotected from sensitisation. Conversely, if maternal anti-D is misinterpreted as passively acquired, a sensitised pregnancy might not be managed appropriately. Laboratories supporting maternity units should have a strategy for dealing with positive antibody screens in D-negative mothers at, or after, 28 weeks, firstly establishing that anti-D is the only detectable antibody and then proceeding to quantify the antibody.

If the anti-D level is <0.2 iu/ml, with a negative antibody screen at 28 weeks and a record of anti-D Ig administration, anti-D prophylaxis should continue. In all other situations the case should be managed individually with close monitoring of the anti-D level as for sensitised pregnancies and with anti-D prophylaxis being continued until it is proven beyond doubt that the anti-D represents a maternal immune response.

Measurement of fetomaternal haemorrhage

The most commonly used test to estimate the quantity of fetal cells in the maternal circulation is the Kleihauer or acid elution (AE) test, which depends on the haemoglobin F in fetal cells resisting acid elution to a greater extent than the haemoglobin A in maternal cells.

The calculation of the volume of fetal cells is based on the work by Mollison,[30] which assumed that the maternal red cell volume was 1800 ml, fetal red cells were 22% larger than maternal cells and only 92% of fetal cells were stained darkly (p. 317). Mollison's formula for calculating volume of FMH is as follows:

$$\text{Uncorrected volume of bleed} = \frac{1800 \times \text{fetal cells counted (F)}}{\text{Adult cells counted (A)}}$$

$$\text{Corrected for fetal volume (1.22)} = \left(1800 \times \frac{F}{A}\right) \times 1.22 = J$$

Corrected for staining efficiency (1.09):
Volume of FMH (ml fetal cells) = J × 1.09.

Occasionally, a FMH test is used to investigate an intrauterine death or stillbirth where a large but silent FMH is suspected as the cause of death. Acid elution is the preferred test in this situation as the fetal cells can be detected and the volume of FMH estimated irrespective of the D group of the mother and fetus. Anti-D prophylaxis should be given to women who are D negative if the fetus is D positive or the D type of the fetus is unknown.

The flow cytometry method uses a fluorochrome-labelled anti-D antibody to measure a minority of D-positive cells among the D-negative cells in the maternal circulation and is recommended for confirmation of a positive AE test where the estimated FMH exceeds 2 ml. However, flow cytometry may not always be available. Flow cytometric techniques using antihaemoglobin F have also been developed. The BCSH guidelines[68] give full details on performance and use of all these tests.

Recommended action at delivery (or potentially sensitising event)

All women who are D negative should be given a standard intramuscular dose of anti-D Ig into the deltoid muscle

BOX 22-1 Dosage of anti-D immunoglobulin to cover calculated fetomaternal haemorrhage

- 125 iu anti-D immunoglobulin given intramuscularly is sufficient for a fetomaternal haemorrhage of 1 ml fetal red cells.
  - 500 iu will cover an FMH of less than 4 ml
  - 1500 iu will cover an FMH of less than 12 ml
- Additional dosages should be calculated using 125 iu for each 1 ml fetal cells and rounded to the nearest vial size.
- Intravenous preparations are available for large bleeds.
- The dosage calculation for intravenous anti-D immunoglobulin is 100 iu for each 1 ml fetal cells.

within 72 h of delivery or potentially sensitising event unless the baby (or fetus) is known to be D negative (Box 22-1). The minimum anti-D Ig dose is 500 iu after 20 weeks and 250 iu before 20 weeks' gestation.

On the basis of a confirmed FMH result, further anti-D Ig should be given if the FMH exceeds the volume covered by the standard anti-D Ig (Fig. 22-7).

If the confirmed FMH results exceeds 4 ml, irrespective of whether or not additional anti-D Ig has been required, the FMH test should be repeated 72 h later (48 h later if the anti-D Ig was given intravenously) to check for clearance of fetal cells. Further anti-D Ig may be required if fetal cells are still present.

It is good practice to counsel women with a large FMH about the risk of sensitisation, and an antibody screen six months postpartum can be arranged to see if sensitisation to the D antigen has occurred, although a negative antibody screen at this stage does not completely exclude sensitisation.

ABO haemolytic disease of the newborn

High-titre maternal IgG anti-A or anti-B antibodies present in mothers who are group O can cause prolonged neonatal jaundice and anaemia associated with spherocytosis if their newborn babies are group A or B respectively. ABO HDN needs to be distinguished from hereditary spherocytosis, nonspherocytic haemolytic anaemia and HDFN resulting from other red cell antibodies.

ABO HDN may occur in a first pregnancy. In Caucasian populations, about 15% of births are susceptible, but only about 1% are affected; even then the condition is mild and very rarely severe enough to need exchange transfusion. The condition is more common in other racial groups. A number of special factors combine to protect the fetus from the effects of ABO incompatibility. These include the relative weakness of A and B antigens on the fetal red cells and the widespread distribution of A and B glycoproteins in fetal fluids and tissues, which divert much of the maternal IgG antibody away from the fetal red cell 'target'. Antenatal prediction of ABO HDN is not essential for medical management because there is time to observe the baby after birth and treat according to the severity of the condition. For details on serological investigation of ABO HDN see section in this chapter on antibody titration.

ABO titrations

Anti-A and anti-B titrations are used primarily in the context of ABO-incompatible renal transplantation where group O recipients may be transplanted with a kidney from a group A or B donor. Prior to transplantation the initial isoagglutinins titre determines whether the recipient is suitable for the ABO-incompatible renal transplant programme. When antibody reduction regimes are started, serial anti-A or anti-B titres are used to monitor immunosuppression and physical removal of the recipient's isoagglutinins until a level has been reached where the transplant can proceed without risk of graft rejection.

Other clinical situations where anti-A and anti-B titres may be used include haemopoietic stem cell transplantation where there is a major ABO mismatch between the recipient and donor and also rarely to support a diagnosis of ABO HDN. A technique for ABO titrations is given in Chapter 21.

Approach to the Diagnosis and Classification of Blood Cell Disorders

Jecko Thachil • Imelda Bates

CHAPTER OUTLINE

COMMON PRESENTATIONS OF HAEMATOLOGICAL DISEASES

An abnormal blood count or blood cell morphology does not necessarily indicate a primary haematological problem because it may reflect an underlying nonhaematological condition or may be the result of therapeutic interventions. Anaemia occurs in many conditions, but a primary blood disease should be considered when a patient has splenomegaly, lymphadenopathy, a bleeding tendency or thrombosis and/or nonspecific symptoms characteristic of leukaemias and lymphomas such as malaise, sweats or weight loss.

As with any clinical problem, the first steps in determining the diagnosis include obtaining a careful clinical, travel and drug history and a thorough physical examination. The result of these, in combination with the patient's age, sex, ethnic origin, social and family history and knowledge of the locally prevalent diseases, will determine subsequent laboratory investigations.

INITIAL SCREENING TESTS

Although the range of haematological tests available to support clinical and public health services is broad, it is often the simplest investigations that are most useful in indicating the diagnosis. Even poorly resourced laboratories are usually able to provide an initial panel of tests such as haemoglobin concentration (Hb), white blood cell count (WBC) and platelet count (Chapter 26) and examination of a peripheral blood film for a differential leucocyte count (Chapter 3) and cellular morphology (Chapter 5). These screening tests will often enable the underlying pathological processes to be suspected promptly and point to a few key diagnostic tests.

Interpretation of screening tests

Results of laboratory screening tests should always be interpreted with an understanding of the limitations of the tests and the physiological variations that occur with sex, age, ethnic group and conditions such as pregnancy and exercise. Physiological variations in cell counts are detailed

in Chapter 2. Abnormalities of red cells, white cells or platelets may be quantitative (increased or reduced numbers) or qualitative (abnormal appearance and/or function).

Quantitative abnormalities of blood cells

Increased numbers of cells

Increases affecting more than one cell line. A simultaneous increase in the cells of more than one cell line suggests overproduction of cells originating in an early precursor cell. This occurs in myeloproliferative neoplasms in which one cell type may predominate, e.g. platelets in essential thrombocythaemia and red cells in polycythaemia vera.

Erythrocytosis

Patients with a persistently (e.g. >2 months) raised venous haematocrit (Hct) (>0.52 males, >0.48 females) should be assessed to determine the cause. Erythrocytosis can be relative or absolute and, if absolute, primary or secondary.

Relative: normal total red cell volume with reduced plasma volume (e.g. dehydration).

Absolute: males and females with Hct values above 0.60 and 0.56, respectively, can be assumed to have an absolute erythrocytosis and do not require confirmatory studies.[1] However, the reason for the elevation of the Hct must still be elucidated.

Primary: this is usually polycythaemia vera (PV), part of the spectrum of myeloproliferative neoplasms. The mutation *JAK2* V617F is present in approximately 95% of patients with PV and mutations affecting exon 12 occur in many of those who lack the V617F mutation.[2]

Secondary: to chronic hypoxia (e.g. chronic lung disease, congenital heart disease, high-affinity haemoglobins) or aberrant erythropoietin production. Secondary polycythaemia can generally be excluded by the clinical history and examination, assessment of serum erythropoietin concentration and arterial oxygen saturation, haemoglobin electrophoresis or high performance liquid chromatography (HPLC) plus an oxygen dissociation curve and abdominal ultrasound examination. If initial screening tests are negative for a *JAK2* mutation and there is no obvious secondary cause for the high Hct, then red cell mass studies are indicated (Chapter 17).

Leucocytosis

Neutrophilia. Neutrophils are commonly increased during pregnancy and in acute infections, inflammation, alcohol intoxication, corticosteroid therapy and acute blood loss or red cell destruction. Additional findings on the full blood count can be helpful to identify the cause of neutrophilia. The combination of anaemia and neutrophilia occurs in chronic infection or inflammation, and also in malignant conditions; a high Hct with neutrophilia suggests polycythaemia vera. Neutrophilia with an increased platelet count occurs in infectious or inflammatory processes or malignant conditions and during marrow recovery. Neutrophilia with thrombocytopenia is classically seen in sepsis and occasionally in microangiopathic haemolytic anaemia. Examination of the peripheral blood film also provides additional clues to confirm or exclude a particular diagnosis. For example, neutrophilia with the neutrophils showing heavy cytoplasmic granulation ('toxic' granulation) is a common finding in severe bacterial infections. In the absence of any underlying cause, a high neutrophil count with immature myeloid cells suggests chronic myelogenous leukaemia (CML), and cytogenetic and molecular studies to look for t(9;22) and the *BCR–ABL1* fusion gene are indicated (Chapter 8).

Lymphocytosis. Lymphocytosis is a feature of certain infections, particularly infections in children. It may be especially marked in pertussis, infectious mononucleosis, cytomegalovirus infection, infectious hepatitis, tuberculosis and brucellosis (Table 23-1). Elderly patients with lymphoproliferative disorders, including chronic lymphocytic leukaemia and lymphomas, often present with lymphadenopathy and a lymphocytosis. Morphology and immunophenotyping of the cells combined with histological examination of a bone marrow trephine biopsy specimen (and if necessary other tissue biopsy) are used to classify these disorders and to give an indication of management and prognosis.[3] If lymph nodes are enlarged, a lymph node biopsy for histology and immunohistochemistry may be helpful in diagnosis. It is occasionally difficult to differentiate between a reactive and a neoplastic lymphocytosis. In this situation, immunophenotyping, to provide evidence of light chain restriction and polymerase chain reaction for immunoglobulin or T-cell receptor gene rearrangements, may indicate the presence of a monoclonal population of lymphocytes, thereby supporting a diagnosis of neoplastic, rather than reactive, lymphoproliferation.

TABLE 23-1

CAUSES OF LYMPHOCYTOSIS

Infections
- Predominantly viral (commonest is infectious mononucleosis)
- Occasionally bacterial (e.g. pertussis and chronic infections like tuberculosis)
- Unusually parasites (e.g. babesiosis)

Stress and Postsplenectomy

Smoking

Hypersensitivity Reactions

Autoimmune Disorders

Thymoma

Clonal
- Monoclonal B cell lymphocytosis
- Lymphoproliferative disorders especially chronic lymphocytic leukaemia and lymphomas

Monocytosis. A slight to moderate monocytosis may be associated with some protozoal, rickettsial and bacterial infections including malaria, typhus and tuberculosis. Monocytosis associated with neutrophilia is suggestive of chronic myelomonocytic leukaemia. High levels of monocytes (monocyte count $>1\times10^9$/l) in an elderly patient suggest chronic myelomonocytic leukaemia or sometimes, atypical chronic myeloid leukaemia. These conditions fall into the myelodysplastic/myeloproliferative neoplasm group of disorders,[4] so the diagnosis is supported by finding splenomegaly, quantitative and qualitative abnormalities in other cell lines or a clonal cytogenetic abnormality.

Eosinophilia. Eosinophilia is typically associated with parasitic infections, skin diseases and allergic disorders. Eosinophils have a tendency to infiltrate and damage tissues such as the heart, lungs and gut, so in patients with eosinophilia, assessment of these organs is necessary. In most cases, the cause of the eosinophilia is indicated by the clinical history, which should include details of all medications and foreign travel, and by examination of the stool and urine for parasites, cysts and ova. Other causes of eosinophilia are given in Table 23-2.

Basophilia. Basophilia as an isolated finding is unusual. However, it is a common feature of myeloproliferative neoplasms, and basophils may be particularly prominent in CML. In this condition, an increasing basophil count may be the first indication of accelerated phase disease. Endocrinopathies such as myxoedema and oestrogen abnormalities, infections and allergic diseases – and rarely, other haematological malignancies – can also cause basophilia.

TABLE 23-2

CAUSES OF EOSINOPHILIA[13,14]

Parasitic Infections – Especially with Helminths

Neoplastic Diseases

- Primary (or neoplastic) hypereosinophilia, e.g. associated with *FIP1L1-PDGFRA* fusion gene (or occasionally *PDGFRB* or *FGFR1* rearrangement or *PCM1-JAK2* fusion)
- Other acute or chronic eosinophilic leukaemia
- Other myeloproliferative neoplasms such as chronic myeloid leukaemia and systemic mastocytosis
- Reactive to other neoplasms, e.g. to B- or T-cell lymphoma or leukaemia or solid tumour

Allergic Disorders

- Gastrointestinal disorders – may be associated with tissue eosinophilia rather than peripheral blood eosinophilia
- Drug reactions including the DRESS syndrome (drug reaction with eosinophilia and systemic symptoms)
- Allergic rhinitis, asthma and atopic dermatitis

Immunodeficiency Disorders

- Hyper IgE (Job) syndrome
- Autoimmune lymphoproliferative syndrome
- Graft-versus-host disease

Connective tissue/rheumatology disorders

Ig, immunoglobulin.

Thrombocytosis

Thrombocytosis can be primary or secondary (reactive) to surgery, infectious and inflammatory conditions, hyposplenism, blood loss and malignancy, and can occur as a rebound phenomenon following recovery from marrow suppression. Spurious thrombocytosis can also occur in severe burns and cryoglobulinaemia because the size of the red cell fragments or cryoglobulin particles is similar to that of platelets. A moderately increased platelet count (e.g. $450–800\times10^9$/l) often does not indicate a primary haematological disorder. When there is isolated persistent thrombocytosis in a myeloproliferative neoplasm the diagnosis is essential thrombocythaemia (providing that the presence of a *BCR–ABL1* fusion gene has been excluded). Thrombotic or haemorrhagic complications can occur with thrombocytosis but often the diagnosis is made incidentally.[5] Individuals with essential thrombocythaemia have been noted to have *JAK2* V617F (50%), *MPL* (10%) or *CALR* mutations, with the *JAK2* mutation being associated with an increased risk of thrombosis.

Reduced numbers of cells

Reductions in more than one cell line. A reduction in cell numbers occurs because of increased destruction, reduced production or increased pooling in the spleen or other organs. Reduced production of cells may be the result of aplastic anaemia, a lack of haematinics such as folate or cobalamin or interference with normal haemopoiesis by infiltration (e.g. leukaemia), infection (e.g. human immunodeficiency virus (HIV) infection, tuberculosis, leishmaniasis) or exposure to toxins (e.g. alcohol) or myelosuppressive drugs (e.g. hydroxycarbamide or methotrexate). Certain myeloid neoplasms, e.g. primary myelofibrosis and myelodysplastic syndromes (MDS), are characterised by cytopenias, which are at least in part the result of ineffective haemopoiesis. Cytopenia is also sometimes a feature of acute myeloid leukaemia (AML), when it is due both to ineffective haemopoiesis and to replacement of normal haemopoietic stem cells by leukaemic cells. A relatively common cause of a global reduction in circulating cells is pooling of the cells in a markedly enlarged spleen (hypersplenism), which may be secondary to conditions such as primary myelofibrosis and portal hypertension. Examination of a bone marrow aspirate and trephine biopsy specimen is often helpful in determining the cause of cytopenias for which no obvious cause is apparent.

Anaemia

The mechanisms which result in anaemia are decreased production, reduced red cell lifespan, blood loss and splenic pooling. Anaemia is broadly divided into three types: microcytic (low mean cell volume (MCV)), macrocytic (high MCV) and normocytic (normal MCV). The choice of investigations is guided by the MCV and red cell morphology in

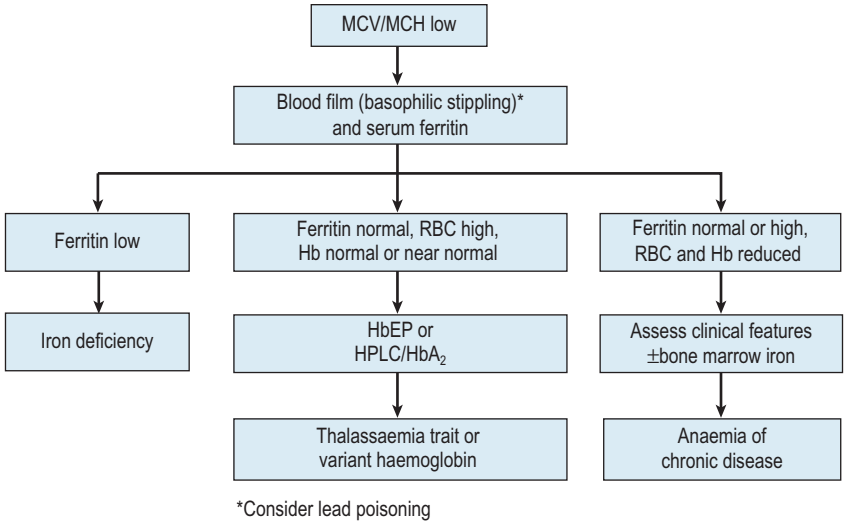

FIGURE 23-1 Investigation of a microcytic hypochromic anaemia. HbEP, haemoglobin electrophoresis; HPLC, high performance liquid chromatography.

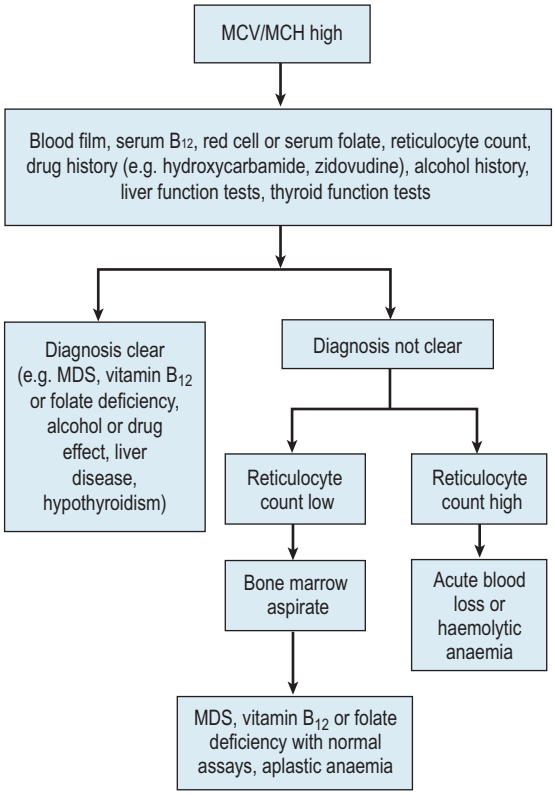

FIGURE 23-2 Investigation of a macrocytic anaemia. MDS, myelodysplastic syndrome.

addition to clinical features. Figures 23-1 to 23-3 are flow charts that provide an orderly sequence of investigations for the different types of anaemia on the basis of these indices. Examination of a blood film will usually suggest the quickest route to the diagnosis, though confirmation may require more specific tests. The presence of basophilic stippling with microcytic red cells suggests thalassaemia trait or, much less often, lead poisoning. A dimorphic blood film is typical of congenital sideroblastic anaemia but is more often the result of iron deficiency responding to treatment. Pappenheimer bodies suggest that a microcytic anaemia is the result of sideroblastic erythropoiesis.

Microcytic anaemia

The most common cause of anaemia worldwide is iron deficiency, which can be suspected from a low MCV (Fig. 23-1) and the presence of hypochromic, microcytic red cells. Laboratory confirmation of iron deficiency can be based on measurement of (1) serum ferritin or (2) serum iron plus either total iron-binding capacity or transferrin or (3) red cell protoporphyrin or (4) staining of bone marrow aspirates for iron (see Chapter 4).[6] A diagnosis of iron deficiency must be followed by a search for the cause. This should include specific questions relating to blood loss and dietary insufficiency and may require stool examination for parasites and occult blood, endoscopic examination of the gastrointestinal tract to exclude occult malignancy and tests for coeliac disease. The differential diagnosis of iron deficiency anaemia includes anaemia of chronic disease (also known as anaemia of inflammation). Clinical and laboratory features of inflammation or chronic infection may suggest this diagnosis, which is confirmed by demonstration of normal or high serum ferritin and reduced serum iron, transferrin and iron-binding capacity. Serum soluble transferrin receptors may be helpful in distinguishing between iron deficiency anaemia and anaemia of chronic disease when interpretation of ferritin levels is difficult, though additional research is needed to define the overall diagnostic accuracy of these tests.[7]

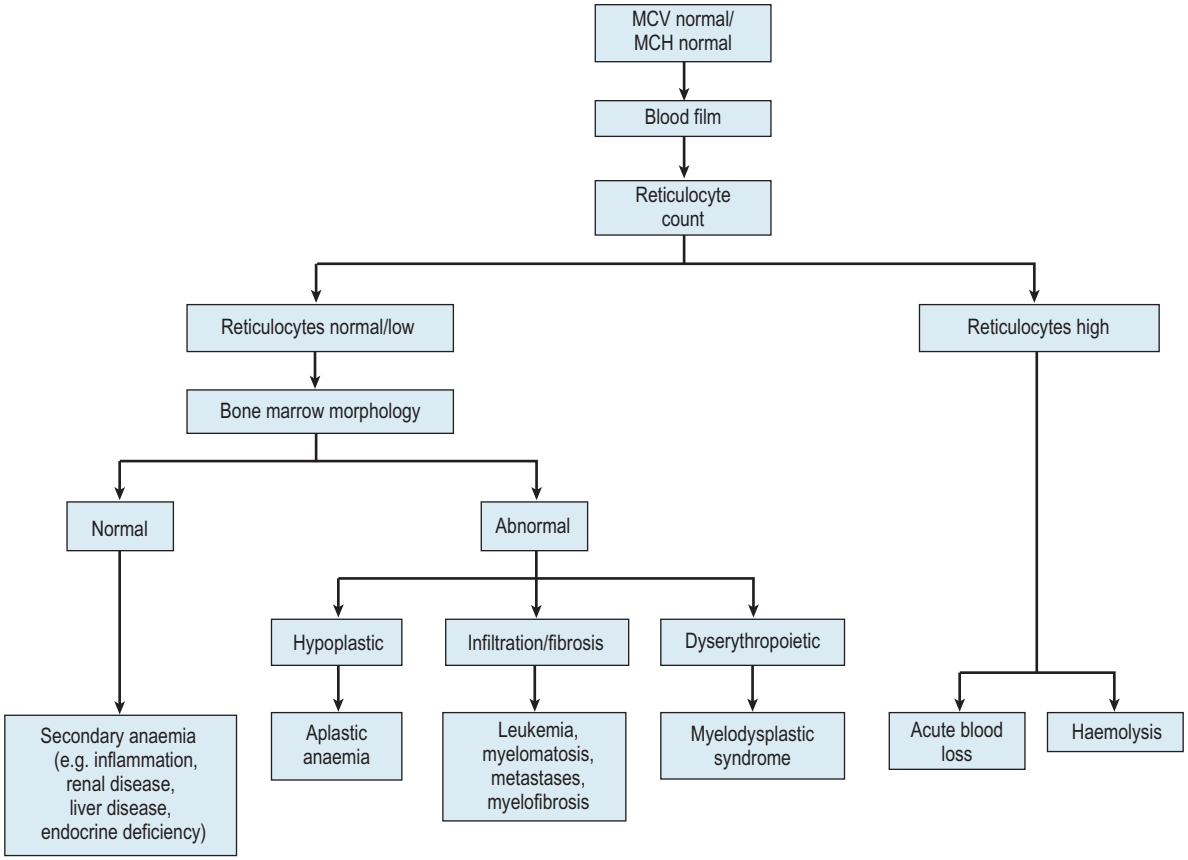

FIGURE 23-3 Investigation of a normocytic, normochromic anaemia.

The thalassaemias also cause microcytosis, but both α and β thalassaemia trait are usually associated with an increased red blood cell count (RBC) and a normal or near-normal Hb despite a considerable reduction of the MCV and mean cell haemoglobin (MCH). In contrast, in iron deficiency the MCV and MCH do not fall until the Hb is significantly reduced. Further investigations, such as HPLC or haemoglobin electrophoresis supplemented by measurement of haemoglobin A_2 and haemoglobin F usually confirm the diagnosis of β thalassaemia trait. The diagnosis of α thalassaemia trait is more difficult; detection of infrequent haemoglobin H inclusions is usually possible in α^0 thalassaemia trait, but definitive diagnosis requires deoxyribonucleic acid (DNA) analysis (see Chapter 8).[8] A diagnosis of α^0 thalassaemia heterozygosity can be clinically important for prediction of haemoglobin Bart's hydrops fetalis.

Macrocytic anaemia

A high MCV (Fig. 23-2) with oval macrocytes and hypersegmented neutrophils suggests folate or cobalamin deficiency and is an indication for assays of these vitamins (see Chapter 10). Plasma methylmalonic acid assays may be a useful second-line test to help clarify uncertainties of underlying biochemical or functional cobalamin deficiencies. Serum folate is the first-line test to assess folate status and has equivalent diagnostic capability to red cell folate.[9] Subsequent investigations could include malabsorption studies, tests for coeliac disease and screening for intrinsic factor antibodies. In patients with these blood film findings and normal folate and cobalamin assays, haematinic deficiency cannot be completely excluded and further investigations are indicated (see Chapter 10). As there is no definitive test to define cobalamin deficiency, treatment should be started if there is a strong clinical suspicion of deficiency irrespective of the test results to avoid neurological impairment. In the absence of intrinsic factor antibodies, the diagnosis of pernicious anaemia may be presumptive. Pernicious anaemia is commonly associated with autoimmune thyroid disease and other autoimmune disorders, such as diabetes mellitus.

A high MCV may also be the result of alcohol excess and liver disease or the use of drugs such as hydroxycarbamide. Macrocytosis resulting from chronic haemolysis is associated with increased numbers of immature red cells, which appear slightly larger and bluer than normal red cells (polychromatic macrocytes) on a Romanowsky-stained peripheral blood film. An automated reticulocyte count or supravital staining of blood films (see p. 27) can be used to confirm reticulocytosis. Untreated anaemia

associated with polychromasia is likely to indicate blood loss or haemolysis. The combination of red cell fragments, thrombocytopenia and polychromasia indicates a microangiopathic haemolytic anaemia. This is a medical emergency because these may be features of thrombotic thrombocytopenic purpura, which requires immediate treatment, usually by plasma exchange. These features should therefore trigger further tests such as a platelet count, coagulation studies, assessment of renal function, measurement of ADAMTS13 concentration and a search for infection or neoplastic disease.

Normocytic anaemia

Normochromic, normocytic anaemia (Fig. 23-3) is frequently the result of an underlying chronic, nonhaematological disease. Investigations should include screening for renal insufficiency, subclinical infections, autoimmune diseases and neoplasia. In the presence of anaemia, a lack of polychromasia, confirmed by reticulocytopenia, points toward a primary failure of erythropoiesis or lack of compensatory increased red cell production in blood loss or haemolysis. Examination of the bone marrow may be helpful in demonstrating haematological causes for a normochromic, normocytic anaemia such as MDS or aplastic anaemia.[10] Staining for iron may also show that there is a block in iron metabolism suggestive of anaemia associated with chronic inflammatory disease.

Leucopenia

Neutropenia. Once physiological variation, ethnicity and familial or cyclic neutropenia have been excluded (see p. 15), the nonhaematological causes of isolated neutropenia to be considered include overwhelming infection, autoimmune disorders such as systemic lupus erythematosus, irradiation, drugs (particularly anticancer agents) and large granular lymphocytic leukaemia. Bone marrow examination may assist in determining whether the problem is the result of peripheral destruction (increased marrow myeloid precursors) or stem cell failure (lack of marrow myeloid precursors). Typical marrow appearances occur in drug-induced neutropenia, in which there is a relative paucity of mature neutrophils and in infant genetic agranulocytosis (Kostmann syndrome) in which there is maturation arrest at the promyelocytic stage.

Reduced numbers of lymphocytes, monocytes, eosinophils and basophils. Lymphocytes, eosinophils and basophils may all be reduced by physical stress such as surgery, trauma and infection. Lymphopenia with neutrophilia is a common combination of haematological abnormalities in severe acute respiratory syndrome and in many other patients with acute illness or trauma. Lymphopenia, especially affecting the CD4 cells, may occur in HIV infection and renal failure. Monocytopenia (monocyte count $<0.2\times10^9/l$) is typically found in hairy cell leukaemia, which is also associated with pancytopenia, typical bone marrow histology and lymphocytes with a characteristic cytology and immunophenotype.

Thrombocytopenia

Thrombocytopenia is a common isolated finding, and it is important to ensure that the laboratory result reflects a true reduction in platelet count before embarking on further diagnostic tests. Frequent causes of spurious thrombocytopenia include blood clots in the sample, platelet clumping and platelet satellitism. Platelet clumping, which is seen on the blood film, can occur *in vitro* as the result of a temperature-dependent or anticoagulant-dependent autoantibody or on slides that have been made directly from a finger prick sample. True thrombocytopenia is most frequently the result of autoantibodies (i.e. immune thrombocytopenia), HIV infection, anticancer chemotherapy, other drugs (such as thiazide diuretics), alcohol excess, hypersplenism and MDS. Heparin-induced thrombocytopenia and thrombosis is a particularly important syndrome to recognise (see Chapter 20).

The first step in the assessment of patients with thrombocytopenia is the examination of a blood film. The clinical circumstances, together with blood film and bone marrow examination, usually enable the various causes of thrombocytopenia to be differentiated. An association with thrombosis, disturbed renal or hepatic function and haemolytic anaemia should prompt investigations for other diseases, such as thrombotic thrombocytopenic purpura and, in a pregnant woman, the HELLP (haemolysis, elevated liver enzymes, low platelet count) syndrome. The presence of thrombocytopenia with atypical features on the blood film may prompt a bone marrow examination to exclude conditions such as acute leukaemia, especially in children.

Pancytopenia

Pancytopenia means a reduction in the WBC, Hb and platelet count and is most often the result of anticancer chemotherapy, HIV infection, hypersplenism and bone marrow infiltration or failure. Reduction of two cell lineages is referred to as bicytopenia and has similar causes to pancytopenia. Careful examination of a blood film is important if the reason for the cytopenia is not apparent from the clinical history. If this does not reveal the cause, bone marrow aspiration and trephine biopsy may be needed.

Qualitative abnormalities of blood cells

In health, only the most mature forms of cells appear in the peripheral blood. Cells at various stages of immaturity, such as nucleated red blood cells, polychromatic red cells, myelocytes and metamyelocytes, may be released from the bone marrow in conditions where the bone marrow is overactive (e.g. acute haemolytic states or recovery from suppression) or functionally abnormal. Their presence in the peripheral blood indicates that active haemopoiesis is taking place.

