FBC Chapter 44, Section R4402.7.8.1.1 currently requires that all roof tile mortar be premixed/prepackaged and contain a corresponding product approval which has also been tested in accordance with TAS 123. Job site mix approvals are also acceptable if they comply with TAS 113 and they are approved by the building officials. Workmanship requirements are discussed in FBC, Residential, Chapter 44, Section R4402.1.2.5 and FBC, Building, Chapter 15, section 1512.2.5.

These and other code related measures have been enacted in order to make an attempt at providing better installation procedures and techniques that are more actively monitored and more tightly controlled for the purpose of protecting the general public's interest, safety and well being.

MIAMI-DADE COUNTY NOTICE OF ACCEPTANCE (NOA) AND ITS USE FOR PURPOSES OF EDUCATING ALL INVOLVED PARTIES ON THE ACTUAL PHYSICS OF TILE PERFORMANCE UNDER WIND LOADING

A very important, yet subtle, point about roof tile storm damage is often overlooked or misunderstood by many. It relates to the physics involved with tile resistance values and wind uplift forces required to detach/remove tile from the roof. These resistance values are documented with published values, obtained through rigorous testing, which is required prior to a "Notice of Acceptance" (NOA) being issued for each and every roofing system to be included in the product approval list in Miami-Dade County, Florida. For discussion purposes, we have included herein tables 3 and 8, which apply to MonierLifetile Corporation's NOA 07-1023.07. This NOA is specifically related to the Vanguard Roll concrete roof tile profile and the associated tables are shown for discussion and clarification purposes. See Figure 3. The product approval is a requirement of FBC, Chapters 15 and 44 – High Velocity Hurricane Zones. ESI references the Miami-Dade County building department NOA materials for each specific roofing system in question, as applicable during an investigation.

Figure 3 – Tile resistance tables from NOA No. 07-1023.07 (Notice of Acceptance)

Homeowners are sometimes convinced by their representatives that because the roof tiles are loose and can be lifted up from the roof surface by hand, during an inspection or routine maintenance, that this must be hurricane/storm related damage. This assessment can be discounted very easily by the table provided in Figure 3. What this table represents is the roof tile's "resistance" to wind uplift forces. Values provided in the table are derived from the tile "self weight" as it rests on a particular roof slope and they are listed in the "Restoring Moments due to Gravity" table of Figure 3. This resistance value for a 5":12" roof slope is 5.75 ft-lbf of resistance provided by the individual tile weight alone and does not include any of the resistance that is provided by the tile's attachment method to the roof (nails, foam adhesive, mortar paddy, etc.).

Next, when comparing the resistance provided by the "mortar-set" attachment method, it is documented that a properly bonded/installed "Vanguard Roll" roof tile will provide 20.6 ft-lbf of additional wind uplift resistance. This resistance helps to prevent the storm/wind forces from uplifting/removing the roof tiles. This is an obvious yet subtle point, but one that is often overlooked or not necessarily understood. The proper bond of the tile to the roof, in this instance, provides more than 3½ times greater resistance to potential wind uplift forces as compared to the tile self weight alone (5.75 from Table 3 and 20.6 from Table 8 in Figure 3).

The most important point that should be taken away from and/or understood by reading this discussion is that the existing tile condition being "loose" and "not bonded" on any particular home is not usually the result of storm forces. This is because of the fact that if the loose tile is still remaining on the roof in its original position, as installed, then the wind forces were not large enough to overcome simply the tiles own self weight. Any storm that is capable of "breaking" the tile-to-mortar-to-roof bond (typically 3 to 5 times greater than the tile self weight resistance for a typical tile profile and even greater for a flat tile profile) is also, by the mere physics of the situation, going to also be capable of then uplifting/removing the unbonded/unadhered tile completely off of the roof. Without any further positive bond or attachment mechanism, the tile self weight resistance is too low to stay on a roof under a wind loading event required to, or being blamed for "breaking the bond" that was or that should have been provided by its mortar attachment to the roof. If the wind was strong enough to remove a 3 to 5 times multiplier (or greater) of units for bond resistance then it could definitely overcome the remaining unbonded tile self weight resistance. See Figure 4.

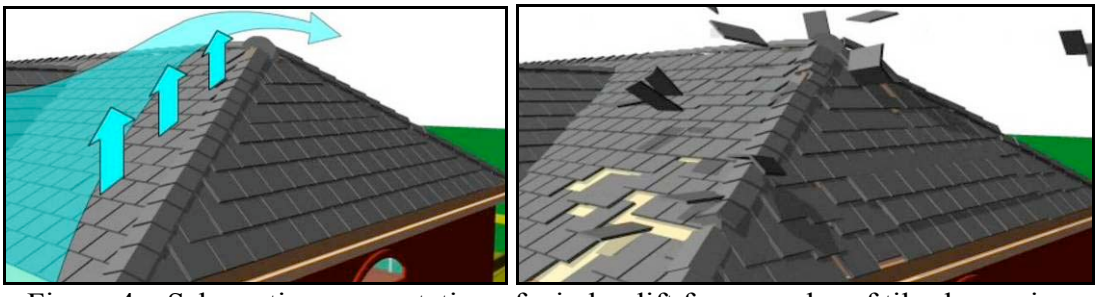

Figure 4 – Schematic representation of wind uplift forces and roof tiles becoming windborne debris (My Safe Florida Home)

This is a key point for any cause and origin analysis as it relates to a roof tile damage/deficiency assessment and decision. This is why ESI can state with confidence in engineering assessment reports what damage is, or is not, related to high winds/hurricane forces depending on each particular case. And it can be backed up with published numbers obtained by unbiased agencies (Miami-Dade County) who have the best interests in mind for the general public, and homeowners, at large.

The fact that a properly bonded tile exhibits a resistance strength which is several times greater than an unbonded/loose/unattached tile has been completely misunderstood/overlooked by many homeowners and/or their representatives. The logic and belief that a loose tile must be related to hurricane winds is shown to be false from this analysis and wind should not be stated as the cause or be associated with unbonded and loose tiles that remain on a roof in their originally installed position. Wind does not turn on and off with the flick of a switch and if wind was responsible for "breaking" the mortar bond, then the tile would also be removed from the roof surface to then most likely become windborne debris, as depicted in Figure 4.

TYPICAL CONDITIONS OBSERVED AND DOCUMENTED IN RELATION TO LEGITIMATELY AFFECTED HURRICANE DAMAGED TILE ROOFS

The FBC states that ASCE 7 shall be utilized for design of wind loads. This design code has documented that certain areas on a roof undergo various degrees of increased wind loading/pressures, according to location and geometry on the roof structure itself. See Figure 5.

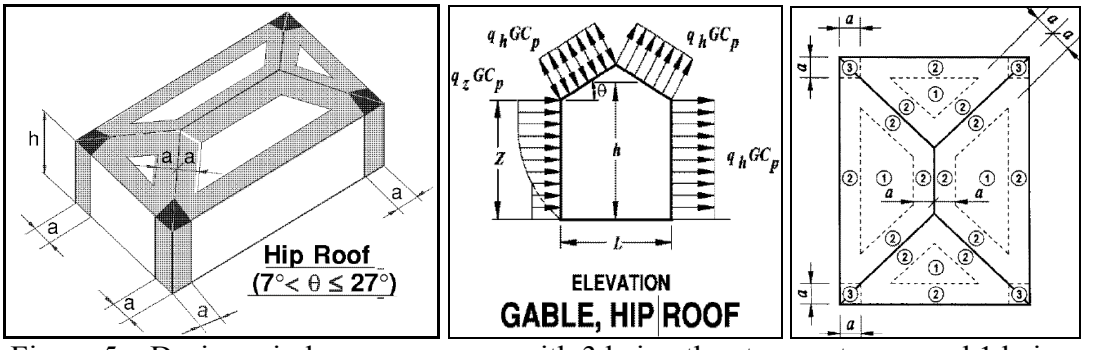

Figure 5 – Design wind pressure zones with 3 being the strongest zone and 1 being the weakest zone (Courtesy of ASCE 7)

This schematic representation shows three locations where wind loads vary in strength. These include (weakest wind zone to strongest wind zone) the field tile, the hips/ridges/perimeter eaves, and the corner eave intersections. Increased wind forces have been witnessed by case studies after storm events along with corresponding tile damage patterns which exhibit greater damages in the higher pressure wind zones and comparatively reduced damages in the lower pressure wind zones. See Figure 6.

Figure 6 – Classical zone 2 roof tile damage pattern from hurricane induced forces (Post Hurricane Wilma Progress Assessment-left, Hurricane Charley in Florida-right)

Ample documentation exists which can be utilized and may aid the homeowner as well as property damage adjusters in assessing possible causes of roof deficiencies and/or damages (Evaluating the condition of Your tile Roof) as well as typical wind related damages expected to be seen in a legitimately wind affected roof loss. Homeowner awareness can be increased by reviewing information provided from the attached reference list at the end of this document.

CONCLUSIONS

The NOA is a valuable resource to aid in determining if/that an existing tile condition, being "loose"/"not bonded" on any particular home, is not automatically or necessarily the result of storm induced wind uplift forces. The fact that the loose tile remains on the roof, in its original position as installed, helps to affirm that the wind forces in question were not large enough to overcome simply the tile's own weight. An existing tile condition being "loose" and "not bonded" on any particular home is not usually the result of storm forces. This is because of the fact that if the loose tile is still remaining on the roof in its original position, as installed, then the wind forces were not large enough to overcome simply the tiles own self weight. Any storm that is capable of "breaking" the mortar bond is also, by the mere physics of the situation, going to be capable of then uplifting the unbonded/unadhered tile, still remaining on the roof to create windborne debris by removing the tiles from the rooftop.

Non-Destructive Examination Techniques of Tubular Steel Pole Sports Lighting Structures

Brian R. Reese, P.E., C.W.I., M.ASCE[1]

[1] Vice President Northeast Region, ReliaPOLE Inspection Services Co., 22955 Tomball Parkway, Suite 24, Tomball, TX 77375; Chairman TIA TR-14.7 Engineering Subcommittee; PH (281) 259-7000; FAX (281) 754-4166; email: breese@polesafety.com

ABSTRACT

For many years, steel poles have been reliable sports lighting support structures. Tubular steel poles have performed admirably at some of America's most popular sporting venues. However, in recent years, there have been numerous failures of sports lighting structures across the country. Planned maintenance and inspection of steel poles including careful attention to the base welded connection will ensure the safety of the structure, prolong their lifespan, and protect the public.

A pole base plate connects the structure via the anchor bolts to the foundation. As the only connection and one that is non-redundant, the structural adequacy and integrity of this connection is crucial to the performance of the pole structure. A failure, if one was to occur at this joint, will in almost all cases be catastrophic resulting in the collapse of the pole.

A crack in a pole base plate weld connection can occur during fabrication, galvanizing, or after loading of the structure. It is imperative that inspections of this connection are carried out by qualified personnel with CWI and non-destructive ASNT credentials.

This article will present current methods used to inspect sports lighting structures from a non-destructive examination standpoint. Specific techniques for non-destructively examining the base weld connection including visual testing, magnetic particle testing, and ultrasonic testing will be discussed.

INTRODUCTION

Tubular steel poles are a popular support structure in many industries. Steel poles have been utilized as support structures in the sports lighting, utility, transportation, and communications industries for many decades. Combining a long history of reliable performance, competitive pricing, and ease of use and installation, steel poles are the sports lighting industry's preferred support structure and have performed admirably at some of America's most popular sporting venues. A typical application and sports lighting pole can be seen in Figures 1 and 2 below. However, in recent years, there have been numerous failures of sports lighting pole structures across the country. The property damage in some cases has been significant. As with America's other aging infrastructure, the cost of ignoring this issue can be significant to public safety and welfare.

Figure 1. Typical sports lighting structure application

Figure 2. Sports lighting pole

STEEL POLES

Steel poles in the sports lighting industry can be anchor based, direct burial, or stub based. Anchor based poles are supported with anchor bolts embedded into a concrete foundation. Direct burial structures are directly embedded into the soil. Stub based poles are flanged to a pipe section that is also directly embedded into the soil. Typically galvanized and in some cases weathering steel, steel poles are pressed in polygonal shapes such as 12-sided, 16-sided, or 18-sided cross sections. Poles may also be provided in round cross sections. Polygonal pole shells are longseamed

(vertical weld along pole axis joining pole half-shells) via submerged arc welding (SAW) techniques and round tapered poles are longseamed via SAW or electric resistance welding (ERW) methods. In most cases, the structures taper over their height to a smaller tip diameter at the top. Entry ports for interior access are welded, reinforced steel frames. Steel poles are typically fabricated with high strength steel plate and range in height from 55 ft to 150 ft. The structures can be designed to support as little as four lighting fixtures or as many as one hundred fixtures. A large percentage of structures are of the steel anchor based variety.

An anchor based pole base plate connects the structure via the anchor bolts to the foundation. More specifically, the base plate attaches the pole shaft structure to the anchors. The connection is facilitated by welding of the members during fabrication at the original manufacturer's facility. As the only connection and one that is non-redundant, the structural adequacy and integrity of this connection is crucial to the performance of the structure. A failure, if one was to occur at this joint, will in almost all cases be catastrophic resulting in the collapse of the pole structure. The connection detail of the pole shaft structure to the base plate can vary depending on the type of pole or the original manufacturer.

Typical pole base details include complete joint penetration groove weld (CJP) and socket style connection as shown below in Figures 3 and 4. The CJP connection base plate is butted against the pole shaft and consists of a groove weld with 100% complete weld penetration and reinforcing fillet weld. In other words, the connection zone is all weld material. This connection style is very popular and is a cost economical method of fabrication for a pole manufacturer. The socket connection base plate sleeves over the pole shaft and is welded with double fillet welds. This connection is also popular due to the fact that a non-destructive examination (NDE) ultrasonic test is not performed on this joint post-fabrication reducing quality assurance costs. While other joints may be possible including stiffeners, the majority of anchor based poles manufactured fall into one of these two base joint categories.

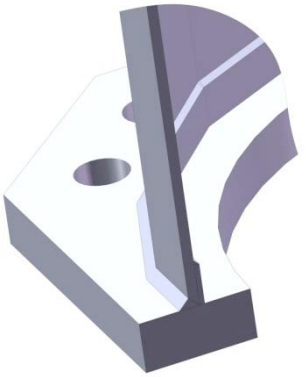

Figure 3. Complete penetration joint (CJP)

Figure 4. Socket joint

FAILURES

Pole collapses in the sports lighting industry, while traditionally an infrequent occurrence, have made news in recent years due to a rash of failures. With their proximity to areas where the public gathers for sporting events, there is a significant potential for loss of life and injury. A typical full height collapse of a sports lighting pole is show in Figure 5.

The recent pole failures have possessed similar characteristics:

1. Toe cracks in the pole structure shaft wall above the base plate weld that propagate along the weld over time causing the pole to collapse full height
2. Thin base plates allowing for excessive movement resulting in fatigue at the base plate/pole wall welded connection
3. Anchor bolt failure

Figure 5: Sports lighting pole failure

Understanding defects and cracks in steel pole structures is critical to establishing a maintenance and NDE program for sports lighting poles. According to the American Welding Society (AWS), a defect is a discontinuity which exceeds the permissible limit of a code (AWS A3.0, 2010). A crack is a fracture type discontinuity characterized by a sharp tip and high ratio of length and width to opening displacement (AWS A3.0, 2010). Cracking occurs in a weld and base metal when the localized stresses at the connection exceed the ultimate strength of the steel material. Left in place without repair, cracks may propagate over time and loading and can be very detrimental to structural adequacy. In addition, cracks greatly reduce the fatigue strength of a member. AWS Structural Welding Code D1.1 does not allow a crack to

be left in the weldment after inspection per Table 6.1, Part 1, regardless of size or location (AWS D1.1, 2008).

While all the contributing issues and their interactions are not yet fully understood, cracks at pole bases can occur due to problems in the following areas:

1. Design – incorrect base plate design resulting in an under-sized base plate and too much joint flexibility.
2. Materials – includes quality of material being joined, yield strength, and brittleness.
3. Production – poor welding quality, lack of pre-heat during welding fabrication, incorrect welding settings in the factory.
4. Quality – poor manufacturing quality control; quality checks at the original manufacturer after fabrication and galvanizing overlooked or incorrectly performed.
5. Galvanizing – cracks due to thermal expansion during the galvanizing process – referred to as 'toe cracks' occurring immediately after galvanizing or delayed.
6. Installation – loose leveling nuts or improper grouting of the base plate which may cause unanticipated stress increase in the weld joint.
7. Fatigue – long term loading effects in combination with any of the above.

In instances where preventative field repairs have been performed on the base plate weld connection, cracks have been found in the pole shaft wall in the toe above the base plate weld at the bend points. This has occurred on multi-sided poles in both complete joint penetration (CJP) groove weld and socket base plate connections. In addition to the base weld, cracks can occur and have been found in the pole longseams, around handhole penetrations (high stress areas), and in the anchor bolts. Field repairs conducted to date show the importance of monitoring and repairing this important connection on an on-going basis.

MAINTENANCE

In many cases in the sports lighting industry there is little to no maintenance of steel pole structures. The structures are typically installed and forgotten. Unfortunately, this issue combined with economic challenges, budget constraints, and manpower has resulted in many structures going virtually unmaintained since installation. Planned maintenance and inspection of steel poles including careful attention to the base welded connection will ensure the safety of the structure, prolong the structure lifespan, and protect the public. Properly maintained, tubular steel poles can safely remain in service well over a half century.

Routine structural maintenance includes the NDE of the base welds and anchors, visually inspecting the pole and its connections, checking the tightness of the anchor hardware, and inspecting the foundation. To ensure the long term performance of a sports lighting pole structure, the maintenance of a pole should be accomplished as follows:

1. Visual inspection (VT)
2. Coating thickness test
3. Magnetic particle test (MT)
4. Ultrasonic test (UT)
5. Structure connections inspection

VISUAL INSPECTION

The first step of a sports lighting steel pole visual inspection (VT) should be identifying the type of pole base weld connection (CJP vs. socket). In addition, the locations of other base welds to be inspected should be located and identified. These welds will include longseam welds if present and reinforcing handhole welds. VT consists of a visual inspection of all welds in the base area of the structure. The goal is to identify any abnormalities in the weld joints to AWS D1.1 Table 6.1 criteria (2008).

Per AWS, the inspector will specifically look for the following (AWS D1.1, 2008) and (AWS B1.10, 2009):

1. Crack – a fracture type discontinuity characterized by a sharp tip and high ratio of length and width to opening displacement. Any crack shall be unacceptable, regardless of size or location.
2. Weld/base-metal fusion – thorough fusion shall exist between adjacent layers of weld metal and between weld metal and base metal.
3. Crater cross section – all crates shall be filled to provide the specified weld size.
4. Weld profile – slightly convex, flat, or slightly convex fillet weld profiles. Groove welds should have minimum face reinforcement; weld finish.
5. Undersized weld – the size of a fillet weld versus drawing requirements.
6. Undercut – a groove melted into the base metal adjacent to the weld toe or weld root and left unfilled by weld metal.
7. Porosity – cavity-type discontinuities formed by gas entrapment during solidification.

VT should be conducted by a Certified Welding Inspector (CWI) or inspector meeting the qualifications as stated in the AWS Structural Welding Code (2008).

While crucial to the overall inspection system, note that VT will only detect surface defects. In almost all cases, this is not sufficient for a thorough inspection and conclusive results of the integrity of the base weld connection.

As can be seen in Figure 6, visual inspection tools required include the following:

1. Fillet weld gauges
2. V-WAC gauge
3. Butt-weld reinforcement gauge
4. Tape measure
5. Ruler
6. Caliper
7. Micrometer
8. Magnifying glass
9. Flashlight
10. Soapstone and marker

Figure 6. Visual inspection tools (Courtesy E. Lair)

COATING THICKNESS TEST

The majority of sports lighting pole structures are hot-dip galvanized per ASTM's Standard A123 *Standard Specification for Zinc (Hot-Dip Galvanized) Coatings on Iron and Steel Products* (2009). As part of the sports lighting pole maintenance program and structure examination, the thickness of the galvanizing coating should be measured and recorded. This will alert the weld inspector to the thickness of coating he will be inspecting while conducting his non-destructive weld examinations (NDE)

and will also serve to alert the owner on the condition and expected lifespan of the coating. Per ASTM A123, the coating thickness for hot-dip galvanized steel plate for common steel pole shaft thicknesses should be around 3.0 to 3.9 mils (ASTM A123, 2009). It is not uncommon to measure a thicker galvanizing coating. Coating thickness can be measured with a paint and coating thickness gauge for steel materials as shown in Figure 7.

Figure 7. Galvanizing coating thickness check

MAGNETIC PARTICLE TESTING

Magnetic particle testing (MT) is conducted by creating a magnetic field in a part and applying iron particles onto the surface of the part. This non-destructive examination is utilized to assess surface and near-surface cracks in welded joints. Typically red iron particles are applied to the joint with a blower while the area is magnetized with a yoke as can be seen in Figure 8. Any defects present in the material hold the magnetic iron particles applied during the test and identify the presence of a crack as shown in Figures 9 and 10. The base weld connection, longseam(s) if present, and reinforcing handhole welds should all be tested with MT. Note that the galvanizing coating and/or paint coating is typically not removed for this process. Experienced MT inspectors will utilize a pie gauge or Castrol strips and MT over the existing coating to verify that the MT exam will be effective over the coating.

MT is a relatively easy and fast inspection method in the field. The test is very effective at locating surface defects. A drawback of this particular NDE exam in the field is wind which has a tendency to blow the iron particle away from the surface being examined. MT should be conducted by an inspector with American Society for Non-Destructive Testing (ASNT) II Certification (SNT-TC-1A, 2006).

Figure 8. Magnetic particle test of pole base weld connection

Figure 9. Base weld crack defect shown holding red powder at weld toe

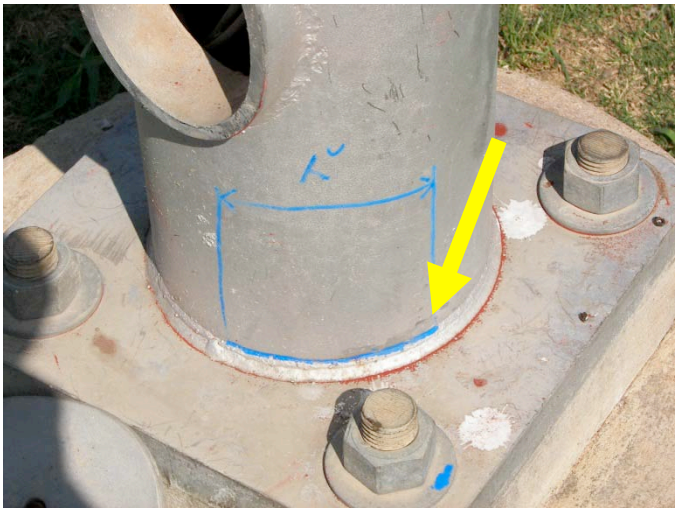

Figure 10. Base weld crack defect marked after MT; also at weld toe

As shown in Figure 11, equipment required for MT includes the following:

1. Yoke
2. Power source
3. Iron particles
4. Particle blower
5. Pie gauge or Castrol strips

Figure 11. Magnetic particle test tools (Courtesy E. Lair)

ULTRASONIC TESTING

Ultrasonic testing uses high frequency sound waves, well above the range of human hearing, to measure geometric and physical properties in materials. The test utilizes ultrasonic waves that are interrupted by any material inconsistency (crack) in the joint and can 'see' through the material (AWS WIT, 2008). UT is not limited to seeing surface defects only. This test is specifically utilized for testing of pole base weld joints that are 100% complete penetration joints (CJP) and for longseam welds. UT of a socket joint will readily show that this joint is not 100% weld material. UT will determine the presence of any defect in a CJP connection or the presence of a defect or lack of penetration in a longseam weld. UT is performed with a transducer and an electric base unit.

Shear waves, or angle beam transducers, are used for weld evaluation because they transmit sound at an angle avoiding the removal of the weld reinforcement. A 70 degree transducer is commonly used. Longitudinal waves or straight beam transducers are used to determine material thickness or the depth of a discontinuity

below the material surface. Shear wave and straight beam can be seen in Figures 12 and 13, respectively.

Figure 12 – UT shear wave

Figure 13 – UT straight beam of anchor bolt

UT is a volumetric test capable of helping the inspector locate the length, lateral location, and depth of the defect (AWS WIT, 2008). However, UT requires more inspector skill and experience for interpreting the results of the examination. It also can be implemented from one side only, not requiring access to the back side of the weldment. UT should also be conducted by an inspector with ASNT Level II Certification (ASNT SNT-TC-1A, 2006).

As shown in Figure 14, equipment required for UT includes the following:

1. Electronic instrument
2. Straight beam transducer
3. Angle beam transducer
4. Transducer couplant
5. Calibration standards
6. Ultrasonic thickness gauge

Figure 14. Ultrasonic test tools (Courtesy E. Lair)

OTHER STRUCTURE CONNECTIONS AND COMPONENTS

The inspector should inspect the pole structure connections. The structure connections include the telescoping slip joints and/or flanged connections. Excessive gaps or movement in the slip joints and loose or missing hardware in flanged connections or light supports should be identified. Any safety climb equipment installed should be visually inspected, also.

The anchor bolt connection hardware should be inspected and checked for tightness. Typically, the full effort of a man on a 4 ft wrench will be sufficient. With structures that have not been maintained, it is common to find loose anchor bolt nuts. In addition, loose anchor nuts are often removed by vandals. Improperly tightened anchor nuts or missing anchor nuts increase the possibility of fatigue related defects. The foundation top, if visible, should be inspected for cracks, spalls, or any other structural issues.

CONCLUSION

It is imperative that sports lighting pole inspections are carried out by qualified personnel with pole engineering experience, CWI credentials, and non-destructive ASNT credentials. It is strongly recommended sports lighting structures are inspected at a two (2) to five (5) year intervals depending upon age, type of structure, condition of the structure, and initial inspection results.

There is certainly much to be learned on this subject by the industry. While there appears to be many contributing factors and variables, careful attention to the following is recommended to prolong the lifespan of sports lighting poles:

1. A maintenance program should be established for sports lighting structures
2. An inspection of sports lighting poles must include NDE of all base welds and anchors
3. Do not relocate or change loading on a sports lighting structure without a complete inspection including NDE
4. Following any significant wind event a comprehensive inspection including NDE should be completed

With increased attention to sport lighting pole maintenance including base weld connection NDE, the owner will prolong the structure lifespan and ensure public safety.

ABSTRACT

The behaviour of masonry under seismic loads has recently become of great interest. New methods for design and analysis, as well as models for resistance, have been developed. The main focus has been on experimental and analytical research for the development of new brick and mortar material whilst the characteristics of old brick material and mortar have been neglected. With the introduction of Eurocode 8 (EC), the behaviour of old masonry structures under seismic load became an interesting topic for architects and engineers. In particular, the available resistance capacity of existing masonry structures is highly relevant to the retrofit and/or improvement of existing buildings.

Deformation energy, or ductile response, is a source for energy dissipation of structures. Since normal levels of internal damping represent only a small portion of energy dissipation, large material deformations such as those required in building components to perform a ductile behaviour, are often associated with cracking and degradation of its stiffness, particularly in masonry structures.

The stiffness identification of masonry walls in an uncracked state is examined by laboratory tests. Further, stiffness degradation due to an imposed pseudo dynamic horizontal load pattern is evaluated. In particular, the wall specimens are distinguished by different mechanical characteristics like old and new brick units, low and high strength bricks and two common brick layouts. Beyond the effect of stiffness degradation in masonry on the inelastic response characteristic parameters for energy dissipation are compared within the varying masonry specimens.

Due to damage propagation, caused by imposed shear load, typical failure states are determined.

The results of a series of laboratory tests are analysed. Resistance and deformation characteristics of masonry under shear are compared to specifications according EC 6.