Abnormalities of all cell lines

The combination of anisopoikilocytosis, mild macrocytosis, hypogranular neutrophils with abnormal nuclear morphology and platelet anisocytosis, often with

quantitative abnormalities, is virtually pathognomonic of MDS. These features are reflected in the bone marrow with disturbance of the normal developmental pathway and sometimes nuclear:cytoplasmic asynchrony. Cytogenetic studies are helpful for confirming the diagnosis, especially when cytological abnormalities are minor, and can also assist in determining the prognosis.[11]

Abnormalities of individual cell lines

Red cells. Congenital abnormalities of the red cell affecting the structure (e.g. spherocytosis, elliptocytosis) and content (e.g. haemoglobinopathies, enzymopathies) often produce typical morphological changes (see Chapter 5). The type of changes will guide further investigations such as analysis of structural proteins, haemoglobin electrophoresis or HPLC, or enzyme assays. The type of red cell abnormality may also help to indicate underlying pathology. For example, target cells may prompt investigation of liver function, whereas increased rouleaux formation may indicate the need for investigations for multiple myeloma or inflammatory conditions.

White cells. Congenital abnormalities of neutrophils are unusual, but similar morphological abnormalities (e.g. pseudo-Pelger–Huët cells) may be seen in acquired conditions such as MDS (see Figs. 5-83 and 5-84). Reactive changes in lymphocytes, including increased size, irregular shape and basophilic cytoplasm, are typically seen in infectious mononucleosis (see Fig. 5-90), which can be diagnosed using an appropriate serological screening test or, if this is negative, by demonstration of immunoglobulin M (IgM) antibodies to the Epstein–Barr virus (EBV). These atypical lymphocytes can sometimes be difficult to differentiate from circulating lymphoma cells. Immunophenotyping studies and determination of lymphocyte clonality, by demonstration of light chain restriction or by gene rearrangement studies, may be needed to reach a firm conclusion.

Platelets. Platelets that function poorly may not necessarily appear morphologically abnormal, although sometimes they are hypogranular or larger than normal. A normal platelet count with an abnormal *in vitro* platelet function test is characteristic of a disorder of platelet function, but some patients with abnormal platelet function also have thrombocytopenia. Hereditary disorders of platelet function are uncommon and usually present as a bleeding diathesis. When a qualitative disorder of platelets is suspected, platelets should be examined to assess size and to detect the cytological features of platelet alpha-granule deficiency (i.e. grey platelet syndrome). Neutrophils should also be examined for inclusions indicative of *MYH9*-related disorders such as the May–Hegglin anomaly. Qualitative disorders of platelets can broadly be divided into two categories: abnormalities of the platelet membrane glycoproteins (e.g. Bernard–Soulier syndrome, Glanzmann thrombasthenia) and abnormalities of platelet secretory function (e.g. storage pool diseases).

Acquired disorders of platelet function are more common than inherited disorders. Haematological conditions associated with platelet dysfunction include myeloproliferative neoplasms, MDS and dysproteinaemias (in plasma cell neoplasms). Many widely prescribed drugs, including aspirin and nonsteroidal anti-inflammatory agents, interfere with platelet function. Systemic conditions, particularly chronic renal failure and cardiopulmonary bypass, are also associated with a bleeding tendency as a result of qualitative platelet defects. Most of these acquired functional defects are not associated with any abnormality in platelet appearance but in MDS and, to a lesser extent, in the myeloproliferative neoplasms, there may be hypogranular and giant platelets.

SPECIFIC TESTS FOR COMMON HAEMATOLOGICAL DISORDERS

Common haematological disorders are outlined in the following sections with suggestions for investigations that may be helpful in confirming the diagnosis. The lists are indicative and are not intended to be exhaustive because the protocols and range of tests provided locally will depend on the availability of expertise and technology. The investigations discussed are those that are likely to be available within a general haematology department.

Red cell disorders

Microcytic hypochromic anaemias

For more information, see Chapters 9 and 14.

- Measurement of serum ferritin or iron plus either total iron-binding capacity or transferrin assay, red cell protoporphyrin or soluble transferrin receptors
- Bone marrow aspirate with staining for iron
- Stool examination for occult blood
- Gastrointestinal imaging and endoscopy, with biopsies if appropriate; rarely, blood loss studies with ^{51}Cr-labelled red cells
- Tests for malabsorption
- Serological tests for coeliac disease (e.g. tissue transglutaminase antibodies)
- Serum lead (if lead poisoning is suspected)

If thalassaemia is suspected:

- HPLC or haemoglobin electrophoresis plus haemoglobin A_2 and F measurements
- Haemoglobin H preparation
- Family studies
- DNA analysis (when the diagnosis is clinically important).

Macrocytic anaemias

If macrocytic, megaloblastic erythroid maturation is demonstrated, further investigations should be undertaken as described in Chapter 10. If the blood film is typical of megaloblastic anaemia, relevant assays and further

investigations can often indicate the diagnosis without the need for a bone marrow aspirate. Macrocytosis may also be secondary to conditions such as alcohol excess, liver disease, MDS, hydroxycarbamide administration and hypothyroidism. Reticulocytosis from any cause can also increase the MCV.

Aplastic anaemia[10]

- Cobalamin and folate assays (although bone marrow hypoplasia is rare)
- Viral studies, particularly for EBV, HIV and hepatitis viruses
- Bone marrow aspirate and trephine biopsy including cytogenetic analysis
- Flow cytometry for glycosylphosphatidylinositol-anchored proteins to detect a paroxysmal nocturnal haemoglobinuria (PNH) clone, followed by urine examination for haemosiderin if positive
- Peripheral blood gene mutation analysis for dyskeratosis congenita if there are relevant clinical features or lack of response to immunosuppressive therapy.

If Fanconi anaemia is suspected:

- Studies of sensitivity of chromosomes to breakage by DNA cross-linking agents.

Haemolytic anaemias

A haemolytic process may be suspected by the presence of a falling Hb, a reticulocytosis and jaundice with an increase in unconjugated bilirubin level (see Chapters 9, 10 and 11).

White cell disorders

The blood film is often of critical importance in the differential diagnosis of white cell disorders though it may sometimes be normal (e.g. in some patients with lymphoma or neutrophil functional defects). Changes in white cell numbers or morphology may occur rapidly in response to local or systemic disorders. In chronic leukaemias, bone marrow aspiration may add little to the diagnosis, but the pattern of infiltration of neoplastic cells seen on trephine biopsy can have diagnostic value or prognostic significance (e.g. in lymphoma and chronic lymphocytic leukaemia).

Acute leukaemia

- Full blood count and peripheral blood film
- Bone marrow aspirate and trephine biopsy
- Blood or marrow immunophenotyping for monitoring minimal residual disease (cytochemical stains can be used if immunophenotyping is not readily available)
- Cytogenetic analysis
- Molecular studies (e.g. fluorescence *in situ* hybridisation (FISH) analysis) for identification of acute lymphoblastic leukaemia (ALL) with hyperdiploidy or *ETV6–RUNX1* fusion, detection of *BCR–ABL1* fusion in adults with ALL and detection of other mutations of specific oncogenes (e.g. *NPM1, CEBPA* and possibly *FLT3* in AML).

Neutropenia

- Cobalamin and folate assays
- Autoantibody screen including rheumatoid factor and investigations for systemic lupus erythematosus
- Serial neutrophil counts for cyclical neutropenia
- Tests for antineutrophil antibodies
- Bone marrow aspirate and trephine biopsy
- Flow cytometry for PNH (see aplastic anaemia above)
- Consider the need for clonality studies for investigation for an abnormal T-cell population.

Chronic myelogenous leukaemia

- Full blood count and peripheral blood film
- Bone marrow aspirate
- Cytogenetic analysis
- Molecular studies (e.g. real-time quantitative reverse transcriptase or FISH) for *BCR–ABL1* transcripts
- Neutrophil alkaline phosphatase score using cytochemistry (only if cytogenetic and molecular genetic analysis are not available).

Chronic lymphoproliferative disorders and/or lymphadenopathy

Various specimens can be used for investigations including lymph nodes, bone marrow aspirates, trephine biopsy cores and peripheral blood and other fluids such as cerebrospinal fluid, ascitic fluid and pleural aspirates.[3]

- Full blood count and peripheral blood film
- Serum protein electrophoresis and immunoglobulin concentrations
- Plasma uric acid, calcium and lactate dehydrogenase (LDH)
- Serological screening for infectious mononucleosis, cytomegalovirus infection, HIV infection and toxoplasmosis (if infectious cause suspected) and human T-cell lymphotropic virus, when clinically relevant
- Bone marrow aspirate and trephine biopsy (to demonstrate the presence and distribution of abnormal lymphocytes) and/or lymph node or other tissue biopsy
- Flow cytometry immunophenotyping or immunohistochemistry of biopsy specimens
- Cytogenetic or molecular genetic analysis including investigation for immunoglobulin heavy chain or T-cell receptor gene rearrangement if the diagnosis of lymphoma is in doubt
- Imaging (plain radiographs, ultrasonography, computed tomography scan, magnetic resonance imaging).

Myelomatosis (plasma cell myeloma)[12]

- Full blood count and peripheral blood film
- Serum protein electrophoresis, immunofixation and quantification of immunoglobulins and any paraprotein
- Urine electrophoresis and immunofixation for Bence–Jones protein (early morning urine sample and, if positive, quantification on 24 h collection)

- Serum free light chain quantification and ratio
- Serum albumin, tests of renal function, plasma uric acid, calcium, phosphate and alkaline phosphatase measurements
- β_2 microglobulin quantification
- Plasma viscosity
- Bone marrow aspirate (with cytogenetic or FISH analysis if results will influence treatment decisions, and flow cytometry immunophenotyping or DNA analysis if these analyses are to be used for monitoring minimal residual disease)
- Trephine biopsy
- Radiologic skeletal survey.

Other disorders

- Thrombocytopenia
- Full blood count and blood film
- Reticulocyte count
- Rh blood group
- Direct antiglobulin test
- HIV test
- Hepatitis screen
- *Helicobacter pylori* test
- Antinuclear antibodies
- Lupus anticoagulant
- Immunoglobulin profile

Myeloproliferative neoplasms

- Full blood count and blood film
- Cobalamin (or B_{12}-binding capacity)
- Uric acid assay
- *JAK2* and *CALR* mutation analysis if PV, ET or primary myelofibrosis is suspected
- Arterial oxygen saturation and carboxyhaemoglobin level (selected patients only)
- Abdominal ultrasound examination
- Cytogenetic analysis
- Bone marrow aspirate and trephine biopsy
- Serum erythropoietin assay
- Red cell and plasma volume (selected patients only).

If splenectomy is contemplated:

- Ferrokinetic and red cell survival studies
- Spleen scan and red cell pool measurement.

Myelodysplastic syndromes

- Full blood count and blood film
- Bone marrow aspirate and trephine biopsy
- Cytogenetic analysis.

Pancytopenia with splenomegaly

- Cobalamin and folate assays
- Serum rheumatoid factor and autoantibody screen
- Bone marrow aspirate and trephine biopsy
- Examination of bone marrow or splenic aspirate for amastigotes of *Leishmania donovani* and bacterial culture of marrow for infectious agents including mycobacteria
- Biopsy of palpable lymph nodes
- Liver biopsy
- Tests for PNH (see p. 271).

The rationale behind these tests and details of specialised investigations can be found in comprehensive haematology textbooks, in electronic databases and on websites.

CLASSIFICATION OF HAEMATOLOGICAL NEOPLASMS

Classifications for haematological neoplasms are based on World Health Organisation publications[3,13,14] which outline the international standards for assessment and diagnosis of haematological neoplasms. Application of the WHO criteria depends on the clinical history and physical examination, morphology (cytology or histology), immunophenotyping, cytogenetic analysis and, in some circumstances, molecular genetic analysis. The previous French–American–British (FAB) group classifications may be used (1) when these techniques are not all available and (2) in making a provisional morphological diagnosis (e.g. in acute leukaemia), while awaiting the results of further tests. Whichever classification is used, the criteria should be strictly observed so that there is consistency between different centres and countries. The WHO classification of haematological neoplasms has several major categories (Table 23-3).

Classification of acute myeloid leukaemia and related neoplasms

The WHO classification categorises cases as AML (Fig. 23-4) if the following criteria are met:

1. There are at least 20% of blast cells of myeloid lineage in the blood or bone marrow *or*

TABLE 23-3

WHO CLASSIFICATION OF MAJOR CATEGORIES OF MYELOID NEOPLASMS AND ACUTE LEUKAEMIAS

Myeloproliferative neoplasms (MPN)
Myeloid and lymphoid neoplasms associated with eosinophilia and abnormalities of *PDGFRA, PDGFRB* or *FGFR1* or with *PCM1-JAK2*
Myelodysplastic/myeloproliferative neoplasms (MDS/MPN)
Myelodysplastic syndrome (MDS)
Acute myeloid leukaemia and related neoplasms
Acute leukaemias of ambiguous lineage
B lymphoblastic leukaemia/lymphoma
T lymphoblastic leukaemia/lymphoma

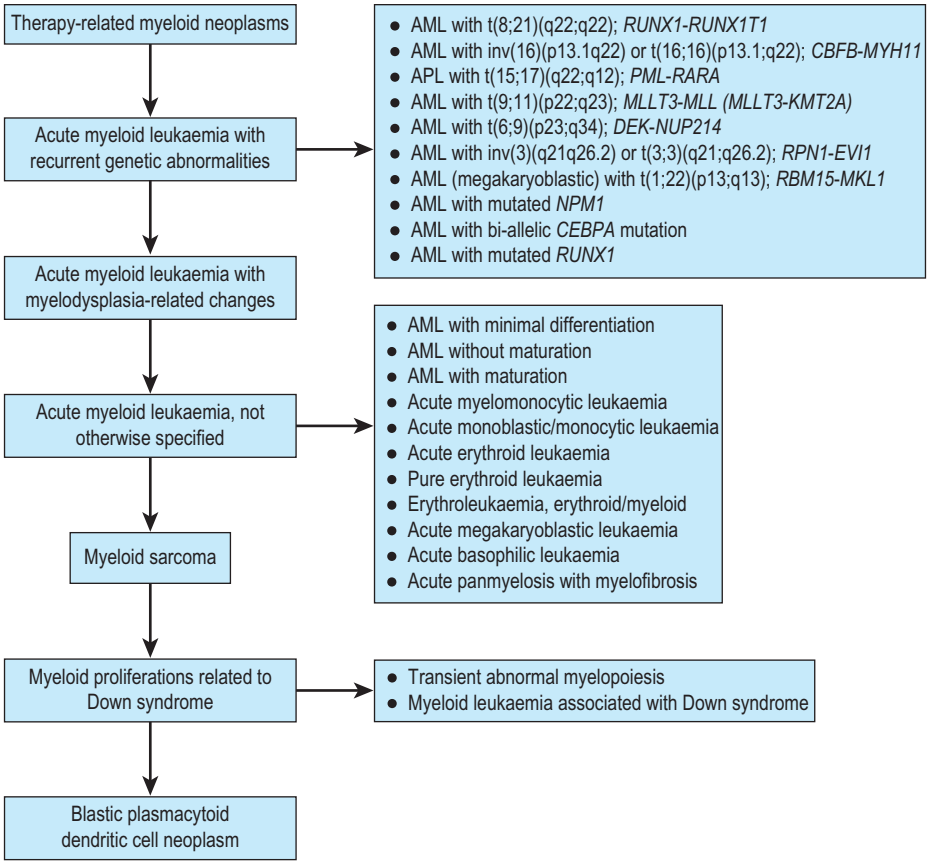

FIGURE 23-4 Hierarchical classification of acute myeloid leukaemia and related neoplasms. *Data from J. Vardiman, J. Thiele, D. Arber, et al. 2009. The 2008 revision of the World Health Organization (WHO) classification of myeloid neoplasms and acute leukemia: rationale and important changes.* Blood *114 (5), 937–951.*

2. If the erythroid cells are at least 50% of bone marrow cells, blast cells are at least 20% of nonerythroid cells *or*
3. Primitive erythroid cells constitute at least 80% of bone marrow cells *or*
4. There is a myeloid sarcoma (granulocytic sarcoma) *or*
5. One of a number of specified chromosomal rearrangements is present.

It should be noted that the WHO classification is hierarchical. If appropriate, cases are first assigned to the category of therapy-related leukaemia. Next, cases are assigned, if appropriate, to the category of AML with recurrent genetic abnormalities. Cases continue to be assigned to successive categories in the order shown in Table 23-4, with remaining cases finally being categorised as 'AML not otherwise specified.' Blastic plasmacytoid dendritic cell neoplasm and myeloid neoplasms associated with Down syndrome are recognised as specific entities.

The WHO classification of acute leukaemia[15] lists cytogenetic abnormalities that, in combination with ≥20 blasts, indicate a diagnosis of AML with myelodysplasia-related changes; assignment to this category can also be based on a previous history of MDS or on morphological evidence of dysplasia.

Classification of the myelodysplastic syndromes

The WHO classification of MDS (Table 23-4) requires evidence for a myeloid neoplasm with ineffective and, generally, dysplastic haemopoiesis; blasts must be <20% in both blood and bone marrow (Table 23-5). It will be noted that cytogenetic analysis is essential for the application of the WHO classification because cases of the 5q-syndrome cannot otherwise be recognised. Like the classification of AML, this is a hierarchical classification. Therapy-related MDS is categorised with therapy-related AML. Remaining cases are then assessed to ascertain whether they meet the criteria for the 5q-syndrome. If they do not, they are assigned to one of the remaining categories, depending on the number of lineages showing dysplasia, the percentage of ring sideroblasts, the presence or absence of Auer rods and the percentage of blast cells in the blood and marrow.

Classification of acute lymphoblastic leukaemia

The WHO classification requires that acute leukaemia must be shown to be lymphoid before it is categorised as ALL. This classification groups together ALL and lymphoblastic lymphoma, using the designations B lymphoblastic leukaemia/lymphoma and T lymphoblastic leukaemia/lymphoma. These designations are clearly too cumbersome to use in clinical practice and undoubtedly haematologists will continue to refer to 'acute lymphoblastic leukaemia.' The FAB classification of ALL is now redundant except that FAB L3 morphology (i.e. the presence of 'blast cells' with basophilic cytoplasm and vacuolation) is of considerable clinical significance and should be recognised. In most, but not all, of these cases the cells are

TABLE 23-4

WHO CLASSIFICATION OF THE MYELODYSPLASTIC SYNDROMES (MDS)

2008 WHO classification	Terminology proposed for the 2016 update of the WHO classification
Refractory cytopenia with unilineage dysplasia	MDS with single lineage dysplasia
Refractory anaemia	
Refractory neutropenia	
Refractory thrombocytopenia	
Refractory anaemia with ring sideroblasts	MDS with single lineage dysplasia and ring sideroblasts
Refractory cytopenia with multilineage dysplasia (with or without ring sideroblasts)	MDS with multilineage dysplasia MDS with multilineage dysplasia and ring sideroblasts
Refractory anaemia with excess blasts-1	MDS with excess blasts-1
Refractory anaemia with excess blasts-2	MDS with excess blasts-2
Myelodysplastic syndrome with isolated del(5q)	Myelodysplastic syndrome with isolated del(5q)
Myelodysplastic syndrome, unclassifiable	Myelodysplastic syndrome, unclassifiable
Childhood myelodysplastic syndrome	Childhood myelodysplastic syndrome
Provisional entity: refractory cytopenia of childhood	Provisional entity: refractory cytopenia of childhood

(Updated from Vardiman J, Thiele J, Arber D, et al. The 2008 revision of the World Health Organization (WHO) classification of myeloid neoplasms and acute leukemia: rationale and important changes. Blood 2009;114:937–951)

TABLE 23-5

WHO DIAGNOSTIC CRITERIA FOR THE MYELODYSPLASTIC SYNDROMES (MDS)

Disease	Blood Findings	Bone Marrow Findings
Refractory cytopenia with unilineage dysplasia (RCUD): (refractory anaemia [RA]; refractory neutropenia [RN]; refractory thrombocytopenia [RT])	Unicytopenia or bicytopenia* No or rare blasts (<1%)**	Unilineage dysplasia: ≥10% of the cells in one myeloid lineage <5% blasts <15% of erythroid precursors are ring sideroblasts
Refractory anaemia with ring sideroblasts (RARS)	Anaemia No blasts	≥15% of erythroid precursors are ring sideroblasts† Erythroid dysplasia only <5% blasts
Refractory cytopenia with multilineage dysplasia with or without ring sideroblasts (RCMD)	Cytopenia(s) No or rare blasts (<1%)** No Auer rods $<1\times10^9$/l monocytes	Dysplasia in ≥10% of the cells in ≥2 myeloid lineages (neutrophil and/or erythroid precursors and/or megakaryocytes) <5% blasts in marrow No Auer rods ±15% ring sideroblasts
Refractory anaemia with excess blasts-1 (RAEB-1)	Cytopenia(s) <5% blasts** No Auer rods $<1\times10^9$/l monocytes	Unilineage or multilineage dysplasia 5–9% blasts** No Auer rods
Refractory anaemia with excess blasts-2 (RAEB-2)	Cytopenia(s) 5–19% blasts‡ Auer rods ±‡ $<1\times10^9$/l monocytes	Unilineage or multilineage dysplasia 10–19% blasts‡ Auer rods ±‡

Continued

TABLE 23-5

WHO DIAGNOSTIC CRITERIA FOR THE MYELODYSPLASTIC SYNDROMES (MDS)—CONT'D

Disease	Blood Findings	Bone Marrow Findings
Myelodysplastic syndrome – unclassified (MDS-U)	Cytopenias ≤1% blasts[**]	Unequivocal dysplasia in <10% of cells in one or more myeloid lineages when accompanied by a cytogenetic abnormality considered as presumptive evidence for a diagnosis of MDS (see Table 23-6) <5% blasts
MDS associated with isolated del (5q)	Anaemia Usually normal or increased platelet count No or rare blasts (<1%)	Normal to increased megakaryocytes with hypolobated nuclei <5% blasts Isolated del(5q) cytogenetic abnormality[¶] No Auer rods

[*]Bicytopenia may occasionally be observed. Cases with pancytopenia should be classified as MDS-U.
[**]If the marrow myeloblast percentage is <5% but there are 2–4% myeloblasts in the blood, the diagnostic classification is RAEB-1. Cases of RCUD and RCMD with 1% myeloblasts in the blood should be classified as MDS-U.
[†]It is proposed that, if an *SF3B1* mutation is present, cases with at least 5% ring sideroblasts be included in this category, and should similarly be included in the newly proposed category of MDS with multilineage dysplasia and ring sideroblasts (Arber 2015).
[‡]Cases with Auer rods and <5% myeloblasts in the blood and <10% in the marrow should be classified as RAEB-2. Although the finding of 5–19% blasts in the blood is, in itself, diagnostic of RAEB-2, cases of RAEB-2 may have <5% blasts in the blood if they have Auer rods or 10–19% blasts in the marrow or both. Similarly, cases of RAEB-2 may have <10% blasts in the marrow but may be diagnosed by the other two findings, Auer rods and/or 5–19% blasts in the blood.
[¶]It is proposed that one additional cytogenetic abnormality (excluding monosomy 7) be accepted in this category (Arber 2015).
(From Vardiman J, Thiele J, Arber D, et al. The 2008 revision of the World Health Organization (WHO) classification of myeloid neoplasms and acute leukemia: rationale and important changes. *Blood* 2009;114:937–951. It is anticipated that terminology will be altered in the 2016 update of the WHO classification.)

TABLE 23-6

MYELOPROLIFERATIVE NEOPLASMS (MPN) AND RELATED CONDITIONS[13-16]

Myeloproliferative neoplasms
Chronic myelogenous leukaemia/chronic myeloid leukaemia
Polycythaemia vera
Essential thrombocythaemia
Primary myelofibrosis
Chronic neutrophilic leukaemia
Chronic eosinophilic leukaemia, not otherwise categorised
Mast cell disease
MPN, unclassifiable
Lymphoid and myeloid neoplasms associated with rearrangement of *PDGFRA, PDGFRB* or *FGFR1* or with *PCM1-JAK2*
Lymphoid and myeloid neoplasms associated with rearrangement of *PDGFRA*
Lymphoid and myeloid neoplasms associated with rearrangement of *PDGFRB*
Lymphoid and myeloid neoplasms associated with rearrangement of *FGFR1*
Lymphoid and myeloid neoplasms associated with *PCM1-JAK2*

immunologically mature, expressing surface membrane immunoglobulin and the condition represents a leukaemic presentation of Burkitt lymphoma. The WHO categorisation of such cases as lymphoma is more appropriate than their being categorised as ALL and is clinically important because the treatment is urgent and differs considerably from the treatment of ALL.

Classification of myeloproliferative neoplasms and related conditions

The WHO classification of myeloproliferative neoplasms (previously called 'disorders') and related conditions (Table 23-6) is increasingly taking account of cytogenetic or molecular genetic analyses.

WHO criteria for a diagnosis of essential thrombocythaemia are: platelet count $\geq 450 \times 10^9$/l; megakaryocyte proliferation with large and mature megakaryocytes on examination of the bone marrow with little or no granulocyte or erythroid proliferation; not meeting WHO criteria for CML, PV, primary myelofibrosis, MDS or other myeloid neoplasm; demonstration of *JAK2* V617F or other clonal marker or no evidence of reactive thrombocytosis.[16]

WHO criteria for a diagnosis of primary myelofibrosis are divided into major criteria (e.g. megakaryocyte proliferation and atypical megakaryocytes accompanied by reticulin and/or collagen fibrosis; demonstration of *JAK2* V617F or other clonal marker; no evidence of reactive marrow fibrosis; not meeting WHO criteria for CML, PV, MDS or other myeloid neoplasm) and minor criteria (e.g. leucoerythroblastosis; increased serum LDH; anaemia; palpable splenomegaly).

WHO criteria for a diagnosis of systemic mastocytosis are highly complex.[17] A trephine biopsy with a mast cell

TABLE 23-7

SUMMARY OF THE WORLD HEALTH ORGANISATION CATEGORIES OF MYELODYSPLASTIC/MYELOPROLIFERATIVE NEOPLASMS

Category	Criteria
Chronic myelomonocytic leukaemia (CMML)	A Ph-negative, *BCR–ABL1*-negative disorder with monocyte count $>1\times10^9$/l Fewer than 20% blasts plus promonocytes in PB or BM Either dysplasia of one or more myeloid lineages or alternative criteria met (acquired clonal cytogenetic abnormality or monocytosis persisting for at least 3 months and alternative causes of monocytosis excluded)
Atypical chronic myeloid leukaemia (aCML)	A Ph-negative, *BCR–ABL1*-negative disorder with leucocytosis resulting from an increase in neutrophils and their precursors, the precursors (promyelocyte to metamyelocytes) constituting a least 10% of PB white cells Basophils <2% of white cells Monocytes <10% of white cells Hypercellular BM with granulocytic hyperplasia and dysplasia, with or without dysplasia of other lineages Fewer than 20% blasts plus promonocytes in peripheral blood or bone marrow
Juvenile myelomonocytic leukaemia (JMML)	A Ph-negative, *BCR–ABL1*-negative disorder with monocyte count $>1\times10^9$/l Fewer than 20% blasts plus promonocytes in peripheral blood or bone marrow Plus two or more of the following Haemoglobin F increased for age Immature granulocytes in the PB WBC $>10\times10^9$/l Clonal chromosomal abnormality (monosomy 7 not excluded) GM-CSF hypersensitivity of myeloid precursors *in vitro*
Myelodysplastic/myeloproliferative neoplasm with ring sideroblasts and thrombocytosis (MDS-RS-T)	Ring sideroblasts ≥ 15% Platelet count $\geq 450\times10^9$/l Blast cells < 1% in peripheral blood and < 5% in bone marrow
Myelodysplastic/myeloproliferative neoplasm, unclassifiable	A myelodysplastic/myeloproliferative disorder in which the criteria of one of the myelodysplastic syndromes are met There are prominent proliferative features (e.g. a platelet count of $\geq450\times10^9$/l or a white cell count of $\geq13\times10^9$/l) The condition has developed *de novo* The criteria for other MDS/MPN (CMML, aCML and JMML) are not met There is no Philadelphia chromosome, *BCR–ABL1* fusion gene, 5q−, inv(3)(q21q26) or t(3,3)(q21;q26)

aCML, atypical chronic myeloid leukaemia; BM, bone marrow; CMML, chronic myelomonocytic leukaemia; GM-CSF, granulocyte-macrophage colony-stimulating factor; JMML, juvenile myelomonocytic leukaemia; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; PB, peripheral blood; Ph, Philadelphia; WBC, white blood cell count.

tryptase stain is often crucial in the diagnosis. Molecular analysis for a *KIT* mutation can also be important.

Recognition of lymphoid and myeloid neoplasms associated with rearrangement of *PDGFRA, PDGFRB* or *FGFR1* and *PCM1-JAK2* requires cytogenetic and molecular analyses. Appropriate molecular analysis may be either FISH or reverse transcription polymerase chain reaction (RT-PCR). The diagnosis of chronic eosinophilic leukaemia, not otherwise specified, requires exclusion of the above-specified molecular abnormalities.

The categorisation of neoplasms with features of both myelodysplasia and myeloproliferation and their diagnostic criteria are summarised in Table 23-7.

Laboratory Organisation, Management and Safety

Anne E. Bradshaw • Christopher McNamara

CHAPTER CONTENTS

The services provided by laboratories are an essential and fundamental component of health systems across the globe. The essential functions of a haematology laboratory are (1) to provide clinicians with timely, unambiguous and meaningful information to assist in the clinical diagnosis of disease and to monitor response to treatment; (2) to obtain reliable and reproducible data for health screening and epidemiological studies; and (3) to keep abreast with advancing technology as well as aspects of healthcare legislation that might be relevant to modern laboratory practice. The laboratory should also be involved in both the pre-analytical stage (i.e. test selection, blood collection, specimen transport) and the postanalytical stage (i.e. preparing reports, transmission of results and maintaining a data file).

For good laboratory practice, it is essential to have a well-structured organisation with competent direction and management. The principles outlined in this chapter apply to all laboratories, irrespective of their size, although large departments are likely to require the more complex arrangements that are described.

MANAGEMENT STRUCTURE AND FUNCTION

The management structure of a haematology laboratory should indicate a clear line of accountability of each member of staff to the head of department. In turn, the head of department may be managerially accountable to a clinical director (of laboratories) and thence to a hospital or health authority executive committee. The head of department is responsible for departmental leadership, for ensuring that the laboratory has authoritative representation within the hospital and for ensuring that managerial and administrative tasks are performed efficiently. Where the head of the department delegates managerial tasks to others, these responsibilities must be clearly defined and stated. Formerly, the director was usually a medically qualified haematologist, but nowadays in many laboratories, this role is being undertaken by appropriately qualified biomedical scientists, while haematologists serve as consultants. In that role, haematologists should be fully conversant with the principles of laboratory practice, especially with interpretation and clinical significance of the various analytical procedures, so as to provide a reliable and authoritative link between the laboratory and clinicians. Furthermore, all medical staff, especially junior hospital doctors, should be invited to visit the laboratory, to see how it functions and how various tests are performed; they should gain an understanding of the level of complexity of tests, their clinical utility and their cost, which should give them the ability and confidence to order tests rationally.[1]

Management of the laboratory requires an executive committee answerable to the head of department. Under this executive, there should be a number of designated individuals responsible for implementing the functions of the department (Table 24-1).

The activities of the various members of staff clearly overlap and there must be adequate effective communication between them. There should be regular briefings at meetings of technical heads, with their section staff. The only way to avoid unauthorised 'leakage' of information from policy-making committees is to ensure that all members of staff are kept fully informed of any plans which might have a bearing on their careers, working practices and wellbeing.

In many countries, there are now requirements established by regulatory agencies for accreditation of laboratories and audit of their performance, as well as documents on laboratory management and practice from standards-setting authorities; there is also a plethora of guidelines from national and international professional bodies. These may have a profound impact on the broader organisation of a laboratory. For example, the National Institute for Health and Care Excellence has responded to well documented concerns regarding the accuracy of diagnosis of haematological malignancies by mandating formal integration of the affected laboratory services into a single laboratory structure, with its own lead and governance structure. At a single stroke this guidance eliminates the possibility of a single-handed scientist, haematologist or histopathologist reporting on the presence or absence of a haematological malignancy without being part of a larger laboratory organisation that accepts responsibility for the internal validation and cross-checking of results. These changes are likely to require significant reconfiguration of existing services and better collaboration between haematologists, histopathologists, cytogeneticists and molecular geneticists.