Keywords: *masonry, seismic resistance, energy dissipation, damping, stiffness degradation, damage*

INTRODUCTION

Masonry has an inelastic, anisotropic and non-homogeneous material behaviour. Old masonry incorporates of brick units and horizontally and vertically oriented mortar interfaces. However, the material properties of bricks and mortar are different and consequently the behaviour of masonry is not elastic even in the range of small deformations and in the uncracked state respectively. Since the introduction of EC 8 in Austria in the year 2009, buildings must correspond with the requirements of this standard.

Masonry is a typical construction material to withstand compression, but shows low shear resistance. Because of this circumstance unreinforced masonry buildings under horizontal became of high interest. The aims of research are (a) to gather mechanical properties and their wide scatter, which is characteristic for old masonry and (b) to obtain appropriate tools for seismic assessment, analysis and retrofit methods.

Structural measures are a combination of both: Conceptional design and design layout of the bearing and non-bearing structure, especially in the case of retrofit. The prior objective is to minimize the earthquake risk and the vulnerability of buildings, Bachmann (2002).

According to EC 8 the design seismic action is an earthquake with a return period of 475 years and a 10 % probability of exceedance in 50 years. Structures should withstand the action without local or global collapse, thus retaining its structural integrity and a residual load bearing capacity after the seismic events – "No-collapse requirement". The structure should also withstand a seismic action having a larger probability of occurrence than the design seismic earthquake. Thereby no damage and/or no associated restriction in usability should occur, where the costs of repair would be disproportionately high in comparison with the costs of the structure itself – "Damage limitation requirement".

Parameters regarding the seismic behaviour, i.e. energy dissipation, are important for the assessment of existing structures and the design of retrofit. Masonry buildings can reduce seismic actions due to non-linear material behaviour. Accordingly design forces are reduced to fulfil equivalence to linear elastic behaviour.

Another point of interest is the actual situation of an existing structure. While new structures remain in an elastic and uncracked state until the first earthquake event occurs, old structures may have certain damage and cracks form prior events.

The main objective of the research presented in this paper is the evaluation of seismic response of old masonry and associated with that stiffness degradation and energy dissipation. Further, mechanical material properties obtained by experiments are compared to recommended characteristics of EC 6 and EC 8.

LABORATORY TESTS

In order to obtain mechanical properties of masonry, laboratory tests were performed. The walls were built using three types of bricks: old bricks, new bricks

and clinker bricks. Lime-cement mortar with compressive strength 2.78 MPa was used. First, three masonry prisms built out of old bricks were tested in vertical compression. The compressive strength f_{kn} = 6.46 MPa and modulus of elasticity of masonry E = 2459 MPa were obtained.

Second, nineteen wall specimens were tested by subjecting them to constant vertical load and cyclic lateral load in order to obtain the lateral resistance, strength and stiffness degradation and displacement and energy dissipation capacity. Two types of brick layout were used for the construction of wall specimens with old bricks, in order to obtain the influence of such layouts on the seismic behaviour of masonry: No.1 (OL1): alternate courses of headers and stretchers and No.2 (OL2): all courses with headers. Only the former was used to construct specimens with new bricks (NL1) and clinker bricks (CL1).

The specimens were 60 cm long, 68 cm high and 29 cm thick if built out of old bricks and 51 cm long, 68 cm high and 25 cm thick if built out of new bricks or clinker bricks, respectively. They were tested as vertical cantilevers and equipped with instruments to measure the displacements and forces. Three different levels of vertical load were used for specimens with old bricks and only one level of vertical load for specimens with new and clinker bricks. A detailed description of the laboratory tests can be found in Zimmermann and Strauss (2010).

On the basis of the observed damage propagation, typical limit states were defined. A prevalent rocking type of behaviour with horizontal cracks in the lower bed joints developed in the initial state. As the imposed displacement amplitude was increased, first vertically to diagonally oriented cracks passing through the bricks in the compressed toes represent the cracking limit state (Index *cr*). The propagation of these cracks lead to the maximum resistance limit state (Index *max*). At ultimate limit state (Index *u*) a diagonal crack, from one corner to the opposite corner, split the wall, which failed in a brittle shear mode. The results of all tests are summarized in Table 1.

Table 1 Test results: lateral load and rotation angle at shear cracking, maximum resistance and ultimate state.

ELASTIC STIFFNESS

Generally, masonry is an inelastic material. Elastic behaviour can be assumed only in the range of small imposed deflections. For practical use in that state the effective, elastic stiffness K_e of the wall is evaluated as the ratio between a horizontal load H, and the corresponding displacement d:

$$K_e = \frac{H}{d} \tag{1}$$

If we use the theory of elasticity, the displacement d of a simple cantilever wall can be calculated as follows by taking into account bending and shear deformations:

$$d = \frac{H \cdot h^3}{\delta \cdot E \cdot I} + \frac{\kappa \cdot H \cdot h}{G \cdot A} \tag{2}$$

thereby I = moment of inertia of the horizontal cross section of the wall, κ = shear coefficient (κ = 1.2 for rectangular section), δ is a coefficient depending on boundary conditions (δ = 12 when the wall is fixed at both ends and δ = 3 if it is fixed at the bottom and free to rotate on the top – cantilever), h = height of the wall specimen and G = shear modulus.

Hence we can calculate the shear modulus by introducing equation (1) into equation (2) and rearranging:

$$G = \frac{K_e}{\frac{A}{\kappa \cdot h} - \frac{12}{\delta} \cdot \frac{1}{\kappa} \cdot \frac{K_e}{E} \cdot \left(\frac{h}{L}\right)^2} \tag{3}$$

where L = length of the wall. Taking into account the values the effective stiffness K_e at the 2/3rds of the maximum resistance H_{max} and the modulus of elasticity E = 2459 MPa, determined by compression tests, the values of shear modulus G have been obtained. Since (a) experimentally obtained horizontal resistance for both brick layouts are in the same range in the case of old bricks and (b) the brick layout of the walls for compression tests was not the same as either of the two brick layouts for the shear tests, the shear modulus of masonry for both layout types has been estimated as an average value of all tested specimens, yielding G = 546 MPa and G/E = 0.222.

ANALYTICAL INVESTIGATIONS

If we consider an elastic, homogeneous and isotropic material behaviour for the cantilever walls, the principal stress states can be calculated on the basis of the theory of elasticity. Hence we get the principal compressive and tensile strength:

$$\sigma_{c,t} = \sqrt{\left(\frac{\sigma_v}{2}\right)^2 + (b \cdot \tau)^2} \pm \frac{\sigma_v}{2} \tag{4}$$

where σ_v = vertical imposed compression stress, τ = shear stress and b = a parameter which takes into account the wall geometry h/L as well as the shear stress distribution. Equation (4) is affected by the parameter b which according to Magenes and Calvi (1997) can be assumed to be: $b = 1$ for $h/L \leq 1$, $b = h/L$ for $1 < h/L < 1.5$ and $b = 1.5$ for $h/L \geq 1.5$.

If we use the average shear stress $\tau = H/A$ and assume the idealised material behaviour up to the maximum attained horizontal load H_{max} the tensile strength f_{tn} of masonry is equal to the principal stress state σ_t in equation (4):

$$f_{tn} = \sqrt{\left(\frac{\sigma_v}{2}\right)^2 + \left(b \cdot \frac{H_{\max}}{A}\right)^2} - \frac{\sigma_v}{2} \tag{5}$$

where A = area of the horizontal cross section of the wall.

In order to compare experimentally obtained and calculated horizontal loads, a shear strength formulation according to Magenes and Calvi (1997), Tomaževič and Klemenc (1997) and Turnšek and Čačovič (1971) has been used to asses the horizontal resistance:

$$H_{\max} = \frac{f_{tn} \cdot A}{b} \sqrt{\frac{\sigma_v}{f_{tn}} + 1} \tag{6}$$

Table 2 Deviation between calculated and experimentally measured horizontal resistance for old and new bricks and clinkers, using tensile strength from numerical investigations.

The values of tensile strength, obtained by the numerical nonlinear constitutive material model SBETA, have been used in the equation (6) in order to estimate the horizontal resistance. A detailed description of numerical simulation can be found in Zimmermann et.al. (2010).

Table 2 shows the calculated values of horizontal resistance H and their deviations for different vertical loads V.

As can be seen, the analytical approach according to equation (6) and the obtained tensile strength from numerical investigations result in a rather low deviation between the experimental and calculated horizontal loads. Especially for walls with old bricks there is a good agreement. This analytical formulation can be used to estimate the horizontal resistance of unreinforced masonry in a rough but fast way.

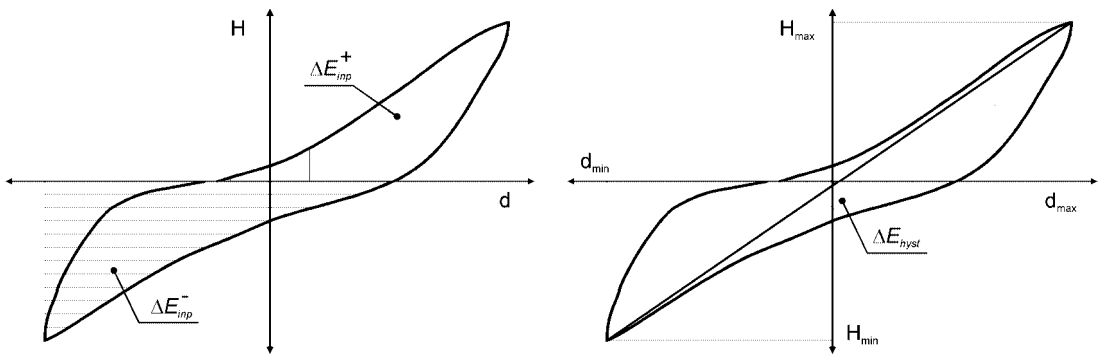
Further, more experimental data are necessary to evaluate the behaviour of bricks, mortar as well as their interaction.

ENERGY DISSIPATION AND HYSTERETIC BEHAVIOUR

Energy dissipation capacity has been evaluated on the basis of an experimentally obtained hysteretic relationship between horizontal displacement and horizontal force. It represents one of the important parameters of seismic resistance.

Cumulative input energy E_{inp} is needed to deform the wall according to an imposed deformation. It has been defined as the cumulative work of the horizontal actuator needed to cause a given deformation status. In one cycle of loading (push and pull), ΔE_{inp} is calculated as the area under the hysteretic loop, see Figure 1 a:

$$E_{inp,j} = \sum_{i=1}^{j} \Delta E_{inp,i} \; ; \quad \Delta E_{inp,i} = \int_{(H=0)_i}^{(H=0)_{i+1}} dE_{inp} \tag{7}$$



where:

$$dE_{inp} = \begin{cases} 0, & if \quad Hd(d) \le 0 \\ Hd(d), & if \quad Hd(d) > 0 \end{cases}$$

and $d(d)$ = differential displacement increment and H = horizontal force.

The amount of dissipated energy, ΔE_{hyst} in one cycle of loading has been defined as the area of the hysteretic loop between two consecutive maximum deformation states. The cumulative dissipated energy E_{hyst} has been defined as the sum of the dissipated energy of all loading cycles i from the beginning until the end of testing, see Figure 1 b:

$$E_{hyst,j} = \sum_{i=1}^{j} \Delta E_{hyst,i} \; ; \quad \Delta E_{hyst,i} = \int_{(H=0)_i}^{(H=0)_{i+1}} Hd(d) \tag{8}$$

(a) Input energy (b) Dissipated energy

Figure 1 Input energy and dissipated energy during one cycle of loading.

The ratio between the cumulative dissipated energy E_{hyst} and the cumulative input energy E_{inp} can be used as one of the energy dissipation indicators $I_{E,diss}$:

$$I_{E,diss} = \frac{E_{hyst}}{E_{inp}} \tag{9}$$

Another indicator of energy dissipation capacity is the coefficient of equivalent viscous damping ξ, defined as the ratio between the energy dissipated in one cycle of loading and the input potential energy, defined by the displacement amplitude and the lateral load:

$$\xi_i = \frac{\Delta E_{hyst,i}}{2 \cdot \pi \cdot E_{p,i}} \tag{10}$$

where $E_{p,i}$ = input potential energy in the same loading cycle, defined as:

$$E_{p,i} = \frac{1}{4}\left(H_{\max,i} - H_{\min,i}\right) \cdot \left(d_{\max,i} - d_{\min,i}\right) \tag{11}$$

The calculated values of the energy dissipation indicator $I_{E,diss}$ and the coefficient of equivalent viscous damping ξ are summarized in Table 3.

Table 3 Correlation of energy dissipation indicators at characteristic limit states.

Type	cracking limit		maximum resistance		ultimate limit	
	$I_{E,diss-cr}$	ξ_{cr}	$I_{E,diss-max}$	ξ_{max}	$I_{E,diss-u}$	ξ_{u}
OL1	0.32	7.78	0.29	7.69	0.43	39.48
OL2	0.33	8.02	0.29	7.70	0.36	24.22
NL1	0.27	5.85	0.21	5.75	0.26	17.85
CL1	0.20	5.20	0.20	6.65	0.30	32.90

According to Table 3, no significant difference can be observed in the energy dissipation capacity of the different types of brick layouts for the construction of wall specimens with old bricks. On the other hand, the dissipation capacity of the wall specimens with new bricks and clinkers is noticeably lower. Figure 2 shows the progress of equivalent viscous damping over the relative loading cycles (= load cycle *i* with respect to ultimate load cycle) for specimens with old bricks.

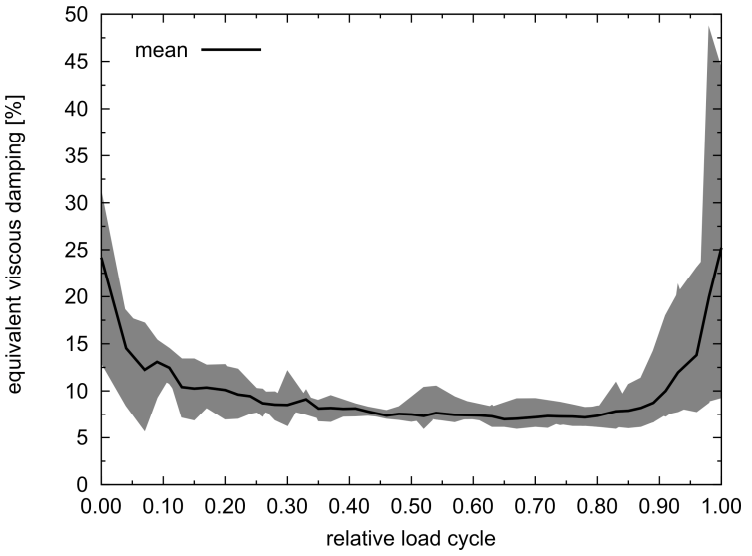


Figure 2 Progress of equivalent viscous damping ξ for old masonry.

DAMAGE PROPAGATION AND STIFFNESS DEGRADATION

When the walls are subjected to repeated pseudo-dynamic load reversals, increasing degree of damage can be described by the damage index I_d, Tomaževič (1999) and Tomaževič et.al. (1999). In accordance with the three characteristic limit states as indicated e.g. in Table 3 the increasing degree of damage or damage state can be described by a damage index. Figure 3 shows these various damage states and an idealised envelope of the horizontal resistance.

The damage index can be divided in the following four types:

- $I_d = 0.00$: Actually this first state represents the elastic state with no damage, the state without any cracking.
- $I_d = 0.25$: The initiation of vertically to diagonally oriented shear cracks, passing through the bricks and mortar joints in the compressed zone. This index defines the cracking limit state.
- $I_d = 0.50$: Due to increasing horizontal deflection, the number of horizontal as well as vertical cracks increases. The cracks appear along mortar joints but also pass through brick units. Generally this crack pattern can be observed at the applied maximum horizontal force.
- $I_d = 1.00$: Again, due to increasing horizontal deflection, the number and width of cracks increase. Thereby also crushing of bricks in the compressed

zone can be observed. Finally there is a collapse of the specimen. This state represents the ultimate limit state.

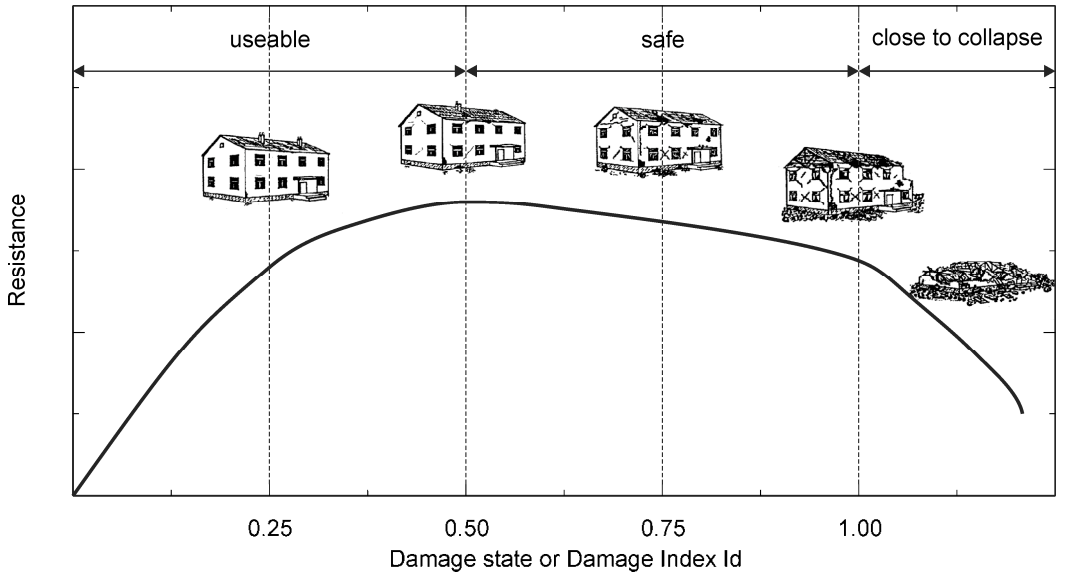

Figure 3 Damage states and envelope of horizontal resistance.

Stiffness degradation occurs, when the walls are subjected to repeated pseudo – dynamic load reversals. Figure 4 shows the stiffness degradation. Thereby the stiffness ratio is plotted with respect to the damage index. In the case of old bricks stiffness degradation is in the same range for both brick layouts. The shape of stiffness degradation can be described by the following simple exponential decay function:

$$\frac{K}{K_e} = e^{-\beta \cdot I_d} \tag{12}$$

where β is the parameter of stiffness degradation which is dependent on the compressive strength. As found out by curve fitting of experimentally obtained degradation curves, β = 4.1 for the masonry walls with old bricks. At the occurrence of the first cracks (I_d = 0.25) and at the state of maximum horizontal force (I_d = 0.50) the stiffness ratio drops down dramatically. Between the last two damage indices rather small stiffness degradation takes place. It is the same phenomenon for all investigated masonry walls.

In the first damage states the plotted equation (12) in Figure 4 a (old bricks) is in good agreement with the average values of obtained experimental data. In later damage states equation (12) it is on the conservative side. A curve fit for masonry walls with new bricks results in β = 4.7, for clinkers the stiffness degradation parameter β = 9.6 (both Figure 4 b). Again, for both masonry walls (new bricks and clinkers) the plotted equation (12) is comparable to an average value in the early damage states and it is on the conservative side for the later damage states.

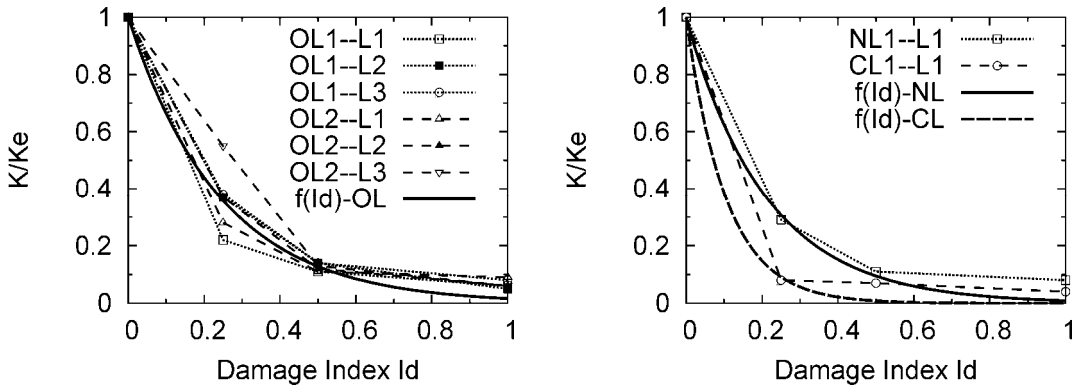

Figure 4 Correlation Correlation between stiffness ratio K/K_e and damage index I_d for (a) old bricks and (b) new bricks and clinkers.

For a seismic assessment of new structures and structures without any damage a stiffness ratio of 1.0 or slightly below can be assumed because they remain in an elastic state. On the other side, for a seismic assessment or a retrofit for old structures the stiffness ratio should be assumed << 1.0, since a cracked state from earlier events can not be excluded.

Figure 5 shows the stiffness degradation with respect to the damage index for various values of compressive strength and decay parameter β.

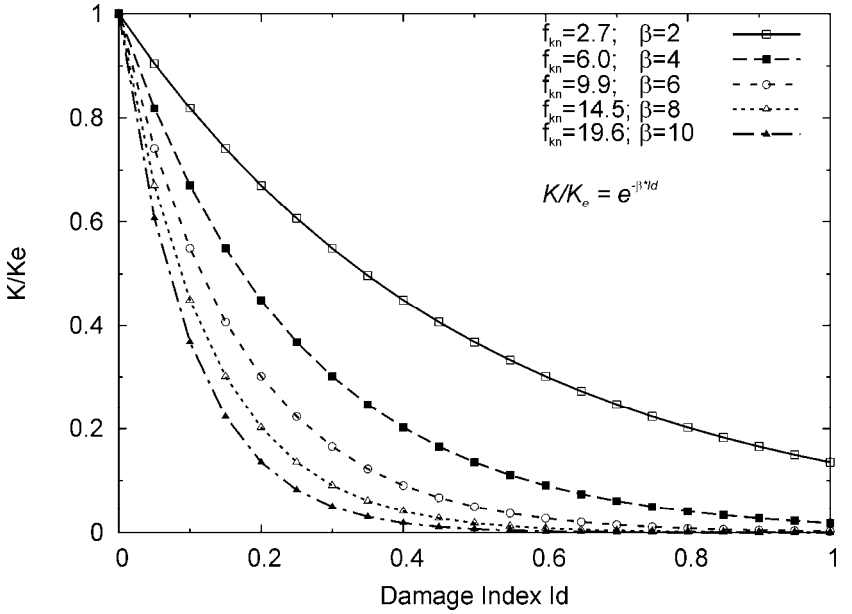

Figure 5 Correlation between stiffness ratio K/K_e and damage index I_d for various compressive strength f_{kn}.

CONCLUSIONS

Typical failure mechanisms of masonry under seismic load can be summarized by the following points:

- *failure due to rocking:* with an increasing horizontal deflection, horizontal joints in the lower part of the specimen fail in tension and the shear load is carried by the masonry part under compression. The final failure occurs by overturning of the specimen and a local failure in compression in the compressed toes of the wall.
- *failure due to sliding:* again, cracks in horizontal joints develop and go along the interface between brick and mortar. This failure type is typical for low vertical compression stress levels.
- *failure in shear:* the crack pattern consists of diagonally oriented cracks, which follow along head and bed joints or pass through brick units. This failure depends on the relative strength between mortar and bricks as well as the strength of the interface.
- *failure in tension:* due to the combination of normal stress and shear stress a inclined principal stress state arises and if the tensile strength of bricks is exceeded, the brick units fail in tension.
- *failure in compression:* mainly for high compression stress levels, but it is also typical for local failure mechanism in the compressed toes of the wall.

Introducing numerical data, in particular the tensile strength, received from Zimmermann et.al. (2010), in analytical investigations results in a good correlation with experimentally obtained data.

Basic mechanical characteristics (modulus of elasticity and shear modulus) have been obtained by experimental testing. The resulting ratio between shear modulus and modulus of elasticity yields $G/E = 0.22$ for masonry walls with old bricks. Thus, the ratio is smaller for the tested walls than the proposed ratio by EC 6 ($G/E = 0.40$). Hence, for numerical simulations this smaller ratio should be considered. The use of $G/E = 0.22$ for numerical simulations is proposed based on isotropic assumptions for masonry. The proposed ratio does not match with the range of the Poisson's ratio for isotropic material. The obtained parameters indicate a rather orthotropic than isotropic material behaviour. In addition, there is the requirement for further investigations and laboratory tests in order to determine deviations between parameters of isotropic and orthotropic material behaviour.

The interaction between deflection and horizontal resistance of shear walls results in a hysteretic relationship. Based on this relation the energy dissipation of each shear wall was analysed based on energy dissipation indicator and equivalent viscous damping ratio. Thereby no significant difference can be observed in the energy dissipation capacity for the construction of wall specimens with old bricks. On the other hand, the dissipation capacity of the wall specimens with new bricks and clinkers is noticeably lower.

Due to repeated pseudo – dynamic load reversals stiffness degradation takes place. For the calculation of the elastic stiffness K_e elastic behaviour of masonry has been assumed until the occurrence of first cracks. The stiffness degradation has been evaluated with respect to a damage index whereby the stiffness is normalized by means of the stiffness ratio. This degradation can be described with a simple exponential decay function. Further a relation between this degradation and the compressive strength of masonry has been obtained. In accordance with a certain

damage state the actual stiffness of masonry should be adjusted according to such a degradation function.

ACKNOWLEDGEMENT

Research results discussed in this conference contribution have been carried out within the European research project SEISMID, supported and financed in cooperation with the Centre for Innovation and Technology (ZIT). We also wish to thank Prof. Miha Tomaževič for his advices and Mr. Uroš Bohinc for his efficient help during testing in the Laboratory of Slovenian National Building and Civil Engineering Institute (ZAG).

Abstract

The question of commonality of damages was posed in a proposed class of members that was intended to represent the city of New Orleans as a whole. Were patterns of damage common such that they were identifiable by predictive means without individual site assessments? The authors were presented this question in the *Katrina Canal Breaches Consolidated Litigation Levee* with a putative class size of 36 members. Data collection efforts, which involved site specific testing, resulted in detailed class property information such as watermarks; levelness; plumbness; architectural and structural condition; and mechanical, electrical, plumbing (MEP) condition.

Hurricane forces of wind and water and degradation of materials affected structures differently; the extent of subsequent material degradation was related to characteristics unique to each structure (age, design, construction, materials, soil condition, and maintenance). Focusing on flood damages due to canal breaches, predictability was not found due to unknown variables of building height, characteristics, and length of time flood water was present.

The type and degree of damage varied considerably not only in the global putative class but also in the local subclasses, indicating a lack of meaningful subclass boundaries. Damages were not predictive by formula and therefore commonality was not present in the class. The only reliable method of damage assessment due to hurricane related distress is by individual site evaluation. Based on the scientific method, a test methodology is developed for assessing commonality of damages.

Introduction

On August 29, 2005, Hurricane Katrina made landfall between Grand Isle, Louisiana and the mouth of the Mississippi River. At about 8:00 a.m. CDT, Katrina was located 40 miles southeast of New Orleans, and at 10:00 a.m. CDT, Katrina made a second gulf coast landfall near the Mississippi-Louisiana border. The path of this hurricane traveled north to northeast across Louisiana and Mississippi and into Tennessee.

The storm surge associated with Katrina caused the level of Lake Pontchartrain to rise, and the majority of the City of New Orleans was underwater due to rainfall, levee overtopping, and levee breaches. The focus of this paper relates to the damages that occurred due in part to the aforementioned and the influence of wind and other elements during and after the storm event.

The factors that must be present for a class action lawsuit to be certified by the court are numerosity of plaintiffs, commonality of the damages and legal issues of the class, typicality of each class member's claim, adequacy of representation of the class, and viability of the defendant(s) to compensate for the damages (Fed. R. Civ. P. 23(a)). The main purpose of the authors was to establish data for evaluating the validity of the commonality of damages in the class action claim in the *Katrina Canal Breaches Consolidated Litigation*.