TABLE 24-1

EXAMPLE OF COMPONENTS OF A MANAGEMENT STRUCTURE

- Executive committee
  - Head of department
  - Business manager
  - Consultant haematologist
  - Principal scientific officer
- Safety officer
- Quality control officer
- Computer and data processing supervisor
- Sectional scientific/technical heads
  - Cytometry
  - Blood film morphology
  - Immunohaematology
  - Haemostasis
  - Blood transfusion
  - Special investigations (haemolytic anaemias, haemoglobinopathies, cytochemistry, molecular techniques, etc.)
- Clerical supervisor

Staff appraisal

All members of staff should receive training to enhance their skills and to develop their careers. This requires setting of goals and regular appraisal of progress for both managerial and technical ability. The appraisal process should cascade down from the head of department and appropriate training must be given to those who undertake appraisals at successive levels. The appraiser should provide a short list of topics to the person to be interviewed, who should be encouraged to add to the list, so that each understands the items to be covered. Topics to be considered should include: quality of performance and accurate completion of assignments; productivity and dependability; ability to work in a team; and ability to relate to patients, clinicians and co-workers. It is not appropriate to include considerations relating to pay. An appraisal interview should be a constructive dialogue of the present state of development and the progress made to

date; it should be open-ended and should identify future training requirements. Ideally, the staff members should leave the interviews with the knowledge that their personal development and future progress are of importance to the department, that priorities have been identified, that an action plan with milestones and a time scale has been agreed and that progress will be monitored. Formal appraisal interviews (annually for senior staff and sometimes more often for others) should be complemented by less formal follow-up discussions to monitor progress and to check that suboptimal performance has been modified. Performance appraisal can have lasting value in the personal development of individuals, but the process can easily be mishandled and should not be started without training in how to hold an appraisal interview.[2]

Continuing professional development

Continuing professional development is a process of continuous systematic learning which enables health workers to be constantly brought up to date on developments in their professional work and thus ensure their competence to practice throughout their professional careers. Policies and programmes have been established in a number of countries and, in some, participation is a mandatory requirement for the right to practice.[3]

In the UK, haematologists and clinical scientists who have the relevant qualifications awarded by the Royal College of Pathologists (RCPath) are licenced to practice by the General Medical Council. They are required to participate in a scheme organised by the College that involves maintenance of a portfolio showing their participation in relevant educational and academic activities and demonstration of their professional skills.

The Institute for Biomedical Science undertakes a similar scheme for scientists/technologists working in the laboratory, which is mandatory for registration to practice by the UK Health Professions Council. The procedure is based on obtaining 'credits' for various activities that qualify, such as attendance at specified lectures, workshops and conferences; giving lectures; writing books or journal articles; using journal-based programmes and taking part in peer review discussions.

Strategic and business planning

The head of department is responsible for determining the long-term (usually up to 5 years) strategic direction of the department. Strategic planning requires awareness of any national and local legislation that may affect the laboratory and of changes in local clinical practice that may alter workload. Expansion of a major clinical service, such as organ transplantation, or the opportunity to compete for the laboratory service of other hospitals and clinics, may pose an external opportunity, but may also be a threat to the laboratory, depending on its ability to respond to the consequential increase in workload. Technical or scientific expertise would be a strength, whereas a heavy workload without adequate staffing, or a lack of automation for routine tests, is likely to preclude any additional developmental work and would, thus, be a weakness.

Increasingly, laboratories must meet financial challenges and the need for greater cost-effectiveness. This may require rationalization by eliminating unused laboratory capacity, avoiding unnecessary tests and ensuring more efficient use of skilled staff and expensive equipment. This may require centralisation of multiple laboratory sites or, conversely, the establishment of satellite centres for the benefit of patients and clinicians when this can be shown to be cost-effective. Account must also be taken of the role of the laboratory in supervision of the extra-laboratory point-of-care procedures that have become increasingly popular.

A business plan is primarily concerned with determining short-term objectives that will allow the strategy to be implemented over the next financial year or so. It requires prediction of future work level and expansion. Planning of these objectives should involve all staff because this will heighten awareness of the issues and will develop personal concern in the strategy. In all but the smallest laboratory, a business manager is required to coordinate such planning and to liaise with the equivalent business managers in other clinical and laboratory areas.

The largest and most important strategic review of pathology services ever undertaken in the UK concluded that the principle mechanism for performance improvement in laboratories was reconfiguration of individual laboratories into managed pathology networks. This allows for improvements in the efficiency and the quality of the laboratory service provided. The cost-per-test frequently falls as a service carries out more tests, as laboratories develop staff and process expertise (especially in less frequently needed tests) and as throughput increases. A pathology network may be arranged in many ways but is often in the form of 'hub-and-spoke' arrangement where a local, rapid response 'spoke' laboratory provides those tests that are required to support acute services (e.g. full blood count, basic electrolytes, clotting profile, blood transfusion) while the 'hub' or core laboratory provides most of the more specialised pathology service. The hub may be located away from the location of the clinical service, provided that communication links are maintained between the laboratory and clinicians.

Workload assessment and costing of tests

Laboratories should maintain accurate records of workload, overall costs and the cost per test in order to apportion resources to each section. Computerisation of laboratories has greatly facilitated this process. In assessing workload, account must be taken of the entire

cycle from specimen receipt to issuing of a report, whether the test is by a manual or semiautomated method or by a high-volume multiple-analyte automated analyser. Apportioning of resources should also take account of the roles of biomedical scientists/senior technologists, junior technicians, laboratory assistants, clerical staff and medical personnel responsible for reviewing the report. Out of hours service requires a different calculation of costs.

Methods have been developed for determining the workload and costs for various laboratory tests taking account of test complexity, total number of tests performed, quality control procedures, cost of reagent and use of material standards so that laboratories can compare their operational productivity with a peer group of participating laboratories. A good example is given on the website Standards for Management Information Systems in the Canadian Health Service Organisations (www.cihi.ca/en/data-and-standards/standards/mis-standards/standards-for-management-information-systems-in-canadian).

A similar workload recording method was published by the College of American Pathologists,[4] and the Welcan system was established in the UK.[5] However, more recently, benchmarking schemes have been established that take account of productivity, cost-effectiveness and utilisation compared with a peer group. The College of American Pathologists created their Laboratory Management Index Program in which participants submit their laboratories' operating data on a quarterly basis and receive peer comparison reports from similar laboratories around the country by which their own cost-effectiveness can be evaluated.

Financial control

Full costing of tests includes all aspects of laboratory function (Table 24-2).

The amount allocated for staff salaries should include the cost of training and should take into account absences for annual leave, study leave or sickness. It needs also to take into account the extent to which staff of various levels, as described earlier, are involved. Indirect costs may be apportioned to different sections of a department that share common overhead costs.

Calculation of test costs

When preparing a budget, the following formula provides a reasonably reliable estimate of the total annual costs:

$$[L \times N] + [C \times N] + E + M + O + S + T + A$$

where

L = Labour costs for each test from estimate of time taken and the salary rate of the staff member(s) performing the tests
N = Number of tests in the year
C = Cost of consumables per test (including controls)

TABLE 24-2

FACTORS CONTRIBUTING TO COST OF LABORATORY TESTS

Direct costs
- Staff salaries
- Laboratory equipment purchases
- Reagents and other consumables
- Equipment maintenance
- Standardisation and quality control
- Specific technical training on equipment

Indirect costs
- Capital costs and mortgage factor
- Depreciation
- Building repairs and routine maintenance
- Lighting, heating and waste disposal
- Personnel services
- Cleaning services
- Transport, messengers and porters
- Laundry services
- Computers and information technology
- Telephone and fax
- Postage
- Journals and textbooks

E = Annual equipment cost based on initial cost divided by expected life of the item or the annual cost of hire (see below)
M = Annual maintenance and servicing of equipment
O = Laboratory overheads (Table 24-2)
S = Supervision
T = Transport and communication
A = Laboratory administration, including salaries of clerical and other nontechnical staff.

Efficient budgeting requires regular monitoring, at least monthly. Computer spreadsheets provide an easily comprehended view of the financial state and the likely responses in the running of the laboratory.

In general, staff cost is by far the largest component of the total costs of running a laboratory. Furthermore, many of the other costs are obligations outside the direct control of the laboratory. If financial savings become necessary, they can be achieved in a variety of ways, but large savings usually necessitate a reduction in staff because employment costs can account for three-quarters of total expenditure. Possible initiatives include the following:

- Rationalisation of service with other local hospitals to eliminate duplication
- Restructuring within a hospital laboratory for cross-discipline working (usually between haematology and clinical chemistry)
- Subcontracting of labour-intensive tests to a specialist laboratory
- Greater use of automated instruments/methods

- Employment of part-time contract staff (e.g. for overnight and weekend emergency service or for the phlebotomy service) and sharing of emergency service between local hospitals
- Review of price setting on the basis of workload and calculated cost per test.

Increasingly, use of automated systems for routine screening tests allows the laboratory to consider staff reduction, although an estimate of savings must take account of capital costs, maintenance contracts and running costs of the equipment, especially the high cost of some reagents, and whether the system can be used to high capacity and throughout a 24 h service.

Purchasing expensive equipment outright adds to the capital assets of the laboratory, with the consequential cost of depreciation (usually 8–10% per annum). Leasing equipment can be a better alternative, and in many countries most equipment is obtained in this way. Careful calculation of the lease cost is required because this can be up to 20% higher than outright purchase. An advantage of leasing is flexibility to upgrade equipment should workload increase or technology change. If maintenance and consumable costs are included in the same agreement, it may be possible to negotiate a reduction in charge for the consumables, but it is important to neither underestimate nor overestimate the annual requirements that will be included in the contract.

When automation is coupled with centralisation of the service to another site, care must be taken to maintain service quality.[6] Failure to do so will encourage clinicians to establish independent satellite laboratories. Loss of contact between clinical users and laboratory staff may compromise the pre-analytical phase of the test process and may lead to inappropriate requests, excessive requests and test samples that are of inadequate volume or are poorly identified. When services are centralised, attention must be paid to all phases (pre-analytical, analytical and post-analytical) of the test process, including the need for packaging the specimens and the cost of their transport to the laboratory.[6]

TEST RELIABILITY

The reliability of a quantitative test is defined in terms of the *uncertainty of measurement* of the analyte (sometimes referred to as 'measurand'). This is based on its accuracy and precision.[7]

Accuracy is the closeness of agreement between the measurement that is obtained and the true value; the extent of discrepancy is the *systematic error* or *bias*. The most important causes of systematic error are listed in Table 24-3. The error can be eliminated or at least greatly reduced by using a reference standard with the test, together with internal quality control and regular checking by external quality assessment (see Chapter 25, p. 539).

TABLE 24-3

SYSTEMATIC ERRORS IN ANALYSES

Analyser calibration uncertain (no reference standard available)
Bias in instrument, equipment or glassware
Faulty dilution
Faults in the measuring steps (e.g. reagents, spectrometry, calculations)
Sampling not representative of specimen
Specimens not representative of *in vivo* status
Incomplete definition of analyte or lack of critical resolution of analyser
Approximations and arbitrary assumptions inherent in analyser's function
Environmental effects on analyser
Pre-analytical deterioration of specimens

Precision is the closeness of agreement when a test is repeated a number of times. Imprecision is the result of random errors; it is expressed as standard deviation (SD) and coefficient of variation (CV). When the data are spread normally (Gaussian distribution), for clinical purposes, there is a 95% probability that results that fall within a range of +2SD to −2SD of the target value are correct and a 99% probably if within the range of +3SD to −3SD (see also Fig. 2-1).

Some of the other factors listed in Table 24-3 can be quantified to calculate the combined uncertainty of measurement. Thus, for example, when a calibration preparation is used, its uncertainty is usually stated on the label or accompanying certificate. The standard uncertainty is then calculated from the sum of the quantified uncertainties as follows:

$$\sqrt{(SD_1)^2 + (SD_2)^2}$$

Expanded uncertainty of measurement takes account of nonquantifiable items by multiplying the previous amount by a 'coverage factor' (k), which is usually taken to be × 2 for 95% level of confidence.[7,8]

It may be necessary to decide by statistical analysis whether two sets of data differ significantly. The *t*-test is used to assess the likelihood of significant difference at various levels of probability by comparing the means or individually paired results. The *F*-ratio is useful to assess the influence of random errors in two sets of test results (see Appendix, p. 566).

Of particular importance are reports with 'critical laboratory values' that may be indicative of life-threatening conditions requiring rapid clinical intervention. Haemoglobin concentration, platelet count and activated partial thromboplastin time have been included in this category.[9] The development of critical values should involve consultation with clinical services.

TEST SELECTION

It is important for the laboratory to be aware of the limits of accuracy that it achieves in its routine performance each day as well as day-to-day.[10] Clinicians should be made aware of the level of uncertainty of results for any test and the potential effect of this on their diagnosis and interpretation of response to treatment (see below).

To evaluate the diagnostic reliability and predictive value of an individual laboratory test, it is necessary to calculate test sensitivity and specificity.[11] *Sensitivity* is the fraction of true positive results when a test is applied to patients known to have the relevant disease or when results have been obtained by a reference method. *Specificity* is the fraction of true negative results when the test is applied to normals.

$$\text{Diagnostic sensitivity} = TP \div (TP + FN)$$
$$\text{Diagnostic specificity} = TN \div (TN + FP)$$
$$\text{Positive predictive value} = TP \div (TP + FP)$$
$$\text{Negative predictive value} = TN \div (TN + FN)$$

where TP = true positive; TN = true negative; FP = false positive; FN = false negative.

Overall reliability can be calculated as:

$$\frac{TP + TN}{\text{Total number of tests}} \times 100\%$$

Sensitivity and specificity should be near 1.0 (100%) if the test is regarded as diagnostic for a particular condition. A lower level of sensitivity or specificity may still be acceptable if the results are interpreted in conjunction with other tests as part of an overall pattern. It is not usually possible to have both 100% sensitivity and 100% specificity. Whether sensitivity or specificity is more important depends on the particular purpose of the test. Thus, for example, if haemoglobinometry is required in a clinic for identifying patients with anaemia, sensitivity is important, whereas in blood donor selection, for selecting individuals who are not anaemic, specificity is more important.

Likelihood ratio

The ratio of positive results in disease to the frequency of false-positive results in healthy individuals gives a statistical measure of the discrimination by the test between disease and normality. It can be calculated as follows:[12]

$$\frac{\text{Sensitivity}}{1 - \text{Specificity}}$$

The higher the ratio, the greater is the probability of disease, whereas a ratio <1 makes the possibility of the disease being correctly diagnosed by the test much less likely. Conversely, the likelihood of normality can be calculated as:

$$\frac{1 - \text{Specificity}}{\text{Sensitivity}}$$

An alternative method is that of Youden, which is obtained by calculating Specificity/(1 − Sensitivity) (see p. 542).[13] Values range between −1 and +1. With a positive ratio rising above zero towards +1 there is an increasing probability that the test will discriminate the presence of the specified disease and there is decreasing likelihood that the test is valid when the ratio falls from 0 to −1.

Receiver–operator characteristic analysis

The relative usefulness of different methods for the same test or of a new method against a reference method can also be assessed by analysing the receiver–operator characteristics (ROC).[12] This is demonstrated on a graph by plotting the true-positive rates (*sensitivity*) on the vertical axis against false-positive rates (1 − *specificity*) on the horizontal axis for a series of paired measurements (Fig. 24-1). Obviously, the ideal test would show high sensitivity (i.e. 100% on vertical axis), with no false positives (i.e. 0% on horizontal axis). Realistically, there would be a compromise between the two criteria, with test selection depending on its purpose, (i.e. whether as a screening to exclude the disease in question or to confirm a clinical suspicion that the disease is present). In the illustrated case, Test A is more reliable than Test B in both circumstances.

Test utility

To ensure reliability of the laboratory service, tests with no proven value should be eliminated and new tests should

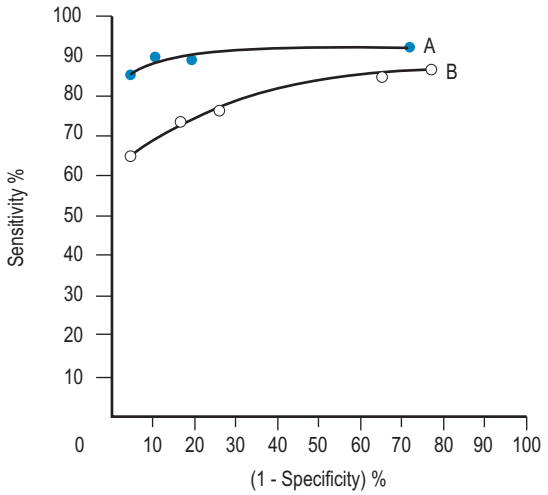

FIGURE 24-1 Receiver–operator characteristic (ROC) analysis. Graph shows curves relating true-positive rates (sensitivity) to false-positive rates (1 – specificity) for two tests A and B making the same measurements.

be introduced only when there is evidence of technical reliability as well as cost-effectiveness.

For assessing cost-effectiveness of a particular test, account must be taken of (1) cost per test as compared with other tests that provide similar clinical information; (2) diagnostic reliability; and (3) clinical usefulness as assessed by the extent with which the test is relied on in clinical decisions, whether the results are likely to change the physician's diagnostic opinion and the clinical management of the patient, taking account of disease prevalence and a specified clinical or public health situation. This requires audit by an independent assessor to judge what proportion of the requests for a particular test are actually used intelligently and what percentage are unnecessary or wasted tests.[14,15] Information on the utility of various tests can also be obtained from benchmarking (see p. 526) and published guidelines. Examples of the latter are the documents published by the British Committee for Standards in Haematology (http://www.bcshguidelines.com/). The realistic cost-effectiveness of any test may be assessed by the formula:

A/(B × C), where A = cost/test, as described on p. 515
B = diagnostic reliability, as described on p. 514
C = clinical usefulness, as described above.

Economic aspects should also be considered when providing an automated total screening programme for every patient, in contrast to specifically selected tests. Thus, while many clinicians may not be familiar with all of the 12 or more parameters included in the blood count as reported routinely by modern automated analysers, and in most cases, some of these measurements are unlikely to be clinically useful, nevertheless the 'not requested' information may be provided at no extra cost and even significant saving of time in the laboratory. In addition, this 'not requested' information will be meaningful to some users, including haematologists who might be consulted about a patient.

INSTRUMENTATION

Equipment evaluation

Assessment of the clinical utility and cost-effectiveness of equipment to match the nature and volume of laboratory workload is a very important exercise. Guidelines for evaluation of blood cell analysers and other haematology instruments have been published by the International Council for Standardisation in Haematology.[16] In the UK, appraisal of various items of laboratory equipment was formerly undertaken by selected laboratories at the request of the Department of Health's Medical Devices Agency, subsequently renamed Medicines and Healthcare products Regulatory Agency (MHRA) and now replaced by the Centre for Evidence-based Purchasing (CEP). (Their reports can be accessed from the website http://nhscep.useconnect.co.uk).

Principles of evaluation

The following aspects are usually included in evaluations:

1. Verification of instrument requirements for space and services
2. Extent of technical training required to operate the instrument
3. Clarity and usefulness of instruction manual
4. Assessment of safety (mechanical, electrical, microbiological and chemical)
5. Determination of the following:
   a. Linearity
   b. Precision/imprecision
   c. Carryover
   d. Extent of inaccuracy by comparison with measurement by definitive or reference methods
   e. Comparability with an established method used in the laboratory
   f. Performance when used in an external quality control scheme
   g. Sensitivity (i.e. determination of the smallest change in analyte concentration that gives a measured result)
   h. Specificity (i.e. extent of errors caused by interfering substances)
6. Throughput time and number of specimens that can be processed within a normal working day
7. Reliability of the instrument when in routine use and adequacy of service and maintenance provided
8. Cost per test, including operating time, reagents, daily start-up procedure and regular (usually weekly) maintenance procedures
9. Staff acceptability, impact on laboratory organisation and level of technical expertise required to operate the instrument
10. Any relevant authority label, e.g. CE mark on a device indicates that it conforms to defined specifications of the EU directive 98/79 for *in vitro* diagnostic medical devices (IVDD), as described in the Official Journal (OJ) of the EC: 7.12.98 (http://ec.europa.eu/growth/single-market/european-standards/harmonised-standards/medical-devices/index_en.htm).

After an instrument has been purchased and installed, it is useful to undertake regular less extensive checks of performance with regard to precision, linearity, carryover and comparability.

Precision

Carry out appropriate measurements 10 times consecutively on three or more specimens selected to extend into the pathological range so as to include a low, a high and a middle range concentration of the analyte. Calculate the replicate SD and CV as shown on p. 566. The degree of precision that is acceptable depends on the purpose of the test (Table 24-4). To check between-batch precision,

TABLE 24-4

TEST PRECISION FOR DIFFERENT PURPOSES

Purpose of test		Expected CV% (Automated Counters)		
		Hb	RBC	WBC
Scientific standard		<1	1	1–2
State of art:				
	Best performance	1.5	2	3
	Routine laboratories	2–3	3	5–6
Clinical needs		5–10	5	10–15

CV, coefficient of variation; Hb, haemoglobin concentration; RBC, red blood cell count; WBC, white blood cell count.

measure three samples in several successive batches of routine tests; calculate the SD and CV in the same way.

Linearity

Linearity demonstrates the effects of dilution. Prepare a specimen with a high concentration of the analyte to be tested and, as accurately as possible, make a series of dilutions in plasma so as to obtain 10 samples with evenly spaced concentration levels between 10% and 100%. Measure each sample three times and calculate the means. Plot results on arithmetic graph paper. Ideally, all points should fall on a straight line that passes through the zero of the horizontal and vertical axes. In practice, the results should lie within 2SD limits of the means calculated from the CVs, which have been obtained from analysis of precision (see earlier). Inspection of the graph will show whether there is linearity throughout the range or whether it is limited to part of the range.

Carryover

Carryover indicates the extent to which measurement of an analyte in a specimen is likely to be affected by the preceding specimen. Measure a specimen with a high concentration in triplicate, immediately followed by a specimen with a low concentration of the analyte:

$$\text{Carryover}(\%) = \frac{l_1 - l_3}{h_3 - l_3} \times 100$$

where l_1 and l_3 are the results of the first and third measurements of the samples with a low concentration and h_3 is the third measurement of the sample with a high concentration.

Accuracy and comparability

Accuracy and comparability test whether the new instrument (or method) gives results that agree satisfactorily with those obtained with an established procedure and with a reference method. Test specimens should be measured alternately, or in batches, by the two procedures. If results by the two methods are analysed by correlation coefficient (r), a high correlation does not mean that the two methods agree. Correlation coefficient is a measure of relation and not agreement. It is better to use the limits of agreement method.[12] For this, plot the differences between paired results on the vertical axis of linear graph paper against the means of the pairs on the horizontal axis (Fig. 24-2); differences between the

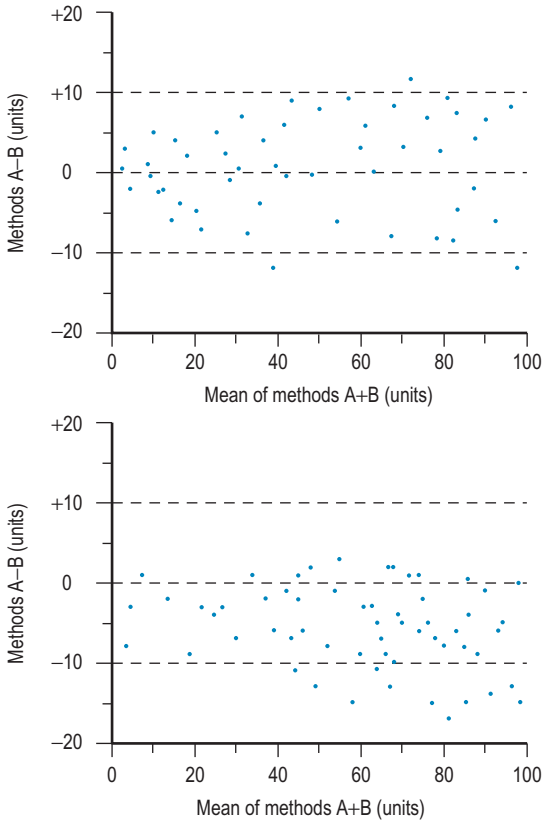

FIGURE 24-2 Limits of agreement method. Shows mean values for paired results by two methods A plus B (horizontal axis) plotted against the differences (A minus B) between the paired results (vertical axis). Horizontal lines represent equality with range of ±10 units (mean ±SD). Upper figure shows no bias between methods A and B, whereas lower figure shows false high results (negative values) for method B.

methods are then readily apparent over the range from low to high values. If the scatter of differences increases at high values, logarithmic transformed data should be plotted.

It is also useful to check for bias by including the instrument or method under test in the laboratory's participation in an external quality assessment scheme (see p. 539). Bias is expressed by:

$$\frac{R - M}{M} \times 100$$

where R = measurement by the device/method being tested and M = target result.

Another method to check for bias is by means of the variance index. For this, the coefficient of variation is established at an optimal chosen value (CCV) to ensure a reliable method and the variation index (VI%) is calculated as:

$$\frac{R - M}{M} \times \frac{100}{CCV} \times 100$$

Maintenance logs. All laboratory equipment should be inspected regularly and specific maintenance procedures should be carried out. Each item of laboratory equipment should have a maintenance log to document what maintenance is required, the desired frequency and when it was last carried out. The log includes servicing and repairs by the manufacturer. Equipment used to test biological specimens must be cleaned thoroughly before a maintenance procedure is carried out to reduce the biohazard. The procedure for such cleaning must be documented (as a standard operating procedure), together with the name of the responsible worker and the date.

DATA PROCESSING

It is essential that accurate records of laboratory results are kept for whatever period is stipulated by national legislation. Computer-assisted data handling is essential for all but the smallest laboratory. For long-term storage of data, possibilities include a printed (hard) copy, a memory stick and external hard drive or a local server. Laboratory results are usually issued as numerical data with abnormal results highlighted for the clinician. Report forms should be reader friendly. Serial data are particularly useful to illustrate any trend with time and may be in the form of a cumulative tabulation or a graph. For the latter, an arithmetic scale should be used for haemoglobin concentration, red cell count and reticulocytes, whereas platelet and leucocyte counts are best displayed on a logarithmic scale (Fig. 24-3). A graph is particularly useful for displaying results in relation to target intervals because this facilitates adjustment of dosage of drugs that are likely to affect the blood. Furthermore, this method of archiving reduces the number of pages of laboratory reports in the patient's file.[17]

Laboratory computers

Developments in computer technology have made available powerful microcomputers and sophisticated computer software at moderate prices. Such computers may be an integral part of an analytical instrument or interfaced to it by cable. A modem is required to link the computer to the telephone or broadband for access to the internet and electronic mail and also to interconnect within a local area network, so as to provide for data interchange and to enable multiple workers to use a common database. Because computers are developing at such a rate, it is essential to seek expert advice to ensure that the instrument being purchased is fit for purpose. Programmes that provide access to a vast amount of information include Google Scholar and the US National Library of Medicine PubMed and Medline, the latter being the primary component of PubMed especially on biomedical topics. Publishers of journals also provide internet access to citations and abstracts of articles, both current and archived, for a large number of medical journals. Access to the full journal articles usually requires a subscription fee for the full articles that can be read directly on the computer or printed out, conveniently as a pdf file. In a scheme known as Health Inter-Network Access to Research Initiatives, an agreement was made between the World Health Organisation (WHO) and the world's leading publishers, whereby in more than 100 developing countries this access is available free of charge or at greatly reduced prices to staff and students of teaching hospitals, research and public health institutes, universities and professional colleges.

A comprehensive overview of various topics relating to life sciences is provided by the *Encyclopedia of Life Sciences* (ELS, www.els.net) published on the internet by Wiley-Blackwell. Many individual experts have their own websites for presenting dissertations and comments in their specialties, while manufacturers provide up-to-date information on their products.

It is impractical to provide a comprehensive index of all relevant websites; however, Table 24-5 lists some that are of particular interest for the haematology laboratory, including some that are also noted in the text.

PRE-ANALYTICAL AND POSTANALYTICAL STAGES OF TESTING

The haematology laboratory should be involved in the pre-analytical stage (test requesting, blood sample collection and transport to the laboratory) as well as the postanalytical stage (return of results to the clinician). Account must also be taken of physiological variables (see Chapter 2) and endogenous variables, such as medicines and other substances taken by the patient.[18] Both variables

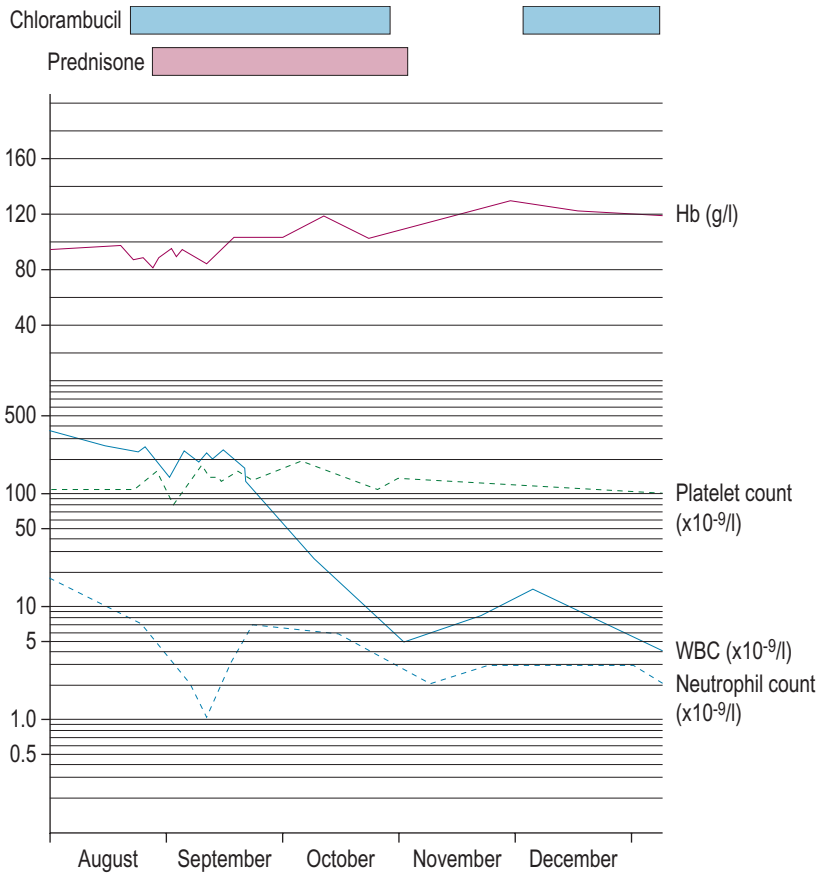

FIGURE 24-3 Haematological chart for plotting blood count data on a time-related graph. This illustrates the course in a patient with chronic lymphocytic leukaemia. Haemoglobin concentration is recorded arithmetically; the other components are on a logarithmic scale. If reticulocytes are included, they should be recorded arithmetically. Explanation of units: if the platelet count or white cell count (WBC) is 100×10^9/l, then 100 is the count $\times 10^{-9}$/l.

have a significant impact on test reliability, laboratory performance and client satisfaction.

Test requesting

There is considerable variation between clinicians in their test ordering patterns, and laboratory staff have historically exerted little influence on test request patterns, although sustained educational programmes may achieve more selective testing. Unnecessary requests often result from inappropriate request forms, such as those that permit clinicians to tick from a list instead of requesting specific tests. Modification of the requesting pattern might focus on specific needs, include use of problem-orientated request forms[19] and a computer-based ordering of tests using protocols written by specialist clinical teams.[20]

Specimen collection and delivery

It is essential to have positive identification of the patient as well as reliable sample identification and thus patient-sample and intersample identification must be checked at all times. Failure to do so can result in delayed diagnosis, even misdiagnosis, resulting in incorrect treatment of the patient, and it may be a serious cause of error in blood transfusion. In one interlaboratory Q-probe analysis in the USA (see p. 526), 0.1–5% of specimens were unacceptable due to mislabelling, incomplete label, illegible label and even no label.[21,22] Methods have been developed for electronic ordering of tests using the hospital's patient identification barcode for checking the patient's identity at the time of phlebotomy, printing the barcode onto the specimen containers and checking this by means of a hand-held scanner at all stages during processing in the laboratory until the report is issued.

After the blood has been collected, every effort must be made to ensure its delivery to the laboratory without delay. If this is not coordinated, samples may remain in clinical areas awaiting collection by porters who then follow a fixed circuit of other hospital areas before eventually reaching the laboratory. However, if responsibility for blood collection and transport is held by the laboratory, these separate activities can be coordinated. Alternative and faster means of specimen delivery to laboratories,

with no significant effect of the specimens, include pneumatic tube conveyor or rail-track conveyor systems,[23,24] although there has been a report of lysed specimens due to a defect in the system.[25] Specimen transport from remote clinics to a central laboratory is referred to in Chapter 26 (see p. 557).