Forensic Testing Program

Using the putative class of 36 members (proposed class) located in the City of New Orleans, the cause, origin, and extent of damages from structural, MEP, and architectural standpoints were determined. Following the scientific method, a testing program was developed for the evaluation of the subject structures. Detailed data was collected from each structure using several test methods for the purpose of evaluating damages to the structure. Observed distress, hurricane related or otherwise, and existing conditions were documented and photographed. Data collection and compilation techniques included:

Descriptive Information: The authors developed field-measured floor plans and documented the following information through field observations or review of deposition testimony of proposed class members: structure type: i.e., single-family residential, multi-family residential, commercial, size, number of stories, foundation type, exterior veneer, interior finish, roof type, age, condition of surrounding properties, quality of workmanship, and quality of maintenance prior to/post Katrina.

Elevations: The elevation of each structure relative to the North American Vertical Datum of 1988 (NAVD 88) was determined by a surveying company using a global positioning device. (NAVD 88 is the vertical control datum of orthometric height established for vertical control surveying in the United States.)

Floor levelness: The authors evaluated the levelness of each structure's floor framing by completing a relative elevation survey using an electronic surveying instrument. **Figures 1 and 2** are examples of elevation data.

For comparison purposes within the scope of the forensic testing, the authors classified total floor out-of-levelness less than 3" as minor (**Figure 1**), greater than or equal to 3" and less than 5" as moderate, and greater than or equal to 5" as severe (**Figure 2**). The authors correlated relative elevation data with distress patterns and

determined that the majority of damage was due to long-term differential foundation movement, and was not hurricane related.

Wall plumbness: The authors assessed the plumbness of the exterior or interior walls of the structures. The authors measured the angle of each surface relative to the vertical plane using an electronic plumbness measuring tool.

Using the maximum reading at each structure, for comparison purposes within the scope of the forensic testing, the authors categorized out-of-plumbness readings between 89.5° and 89.1° as minor, between 89.0° and 88.5° as moderate, and severe out-of-plumbness as 88.4° or less.

Based on the plumbness measurements, the authors detected no racking or twist resulting from hurricane winds. Rather, the findings are consistent with long term foundation movement as evidenced by the significant floor out-of-levelness and aged veneer distress.

Watermarks: The authors estimated the maximum flood level within the structures by measuring stains/watermarks left by standing water on interior and exterior finishes including glass window panes, gypsum board, exterior siding, etc. All watermark data were referenced to NAVD 88. The authors found good correlation between watermark data and IPET published data as illustrated in **Figure 3**. (In the Fall of 2005, the U.S. Army Corps of Engineers established the Interagency Performance Evaluation Taskforce (IPET) to provide scientific and engineering answers to questions about the performance of the New Orleans and Southeast Louisiana Hurricane Protection System during Hurricane Katrina. As part of its evaluation, IPET documented flood water elevations throughout New Orleans)

The authors estimated damage to interior finishes using water elevations above finished floor (AFF) based on the IPET high water elevations (IPET, 2006). For comparison purposes within the scope of the forensic testing, damages to interior finishes were categorized as minor for high water levels between 0'-0" and 1'-11" AFF, moderate for high water level between 2'-0" and 5'-11" AFF, and severe for high water level 6'-0" AFF and above.

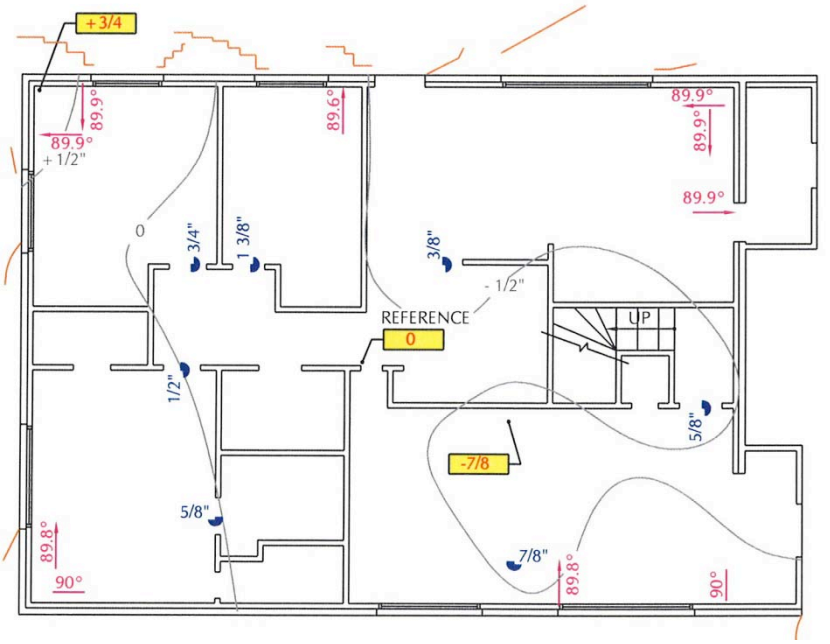

Figure 1: Minor floor total out-of-levelness

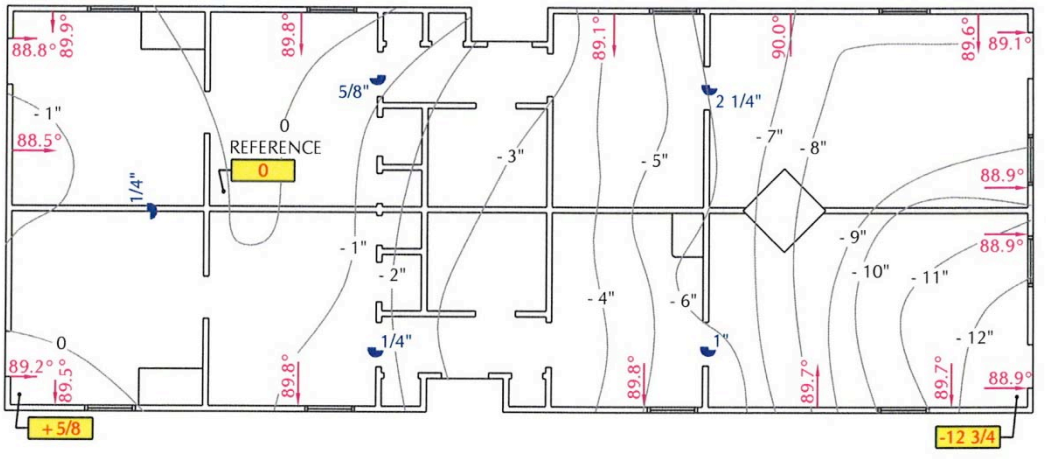

Figure 2: Severe floor total out-of-levelness

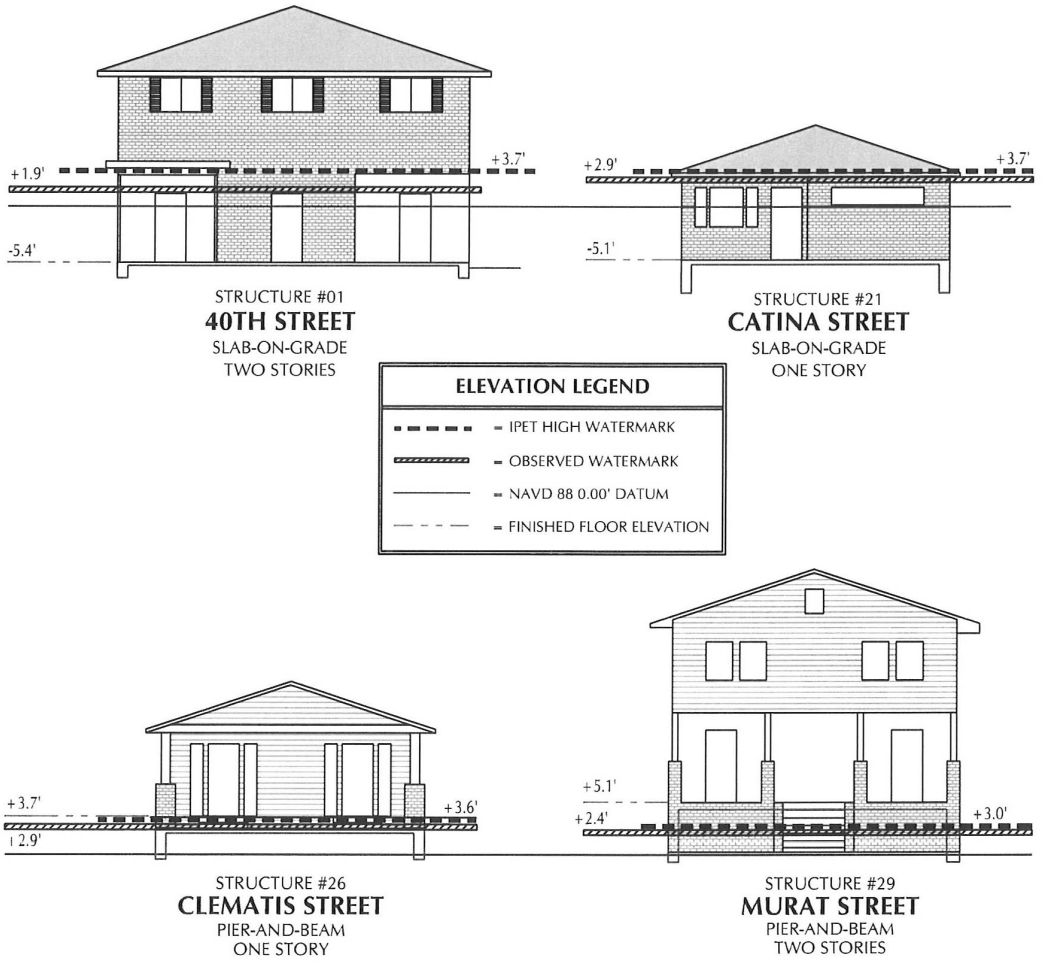

Figure 3: Watermark Data

Distress Mapping: The authors visually identified and mapped distress observed in each structure on a field-developed floor plan. The authors investigated crawl spaces, attics, and roofs as safety and accessibility allowed. For comparison purposes within the scope of the forensic testing, with the exception of window distress, distress was categorized as minor, moderate, or severe based on the percentage of the system impacted. The following types of distress were documented when observed in the subject structures:

- Termite damage: Structural members and veneers impacted by termites.
- Wood deterioration: Structural members and veneers.
- Tilted and/or damaged piers (the pier and beam foundations were typically constructed of brick or concrete masonry units (CMU)): Cracks and/or mortar joint separations and out-of-plumbness, generally due to long-term foundation movement.
- Window damage: Broken glass panes, broken frames/sashes, or missing or boarded-up windows, some likely related to post-storm vandalism.

- Veneer damage: Cracks and/or mortar joint separations on brick veneers, detached and/or missing siding, and cracks on stucco.
- Mechanical equipment damage: Corrosion at heating, ventilating, and air-conditioning (HVAC) equipment and plumbing fixtures and vandalism/theft of components.
- Electrical systems damage: Dislocated weatherheads, electrical service boxes, and electrical conduit; corrosion at receptacles, switches, junction boxes, and cabling; and some vandalism/theft of components.
- Scouring of soils: Loss of soil and exposure of foundation elements.
- Roof damage: Missing shingles, deteriorated and/or damaged roof shingles, rotted and/or exposed roof sheathing, missing, detached or broken ridge tiles, missing, detached or damaged flashing, and detached and/or punctured flat roofing membranes.
- Suspected mold/fungal growth at gypsum board walls and ceilings.

Table 1 is a compilation of damages observed by type.

Table 1: Observed Damages by Type

Damage Type	% of Bldgs w/ Damage	# of Buildings with Similar Damage (0 5 10 15 20 25 30 35)	Proximate Cause: Non-Hurricane	Wind	Flood
Termite	63%	(22)	X

Discussion

Hurricane-related damages can be classified by type and cause. Structural damages can be caused by hurricane-applied forces (wind and flowing water). Degradation of architectural building materials can be caused by exposure to wind driven rain, flood water, and wind.

Structural damage is a function of the magnitude of the forces (wind and flowing water) exerted on a structure and a structure's resistance to those forces, also commonly referred to as demand to capacity ratio. Structural damage ($\mathbf{D_s}$) occurs via deformation or failure when the demand to capacity ratio exceeds 1.0. Increasing the applied forces or decreasing the structural resistance increases damages.

Wind damages buildings through velocity-generated pressures (positive and negative) and via debris impact. Flowing water damages structures through dynamic action of storm surge (waves, high velocity flow, scouring, flood-borne debris impact). Riverine (rising water) flooding typically has minimal or no velocity and generally does not lead to structural damage, except in the case of buoyancy.

A particular structure's resistance (**R**) to applied forces (**P**) is determined by its individual and unique characteristics, which include its property topography (its elevation relative to flood levels), age, building design, construction, type and quality of materials, underlying soil properties, pre-existing damage (including termites and wood rot), and maintenance thereof.

The relationship is as follows:

$$D_s \text{ (structural damages)} = f\left[\begin{array}{l} P \text{ (wind, water)} \\ R \text{ (topography, age, design, construction, materials,} \\ \quad \text{soil, pre-existing damage, maintenance)} \end{array}\right]$$

The authors found a wide range of variability in the subject structures' resistances, which resulted in a wide range of variability in damages observed. For example, the structures with pre-existing damage (pre-Hurricane Katrina) such as wood rot and/or termite damage were significantly weaker than structures that were not impacted. No two structures featured identical type, degree, and extent of structural damages.

Degradation of a structure's architectural finishes is a function of exposure to flood water, wind driven rain, and wind forces. A structure's finishes' resistance to water and wind is determined by its unique characteristics, including its property topography, age, height, design, and its material water resistive properties. For example, an increase in the flood water exposure height (**E**) or immersion time (**T**), or a decrease in the building material's water resistance increases the flood damage ($\mathbf{D_f}$) to an individual structure. The relationship for material degradation damages is as follows:

$$D_f \text{ (finish degradation)} = f\begin{bmatrix} E \text{ (water exposure height)} \\ T \text{ (immersion time)} \\ R \text{ (topography, age, height, design, and material water resistance)} \end{bmatrix}$$

As the height of the flood water rises within a structure, more surface area of building materials and electrical and mechanical systems are exposed to water and the damage increases. The flood water height above the structure foundation was a distinct and variable parameter in the flooded structures in New Orleans. The water level varied due to four conditions: subclass basin, topography, type of foundation system and the structures' height, or generally, the number of stories. Flood damages varied from structure to structure and ranged from no flood damage to complete damage to finishes.

Comparative Case Study Examples

Case study comparison examples of several structures by structure type, damage type and cause of damage are presented in this section. The comparisons indicate that individual site assessments are required to evaluate the type and extent of damage, which vary as a function of the hurricane forces and the resistive characteristics of the building.

Example 1 – Variability of Structural Damage: This example illustrates different causes of structural damages at different structures. Structural damage varied at each structure and individual site assessments were necessary to ascertain structural damage and the cause thereof at a specific structure.

Tilted Piers Termite Damage Scour Damage

Figure 4: Structural Damage

At Structure #29, the authors observed several tilted piers, including what appeared to be remedial piers under the floor structure. As the piers tilted, the floor system deflected, causing the superstructure to move. This movement caused distress to architectural finishes as evidenced by plaster cracks and out of square door frames. The tilting of the piers was most likely caused by long-term movement of the subgrade. The maximum riverine type flood water level recorded by IPET was

approximately 2'-1" *below* the finished floor elevation (placing the water level near grade), and unlikely to have caused the tilting of the piers.

Structure #12 featured significant pre-existing (non-hurricane) structural damage caused by termite and wood rot. The extent of the damage was such that large sections of framing members had disintegrated. For example, two ceiling joists had collapsed and several wall top plate sections were near failure. The extent of termite damage at this structure rendered the dwelling structurally compromised and unsafe for habitation.

Structure #6 featured damage in the form of scouring and/or undermining of the wooden piles and concrete grade beams. The IPET observed watermark at this structure was 5'-1" A.F.F. The observed scouring was attributed to flood and/or surge.

Example 2 – Structure #1 (slab-on-grade vs. pier and beam): This second example is a comparative case analysis illustrating different causes of distress based on foundation type. Structures with pier and beam foundations behave differently than structures with slab-on-grade foundations during hurricane and flooding events.

The piers in a pier and beam foundation system transfer the weight of the structure to the load bearing soils. The open pier and beam system allows for fairly unobstructed flow of water during floods (FEMA 2005), but a dangerous condition is created once the flood level reaches the finished floor. In pier and beam construction, the floor system typically consists of lightweight, buoyant wood framing. The combination of buoyancy uplift forces, and possibly wind forces, tends to overstress the piers and the pier to floor connections, potentially resulting in the displacement of piers and/or the entire structure.

In contrast, most of a slab-on-grade foundation lies below grade, so the structure will sustain architectural damage due to flood water at lesser flood elevations than a pier and beam structure. However, slab-on-grade foundations are constructed of concrete and are not as buoyant as lighter structures with pier and beam systems.

A satellite image obtained from Google Earth (Google Earth, 2005) (**Figure 6**) shows the condition of Structure #1, a slab-on-grade structure, and the adjacent structures post Hurricane Katrina (Spring 2006). The image shows that the structure located east of Structure #1 was detached from its foundation and displaced from its original plan position approximately 50' south and 8' east. In addition, the structure had been rotated around its original north-south axis by approximately 45 degrees counter-clockwise. Displacement of the structure and associated damage was the result of flood.

The impact of flood and storm surge was very different for the subject 40th Street structure and the adjacent structure on the east side. While the structure east of Structure #1 was detached from its foundation, displaced, and rotated well beyond its

original as-built condition, Structure #1 remained at its original position without any significant displacement, tilting and/or rotation.

The different behavior of these structures during the storm is most likely the result of the structures' different foundation systems. Structure #1 has a slab-on-grade foundation while the adjacent east structure had a pier and beam foundation. Most likely, upward buoyancy (and possibly lateral water forces due to the proximity to the 17th street canal breach) contributed to the displacement and rotation of the structure east of Structure #1. In addition, improper, failed and/or missing hold-downs at the pier and beam foundation might have contributed to the detachment of the structure from its foundation.

Although the above comparison of substantially different structure responses to flood water forces was not evident at any of the other subject (proposed class) properties, this condition was not isolated and occurred at many other structures as evident by at least nine properties in a three-block area noted to be displaced and/or rotated in plan.

Figure 6: Structure #1 & Adjacent Properties

Example 3 – Structure #5 (two-story) vs. Structure #21 (one-story): The third example is a comparative case illustrating the observed variation and degree of distress between two structures based on the number of floors. On all of the two-story structures, the water level did not reach the second floor (**Figure 3**). Damage consistent with flood was not observed (on the second story of these structures.) Therefore, on a per-living-area basis for a given structure, two-story structures sustained less flood damage than one-story structures.

Conclusions

The study of the 36 class member structures illustrates the varying degrees of damage and uncommon effects related to the wind and water forces from Hurricane Katrina. The causes, types, and extent of damages to one particular structure were not indicative or predictive of causes, types, and extent of damages to another structure.

The cause and effect of damage at each structure depended on the applied hurricane forces and the structure's resistance thereto. Hurricane forces of wind and water and degradation of materials affected structures differently; the extent of subsequent material degradation was related to characteristics unique to each structure.

Based on this analysis, estimates of damages cannot be properly or fairly determined without individual site assessments. A mass assessment of damages without specific site evaluations would be inaccurate because it would not take into account the variability of the applied hurricane forces and the structure-specific resistance characteristics. In this study, each of these variables required site-specific evaluation.

In summary, the authors did not find commonality of type, degree, or extent of damages for the residential structures in the city of New Orleans. Damages were not predictive by formula and therefore, commonality was not present in the class. The cause, type, and degree of damage varied considerably not only in the global putative class, but also within the local subclasses, indicating that the proposed subclass boundaries presented no meaningful divisions.

ABSTRACT

Water ingress into unbonded post-tensioning tendons can lead to serious and expensive structural problems. The severity of this condition can be difficult to detect as often there are limited signs of distress until one or more tendons have lost tension as a result of section loss from corrosion. This paper presents a case study illustrating the investigation and the rehabilitation of tendon failures in a two-way, unbonded post-tensioned roof slab. Techniques for identifying deficiencies with the tendons are summarized as well as the proprietary cable drying procedure that was used for tendon rehabilitation. The authors' observations regarding the effectiveness of the tendon drying based upon continued monitoring of the structure are presented.

INTRODUCTION

Post-tensioned concrete structures can provide efficiencies by allowing longer spans between columns and reducing the amount of material required for construction, as compared to conventionally reinforced structures. However, without proper detailing to ensure that water does not enter the tendon sheath, serious and expensive structural problems can result. These issues can be difficult to identify and remediate because they often produce very limited visible signs of distress. Post-tensioning end anchorages in newer structures located in aggressive environments are typically protected by waterproof encapsulation; however, before the late 1980's, end anchorages and intermediate anchorages were left unprotected in the concrete as the tendon movement during stressing and the anchorage geometry made them difficult to protect. Additionally, because the grout used to fill the stressing pockets at the anchorages is often more porous than the surrounding cast-in-place concrete and a cold joint in the concrete is required at intermediate stressing locations, there is often a path for water to reach the interior of the tendon sheath at these locations. Once water has accessed the tendon sheath, there is typically no easy way for it to escape, resulting in corrosion and section loss of the tendon. This paper describes the investigation and remediation of a two-way unbonded post-tensioned concrete roof slab subject to deterioration as a result of water ingress into the tendon sheaths.

STRUCTURE DESCRIPTION

Located in Southeast Michigan and constructed in 1984, the structure is a four story post-tensioned concrete office building with an arched skylight covering a center atrium which divides the interior of the building into east and west halves. As shown in the roof plan in Figure 1, there is an expansion joint, with hollow-core concrete slabs acting as closure elements, dividing each half into north and south sections. The

post-tensioned roof slab is 8 inches thick and spans between columns typically spaced at 30 feet on center in each direction. The post-tensioning strands are ½ inch diameter, 270 ksi, 7-strand low-relaxation tendons that have a parabolic drape profile; they are evenly distributed in the east-west direction and banded in the north-south direction. Each north-south band of tendons typically consists of 14 to 20 individual strands, placed in groups of 2 or 3. There is conventional reinforcing steel in the bottom of the slab at midspan and in the top of the slab over the column lines. At the north and south ends of the building there are conventionally reinforced concrete towers which contain mechanical rooms and elevators, and which are separated from the remainder of the structure by an expansion joint at each end.

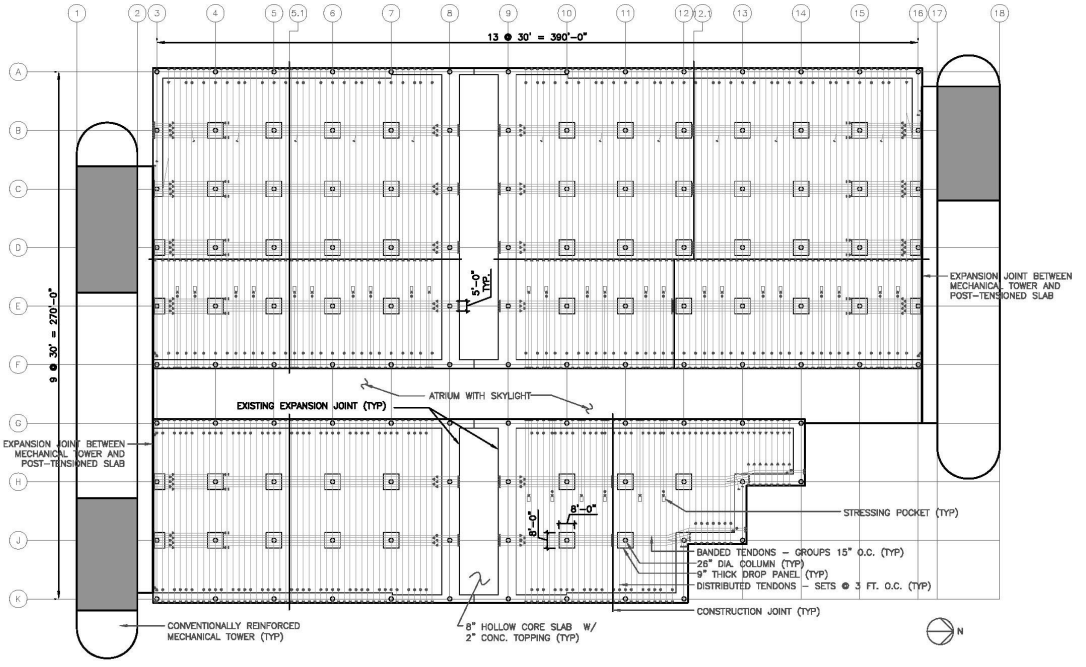

Figure 1. Plan view of roof slab.

In May of 2006, Wiss, Janney, Elstner Associates, Inc. (WJE) was contacted by the Owner of the building as a result of a post-tensioned tendon which had broken during the workday. The sound associated with the sudden release of tension in the tendon was described as being like a gunshot and had scared the building occupants. In investigating the cause of the noise, the onsite building engineers had found two failed tendons protruding from the slab. The Owner required an initial assessment to determine whether the structure remained safe for occupancy, as well as an investigation into the cause of the post-tensioning failures and the extent of tendons affected.

INITIAL INVESTIGATION AND ASSESSMENT

A review of the post-tensioning shop drawings on file at the building showed that the failed tendons were located in a banded tendon line which contained 14 total tendons, with an additional six add-tendons in the end span. A limited inspection was performed on the underside of the structure along the column line with the two known broken tendons to look for evidence of additional breakages or significant

cracking in the concrete at the positive moment regions in the slab, which could be an indication of structural deficiency. While some narrow cracks with water staining were visible in the underside of the slab, they did not appear to be concentrated in positive moment regions, nor did they appear to be widening. Negative moment regions over the tops of the columns, where cracking related to a structural deficiency would likely occur first, were not visible as they were covered with a roof membrane.

Since the discovery of the broken tendons occurred in the springtime, the roof was not expected to be subjected to snow loads in the near future. ADAPT-PT software was used to perform an analysis using the effective frame method to determine whether the structure could safely support the roof dead load and minimum live load with two broken tendons. From this analysis, it was concluded that the structure required only 60 percent of the tendons to safely support the dead load with the code-prescribed load factors. As other evidence of distress was not observed, it was concluded that it was unlikely that eight additional tendons were broken in the affected band of tendons and that the structure was safe for occupancy. Along with those conclusions, it was recommended that the Owner should have a more extensive investigation into the cause and extent of the tendon distress at the building completed prior to the upcoming winter.

DETAILED INVESTIGATION

WJE was authorized to proceed with a detailed investigation of the roof slab post-tensioning system in the summer of 2006. This included a visual survey of the entire underside of the roof slab, removal of two broken tendons from the slab to determine their break location and to allow for inspection of their condition, and investigative openings in selected areas. From discussions with the Owner and onsite building engineers, it was learned that the roofing system had previously leaked over a long period of time, but had been repaired five years earlier. This could have allowed water to reach the roof structure and to subsequently become trapped in the tendon sheaths.

Visual Observations

Access to the slab underside was gained by removing ceiling tiles. While the majority of the slab soffit was visible, some areas were obstructed by large mechanical ducts and hard ceiling finishes, as well as firewall partitions which extended above the ceiling tile. Crack locations were evaluated for patterns which could be indicative of structural distress. Water staining was typically observed along the expansion joints at the center and both ends of the structure, at crack locations, at construction joints, and around drains. Water staining and cracking were generally more severe in the western portion of the roof.

Most of the cracks observed in the slab soffit ran parallel to tendon bands, although some diagonal cracks were observed as well. One additional broken tendon was identified during the investigation; it had erupted through the bottom of the slab and had damaged the sheath of the adjacent tendon.