Pre-analytical phase

The time of receipt of the specimens in the laboratory should be registered.[18] The specimens must be checked to ensure that they are appropriate for the tests that are requested and that there has been no contamination, by leakage, of the outside of the tubes and/or the request forms. Requests should be registered and the specimens should be separated into 'routine' and 'urgent', the latter being handed directly to the appropriate staff member.

Postanalytical phase

After the tests have been carried out, the following procedures are required to ensure proficiency in the postanalytical phase:

1. Processing of results for transcription onto report forms
2. Immediate scrutiny of urgent results with issue of provisional report and its delivery to the requesting clinician
3. Assessment of the significance of results in the context of established reference values and decision for further tests. '*Critical laboratory values*' for adults and for children should be established for life-threatening conditions requiring rapid clinical intervention (e.g. haemoglobin concentration, platelet count, activated partial thromboplastin time)[26]
4. Transmission of final report without unreasonable delay to the location indicated on the request form. Computer-assisted reporting of results to linked monitors and printers located in clinical areas is very helpful,[27] but in some countries most hospitals rely on manual transport of result sheets and this can significantly prolong request completion times. Pneumatic tube and rail-track conveyor systems used for the pre-analytical stage can also be used for rapid return of results to wards and clinics.

5. Return of results is, of course, no guarantee that ward or clinic staff will react in a timely way to change a patient's treatment or even file report forms in the patient's medical record. It is the responsibility of the clinician to ensure that the reports of tests requested by them are received, noted and acted on. However, good laboratory practice includes speedy notification to the responsible clinical staff of a result that shows an apparently unexpected serious abnormality. The use of mobile camera phones to transmit test results to the relevant clinician, or even images (e.g. a stained blood film from the laboratory) to an expert at a remote location in order to obtain rapid authoritative support, has grown in popularity.[28] In these situations, it may be necessary to comply with local or national regulations concerning confidentiality of patients records, including the use of encrypted memory sticks to store the information.
6. As an audit of utility of the laboratory, there should be regular contact with users to ensure that the reports arrive in due time for optimal use during clinical management and that the clinicians are satisfied that results are presented in a clear and unambiguous form. There should also be discussions on test selection, taking account of the clinical relevance of the tests that are undertaken, the introduction of new tests and evaluation of benefit versus cost, as discussed earlier.

Test turnaround time

As described above, it is essential to ensure that tests are carried out and results reported to clinicians as rapidly as possible. The usual measure of this is the test turnaround time, which takes account of work scheduling, selection of equipment and training.[29] It is most easily measured as the time lapse between arrival of a blood specimen in the laboratory and issue of the validated result. In a small unit, this can be undertaken manually, albeit tediously. In a computerised laboratory, however, it is relatively easy to record these times and then to calculate the median time, the 95th percentile for completing each test and the percentage of tests completed within a preselected time.[30] While this information is based on the performance of an individual laboratory, it should be possible to make comparisons with a peer group in benchmarking studies (see page 526).

It should, however, be noted that *turnaround time* as described above usually refers only to the analytical stage of testing and excludes the time delay of the pre-analytical and postanalytical stages of testing. When the laboratory has responsibility for all three stages, it becomes possible to extend the measurement of analytical turnaround time to the more meaningful parameter of request completion time (total time from initiation of the request to delivery of the result). The speed with which modern systems perform reduces the need for interrupting the analysis of routine specimens for urgent tests, but the laboratory should also have an efficient way to convey urgent results to the requesting clinician.[31] In critically ill patients, it is especially important to avoid any delay between receipt of the test results by the ward staff and its relay to the relevant clinician for an active response. A report on this specific point by a College of American Pathologists Q-probe survey showed that while reports on tests from critically ill patients were generally received in the ward by computer link within less than 5 min, there was often a significant, and thus potentially serious, delay before they reached the relevant clinician.[32] The use of mobile camera phones as described above to transmit test results directly to the appropriate clinician could provide a solution, especially in an after-hours service.[28]

Point-of-care testing

Point-of-care testing (POCT), also known as *near-patient testing,* refers to any analytical test performed outside the laboratory and may be located either within a hospital as an adjunct to the main laboratory or for primary healthcare outside the hospital setting. The users of this service are often nonlaboratory staff. Public awareness of the availability of POCT has increased dramatically, and access to this technology has never been greater. When results need to be used for making rapid clinical decisions, laboratory testing within the clinical area may be the best arrangement for patients.

Diagnostic laboratories are often located in areas of the hospital that are remote from critical care and outpatient areas. Rapid transit systems, including pneumatic tubes (see earlier), may be the preferred alternative to multiple satellite testing areas, particularly when the main laboratory already offers a rapid results service. Knowledge of test turnaround time in the laboratory (see above) is required in order to make an informed decision on the need for near-patient testing in satellite areas. When POCT equipment is the preferred option, the running of the satellite laboratory and maintenance of its equipment should be the responsibility of the appropriate pathology discipline. The head of the haematology laboratory or a dedicated POCT co-ordinator should take overall responsibility for the service. This is essential for quality control, safety and accreditation, whether the satellite is staffed by laboratory staff, as in busy locations, or used by medical staff or nurses as a marginal activity. A designated member of laboratory staff should supervise this service, visiting each test location daily and ensuring that all results and quality control data are integrated into the main laboratory computer system. Guidelines on the organisation of a POCT service have been published by the British Committee for Standards in Haematology[33] and the UK Medical Devices Agency,[34] in the USA by the Clinical and Laboratory Standards Institute[35] and internationally by the International Council for Standardisation in Haematology[36] and the International Standard Organisation.[37]

Point-of-care testing beyond the laboratory

POCT beyond the laboratory is increasingly popular in some countries and it is particularly useful when patients live a distance away from a hospital laboratory. Instrument manufacturers are now producing tabletop or hand-held devices that are simple to use, are autocalibrated and require minimum maintenance. The haematology tests that are usually undertaken include haemoglobin concentration, blood cell counting by simple analysers, erythrocyte sedimentation rate and prothrombin time for oral anticoagulation control.

Although this use of POCT is independent, the local hospital laboratory should encourage the doctors and clinics to seek advice and help with selection of appropriate instruments and their standardisation/calibration and quality control, including a link into the external quality assessment scheme in which the laboratory participates. Harmonisation of reports with laboratory records is helpful when a patient is referred to the hospital. Studies on the management of anticoagulation control have shown that with appropriate training and cooperation from the laboratory, pharmacists are able to provide as reliable a service as the hospital-based one and, in general, with more convenience for the patient.[38]

A major source of error in POCT outside the hospital is faulty specimen collection, whether for venous or finger-prick samples. Clinic staff who undertake this procedure should be given supervised training (see Chapter 1, p. 1).

Patient self-testing

There is an increasing trend toward self-testing by patients, and simple portable precalibrated coagulometers, which use capillary blood to measure prothrombin time and the International Normalised Ratio, are now available. It has been shown that patients are able to use these instruments correctly and, once their treatment has been established, the individual patients can be relied on to maintain their anticoagulation within the therapeutic range[39] (see also Chapter 20, p. 429). It is important that the selected instruments conform to national, European (European Committee for Standardisation, CEN) or international (ISO) standards to ensure that they are reliable and that the instructions for their use are clear, unambiguous and written for the users.

Laboratory services for general practitioners

The customers of a haematology laboratory include not only hospital clinicians but also general practitioners/family doctors who have different priorities from hospital practitioners. They may have simple POCT on site, but appropriate service beyond that is outlined in the following sections.

Pre-analytical service

Provision of adequate information to the general practitioner is important. This may include a users' handbook or an encyclopaedia listing all available tests, their utility and normal reference ranges, together with a wall chart to show the correct specimen container and volume of blood required, requirements for patient preparation (e.g. fasting), the timing of any medication that may affect the test result and the turnaround time for each test. The latter is important so that patients can be given a follow-up appointment to be told the result. Handbooks should be of loose-leaf format to facilitate updating. Education should cover safety aspects, such as how to deal with blood spillage or a needlestick injury. A specimen transport system at an agreed time of day is particularly important so that patients can be given a suitable appointment for blood collection.

Postanalytical service

The general practitioner needs a fast report service for abnormal test results. Ideally, there should be an interfaced computer connection to the laboratory and to the duty haematologist or at least a direct e-mail address, telephone or fax number at the health centre. With transmission of results by fax or e-mail, confidentiality must be ensured by secure identification of the recipient and, when internet access is available, a secure password entry is essential. When there is no electronic link to the laboratory, it may prove economical to use the specimen transport service to return test results to general practitioners.

Standard operating procedures

Standard operating procedures (SOPs) are written instructions that are intended to maintain optimal consistent quality of performance in the laboratory. They should cover all aspects of work, with some relating to test procedures and others relating to specimen collection, laboratory safety, handling of urgent requests, data storage, telephone reporting policy, and so on. They may be based on standard textbook descriptions or an instrument manufacturer's instruction manual, but they should reflect daily practice and each laboratory must prepare its own individual set of SOPs. They should be reviewed regularly and any revisions must be highlighted with the date. Older versions must be archived and numbered copies of the new version must be distributed to authorised locations. A suggested format for an SOP is given in Table 24-6.

LABORATORY AUDIT AND ACCREDITATION

Audit

Laboratory audit is the systematic and critical analysis of the quality of the laboratory service. The essence of audit

TABLE 24-6

FORMAT FOR A STANDARD OPERATING PROCEDURE (SOP)

Cover page
- Title, reference number, date of preparation, name of author, name of authoriser, distribution of the SOP and its availability

Scope
- Purpose of the SOP; principles of procedure or test; grade(s) of staff permitted to undertake the task(s), responsibility for implementation of SOP, training requirement file

Specimen requirements
- Type and amount; delivery arrangements; storage conditions, any time or temperature restrictions

Specimen reception
- Registration and check of request form; criteria for rejecting a specimen

Health and safety precautions
- Obligatory protection requirements
- Handling and disposal of 'high-risk' samples, broken specimen containers and blood spillage

Equipment, materials and reagents
- Lists of equipment, apparatus, reagents, controls, calibrators, forms and other stationery

Test procedure
- Step-by-step details of sample processing, test procedure, quality control checks and use of standards, calculation of results

Reporting
- Procedure for reporting results for routine and urgent requests; printed instructions to patient when relevant

Clinical significance
- An understanding of the clinical reason for the test and significance of abnormal results
- Reference range and confidence limits for healthy normal men, women and children

Test limitations
- How to recognise errors and steps to avoid or correct them

Maintenance of equipment
- List of schedule for routine in-house maintenance (daily, weekly) and servicing

Specimen storage post-test
- Period of retention and conditions for storage: instructions for disposal of specimens and diluted subsamples

List of relevant literature

Date when SOP is due to be reviewed

is that it should be continuous and designed to achieve incremental improvement in quality of the day-to-day service. It should encompass the pre-analytical, analytical and postanalytical stages of laboratory practice; and should take account of five components:[40]

1. Solving problems associated with process or outcome
2. Monitoring workload in the context of demand control
3. Monitoring introduction of new tests or changes in practice
4. Monitoring adherence to guidelines and best practice
5. Monitoring of analytical quality.

Examples of specific aspects of laboratory practice requiring audit are given in Table 24-7.

The first stage of audit is to define the standard to be achieved; this may be in the form of a standard operating procedure for an analytical procedure, a protocol for test ordering, presurgery blood transfusion order schedule or a target turnaround time. These standards will have been agreed within the laboratory and, whenever possible, in conjunction with relevant users of the laboratory. Clinical input is invaluable in relation to the clinical significance of analyser-generated results, test utility (see p. 516), appropriate laboratory utilisation,[12] and the advantages and disadvantages of POCT (see p. 522). To monitor performance against the agreed standards, each laboratory section should form its own audit group or, if there is an audit group for the whole department, it should be open to all grades of staff to allow peer review and to take advantage of the educational value of audit. Laboratory staff should lead the audit process rather than having it imposed on them. It is good practice to make a short report of each audit meeting, recording attendance, the items identified for improvement and an action list.

In the UK, a national steering group monitors serious hazards of transfusion (SHOT, Serious Hazards of Transfusion, www.shotuk.org). A large proportion of the incidents that have occurred have been the result of incorrect identification of patient–specimen link, with the wrong blood being collected from the hospital blood bank or satellite refrigerator, or failure in bedside checking procedures (see p. 488).

The audit process improves quality simply by examining and questioning established standards and guidelines. The ever-increasing need for cost-effectiveness is likely to forge closer working relationships between the different

TABLE 24-7

EXAMPLES OF LABORATORY AUDIT

- Understanding of laboratory functions by users
- Request forms: patient identity, clear indications for test(s) and relevant clinical information
- Specimen labels with unambiguous identification of the patient
- Appropriateness of test requests
- Test menu in response to clinical needs
- Appropriateness of blood samples (e.g. adequate volume, choice of anticoagulant)
- Storage of reagents and specimens
- Reference ranges and interpretation of abnormal results
- Timeliness of reports
- Internal quality control results
- External quality assessment scheme performance
- Cost-effectiveness of specialist tests
- Precise and clear laboratory reports, especially highlighting abnormal results
- Reporting methods (e.g. personal contact, computer, telephone, fax, camera phone)
- Compliance with safety policies
- Use of blood and blood products
- Frequency and cause of transfusion reactions
- Turnaround time for emergency requests
- Satisfaction of outpatients undergoing venepuncture
- Satisfaction of laboratory users on laboratory competence

pathology disciplines, as well as between laboratories within the same discipline. This changing laboratory environment highlights the need for continuous training of haematology staff in good laboratory management and in the importance of audit.

Accreditation

The purpose of laboratory accreditation schemes is to allow external audit of a laboratory's organisation, staffing, direction and management performance in an appropriate quality assurance programme and level of user satisfaction. The advantage to the accredited laboratory is that this indicates to clinical users that it has a demonstrable standard of practice with competence, impartiality and capability that has been independently confirmed by external peer review. Such review should include assessment of basic functional structure (laboratory facilities such as staff and equipment), processes (test analyses), outcome (quality of test results including timeliness and interpretation), interaction with clinical users and optimal use of resources.

In the UK, this proficiency testing function is undertaken by an independent organisation, the UK Accreditation Service (UKAS, www.ukas.com), which is the sole national body recognised by the UK Government and by the European Union (EU) with authority to validate specified tests that are undertaken by a laboratory, certifying that these tests are up to date, recognised as standard practice and comply with ISO and CEN standards (see below). Previously, the majority of clinical laboratories in the UK were accredited by Clinical Pathology Accreditation Ltd (CPA), a body established by the Royal College of Pathologists and working in association with UKAS; however, as CPA has more recently been considered not to be independent of its participating laboratories, its function has been assumed directly by UKAS. As part of its modernisation program, UKAS is currently managing the transition of all CPA-accredited laboratories to UKAS accreditation using the internationally recognised standard *ISO 15189:2012, Medical Laboratories – particular requirements for quality and competence* (see International Standards of Practice, below).

In other countries, certification for accreditation may also be undertaken by government-authorised bodies. Thus, in the USA, control is undertaken mainly by the CAP Accreditation and Laboratory Improvement scheme in accordance with the Clinical Laboratories Improvement Amendments (CLIA 1988) regulations.[41,42] In Australia, control is maintained by a government authority, the National Pathology Accreditation Advisory Council (NPAAC), which sets the standards for accreditation of laboratories. Descriptions of the requirements for national accreditation programmes are available on the relevant websites.

An important component of all accreditation programmes is participation in proficiency testing/external quality assessment schemes (see Chapter 25). These schemes are expected to conform to standards that are specified by the International Laboratory Accreditation Cooperation (ILAC) and are described in ISO/IEC Guide 43. ISO 17043 (see Table 24-8) is an updated version of ISO Guide 43. Another useful document is *ILAC G22*: 'Use of proficiency testing as a tool for accreditation in testing'.

Some national schemes have established formal links with each other, such as the Western European Laboratory Accreditation Cooperation. The website of the European Proficiency Testing Information Service (EPTIS, www.eptis.bam.de/en/index.htm) lists a wide range of schemes worldwide in various sciences, including laboratory medicine.

INTERNATIONAL STANDARDS OF PRACTICE

The International Standards Organisation has established guidelines for laboratory practice. Of special importance are ISO 15189: 'Medical laboratories – particular requirements for quality and competence', which sets out

the rules for laboratory management; ISO 9000 series: 'Quality management and quality systems' and ISO 17025: 'Competence of testing and calibration laboratories'. These and other relevant standards from ISO and the European authority CEN are listed in Table 24-8.

BENCHMARKING

Benchmarking is now recognised as an essential technique for achieving continuous improvement in laboratory performance to ensure that it is effective and efficient with elimination of waste. It functions by providing a reference point for laboratories to assess their performance by comparison with their peers and the leaders in the field.[43] Departments are divided into several categories on the basis of their size, whether academic or nonteaching and whether responsible for special activities. Their responses to an annual questionnaire permit evaluation of various aspects of laboratory practice. By standardising definitions of tests and requests, it is possible to establish an agreed method for estimating workload in a standard way and to provide the optimal criteria for staffing levels, skill-mix, productivity, reliability and cost-effectiveness, taking account of clinical needs and local patient population ('case-mix'). Thus benchmarking judges the quality of service of a laboratory, by assessing whether it can be run more efficiently with improved cost-effectiveness and clinical effectiveness. It provides an assessment of the adequacy of staffing with a realistic measure of workload and how test throughput and reporting time might be improved, taking account of how variation in clinical practice might affect the laboratory service and whether cost-effectiveness and clinical benefit might be improved by decentralising some components or conversely by eliminating satellite units. This has become an essential method for achieving continuous sustainable improvement based on evidence rather than intuition.

In the USA, the scheme known as 'Q-probe' was established in 1989 by the College of American Pathologists Laboratory Improvement Program, to facilitate implementation of CLIA '88 requirements by providing laboratories with continuing peer review and education with periodic on-site audit. Reports of various Q-probe studies are published regularly in the *Archives of Pathology and Laboratory Medicine*. In the UK, a similar scheme has been developed in keeping with the requirements of the Commission for Health Improvement (CHI). It is undertaken by the Clinical Management Unit of the Centre for Health Planning at Keele University (http://www.who.int/workforcealliance/members_partners/member_list/kuchpm/en/). For its laboratory services, it operates with a team of advisers appointed by the Royal College of Pathologists. Assessment of performance of an individual laboratory is based on comparison with best performance in a comparable peer cluster

TABLE 24-8

ISO AND CEN (EN) STANDARDS RELATING TO MEDICAL LABORATORY PRACTICE

ISO 9000	A series of standards and guidelines on selection and use of quality management systems and quality assurance (complementary aspects are specified in ISO 9001–9004)
ISO 22869	Guidance document on implementation of ISO 15189 (formerly ISO Guide 25)
ISO 15194	*In vitro* diagnostic medical devices: measurement of quantities in samples of biological origin; description of reference materials
EN 12286	*In vitro* diagnostic medical devices: presentation of reference measurement procedures
EN 13612	Performance evaluation of *in vitro* diagnostic medical devices
ISO 15198	Validation of manufacturers' recommendations for user quality control
ISO 25680	Calculation and expression of measurement uncertainty
ISO 22870	Point-of-care testing (POCT) – requirements for quality and competence
ISO/IEC 17043	Conformity assessment – general requirements for proficiency testing. This is update of ISO Guide 43–1 & 2
ISO/EN 17025	Competence of Testing and Calibration Laboratories; formerly ISO Guide 25 and EN45001
EN 375	Information supplied by manufacturers with *in vitro* diagnostic reagents
EN 591	Instructions for use of *in vitro* diagnostic instruments
EN 592	Instructions for use of *in vitro* diagnostic instruments for self-testing
EN 13532	General requirements for *in vitro* diagnostic medical devices for self-testing
ISO 17593	Requirements for *in vitro* monitoring systems for self-testing of oral anticoagulation therapy
EN 14136	Use of external quality assessment schemes in assessment of performance of *in vitro* diagnostic procedures
ISO 6710	Single-use containers for venous blood specimen collection
ISO 15190	Safety management for medical laboratories
ISO/EN 14971	Medical devices – application of risk management to medical devices

and performance in the UK National External Quality Assessment Service (see Chapter 25). Another organisation with similar function with regard to anticoagulant testing is DAWN Benchmarking (www.4s-dawn.com/products/anticoagulation/dawn-ac-benchmarking-service/).

LABORATORY SAFETY

Principles of safety policy

Every laboratory worker should receive instructions on the potential hazards in his or her workplace. This should range from specimen collection to waste disposal, and should include both sites where POCT is carried out and reagent stores and satellite storage refrigerators that hold blood and blood products. There should be a procedure to protect the health and wellbeing of all members of staff and legitimate visitors, taking account of rules and regulations as well as local practices.

There should be a designated safety officer of sufficient seniority, with authority to implement departmental safety policy in all sections of the laboratory. The safety officer should be responsible for day-to-day management of safety issues and should be directly accountable to the head of department. There must be an established protocol for handling needle-stick injury to a member of staff, with immediate referral to the appropriate hospital department of occupational health, which should provide a 24 h advisory service. All incidents must be recorded, safety protocol must be reviewed and measures must be taken to prevent recurrence.

The safety officer must have the training and time to do the job well and provide ongoing training for other staff who must not be allowed to handle potentially hazardous materials until they have completed training in accordance with the safety requirements. The safety officer should represent the laboratory on relevant safety committees and work closely with hospital occupational health, control of infection and radiation protection officers. Within the department, a safety committee should be established as a useful forum for safety audit.

Departmental safety policy should be documented in a readily accessible form in each section of the laboratory. It must provide a comprehensive account of departmental safety policy (Table 24-9). Attention must be drawn to known and potential hazards in relation to infection, toxic substances, fire, radiation and mechanical injury. Where a hazard cannot be eliminated, the risk should be reduced so far as is reasonably practicable (e.g. by reducing the frequency and period of exposure). The safety booklet should refer to relevant local, national and international safety legislation.

In addition to the laboratory safety policy, SOPs should also include information on handling reagents that are classified by relevant authorities as *hazardous to health* (see below), together with relevant safety and decontamination protocols (see p. 530).

TABLE 24-9

ITEMS TO BE INCLUDED IN LABORATORY SAFETY POLICY DOCUMENT

- Blood collection
- Labelling, transport and reception of specimens
- Handling of specimens and containment of high-risk specimens
- Location of protective equipment
- Managing and reporting needle-stick injury
- Management of eye-splash
- Disposal of used needles, syringes and lancets
- Procedure for blood spillage
- Hazard risk assessment for all substances in the laboratory
- Safety in near-patient testing
- Protective clothing
- Health records of staff, including immunisation
- Laboratory security, out-of-hours working and visitors to the department
- Waste disposal
- Electrical equipment testing
- Recording of accidents
- Safety cabinet monitoring
- Laboratory cleaning policies
- Policy for receiving and sending postal specimens
- Radiation protection
- Fire precautions
- Staff training programmes
- Safety inspections
- Schedule for safety committee meeting

The standard for safety management in medical laboratories has been established by the ISO (ISO 14971 and 15190; Table 24-8). This provides rules for a safe working environment in the laboratory and includes a comprehensive list of items to be checked when auditing safety practice. A similar document on safety of electrical equipment used in the laboratories has been established by the International Electrotechnical Commission (IEC).[44] The WHO has also published comprehensive manuals on safety in healthcare laboratories,[45,46] and there is a WHO website linked to the Safe Injection Global Network (www.who.int/injection_safety/en/), which describes strategies for safe handling of blood intended for transfusion. This includes (1) selection of blood donors, testing of blood units, appropriate clinical use of blood and, when applicable, viral inactivation of human material for therapeutic use; (2) safe and appropriate use of injections, sharps waste management and prevention of cross-infection; and (3) procedures conducted according to universal precautions. Proposals for best practices and global activities are reviewed at www.who.int/injection_safety/sign/en/.

At a national level, in many countries there are mandatory requirements for safety at work and these include hospitals and clinical laboratories. In the UK, the authority for this is the Health and Safety Executive, which has established procedures for prevention of infections in clinical laboratories.[47] The toxicity of all chemical reagents used in the laboratory, including those incorporated into kits, is governed by the Health and Safety Executive (HSE), which is responsible for the Control of Substances Hazardous to Health (COSHH) regulations and requires that any substances hazardous to health should be categorised and certified by COSHH with regard to degree of physical and biological hazard, safety measure for use, handling of spillage and waste disposal (see http://www.hse.gov.uk/coshh/).

Other essential sets of regulations for the laboratory concern the use of radioactive materials. These are described in the Ionizing Radiations Regulations 1999 (No. 3232). The management of these various regulations and methods for investigation of accidents are described by Holt.[48]

The specific safety requirements to be considered in laboratory practice are described below. They include design of premises, electrical and radiation safety; fire hazard, toxic and carcinogenic reagents; handling of biohazardous material and waste disposal.

Design of laboratory

The area where work is carried out should be sufficiently large to easily accommodate items of equipment, all of which should be installed on fixed surfaces or stable trolleys. If possible, equipment which produces excessive noise should be kept separate from the general working area. Optimal lighting should be ensured, and there should be adequate ventilation with protection from dust as well as a comfortable ambient temperature for workers and for optimal functioning of equipment. There should be appropriate storage facilities for chemicals (see below). Fire extinguishers and first-aid cabinets should be placed in easily accessible sites. The laboratory working area must meet design standards for 'level 2 containment' and there should be restricted access, which should be enforced where possible.

Electrical and radiation safety

All electrical equipment used should be certified by its manufacturer to comply with the national or international safety standards. Electrical equipment should not interfere electrically with *in vivo* medical devices (e.g. pacemakers) unless clearly marked with an appropriate caution. Before installation, all electrical devices should be inspected by someone trained in portable appliance testing, who must ensure that all plugs, fuses and electrical cables are appropriate and functional and that the plugs and cables are not adjacent to water taps. There should be a planned programme of preventive maintenance for each item of electrical equipment. All equipment should be decontaminated before inspection or repair.

Protection when handling radioactive material and using equipment for measuring radioactivity is described in Chapter 17, p. 352.

Fire hazard

Most fires result from accidents with flammable substances such as alcohol and solvents. All manipulations of such substances must be carried out away from naked flames. Bulk stocks should be kept in flame-protected bins in a storage area separated from the laboratory and clearly marked as 'FIRE RISK'. Not more than 400 ml should be kept on an open bench or shelf. In many countries, gas burners are no longer available, but where they are used, they must never be left unattended and pilot lights must never be left on overnight. The burners should be as close as possible to the gas source and lengthy connecting tubes must be avoided.

Fire blankets and fire extinguishers, especially those suitable for dealing with electrical and chemical fires, should be placed near to doors of rooms and at strategic points in corridors. They should be inspected regularly.

Chemical safety

Dangerous chemicals such as strong acids and alkalis must be stored at floor level; chemicals that are likely to react with each other must be stored well apart; poisons should be stored in locked cabinets. Manufacturers' product safety data sheets must be checked for advice on safe handling of any potentially toxic or carcinogenic substances. Such reagents must be stored in a secure place with restricted access; they should be handled only by experienced staff wearing protective clothing and weighing should be carried out in an air-flow cabinet at face velocity of around 0.8 m/s.

Eyewash facilities

An eyewash station should be conveniently located where hazardous chemicals or biological materials are handled. This should consist of a spray device attached to the water supply by a flexible hose. If access to plumbing is not available, the alternative is an ample supply of easy-to-open containers of water.

Biohazardous specimens

When handling blood, the most commonly encountered pathogens are human immunodeficiency virus (HIV) and hepatitis viruses. All specimens of human origin should be regarded as potentially infectious and must be handled appropriately by means of *universal precautions*

in order to minimise exposure of skin and mucous membranes to the hazard. Special precautions are necessary with highly infectious specimens (see below).

Universal precautions

1. Personal hygiene precautions to be adopted in areas where blood is collected, specimens are handled and analytical work is carried out:
   a. Eating, drinking and the application of cosmetics are absolutely forbidden.
   b. Staff should not wear jewellery and ideally, watches and rings should be removed.
   c. Disposable latex rubber or plastic gloves should be worn during sample handling and analytical work.*
   d. An outer protective gown or coat should be worn and personal clothing should not be allowed to protrude beyond the sleeves of the protective clothing.
   e. Any exposed cuts or abrasions must be kept covered with waterproof dressings.
   f. Hands must be washed when leaving analytical areas.
2. Venepuncture should be performed wearing disposable thin plastic or rubber latex gloves. Care must be taken to prevent injuries when handling syringes and disposing of the needles. Do not recap used needles by hand; do not detach the needle from the syringe or break, bend or otherwise manipulate used needles by hand. Used disposable syringes and needles, lancets and other sharp items such as glass slides, must be placed in a puncture-resistant plastic 'sharps' container for disposal. Care must be taken to avoid blood contamination of tourniquets as a potential cause of cross-infection. If necessary, they should be washed with soap and water.
3. As far as possible, only disposable syringes, needles and lancets should be used. Disposable syringes and lancets must never be reused on a different person.
4. Specimens should be sent to the laboratory in individual closed plastic bags, separated from the request forms to prevent their contamination should there be any leakage from the specimens. Ideally, the plastic bag should be placed inside another container. Tubes that minimise the risk of leakage are available.
5. Mouth pipetting is absolutely prohibited.
6. Centrifugation must be performed in sealed centrifuge buckets.
7. Blood and bone marrow slides must be handled in the same way as blood samples until they are fixed in methanol, stained and covered with a cover slip.
8. Used material must be placed in designated biohazard plastic bags awaiting disposal (see below).
9. Protective laboratory clothing (e.g. white coats) must never be worn outside the laboratory.
10. Additional precautions with infectious or potentially infectious material:
    a. Only experienced staff should perform procedures.
    b. Specimens should be handled in a microbiological safety cabinet (if the procedure involves generation of an aerosol) or in a clearly segregated and designated area of the laboratory.
    c. Specimens should be handled using protective clothing (close-fitting disposable gloves, disposable plastic apron, glasses or goggles, face mask).
    d. Disposable plastic should be used instead of glassware; sharp-pointed instruments (e.g. scissors) should not be used.
    e. There should be special arrangements for waste disposal (see p. 531).

*Irritant reactions to latex rubber or plastic gloves may be due to mechanical friction of the skin from poor fitting, prolonged use without changing the gloves, perspiration or a specific allergy. Handwashing with a mild antiseptic soap and application of an anti-inflammatory hand cream may be helpful. It may also be helpful to wear powder-free gloves and to wear a larger-sized glove to increase air circulation until the hands heal. In the event of a specific allergy to the chemical ingredients within the gloves, it may be worthwhile trying a different type or brand of glove.

Disinfectants

There are several types of chemical that have been used as germicides, including aldehydes, phenols, halogens, alcohols and hypochlorites. However, some of these are no longer available in laboratories. Those that are now used are indicated in Table 24-10. No single disinfectant is effective against all pathogens and their effectiveness depends on the nature of the organism.[46,49]

Sodium hypochlorite (chlorine). This is the most commonly used disinfectant in the laboratory as it is very active against all microorganisms, although less active against fungi. Its disadvantage is that it is corrosive to metal. As hypochlorite solutions gradually lose their strength, fresh dilutions must be made daily. For general use, a concentration of 1 g/l (1000 ppm) as available chlorine is required; a stronger solution containing 5 g/l (5000 ppm) is necessary for dealing with blood spillage.

Household bleaches usually contain 50 g/l as available chlorine and should thus be diluted 1:50 for general use and 1:10 for blood contamination. Other chlorine-containing compounds which can be used are prepared as follows:

Calcium hypochlorite. (70% available chlorine) 1.4 g/l; 7 g/l for blood contamination.

Sodium dichloroisocyanurate (NaDCC). (60% available chlorine) 1.7 g/l; 20 g/l for blood contamination.

Chloramine. (25% available chlorine) 20 g/l in all conditions.

Alcohols. Ethanol and isopropyl alcohol have similar disinfectant properties at a concentration of 70–80% in water; higher or lower concentrations reduce their germicidal effectiveness. They are active against vegetative bacteria

TABLE 24-10

PROPERTIES OF COMMON DISINFECTANTS

Reagent	Concentration (See Text)	Active Against					
		Fungi	Bacteria	Mycobacteria	Spores	Lipid-Coated Viruses	Non-Lipid-Coated Viruses
A: Hypochlorites	1–10%	+	+++	++	++	+	+
B: Ethanol	70–80%	0	+++	+++	0	+	±
C: Isopropanol	70%	0	+++	+++	0	+	±
D: Iodoform	0.1–2%	+++	+++	+++	+	+	+

+, ++ and +++, extent of effectiveness; ±, variable, dependent on virus; 0, not effective. The disinfectants must be handled as toxic substances; all are eye irritants while A and D are also skin irritants and corrosive.

and lipid viruses but not against spores or fungi. Their effect on nonlipid viruses is variable. Alcohol is especially effective when mixed with other agents (e.g. 80% alcohol with 100 g/l of formaldehyde or with 2 g/l (2000 ppm) available chlorine).

Applications of disinfectants

Routinely, on completion of the day's work, the working area should be wiped with a freshly prepared 1% weight/volume (w/v) sodium hypochlorite solution (chlorine bleach). Reusable pipettes should be soaked in a 2.5% solution for 30 min or longer. A 10% solution must be used for cleaning up blood spillage. The diluted sodium hypochlorite solution should be freshly made each day. It is helpful to add detergent to the solution as disinfectants are most active on clean surfaces. A stabilised blend of peroxide with surfactant and organic acids in a buffer system is available as a commercial product, Virkon (Antec-DuPont). It appears to be effective as a general disinfectant for all hard surfaces, plastic and stainless steel laboratory equipment, medical instruments and laundry and also for absorbing spilled blood or other body fluids.

Automated equipment. Some automated equipment can be disinfected by flushing several times with 10% w/v sodium hypochlorite, followed by several flushes with water. Hypochlorite causes corrosion of metal surfaces. Other instruments have special requirements for decontamination; always refer to the manufacturer's instructions.

Centrifuges. Laboratory centrifuges require particular attention. They should never be cleaned using hypochlorite solution or other metal corrosives. Any spillage of blood should be dealt with immediately and the bowl, head and buckets (including rubber pads) should be disinfected regularly (e.g. with 2% Virkon) and then rinsed with a detergent (e.g. Decon 90, http://www.decon.co.uk/) or 70% ethanol. Special care is required when a glass or plastic tube breaks in a centrifuge (Table 24-11).

TABLE 24-11

PROCEDURE FOR DECONTAMINATING A CENTRIFUGE AFTER BREAKAGE OF A TUBE

1. Switch off centrifuge motor and do not open lid for 1 h to allow aerosols to settle. Inform the safety officer.
2. When breakage involves a known high-risk specimen in a sealed bucket, strong gloves, goggles and a protective apron must be worn and the bucket must be opened in a safety cabinet.
3. If the leakage was confined to a sealed bucket, manually open the centrifuge and, using forceps to remove broken tubes and any solid debris, discard the contents of the bucket into 2% Virkon.
4. Decontaminate the inside of the lid, bowl and external surfaces of the buckets with 2% Virkon, rinse with a detergent such as Decon 90 or 70% ethanol and leave to dry.
5. Buckets, rotors and other small centrifuge items may be autoclaved where appropriate. Alternatively, more delicate items (e.g. whole microfuges) may be fumigated within a safety cabinet.
6. All contaminated disposable material must be placed in appropriate bags for autoclaving.

Syringes and needles. Cleaning and sterilisation of syringes and needles for reuse is not recommended (see page 558).

Gloves. Disposable gloves must not be reused as they may retain contaminated material and may deteriorate when cleaned. Rubber household gloves may be washed and decontaminated by soaking in 1% hypochlorite solution for 30 min, but they must be discarded if they have punctures or tears or if they show signs of deterioration such as peeling or cracking.

Laundry. Soiled laundry must be placed in leak-proof labelled bags for transport to the laundry where the items

should be washed in hot water (>70°C) with detergent for 25–30 min before being rinsed or alternatively soaked in 1% w/v sodium hypochlorite solution (see above) before being washed by hand.

Waste disposal

The safe disposal of laboratory waste is of prime importance. Laboratory waste and contaminated materials present health hazards both to laboratory workers and to the community. The careless dumping of solid and liquid chemical and biological waste is also a threat to the environment. The WHO (http://www.healthcare-waste.org/resources/documents/) provides up-to-date information on various aspects of waste management, including country-specific and region-specific problems and legal requirements (http://www.who.int/mediacentre/factsheets/fs253/en/).

Laboratory waste is classified under the following headings:

- Infectious materials
- Pathological materials
- Radioactive materials
- Genotoxic substances
- Sharps
- Chemicals, including analyser effluents
- Pharmaceuticals
- Heavy metals, including batteries, broken thermometers
- Pressurised containers
- General, nonclinical waste.

Blood and other potentially infected body fluids can be poured down a drain safely only if it is connected to a sanitary sewer. The drain should then be immediately flushed with water, followed by 250 ml of 10% hypochlorite and finally again flushed with water. In the absence of a sewer system, the material should be ducted into holding tanks for steam heating or chemical treatment before final discharge to the public sewers. Specimen containers, used syringes, swabs and tissues should be collected in special colour-coded bags for subsequent incineration or autoclaving before being disposed of in a rubbish dump. 'Sharps' containers should be incinerated without opening.

Highly infectious specimens require special management:

- They should be segregated from other potentially infectious waste and placed immediately in a leak-proof bag or container.
- If possible, they should be disinfected immediately by autoclaving or by chemical treatment; the waste can then be handled alongside other clinical waste.
- If not immediately disinfected, they should be placed in identifiable (e.g. yellow) bags, labelled with the biohazard symbol and marked as 'HIGHLY INFECTIOUS WASTE'. The bags should then be taken immediately to a central storage point for disposal.

Information about the disposal of specific chemicals is usually given in the manufacturer's safety data sheet and a waste control strategy should be established, taking account of toxic and carcinogenic materials, corrosive substances, flammable substances and reactive chemicals with risk of explosion. Analyser effluents which do not contain chemicals that potentially react with metal waste piping can be discharged directly into a main sewer.

Pressurised containers must not be punctured or incinerated. They should be carefully discharged in the open air away from people and then discarded in nonhazardous waste containers.

General waste includes office and domestic material, paper and packaging and other substances not hazardous to human health. This may either be incinerated or disposed of according to local facilities.

SPECIMEN SHIPPING

There are strict national and international regulations about packaging and shipment of patients' specimens and other biological material by post or air transport; these also apply to courier services.[50,51] The International Air Transport Association (IATA) requires that specimens be packaged in accordance with requirements described on their website.

The following is a summary of the requirements:

1. A primary sealed, leak-proof container for the specimen
2. Absorbent material surrounding the primary container; if several primary containers are packed together they must be individually wrapped to prevent contact with each other and to ensure a tight packing
3. Secondary protecting container (e.g. rigid plastic tube, corrugated fibre-board or polystyrene box). If being sent by air, this container must be capable of withstanding a 95 kPa pressure differential without leakage.
4. Outer packaging, such as a secure rigid cardboard or fibre-board box or a bubble-wrap mailing envelope
5. The outer package must be clearly labelled 'BIOHAZARD' together with the universal biohazard symbol. It is also advisable to add a warning that the parcel must only be opened by an authorised person, preferably in the laboratory. If sent by air, the label must state 'Packed in Compliance with IATA Packing Instruction 650'.

When plasma or serum must be maintained in a frozen state, the packed specimen should be placed in an insulated container surrounded by dry ice. Conversely, care must be taken to prevent freezing of whole blood specimens. The container must also permit release of CO_2 gas to prevent build-up of pressure. Specific airline regulations should be checked to ensure that dry ice is not deemed to be a hazardous material.

ACKNOWLEDGEMENT

The authors wish to acknowledge the major contribution of Dr Mitchell Lewis, the author or co-author of this chapter in previous editions.

Quality Assurance

Barbara De la Salle • David J. Perry

CHAPTER OUTLINE

Quality assurance (QA) in the haematology laboratory is intended to ensure reliable diagnostic test results with the necessary degree of accuracy and precision. There are some key definitions in QA that are fundamental to an understanding of its practice (Table 25-1).

In any test, inaccuracy, imprecision or both can occur as a result of using unreliable standards, controls or reagents, incorrect instrument calibration or poor laboratory technique. Precision can be controlled by replicate tests and by repeated tests on previously measured specimens. Accuracy can, as a rule, be checked only by the use of reference materials that have been assayed by reference methods and against standards of known concentration e.g. World Health Organisation (WHO) reference plasma.

Quality assurance must ensure adequate control of the pre-analytical and postanalytical phases (i.e. from test selection and specimen collection to the timely despatch of an informative report) as well as the analytical phase, as the majority of diagnostic errors occur as a result of untoward events in these stages of the diagnostic cycle. There are essentially two parts to QA:

1. Internal quality control (IQC)
2. External quality assessment (EQA) – often termed proficiency testing

This chapter describes the use of reference preparations and the principles and procedures of QA. The blood count is used as the illustrative model.

STANDARDISATION

Standardisation of medical laboratory practice is essential for the quality of patient care, especially when patients may be served by multiple pathology providers. It encompasses the materials and methods used and the harmonisation of terminology, units and reference ranges. A variety of standards, reference preparations

TABLE 25-1

SOME KEY DEFINITIONS USED IN QUALITY ASSURANCE

Specificity	Measures only the analyte of interest
Accuracy	The closeness of agreement between the true value and the observed value
Precision	The closeness of agreement among a series of measurements of a single sample. A test can be precise without being accurate.
Linearity	The ability of a test to obtain results that are directly proportional to the analyte concentration
Limits	The upper and lower limits of detection of the assay
Range	The interval between the upper and lower limits of detection
Robustness	A measure of how much a test or assay is affected by small variations in methodology

and methods may be used to facilitate standardisation of laboratory outcomes but these are not available for all analytes or tests.

1. *Material standards or reference preparations* are used to calibrate analysers and to assign values to calibrators. Where possible, they are traceable to defined physical or chemical measurement based on the metrological units of length (metre), mass (kilogram), amount of substance (mole) and time (seconds).
2. A *reference method* is a precisely defined technique which, in association with a reference preparation, provides sufficient precise and accurate data for scientific purposes and for assessing the validity of other methods.
3. A *selected method* is one that is directly comparable with and traceable to the international reference method. It serves as an alternative to the reference method when an international reference material is not available; it should be used for evaluation and validation of a proposed routine (working) method.
4. A *working (or recommended) method* is intended for use in routine practice, taking account of economy of labour and materials and ease of performance and having been shown by a validation study with a reference method to be sufficiently reliable for its intended purpose.

Standardisation in haematology is the concern of the International Council for Standardisation in Haematology (ICSH) and other international and national organisations, whose recommendations are published in haematology journals or are available from the organisations' websites (see Table 25-2). The International Organisation of Standardisation (ISO) and the Comité Européen de Normalisation (CEN) have established standards for

medical laboratory practice, the use of *in vitro* medical devices (IVDs) and the provision of EQA. At a national level, the British Committee for Standards in Haematology (BCSH) publishes guidelines in books, on websites or as journal articles, and in the USA, a wide range of practice guidelines have been published by the Clinical and Laboratory Standards Institute (CLSI) (formerly the National Committee for Clinical Laboratory Standards, NCCLS). Table 25-3 lists international standards and guides applicable to laboratory medicine.

Accreditation (see p. 525) is a process by which an authorised national body or organisation gives formal recognition that a laboratory is considered competent to carry out specific tasks, as measured against published quality standards. It is a procedure that ensures the correct conditions for the provision of a quality service, providing a measure of confidence for the service user, although it does not measure the quality of the laboratory's output. Accreditation requires the laboratory to demonstrate a process of continuous quality improvement and audit of its quality management system and internal processes.

In the European Union (EU), the production and supply of *in vitro* devices, including instruments, kits, calibrators and reagents used in the laboratory, is regulated by the EU *In Vitro* Diagnostic Medical Devices directive. This requires that manufacturers use the *Conformité Européenne* (CE) mark on their products to certify compliance with their claims. The CE marking process is supervised nationally by the appropriate authority in each EU member state and is applicable to 'in-house' test methods where these are used to test samples from patients from other organisations. EQA schemes have a role in identifying unsatisfactory performance by *in vitro* diagnostic devices.

TABLE 25-3

INTERNATIONAL STANDARDS AND GUIDES APPLICABLE TO LABORATORY MEDICINE AND QUALITY ASSURANCE

Standard	Title
BS EN ISO 9001	Quality management systems – requirements
BS EN 14136	Use of external quality assessment schemes in the assessment of the performance of *in vitro* diagnostic examination procedures
BS EN ISO 15189	Medical laboratories – particular requirements for quality and competence

BS EN ISO 9000	Quality management systems – fundamentals and vocabulary
BS EN ISO/IEC 17025	General requirements for the competence of testing and calibration laboratories
BS EN ISO/IEC 17043	Conformity assessment – general requirements for proficiency testing
BS ISO 13528	Statistical methods for use in proficiency testing by interlaboratory comparisons

REFERENCE PREPARATIONS AND CONTROL MATERIALS

The main international authority concerned with reference preparations or reference reagents for laboratory medicine is the WHO. In the European Union, the Institute for Reference Materials and Measurements (IRMM) has established a number of 'certified reference materials' for haematology and clinical chemistry. International standards are not intended for routine use but serve as stable standards for assigning values to commercial (or laboratory produced) '*secondary standards*' or *calibrators*. International reference materials relevant to haematology (Table 25-4) are held at designated institutions; the relevant websites should be checked for availability of any particular one.

Methods used for assigning values to reference materials must be as accurate and precise as is practical. Standardised reference methods have been described for haemoglobin concentration (Hb), red blood cell count (RBC), white blood cell count (WBC) and packed cell volume/haematocrit (PCV/Hct) (see Chapter 3).

Haemoglobin reference preparations

The accessibility of an international reference standard of haemiglobincyanide (HiCN), first developed by the ICSH, has improved the accuracy of haemoglobin measurement. In some countries, preparations that conform to the international standard are certified by the appropriate national authorities. An important feature of this material is that it is stable for at least several years. A limited quantity of the international standard can be obtained from the WHO; a comparable certified reference material is available from IRMM, and the ICSH has produced a new preparation with similar specifications[1] (see Table 25-4). Where the use of the cyanide reagent for routine haemoglobinometry is prohibited, the haemiglobincyanide standard can still be used to assign a haemoglobin value to a lysate or a whole blood preparation, which is then used as the local secondary standard after appropriate dilution. Undiluted lysate is usually stable for up to 6 months, if frozen for several years. Whole blood is stable for about 3 weeks, but for only a few days after dilution. Both whole blood and lysates are useful for QA of haemoglobinometry; reference samples should be introduced into batches of blood samples with all the samples being assayed together. This applies to both automated and manual methods. Many laboratories are unable to make use of this reference preparation as

TABLE 25-4

REFERENCE STANDARDS AND MATERIALS AVAILABLE INTERNATIONALLY

Organisation	Materials of interest	Source
WHO	Blood products, including haemoglobin A_2 and haemoglobin F Blood safety Coagulation factors Fibrinolytic agents, protease inhibitors, anticoagulants Immunoglobulins and human sera Platelet-specific proteins Haematinics	www.who.int/bloodproducts/catalogue Most products are kept at the National Institute for Biological Standards and Controls (www.nibsc.org). The catalogue lists other custodian laboratories where appropriate.
IRMM	Clinical chemistry Haemoglobincyanide Human serum proteins Leukaemia monitoring Thromboplastin (bovine and rabbit)	https://ec.europa.eu/jrc/en/reference-materials
ICSH	Haemoglobin reference standard	www.eurotrol.com

it is unsuitable for direct use in automated haematology analysers; however, the analyser manufacturer will trace the instrument's calibration to the reference preparation.

Quality control preparations

Controls are preparations which are used for either IQC or EQA. Some control preparations have assigned values but they should not be used as standards as the assigned values are usually only approximations and the preparations may be stable for a limited time only.

Control materials are available commercially and they can also be made locally, although there are difficulties in the preparation and validation of such 'homemade' materials. For example, stored plasma may become turbid; chemical or serological analysis may be affected by instability of enzymes; added preservatives may interfere with immunological reactions. With the blood count, there are especially difficult problems due to the instability of blood cells and the need to ensure homogeneity in aliquot samples, while procedures that enhance the stability of blood samples may also affect the behaviour of the cells. The preparation of extended life materials for QA is described at the end of this chapter.

QUALITY ASSURANCE PROCEDURES

The procedures that should be included in a QA programme vary with the tests undertaken, the instruments used, the size of the laboratory, the numbers of specimens handled, the computer facilities available and the amount of time that can be devoted to QA. At least some form of IQC must be undertaken and there must be participation in EQA for any test that a laboratory offers. Where no EQA programme is available the laboratory should establish some other means of assessing interlaboratory comparability, e.g. sample exchange with another laboratory. Some control procedures should be performed daily and other performance checks should be done at appropriate intervals. A review of performance is particularly important when there is a change in staff and after maintenance service or repair has been carried out on equipment. An example of a QA protocol is summarised in Table 25-5.

TABLE 25-5

SCHEDULE FOR QUALITY ASSURANCE PROCEDURES

Calibration with Reference Standards	
Instruments:	6-month intervals or more frequently if control chart or EQA indicates bias or fluctuation in results and after any repair/service
Pipettes, balances:	6–12 month intervals
Diluting systems:	Initially and at 1–2-week intervals
Control Chart with Control Material	
Daily, with each batch of specimens or at regular intervals in a continuous process	
Duplicate tests on two or three patients' samples: if control chart or delta check shows discrepancies	
Analysis of Patients' Results	
Daily to check constancy of mean MCV, MCH, MCHC	
Correlation Assessment of Test Report	
Cumulative results: following previous tests and if changes in clinical state	
Blood film examination if unusual test results and/or instrument flags appear	

EQA, external quality assessment; MCH, mean cell haemoglobin; MCHC, mean cell haemoglobin concentration; MCV, mean cell volume.

All laboratory staff require training in QA and how it is implemented in the laboratory. A useful training manual from WHO describes the principles and methods, together with practical exercises to illustrate these.[2] Another invaluable teaching source is the Westgard QC website (www.westgard.com). Similarly, EQA providers will include guides on their programmes and may supply educational information as part of, or in addition to, their performance reports.

Internal quality control procedures

Internal quality control monitors the performance of the test procedures in the laboratory on daily or a batch-to-batch basis. It includes measurements on specially prepared control materials, repeated measurements on patients' specimens and statistical analysis of patients' test data. This ensures continual validation of the reliability of the results produced by the laboratory, before reports are released.

Control charts

These were first applied in clinical chemistry by Levey and Jennings[3] as a means to monitor laboratory performance using control materials and are now widely used in haematology for both automated and manual procedures. Control material is included in every batch of patients' specimens or at specified intervals during the shift, and the result is logged on a control chart. To check precision, it is not necessary to know the exact value of the control specimen; however, if its value has been determined reliably by a reference method, the same material can also be used to check accuracy or to calibrate an instrument. If possible, controls with high, normal and low values should be used to monitor the method across the range of its linearity. It is advisable to use at least one control sample per batch, even if the batch is small, or at set intervals during a large run or a continuous process. Because the controls are intended to simulate random sampling, they must be treated in the same way as the patients' specimens as far as possible. The results obtained with the control samples can be plotted manually on a Levey–Jennings style chart, as described below, or can be plotted automatically by the instrument, which may also provide an alert if the analysis falls outside the preset, acceptable limits of performance.

When plotting a control chart manually, the mean value and standard deviation (SD) of the control specimen is first established in the laboratory. Using arithmetic graph paper, draw a horizontal line to represent the mean (as a base) and, on an appropriate scale of quantity and unit, draw lines representing +2SD and −2SD above and below the mean. Plot the results of successive control sample measurements. If the test performance is satisfactory, sequential results oscillate about the mean value and less than 5% of the results fall outside ±2SD.

Figure 25-1 illustrates a control chart from an automated system; a similar principle can be used for simple methods where the data are plotted manually (Fig. 25-2).

Any of the following indicates a fault in technique or in the instrument or reagent:

1. One deviant result outside ±3SD may indicate a gross error or 'blunder'.
2. One or two results on or beyond ±2SD may indicate a random error in the system.
3. Several consecutive similar results on one side of the mean indicate a consistent bias, possibly due to a calibration fault or a systematic error.
4. Consecutive fluctuating values, rising and falling by ±2SD, indicate imprecision.
5. A trend of sequentially increasing or decreasing values with the repeated measurements is indicative of drift.

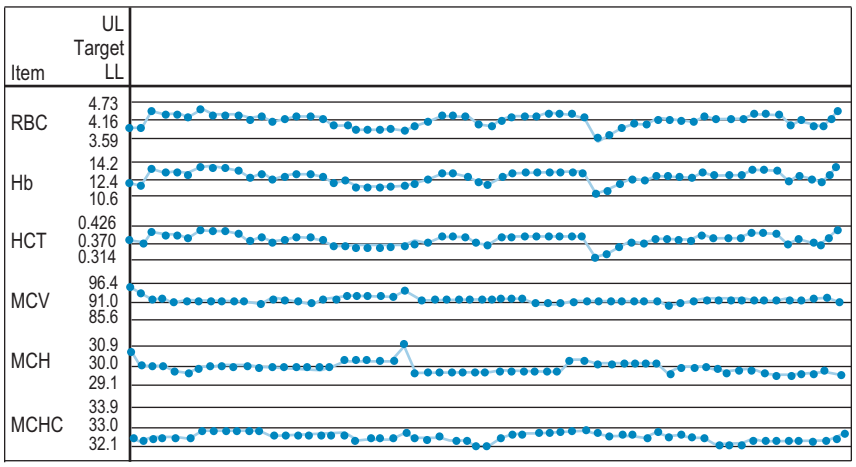

FIGURE 25-1 Levey–Jennings control chart from an automated blood count analyser. The mean value for each component of the blood count is shown on the left together with the upper (UL) and lower (LL) limits for satisfactory performance, which have been set at +2 and −2SD respectively.

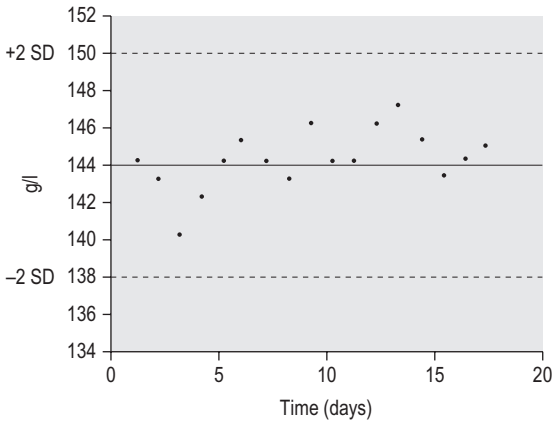

FIGURE 25-2 Control chart for a manual haemoglobinometry method. The limits for satisfactory performance have been set at ±2SD.

The fault may be in the reagents or the laboratory-ware, caused by incorrect adjustment/calibration of the instrument or other equipment (e.g. pipettes), technical error or even clerical error in transcribing the results. Before an intensive investigation is carried out, the test should be repeated with another control sample, and the possibility that the inconsistency is the result of deterioration of the batch of control material or insufficient mixing of the sample should be excluded. This control process is unlikely to detect an error in an individual specimen, which can only be detected by correlation checks. For haemoglobinometry, it may be useful to use both whole blood and lysate in a quality control check because differences in results obtained with these two preparations help to identify errors resulting from incorrect dilution, inadequate mixing or failure of a reagent to bring about complete lysis. If the control specimen is included with each batch of tests or is repeated during the course of a day, the measurements should not differ by more than the established coefficient of variation (CV) (see p. 566).

Duplicate tests on patients' specimens

Duplicate tests on patients' specimens provide another way of checking the precision of routine work.[4] To start the process, test 10 consecutive specimens in duplicate under careful conditions. Calculate the differences between the pairs of results and derive the SD (p. 566). Subsequent duplicate measurements on any specimen in the same batch of tests should not differ from each other by more than ±2SD. This method will detect random errors but not incorrect calibration. It is also insensitive to gradual drift which may, however, be detected if duplicate measurement is carried out in a later batch, provided that the specimen has not altered on standing. If the test is always badly done or has an inherent fault, the SD will be wide and the procedure may be ineffective.

This procedure is suitable for both manual and automated methods; it is impractical for routine blood counts in a busy laboratory, where three or four specimens in a batch can be tested in duplicate from time to time as a rough check of consistency.

Use of patient data for internal quality control

Where a minimum of 100 test requests are processed each day, there should be no significant day-to-day variability in the means of the red cell indices obtained by an automated blood counter, provided that the population of patients remains stable and that samples from a particular clinical source (e.g. renal or oncology patients) are not processed all in the same set, disproportionately influencing the mean. Assuming that the sample population is stable, any significant change in the means of the red cell indices will indicate a change in instrument calibration or a drift owing to a fault in its function. The procedure was developed by Bull[5,6] using a computerised algorithm to estimate the daily patient means of absolute values for mean cell volume (MCV), mean cell haemoglobin (MCH) and mean cell haemoglobin concentration (MCHC). In laboratories using manual methods, a simple adaptation of the same principle can be applied, confined to MCHC and excluding results from any specific clinic that are likely to be biased. From the daily means for all measurements on 10 consecutive working days, an overall daily mean and SD are established. The mean MCHC is then calculated at the end of each day. If the test does not vary by more than ±2SD, it is considered to be satisfactory, but may be misleading if there is a simultaneous error in the same direction in both Hb and Hct. The results may be displayed graphically as illustrated in Figure 25-3.

To start this programme for an automated laboratory, it is first necessary to assay samples from at least 300 to 500 patients using an automated blood counter over several days and to establish the means of the MCV, MCH and MCHC. Then, using the algorithm, it is possible to

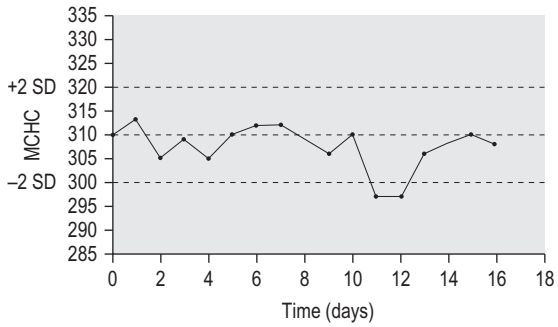

FIGURE 25-3 Quality control chart based on patients' data, using the mean cell haemoglobin concentration (MCHC) as an indicator.

analyse the means in successive batches of 20 specimens. Plotting these means will allow any drift of the three indices to be recognised and used to identify instrument faults; an increased SD will signify loss of precision. To ensure that each batch is representative, the samples should be randomised before analysis and, if possible, within any batch of 20, no more than seven should come from one clinical source or have the same clinical condition. The method is now incorporated in automated blood counters (Fig. 25-4).

A similar instrument-specific procedure is used by some manufacturers who gather the data submitted through network links by users of their instruments. This enables them to maintain a constant check of performance of these instruments overall and to detect any that require recalibration or investigation of faults.

Correlation check

A correlation check implies that any unexpected patient's result must be checked to see whether it can be explained on clinical grounds or whether it correlates with other tests. For example, an unexpectedly higher or lower Hb might be explained by blood transfusion or haemorrhage, respectively. A low MCHC may be confirmed by demonstrating hypochromic red cells on a stained blood film; a high MCV must correlate with macrocytosis. Similarly, the laboratory should have a policy on the examination of a blood film to confirm marked leucocytosis or leucopenia, thrombocytosis or thrombocytopenia, to distinguish between platelets and red cell fragments or conversely between giant platelets and normal-sized red cells and to check features flagged by the automated analyser. The examination of a stained blood film as a correlation check will only be effective if the film is correctly made, stained and examined systematically by an experienced member of staff.

Recording or reviewing cumulative laboratory data on an individual patient is good clinical practice and provides an inbuilt quality control system. This is especially useful in detecting pre-analytical phase errors (e.g. patient and sample identification errors, incorrect sample collection, inadequate suspension of the blood before testing, partial clotting or deterioration on storage).

A formal way of detecting aberrant results is the 'delta check'. The blood count on any patient should not differ from counts obtained in the previous 2–3 weeks by more than an amount that takes into account both the test CV and physiological variation, providing that the patient's clinical condition has not altered significantly. A discrepant result without apparent clinical reason must be suspect until confirmed by a repeat test on a fresh specimen. The occurrence of a contrasting discrepancy in two different specimens on the same day would suggest that two specimens have been transposed. The test can, of course, also be carried out on the blood of healthy individuals whose blood count remains virtually constant on a day-to-day basis, subject only to physiological change (see p. 13).

EXTERNAL QUALITY ASSESSMENT PROCEDURES

External quality assessment (EQA) is the evaluation by an outside agency of the performance of a number of laboratories using specially supplied samples of known but undisclosed content. The objective is to achieve between laboratory and between method comparability, but this does not necessarily guarantee accuracy unless the content of the specimen distributed for testing is traceable to a reference material.

EQA complements IQC, providing a long-term, retrospective assessment of participant performance against that of other laboratories and is a requirement for medical laboratories for accreditation to ISO15189.[7] Even when all precautions are taken to achieve accuracy and precision in the laboratory, errors arise that are only detectable by objective EQA of performance on material that has been

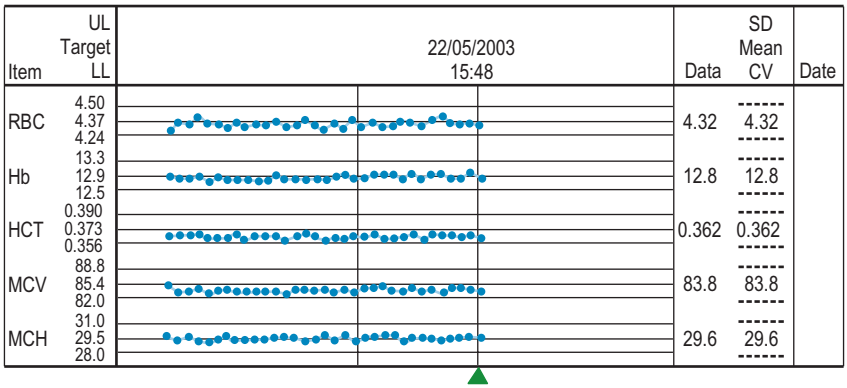

FIGURE 25-4 Quality control chart for an automated blood count analyser based on patients' data, using red cell indices. The predetermined mean values are shown with the upper (UL) and lower (LL) limits for satisfactory control.

supplied specially for the purpose. Such schemes may be organised internationally, nationally or regionally and are accredited against the ISO17043 standard.[8] The operation of EQA schemes is based on the circulation of survey material to a number of participating laboratories or individuals who return their results to the EQA organiser for analysis. Performance of each participant is evaluated against the target value for the material and out of consensus results identified. The participant is encouraged to review performance and take appropriate action in response to unsatisfactory performance. Action may be taken by the EQA organiser or appropriate professional body to improve performance if the problem becomes persistent.

The term EQA and proficiency testing are frequently used interchangeably, although proficiency testing may be defined as laboratory performance evaluation for regulatory purposes.[9]

EQA has a number of complementary functions in addition to assessment of laboratory performance:

1. Collecting information on the reliability of particular methods, materials and equipment
2. Identifying problems with any device that require reaction from the manufacturer and/or reporting to the responsible national authority as described in EN 14136.[10]
3. Providing information on performance required for the purpose of licensing or accreditation
4. Identifying laboratories whose performance provides a benchmarking standard
5. Improving performance through education and the sharing of best practice
6. Demonstrating competence to third parties and service users
7. Promoting harmonisation of medical laboratory procedures

There are many EQA schemes available to laboratories. Some are officially promoted or sponsored by national governments or local health authorities. Unless participation in a particular scheme is mandatory, the laboratory must understand how EQA supports quality and how to select an appropriate EQA scheme.[11] ICSH has prepared guidelines for the organisation and management of EQA schemes[12] which are intended to help maintain a meaningful standard in the organisation of such schemes and to harmonise the way in which they function. The following principles and technical criteria are important in the provision of an effective EQA scheme, although some elements will depend upon the availability of survey material:

1. Surveys should be sufficiently frequent to make sequential performance records meaningful and to identify participants who are persistently unsatisfactory as soon as possible.
2. Specimens for blood count and other high throughput tests should be distributed at least monthly, other tests every 2 to 3 months, depending on their clinical importance and reliability of analytical methods.
3. There should be at least two specimens for every test, with values at diagnostically critical levels.
4. To ensure that EQA relates to practice, survey samples should simulate natural specimens as closely as feasible and participants should be obligated to handle them in the same way as they handle routine specimens.
5. The material used in surveys should be stable, at least until the closing date of the survey.
6. The survey specimens must test negative for antibodies to human immunodeficiency virus (HIV) and hepatitis B and C antigens and must be labelled in accordance with national regulations for packaging and transport of biological material.
7. Data processing must be as rapid as possible, with prompt reports to participants.
8. Organiser/participant confidentiality must be maintained. Provision of information on an individual participant's results to a third party (e.g. a licensing authority) is the responsibility of the participant and not the EQA organiser, unless this is explicitly required by legislation.
9. EQA provider organisations must be professionally led and should function independently of government health authorities.
10. EQA schemes must be financially and operationally independent of commercial pressures, although industry may provide a useful service by organising interlaboratory comparison services for their users.