Tendon Removal

A contractor was engaged to remove two broken tendons from the slab. Tendon removal was accomplished by attaching one end of a come-along to the exposed portion of the broken tendon, wrapping the other end around a column to provide anchorage, and then tightening to exert enough force on the tendon to pull it from the slab. Both extracted tendons, located along different column lines, were found to be broken near midspan, at the low-point of the tendon drape, in the bay adjacent to the expansion joint at the north side of the structure. Observations were made regarding the condition of the strands and the grease along the length of the extracted section of strand. Little or no evidence of emulsification of the grease, corrosion of the tendon, or other evidence of water ingress was found outside of the end bay. Furthermore, almost all the evidence of water in these strands was observed at the low portion of the tendon drape in the end bay. These findings indicated that the source of the water in these tendons was most likely the end anchorages at the slab edge, and that the water ran down the strand to its low spot in the tendon drape, where corrosion and ultimately failure of the strand then occurred.

Investigation Openings

Six locations were selected for inspection openings to further investigate the extent of water in the banded tendons and to identify signs of distress in the distributed tendons. A total of 48 tendons were exposed; these openings were typically located at the midpoints of tendon drapes in end bays or at intermediate anchorages where moisture penetration into the tendon sheaths could have occurred. Portions of the tendon sheaths were removed to allow for visual inspection of the steel wires. Also, each exposed tendon was probed with a screwdriver, which is a commonly used, qualitative test to evaluate whether a post-tensioning tendon is still stressed. If the tip of the screwdriver can be forced between the individual wires, then the tendon has likely failed or has lost a portion of its initial force.

At these openings, almost 40 percent (15 of 38) of the exposed banded tendons were observed to have water trapped in the sheath, 20 percent of which (three of 15) were no longer tensioned. Evidence of corrosion was observed at some of these locations. In the distributed tendons, however, no indications of deterioration or distress were identified.

Figure 2. Exposed tendon which is no longer stressed. Note the grease is emulsified and contains debris, which are indications of water in the tendon sheath.

Summary of Investigation Results

Investigation into the cause of the post-tensioning tendon failures in the roof slab revealed a systematic problem with the banded tendons as water was found in 15 of 38 sheaths opened at the low point in the tendon drape adjacent to the end anchorages. The most likely source of this water was identified to be leakage through the expansion joints between the post-tensioned slab and the conventionally reinforced slabs for the towers located at the north and south ends of the building. Leakage at this joint could have allowed water to enter the tendon sheath through the live end anchorages. Due to the adjacent concrete beam, visual observation of these stressing pockets was very difficult. The observed water staining on the concrete beams and slab soffit at either side of these joints provided evidence of previous water leakage in these areas, but there were no indications of continued water leakage along these joints at the time of the investigation.

In the presence of oxygen, pitting corrosion and stress cracking will occur in tendons which are exposed to moisture. Since only three of the 15 strands identified to have water in their sheaths had failed, it appeared that the level of corrosion was just reaching the point where it would be severe enough to result in tendon failure. Post-tensioning tendons are continually subjected to high stresses (approximately 50 to 65% of their ultimate strength) and have a fairly small cross sectional area. Consequently, it does not require a large amount of section loss to result in full tendon failure.

There was no evidence of water or corrosion at any of the ten locations opened in the distributed tendons. While the distributed tendon openings were made in locations where problems would most likely occur, they were less than 1 foot in length and were made at less than 3 percent of the distributed tendons in the slab. This sample size is too small to draw any statistically significant conclusions as it is possible that moisture or corrosion affected tendons that were not exposed or are located away

from the inspection openings. To date, there is still no evidence of deterioration of the distributed tendons.

REPAIR OPTIONS

Due to the use of the building, the Owner did not have the ability to relocate a significant amount of personnel to perform repairs; therefore, the method of addressing the deterioration would require minimizing disruption of the office space below. Consequently, it was necessary to consider methods that had the potential to minimize future tendon failures in conjunction with monitoring the amount of failed tendons in the structure. The inherent risks associated with tendon failures include physical damage that could occur if tendons erupt out of the slab and reduction in load-carrying capacity; these risks were communicated to the Owner for their consideration regarding the urgency of repairs and tendon rehabilitation. At that time, the locations where the tendons came out of the slab upon failure were all at locations with less than ¼ inch of concrete cover and only very small pieces of concrete debris were dislodged from the roof slab. All the dislodged concrete had been contained by the ceiling tile; therefore, there did not appear to be significant danger to the occupants from falling debris.

Due to the number of failed tendons and the potential for additional tendon failures, the following recommendations were made to the Owner to address the observed tendon distress:

- Conduct inspections of the banded tendons at locations judged to have significant indications of moisture ingress and/or potential distress;
- Perform a rehabilitation program to remove existing moisture from the banded tendon sheaths;
- Repair failed tendons where sufficient tendons have failed within a single band to significantly affect the structural performance;
- Enact a long-term monitoring program for the banded tendons.

Tendon Rehabilitation Program

In order to reduce the probability of future tendon failures, it was recommended that the selected tendon rehabilitation method include the removal of water from the tendon sheaths. Two methods for achieving this were considered: the Post-Tech® PT Cable Drying method offered by Vector Corrosion Technologies and a hydrophobic urethane grout injection system. After consideration of each system, it was recommended that the gas purging method be implemented as the cost per tendon was slightly less and there was less potential for damage to the interior finishes since re-greasing of the tendons would not be performed in the interior environment. The cable drying system involves forcing air at a very low dew point through the tendon sheath over a period of time to draw the existing moisture out of the sheathing.

While initially expensive, this investment had the potential to produce significant savings in construction costs by either eliminating or deferring post-tensioning repairs. Additional cost savings would be realized by avoiding the temporary relocation of personnel required during post-tensioning repairs. The Owner decided that it was worth the added initial cost to rehabilitate the banded tendons in this

manner in order to reduce the risk of failure, due to the disruptive and expensive nature of the post-tensioning repairs.

It should be noted that if tendon corrosion is already in an advanced state, and particularly if stress corrosion cracking exists on the strand, the drying method for tendon rehabilitation may not effectively decrease the probability of tendon failure. Additionally, for projects where only a small number of tendons are affected by moisture or a significant number of those tendons affected by moisture have already failed, it would not be economical to utilize this rehabilitation method to protect a small number of tendons.

Tendon Monitoring Program

While the rehabilitation program was intended to minimize the rate of corrosion, it is not possible to reverse the effects of corrosion or to ensure that the rate of corrosion is stopped completely. To monitor the banded tendons for possible subsequent failures, the installation of an acoustical monitoring system that would detect vibrations resulting from the release of energy during failure, such as that offered by Pure Technologies, was considered but was determined to be cost prohibitive. Acoustic monitoring would have the added benefit of detecting failures in the distributed tendons as well.

As an alternative, bi-annual follow-up inspections, including testing the tension in the tendons with a screwdriver, were recommended to monitor the tendon condition. By regularly observing the tendons, the condition of the roof structure can be monitored to ensure that it remains structurally adequate and that the rate of tendon failures is decreasing as expected.

Post-Tensioning Repairs

Lastly, traditional post-tensioning repairs were recommended for tendon bands identified to contain more than 2 broken tendons. This corresponds to when the maximum tensile stress in the roof slab due to flexure under service loads exceeds 6 times the square root of the compressive stress of concrete (or $6\sqrt{f'_c}$), which is the serviceability criteria for two-way post-tensioned flat slabs according to ACI 318-05. This limitation is intended to prevent cracking in the slab and also accounts for unconservative methods of calculating the moment in the slab at the supports. In our judgment, this provided a reasonable safety factor and also accounted for the uncertainties in the simplistic methods of testing the tension in the tendons, as well as the understanding that there would be some delay associated with engaging a contractor to perform required repair work. As the tension testing was performed at limited areas, it was possible that there were undetected failed tendons, which could have occurred in instances where there might have been significant friction along the tendon length between the test location and the break location.

At the conclusion of the 2006 investigation, it was determined that no post-tensioning repairs were required immediately because no single band had more than two failed tendons. The Owner chose to move forward with the drying operations and construction documents were developed by WJE in early 2007.

ADDITIONAL TENDON FAILURES

In June 2007, prior to initiation of the tendon drying work, an additional tendon failure was reported by the building staff. The tendon failure occurred in a band with two previous failed tendons, bringing the total number of failed tendons in that band to three. This particular tendon failure resulted in a sizable piece of concrete dislodging from the underside of the roof slab and penetrating the ceiling tile. Due to the potential safety hazard of loose concrete falling into the occupied space below, permanent safety netting was designed and installed at locations where tendon failure could result in further dislodged concrete.

The safety nets were constructed with welded wire mesh suspended from steel cables. The cables were looped and clamped at steel eye-bolt anchors embedded into the column drop down panels or, as necessary, into the underside of the roof slab. The nets were installed at select locations along the low point of the draped tendons, where the concrete cover is the thinnest and where all of the previous tendon break outs were observed. As necessary, the nets were cut and lapped to accommodate obstructions within the plenum such as HVAC ducts, plumbing and partition walls.

Another tendon failure was reported by the building staff in July 2007, also located in a band with two previous failed tendons, bringing the total number failed tendons in that band to three. At this location only a small amount of concrete was displaced and was captured in the safety netting.

Because the additional tendon failures in June and July 2007 resulted in bands of tendons with more than two failed tendons, tendon repairs were recommended for those bands. The Owner agreed that the repairs were necessary and, in the interest of minimizing disruption to building tenants, requested that the repairs be performed in conjunction with the tendon drying work. The contractor performing the tendon drying operations (Vector Corrosion Technologies) was also capable of performing the repairs as well. Construction documents for the repair work were developed and the additional work was added to the original tendon drying contract as a change order.

TENDON DRYING AND ADDITIONAL INSPECTION

The tendon drying operations commenced in August 2007, approximately two weeks after completion of the safety netting installation. The scope of work for the tendon drying operations included drying and inspecting all accessible tendons in Bands C, D, E, H, and J between Column Lines 3 and 8; and Bands B, C, D, and E between Column Lines 12.1 and 16 (see Figure 1). These bands contain a total of 184 tendons; however, three tendon groups (nine tendons total) were not accessible for drying or inspection because they were obstructed by HVAC ductwork within the plenum space. The tendon drying operations included chipping an inlet port and drilling an outlet port at the ends of each tendon (see Figures 3 and 4), using specialized equipment to create and force air at a very low dew point through the tendon sheath, and measuring the moisture levels in the air removed from the tendon sheathing until they reached an acceptable level.

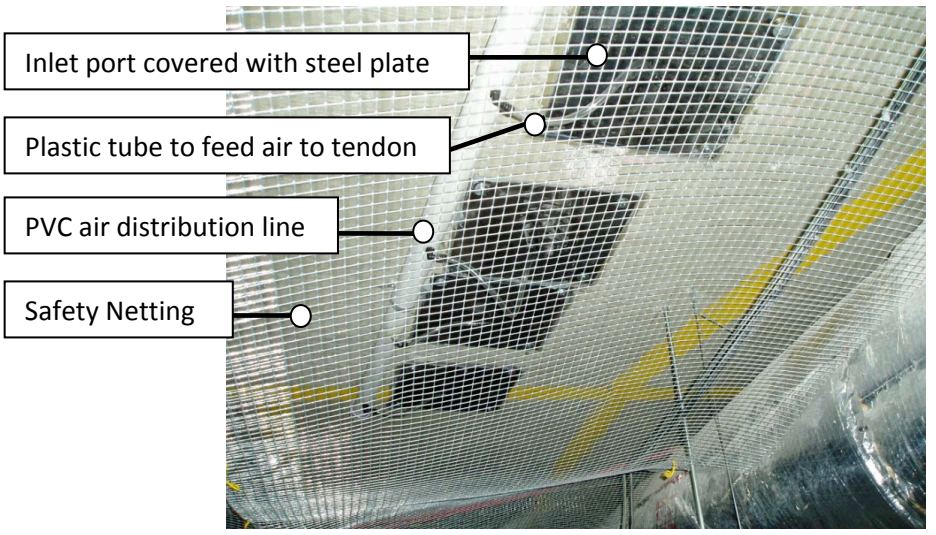

Figure 3. Air inlet ports, also used for tendon inspection, covered with steel plates.

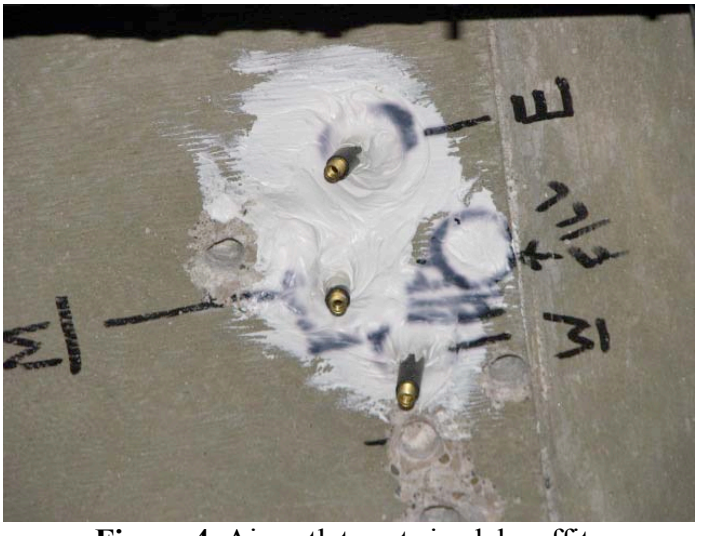

Figure 4. Air outlet ports in slab soffit.

The air inlet ports located in the end bays adjacent to the expansion joints were also used for inspection of the exposed tendons. An initial inspection, consisting of visually observing exposed portions of the tendons and probing the tendons with a screwdriver to assess the presence of tension, was performed at each tendon. A total of eight failed tendons were observed out of the 176 tendons inspected, including the six tendons noted previously which were scheduled to be repaired. Evidence of water and/or corrosion was observed in 55 of the tendons sheaths, or approximately 30 percent of the banded tendons. Each inlet port was then capped with a steel plate anchored and sealed to the underside of the slab after inspection. The cover plates on the inlet ports are removable and continue to be used for bi-annual inspection of the tendon condition.

A plastic air port was installed in the cover plate to serve as the air inlet point. PVC manifolds and plastic tubing were installed as necessary throughout the plenum to supply the dry air to the air inlet ports from the air-drying equipment (see Figure 5), which was located in the mechanical rooms at either end of the building. The

temperature and relative humidity of the air was measured at the outlet ports routinely throughout the drying work. This data was used by the Contractor to determine the moisture content within the tendon sheaths. Testing performed by the Contractor on previous projects had shown that tendons were considered to be sufficiently dry to limit corrosion when the moisture content of the air removed from the sheathing was below 0.3 percent.

Figure 5. Equipment used to manufacture dry air on-site, including a transformer, compressor, and air tank.

All 176 accessible tendons were dried. Initial moisture testing indicated that 38 tendons, or approximately 20 percent, had moisture contents in excess of 0.30 percent prior to drying, with a maximum measured moisture content of 1.43 percent. The time needed to achieve a dry condition for each band of tendons varied from 15 to 47 days, and the drying operations were completed in early November 2007. At the completion of the drying operations, the final reported values included an average moisture content of 0.02 percent with a maximum of 0.09 percent, representing a substantial reduction in the amount of moisture within the tendon sheaths.

MOISTURE TESTING

As there is an intermediate anchorage in the west portion of the structure at Line 12.1, moisture testing was performed on one group of tendons from each band south of the anchorage to assess the need for drying the length of tendons located away from the north side expansion joint, where leakage was identified. The moisture testing method was very similar to the tendon drying, except the inlet ports were drilled (no visual inspection was made) and the air was only forced through the sheath for a short period of time to measure the air content at the outlet port. Of the 12 tendons tested, none had moisture contents in excess of 0.30 percent, indicating a very low probability of corrosion. Since there were no failures observed in this portion of the building either, it was concluded that tendon drying or further investigation was not warranted past the intermediate anchorage at the time.

TENDON REPAIRS

At the two tendon bands where more than two broken tendons were observed, tendon repairs were completed by replacing the deteriorated sections of strand between the end anchorage and an intermediate point where a 'dog-bone' type central stressing splice could be installed beyond the area of strand deterioration. Whenever possible, the length of tendon to be replaced was minimized; however, at a few locations, observations made in the field during the repair work was being performed resulted in longer sections of tendon replacement than originally anticipated. At all tendon repair locations, the repaired tendon was restressed, the new strand and splicing hardware protected, and the slab cross-section restored in a manner consistent with industry standards and PTI recommendations.

The end of one known failed tendon was no longer present in the anchor at the south end of the tendon at Column Line 9. Given the unknown circumstances regarding the release of the tendon end, it was agreed that the entire tendon should be replaced (from Column Line 9 to 16), rather than only the portion that contained the observed failure (from Column Line 14 to 16). This decision was confirmed as frayed (or "birdcaged") sections were observed in the additional portions of the removed tendon.

As necessary, WJE and the Contractor worked together throughout the project to address unique and challenging conditions encountered in the field. Proposed changes to the scope of repairs were reviewed by WJE and the building Owner. In all cases, it was agreed by all parties that the decision to increase the amount of replaced tendons provided a more reliable repair than other alternatives and did not significantly increase the total cost of the repair work. The tendon repairs were completed in January of 2008.

BI-ANNUAL TENDON INSPECTIONS

As of November 2010, six bi-annual follow-up inspections of the 176 accessible tendons were performed to visually observe exposed portions of the tendons and probe the tendons with a screwdriver to assess the presence of tension. Based on the observations, each tendon was assigned a repair priority designation ranging from Priority 5 (good condition) to Priority 1 (repair is required). Individual observations and priority classifications are recorded and compared to those from previous inspections to identify changes in the tendon conditions. In addition to the individual tendon inspections, a limited visual inspection of the underside of the roof slab is performed, including checking the safety nets for dislodged concrete.

Over the nearly three years since the tendon drying and repair work was completed, three additional tendon failures have been observed. Of these failures, only one broke through the underside of the roof slab and all of the dislodged concrete was captured in the safety net. None of these failures were noticed or reported by the building staff. In general, the visible appearance of the exposed portions of the tendons has remained similar between inspections and no additional water or notable increases in corrosion level have been observed. There are currently five failed tendons out of the total of 176 inspected, but no band contains more than one failed tendon; therefore,

no additional repairs have been recommended or performed. Considering that up to six tendon failures were noted within less than a year prior to the tendon rehabilitation and that only three failures were noted in the three years since the Post-Tech® PT Cable Drying was performed by Vector Corrosion, the tendon drying operations were apparently effective at slowing the rate of tendon failures.

CONCLUSIONS

The investigation and rehabilitation of the post-tensioned roof slab was a difficult task as a result of the challenges associated with working in interior, occupied space, in addition to the typical issues associated with unbonded post-tensioning tendon failures. After the completion of the investigation, tendon repair and rehabilitation, and three years of monitoring, the following conclusions can be made based on the work performed:

- A well-planned investigation was critical to the success of the project. In this case, the information gained from removing the broken strands from the slab to locate the break location in combination with visual observations of water staining on the slab soffit was used to determine the optimum locations for inspection openings, and resulted in the identification of a systematic problem of water ingress at the banded tendons.
- Tendon drying using the proprietary Post-Tech® PT Cable Drying system has likely resulted in a good investment for the Owner. While there is no way to tell how many strands would have broken if the drying had not been performed, the rate of tendon breaks has decreased and no additional tendon repairs have been required since the completion of the project.
- Drying of the tendons was successful and efficient in this instance because it resulted in a relatively low impact on the building's occupants and finishes, because the source of the water had already been eliminated, and because there were a significant amount of tendons that had evidence of deterioration which still remained tensioned. Each circumstance should be assessed individually.
- Even after drying is completed, continued monitoring of the tendons is required to ensure that the structure remains in serviceable condition as the effects of corrosion cannot be reversed.
- Decisions regarding the initiation of tendon repairs require an analytical understanding of the applied loads and capacity of the structure as designed, as well as an understanding of what variables exist.
- Tendon failures result in the release of a large amount of energy. Because many failures do not produce significant visible signs of distress, the potential for hazards to the structure's occupants can be easily underestimated. The risks associated with falling concrete or blown out end anchorages on a structure's occupants should be assessed, communicated to the Owner, and mitigated as necessary.

Saving the Bodie Island Lighthouse: Preservation and rehabilitation challenges in a 140-year old coastal structure

by

Located on Oregon Inlet on the Outer Banks of North Carolina, near the town of Nags Head, is the Bodie Island Light Station, a collection of buildings constructed circa 1872 to serve as an aid to navigation along the dangerous section of the Atlantic coastline known as "The Graveyard of the Atlantic." Listed in the National Register of Historic Places, the Light Station today consists of the historic Lighthouse, Oil House, Light Keeper's Quarters, storage buildings, brick walkways, and a modern Visitor Comfort Station. The Light Station is within the environs of the Cape Hatteras National Seashore, which is maintained by the National Park Service.

History of Lighthouse

The existing Lighthouse at Bodie Island is the third built in this vicinity, but it is not on the foundations of either of the first two as they are under water in the Oregon Inlet. The first Lighthouse was constructed by the Lighthouse Board of the United States Treasury Department in 1848, but was replaced ten years later due to defects in the foundation. The foundation had not been designed to accommodate the soils on which the structure was placed, causing it to settle unevenly, leaning nearly a foot out of plumb by 1851. Additionally, the decision was made to upgrade the light apparatus of this Lighthouse. By 1859 a new Tower had been constructed. Whereas the first Tower took nearly 20 years to complete, the second Tower was completed within a year and the old Tower was subsequently razed. Despite efforts to make the second Tower more durable, it did not last as long as the first. In 1861, after North Carolina had seceded from the Union, Confederate forces blew up the Lighthouse – though they salvaged the light – apparently to prevent the Federals from using it as a lookout. The second Lighthouse was left in ruins by the Federal government for the duration of the Civil War because it was felt that the Cape Hatteras light located approximately 50 miles away was adequate to serve the coast at that time.

After the Civil War, normal shipping resumed along the North Carolina coast and by 1867, the number of shipwrecks in the area caused the Lighthouse Board to urge the reconstruction of the Bodie Island Lighthouse. Plans were made to construct the third Lighthouse Tower on a site just north of Oregon Inlet. The decision to build the

Lighthouse on a new location was prompted by the steady advancing of the inlet on the original site.

In 1871, construction of the new Lighthouse began with site preparation, building of storage buildings, workers' quarters, a wharf, and a tramway connecting the wharf to the site. The pit for the Tower foundation was dug, and the foundation was laid. Beams were forged in Baltimore and loaded onto ships bound for Bodie Island. By the late fall the bricks for the Tower were shipped to the site. One year later, in the fall of 1872, the First Order Fresnel lens was installed and the Lighthouse was in operation. A Fresnel lens is a type of lens that was invented in 1822 by French physicist Augustin-Jean Fresnel for use in lighthouses. This type of lens is much thinner than earlier lenses, therefore transmitting more light and allowing lighthouses to be visible over much longer distances. The original Fresnel lens remains in the lighthouse today.

Constructed in the Italianate style, the existing building is made up of three primary elements: the Oil House, consisting of three rooms (including a hall), the connecting hall between the Oil House and the Tower and the Tower. All sections of the building were constructed at the same time. The date carved into the head of the front door is 1871 (per the 1871 construction drawings). Both the Tower and the Oil House have load-bearing masonry wall systems. The Oil House has a wood floor system in the north area and stone on fill in the hall and south room (the Oil Room). The roof structure of the Oil House is wood frame. The stair, landings, and upper rooms of the Tower are cast iron. The exterior finish of the Tower and Oil House is painted brick. The upper exterior of the Tower is cast iron. The Oil House is painted white, and the Tower is painted alternating black and white stripes, consistent with the original exterior markings. The Tower stands 165 feet tall.

Other than substitutions in the fuel source for the lamp and subtle variations in the interior and exterior paint scheme, the Lighthouse remained largely unchanged until 1932, when electricity was introduced to the Tower and the light was converted from a fixed to a flashing light. At this time a generator was installed in the former Oil Room of the Oil House. In 1910, the Lighthouse Board was abolished and the Bureau of Lighthouses was created under the Department of Commerce. The Bureau maintained control of lighthouses until 1939 when they were consolidated with the United States Coast Guard. In 1953, after nearly a century of service, the Coast Guard declared the property surrounding the Light Station as surplus and transferred title to the National Park Service. Except for the Fresnel lens, ownership of which was retained by the Coast Guard, all property associated with the Light Station had been transferred to the National Park Service by 2000. In 2005, the Coast Guard transferred ownership of the Fresnel lens to the National Park Service. However, the Coast Guard continues to use the Lighthouse as a navigational aid and coordinates all maintenance affecting the lens with the National Park Service.

Beyond its obvious age, the historic significance of the Bodie Island Lighthouse is tied to its architectural character as well as its association with maritime, transportation and engineering history in the United States. Until late 2009, when

construction for the preservation and rehabilitation project began, the Lighthouse has continually served as a navigational aid since 1872. As such, the official Period of Significance represents a collective history of the building. Defining this period was important in understanding how to best approach the preservation treatments for the Lighthouse and associated Oil House.

The entire Light Station is a wonderful example of the lighthouse system that was established by the United States during the nineteenth century. It was constructed during a period of building of several such aids along the shores of this country and stands largely unchanged. And it's relevance to United States history extends beyond a regional building type, as there are several sister lighthouses to Bodie Island Lighthouse on the east and west coasts. Two examples of these are Currituck Light in Corolla, North Carolina, located just north of Bodie Island Lighthouse, and Pigeon Point Light in Pigeon Point, California. Such ties contribute to the historic significance of the Bodie Island Lighthouse and the roll it played in the development of maritime history in this country. Furthermore, having witnessed the development of the Outer Banks throughout the twentieth century, while maintaining its pristine environment, the Light Station is a significant part of the North Carolina maritime history and culture.

Project History: The Preservation and Rehabilitation Design Process

The Lighthouse and Oil House had suffered deterioration in their architectural and structural components due to the harsh conditions of their coastal environment and deferred and, in some cases, inappropriate maintenance treatments due to a lack of adequate funding over the years. The exposure of the Lighthouse and Oil House to years of moisture, sand, and salt has had the most significant impact on their condition. As a first step towards preservation and rehabilitation of these buildings, the National Park Service initiated development of a Historic Structure Report (HSR) in 2002. Working with the National Park Service, Hartrampf, Inc. was hired to prepare this report and assembled a team of architects, structural engineers, historic preservation planners, and historians to undertake the physical investigation and historic research. Hartrampf prepared the HSR, as well as the associated Conditions Assessment Report for the buildings, providing information on their history of development and use, physical characteristics, and recommendations for treatment.

Findings of the structural investigation and review of historic documents indicated that substantial repair of the cast iron features on the upper levels of the Lighthouse, as well as replacement of some of the cast iron stair treads was necessary to retain its structural stability and the overall historic integrity of the building. Additionally, repairs to the masonry walls were necessary due to their integral relationship with the cast iron elements. Numerous architectural finishes and features also required repair to preserve them for generations to come.

In 2002, annual visitation to the Bodie Island Light Station was estimated at around 200,000 people, and the Light Station was open to visitors year round. Despite this level of visitation the public had never been permitted to climb the lighthouse, and visitation inside the building was limited to the interior of the Oil House and to the first level of the Tower. In 2005, due to unsafe conditions from several cast iron features falling from the upper structure, the Oil House and first level of the Tower, and the immediate grounds surrounding the Tower were closed to visitors. Prior to this closing the National Park Service had received numerous requests from visitors to climb the stairs to the top of the Lighthouse, but, due to the documented deficiencies in the cast iron stair system and exterior galleries, it had been deemed unsafe for visitors to do so. Furthermore, continued deterioration was eroding the safety of Park personnel during routine maintenance work on the Lighthouse.

In 2005, funds became available to review the recommendations of the 2002 Historic Structure Report and 2003 Condition Assessment Report to open the Tower to the public. This review became the basis for a multi-year design project to preserve and rehabilitate the Lighthouse and Oil House. This design process involved producing schematic design, design development and construction documents to preserve the remaining historic fabric, rehabilitate the electrical system, introduce a fire suppression system in the Oil House and a fire detection system in the Lighthouse, and, most importantly, rehabilitate the structural systems throughout the Tower to ensure public safety while maintaining the integrity of this important historic resource.