ANALYSIS OF EXTERNAL QUALITY ASSESSMENT DATA

The analysis of participants' results and assessment of performance are different for quantitative, semiquantitative (ordinal) and qualitative (categorical or nominal) EQA data. Although the procedure for data analysis may vary according to the scheme, the purpose should be to allow an objective assessment of the participating laboratory's result against an assigned or target value. All schemes should monitor nonparticipation, as EQA is only effective if results are submitted regularly.

Target values

The absence of metrological standards in haematology (with the exception of Hb) makes it difficult to establish the 'true' value for a test in haematology EQA. The EQA target value for a quantitative haematology assay can usually be assumed to be the result obtained by best performance of selected participants in the survey, by experts using reference methods or the consensus mean or median of participants' results after trimming to remove outliers.

In practice, the consensus of participants' results is the usual method for determination of the target value in automated cell counting EQA. Consensus values for quantitative tests should only be calculated when the number of participants' results available is sufficient to allow statistically meaningful analysis of results, and this generally will require a minimum of 20 participants per analysis group. Where a consensus all methods mean is used, it may be skewed by the instrument or method that has the greatest number in the data set; therefore, it is desirable to provide both all methods and method or submethod statistical analysis to elucidate performance problems and ensure fair treatment of participants. The use of stabilised EQA survey material (e.g. in automated counting) may also require analysis by matrix, instrument or method group as the performance of the stabilised material may not be analogous to fresh blood.

Before the consensus summary statistics (mean or median, SD and CV) are calculated, it is necessary to remove outliers using appropriate statistical methods. Major blunders (e.g. resulting from transposition of the EQA test specimens or reporting in the incorrect units) should be removed, either by the removal of any result that is more than ±3SD from the mean or by the exclusion of the top and bottom 5% of participants' results. The resulting 'trimmed' consensus mean and SD are then recalculated. The median is used when there is a non-Gaussian distribution of data with a wide scatter of results.[12] If the median is used the estimated SD is calculated as:

$$\text{Estimated SD} = \text{Central 50\% spread of data (interquartile range)} \div 1.349$$

The target value for a quantitative test should be accompanied by an assessment of the uncertainty of the result, which gives a measure of its reliability.

Although outlier results are removed for the calculation of the target value and summary statistics, they should be returned to the data set for assessment of the individual participant's performance.

Quantitative tests

Participants' results are compared to the target value through statistical analysis, which relates the deviation of the EQA result from the target. Guidance on the statistical analysis of EQA data is given in ISO 17043, ISO 13528 and by IUPAC.[8,13,14]

Bias. The bias (D%) expresses the percentage difference of the EQA result from the target value. It is calculated as follows, where x_i is the test result and x_{pt} is the target or assigned value:

$$Bias(D\%) = \frac{x_i - x_{pt}}{x_{pt}} \times 100$$

The pattern of bias in successive surveys indicates whether there is a constant calibration error or a progressive fault.

Deviation index. The deviation index (DI), which is analogous to a 'z-score', may be used for assessing performance in quantitative tests. The DI is the amount of deviation of the participant's result (x_i) from the target value (x_{pt}) relative to a unit of 1 SD calculated for use in the EQA or proficiency testing scheme (σ_{pt}). The DI is then calculated using the formula:

$$DI = \frac{x_i - x_{pt}}{\sigma_{pt}}$$

Instead of calculating σ_{pt} from the trimmed data, it can be calculated from a constant or historical CV, taking account of technical variance of the method, clinical utility of the test and the critical range of measurement for diagnostic discrimination in this method.

Based on ISO 13528,[13] a z-score or DI of less than ±0.5 from the target mean or median denotes excellent performance; one between 0.5 and 1.0 is satisfactory and one between 1.0 and 2.0 is still acceptable. However, a value greater than 2.0 from the target suggests that the analyser calibration should be checked, whereas a DI greater than 3.0 may indicate a defect requiring urgent attention.

Consecutive performance assessment. For EQA results to detect persistent unsatisfactory or out of consensus performance, it is necessary to have a scoring system that assesses long-term performance in a rolling time window of consecutive surveys. The exact time period and scoring system will depend upon the scheme design. Each EQA organiser will include details of their scoring system either in the survey report or in the scheme literature.

The frequency of the challenge for any single parameter in a series of EQA distributions will affect how rapidly the score responds to a fault or a corrective action. Where there is surveillance over a period of time, a laboratory's performance may remain unsatisfactory for several consecutive distributions if there have been insufficient challenges for the score to respond, even though adequate corrective action has been taken.

A convenient method of consecutive monitoring is to use the sum of recent DI values (with the arithmetic sign removed and truncating any very high DI values to a maximum value, for example 3.5, to remove the impact of an isolated high value) and then applying a multiplication factor to scale the analytical performance score from different surveys to the same action threshold. Empirical adjustment of the truncation and multiplication factors allows the sensitivity of the monitoring system to be adjusted.

Out of consensus method. This is a refinement of the non-Gaussian procedure described earlier, which can be used, for example, for blood coagulation EQA. The median is calculated and all the participant results are then ranked in five grades as follows:

Group A: 25% of all results immediately adjacent to and above the median and 25% immediately adjacent to and below the median
Group B: The next 10% on each side of A
Group C: The next 5% on each side of B
Group D: The next 5% on each side of C
Group E: The final 5% on each side of D (and also no participation).

Performance in any particular test is assessed from the grades obtained in a rolling time window of consecutive exercises. Unsatisfactory performance is designated when the combination is D-D, E-C, E-D or E-E.

Youden (*xy*) plot. The Youden plot is a useful method for relating measurements on two samples in a survey to provide a graphic display and, when a participant's results are unsatisfactory, for distinguishing between a consistent bias and random error. Results for the two samples are plotted on the horizontal (*x*) and the vertical (*y*) axis, respectively, and the standard deviations (2SD or 3SD) for the two sets are drawn and interpreted as shown in outline in Figure 25-5. Results in the central block are satisfactory; those in blocks B indicate a consistent bias, which may be positive (to the right) or negative (to the left), while results in other areas indicate random errors (inconsistency) in the two samples.

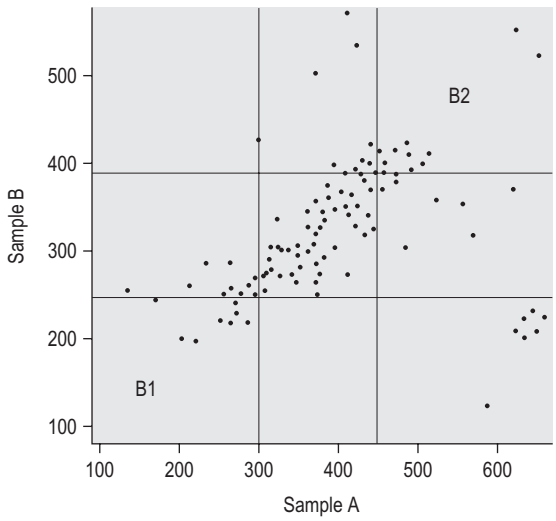

FIGURE 25-5 Youden *(xy)* graph. The range of standard deviations (SDs) calculated from the overall results for sample *x* and sample *y*, respectively, are drawn on the *x* axis and *y* axis; the individual paired results are then plotted on the graph. Results in the central square are satisfactory; those in areas labelled B demonstrate consistent bias with measurements that are too low (*B1*) or too high (*B2*). Results in other areas indicate random errors.

Methodology check. It is sometimes useful to check separate components of a method. Thus appropriate samples can be used to check adequacy of mixing to ensure sample homogeneity, the reliability of the dilution procedure and how an instrument is used. As an example, a survey might include a whole blood sample and a prediluted specimen from the same batch of survey material to simulate part of the preparation process. The results of checks such as these may be excluded from consecutive scoring and reported for educational purposes only, depending on the scheme design.

Clinical significance in performance assessment. In assessing performance, the use of limits based on the SD may be too rigid in some cases and too lenient in others. Testing at the limit of clinical decision making or for rare conditions will produce worse performance scores than testing, for example, in the middle of the normal reference range. Where performance overall is very good, a performance score beyond the action limit may be technically undesirable but may not reflect a clinically significant problem; by contrast, where performance overall is very poor, a performance score within the action limit may not be a guarantee that the result produced would not be a matter of clinical concern. In some circumstances, therefore, it may be better to use clinical relevance when determining the acceptable limits of deviation from the target value. To ensure that results are clinically reliable, results should be within a certain percentage of the assigned value. This must take account of unavoidable imprecision of the method and normal diurnal variations. In practice, the following limits are adequate to meet these requirements for deciding whether there is a risk to patient care.

Hb and RBC (by cell counter)	3–4%
Hct, MCV, MCH, MCHC	4–5%
Leucocyte count	8–10%
Platelet count	10–15%
Vitamin B_{12}, folate, iron, ferritin	20%
Haemoglobin A_2 and haemoglobin F quantitation	5%

Semiquantitative tests

Semiquantitative tests (e.g. reactions based on lysis, agglutination or colour change) may be recorded on an ordinal scale as 0, 1+, 2+, 3+ or 4+. Performance assessment is based on the extent of divergence from the target value, which might be a consensus of participant results, or a reference or expert laboratory's results. Summary statistical analysis of ordinal data is not appropriate, but results may be ranked or presented graphically to display the deviation of the result from the target value and scores allocated according to the

closeness of the result to the target value. Performance assessment must take account of the diagnostic and clinical significance of an incorrect or confusing result.

Qualitative tests

Qualitative or categorical tests (e.g. blood film morphology, blood group or sickle solubility test results) are evaluated in comparison to the target value, which may be determined from a gold standard method, a model answer from an expert panel or the consensus participants' result. Where a consensus result is used, this should be reported by 80% or more of the participants; even when a gold standard method result is available, 75% or more of participants' results should be in agreement before it is used for performance evaluation.

Performance assessment may be straightforward, with an out of consensus result incurring a standard adverse score. Out of consensus results can be weighted according to their clinical significance using a 'look up' table of performance scores, e.g. failing to report *Plasmodium falciparum* in a blood film will incur a greater adverse score than reporting *Plasmodium ovale* as *Plasmodium malariae*. Some tests, e.g. blood film morphology, require a more complex grading system, based upon the clinical significance of the features reported and taking into account the specific medical condition. An example system might be to allocate a score to the morphology features reported according to whether they are essential, desirable, helpful or not useful for diagnosis. All correct observations are given a positive score and false-positive observations are subtracted in accordance with the grading. The result is expressed as a percentage of the total possible score established for the model answer for the case.

Interpretation of results

EQA schemes should assess not only analytical reliability but also the interpretation of results. This may be done as part of the EQA survey, with participants required to report on the significance of their results (i.e. whether within normal reference values for the specified method) or to provide a suggested diagnosis, taking into account any clinical details provided. Alternatively, a scheme based entirely on the interpretation of clinical scenarios may be provided. When performance is assessed by an individual practitioner, rather than a laboratory, interpretive schemes have the potential to demonstrate competency.

PREPARATION OF EXTENDED-LIFE MATERIAL FOR USE IN QUALITY ASSESSMENT

Commercial products are available, but with appropriate expertise, control materials can also be made locally. All such preparations should have in-house values assigned for the relevant parameters, and this should be done to the greatest degree of accuracy as possible.

Preparation of preserved whole blood

Method[2]

1. Collect blood into a sterile container (e.g. a blood transfusion donor bag) with acid–citrate–dextrose (ACD) or citrate–phosphate–dextrose (CPD) anticoagulant (see p. 4). Leave for 2–3 days at 4 °C.
2. Centrifuge the blood for 20 min at approximately 2000 *g*. Separate (and keep) the supernatant plasma but discard the buffy coat. Transfer the red cell concentrate into 500 ml bottles.
3. Mix 3 volumes of the red cells with 1.5 volumes of 9 g/l NaCl, centrifuge for 20 min at approximately 2000 *g* and remove the supernatant and upper layer of the red cells by suction.
4. Repeat step 3.
5. Dilute 5 volumes of the plasma with 2 volumes of 9 g/l NaCl and add broad-spectrum antibiotics (e.g. 1 mg penicillin and 5 mg gentamicin per 100 ml).
6. Add the diluted plasma from step 5 to the red cell concentrate at an appropriate ratio to obtain a preparation suitable for use as an RBC control.
7. Mix well and, with continuous mixing, dispense in aliquot volumes into clean sterile vials,* and cap tightly. Store at 4 °C.

Preparation of haemolysate

Method

1. Collect blood as described earlier (e.g. into a blood transfusion donor bag). Blood unsuitable for transfusion, such as an underweight donor pack, can be used, providing that the red cells are not lysed. Transfer blood into containers suitable for use with toluene and carbon tetrachloride. Centrifuge at approximately 2000 *g* for 20 min and discard the plasma and buffy coat.
2. Wash with equal volumes of 9 g/l NaCl 3 times to ensure complete removal of the plasma, leucocytes and platelets. Mix well between washes.
3. Ensure the last centrifugation packs the red cells well, remove saline and to each 10 ml volumes of the washed cells, add 2 volumes of water and 2 volumes of toluene or carbon tetrachloride (in some countries carbon

*A mixing-dispensing unit is recommended for large-scale dispensing. A suitable one can be constructed using standard glassware, etc., except for the specially manufactured flask head which is not commercially available and needs to be made by a company specialising in medical engineering. See Ward PG, Chappel DA, Fox JG, *et al.*[15]

tetrachloride is not available). Cap and shake vigorously on a mechanical shaker or vibrator for 1 h. Then store at 4 °C for 24–48 h to allow the lipid/cell debris to form a semisolid surface between the toluene/carbon tetrachloride and lysate.
4. On the following day, centrifuge at approximately 2000 *g* for 20 min, remove the lysate layers and pool them in a clean bottle.
5. Centrifuge the lysate at 2000 *g* for 1 h, remove the top 90% (leaving any debris), and then bottle in a clean container.
6. To each 70 ml of lysate, add 30 ml of glycerol and broad-spectrum antibiotics (see previous section). Hb values can be adjusted using 30% glycerol in saline, when the lysate is used. Mix well, dispense into sterile containers and cap tightly.

Stored at 4 °C, the product should retain its assigned value for at least several months or for 1–2 years if kept at –20 °C.

Preparation of stabilised whole blood control material

Method[16]

1. Obtain whole blood in CPD or ACD. This should be as fresh as possible and ideally not more than 3 days old. Filter through a 40 µm blood filter into a series of plastic bottles.
2. If an increased RBC is required, centrifuge the blood and remove part of the plasma; if a lower RBC is required, dilute the blood with an appropriate amount of that plasma. If paired bottles are gently centrifuged (approx. 1500 *g*) for 15 min to produce buffy coats, these can then be manipulated in a similar way to provide different levels of leucocyte and platelet counts. As many blood transfusion services only provide leucodepleted, platelet and plasma poor blood, platelet concentrate can be added to increase the platelet count. Similarly, to raise a white blood cell count, buffy coat packs can be used. Add broad-spectrum antibiotics (see above) to each sample.
3. Mix well and add 1 volume of fixative (6.75 ml formaldehyde 37–40% + 0.75 ml glutaraldehyde 50% + 26 g trisodium citrate to 100 ml water) to 50 volumes of the cell suspension. Mix on a mechanical mixer for 1 h at room temperature and leave at 4 °C for 24 h.
4. With continuous mixing, dispense into sterile containers; cap tightly and seal with plastic tape. Refrigerate at 4 °C until required. Unopened vials should remain in good condition for several months if stored at this temperature.

Simple method for producing quality control preparations for individual types of blood cell material

The following method for control material preparation provides a suitable procedure for red blood cell, leucocyte and platelet counting by some semiautomated blood cell counters, but is not suitable for more complex automated systems. If kept at 4 °C, this material is stable for a maximum of 3 weeks.

Method

1. Collect a unit of human blood into CPD anticoagulant (see p. 561). Carry out the subsequent procedure within 1 day after collection.
2. Filter the blood through a blood transfusion recipient set into a 500 ml glass bottle.
3. Add 1 ml of fresh 40% formaldehyde. Mix well by inverting and then leave on a roller mixer for 1 h.
4. Leave at 4 °C for 7 days, mixing by inverting a few times each day. At the end of this period of storage, mix well on a roller mixer for 20 min, and with constant mixing by hand, dispense in 2 ml volumes into sterile containers.

Preparation of stable control material for external quality assessment

Preparation of surrogate leucocytes

Chicken and turkey red blood cells are nucleated, and when fixed, their size is within the human leucocyte range as recognised on electronic cell counters. They are thus suitable to serve as surrogate leucocytes. This material may not be suitable for counting systems that are based on technologies other than impedance cell sizing.

Method

1. Centrifuge anticoagulated blood (any can be used) at approx. 2000 *g* for 20 min and remove the plasma aseptically.
2. Add an equal volume of 0.15 mol/l phosphate buffer, pH 7.4 (see p. 563); mix and transfer to a sterile centrifuge bottle; recentrifuge and discard the supernatant and buffy coat.
3. Repeat the wash and centrifugation twice. To the washed cells, add 10 times their volume of glutaraldehyde fixative (0.25% in 0.15 mol/l phosphate buffer, pH 7.4). Mix for 1 h on a mechanical mixer. Then leave overnight at 4 °C. To check that fixation has been complete, centrifuge 2–3 ml of the suspension, discard the supernatant and add water to the deposit. If lysis occurs, the cells are not fixed, and the stock glutaraldehyde requires replacement.
4. When fixation is complete (i.e. after approximately 18 h of exposure), centrifuge the suspension at

approximately 2000 *g* for 10 min and discard the supernatant. Wash and centrifuge at approximately 2000 *g* for 10 min twice.

5. Resuspend the fixed cells to approximately 30% concentration in 9 g/l NaCl. Mix well with vigorous shaking. Add antibiotics (see above), cap tightly, seal with a plastic seal and store at 4 °C.

Preparation of quality control material for platelet count[2]

Reagent

- *Alsever solution (ACD).* (A) Trisodium citrate, 16 g; NaCl, 8.2 g to 1 litre with water; (B) dextrose, 41 g to 1 litre with water. Store at 4 °C. Immediately before use, mix equal volumes of A and B; filter through 0.2 µm micropore filter.
- *EDTA solution.* 100 g/l of K_2 EDTA in the Alsever solution; stable for 6 months at 4 °C.

Method

1. Collect a unit of blood into ACD or CPD anticoagulant. Centrifuge for 10 min at 200 *g* and collect the platelet suspension into a plastic container; alternatively, obtain a unit of pooled platelet concentrate prepared for therapeutic platelet transfusion.
2. Add 1 ml of 100 g/l EDTA solution (100 g/l of K_2 EDTA in the Alsever solution). Mix well and leave at 37 °C for 2 h to allow the platelets to disaggregate.
3. Add 200 ml of glutaraldehyde fixative (0.25% in 0.15 mol/l phosphate buffer, pH 7.4). Shake vigorously by hand to ensure complete platelet distribution and leave for 48 h at room temperature with occasional shaking.
4. Centrifuge for 30 min at 3500 *g*. Wash the deposit twice in Alsever solution and finally resuspend in 15–20 ml of Alsever solution and broad-spectrum antibiotics.
5. Cap and seal. At 4 °C, the preparation should have a shelf life of at least 6 months. Before use, resuspend by thorough shaking by hand, followed by mechanical mixing for approximately 15 min.

A simpler method for preserving platelets by adding prostaglandin E_1 to blood in ACD has been reported to provide a control preparation with stability of about 14 days.[17]

Haematology in Under-Resourced Laboratories

Imelda Bates • Jane Y. Carter

CHAPTER OUTLINE

INTRODUCTION: TYPES OF LABORATORIES

In most countries, there are likely to be some laboratories with limited resources, but in under-resourced countries, the majority of laboratories face chronic shortages of trained staff, low morale, inadequate and poorly maintained equipment and erratic supplies of reagents and essential supplies. These factors have a major impact on the range and quality of services offered. Many laboratories lack the highly sophisticated equipment found in better resourced settings and some still operate using predominantly manual techniques. The most peripheral laboratories tend to be multifunctional, with staff performing a range of haematology, parasitology, clinical chemistry and microbiology tests. A blood transfusion service is usually available at larger facilities and, although nationally organised blood services are expanding, much blood for donation is still sourced and used at individual hospital level. In practice this means that laboratory staff may be responsible for donor selection, blood collection and issuing of blood. If there is no separate system of public health laboratories, clinical laboratories may also be required to provide reliable health surveillance data for epidemiological and public health monitoring and to investigate disease outbreaks and refer samples for confirmation.

In under-resourced countries, these difficulties are compounded by the high burden of infectious diseases such as malaria, human immunodeficiency virus infection/acquired immune deficiency syndrome (HIV/AIDS), tuberculosis and neglected tropical diseases such as schistosomiasis and helminthiasis. There are also additional pressures from external agencies such as donors, funders and research projects which may not align closely with local public health priorities. Parasitological diagnosis is now recommended for all suspected cases of malaria to prevent overdiagnosis and reduce inappropriate use of antimalarial drugs. World Health Organisation (WHO) guidelines state that malaria treatment based on clinical grounds should only be given if diagnostic testing is not immediately accessible within 2 h of patients presenting for treatment.[1] In higher level or specialised treatment centres, the diagnosis of leishmaniasis may require aspiration of bone marrow or splenic pulp. The diagnosis of tuberculosis may require aspiration and culture of bone marrow and trephine biopsy examination, especially in patients who are HIV positive, in whom sputum tests for acid-fast organisms are frequently negative.[2] The decision to initiate antiretroviral therapy, to switch to second-line drugs and the monitoring of therapy require regular haemoglobin concentration (Hb) measurements, CD4-positive lymphocyte counts (or percentages for paediatric care) and, ideally, plasma viral load determinations (HIV ribonucleic acid (RNA) monitoring), although provision of some of these tests is challenging for low-income countries.[3,4]

The purpose of this chapter is to provide guidance for an effective haematology service at the different levels of the healthcare system in resource-limited countries. In planning such services, it is necessary to determine what tests are needed at each level, to ensure that tests are reliable and accurate and to establish effective referral networks for patients and samples. In some cases this may involve regional and international partnerships if resources for quality diagnoses are not available in-country.[5]

ORGANISATION OF CLINICAL LABORATORY SERVICES

In under-resourced countries clinical laboratory services may be considered at four levels according to size, staffing and services offered. These levels are: primary facilities, including subdistrict hospitals and health centres (Level 1); intermediate facilities, including district and county hospitals (Level 2); regional and provincial hospitals (Level 3); and national referral and teaching hospitals (Level 4) (Fig. 26-1).

Level of Laboratory	Haematology Services Performed
Primary Facilities	Haemoglobin measurement
	Screening for malaria
	HIV testing
Intermediate Facilities	Haemoglobin measurement
	Examination of blood films (morphology and differential white cell count)
	Total platelet and white cell counts
	Screening for sickle haemoglobin (when appropriate)
	Malaria rapid test
	CD4 count
Regional and Provincial Hospitals	Automated blood count
	G6PD screen
	Haemoglobin electrophoresis
	Immunophenotyping
	HIV viral load estimation
	Basic clotting tests
	Oral anticoagulant control
	Processing of bone marrow aspirates
	Cross matching and antibody screening
	Preparation of some blood components
National Referral and Teaching Hospitals	All relevant tests

FIGURE 26-1 Network of laboratories.

Level 1: primary and subdistrict laboratories

Level 1 laboratories provide first-line diagnostic services to support patient management decisions, initial public health investigations and specimen referral. Laboratory staff may comprise one or two qualified laboratory technicians supported by assistants who often have little or no formal training but have learnt various techniques at the bench. In very peripheral settings, there may be no formal laboratory, and some point-of-care tests are carried out by nurses or assistants with limited training. There is increasing availability of point-of-care diagnostics for an expanding repertoire of conditions, which while enabling more patients to access diagnostic tests, requires adherence to standards to ensure test quality, satisfactory operator performance and correct use of results for patient treatment.[6] This 'task shifting' may be an increased burden for already overworked staff and requires intensive supervision and quality monitoring. Maintenance of equipment in rural areas is often difficult, which can significantly compromise the quality of results or interrupt services altogether. Haematology laboratory tests at this level generally include a method for measuring Hb; microscopy for malaria and other blood parasites, blood cell morphology; and HIV and sickle cell screening.

Level 2: intermediate (district) level laboratories

Intermediate level laboratories are usually multipurpose, and perform microbiological and biochemical as well as haematological tests. Laboratory staff may comprise a limited number of qualified laboratory technicians or biomedical scientists. Equipment available for haematology may include a microscope, centrifuge and basic colorimeter for measurement of Hb. In some intermediate laboratories more sophisticated equipment such as automated haematology and clinical chemistry analysers are available, but long-term sustainability requires funding for regular servicing and maintenance at the time of procurement and installation and purchase of appropriate reagents. In the absence of access to a national blood service, intermediate hospital laboratories are responsible for blood transfusion services with the laboratory expected to perform blood grouping and crossmatching as well as screening for HIV, hepatitis B virus (HBV), hepatitis C virus (HCV) and syphilis.

Level 3: regional and provincial hospitals

At this level, laboratory staff have usually received multidisciplinary training and specialist laboratory staff are available. Level 3 laboratories are usually multipurpose, performing microbiological, biochemical and haematological tests, as well as some more specialised tests. Automated haematology and chemistry equipment, and tests such as CD4-positive lymphocyte counting and coagulation tests are available.

Level 4: national referral and teaching hospitals

At this level, laboratory staff have usually received multidisciplinary training and some of the senior staff have received postgraduate training in a specialist laboratory discipline. Each laboratory usually has a specialist technical head who works closely with the clinician responsible for laboratory services. Equipment generally available includes centrifuges, colorimeters, microscopes, haemoglobin electrophoresis equipment, automated haematology and clinical chemistry and blood grouping and crossmatching analysers, and possibly high performance liquid chromatography and blood bank centrifuges for the separation of blood components.

AVAILABILITY OF HAEMATOLOGY TESTS AT EACH LEVEL

In under-resourced countries, haematology tests available at the different levels of healthcare vary widely and depend on local clinical and public health needs as well as availability of equipment and qualified technical laboratory personnel. The following is a general description of the haematology-related tests that are likely to be required at each level.

Level 1

- Hb measurement by a manual method (see p. 22)
- Malaria and other blood parasite testing on thick and thin peripheral blood films (see p. 101) or rapid malaria diagnostic test (see p. 102)
- Peripheral blood cell morphology, especially to identify the cause of anaemia
- Sickle cell screening
- Testing for HIV for blood transfusion screening

Level 2

- Hb measurement (see p. 19)
- Peripheral blood cell morphology[7]
- Total white blood cell counts (see p. 36)
- Differential white cell count (see p. 25)
- Platelet estimates (usually from blood film)
- CD4-positive lymphocyte count (see p. 557)
- Malaria and other blood parasite testing by thick and thin peripheral blood films (see p. 101) or rapid diagnostic test for *Plasmodium falciparum* and other species (see p. 102)
- Screening test for sickle haemoglobin in areas where this is relevant (see p. 297)

- Blood grouping and compatibility testing (Chapter 21)
- Testing for HIV, HBV, HCV and syphilis infection for blood transfusion screening
- Some larger laboratories may be able to provide automated measurements of Hb, mean cell volume (MCV), mean cell haemoglobin (MCH), mean cell haemoglobin concentration (MCHC), white blood cell total count (WBC), differential count and platelet count (see p. 30).

Levels 3 and 4

In addition to tests carried out at level 2, the haematology services offered by level 3 and 4 laboratories may include the following:

- Automated Hb, MCV, MCH, MCHC, WBC and differential counts, platelet counts (see p. 30)
- Haemoglobin electrophoresis or high performance liquid chromatography (Chapter 14)
- Haemoglobin A_2 and haemoglobin F measurements (see pp. 302 and 306)
- Glucose-6-phosphate dehydrogenase screen (by fluorescent spot or methaemoglobin reduction method) or molecular methods (see p. 238)
- Flow cytometric immunophenotyping (see Chapter 16)
- Polymerase chain reaction (PCR) or other method for diagnosis of mutations associated with haematological malignancies (see Chapter 23)
- HIV plasma viral load estimations
- Staining of bone marrow films for morphological assessment (see p. 52) and estimation of iron status (see p. 120)
- Bone marrow trephine biopsy examination (see p. 120)
- Identification of blood group antibodies (see Chapter 21)
- Basic clotting screen (prothrombin time (PT), thrombin time (TT) and activated partial thromboplastin time (APTT)) and possibly thrombophilia tests (see p. 410)
- Oral anticoagulant control (see p. 426)
- Separation of whole blood into packed cells, plasma and, occasionally, platelets and cryoprecipitate.

MICROSCOPES

The microscope is the most important piece of laboratory equipment in under-resourced countries and is essential for the diagnosis of anaemia, malaria and other blood parasitic infections and for performing differential white blood cell counts and sickle cell screening tests. Reliable assessment of morphological features requires a microscope that is clean and correctly set up with aligned lenses and an electric light source (either inbuilt or reflected light) to ensure clear images, especially at high magnification. Failure to maintain microscopes to a high standard through routine user maintenance or, ideally, with regular professional servicing, can lead to inaccurate diagnoses and inefficient use of technician time.[8,9] Routine maintenance of the microscope is described on p. 46.

Care of the microscope

In hot, humid climates, if no precautions are taken, fungus may grow on the surface of the lenses, in the grooves of the screws and under the paint. This can be prevented by placing the microscope every evening in an airtight dust cover together with silica gel. Dry the silica as necessary and reuse it. An alternative method is to place the microscope in a warm cupboard with a tight-fitting door, heated by a 40-watt light bulb. Check that the temperature inside the cupboard is at least 5 °C warmer than that of the laboratory, but take care that it does not overheat.

In hot, dry climates, the main problem is dust. Fine particles work their way into the threads of the screws and under the lenses. This can be avoided as follows:

1. Always keep the microscope under a dustproof plastic cover when not in use.
2. At the end of the day's work, clean the microscope thoroughly by blowing air onto the lenses and moving parts.
3. Finish cleaning the lenses with a lens brush or fine paintbrush. If dust particles remain on the surface of the objectives, remove with a clean lens tissue.

ESSENTIAL HAEMATOLOGY TESTS

Despite the relatively high cost of running a laboratory service and the low *per capita* healthcare budget in under-resourced countries, there is little guidance available on how to make rational decisions on the choice of 'essential' laboratory tests.[10,11] Decisions about which tests to provide must be made in consultation with laboratory professionals and clinical staff. The selection of 'essential' tests at each level should be based on the clinical and public health needs of the local community and the availability of qualified clinical and laboratory staff, as well as the availability of funds. Essential test packages are usually defined as part of national policy and standards, taking into consideration medium- and long-term trends and the requirements of disease control programmes.

To ensure cost-effectiveness of the laboratory service, tests with no proven value should be eliminated and new tests for which there is independent evidence of clinical usefulness should be introduced,[12] as described in Chapter 24. Tests that provide objective qualitative or quantitative information are preferred. Although it is not possible to draw up a list of essential tests applicable to all countries, or even to different regions within a country, the following aspects should be considered.

Cost per test

Often the cost of a test is calculated from the price of reagents divided by the number of tests performed. However, this oversimplifies the situation and is not accurate enough to form the basis for national policy decisions and budget allocation.[11] The factors that need to be taken into account when calculating the total annual costs for a laboratory are given in Chapter 24.

Diagnostic reliability

It is important to know the sensitivity and specificity of a test and its predictive values (as calculated on p. 568) when selecting a laboratory test for clinical use. This information may be provided by manufacturers but may not be locally applicable, and local test evaluation data are usually not available in under-resourced countries. In some countries, the 'gold standard' diagnostic services needed to determine 'true positive' and 'true negative' data in the local context are also lacking.

The quality of all tests carried out by a laboratory should be regularly monitored. Systems for achieving this are well established (see Chapter 24) but are not easily implemented in under-resourced settings. The quality of a test influences its usefulness as well as its utilisation by clinicians and community members. For example, if the result of a test in routine practice is correct only 80% of the time, then one in five tests will be wasted, reducing the effectiveness of the test by 20%. Furthermore, an inaccurate test may result in a patient receiving inappropriate treatment. Clinicians and the general public are increasingly aware of the need for reliable services. Clinicians may not order tests or use the results in patient management decisions if they do not trust the quality of the laboratory results,[13] and poor quality healthcare may deter patients from using health facilities.