Structural Rehabilitation of Tower

In addition to concerns about public and staff safety, preservation of this historically significant resource was in jeopardy. Coupled with the structural deficiencies of the cast iron features on the upper levels of the Lighthouse, the cast iron stair treads and the masonry walls, the continued loss and damage of their architecturally important features had seriously compromised the integrity of the Light Station.

Unique Design Parameters

The location and climate at the Bodie Island Lighthouse presented a number of unique design challenges for all work of this project. The constant humidity and salt air are ideal conditions for moisture problems and rusting of the cast iron. The height of the Lighthouse, combined with its location in the Outer Banks, make it susceptible to high wind loads from hurricanes. The area also has considerable termite activity.

Structurally, the use of cast iron throughout the Lighthouse also presents some unique design considerations. Cast iron is generally not used in modern construction. It is brittle, exhibiting little or no yielding before failure, and it is weak and unpredictable in tension and bending. Different castings also affect its strength and brittleness. The unpredictability of cast iron makes it difficult to accurately determine its load carrying capacity.

Structural System of Lighthouse

The base of the Lighthouse up to approximately 11 feet above grade is comprised of cut granite blocks. The brick Tower walls are approximately six feet thick at the base and taper to approximately two feet thick at the ninth landing. The top of the Lighthouse is constructed of cast and wrought iron elements including belt courses, the Gallery Deck brackets and framing, sheet walls of the Gallery, the Lantern Deck, and the roofing and framing elements of the Lantern. Cast iron is also used in the spiral stairway carriers, stringers, rails and newels, and various window and door frames.

Other dissimilar metals are used in the upper levels of the Lighthouse for various structural and architectural purposes. Bronze was used for window sashes and floor grates at the Lantern Room and door hardware. Brass was used for fittings of the Fresnel lens. The Lantern Room roof is covered in sheet copper, while the underside of the roof is a zinc sheet.

Condition Assessment Findings

Many of the original cast iron components of the Lighthouse were in poor condition and presented structural concerns. All the gallery support brackets were in poor condition with cracks present in all sixteen brackets. Two of the belt course segments had fallen with another five presenting significant cracks or broken pieces. Both the Gallery level decking and the cast iron drum walls had cracks which extended through the entire thickness of the plate material. The Lantern window mullions had racked causing numerous panes of glass to crack and fall out. Numerous stair treads were cracked and required replacement. The stair stringers and landings were in good condition and did not need to be replaced.

As part of this project, five alternatives for providing access to the Lighthouse and Oil House by the public were developed for review by the National Park Service. These alternatives were directly related to access by the public to the stairs within the Lighthouse structure. The five alternatives were:

1. No access to the stairs; interpretation from the exterior only.

2. No access to the stairs; access only to the Oil House and the lowest level of the Lighthouse.

3. Limited access to the stairs up to the Watch Level based on existing structural capabilities of the stair system

4. Limited access up to the stairs up to the Watch Level based on management decisions of the Park and strengthening of the structural systems.

5. Unrestricted access to the stai rs up to the Watch Level based on strengthening structural systems.

For alternatives 3, 4, and 5, those allowing access to the Watch Level, there were the related issues of whether to allow visitor access to the Watch Level Gallery and whether to allow them to partially ascend the stairs at that level to view the lens on the Lantern Level. Public access to the Lantern Level will not be allowed in order to protect the Fresnel lens, and public access to the Lantern Level Gallery will not be allowed because the only access to that gallery is either from a ladder from the Watch Level Gallery or through a window at the Lantern Level.

A Value Analysis study was conducted to assure that all viable project alternatives were considered, evaluation factors were sound, solutions were cost effective, an independent opinion was provided, and all project objectives were satisfied by the chosen alternative. One guideline that pervaded the effort was to select alternatives that minimized impacts to the historic resource, kept future options open, and were reversible to the extent practicable. Estimated initial construction costs were available for the Value Analysis team to evaluate and Life Cycle cost estimates based on a 20-

30 year cycle were prepared. The selected preferred alternative was to allow limited public access to the exterior Gallery Deck area and maintain most of the historic fabric. This alternative had an estimated construction cost of $2.9 million.

In spring 2010, during the construction phase of the rehabilitation design, it was discovered that upper level metals were in worse condition than what was apparent during the design phase of work. As a result, several aspects of the design in the construction documents could not be undertaken without further decisions being made on the treatment of these metals.

This phase of the work concentrated on specific cast and wrought iron elements of the upper levels of the Lighthouse, which exhibited more damage and deterioration than was anticipated from the construction documents prepared from assessments conducted seven to eight years ago. Once the multiple layers of paint had been removed, all of the exterior iron showed corrosion to differing degrees. This included the belt courses, the Gallery deck brackets, the Gallery deck, and sheet iron walls of the Gallery.

A structural engineering investigation of the recently exposed conditions at the upper levels of the Lighthouse was conducted, which included a review of the following:

- Identifying any apparent safety issues. These were relayed to the National Park Service and Contractor personnel immediately and later documented for National Park Service records.

- Identifying the structural deficiencies of the 16 Gallery brackets. Each bracket was reviewed. Some of the masonry alongside one of the brackets was removed to expose the bracket to better assess the extent of the damage. Recommendations on repair or replacement were based on maximizing the retention of the historic fabric without compromising the safety of the structure or visiting public using the Gallery walkway above.

- Identifying the structural deficiencies of the belt course segments. Each segment was reviewed. Recommendations on repair or replacement were based on maximizing the retention of the historic fabric without compromising the safety of the structure.

- Identifying the structural deficiencies of the Lantern Walkway sections. Each section was reviewed. Recommendations on repair or replacement were based on maximizing the retention of the historic fabric without compromising the safety of the structure or National Park Service staff utilizing this walkway. This area will not be open to the public and therefore will have different load carrying requirements.

- Identifying the structural deficiencies of the Lantern barrel sections. Each section was reviewed. Recommendations on repair or replacement were

based on maximizing the retention of the historic fabric without compromising the safety of the structure.

- Investigating the cracking of the Lantern level glass to determine, if possible, the cause of this cracking and recommend remedial action.

- Investigating any of structural issues that may become apparent upon inspection of the exposed metal surfaces.

From the cracking pattern of all of the sections mentioned above, the Gallery brackets and walkway deck appeared to be moving outward and down away from the masonry walls of the Lighthouse. The rotation point appeared to be at the bottom of the brackets at the crack through the web just above where they are bolted into the masonry wall. This crack extends through the entire web section of the bracket embedded in the wall and through the backside flange. This weakens any rotational restraint that had kept the brackets vertically plumb.

Each end of the belt course segments are bolted to the Gallery brackets at their base. As the brackets rotate outward they rotate the belt course as well. These rotational forces push the center sections of these segments against the very hard masonry wall below. This has caused many of these sections to crack and break away at the masonry. As the bracket pulls the deck away from the center of the Lighthouse, the bottom of the Gallery level wall is no longer restrained. This would allow movement of the wall and the Lantern level deck above which it supports. This, in turn, could put additional stresses in the Lantern level window mullions. With some of the windows removed, the mullions could have racked in plane and moved enough to cause additional panes to crack.

Another Value Analysis was conducted in summer 2010 to assure that the original goals for opening the Tower up to the public could be met in a cost effective manner while preserving as much historic fabric as possible for future use on the Lighthouse or for remote interpretation. The selected preferred alternative was to support the existing historic metalwork with new structural framing and cabling.

This alternative consisted of adding new structural elements to support the historic fabric and allow the public to visit the Gallery deck. Since more weight would need to be supported, these structural elements may be slightly visible to the eye from the ground, yet not distract from the historic features. The unexpected strength of the masonry walls will be taken advantage of and allow the installation of new steel beams and brackets extending from below the Gallery brackets and below the Gallery deck. The final treatment and priorities to be undertaken are described below:

- Stabilize the Gallery level walls. This will be accomplished by installing cables around the entire wall.
- Stabilize the Lantern level deck. The fascia sections will be replaced.
- Stabilize the Gallery brackets and deck. New structural framing will be installed adjacent to the Gallery brackets, which will support both the brackets

and the decks above. This framing will be anchored into the masonry wall and would incorporate cabling around the entire Tower to provide a tension ring.

- Stabilize the Belt courses. Existing cracked sections will be replaced per the original Rehabilitation project procedures.
- Stabilize the Lantern level by replacing the broken glass panes

A comparison of the preliminary cost estimates for this additional work shows that the selected alternative's initial costs of approximately $400,000 saved more than $1.3 million over more expensive alternatives while providing a greater value to the Park.

At this writing the National Park Service is awaiting funding to complete this additional work and hopes to open the Lighthouse to the public by summer 2011. Through these repairs the public will for the first time gain access to this beautiful historic lighthouse and see the complex designs that went into its construction as it provides a tangible link to the maritime history of the Outer Banks, and an important part of our transportation history in the United States.

Abstract

This paper provides guidance to engineers, property owners, property managers, and contractors on the mitigation of damage to lightweight, flat (or low slope) roof structures by snow removal. The objectives are to minimize large deflection, prevent blocked drainage paths, minimize snow-induced ponding, and most importantly, to prevent the collapse of roof structures caused by overload due to snow. The structures most susceptible to overload are lightweight, flat roof, commercial structures, such as "Big Box" stores, warehouses, recreation centers, and shopping malls. These structures commonly have low permissible snow load to dead load ratios making them sensitive to extreme snow loads. In February 2010, there were three successive snowstorms extending from Washington, DC to New York, New York that challenged snow removal efforts. Each storm was a significant event and together in quick succession, these storms caused the collapse of roof structures throughout the region. The collapse of roof structures and the forecast for significant accumulation after the first storm prompted property owners and managers to take precautions to protect their property from damage. Conditions and events motivated the development of these snow removal guidelines to protect against overload. Factors influencing a successful snow removal strategy include the amount of snowfall (i.e., depth of snow, unit weight of snow, and drifting snow), design capacity and condition of the roof structure, potential to exceed the design requirements and/or code specified requirements, size of the roof structure, safety of the snow removal crews, economic aspects of snow removal, etc. This paper considers strategies for snow removal, such as taking no action, removing a uniform depth of snow throughout the roof structure, removing channels of snow from the field of the roof, or a combination. The methodology presented may also be adapted to roof structures undergoing rehabilitation, such as re-roofing.

Introduction

News reports of roof collapses and the forecasts for severe winter weather with significant snowfall accumulation attract the attention of the general public. For building owners, property managers, contractors, and engineers, the challenge of severe winter weather is to protect the life, health, and safety of employees and the public within their buildings and also to mitigate the potential damage and collapse of their buildings.

One particular challenge arose in February 2010. On February 4-6, 9-10, and 24-26, 2010, the Mid-Atlantic region, and in particular Washington, DC; Baltimore, Maryland; Wilmington, Delaware; Philadelphia and Pittsburgh, Pennsylvania; New York, New York; and the surrounding areas experienced three severe winter storms. Significant snowfall accumulation combined with dense wet snow resulted in snow loads that were equal to or greater than the design snow load for many of these areas.

Overload and collapse of lightweight, flat (or low slope) roof structures, such as "Big Box" stores, warehouses, recreation centers, and shopping malls, occurred from snow-induced loading. For example, the weight of snow caused the collapse of the hangar sheltering private jets at Dulles International Airport, Prince William Ice Center in Dale City, Virginia, and a warehouse in California, Maryland.

Other buildings were protected against collapse by the removal of snow from their roofs. Ordinarily, the removal of snow from around drainage devices (i.e., roof drains, scuppers, and gutters) is sufficient to promote positive drainage of snow meltwater; however, the quick succession of the February 2010 storms created new challenges.

The removal of snow from a roof structure, particularly on large roof structures is costly and time consuming. The combination of the amount of roof surface, manpower needed to shovel the roofs, length of time between storms, forecast for additional accumulation before the snow from one storm can be removed or melted, and the assessment of the load reduction (or de-loading) requirements presented many important challenges.

This paper presents the lessons learned from the February 2010 events and various factors considered in snow removal. Guidelines for snow removal are presented in two parts. The first part of the guidelines is the removal of snow to promote positive drainage. The second part of the guidelines is the additional considerations in assessing snow-induced overload.

Winter Storms, February 2010

In February 2010, three severe winter storms tracked across the United States culminating with significant snow accumulation and a state of emergency throughout most of the Mid-Atlantic region. These storms were known for their snow

accumulation and for their rapid succession. News reports nicknamed them "Snowmageddon" and "Snowpocalypse."

The first winter storm came ashore on the West Coast of the United States on February 1, 2010. It tracked across the country from California to the Mid-Atlantic region before moving off the East Coast on February 6, 2010. During the period of February 4-6, 2010, blizzard-like conditions occurred through a large part of the Mid-Atlantic region.

Some places across eastern West Virginia, Maryland, northern Virginia, Washington, DC, Delaware, south-central and southeastern Pennsylvania, and southern New Jersey received approximately 20 to 40 inches of heavy wet snow. The depth of snowfall for the period of February 4-6, 2010, is illustrated in Fig. 1.

The second winter storm formed as an "Alberta Clipper" in Canada on February 7, 2010, before tracking southeast to the Mid-Atlantic region affecting many of the same areas as the first storm before moving off the coast of New England on February 11, 2010. During the period February 9-10, 2010, Washington, DC to Boston received 12 to 40 inches of heavy wet snow. The depth of snowfall for the period of February 9-10, 2010, is illustrated in Fig. 2.

The third winter storm tracked through the Mid-Atlantic and Northeast regions on February 24-26, 2010. The most significant snow accumulation fell across New England, New York, and Pennsylvania with 12 to 24 inches of heavy wet snow with locally as much as 36 inches. The depth of snowfall for the period of February 24-26, 2010, is illustrated in Fig. 3.

Individually and collectively these storms presented challenges to building owners. Among the challenges was whether to remove the snow from their roofs; and if so, how much snow to remove and from where. The economic aspects and the time constraints did not permit the snow to be removed over a prolonged period.

Lightweight, Flat (or Low Slope) Roof Structures

For the purposes of this paper, lightweight structures have generally flat or low slope roofs (i.e., less than 5 degrees), simple-span framing with the roof framing exposed to the occupants below, or concealed by lightweight suspended ceilings. They tend to be large in area with the potential for blowing and drifting snow, particularly at the interface of high/low roofs and alongside penthouses and rooftop units.

The potential for damage and the risk of roof collapse from snow-induced overload varies with the type of roof structure, design loads, conditions, and many other factors. The potential for collapse is not limited solely to the type of construction, but in general lightweight roof structures are more susceptible to collapse than heavyweight structures. This is primarily due to the fact that snow load represents is a large percentage of the total roof load.

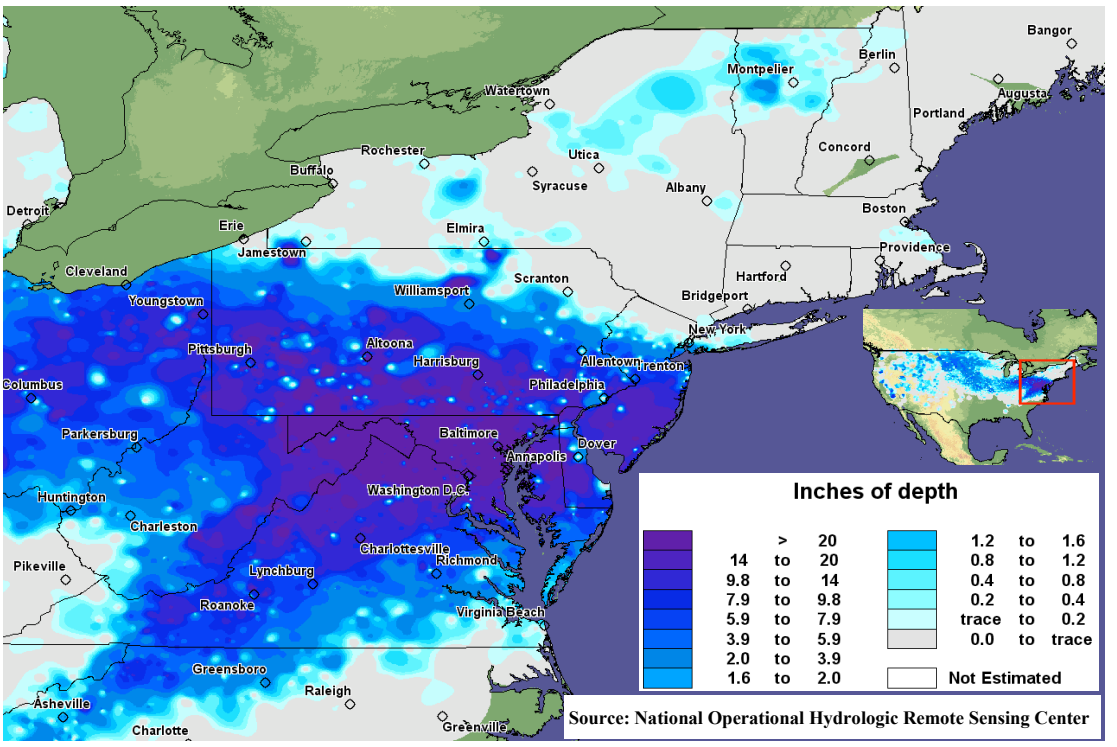

Fig. 1. Depth of Snowfall for the Period February 4-6, 2010

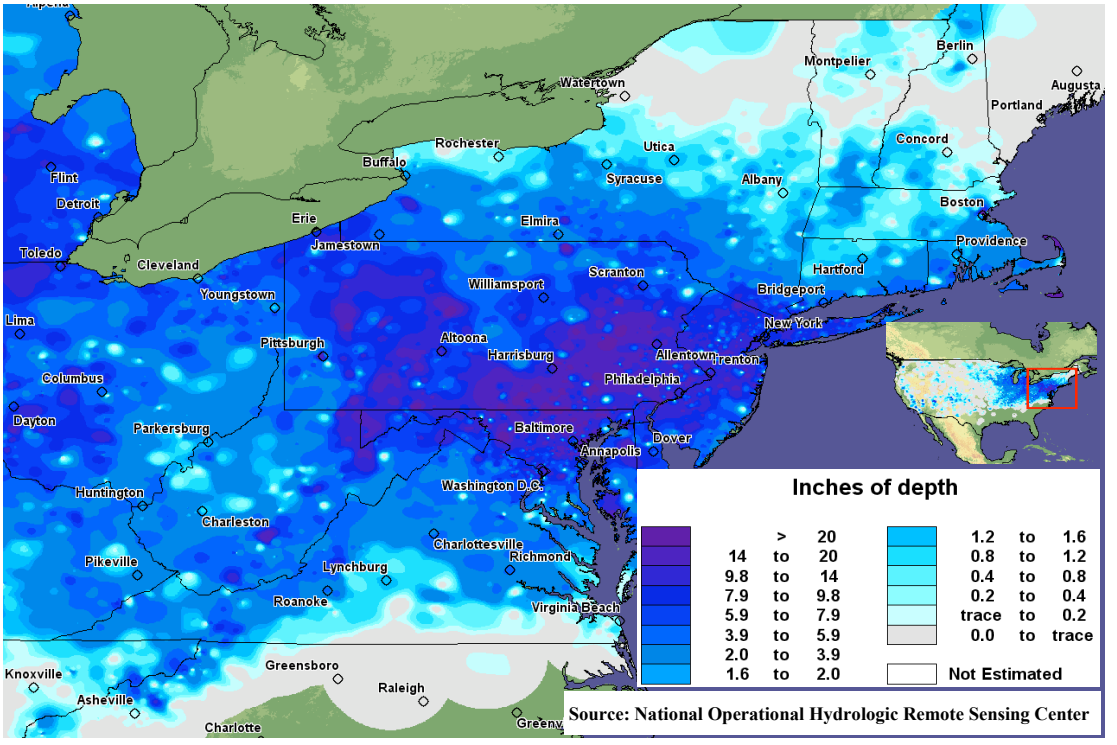

Fig. 2. Depth of Snowfall for the Period February 9-10, 2010

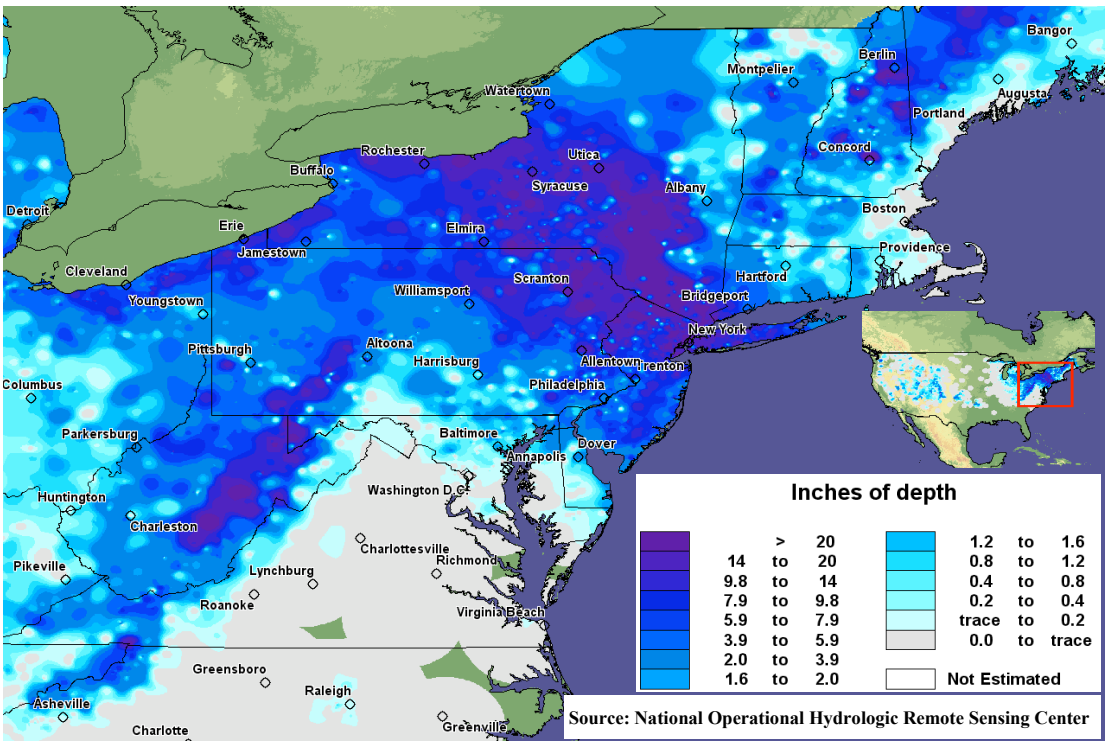

Fig. 3. Depth of Snowfall for the Period February 24-26, 2010

If the design roof snow load on a roof structure is exceeded, the percentage increase in total load would be greater on a lightweight structure than on a heavyweight structure. For example, if a 40 pounds per square foot design roof snow load is exceeded by 20 pounds per square foot for a roof structure having 15 pounds per square foot dead load, the total load increases from 55 pounds per square foot to 75 pounds per square foot, or 36 percent. Whereas, for a 60 pounds per square foot dead load, the total load increases from 100 pounds per square foot to 120 pounds per square foot, or 20 percent.

Guidelines to Promote Positive Roof Drainage

If thawing occurs on snow covered roof structures, but the snowmelt does not drain to the drainage devices or they are blocked by snow and ice, the weight of snow and snow meltwater will not significantly diminish. Therefore, for any snow and ice removal plan to be effective, the roof must be cleared to promote positive drainage. This will also minimize the likelihood of overload.

Diagrams showing the location of snow and ice removal from around drainage devices and drainage channels are illustrated in Figs. 4-5. Guidelines for removing snow and ice from roofs are given below:

1. ***Work Area:*** Provide temporary protection or barricades around areas on the ground where the snow will be dumped or lowered. Do not block fire exits or

exit doors with snow that is removed from the roof or other equipment. Designate work areas and drop zones alongside the building. Provide a secure ladder for access to the roof. Use a front end loader to remove snow accumulation alongside the building that is dropped or lowered from the roof. Distribute snow removal crews within the work area on the roof to avoid localized overload.

2. ***Drainage Devices:*** Locate and remove snow and ice from around drainage devices to promote positive drainage. Use precaution and avoid damaging the roofing membrane or metal roof panels, particularly around drainage devices and also at the base of parapets, rooftop curbs, flashings, etc.

3. ***Drainage Channels:*** Remove snow to create drainage channels as shown in Figs. 6-9. Begin at the drainage device and proceed up slope. Remove the snow from the channels in widths equal to about 5 feet wide to one-third of the column spacing beginning at the mid-span between columns. It is not necessary to remove all of the snow and ice from the field of the roof.

4. ***Means and Methods:*** Remove snow from the roof as it is being cleared. Do not stockpile or relocate snow from one location on the roof to another. Use plastic tip shovels and avoid damage to the roofing membrane or metal roof panels. Avoid using snow blowers, picks, hammers, and other sharp tools to remove snow and ice so as to protect the roof.

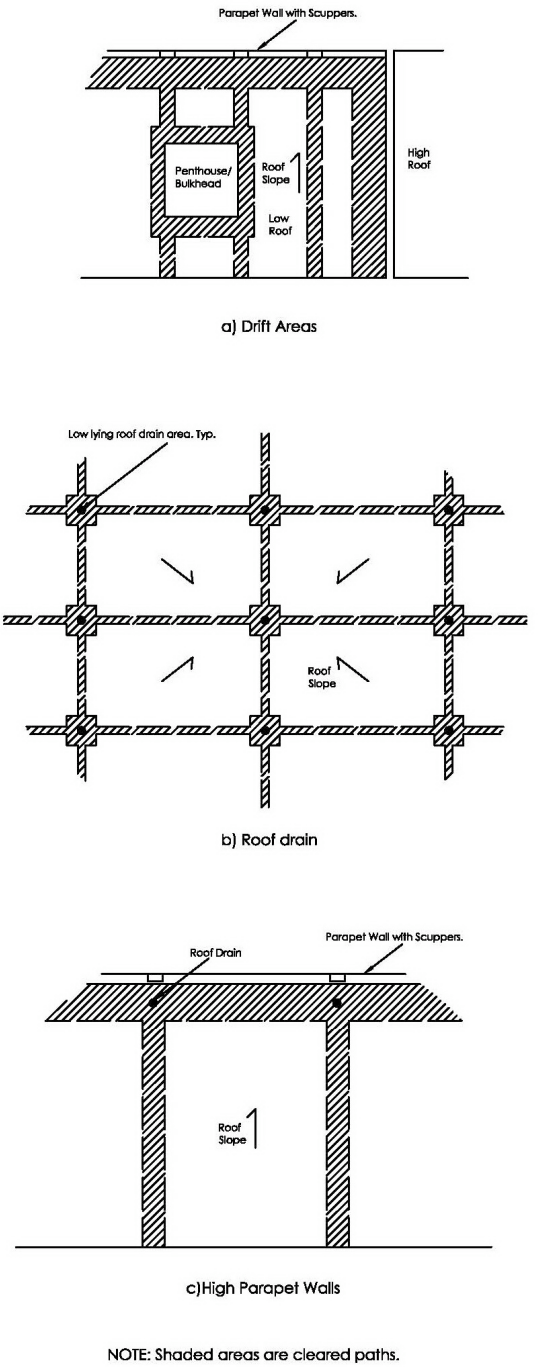
Analysis

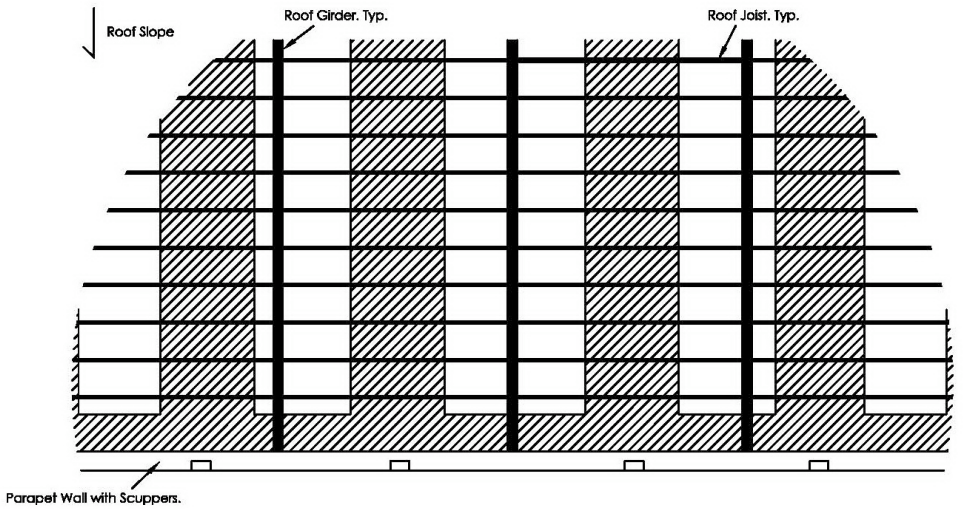
Promoting positive drainage is an important consideration in overload from snow. Also important are other factors, such as the design snow load versus actual load, snow drifts, snow-induced ponding, existing construction and conditions, economics, etc. As a general rule, failures associated with overload tend to be caused by localized snow load, rather than by uniform loads within the field of the roof.

Design Load: A comparison of the design snow load with the measured snow load or an estimate of the potential (i.e., forecasted snowfall) is the first test for assessing overload. However, design calculations and construction documents that may provide the design snow load may not be readily available. In lieu of the known design snow load, the code specified snow load provides a minimum value to be used for comparison.

The snow load design value for flat roofs, p_f (pounds per square foot) is specified in ASCE 7-10, Section 7.3:

$$p_f = 0.7 C_e \, C_t \, I \, p_g \tag{1}$$





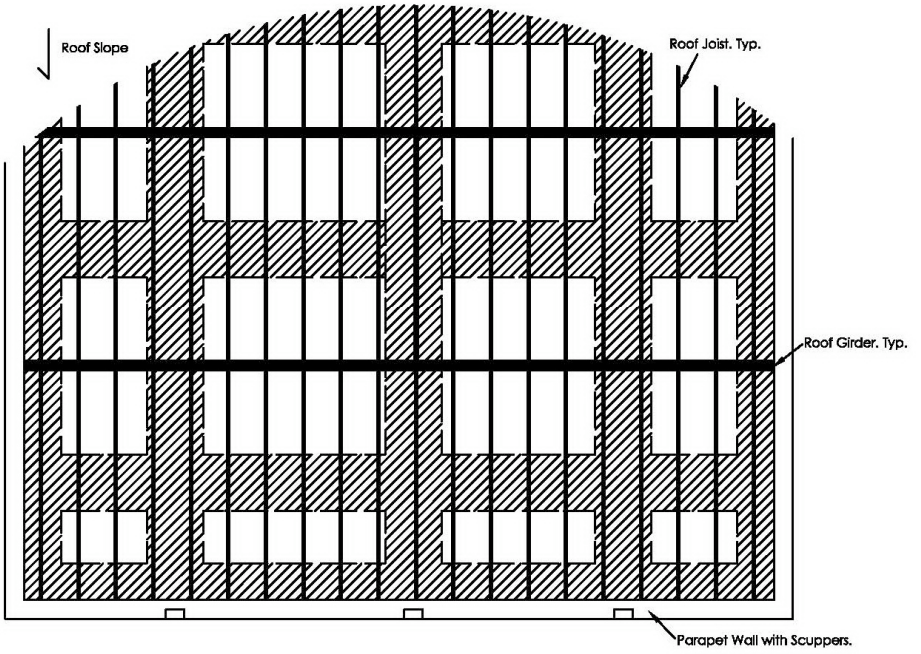


Fig. 4. Snow Removal to Create Drainage Channels

a) Roof Girders perpendicular to Drain Line/Scuppers

b) Roof Girders parallel to Drain Line/Scuppers

NOTE: Shaded areas are cleared paths.

Fig. 5. Snow Removal Patterns Relative to Structural Framing

Fig. 6. Snow Removal in Drainage Channels at Scuppers along High Parapet

Fig. 7. Drainage Channels at Roof Drains (arrows) along Parapet

Fig. 8. Drainage Channels Leading to Roof Drain (arrow)

Fig. 9. Drainage Channels at Scuppers (arrows) along High Parapet

The equation from ASCE-7 acknowledges that the roof snow load is usually less than the ground snow load, because the roof snow load is reduced over time by melting, runoff, and wind between snowfalls. However, the Commentary in ASCE-7 states that a single major storm can generate loads that exceed the amount from this equation. This statement also holds true in the case of two or more large snow events occurring in a short span of time.

Snow Drifts: Snow drifts may form on low roofs at high roof/low roof interfaces, along parapet walls, around penthouses, along snow screens, around rooftop mechanical units, around solar panels, at roof mounted signs, etc. Older structures were generally designed without consideration for snow drift. These may warrant additional snow load reduction.

Condition Survey: Site and condition survey findings may reveal structural distress or indications of distress that warrant additional snow load reduction. For example, joist orientation, displaced sprinkler heads, cracks in drywall, roofing overlays, construction defects, or other construction and conditions may indicate priority areas for snow load reduction.

Snow-Induced Ponding: Snow-induced ponding should be investigated when the with roof slopes less than ¼ inch per foot and also areas around internally drained, mid-span of simple span roof joists, rain-on-snow or snow meltwater, and other low lying areas. Unheated or discontinuous heating of structures as well as cyclic outdoor air temperature (i.e., above and below freezing) may cause thawing of the snow on the roof structure and subsequent refreezing in low lying areas. Exhaust fans and other mechanical equipment on roofs may also generate meltwater. Indicators of roof deflection, such as door binding (i.e., impingement), dropping or sagging suspended ceiling tiles, hanging light fixtures, leaking sprinkler pipes, cracking plaster ceilings and interior partition walls, creaking and crackling noises. These may warrant additional snow load reduction.

Economic Considerations: Economics of snow removal is a challenge for both the building owner/property manager and the snow removal contractor. Factors influencing the cost of snow removal are the uncertainty of the scope of snow removal (i.e., amount of snow and location of snow removal), size of the roof area, limitations on snow removal equipment (i.e., shovels versus snow blowers), the number of people on the roof, severe weather conditions, nighttime and extended hours of work, duration and intensity of forecasted snowfall, hazardous conditions (i.e., slippery surfaces, depth of snow, working at the edge of a roof, etc.), etc.

Additional Snow Removal: In addition to snow removal to promote positive drainage additional snow removal may be warrant to further reduce the snow load at drifts, structural distress, and ponding locations. If additional removal is required, it is not necessary to remove all of the snow throughout the field of the roof. The roof should have sufficient capacity to support a minimum code specified snow load. The additional cost to clear the entire roof is unnecessary. Removal options may include

widening existing drainage channels to accommodate additional snow load reduction. In some situations, unloading continuous beams or cantilevered beams may induce greater stresses in the roof structure than would occur if the entire roof is loaded. Diagrams showing the location of snow and ice removal from drainage channels with structural framing are illustrated in Fig. 5.

Condition survey findings, overload (or the potential for overload), roof deflection, and structural distress may warrant building closure and temporary shoring.

Conclusions

This paper provides two-part guidelines for snow removal. This includes snow removal to promote positive drainage plus additional snow removal for additional load reduction (if necessary).

ABSTRACT

Clark County, Nevada has completed the Nation's very first effort to map earthquake hazard class systematically through an entire urban area. The map will be used in development and disaster response planning, in addition to its direct use for building code implementation and enforcement. The County and the City of Henderson contracted with the Nevada System of Higher Education to classify about 550 square miles of Las Vegas Valley. The Parcel Map includes more than 10,000 measurements that classify individual parcels on the NEHRP hazard scale. We introduce a "C+" Class for sites with Class B average velocities but soft surface soil. The measured Parcel Map shows a clearly definable C+ to C boundary on the west side of the Valley. The C to D boundary is much more complex. Using the parcel map in computing shaking in the Valley for scenario earthquakes is crucial for obtaining realistic predictions of ground motions. We computed using our "ShakeZoning" process 50 separate earthquake scenarios, yielding estimates of earthquake ground shaking in Las Vegas Valley based on physics and geology rather than on statistics. Despite affecting only the upper 30 m, the Vs30 geotechnical shear-velocity from the Parcel Map shows clear effects on 0.1-Hz to 0.3-Hz shaking predictions.

INTRODUCTION

The Building Code demands that peoples' lives be protected in the event of earthquake shaking. A significant challenge for engineers and urban planners is how to meet the demand for life safety while not making the cost of building impossibly expensive. Two municipalities in southern Nevada, together with the Nevada System of Higher Education, have addressed this challenge with a comprehensive Earthquake Parcel Mapping program. A systematic campaign of ten thousand microzonation measurements across the Las Vegas urban area was the main component of the Parcel Mapping program. With the measurements completed, the partners can now assess the effects that the Parcel Map measurements will have on earthquake ground-shaking predictions, using newly realistic and accurate ShakeZoning procedures.

Motivation and objectives. Construction within the last thirty years has experienced a synergistic evolution of seismic code provisions as structures designed and built to contemporary codes have been "put to the test" by experiencing significant ground motions. One of the most significant recent changes to seismic provisions in the building code involves the addition of the "Seismic Site Class" factor that can modify the intensity of ground motion that a building or structure is required to resist. Current building codes include the 2006 and 2009 IBC, which are largely based upon the design recommendations outlined in ASCE 7-05 and the 2003 NEHRP Provisions. These codes all require that the seismic site class factor must be determined based upon the results of onsite tests and evaluation, or otherwise default to the typically low site class value of "D". In most instances utilizing the default site class value of D produces a conservative design (i.e. over designed). The seismic site class (and several other parameters) are utilized to determine appropriate choices for a structure's Seismic Force-Resisting System and will also impact the requirements for restraint/anchorage of nonstructural elements: mechanical; plumbing; electrical and architectural items. Compliance with all of these requirements directly impacts construction costs; in a general sense more seismic force equates to higher costs.

Having a regional microzonation map that correctly identifies the seismic site class provides a valuable asset to a developing community as it assures that structures can be safely designed to meet building code requirements without experiencing unnecessary additional costs due to the inherent conservatism associated with selecting the default parameter value. Undeveloped areas will take full benefit of this information to plan new construction and developed areas will also benefit when repairs, alterations or additions are performed. The community as a whole will benefit from having an improved knowledge of how local subsurface geology is likely to effect ground motion.

Background. Measurement of shear-wave velocity (Vs) in the shallow subsurface is essential for the estimation of seismic hazard, the development of seismic-hazard maps, and the calibration of recorded ground motion data. The site class measurements are represented by the average shear wave velocity value for the top 100 feet or 30 meters (Vs100-foot or Vs30-meter) as per IBC 2006 Section 1613.5.5. It is an integral to seismic design of structures per the International Building Code and International Residential Code, (IBC) and (IRC) respectively.

Because methods for direct measurement of Vs30 have only recently become cost-effective (Louie, 2001), earthquake-hazard mapping has to date relied upon extrapolation of statistical averages of a few measurements along geological units. Wills et al. (2000) built a microzonation map of all of California from only 500 spot measurements of Vs30. Their database shows that adjacent, nearby measurements can vary widely. Thelen et al. (2006) and Scott et al. (2006) made systematic examinations of the spatial variance of Vs30 from transects of closely spaced measurements stretching across the Los Angeles and Las Vegas urban areas. The velocities would not correlate with any existing soil or geologic mapping, with the standard deviations of the average Vs30 in any unit much larger than the differences in the average between units. These results motivated Clark County and the City of Henderson to embark on a program of comprehensive microzonation measurement.

Earthquake-hazard mapping cannot stop with Vs measurement. The earthquake source, wave-propagation path, and site effects must be combined into a prediction of ground-shaking intensities at a building site, for each of the likely earthquake scenarios that could produce damaging shaking. The USGS ShakeMap tool (Wald et al., 1999) is one of the current, comprehensive means of making scenario computations. ShakeMap is based only on the statistics of relatively sparse recordings of the motions of historical earthquakes. Once shaking levels are predicted from individual scenarios, the scenarios can be combined into a probabilistic seismic hazard map (Frankel et al., 1996).

Our new ShakeZoning procedure for seismic hazard mapping will properly apply the physics of wave propagation through a geologically complex earth. Our Parcel Mapping results in Las Vegas Valley represent a revolution in geotechnical characterization, allowing us to predict wave propagation and shaking amplification across terrain that has been measured to an unprecedented degree of detail. This paper will begin to show the effects of the new Parcel Map on earthquake-hazard assessment in southern Nevada, by providing the map as a ShakeZoning input.

A predecessor to the ShakeZoning concept, the Community Modeling Environment (CME), was developed at the Southern California Earthquake Center (SCEC) under U.S. National Science Foundation Information Technology Research sponsorship. SCEC's CME combines, in part, geologically based 3-d velocity and fault databases, developed as consensus models in the regional geophysical community (e.g., Magistrale et al., 2000), with a seismic-modeling computational engine (e.g., Olsen, 2000).

The purpose of ShakeZoning (known earlier as MA-CME) was initially to provide a community velocity model and seismic modeling environment for Nevada urban areas. Las Vegas is subject to earthquake hazards both from below the local basin, and from earthquake faults up to 200 km away. ShakeZoning computations feed geological and geotechnical results such as the Parcel Map to the E3D code (Larsen et al., 2001) from LLNL for elastic wave-propagation computation. E3D was most recently vetted for ground-shaking prediction at the March 24-25, 2004 Next Generation Attenuation (NGA) Workshop. Such vetting helps to physically and geologically validate ShakeZoning results. Validation is completed by comparing ShakeZoning seismogram output against earthquake recordings.

METHODS

Parcel Mapping. The Nevada System of Higher Education (NSHE) was contracted by Clark County Department of Development Services (CCDDS) and the City of Henderson (CoH) to create a soil classification map based on site-specific shear-wave velocities ("microzonation map") of the urbanized part of the County (Figure 1). NSHE subcontracted Optim SDS to perform this work under their supervision. The areas characterized included: the urbanized and urbanizing areas of Unincorporated Clark County, the urbanized area of the City of Henderson, and portions of the City of Las Vegas within Las Vegas Valley; the proposed Coyote Springs development; the Interstate Highway 15 southern corridor including Jean and Primm; Moapa Valley, Logandale, and Overton; and Laughlin (all shaded on figure

1). An extension of the project to additional urbanized areas of the City of Las Vegas, and to the City of North Las Vegas, is under development.

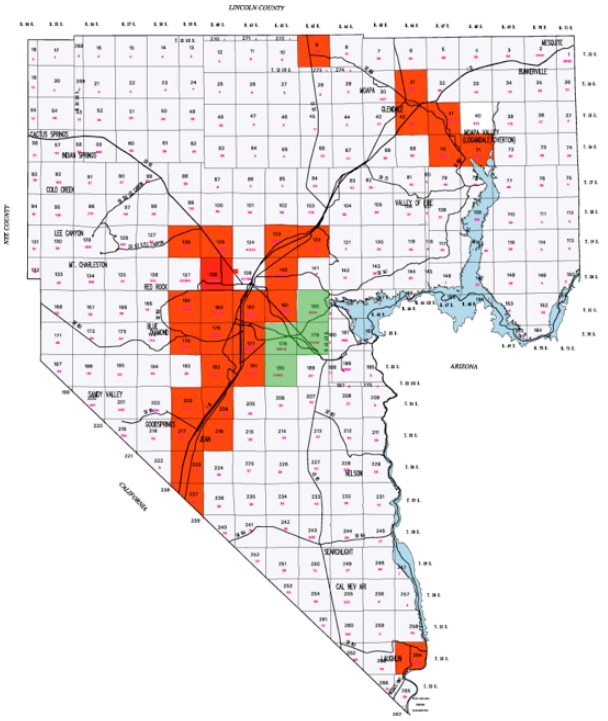

Figure 1. Areas within Clark County mapped for earthquake parcel classification, shaded. CCDDS and the CoH defined the areas mapped.

Optim SDS performed all necessary tasks for completion of the work, including field data acquisition, data processing and reports, working with University personnel to make the products of the work available in a format to be mutually agreed upon during the term of this contract. Optim SDS measured shear velocity as a function of depth at each of the locations using the refraction-microtremor (ReMi) surface array technique. Louie (2001) developed the refraction microtremor technique (commercially available as SeisOpt®ReMi™, © Optim 2001-2010) as a rapid and cost-effective method of measuring Vs30-meter to meet the IBC code (BSSC, 1997), and to derive site conditions. This method has been peer reviewed and blind tested against both borehole measurements and MASW, multi-channel analysis of surface waves (Louie, 2001; Stephenson et al., 2005; Thelen et al., 2006). Refraction microtremor is a volume-averaging surface-wave measurement, averaging velocities where geology is laterally variable, thus providing a more appropriate measure of site effects on earthquake wave propagation than single-point data obtained from downhole logs.

The NEHRP/IBC Site Class is calculated from the measurement results using the equations provided in the 2006 International Building Code book. Section 1613.5.5 of IBC 2006 defines the Vs100-foot vertically averaged shear-wave velocity. Table 1613.5.5 of IBC 2006 defines the NEHRP/IBC site class from the Vs100-foot measurement. Note that even though Vs100-foot values may give you an

average velocity that is Site Class A or B, additional criteria defined in the same section of the IBC 2006 code book must be applied by a geotechnical engineer.

In theory, the accuracy and the resolution of any model is a direct function of the spatial density of the database. In determining the appropriate data density to be used, Optim SDS utilized the Southern Nevada Building Code Amendments as a basis for a data density of one velocity sample per 36 acres. To aid in the capturing of evenly dispersed data, based on 1/36 acres, Optim SDS, CCDDS, and the CoH internally developed a gridded subsection scheme based on the existing book and section projections of Nevada. Site locations typically were reached via street approved vehicles, off highway vehicles (OHV), and hiking, then placed alongside roadways, trails, open fields, or open desert. However, due to limitations imposed by natural terrain, inaccessible areas, large structures, and infrastructure obstructions, the data density across the entire project area varied, rendering the 1/36 acre data density more of a guideline than an absolute standard.

In addition, in several areas, due to proximity to key infrastructure, identified geology of interest, and velocity anomalies discovered in the data set as the project progressed, data density was increased to better define the interpolated modeled surface in those areas. For instance, seismic array locations were intentionally placed with strategic orientation in mind, crossing known faults and fissure zones when possible. In order to maximize the potential to actually cross any subsurface fault or fissure related features, arrays were placed perpendicular to the assumed projected strike when possible.

All seismic array locations were intended to maintain an average test coverage or data density of one array per 36 acres with no less than 1000 feet measured midpoint to midpoint between each array location. The location of the seismic array is further refined from conditions encountered at the proposed location, such as: traffic and other safety and accessibility concerns; private property concerns; ability of the location to fit an array length of 604 feet (up to 2 channels may be omitted from the array under certain circumstances); location of driveways; relative slope and curvature of the array; the availability of parallel noise sources; and avoiding very high energy perpendicular noise sources and artificial underground voids.

Nominally, each site was measured by a linear ReMi array with 24 channels of vertical geophones spaced at 8 meters. Ambient noise microtremor was recorded using standard vertical 4.5 Hz geophones recorded at a rate of two milliseconds for intervals of 30 seconds each. In all, a total of 12 to 20, 30-second recordings were collected for each seismic array. In addition, hammer hits using an 8-pound or 10-pound sledge and strike plate were collected at approximately 15 feet and 30 feet off both ends during normal passive data collection, to increase high frequency energy. This was especially useful in low energy environments, typically rural settings away from traffic and other ambient noise sources.

The noise records were processed using the SeisOpt® ReMi™ software (© Optim, Inc., 2001-2010) that uses the refraction microtremor method (Louie, 2001). processing steps were: 1) create a velocity spectrum (*p-f* image) from the noise data by wavefield transformation; Rayleigh-wave dispersion-curve picking along a ``lowest-velocity envelope" bounding the energy appearing in the p-f image; and 3) interactive shear-wave velocity-profile modeling. The modeling can be subjective and

must be done with constraints: that a minimum number of layers be used to accommodate the observed Rayleigh-wave dispersion; and tests on the necessity and sensitivity of the data to both layer thickness and layer velocity. The resultant model is therefore the simplest to explain the data, following the Occam's Razor principle.

Quality assurance of results begins by plotting of the modeled velocity profiles within each section, to assure consistency. If one model differs from surrounding measurements, or is anomalous given known topographic changes, remodeling of the dispersion curve picks is the first step. An alternate model that is more consistent may be able to be derived. For some data sets, re-analysis of the original data may then occur. This may involve adjustment of picks along indistinct dispersion curves or reconsideration of the curve itself. Consistency of models with adjacent sections is also verified. If there are anomalously high-velocity layers within the upper 100 feet, the reliability of low-frequency dispersion curve picks is examined. In some cases, the accuracy of the dispersion curves at low frequencies is unclear. Again, picks may be adjusted and the dispersion curve at low frequencies is reconsidered. If the site is classified as Class B, the high frequency data are more carefully scrutinized to ensure there is velocity information to determine layers in the upper 20 feet.

"Blind" tests were periodically conducted to test the repeat ability of the data and analysis results. Seismic data were collected using comparable acquisition equipment by engineer James O'Donnell, of Las Vegas, independently at the same location of seismic arrays obtained by Optim SDS. Test locations were spatially dispersed in the map area where data collection was currently occurring. Data acquisition for the two datasets occurred simultaneously. Excerpts of the same ambient noise were therefore recorded by both datasets. Analysis results of the blind test data were compared with those obtained by Optim SDS.

Earthquake Ground-Shaking Prediction. The ShakeZoning tools assemble the available geological and geophysical data sets into a numerical grid for wave-propagation computation, as described by Louie (2008). We develop here an example grid to compute the shaking induced in Las Vegas Valley (LVV) by the June 1992 magnitude 5.5 Little Skull Mountain (LSM) earthquake. Figure 2 shows the location of the tilted grid.

The grid includes two datasets at various scales on Neogene basin thicknesses that are roughly stitched together: 1) Saltus and Jachens's (1995) USGS basin gravity inversions for the Basin and Range, including both sedimentary and Tertiary volcanic basins at 2-km resolution; and 2) the Langenheim et al. (1998) Las Vegas basin model from gravity, refraction, and a few deep wells, at 0.4-km resolution. Figure 3B shows the composite basin-floor model, which sets the LVV basin into its context of the many neighboring basins.

We also incorporate geotechnical data sets, despite their having spacings varying from 0.1 to 0.3 km, and including isolated point measurements. The ShakeZoning tools interpolate all the disparate data sets onto a regular grid, following instructions for how one data set may take precedence over another where they overlap. For the LSM model, three datasets are combined in this way: 1) the regional geologic map controls the default shallow geotechnical Vs30-meter, 250 m/s for basin

sites and 760 m/s for rock sites; 2) the Las Vegas refraction microtremor transect, sites by B. Luke at UNLV, stratigraphy correlated to 1145 wells by W. Taylor of UNLV and G. Wagoner of LLNL, all from Scott et al. (2006); and 3) the raw 10721 Parcel Map measurement results discussed below. Figure 3C shows a geotechnical model developed solely from actual measurements, with no Vs30 prediction.

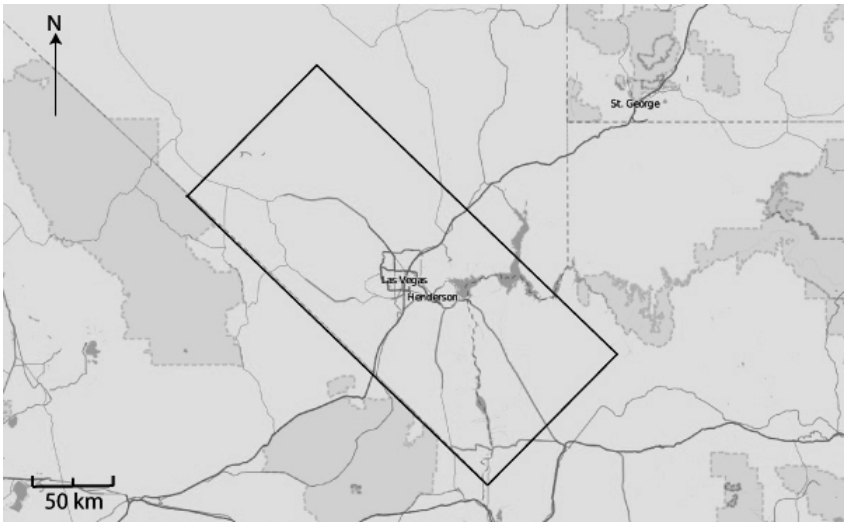

Figure 2. Map of southern Nevada showing the ShakeZoning grid for computing a scenario of the 1992 magnitude 5.5 Little Skull Mountain (LSM) earthquake.

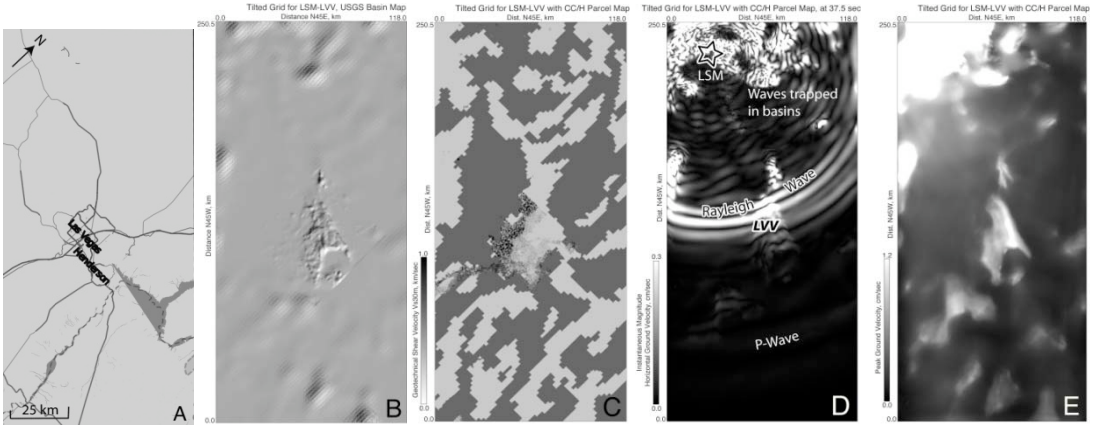

Figure 3. A) Road map on the southeast-tilted LSM ShakeZoning computation grid. B) Shaded-relief map on the grid showing the basement-surface component of the ShakeZoning model. C) Geotechnical shear-velocity map developed from the Clark County and Henderson projects. Higher velocities are shaded darker, with Vs30-meter velocities over 1.0 km/sec black. D) Map snapshot of wave propagation modeled from an LSM scenario, at 37.5 sec after earthquake initiation as Rayleigh waves enter Las Vegas Valley (LVV). E) Peak ground velocity (PGV) map resulting from this 0.1-Hz scenario, with greater shaking as lighter shading. For this scenario white area had greater than 1.2 cm/sec PGV.

We set up the example computation in the ShakeZoning tools to yield 0.1-Hz waves on a 236 NE-SW by 501 NW-SE by 41-node deep grid with a dh=dx=dy=dz

grid spacing of 0.5 km. The grid includes the LSM source zone near its NW end (star in figure 3D). A model of intrinsic seismic attenuation "Q" was developed following Olsen et al. (2003). For this historical earthquake the earthquake source parameters are provided by Smith et al. (2001). Source parameters for scenario earthquakes are derived from the USGS Qfaults database (USGS and CGS, 2010).