Clinical usefulness

An assessment of the clinical usefulness of a test should be carried out by an independent clinician who is familiar with local diseases and the diagnostic support services available. This assessor needs to compare actual clinical practice with locally agreed 'best practice' or, if available, local guidelines.[12] From observation of a range of clinical interactions, the percentage of times that ideal practice is followed can be calculated. For example, transfusion guidelines may recommend that, apart from specified clinical conditions, transfusions should be given only to children with an Hb of <50 g/l. The assessor can record how many children with Hb below this level failed to receive a transfusion and how many transfusions were given without waiting for the Hb result or at an inappropriate Hb level. For each test, the assessor needs to judge whether the test has been appropriately requested and has been used to influence patient management or public health decisions. The percentage of tests that are not used to guide clinical decisions will provide a figure for 'clinical wastage' of the test that can be entered into a simple formula (Chapter 24).

MAINTAINING QUALITY AND RELIABILITY OF TESTS

Paradoxically, it is in under-resourced laboratories, where equipment and supplies are limited and training and supervision may be minimal, that the level of skills and motivation required to maintain a good-quality service need to be highest. Even the most basic of laboratories should ensure that procedures are in place to monitor quality (see Chapter 25). In addition to monitoring the technical quality of each test, quality management and improvement processes should be in place throughout the laboratory. The Centers for Disease Control and Prevention/World Health Organisation (CDC/WHO) *WHO Guide for the Stepwise Laboratory Improvement Process Towards Accreditation (SLIPTA) in the African Region*, being rolled out in developing countries provides a structured quality improvement process comprising workshop-based teaching, laboratory quality improvement projects, on-site mentoring and regular assessments over a period of time (up to 2 years).[14] Standard operating procedures (SOPs) (see p. 523) should be available for every procedure performed in the laboratory; these can be adapted from existing SOP 'models'. In addition to providing standardised techniques, SOPs are excellent teaching resources, and adherence to these procedures will minimise errors. SOPs need to be regularly reviewed and updated to keep pace with technical developments and changes in local circumstances (e.g. changes in availability of reagents or equipment).

Quality control of a test method (technical quality)

Methods for the control of various haematology tests are described in Chapter 25 but some may need to be adapted to specific local circumstances in resource-poor settings. For example, if commercial controls for sickle cell tests are not affordable, each batch of tests should include known positive and negative samples from a previous batch of tests; for monitoring constancy of Hb measurements, a high and a low value sample can be retested several times during the day.

Internal quality control

Internal quality control is a system within an individual laboratory for ensuring that the technical elements of the test are of acceptable quality. Monitoring of quality by processing control samples and plotting a control chart (see p. 539) will highlight problems within the system which need to be investigated and corrected. For example,

an inaccurate differential white cell count may be due to problems with sample collection and handling, slide preparation, fixing and staining, morphological interpretation and microscope quality as well as inadequate microscopy technique. Measures such as the introduction of SOPs, in-service training and equipment maintenance schedules can help to improve performance and reduce inaccuracies.

External quality assessment

The principles of external quality assessment (EQA) are described on p. 539. Since EQA schemes depend on effective distribution of samples and timely return of results, poor communications and transport facilities may make it logistically difficult to conduct EQA for under-resourced laboratories. Although participation in international quality assessment schemes is beyond the resources of most peripheral laboratories, national authorities need to ensure participation of laboratories at all levels in national schemes, even if this initially requires external support. EQA schemes should be educational and supportive and used to identify poorly performing laboratories that require assistance, as well as to detect inaccuracies in test methods or performance, as part of postmarketing surveillance. Laboratories may also exchange samples and results with neighbouring facilities as part of EQA. Laboratories should also take advantage of supervisory visits, for example by tuberculosis or malaria programme officers, to review EQA or difficult slides, and exchange samples and results with other laboratories. Accreditation schemes (see p. 540), either national or local, can be set up to formally recognise laboratories that are performing well and to assist those that are not.[14] Stepwise – rather than pass/fail – accreditation schemes provide a better measure of performance and motivate laboratories to improve their services.

BASIC HAEMATOLOGY TESTS

Haemoglobinometry

Various methods for estimating Hb are given in Chapter 3. All methods, except colour comparison methods, require a power source, either mains electricity, batteries charged by solar or generator power or battery cells. The most accurate method available in under-resourced laboratories is usually the haemiglobincyanide (formerly cyanmethaemoglobin) method performed in a manual colorimeter. However, this requires technical expertise to carry out accurate pipetting and dilutions and to prepare standard calibration curves. Use of preset haemoglobinometers removes the need for calibration curves, but machines may still need to be set correctly and must be quality assured.

Haemoglobin testing kits for home use are becoming increasingly available but are of variable quality and user-friendliness. Methods for measuring Hb that are robust, accurate and are used by health workers in peripheral settings are described below.

Direct reading haemoglobinometers

HemoCue blood haemoglobin system

HemoCue Blood Haemoglobin System (see Chapter 3) is a battery- or mains-operated portable, direct read-out machine that uses disposable dry chemistry cuvettes. Measurements are precise and accurate but only if specified cuvettes are used, the reading surfaces are kept clean and the cuvettes are properly filled with blood. Unlike most other systems, measurement does not require predilution of the sample. Although the use of unique disposable cuvettes makes this method relatively expensive, the cuvettes for the new Hb 301 version are generally cheaper than those for the Hb 201 and are designed for adverse climatic conditions. HemoCue is fast and simple to use so some costs may be offset by savings on training and supervision time. Disadvantages also include need for an effective supply chain to ensure availability of cuvettes and waste management of used cuvettes. In addition, Hb 310 is not suitable for EQA using haemoglobin lysate.

Haemoglobin colour scale*

Many colour comparison methods have been available in the past, but these have become obsolete because the colours were not sufficiently comparable with blood or were not durable. The haemoglobin colour scale was developed for anaemia screening where there is no laboratory.[15] It consists of a set of printed colour shades on a chart representing Hbs between 40 and 140 g/l. The colour of a drop of blood collected onto a specific type of absorbent paper is compared with the colours on the chart (Fig. 26-2). It is intended for detecting the presence of anaemia and estimating its severity in 20 g/l increments. The scale has been tested in resource-poor settings but appeared to be less accurate at mild anaemia levels, where clinical assessment is also less sensitive, and more studies are needed to demonstrate whether it is superior to clinical diagnosis.[16–18] The instructions should be followed carefully because poor lighting, poor eyesight, allowing the blood spot to dry out and using the incorrect type of absorbent paper for the test strips can have detrimental effects on the results.

Other colour comparator methods still in use include the Sahli method where the colour of blood after mixing with a chemical is compared against a range of standard colours.

*Available from Teaching Aids at Low Cost; www.talcuk.org/accessories/haemoglobin-colour-scale.htm (accessed April 2015).

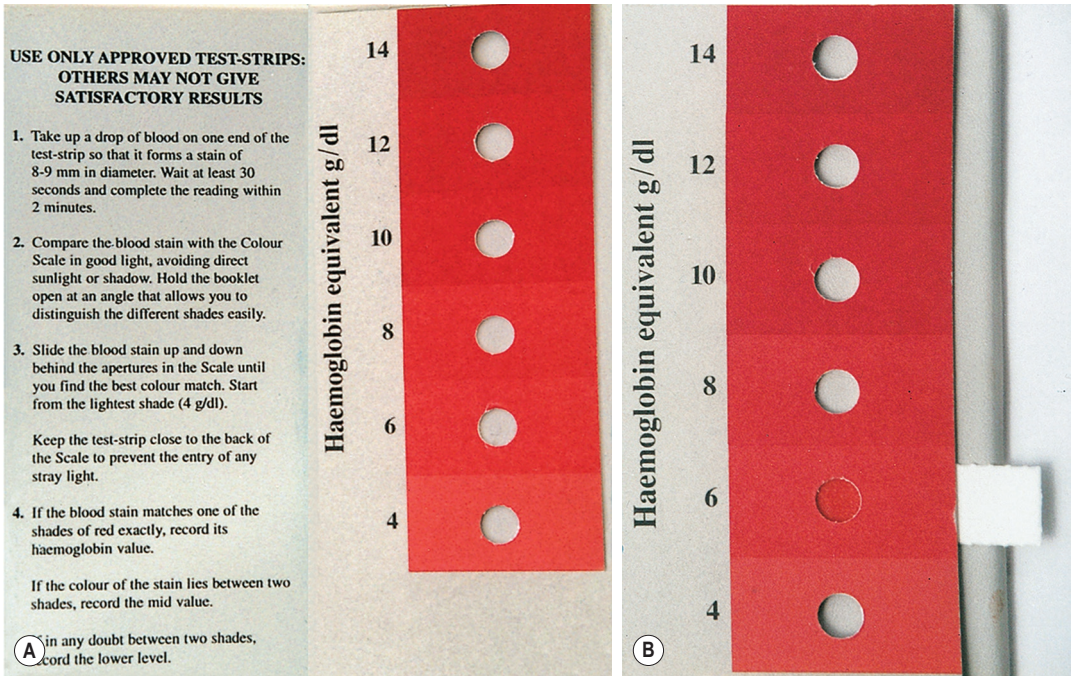

FIGURE 26-2 Haemoglobin colour scale. The stained test-strip being read on the right indicates severe anaemia with a haemoglobin concentration of about 60 g/l.

The same problems associated with inaccuracy and subjectivity apply to these methods, and their use is not recommended.

Packed cell volume

Packed cell volume (PCV) can be used as a screening test for anaemia; however it is not a substitute for a well-performed Hb measurement. In addition to technical problems (outlined on p. 23) there are specific problems with this method in resource-poor settings that may lead to errors in estimating the PCV. Poor-quality sealant can result in the tubes leaking during centrifugation. Because the microhaematocrit tubes are difficult to label, samples may get mixed up in the centrifuge, especially when pressure of work is high and supervision is poor. Erratic power supplies, lack of devices for measuring *g* forces and poor equipment maintenance may result in inadequate centrifugation with incomplete packing of the red cells. In addition, tubes are disposable and require good supply management and waste disposal systems.

Manual cell counts using counting chambers

Visual counting of blood cells is an acceptable alternative to electronic counting for white blood cells but it is not recommended for red blood cell counts because the number of cells that can be counted within a reasonable time in the routine laboratory (e.g. about 400) will be too few to ensure a sufficiently precise result (see below). Although it is possible to perform a manual platelet count,[19] in practice, sufficient information about the platelet count may be obtained from microscopic examination of the peripheral blood film.

Counting chambers

The visibility of the rulings in the counting chamber[19] is as important as the accuracy of calibration, so that chambers with a 'metallised' surface and Neubauer or Improved Neubauer rulings are recommended. These have nine 1 × 1 mm ruled areas, which, when covered correctly with the special thick coverglass, each contain a volume of 0.1 µl of diluted blood (Figs 26-3 and 26-4). Coverslips designed for mounting of microscopy preparations must not be used with counting chambers as they may bow, reducing the volume of the sample. The sample is introduced between the chamber and the coverglass using a pipette or capillary tube, and the preparation is viewed using ×40 objective and ×10 eyepieces. With Neubauer and Improved Neubauer chambers, the cells in 4 or 8 horizontal rectangles of 1 × 0.05 mm (80 or 160 small squares) or in 5 or 10 groups of 16 small squares are counted, including the cells that touch the bottom and left-hand margins of the small squares.

Total white blood cell count

To make the counting of white cells easier, diluted whole blood is mixed with a fluid to lyse the red cells and stain the white cell nuclei deep violet-black.

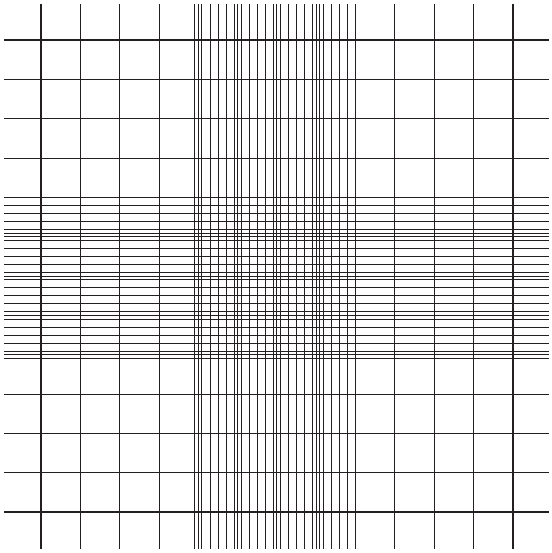

FIGURE 26-3 Neubauer counting chamber. The total ruled area is 3×3 mm; the central ruled area is 1×1 mm. In the central area, 16 groups of 16 small squares are separated by triple rulings.

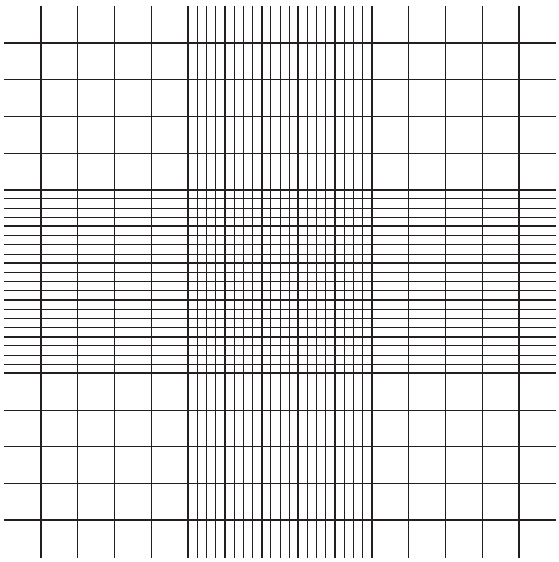

FIGURE 26-4 Improved Neubauer counting chamber. The central area consists of 25 groups of 16 small squares separated by closely ruled triple lines (which appear as thick black lines in the illustration).

Method

Make a 1 in 20 dilution of blood by adding 0.1 ml of *well-mixed* blood (lack of adequate mixing is a major source of error) to 1.9 ml of diluent[†] in a 75×10 mm plastic (or glass) tube. The diluent is 2% (20 ml/l) acetic acid coloured pale violet with gentian violet. After sealing the tube with a lid, mix the diluted blood in a mechanical mixer or by hand for at least 2 min by tilting the tube to an angle of about 120° combined with rotation, thus allowing the air bubble to aid in mixing the suspension. Fill a clean, dry counting chamber, with its coverglass already in position, without delay. This is more easily accomplished with the aid of a plastic Pasteur pipette or a capillary glass tube that has been allowed to take up the suspension by capillarity. Take care that the counting chamber is filled in one action and that no fluid flows into the surrounding moat.

Leave the chamber undisturbed on a bench for at least 2 min for the cells to settle, but not much longer, because drying at the edges of the preparation initiates currents that cause movement of the cells after they have settled. The bench must be free of vibrations, and the chamber must not be exposed to draughts or to direct sunlight or other sources of heat. It is important that the coverglass should be of a special thick glass and perfectly flat, so that when laid on the counting chamber, diffraction rings are seen. The coverglass should be of such a size that when placed correctly on the counting chamber, the central ruled areas lie in the centre of the rectangle to be filled with the cell suspension.

If any of the following filling defects occur, the preparation must be discarded and the filling procedure must be repeated using another clean dry chamber:

- Overflow into moat
- Chamber area incompletely filled
- Air bubbles anywhere in the chamber area
- Any debris in the chamber area.

To obtain a coefficient of variation of 5%, it is necessary to count about 400 cells (Table 26-1); in practice, it is reasonable to count 100 white cells. This can be achieved by counting the cells in the four larger corner squares.[19] To minimise distribution errors, count the cells in the entire ruled area (i.e. 9×0.1 µl areas in an Improved Neubauer counting chamber).

Calculation

White blood cell count per litre (WBC)

$$= \frac{\text{No. of cells counted} \times \text{Dilution} \times 10^6}{\text{Volume counted}\,(\mu\text{l})}$$

Thus, if N cells are counted in 0.1 µl, then the WBC is as follows:

$$\frac{N \times 20 \times 10^6}{0.1} = N \times 200 \times 10^6$$

(e.g. if 115 cells are counted, the WBC is $115 \times 200 \times 10^6/\text{l} = 23 \times 10^9/\text{l}$).

Range of white blood cell count in health. See Chapter 2.

[†]Or a proportionately smaller volume: 0.02 ml (20 µl) of blood in 0.38 ml of lysing fluid.

TABLE 26-1

VARIANCE OF HAEMOCYTOMETRY COUNT

No. of Areas	Total No. of Cells Counted (λ)	$\sqrt{\lambda}$	Count Variance ($\sigma = 0.92 \times \sqrt{\lambda}$)	Uncertainty of Total Count ($\lambda \pm \sigma$)	Range Per 1 mm² Area	Calculated Count/µl
1	50	7.1	6.5	36–64	36–64	7.2–12.8
2	100	10.0	9.2	91–109	40–60	8.0–12.0
4	200	14.1	13.0	187–213	43–57	8.6–11.4
6	300	17.3	15.9	284–316	44–56	8.8–11.2
8	400	20.0	18.4	382–418	45–55	9.0–11.0
10	500	22.4	20.6	479–521	46–54	9.1–10.9
16	800	28.3	26.0	774–826	46–54	9.3–10.7
20	1000	31.6	29.1	891–1029	47–53	9.4–10.6
30	1500	38.7	35.6	1464–1536	47–53	9.5–10.5
200	10 000	100.0	92.0	9908–10 092	49–51	9.8–10.2

The inherent error of a cell count results from the random way in which the cells are distributed in the counting chamber. This is known as the count variance (σ); it is calculated as $0.92\sqrt{\lambda}$ where λ = number of cells actually counted and variance is expressed as a percentage. Ideally count data should be analysed assuming a negative binomial distribution, but a simplified method is to apply a reduction factor of 0.92 to adjust for some clustering of cells within the counting chamber. The uncertainty of the count is in the range $\lambda \pm \sigma$. In this theoretical example the final (calculated) count is based on the number of cells in a 1 mm² area at a dilution of 1:20. There were approximately 50 cells in each 1 mm² area. For convenience, results have been rounded to the nearest whole number. Counting in only one or two fields results in a wide variance that is reduced as more cells are counted. However, high precision is achieved only when thousands of cells are counted, which is only possible with automated cell counters.

Platelet count

Automated haematology analysers produce platelet counts with a precision that is much superior to that of manual platelet counts. The inaccuracy and imprecision of manual platelet counts means that they are rarely performed, but they may occasionally be needed for blood samples with a significant proportion of giant platelets. Manual platelet counts are best performed on ethylenediaminetetraacetic acid (EDTA)-anticoagulated blood that has been obtained by clean venepuncture. It is vital that the proportion of anticoagulant to blood is correct to avoid platelet clumping. Skin-prick samples are associated with platelet clumping, so platelet counts are significantly lower and less consistent than those performed on venous blood. Manual platelet counts are performed by visual examination of diluted, lysed whole blood using a Neubauer or Improved Neubauer counting chamber as for total white cell counts.[20,21]

Method

The diluent consists of 1% aqueous ammonium oxalate which also lyses the red cells. This method is recommended in preference to using formal-citrate as diluent, which leaves the red cells intact and is more likely to give incorrect results when the platelet count is low.

Before diluting the blood sample, examine it carefully for the presence of blood clots. If these are present, a fresh specimen should be requested because clots will cause the platelet count to be artificially low. Make a 1 in 20 dilution of well-mixed blood in the diluent by adding 0.1 ml of blood to 1.9 ml of ammonium oxalate diluent (10 g/l). Not more than 500 ml of diluent should be made at a time, using scrupulously clean glassware and fresh glass-distilled or deionised water. If possible, the solution should be filtered through a micropore filter (0.22 µm) and kept at 4 °C. For use, a small part of the stock is refiltered and dispensed in 1.9 ml volumes in 75 × 12 mm tubes.

Mix the suspension on a mechanical mixer for 10–15 min. Fill a Neubauer counting chamber with the suspension, using a glass capillary tube or Pasteur pipette. Place the counting chamber in a moist Petri dish to prevent the preparation drying out and leave untouched for at least 20 min to give time for the platelets to settle.

Examine the preparation with the ×40 objective and ×10 eyepieces. The platelets appear as small (but not minute), highly refractile particles if viewed with bright light illumination with the condenser racked down; they are usually well separated, and clumps are rare if the blood sample has been properly collected. To avoid introducing dirt particles into the chamber which might be mistaken for platelets, all equipment must be scrupulously clean. Platelets are more easily seen with a phase contrast microscope. A special, thin-bottomed (1 µm) counting chamber is best for optimal phase contrast effect. The number of platelets in one or more areas of 1 mm² should be counted. The total number of platelets counted should always exceed 200 to ensure a coefficient of variation of 8–10%.

Calculation

$$\text{Platelet count per litre} = \frac{\text{No. of cells counted} \times \text{Dilution} \times 10^6}{\text{Volume counted}\,(\mu\text{l})}$$

Thus, if N is the number of platelets counted in an area of 1 mm^2 (0.1 µl in volume), the number of platelets per litre of blood is:

$$N \times 10 \times 20\,(\text{dilution}) \times 10^6 = N \times 200 \times 10^6$$

Range of platelet counts in health. See Chapter 2.

Errors in manual cell counts

The errors associated with manual cell counts are *technical* and *inherent*.

Technical errors can be minimised by avoiding the following:

- Poor technique in obtaining the blood specimen
- Insufficient mixing of the blood specimen
- Inaccurate pipetting and the use of badly calibrated pipettes or counting chambers
- Inadequate mixing of the cell suspension
- Faulty filling of the counting chamber
- Careless counting of cells within the chamber
- Wrong calculations.

Standardised counting chambers

To reduce errors, it is important to have a good-quality counting chamber. The exact chamber depth depends on the coverglass, which should be free from bowing and sufficiently thick so it will not bend when pressed on the chamber. The coverglass must be free from scratches and clean, as even the smallest particle of dust may cause unevenness in its lie on the chamber. The specifications described by WHO[19] outline a tolerance of dimensions for counting chambers that provides reasonable accuracy.

Accurate dilutions

Bulb-diluting pipettes are not recommended as they are difficult to calibrate, easily broken, the volumes of blood used are unnecessarily small and it is difficult to fill the counting chamber so that the exact amount of fluid is delivered. Pipettes of 0.1 ml and 0.02 ml (20 µl) are relatively inexpensive and easy to calibrate. With a 2 ml volume of diluent in a glass or plastic tube provided with a tightly fitting rubber or plastic bung, a suspension is obtained that is easy to label and handle and, with a little practice, perfect filling of the counting chamber can regularly be accomplished with the aid of a fine plastic Pasteur pipette or glass capillary tube. Automatic diluter units are useful. These consist of a dual metering system that enables a volume of diluent and the appropriate volume of blood to be dispensed consecutively into a tube. A variety of automatic diluting systems are now available that have good accuracy and precision, but a regular supply of disposable tips may be too expensive and difficult for smaller laboratories in resource-poor settings to maintain. Pipetting errors apply to all tests that involve dilution of the blood sample, and they also occur with autodiluters (especially with viscid fluids) and when the delivery volume of the unit is not correctly adjusted.

Microscopy artefacts

Dirt or clumped red cell debris may be mistaken for white cells or platelets. Clumping of white cells occurs particularly in heparinised blood, especially when the concentration of heparin exceeds 25 iu/ml of blood. The clumps are most frequently seen in blood that has been allowed to stand for several hours before the count is performed. For this reason, EDTA is the anticoagulant of choice for blood count examinations.

Inherent errors result from uneven distribution of cells in the counting chamber, and no amount of mixing will minimise this inherent variation in numbers between areas. Inherent error can only be reduced by counting more cells in a preparation. In theory, the count varies in proportion to the square root of the number of cells counted, i.e. if four times the number of cells are counted, the variation is halved (see Table 26-1). For example, when performing a manual white cell count, 95% of the observed counts in a sample of true value 5.0×10^9 cells/l would lie within the range 4.0–6.0. In practice, the difference between 5.0 and 6.0×10^9 cells/l for a white cell count is of little clinical significance.

It is also important for the observer not to bias the count by foreknowledge of what result might be expected or by selecting certain areas in the chamber for counting.[22]

Peripheral blood morphology

Examination of a peripheral blood film is one of the most important and useful examinations in the peripheral laboratory but requires a great deal of skill and experience as well as a good-quality microscope (see Chapter 5). In addition to providing information about quantitative changes in blood cells, careful analysis of the morphology of cells may help to elucidate the underlying reasons for clinical problems. These observations may, for example, help to identify the cause of anaemia or undiagnosed fever or the presence of a haemoglobinopathy (see Chapter 14). Problems that might occur when preparing blood films relate to the slides themselves and to the quality of spreading and fixing of the films and the quality of staining reagents. Glass slides are commonly in short supply, so it may be necessary to wash and reuse

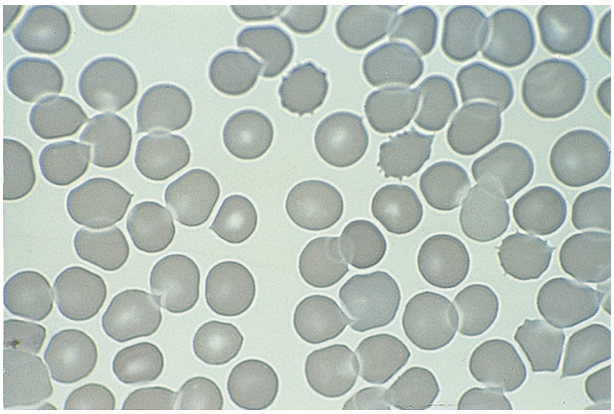

FIGURE 26-5 Red cell appearances on detergent washed slide.

slides, but when this is done, proper procedures need to be followed. Traces of detergent can result in misleading appearances of the red cells (Fig. 26-5), as can residual stains and scratches on the slide. In humid conditions, particularly during the rainy season, water may be absorbed by the methanol used for fixing slides and this can cause gross artefactual changes in red cell appearance (see Fig. 4-2). To reduce this problem, methanol can be double-distilled before use. Stock bottles of methanol should be kept tightly closed after use; small amounts should be aliquotted into a bottle with a tightly fitting cap for daily use and replaced regularly from the stock bottle. Dipping the cap and neck of the bottle in melted paraffin wax provides an airtight seal.

Modified (one-tube) osmotic fragility test

This simple and inexpensive test for screening for β thalassaemia trait is useful when quantification of haemoglobin A_2 is not possible and standardised automated analysers are not available for accurate measurement of MCV and MCH.

A variety of concentrations of buffered saline have been used. A concentration of 0.36% in buffered saline (see p. 562 for preparation) is recommended to ensure a high sensitivity with an acceptable specificity.[23,] Because the false-positive rate is around 10%, confirmation of a positive result requires referral of a sample to a laboratory able to quantitate haemoglobin A_2. The presence of α thalassaemia, glucose-6-phosphate dehydrogenase (G6PD) deficiency and Southeast Asian ovalocytosis may reduce the sensitivity of the one-tube osmotic fragility test for detecting β thalassaemia trait to below 70%.[24] The one-tube osmotic fragility test can also be used to screen for α^0 thalassaemia trait, with positive samples being referred to a reference centre for DNA analysis. About 50% of samples containing haemoglobin E also give a positive result; this is an advantage rather than a disadvantage because detection of haemoglobin E is important in predicting the possibility of thalassaemia major or intermedia in compound heterozygotes with β thalassaemia.

Haemoglobin E screening test

Ideally, the diagnosis of haemoglobin E heterozygosity or homozygosity should be by haemoglobin electrophoresis at alkaline pH or high performance liquid chromatography (which can use dried blood spots) with a second method being used to confirm the provisional identification (see Chapter 14). When these facilities are not available, a screening test using the blue dye 2,6-dichlorophenolindophenol (DCIP), can be used. Samples containing haemoglobin E become faintly turbid when incubated with DCIP.[25,26]

Sickle cell screening test

Screening for sickle cells can be performed using a thin wet film of blood with or without a reducing agent such as sodium metabisulphite to demonstrate sickle cells microscopically. Screening can also be performed using a solubility test. A blood sample is mixed with a high molarity phosphate buffer in which deoxygenated haemoglobin is insoluble and the mixture becomes turbid. A positive test requires haemoglobin electrophoresis to distinguish the heterozygous from homozygous state (Chapter 14).

Tests for paroxysmal nocturnal haemoglobinuria

When facilities permit, flow cytometry for glycosylphosphatidylinositol-anchored proteins is the test of choice to detect paroxysmal nocturnal haemoglobinuria (PNH) clone. If positive, a sample of urine should be examined for haemosiderin. The Ham test and sucrose lysis test (see Chapter 13) can also be used as tests for PNH. They are less sensitive and less quantitative than flow cytometry, but nevertheless are clinically useful.

Reagents for prothrombin time and activated partial thromboplastin time

Freeze-dried rabbit brain thromboplastins for use in the PT and APTT are now widely available commercially, with a shelf-life of 2–5 years or longer. Usually, they are calibrated against the WHO International Reference Preparation of Thromboplastin and are supplied with an International Sensitivity Index (ISI) and a table converting PT to International Normalized Ratios (INR). If a commercial preparation is not available, it is possible to prepare a homemade substitute using acetone-dried rabbit brain that is also suitable for preparing an APTT reagent. It does not require freeze drying and is relatively stable (see previous editions for details).

LABORATORY SUPPORT FOR MANAGEMENT OF HIV/AIDS: CD4-POSITIVE T-CELL COUNTS

The WHO recommends that district hospitals and higher level facilities should be able to provide a CD4-positive lymphocyte count to aid identification of patients who would benefit from antiretroviral drugs and to monitor their progress. Several proven flow cytometry methods are available that perform well in laboratories in resource-limited settings and are cost-effective. For an appropriate method, see Chapter 16.

Device-based point-of-care tests for a CD4-positive lymphocyte count (e.g. PointCare NOW, the Pima CD4 Analyser and the CyFlow CD4 miniPOC) are also available, but data about their performance are limited. Several other methods are under development.[27]

Dried spots of serum or blood can be used to assess HIV-1 viral load and for resistance genotyping and are more stable than blood or plasma, making them easier to transport.[28] The COBAS AMPLICOR HIV-1 MONITOR Test (http://molecular.roche.com/assays/Pages%20not%20published/COBASAMPLICORHIV-1MONITORTestv15.aspx), which is considered the gold standard for HIV-1 DNA PCR testing, is used widely in resource-limited settings and performs well with dried blood spot samples.[27]

LABORATORY MANAGEMENT

Interlaboratory communication

A well-planned infrastructure is necessary to facilitate flow of communication (e.g. about specimens, results, patient management) between remote clinics and referral or central laboratories. Mobile telephones and e-mail using mobile telephone networks are now widely available and are being used to transmit health-related information.[29] In more remote areas, voice and e-mail messages can be transmitted using high-frequency or satellite radio systems. Alternative power sources such as generators, solar energy and batteries are used to support communication facilities in remote rural facilities.

Digital wireless data communications systems such as the Global System of Mobile (GSM) network are being increasingly used for routine laboratory reporting. The data volume required for text-based laboratory reports is extremely modest and their transmission is low cost. Result reporting can either be incorporated into the mainstream laboratory information system or be transmitted using individual handsets for smaller independent laboratories.

Specimen transport

The need to ensure appropriate conditions for keeping specimens after they have been collected and other aspects of specimen transport to the laboratory are described in Chapter 1. The special problem of transporting specimens from remote clinics to laboratories and reference centres in low-resource countries requires further consideration. Peripheral laboratories may need to use innovative transport mechanisms such as bicycle riders, motorcyclists, taxi operators, buses, drones and formal and informal courier companies. Commercial or private air services can be used to deliver samples from peripheral clinics to referral centres. Laboratory staff need to ensure that all specimens are stored and transported in the correct conditions and in a safe and timely manner.

Point-of-care tests

The WHO has produced the following ASSURED criteria for the ideal rapid test which is applicable to the rapid point-of-care tests that have been discussed in this chapter.[30]

A = Affordable
S = Sensitive
S = Specific
U = User-friendly (simple to perform in a few steps with minimal training)
R = Robust and rapid (results available in less than 30 min)
E = Equipment-free
D = Deliverable to those who need the test

Staff training

In countries with limited resources, there may be no formal system for regular supervision of individual laboratory staff, and many staff do not receive regular continuing professional development. Monitoring standards of practice should continue for the whole professional life of laboratory staff to ensure high-quality results. For under-resourced countries, training may be provided in association with vertical health programmes such as HIV or tuberculosis control. However, the need for training in common haematological techniques such as Hb measurement and WBCs is often overlooked because these tests are usually not linked to specific diseases and are therefore not incorporated into vertical programmes. In many countries anaemia prevalence, particularly among pregnant women and children, can exceed 50%, so the importance of reliable haemoglobin measurements cannot be overemphasised. The need for integrated training programmes which cover all the common tests is becoming increasingly recognised, especially for peripheral laboratories. Continuing education therefore needs to include the whole range of tests offered by the laboratory and not only tests that are used to support the diagnosis of specific diseases.