Figure 3D shows a snapshot of the wave propagation 37.5 seconds after the origin time of the earthquake. White modes in the basins show intensive horizontal shaking from waves trapped inside the low-velocity basin sediments. After 200 seconds of computed wave propagation on this grid, occupying a quad-core Intel CPU for a few hours, ShakeZoning produces a map showing the peak horizontal ground velocity (PGV) a the surface of the grid. (No topography is included.) Figure 3E shows the PGV map, with the LVV and surrounding basins getting much greater shaking than bedrock areas at similar distances from the earthquake.

RESULTS

Parcel Mapping. ReMi data from a total of 10721 sites were acquired, processed and submitted to CCDDS and the CoH. This represents more than 100% of the total number of seismic lines scheduled to be collected as part of this project. Figure 4 shows the microzonation map generated using ArcGIS and the Vs100-foot values determined from the distribution of seismic arrays. The method of kriging was used to produce this map.

Parallel "blind" tests were conducted at 93 randomly selected sites by O'Donnell. He analyzed and modeled the blind-test data independently of Optim SDS and NSHE. The blind-test Vs100-foot velocities were on average only 0.26% percent higher (5 ft/sec out of an average Vs100-foot of about 2000 ft/sec) than the velocities obtained at the same sites by Optim SDS. This tiny average difference shows that there was no significant systematic bias in the data analysis or modeling procedures. The root-mean-squared (RMS) difference between O'Donnell's blind analyses and Optim SDS's is 4.92% (98 ft/sec RMS difference). Only six of the 93 blind-test sites showed a difference with a magnitude greater than 10%, and the greatest difference was only 13.55%. These results show the consistent high quality of the Parcel Mapping measurements.

Caliche, a calcareous soil cement, is distributed across much of the Las Vegas region. The high-velocity caliche deposition within subsurface layers can result in high velocity layers within the velocity-depth profile, with lower velocity material below: velocity "reversals." An assumption is made that the soil is not varying greatly over the short distances considered, and that the caliche is developing in the same sedimentary layer within the section.

It is to be noted that, based purely on the Vs100-foot value, Site Class B values would be shown in the microzonation map (figure 4). IBC 2006 Section 1613.5.5 states that: "The rock categories, Site Classes A and B, shall not be used if there is more than 10 feet (3048 mm) of soil between the rock surface and the bottom of the spread footing or mat foundation." So, when the values suggest Class B, site-specific consideration should be made (depth of foundation, competency of rock etc.) before deciding whether it is a Site Class B. At most of the higher-velocity sites, our

shear-velocity profiles show more than 10 feet of low-velocity soil at the surface. Accordingly, we are suggesting a Site Class we call "C+" to describe these areas, denoted with dark gray in figure 4.

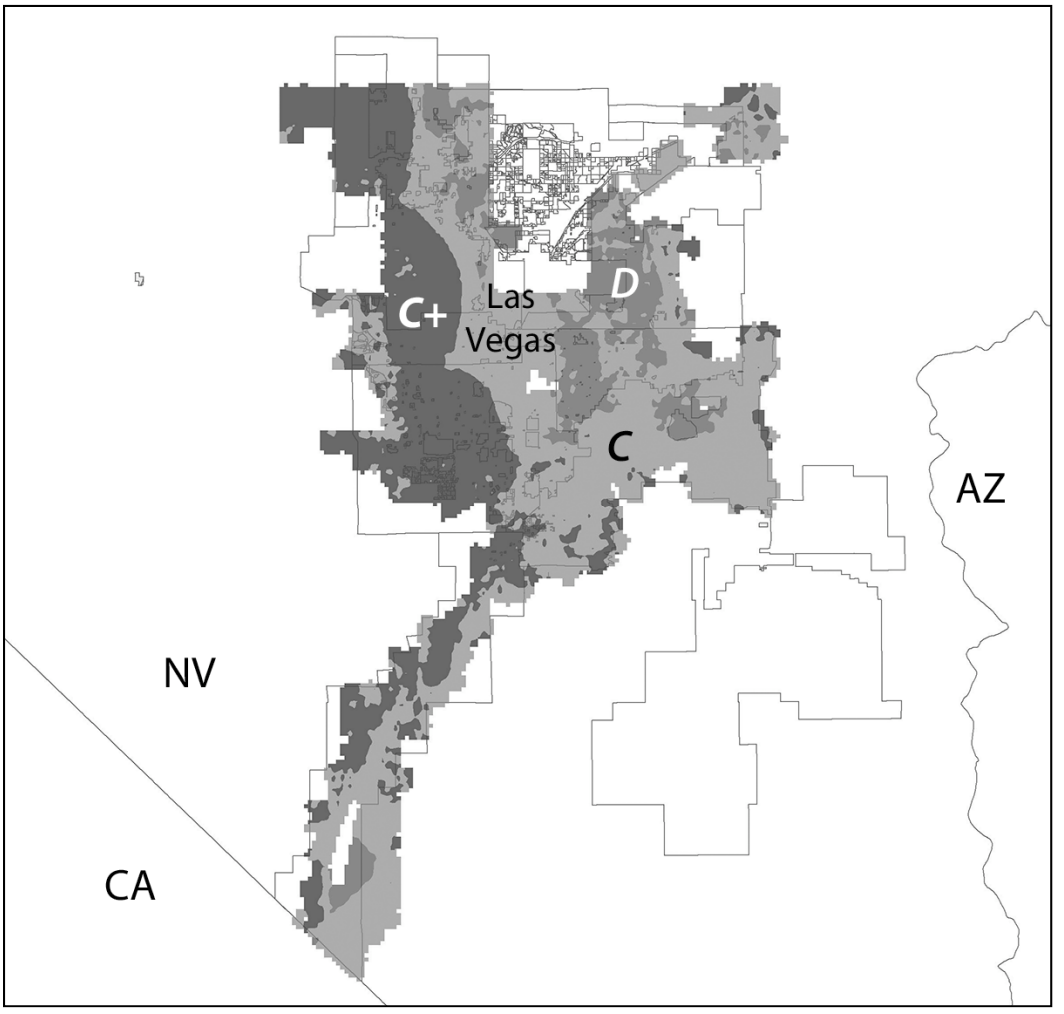

Figure 4. Map showing the IBC seismic zoning results of the Earthquake Parcel Mapping projects sponsored by Clark County and the City of Henderson. Black lines are municipal and state boundaries. The IBC "D" zone is medium gray; the IBC "C" zone is light gray; and the proposed IBC "C+" zone is dark gray.

The measured Parcel Map shows a clearly definable C+ to C boundary on the west side of Las Vegas Valley (dark to light gray in figure 4). The boundary may be associated with the bases of the alluvial fans emanating from the Spring Mountains, where the sediments become finer-grained (Scott et al., 2006). The C to D boundary (light to medium gray) is on the other hand much more complex, and difficult to associate with any known geological features.

Earthquake Ground-Shaking Prediction. The Little Skull Mountain earthquake scenario we show here is one possible example out of the eight additional faults in the USGS Qfaults database (2010) that the USGS National Hazard Maps

(Frankel et al., 1996) rate as probabilistically important to seismic shaking potential in Las Vegas Valley. We use the LSM scenario at 0.1 Hz here to demonstrate the crucial effects the Parcel Map results have on even low-frequency ground shaking in the Valley. Figure 5 shows this effect, unexpectedly strong given that the wavelengths of the 0.1-Hz waves modeled are 100 times larger than the 30-meter depth extent of the Parcel Map measurements.

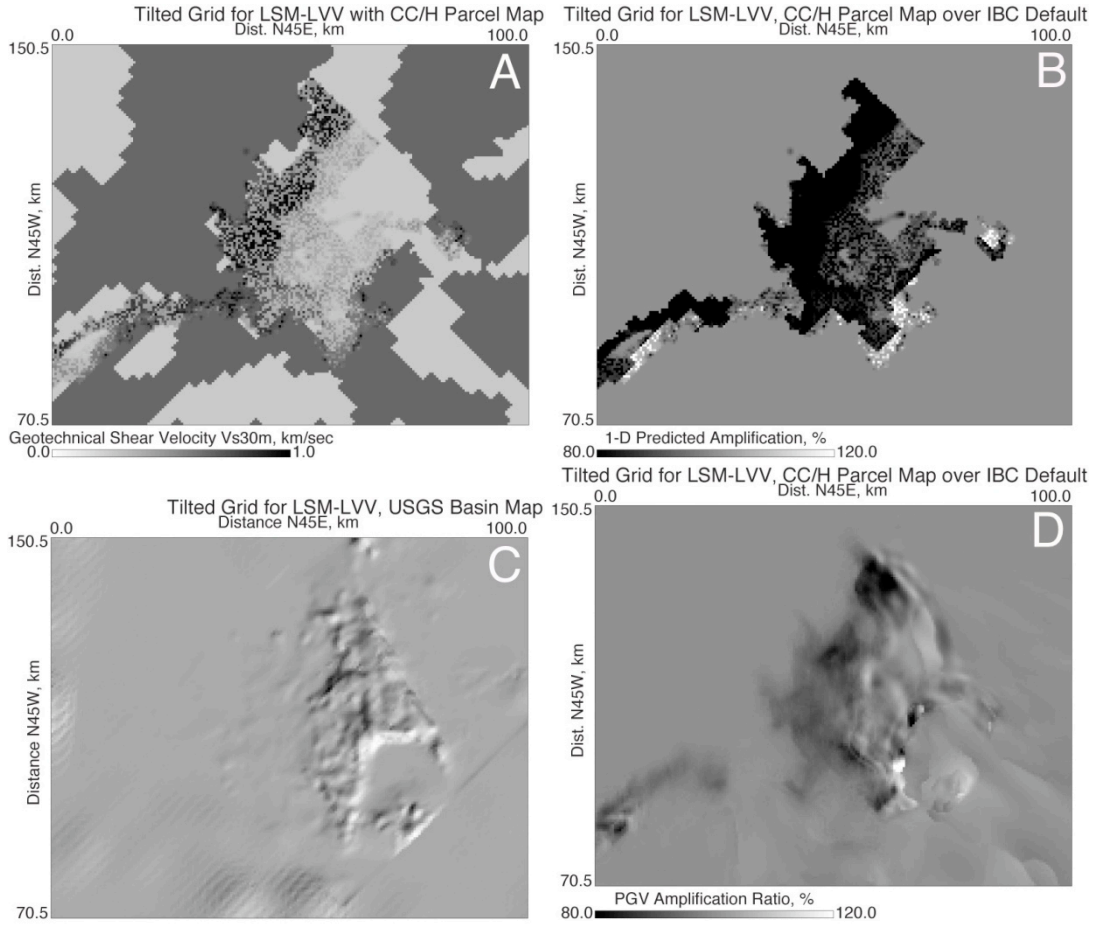

Figure 5. Maps of the Las Vegas Valley (LVV) section of the tilted LSM ShakeZoning scenario grid. A) Default geotechnical map with ~9000 Parcel Mapping Project Vs30-meter measurements included on top of the IBC defaults. B) Shaking amplification expected from the ratios of measured geotechnical velocities over the IBC default velocities, under a simple 1-d model. Amplification of 120% or more is shown as white, and de-amplification to 80% or less is black. C) LVV map showing the basin floor in shaded relief. D) ShakeZoning PGV ratio map comparing the 0.1-Hz results of the LSM scenario, comparing the Parcel Mapping result against the IBC default result. Even at these very low frequencies, 0.1 Hz, where the shallow geotechnical velocities should have minimal effect, comparing the physically correct ShakeZoning computation against the IBC defaults (D) shows surprisingly large and complex patterns of amplification (white) and de-amplification (black), greater than 20%.

At such long wavelengths the effects of the Vs30-meter variations found in the Parcel Map (figure 5A) should be minuscule. The amplifications (white) and de-amplifications (black) are predicted in figure 5B from the measured Vs30 relative to the IBC assumptions only, by the one-dimensional equations in the IBC Code (2006) and in ShakeMaps (Wald et al., 1999). The 1-d amplifications are up to 64% in figure 5B. These amplifications should only appear at much higher frequencies, above 1 Hz. The 0.1-Hz waves should respond mostly to the geologic basin, figure 5C.

However, figure 5D shows 0.1-Hz amplifications, relative to an IBC default geotechnical map, of up to 36%. The 30-meter-deep Parcel Map was the only variant between the two ratioed scenarios. This is from fully 3-d, physically and geologically accurate ShakeZoning computation. Further, the unexpectedly high amplification (white on figure 5D) is not located at either the location of the lowest Parcel Map velocities, nor at the greatest basin depth (nor steepest basin-floor slope). As well, the 64% de-amplifications (black) on the west side of the Valley predicted by the 1-d model in figure 5B are not supported by the realistic 3-d computations. This observation suggests that the current IBC may be too permissive in some higher-velocity areas.

DISCUSSION AND CONCLUSIONS

The Parcel Mapping project was completed successfully for Clark County and the City of Henderson. In all, 10721 individual seismic arrays/lines were assigned, deployed and spatially located in a systematic manner, maximizing the density of the database coverage within urban Clark County. This achievement has put southern Nevada at the forefront of earthquake-hazard mitigation efforts worldwide.

Based on the GIS seismic shear-velocity database developed by NSHE and Optim SDS, the project provides Clark County and the City of Henderson a single shear-wave velocity-based Parcel Map with contoured values corresponding to the site classifications of the IBC and NEHRP definitions for site class. Velocity databases from the CCDDS and the CoH were integrated into a single Vs database and the interpolated velocity map was based on the entire joint database, providing seamless interpolation across the CCDDS and CoH boundaries. This Parcel Map will provide city planners, building officials, design professionals, and researchers alike the opportunity to determine the actual site class value of a particular parcel before a single site-specific investigation is performed.

We show the Parcel Map to be essential for the accurate prediction of earthquake ground shaking across Las Vegas Valley, even at low frequencies that are of interest mostly to the taller buildings in the area. Additional scenario computations are under development, for the eight dangerous earthquake faults in the region, and for higher wave frequencies, up to 1 Hz. The newly accurate ShakeZoning tools developed in this effort will be made available to aid engineers and planners in the region.

Design of the New Mike O'Callaghan Pat Tillman Memorial Bridge at Hoover Dam

David Goodyear, PE, SE, PEng [1]

[1] Chief Bridge Engineer, T. Y. Lin International

Summary

A dramatic new concrete arch joins the setting of the historic Hoover Dam, spanning the Black Canyon between the States of Arizona and Nevada, USA. This 1060 foot (323 m) long arch span is the 4th longest concrete arch in the world, and the longest in the United States. The scale of concrete construction for the bridge is impressive. Four form travelers advanced to the crown of the cast-in-place arch supported by 88 carefully tuned stay cables, while precast segmental construction was used for the tallest precast columns erected to date.

Introduction

A project team of five US government agencies, lead by the Central Federal Lands office of the Federal Highway Administration (CFL-FHWA) collaborated to develop a highway bypass to the existing US93 roadway over the historic Hoover Dam, shown in Fig 1. The existing highway route 93 over the Dam mixed the throng of tourists for whom the Dam is a scenic destination with heavy highway traffic and commercial trucking mixing with pedestrian traffic and crosswalks. The blend of these two created hazard and hardship for both, and served as a bottleneck for commerce along the major north-south route of US93.

Figure 1 (photo by HST)

The Hoover Dam Bypass Project had a decades long history of planning and process. First discussed in the mid 1960's, plans for a highway crossing of the Colorado River were advanced by the US Bureau of Reclamation to address the increasing highway traffic across the top of Hoover Dam. A series of studies ensued, sponsored by several of the project stakeholders throughout the next two decades. In 1997 FHWA Central Federal Lands Division (CFL) became the lead agency for the Project Management Team comprised of the Bureau of Reclamation, Arizona DOT, Nevada DOT, National Park Service and Federal Highway Administration. The project then advanced through the Draft Environmental Impact Statement, Final Environmental Impact Statement and Record of Decision leading to commissioning the project.

General Project Development

A consortium of firms working under the moniker of HST (HDR, Sverdrup, and T.Y. Lin International) teamed with specialty sub-consultants to deliver the design for the 4-mile long bypass project. HDR was the project manager and led the design of the Nevada approaches. Sverdrup (now Jacobs) led the design of the Arizona approaches. T.Y. Lin International led the design of the new Colorado River Bridge.

Bridge Type Screening Process

With the selection of an alignment so close to Hoover Dam, the new bridge would be a prominent feature within the Hoover Dam Historic District, sharing the view-shed with one of the most famous engineering landmarks in the US. The environmental document set a design goal to minimize the height of the new bridge crossing on the horizon, both from the Dam and from a boater's view on Lake Mead. The State Historic Preservation Officers for both Nevada and Arizona – both members of the Design Advisory Panel – emphasized the need to complement and not compete with the architecture of the Dam. The Design Advisory Panel helped establish the mission for the bridge design, which was to "...strive for engineering excellence in the design of today that honors the engineering excellence that went into the Dam in its day" (HDB Design Advisory Panel, 2002).

The typical design approach for a project of this significance would be to conduct a comprehensive type study of all candidate bridge types, carrying design to a level that would permit architectural and economic evaluations of each type. However, since the Hoover Dam Bypass had been studied in one form or another for over 25 years, CFL decided to use previous information developed for prior studies along with new information developed by the design team in an initial Type Screening Process – as a precursor to the type study. This Type Screening process was developed to consider policy-level criteria as a first litmus test on bridge types that should proceed to a more formal type study.

Figure 2 (rendering by TYLI)

Figure 3 (rendering by TYLI)

The Project advanced a full suite of bridge types applicable for a 1000 ft+ span range. Of particular note by all the reviewers was the separation of alternatives. The two most favored options were the natural design choices fitting the site – to span the canyon, or to arch against the canyon walls. The clear spanning suspension option (Fig. 2) was significantly handicapped at the time of this type evaluation in terms of structural vulnerability (time frame was soon after 9/11), first cost and maintenance cost. While being one of the more architecturally alluring options, the suspension span was seen as both the highest life-cycle cost option and the most vulnerable design type, which was a special concern for the Agencies who would soon be maintaining the bridge. As a result of this screening process, the type study proceeded with only deck arch options (Fig. 3).

Type Study

At the time of the type study, detailed geotechnical engineering had just begun. The topography on the Nevada side of the canyon (Fig. 4) included a massive outcropping of rock below the US93 switchback, with a fault line running between this block and the canyon slope behind. Without detailed geotechnical and mapping information, we could not confirm the suitability of the short block as a foundation. Therefore, the type study progressed in parallel with geotechnical exploration assuming either of two different arch spans could be selected; a short span of 1060 ft (323 m) or a longer span of 1325 ft (404 m).

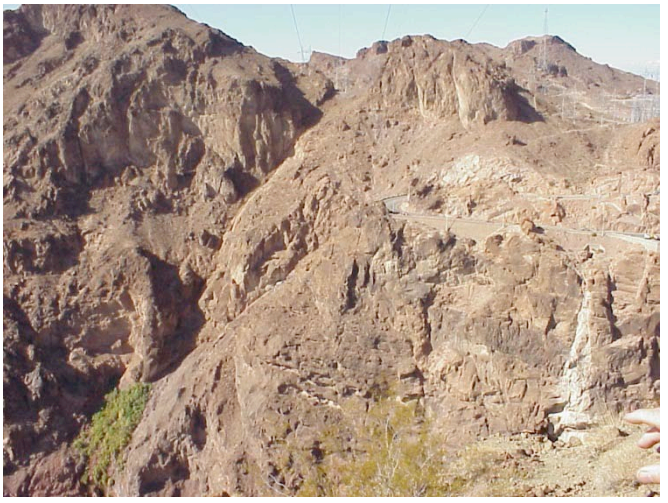

Figure 4 (photo by TYLI)

The family of arch designs (Fig. 5) was reviewed based on architectural and technical criteria. The Design Advisory Panel expressed a desire for simplicity, and rejected any notion of ornamentation or art-decco designs that competed with features on the Dam. Six designs were developed - 3 each for the long and short spans - to the point where general quantities and construction methods could be established for review.

Figure 5

The consensus decision to proceed with the concrete composite alternative was made by the Executive Committee, comprised of the operations chiefs from the 5 Agencies on the Project Management Team.

Major Design Features

The final design is an evolution of engineering considerations, creating a form dictated by efficient resistance to the engineering demands on the structure. Every element of the twin rib framed structure shown in Fig 6 is a product of engineering reasoning.

Figure 6 (rendering by TYLI)

The Arch

At the outset of design the initial seismic hazards evaluation and geophysical analysis of the site led us to believe that earthquake could control the lateral design of the bridge. The twin rib configuration with connecting struts was developed first as a ductile frame for lateral loads, following the successful development of the shear linked tower concept by the Designer for a San Francisco Bay Bridge. A single arch rib would leave no opportunity for tuning stiffness or for providing for frame ductility, whereas twin ribs could provide an excellent means of creating ductile Vierendeel links that could otherwise protect the gravity system of the arch. This ductile frame would allow the concentration of ductility demand in the connecting shear links, rather than in the main arch rib members.

At the time of preliminary design, the current Guide Specification for Seismic Design was in the early stages of development, and the AASHTO design event for the site was a .10g 500 year event. A project specific probabilistic seismic hazards analysis was conducted by AMEC in order to assess the range of ground motion associated with return periods more appropriate for this design. A 1000 year return period was selected (that same return period was later selected by AASHTO for the new Guide Spec), resulting in a design basis PGA of .2g.

Wind was a major environmental loading condition from the outset of design. It played a qualitative role in the type selection, and a key role in design. The unique topography was recognized as a feature requiring special studies. During the preliminary design phase, a site wind study was conducted by West Wind Laboratories to correlate the wind speeds at the bridge site with those at the Las Vegas Airport NOAA station in the valley. With this correlation and a model evaluation of the local terrain effects (Fig. 7), the long term statistics from the Airport were used to develop site wind speeds for design. As a result of this study, the 3 second wind speed was raised

Figure 7

to 56 m/sec, up from the ASCE-7 standard of 40 m/sec. Dynamic studies resulted in a gust loading factor of 2.4 (against mean hourly), which collectively resulted in wind controlling the lateral forces design. Chamfers for the main arch rib were introduced both to control vortex shedding and reduce design-controlling drag forces on the arch. Chamfers were added to the tall columns to control vortex-shedding vibrations observed in the wind tunnel. Wind recordings continued throughout construction, establishing a more complete on-site record. The forecasts produced by West Wind Laboratories based on the NOAA correlation were tested according to the methods of Scanlon based on 4 years of continuous on site record. These records confirmed the accuracy of the initial wind studies conducted with only 6 months of site data.

The 10,000 psi (69 MPa) concrete arch was an efficient element for gravity loads in its final form. There were two aspects of design that favored a twin rib layout instead of the typical single box section for this arch. The first was the seismic framing system noted above. The second was one of practical construction for the open arch section as it cantilevered during construction. A single box would be almost 65 ft (20 m) wide, and weigh approximately 20 kips per ft (292 KN/m). This section size would rule out a precast segmental option. It is for both of these reasons that a twin rib arch framing system was selected (Fig. 8).

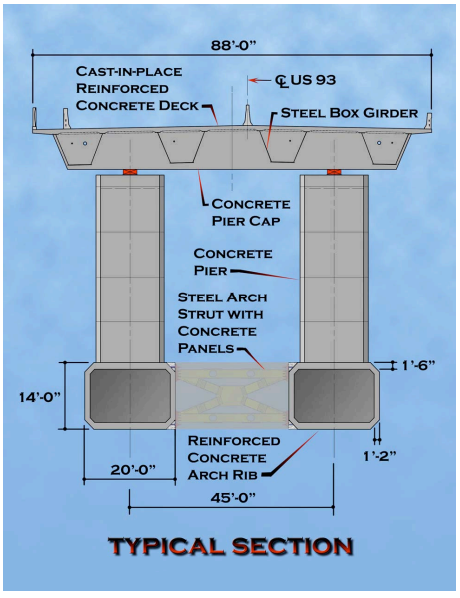

Figure 8

Spandrel Framing

The composite superstructure was selected for speed of erection and to lower weight on the arch. The spacing of spandrels was an extension of the erection concept to erect the bridge using a highline crane system. Above 50 tons, there is a jump in highline cost, so the decision was made to target a 50 ton capacity for major superstructure elements. The span was set in the range that a highline crane could deliver the steel box sections, which resulted in a nominal 120 ft (36.5 m) span. This same span also allows steel girders to be set within the range of most conventional cranes, should an alternative erection system be selected.

One of the many lessons from the smaller Crooked River Arch Bridge in Oregon was that spandrel construction and integral crown construction was very time consuming and expensive. The high rise of the Hoover arch added to the focus on construction of the spandrels, since the height of these columns would exceed what had been built in past segmental structures. Lateral bracing was a system design consideration, affecting the arch, spandrel and approach columns. Bracing for the arch is affected by deck stiffness and continuity conditions in the deck and columns.

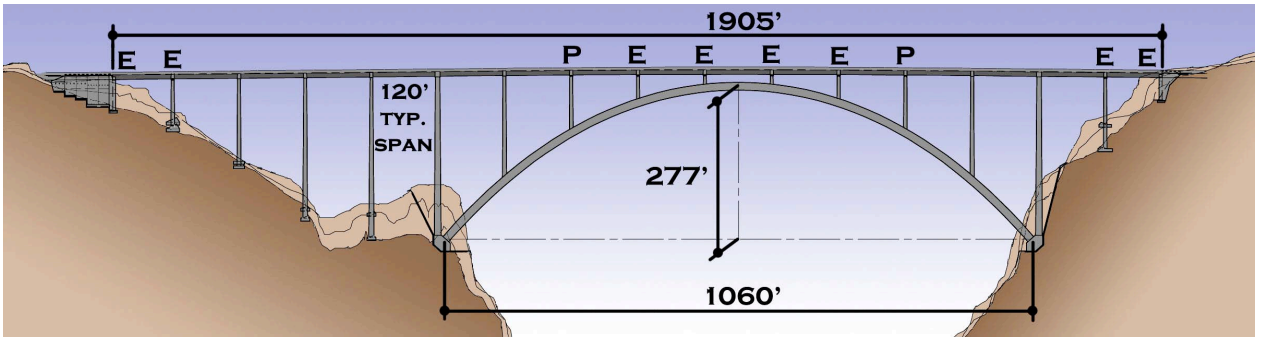

Figure 9

An open arch crown was selected as the best balance for constructability and consistency with the composite deck system. A special consideration for the visual presentation of the short span arch was that the composite steel deck would result in a very abrupt, mechanical looking connection at the crown if an integral crown was selected, due in large part to the high rise of the arch. When studied in either concrete or steel, an integral crown solution for the short span alternatives looked blocky and massive at the crown, and ran counter to the architectural goal of lightness and openness when viewed from Lake Mead. Once selected as an open crown, the statical system included sliding bearings for the short, stiff piers over the arch crown and similar piers near the abutments. This was necessary due to the large secondary moments developed in these piers from creep deflections of the arch. Bearings were also helpful in producing a more even distribution of longitudinal seismic forces among the piers.

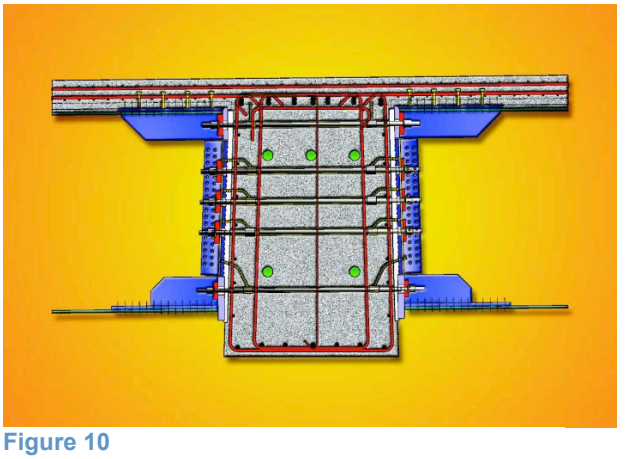

Figure 10

Integral pier caps (Fig. 10) were designed as part of a continuous deck/diaphragm system used for lateral and longitudinal bracing of the columns. Integral concrete pier caps were selected over steel box cap sections to avoid the fracture-critical design and inspection considerations for a steel cap. The integral cap framing was selected to develop the diaphragm action of the deck used to avoid lateral bracing of the spandrel columns and to provide for stability of the flexible columns along station through direct diaphragm action.