Individuals need to keep their own training records, perhaps in the form of a log book, and to have their training achievements and plans documented and

regularly reviewed by their line managers. Central records of all training should also be maintained for monitoring purposes and to ensure equitable and appropriate distribution of training between different levels of staff. One opportunity for ongoing staff development is through regular on-site visits by trained supervisors, who stay for a sufficient length of time to be able to work with the resident staff, and are able to check equipment, supplies, records and attend to other administrative issues. Supervisors themselves need to be trained and monitored to ensure their own proficiency.

Regular monitoring of the quality of results from individual laboratories enables specific problems to be identified. Integrated EQA schemes tailored for peripheral laboratories are an excellent way to monitor laboratory performance across a wide range of tests. In addition, quality monitoring allows discrete training needs to be identified, enabling limited teaching resources to be specifically targeted. Systems need to be established to report issues such as equipment failures, poor performance of test kits or rapid tests, discontinuity of supplies and communication breakdowns to the local or regional management teams.

Access to up-to-date information is important for adapting and enhancing laboratory performance. Many articles from medical and technical journals, and laboratory and clinical guidelines can be freely accessed by laboratory staff with internet access (see www.who.int/hinari/en). Some online educational resources are freely available, e.g. www.bloodmed.com and www.bcshguidelines.com.

Clinical staff interaction

Appropriate clinical use of the laboratory has a direct impact on the cost-effectiveness of the service.[12] Laboratory tests may be initiated by nurses, health field workers and public health officers, as well as clinical officers and doctors. Many of these individuals have little or no training in how to request appropriate tests, how to provide timely and suitable samples and how to use the results for maximal benefit to patients. A major delay in test turnaround time (see p. 523) and slow delivery of reports within the health facility after the test has been performed contribute to the failure of clinicians to use test results in patient management. Training for laboratory users needs to be incorporated into clinical training programmes and to be closely monitored. In resource-limited countries, there is often a dearth of clinicians with both clinical and laboratory experience who have the expertise to provide such training. However, the relationship between the laboratory and clinical staff can be enhanced, and use of the laboratory can be optimised by using a clinician/laboratory team to provide joint training in both disciplines. Various clinical guidelines are now available to guide laboratory users on which test to select for specific conditions, how to interpret the results and how to select and collect the correct samples.

Facility management teams

The management teams for each health facility are responsible for ensuring that the laboratories in their facility are provided with the necessary tools to deliver a high-quality service. Traditionally, these teams have not included laboratory professionals; the laboratory's needs may be represented by other allied professionals such as pharmacists or nurses. Staff in under-resourced laboratories are therefore not always responsible for purchasing supplies and equipment for the laboratory, and this can result in the purchase of inappropriate or poor-quality equipment and reagents. In addition to encouraging adequate representation of laboratory professionals at management level, it is important to ensure that non-laboratory personnel responsible for making procurement decisions for the laboratory are aware of the needs of their laboratory service and that they seek advice from laboratory professionals.

Health and safety

Details of laboratory safety issues are described in Chapter 24. Awareness of these issues should be constantly promoted within all laboratories,[31] and the working environment needs to be made as safe as possible. A 'Code of Safe Laboratory Practice' should be prepared that is affordable and relevant to the local circumstances. It should include the following:

- Risk assessment to identify potential workplace hazards and the risk they pose to individuals working in or visiting the laboratory
- Education on safe working practices
- Provision of appropriate and adequate safety items, such as white coats, gloves, goggles and pipetting devices
- Monitoring of adherence to health and safety regulations
- Prompt reporting and investigation of laboratory accidents
- Addressing medical waste disposal practices including use of sharps containers and waste bags, and disposal of items in incinerators or deep pits.

Single-use disposable syringes and needles should be used rather than reusable syringes and needles. Hypochlorite bleach used in cleaning needles and syringes poses a danger if it enters the vein of a patient. Disposable syringes and needles (see p. 2) are intended for single-use only. They cannot withstand sterilisation and should never be reused. Similarly, disposable lancets for skin puncture must never be reused. The practice of using a single lancet on several patients consecutively and cleaning with alcohol between use is unacceptable. Disposable gloves can be reused if they have been soaked in hypochlorite bleach and then washed thoroughly in running water.

CHAPTER OUTLINE

PREPARATION OF COMMONLY USED REAGENTS

Water

For most purposes, still-prepared distilled water or deionised water is equally suitable. Throughout this text, this is implied when 'water' is referred to. When doubly distilled or glass-distilled water is required, this has been specially indicated, and when tap water is satisfactory or indicated, this, too, has been stated.

Anticoagulants and preservative solutions

Acid–citrate–dextrose (ACD) solution – NIH-a

Trisodium citrate, dihydrate (75 mmol/l)	22 g
Citric acid, monohydrate (42 mmol/l)	8 g
Dextrose (139 mmol/l)	25 g
Water to 1 litre	

Sterilise the solution by autoclaving at 121 °C for 15 min. Its pH is 5.4. For use, add 10 volumes of blood to 1.5 volumes of solution. For use in red cell survival studies, see p. 358.

Acid–citrate–dextrose (Alsever) solution

Dextrose (114 mmol/l)	20.5 g
Trisodium citrate, dihydrate (27 mmol/l)	8.0 g
Sodium chloride (72 mmol/l)	4.2 g
Water to 1 litre	

Adjust the pH to 6.1 with citric acid (*c.* 0.5 g) and then sterilise the solution by micropore filtration (0.22 µm) or by autoclaving at 121 °C for 15 min.

For use, add 4 volumes of blood to 1 volume of solution.

Citrate–phosphate–dextrose (CPD) solution, pH 6.9

Trisodium citrate, dihydrate (102 mmol/l)	30 g
Sodium dihydrogen phosphate, monohydrate (1.08 mmol/l)	0.15 g
Dextrose (11 mmol/l)	2 g
Water to 1 litre	

Sterilise the solution by autoclaving at 121 °C for 15 min. After cooling to *c.* 20 °C, it should have a brown tinge and its pH should be 6.9.

Citrate–phosphate–dextrose (CPD) solution, pH 5.6–5.8

Trisodium citrate, dihydrate (89 mmol/l)	26.30 g
Citric acid, monohydrate (17 mmol/l)	3.27 g
Sodium dihydrogen phosphate, monohydrate (16 mmol/l)	2.22 g
Dextrose (142 mmol/l)	25.50 g
Water to 1 litre	

Sterilise the solution by autoclaving at 121 °C for 15 min. For use as an anticoagulant preservative, add 7 volumes of blood to 1 volume of solution.

Citrate–phosphate–dextrose–adenine (CPD-A) solution, pH 5.6–5.8

Trisodium citrate, dihydrate (89 mmol/l)	26.30 g
Citric acid, monohydrate (17 mmol/l)	3.27 g
Sodium dihydrogen phosphate, monohydrate (16 mmol/l)	2.22 g
Dextrose (177 mmol/l)	31.8 g
Adenine (2.04 mmol/l)	0.275 g
Water to 1 litre	

Sterilise the solution by autoclaving at 121 °C for 15 min. For use as an anticoagulant preservative, add 7 volumes of blood to 1 volume of solution.

Low ionic strength saline (LISS)[1]

Sodium chloride (NaCl) (30.8 mmol/l)	1.8 g
Disodium hydrogen phosphate (Na_2HPO_4) (1.5 mmol/l)	0.21 g
Sodium dihydrogen phosphate (NaH_2PO_4) (1.5 mmol/l)	0.18 g
Glycine (NH_2CH_2COOH) (240 mmol/l)	18.0 g
Water to 1 litre	

Dissolve the sodium chloride and the two phosphate salts in *c.* 400 ml of water; dissolve the glycine separately in *c.* 400 ml of water; adjust the pH of each solution to 6.7 with 1 mol/l NaOH. Add the two solutions together and make up to 1 litre. Sterilise by Seitz filtration or autoclaving. The pH should be within the range of 6.65–6.85, the osmolality 270–285 mmol and conductivity 3.5–3.8 mS/cm at 23 °C.

K_2EDTA

Ethylenediaminetetra-acetic acid (EDTA), dipotassium salt	100 g
Water to 1 litre	

Allow appropriate volumes to dry in bottles at *c.* 20 °C so as to give a concentration of 1.5 ± 0.25 mg/ml of blood.

Neutral EDTA, pH 7.0, 110 mmol/l

EDTA, dipotassium salt	44.5 g
(or disodium salt	41.0 g)
1 mmol/l NaOH	75 ml
Water to 1 litre	

Neutral buffered Na_2EDTA, pH 7.0

EDTA, disodium salt (9 mmol/l)	3.35 g
Disodium hydrogen phosphate (Na_2HPO_4) (26.4 mmol/l)	3.75 g
Sodium chloride (NaCl) (140 mmol/l)	8.18 g
Water to 1 litre	

Saline (normal ionic strength)

Sodium chloride (NaCl) (154 mmol/l)	9.0 g
Water to 1 litre	

Trisodium citrate ($Na_3C_6H_5O_7.2H_2O$), 109 mmol/l

Dissolve 32 g (*or* 38 g of $2Na_3C_6H_5O_7.11H_2O$) in 1 litre of water. Distribute convenient volumes (e.g. 10 ml) into small bottles and sterilise by autoclaving at 121 °C for 15 min.

Heparin

Powdered heparin (lithium salt) is available with an activity of *c.* 160 iu/mg. Dissolve it in water at a concentration of 4 mg/ml. Sodium heparin is available in 5 ml ampoules with an activity of 1000 iu/ml. Add appropriate volumes of either solution to a series of containers and allow to dry at *c.* 20 °C so as to give a concentration not exceeding 15–20 iu/ml of blood.

Buffers

Barbitone buffer, pH 7.4

Sodium diethyl barbiturate ($C_8H_{11}O_3N_2Na$) (57 mmol/l)	11.74 g
Hydrochloric acid (HCl) (100 mmol/l)	430 ml

Barbitone buffered saline, pH 7.4

NaCl	5.67 g
Barbitone buffer, pH 7.4	1 litre

Before use, dilute with an equal volume of 9 g/l NaCl.

Barbitone buffered saline, pH 9.5

Sodium diethyl barbiturate ($C_8H_{11}O_3N_2Na$) (98 mmol/l)	20.2 g
Hydrochloric acid (HCl) (100 mmol/l)	20 ml
NaCl	5.67 g

Before use, dilute the buffer with an equal volume of 9 g/l NaCl.

Barbitone–bovine serum albumin buffer, pH 9.8

Sodium diethyl barbiturate ($C_8H_{11}O_3N_2Na$) (54 mmol/l)	10.3 g
NaCl (102 mmol/l)	6.0 g
Sodium azide (31 mmol/l)	2.0 g
Bovine serum albumin (BSA)	5.0 g
Water to 1 litre	

Dissolve the reagents in *c*. 900 ml of water. Adjust the pH to 9.8 with 5 mol/l HCl. Make up the volume to 1 litre with water. Store at 4 °C.

Citrate–saline buffer

Trisodium citrate ($Na_3C_6H_5O_7.2H_2O$) (5 mmol/l)	1.5 g
NaCl (96 mmol/l)	5.6 g
Barbitone buffer, pH 7.4	200 ml
Water	800 ml

Glycine buffer, pH 3.0

Glycine (NH_2CH_2COOH) (82 mmol/l)	6.15 g
NaCl (82 mmol/l)	4.80 g
Water	820 ml
0.1 mol/l HCl	180 ml

HEPES buffer, pH 6.6

N-2-hydroxyethylpiperazine-N′-2-ethanesulfonic acid (HEPES) (100 mmol/l)	23.83 g
NaOH (1 mol/l)	*c*. 1 ml
Dimethyl sulphoxide	25 ml
Water to 1 litre	

Dissolve in *c*. 100 ml of water. Add a sufficient volume of 1 mol/l NaOH (*c*. 1 ml) to adjust the pH to 6.6. If the buffer is intended for use with Romanowsky staining (see p. 52), then add 25 ml of dimethyl sulphoxide (DMSO). Make up the volume to 1 litre with water.

HEPES–saline buffer, pH 7.6

HEPES (20 mmol/l)	4.76 g
NaCl	8.0 g
NaOH (1 mol/l)	
Water to 1 litre	

Dissolve in *c*. 100 ml of water. Add a sufficient volume of 1 mol/l NaOH to adjust the pH to 7.6. Make up volume to 1 litre with water.

Imidazole buffered saline, pH 7.4

Imidazole (50 mmol/l)	3.4 g
NaCl (100 mmol/l)	5.85 g
Water to 1 litre	

Dissolve imidazole and NaCl in *c*. 500 ml of water. Add 18.6 ml of 1 mol/l HCl and make up the volume to 1 litre with water. Store at room temperature (18–25 °C).

Phosphate buffer, iso-osmotic

(A) $NaH_2PO_4.2H_2O$ (150 mmol/l)	23.4 g/l
(B) Na_2HPO_4 (150 mmol/l)	21.3 g/l

pH	Solution A	Solution B
5.8	87 ml	13 ml
6.0	83 ml	17 ml
6.2	75 ml	25 ml
6.4	66 ml	34 ml
6.6	56 ml	44 ml
6.8	46 ml	54 ml
7.0	32 ml	68 ml
7.2	24 ml	76 ml
7.4	18 ml	82 ml
7.6	13 ml	87 ml
7.7	9.5 ml	90.5 ml

Normal human serum has an osmolality of 289 ± 4 mmol. Hendry[2] recommended slightly different concentrations of the stock solution: namely, 25.05 g/l $NaH_2PO_4.2H_2O$ and 17.92 g/l Na_2HPO_4 for an iso-osmotic buffer.

Phosphate buffered saline

Equal volumes of iso-osmotic phosphate buffer and 9 g/l NaCl.

Phosphate buffer, Sörensen

Stock solutions:

	66 mmol/l	100 mmol/l	150 mmol/l
(A) KH_2PO_4	9.1 g/l	13.8 g/l	20.7 g/l
(B) Na_2HPO_4	9.5 g/l	14.4 g/l	21.6 g/l
or $Na_2HPO_4.2H_2O$	11.9 g/l	18.0 g/l	27.1 g/l

To obtain a solution of the required pH, add A and B in the indicated proportions:

pH	A	B
5.4	97.0	3.0
5.6	95.0	5.0
5.8	92.2	7.8
6.0	88.0	12.0
6.2	81.0	19.0
6.4	73.0	27.0
6.6	63.0	37.0
6.8	50.8	49.2
7.0	38.9	61.1
7.2	28.0	72.0
7.4	19.2	80.8
7.6	13.0	87.0
7.8	8.5	91.5
8.0	5.5	94.5

This buffer is not iso-osmotic with normal plasma (see earlier).

Tris–HCl buffer (200 mmol/l)

Tris (hydroxymethyl) aminomethane (24.23 g/l)	250 ml

To obtain a solution of the required pH, add the appropriate volume of 1 mol/l HCl and then make up the volume to 1 litre with water.

pH	Volume
7.2	44.5 ml
7.4	42.0 ml
7.6	39.0 ml
7.8	33.5 ml
8.0	28.0 ml
8.2	23.0 ml
8.4	17.5 ml
8.6	13.0 ml
8.8	9.0 ml
9.0	5.0 ml

100 mmol/l, 150 mmol/l, 300 mmol/l and 750 mmol/l stock solutions may be similarly prepared with an appropriate weight of Tris and volume of acid.

Tris–HCl bovine serum albumin (BSA) buffer, pH 7.6, 20 mmol/l

Tris (hydroxymethyl) aminomethane (20 mmol/l)	2.42 g
EDTA, disodium salt (10 mmol/l)	3.72 g
NaCl (100 mmol/l)	5.85 g
Sodium azide (3 mmol/l)	0.2 g
HCl (10 mol/l)	
Bovine serum albumin	10 g
Water to 1 litre	

Dissolve the reagents in *c.* 800 ml of water. Adjust the pH to 7.6 with 10 mol/l HCl. Add 10 g of BSA and make up to 1 litre with water.

Buffered formal acetone

Dissolve 20 mg Na_2HPO_4 and 100 mg KH_2PO_4 in 30 ml distilled water. Add 45 ml acetone and 25 ml of 40% formalin. Mix well and store at 4 °C. Use cold. Make up new fixative every 4 weeks.

PREPARATION OF GLASSWARE

Siliconised glassware

Use *c.* 2% solution of silicone (dimethyldichlorosilane) in solvent. Immerse the clean glassware or syringes to be coated in the fluid and allow to drain dry. (Rubber gloves should be worn and the procedure should be performed in a fume cupboard fitted with an exhaust fan.) Then rinse the coated glassware thoroughly in water and allow to dry in an oven at 100 °C for 10 min or overnight in an incubator.

Cleaning slides

New slides

Boxes of clean, grease-free slides are available commercially. If these are not available, the following procedure should be carried out. Leave the slides overnight in a detergent solution. Then wash well in running tap water, rinse in distilled or deionised water and store in 95% ethanol or methanol until used. Dry with a clean linen cloth and carefully wipe free from dust before they are used.

Dirty slides

When discarded, place in a detergent solution; heat at 60 °C for 20 min; and then wash in hot, running tap water. Finally, rinse in water before drying with a clean linen cloth.

Cleaning glassware

Wash in running tap water. Then boil in a detergent solution; rinse in acid; and wash in hot, running tap water, as described above. Alternatively, the apparatus can be soaked in 3 mol/l HCl.

For the removal of deposits of protein and other organic matter, 'biodegradable' detergents are recommended. Decon 90 (www.decon.co.uk) is suitable, but a number of similar preparations are also available.

Iron-free glassware

Wash in a detergent solution, then soak in 3 mol/l HCl for 24 h; finally, rinse in deionised, double-distilled water.

SIZES OF TUBES

The sizes of tubes recommended in the text have been chosen as being appropriate for the tests described. The dimensions given are the length and external diameter (in mm). The equivalent in inches, as given in some catalogues and certain corresponding internal diameters, are as follows:

75 × 10 mm (internal diameter 8 mm) = 3 × ⅜ inch
75 × 12 mm (internal diameter 10 mm) = 3 × ½ inch
65 × 10 mm = 2½ × ⅜ inch
38 × 6.4 mm = 1½ × ¼ inch ('precipitin tubes')
100 × 12 mm = 4 × ½ inch
150 × 16 mm = 6 × ⅝ inch
150 × 19 mm = 6 × ¾ inch.

SPEED OF CENTRIFUGATION

Throughout the book, the unit given is the relative centrifugal force (*g*). Conversion of this figure to rpm (rev/min) depends on the radius of the centrifuge; it can be calculated by reference to the nomogram illustrated in Figure A-1 or from the formula for relative centrifugal force (RCF):

$$RCF = 118 \times 10^{-7} \times r \times N^{-2}$$

where r = radius (cm) and N = speed of rotation (rpm).

The following centrifugal forces are recommended:

'Low-spun' platelet-rich plasma	150–200 *g* (for 10–15 min)
'High-spun' plasma	1200–1500 *g* (for 15 min)
Packing of red cells	2000–2300 *g* (for 30 min)

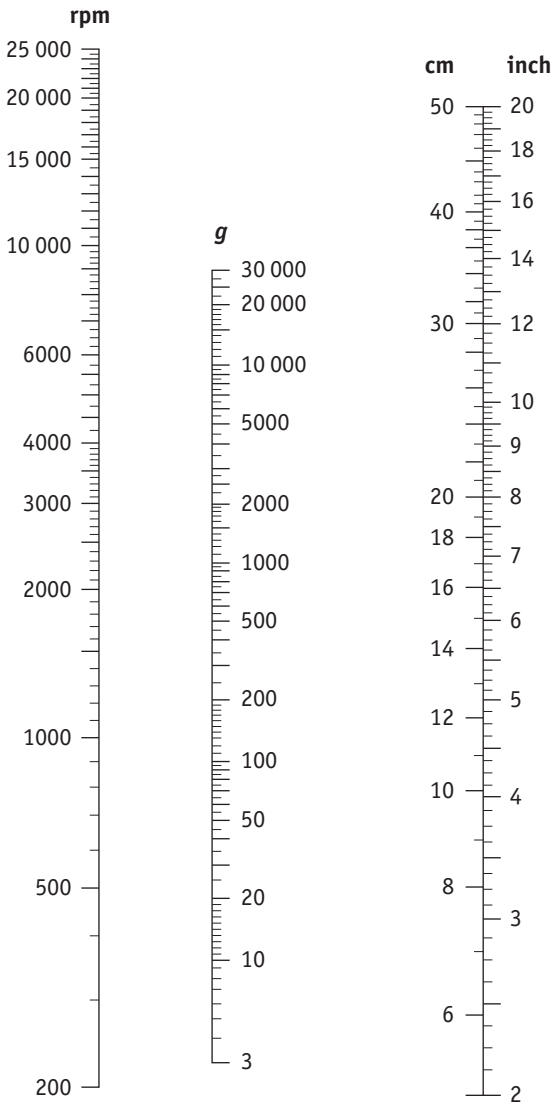

FIGURE A-1 Nomogram for computing relative centrifugal forces.

STATISTICAL PROCEDURES

Statistical analysis is now usually carried out with a statistical package on a computer. For this reason only the principles relevant to diagnostic laboratory practice are summarised here. For further details, reference should be made to the previous edition of this book, a statistics textbook or online resources.

Mean ($\bar{x}$) is the sum of all the measurements (Σ) divided by the number of measurements (*n*).

Median (m) is the point on the scale that has an equal number of observations above and below.

Mode is the most frequently occurring result.

Gaussian distribution describes a bell-shaped curve in which data occur symmetrically about the mean (see Fig. 2-1, p. 9). With this type of distribution, mean, median and mode will be approximately equal. The extent of spread of measurements about the mean is expressed as the standard deviation (SD or s) and its calculation is described below. This means that 68% of the measurement will be within the ±1SD range, 95% will be within ±2SD and 99% will be within ±3SD. Many, but not all, measurements made in a haematology laboratory, for example haemoglobin concentration and mean cell volume, have a Gaussian distribution.

Confidence intervals (CI) of any calculation on a sample indicate the upper and lower limits between which a specified proportion of results (e.g. 95%) of the population from which the sample is derived may be expected to occur.

Log normal distribution describes events that are asymmetrical (skewed) with a larger number of observations towards the lower end. The mean will thus be

nearer that end; the mean, median and mode may differ from each other. To calculate geometric mean and SD, the data are first converted to their logarithms, and after calculating the mean and SD of the logarithms, the results are reconverted to the antilog. The white blood cell count and the absolute neutrophil count have a log normal distribution.

Poisson distribution describes events that are random in their occurrence. This will be the case, for example, when blood cells are counted in a diluted suspension. The number of cells that are counted in a given volume will vary on each occasion; this count variation (σ) is 0.92 $\sqrt{\lambda}$, where λ = the total number of cells counted (see p. 554). It is an estimate of the standard deviation of the entire population, whereas SD denotes the standard deviation of the items that were actually measured.

Coefficient of variation (CV) is another way of indicating standard deviation, related to the actual measurement, so that variation at different levels can be compared. It is expressed as a percentage.

Standard error of mean (SEM) is a measure of dispersion of the mean of a set of measurements. It is used to compare means of two sets of data.

Calculations

Variance (s^2 or SD^2)

$$\frac{\sum(x-\bar{x})^2}{n-1}$$

Standard deviation (SD or s)

$$\sqrt{\text{variance}} \text{ or } \sqrt{\frac{\sum(x-\bar{x})^2}{n-1}}$$

Coefficient of variation (CV) as percentage

$$\frac{SD \times 100\%}{\bar{x}} \text{ or } \frac{s \times 100\%}{\bar{x}}$$

Standard error mean (SEM)

$$\frac{SD}{\sqrt{n}}$$

Standard deviation of paired results

$$\sqrt{\frac{\sum d^2}{2n}}$$

where d = the difference in each pair of tests and n = number of paired measurements.

Standard deviation of median

$$\frac{\text{Central } 50\%}{1.35} \left(\text{betweeen 25\% and 75\%}\right)$$

Confidence interval

Decide on required confidence interval (e.g. 95% or 99%).

From a *t*-test table find the number at $n-1$ degrees of freedom.

Calculate SD and SEM as above.

Then the confidence interval will be between $\bar{x} - (t \times SEM)$ and $\bar{x} + (t \times SEM)$.

When the original data are log normal, convert to their logs, use these figures throughout the calculation and convert the final results to their antilogs.

Analysis of differences by *t*-test

Analysis of differences by *t*-test is a method for comparing two sets of data (e.g. to assess the accuracy of a new method against a reference method).

Calculation

Determine the difference in each pair of tests (d) and the mean difference ($\bar{d}$)

$$\text{Variance is obtained from } \frac{\left(d-\bar{d}\right)^2}{n-1};\ t = \bar{d} \div \frac{s^2}{n}$$

From a *t*-test chart, read the value of *t* for the appropriate degree of freedom (i.e. $n-1$). Express results as the level of probability (p) that there is no significant difference between the sets of data that are being compared.

Analysis of variation by *F*-ratio

Analysis of variation by *F*-ratio is a method to assess the relative precision of two sets of measurements.

Calculation

Determine variance (s^2) as described above for each set. Because the ratio must not be less than 1, use the higher variance as the numerator. Then, from an F distribution chart, read the value at either 95% or 99% probability (i.e. $p = 0.05$ or $p = 0.01$) for the appropriate degrees of freedom (i.e. $n-1$) for the two sets of data.

Interpretation

There is a significant difference in variation between the two sets when the calculated ratio is greater than the value read from the chart.

AUTOMATED (MECHANICAL) PIPETTES

Accurate pipetting is an essential requirement for all quantitative tests. A variety of automated hand-held pipettes are available, many of which incorporate a disposable tip with an ejector mechanism, which allows the user to remove it without hand contact. Some pipettes have a fixed capacity; in others a range of volumes can be obtained by means of an adjusting screw, and the delivery volume is displayed on a digital readout.

Because the designs are varied, the specific manufacturer's instructions must be carefully followed. The following important points are common to all:

1. Always use the specified tip.
2. Washing and reusing tips is not recommended.
3. Ensure that the tip is fitted firmly to the pipette.
4. Keep the pipette clean of dirt and grease.
5. Always pipette in a vertical position.
6. Never leave the pipette on its side with liquid in the tip.
7. Return the pipette to its stand after use.
8. Operate by a slow, smooth, consistent procedure, avoiding bubbles or foaming.
9. Use 'reverse pipetting' for plasma, high-viscosity fluids and/or very small volumes. With the plunger pressed all the way down (2nd stop), dip the tip well below the surface of the fluid and release the plunger knob slowly. Remove the pipette; wipe the outside of the tip carefully with a tissue; and then, with the tip against the inside wall of the receiving container, deliver its contents by depressing the plunger knob to the 1st stop. Then discard the tip with its residual contents.
10. For blood dilution, fill and empty the tip with the blood 2–3 times, then depress the plunger to the 1st stop. With the tip well below the surface of the specimen, release the plunger to fill the tip with blood. Withdraw the pipette from the specimen, wipe the outside of the tip carefully with a tissue, dip the tip into the diluent well below the surface and press the plunger knob repeatedly to fill and empty the tip until the interior wall is clear. Then depress the plunger to the 2nd stop to empty the tip completely.
11. At intervals, monitor the reliability of the pipette by checking its accuracy and precision.

Quality control of pipette reliability involves the following:

1. Ensure that all the items to be used are at ambient room temperature.
2. Record the weight of a weighing beaker using a precision balance sensitive to 0.1 mg.
3. Record the temperature of a tube of distilled water, fill the pipette with the water, wipe the outside of the tip and dispense the water into the weighing beaker with the tip touching the side of the beaker.

TABLE A-1

AMBIENT TEMPERATURE FACTOR FOR CORRECTION OF WEIGHT:VOLUME RATIO

Temp (°C)	Volume Factor
18	0.9986
19	0.9984
20	0.9982
21	0.9980
22	0.9978
23	0.9976
24	0.9973
25	0.9971
26	0.9968
27	0.9965
28	0.9963
29	0.9960
30	0.9957

4. Record the weight of the beaker plus water and calculate the weight of the water.
5. Calculate the volume (in µl) from the weight (in mg) ÷ the ambient temperature factor (Table A-1).
6. Repeat the procedure 10 times, changing the tip each time.
7. Calculate the mean, SD and CV of the dispensed volume. From the mean, calculate the percentage deviation from the expected volume by the formula:

$$\frac{\text{Expected volume} - \text{delivered volume}}{\text{Expected volume}} \times 100$$

For routine purposes, this should not differ by more than 1.5%. The CV should be <1%.

AUTODILUTERS

Autodiluter systems provide a constant dilution of blood in reagent by a single process. To check their accuracy, a calibrated 0.2 ml pipette and 50 ml volumetric flask are required. Equipment certified as conforming to these measurements in accordance with national standards is available commercially, or their accuracy can be checked by the procedure described above.

Mix well a 2–3 ml specimen of anticoagulated fresh whole blood and lyse (see p. 291). Then dilute manually 1:251 in haemiglobincyanide reagent (see p. 20) using the calibrated pipette and volumetric flask. At the same time, dilute a sample of the lysed blood in haemiglobincyanide solution, in duplicate, by means of the autodiluter. Read the absorbance of each solution at 540 nm in a spectrophotometer. The dilution by the autodiluter is obtained from the formula:

$$A_1 \times \frac{\text{Dilution}}{A_2} \left(\text{i.e. } 1:251\right)$$

where A_1 = absorbance at 540 nm of manual dilution and A_2 = absorbance at 540 nm of autodiluted sample.

If indicated, an appropriate adjustment should be made to the autodiluter in accordance with the manufacturer's instructions or a correction factor should be applied whenever the autodiluter is used.

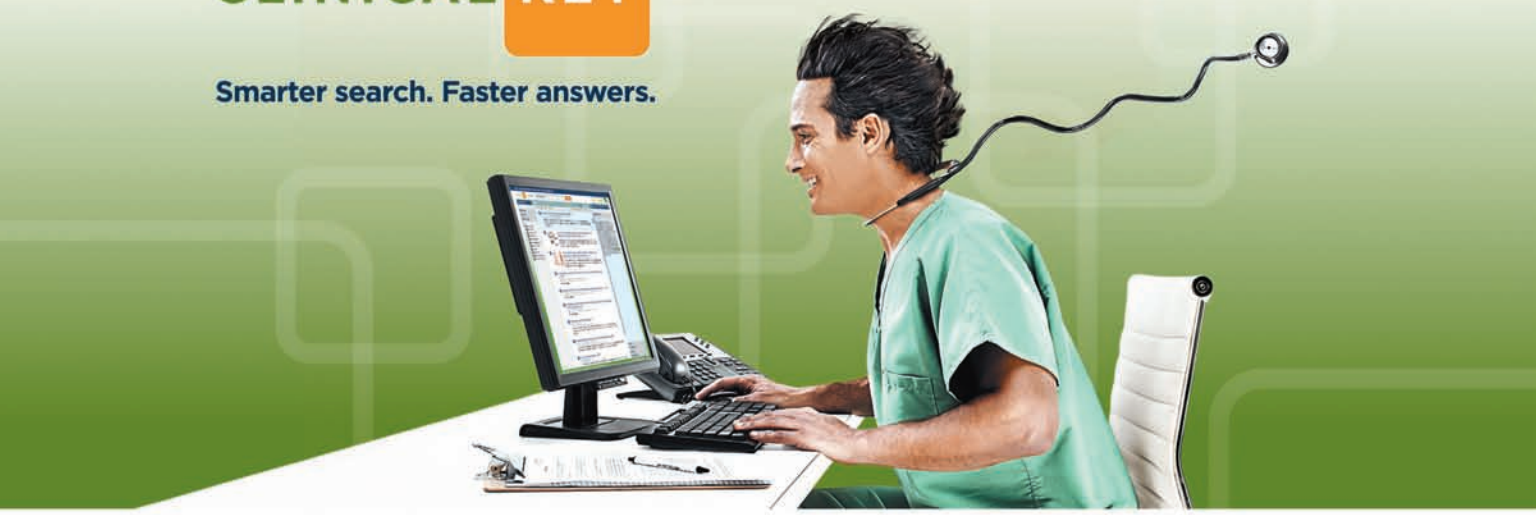
CLINICAL KEY

Smarter search. Faster answers.



Smarter, Faster Search for Better Patient Care

Unlike a conventional search engine, ClinicalKey is specifically designed to serve doctors by providing three core components:

1 Comprehensive Content

The most current, evidence-based answers available for every medical and surgical specialty.

2 Trusted Answers

Content supplied by Elsevier, the world's leading provider of health and science information.

3 Unrivaled Speed to Answer

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!

Visit ***ClinicalKey.com*** for more information and subscription options.

ELSEVIER