Construction Methods

As with any large bridge structure, the dead load design is dominated by the assumptions of a construction scheme. The concrete arch needs little reinforcing for the final closed arch configuration, operating primarily in compression. However prior to closing at the crown, the arch rib is a cantilever box girder. Since post-tensioning has no purpose for the final configuration of the arch, design was based on a conventionally reinforced concrete box for cantilevering conditions. Design for construction was based on allowable stresses in reinforcing

and associated crack controls according to the AASHTO code, eliminating the need for temporary or permanent post-tensioning.

The typical approach in the US is to nominate an erection scheme, but to show it only schematically, and defer responsibility for both the scheme and the details to the contractor. The design management team believed that more informed bids could be developed if there was a more complete erection scheme shown with the plans, even if the contractors elected to use alternative methods. Therefore, the decision was made to show a complete erection scheme for dead load on the plans and allow the contractor to use that scheme or his own.

There are at least two practical erection methods that can be used to erect a cantilevered arch. One is a simple cable-stayed cantilever erection (Fig. 11). The second is the use of temporary stay truss diagonals, erecting the arch, deck and spandrels as a cantilever truss (Fig. 12). In selecting the simple cast-in-place stayed method, we opted for the most conservative method in

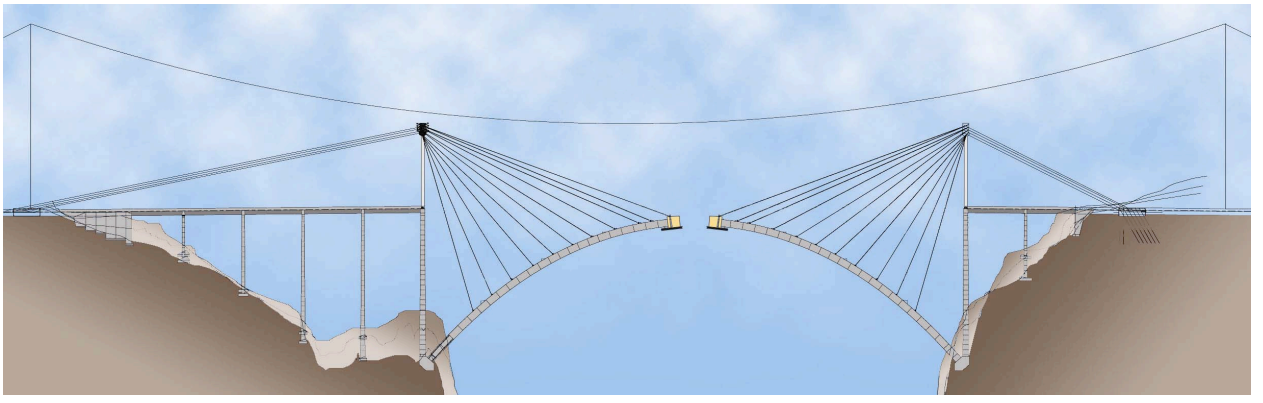

Figure 11

that arch geometry can be controlled and corrected at each step of construction with stays and traveler settings. In addition, this method allows the most flexibility for closing the arch without affecting the geometry of columns and deck (since they are not in place until after closure).

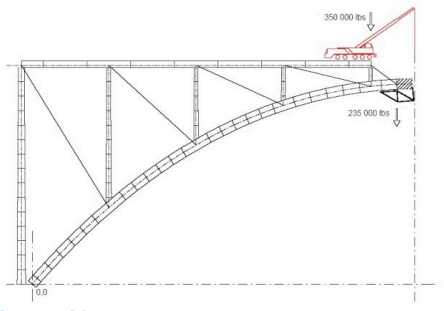

Figure 12

Both precast and cast-in-place methods were permitted for the arch and spandrel columns. The contract was written to allow alternative methods of erection, however both the arch and the columns each were to be of a single type (precast or cast in place) in order to conform to the time dependent assumptions inherent in design. All equipment and ancillary temporary works were also to be designed by the contractor.

Construction

The construction contract was awarded in September of 2004 to Obayashi-PSM, JV, after about a year delay in the funding process. A limited notice to proceed was issued for November, 2004, with full field work beginning in 2005.

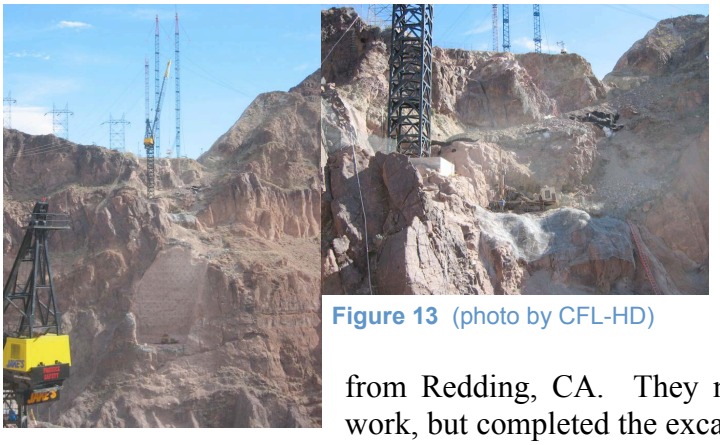

Figure 13 (photo by CFL-HD)

The first challenge for the construction team was creating a foothold for foundation construction (Figs 13, 14). Climbing on the side of the cliff 800 feet over the river below was difficult enough, but excavating (and doing so within the loss limits in the specification) was a considerable challenge. The subcontractor who met this challenge was Ladd Construction from Redding, CA. They not only met the tight schedule for this work, but completed the excavation allowing about half of the rockfall into the river that was permitted.

Initial bridge construction began on site with footing and abutment work, and in the precast yard outside of Boulder City where the contractor set up their own precasting facility and self-performed the precasting. Column sections were trucked to the site as needed for erection, and set into place using both the high-line crane and conventional cranes located at the hairpin in Nevada (Fig. 14, 15).

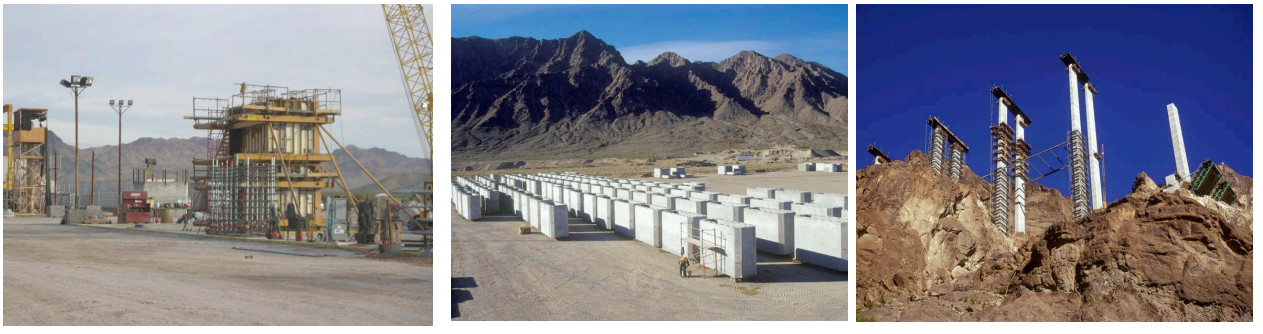

Figure 14 (photo by CFL-HD)

Figure 15 (photo by CFL-HD)

In September, 2006, the high line crane was lost in a strong wind, removing the high line crane from service. The contractor mobilized additional land cranes to continue construction in Nevada, and an S-70 derrick in Arizona (Fig. 16), to both complete approach columns and set approach steel box girders until a new high line could be design, fabricated and erected. Arch Erection was being initiated at the time of the high line crane collapse. The temporary cranes were able to service

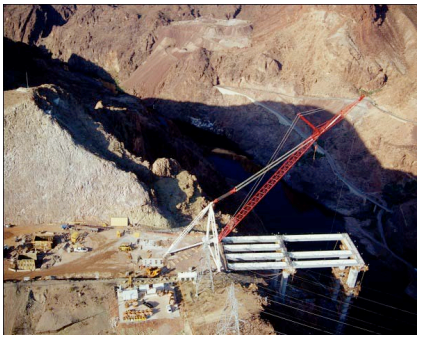

Figure 16 (photo by CFL-HD)

the first few arch segments from the springing, allowing the piece work for the starters and the initial setup of the form travelers to proceed.

Four form traveler headings were used for erection of the arch. Every second arch segment was supported by a temporary stay cable. After erection of the new high line and restarting the main arch erection, the contractor reached a reliable cycle of 2 weeks, and often bested that cycle on segments that did not have a stay cable to install. The arch was closed in August of 2009 within an impressive ¾ inch (19mm) tolerance at closure (Fig. 17).

Figure 17 (photo by CFL-HD)

While the arch construction was the more dramatic effort, construction of the spandrel columns (Fig. 18) and deck structure was just as challenging from a construction standpoint. As the spandrels and deck superstructure are set on the arch, the arch deflects. Staging of the spandrel column erection, column cap construction and box girder placement had to be engineered to achieve final geometry. The contractor was continually monitoring and analyzing the response of the structure as each spandrel column and cap was placed, updating his forecast of geometry throughout the erection process.

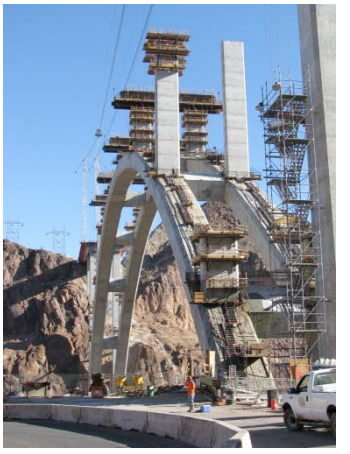

Figure 18 (photo by TYLI)

The assumption during design was that the arch, spandrels and deck would each be completed in series. The contractor decided to complete these tasks in parallel in order to shorten the construction schedule. Deflections were not limited to those from the spandrel columns and caps, but now included the superstructure loads and thermal effects of the steel box girders as they were placed in the partially completed frame. All of this sequence was analyzed in real time by the contractor in the field.

Figure 19 (photo by CFL-HD)

Demobilization of the high line and related temporary works was a project in itself, and had to be completed before final paving and finishing could be completed for the roadway. Bridge construction was essentially completed by August, 2010 (Fig. 19).

The new Colorado River Crossing now frames the view of Black Canyon from Hoover Dam for the coming generations of tourists, and is the cornerstone in a new,

efficient highway system funneling commercial traffic between the States of Nevada and Arizona. The project reflects the skill and determination of the people who built it, all of whom take pride in their accomplishment.

The new bridge has been dedicated as the Mike O'Callaghan Pat Tillman Memorial Bridge in memory of two heroes of the US armed forced from the States of Nevada and Arizona.

Evaluation of Concrete Shear Strength for FRP Reinforced Beams

M. Zeidan[1], M. A. Barakat[2], Z. Mahmoud[2], A. Khalifa[2]

[1] Civil and Environmental Engineering Department, University of Nevada, Las Vegas, 4505 S. Maryland Parkway, Las Vegas, NV 89154-4015.

ABSTRACT

In order to expand the use of FRP in new structures, a satisfactory degree of understanding is required for the behavior of members reinforced with FRP rebars. The aim of the current study is to investigate the concrete contribution to shear strength for beams reinforced with FRP longitudinal bars. A review for the available test results for members reinforced with FRP longitudinal bars without shear reinforcement results a database of specimens from different researchers. The available equations for predicting the value of the concrete shear strength for FRP reinforced members were also collected.

An experimental test program was conducted to verify the results for beams with low longitudinal reinforcement ratios. A comparison was made between the experimental results and the shear strengths calculated using the different available equations. Based on the comparison and the experimental program results, the equation adopted by Building Research Institute (BRI)-Japan was found to fit best with the experimental results.

INTRODUCTION

Deterioration of reinforced concrete structures has become a serious problem in the last decades due to the corrosion of steel bars. An alternative type of reinforcement as fiber-reinforced polymers (FRP) is considered to be one of the solutions for the corrosion problem. During the last decade serious efforts were made to use FRP materials in construction industry. Behavior and strength of concrete members depend primarily on the characteristics of concrete and reinforcement. Shear strength of concrete members is influenced by important parameters which significantly affect the design and structural detailing. Extensive studies have been reported for the shear strength of members reinforced with steel; however limited studies were made for shear strength of beams reinforced with FRP. This paper provides a research program conducted to evaluate shear strength of beams reinforced with longitudinal FRP bars without shear reinforcement. The parameters affecting concrete shear strength were carefully selected to fill a gap in the available range of studied parameters available in literature. The design guidelines for concrete members reinforced with FRP bars were also discussed.

RESEARCH SIGNIFICACE

The conducted analytical and experimental investigations concerning the concrete contribution to shear strength of FRP reinforced members, concluded that the shear strength of members reinforced with FRP can be predicted using the proposed equation. This information is valuable for designers and for the development of design guidelines and codes related to concrete structures reinforced with FRP.

EXPERIMENTAL DATA AND DESIGN EQUATIONS

The concrete contribution to shear strength of concrete beams reinforced with FRP bars as longitudinal reinforcement has been evaluated by many researchers as a part of the total shear strength of concrete beams. On the other hand, few researchers tried to evaluate the shear strength of FRP longitudinally reinforced concrete members without web reinforcement. Test results for the studies concerning the concrete shear strength of concrete beams reinforced with FRP bars are reported in this section. Also, equations proposed by different studies and design codes to evaluate the concrete shear strength in this case are presented and compared with the available experimental results and a discussion of the comparison is introduced.

Experimental Data

In order to assess the validity of the equations used to evaluate the concrete shear strength of members reinforced with FRP bars (V_{cf}), a database of 60 specimens was made from collected experimental data. This database is formed of concrete specimens experienced shear failure including concrete beams without stirrups and one-way slabs. These specimens were tested by 13 different researchers (Alkhajardi *et al.* 2001, Duranovic *et al.* 1997, El-Sayed *et al.*2006, Gross *et al.* 2004 Michaluk *et al.* 1998, Nagasaka *et al.* 1993, Razaqpur *et al.* 2004, Tariq and Newhook 2003, Tottori and Wakui 1993, Tureyen and Frosch 2002, Vijay *et al.* 1996, Yost *et al.* 2001 and Zhao *et al.* 1995). The database included specimens having different cross section dimensions, longitudinal reinforcement ratios, concrete strengths and types of reinforcement. The shear span to depth ratio of the specimens included in the database ranged between 1.78 for the shortest beam and 12.5 for the one-way slabs. The longitudinal reinforcement ratios ranged between 0.25% and 3.03% for all specimens. The compressive strength of concretes used for the specimens varied between 23 MPa and 82 MPa. The FRP longitudinal reinforcement used for the specimens was of aramid (AFRP), glass (GFRP) and carbon (GFRP) fibers with modulus of elasticity (E_f) ranging between 38 and 145 GPa.

Available Equations and Design Recommendations

Some of the available equations for evaluating the concrete shear strength of concrete members longitudinally reinforced with FRP bars are presented herein. These equations were proposed by researchers or stated by design recommendations.

Tottori and Wakui (1993) expressed the shear capacity of concrete beams without shear reinforcement V_{cf} as the larger of V_{cf1} and V_{cf2}, given as follows:

$$V_{cf1} = 0.20 (f'_c)^{1/3} (\rho_f^*)^{1/3} (1000/d)^{1/4} \left[0.75 + 1.4/(a/d) \right] bd \qquad \text{(1-a)}$$

$$V_{cf2} = 0.244 (f'_c)^{2/3} (1 + \sqrt{\rho_f^*}) \frac{[1 + 3.33(r/d)]}{[1 + (a/d)^2]} bd \qquad \text{(1-b)}$$

Where $\rho_f^* = \rho_f (E_f / E_s)$

Zhao *et al.* (1995) used the following expression to predict the concrete contribution (V_{cf}):

$$V_{cf} = 0.20 (1 + \beta_p + \beta_d) \left[0.75 + 1.4/(a/d) \right] (f'_c)^{1/3} bd \qquad \text{(2)}$$

Where $\beta_p = (100 \rho_f^*)^{1/2} - 1 \qquad \leq 0.73$

$\beta_d = (1000/d)^{1/4} - 1$

Tureyen and Frosch (2003) proposed a design equation to calculate shear strength provided by concrete for members reinforced by either steel or FRP. Also, this equation was adopted by ACI-440 committee starting from 2006 recommendations. The equation can be expressed as follows:

$$V_{cf} = 0.415 \sqrt{f'_c}\ bc \qquad \text{(3)}$$

Where $c = kd$ = neutral axis depth of cracked transformed section;

$k = \sqrt{2\rho n + (\rho n)^2} - \rho n$;

ρ = longitudinal reinforcement ratio;

$n = E_r / E_c$ = modular ratio;

E_r = modulus of elasticity of reinforcement;

Razaqpur and Isgor (2006) proposed a shear design equation for calculating the shear strength of FRP-reinforced members without stirrups. The equation can be expressed as follows:

$$V_{cf} = 0.035 k_m k_s k_a (1 + k_r) \sqrt{f'_c}\, bd \quad \leq 0.2 k_s \sqrt{f'_c}\, bd \qquad \text{(3)}$$

Where $k_m = \left(\frac{V_F d}{M_F} \right)^{2/3} \qquad k_r = (\rho_f E_f)^{1/3}$

$k_a = 1.0$ for $\frac{M_F}{V_F d} \geq 2.5$,

$= \frac{2.5}{(M_F / V_F d)} \leq 2.5$ for $\frac{M_F}{V_F d} < 2.5$

And $k_s = 1.0$ for $d \le 300\ mm$,

$= \dfrac{750}{450 + d}$ for $d > 300\ mm$

The American Concrete Institute (ACI) guide for the design and construction of concrete members reinforced with FRP bars (ACI 440) proposed an equation on its earlier version (2001 and 2003) to calculate the concrete shear strength as follows:

$$V_{cf} = \frac{\rho_f E_f}{90\beta_1 f_c'} V_c \qquad \le V_c \tag{4}$$

Where V_c is the shear strength calculated according to ACI 318 code for steel reinforced concrete. It can be noticed that for this equation the concrete shear strength is surprisingly inversely proportional to the square root of the concrete compressive strength ($\sqrt{f_c'}$), as V_c is directly proportional to $\sqrt{f_c'}$.

The Japanese Society of Civil Engineers (JSCE) recommendations for design and construction of concrete structures using FRP adopted two different shear design methods for members reinforced longitudinally and transversely with FRP bars.

Method 1: In this method the shear strength of members longitudinally reinforced with FRP bars and without shear reinforcement (V_{cf}) is given by:

$$V_{cf} = \beta_d \beta_p \beta_n f_{vcd} bd / \gamma_b \tag{4}$$

$$f_{vcd} = 0.2(f'_{cd})^{1/3}$$

$$\beta_d = (1000/d)^{1/4} \qquad \le 1.5$$

$$\beta_p = (100\,\rho_f E_f / E_s)^{1/3} \qquad \le 1.5$$

$$\beta_n = 1 + M_o / M_d \qquad for \quad N_d \ge 0$$

$$\beta_n = 1 + 2M_o / M_d \qquad for \quad N_d < 0$$

β_n should be within the limits: $1 \le \beta_n \le 2.0$

where: γ_b is the member safety factor = 1.3

Method 2: In this method, the shear strength of members longitudinally reinforced with FRP bars and without shear reinforcement (V_{cf}) is given by:

$$V_{cf} = \beta_{pEo} \beta_d (f'_{cd})^{1/3} (h - x) b / \gamma_b \tag{7}$$

Where: $\beta_d = (1000/d)^{1/4} \qquad \le \ 1.5$

$$\beta_{pEo} = 0.17\left(\frac{\rho_f E_f}{5000} + 0.66\right) \qquad \le \ 0.28$$

In Japanese Building Research Institute BRI recommendations for design of concrete structures using FRP, the concrete contribution to shear strength (V_{cf}) is given by (as quoted from Sonobe *et al. 1997)*:

$$V_{cf} = 0.08\left[\frac{k_u k'_p (f'_c + 18)}{M/Vd + 0.12}\right] bd \qquad (8)$$

Where: k_u is a correction coefficient = 0.72 for $d \geq 400$ mm
= 1.0 otherwise
k'_p is an equivalent correction coefficient = $0.82\ (100\ \rho_f E_f / E_s)^{0.23}$

EXPERIMENTAL PROGRAM

It was noticed that the available experimental testing data included in the collected database does not include beams with small reinforcement ratio. Among the 60 specimens included in the database, only 2 specimens had reinforcement ratio (ρ_f) less than the balanced reinforcement ratio (ρ_{fbal}). Therefore an experimental test program is conducted to cover this gap .The test program consists of seven beams reinforced with CFRP bars as longitudinal reinforcement, but without stirrups. The specimens were designed to evaluate the shear strength of these concrete beams. The dimensions, details of the test specimens and loading pattern are shown in Figure 1. As shown in the figure, no transverse reinforcement was used within the span of the beams, but only at the overhanging ends in order to improve anchorage.

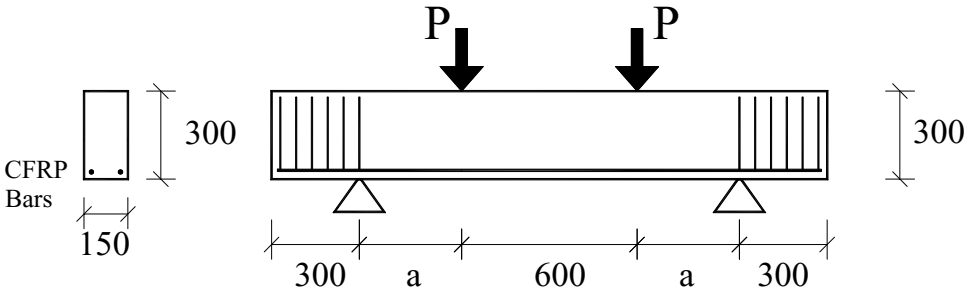

Figure 1. Test specimen details and dimensions.

The tested parameters included in this study were the longitudinal reinforcement ratio, the shear span to depth ratio and the concrete compressive strength. Table 1 presents the dimensions, reinforcement and the considered parameters of each specimen. All the tested beams were simply supported having a rectangular concrete cross section (150×300 mm), an effective depth 280mm, and different spans to match the required shear span to depth ratio (a/d). The beams were designed to have a shear failure prior to flexure failure. CFRP bars of diameter 7.5 mm were used as longitudinal reinforcement for all the tested beams. The modulus of elasticity (Ef) of the used bars was experimentally evaluated to be 148 GPa, while its ultimate strength (ffu) was reported by the manufacturer to be 2840 MPa. In order to investigate the effect of concrete strength, 2 values of fc' were targeted 24 and 48 MPa. The exact concrete strength were determined for each specimen was determined by testing concrete cylinders at the same day of beam testing as shown in Table 1.

Table 1. Dimensions and reinforcement of the tested specimens.

Specimen	*Reinforcement*		f_c' *	*Shear span (a)*	*a/d*
	No. of Bars	(ρ_f) %	*(MPa)*	*(mm)*	
A-I-2.5	1	0.105	24	700	2.5
A-II-1.25	1	0.105	48	350	1.25
A-II-2.5	1	0.105	45	700	2.5
A-II-5.0	1	0.105	49	1400	5.0
B-I-2.5	2	0.210	28	700	2.5
B-II-1.25	2	0.210	54	350	1.25
B-II-2.5	2	0.210	46	700	2.5

* The shown values are the average of the concrete strength for the concrete cylinders tested for each specimen.

Test Setup and Measurements

All the beams were tested up to failure using two concentrated loads 0.6 m apart. The deflection of each tested beam was measured using 3 dial gages one at the mid-span, and one at middle of each shear span. The strains in the longitudinal FRP bars and at the upper surface of the concrete beams were measured at the mid-span using electrical strain gauges. Figure 2 shows the loading setup of the specimens. The load was applied incrementally using hydraulic jack of maximum capacity of 300 kN and was monitored using an electrical load cell. At every load increment the initiation and propagation of cracks were marked; the deflection, concrete strain, reinforcement strain and crack widths were also measured and recorded.

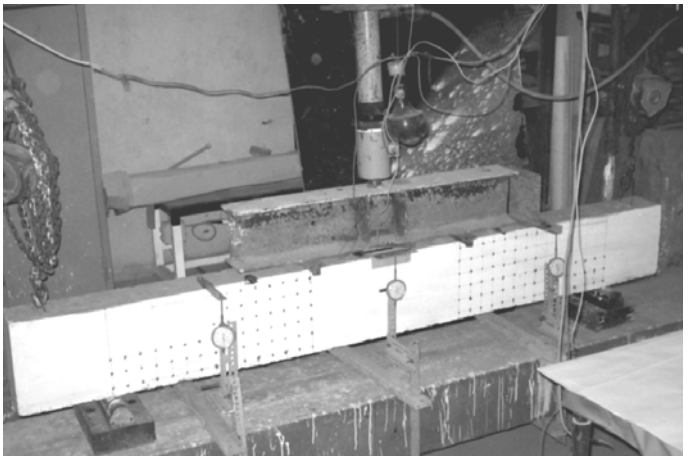

Figure 2. Test setup for the specimens

TEST RESULTS AND ANALYSIS

Table 2 shows the failure loads, and modes of failure for the tested beams in addition to the ratio between the predicted shear strength using BRI equation (Eq.8) and the experimental failure load. For all the tested beams, vertical flexural cracks

were observed in the region of the constant moment at the early stages of loading. With further increase in load, the flexural cracks propagated vertically upwards, and additional cracks were formed in the shear span. All the tested beams failed in shear except specimens A-II-1.25 and B-II-1.25 which have the smallest shear span to depth ratio. Also beam B-I-2.5 unexpectedly failed in flexure. In absence of stirrups, the shear failure of the beams was sudden and no slip of flexural reinforcement was observed during beam testing. Figure 3 shows the failure pattern of the 7 tested beams.

Table 2. Failure loads and cracking loads of the tested specimens.

Specimen	Calculation			Experimental		*Failure Mode*
	$*P_f$ kN	$**P_V$ kN	P_f / P_V	$P_{cracking}$ kN	P_{ult} kN	
A-II-1.25	96.53	64.30	1.50	20.00	92.50	Flexural
A-II-2.5	48.14	32.09	1.50	10.00	22.50	Shear
A-II-5.0	24.15	17.46	1.38	5.00	12.50	Shear
B-II-1.25	157.14	83.41	1.88	17.50	102.50	Flexural
B-II-2.5	74.71	38.77	1.93	8.75	27.50	Shear
A-I-2.5	41.18	21.39	1.93	10.00	22.50	Shear
B-I-2.5	60.18	27.87	2.16	7.50	51.25	Flexural

* The calculated flexural moment capacity.

** The shear strength is calculated using BRI equation (Eq. 8).

Figure 4 shows the relationship between the mid-span and mid-shear span deflections and the load (P) for beam A-II-2.5 which is typical for other beams. On the other hand, Figure 5 shows the relationship between the load (P) and the strain in FRP reinforcement and concrete for specimen B-II-2.5.

Comparison of Design Equations

The values of the concrete shear strength (V_{cf}) were calculated for the 60 specimens included in the database and for the tested beam specimens using the previously mentioned equations (equations 1 to 8). The ratio between the experimental results and the calculated values ($V_{exp.}/V_{calcu.}$) was determined for each specimen using the eight equations. For each equation, the maximum and the minimum values of the ratio ($V_{exp.}/V_{calcu.}$), the mean value of this ratio and its standard deviation are presented in Table 3.

As shown in Table 1, it can be noticed from the mean values of the ratio ($V_{exp.}/V_{calcu.}$), that the available equations used to predict the concrete shear strength generally underestimate this value with different ratios starting from 95% up to 25% of the experimental value. The most underestimating equation is the ACI equation as shown in. The equation is believed to be very conservative and not economic for design purpose. On the other hand, according to Table 3, the values predicted using Razaqpur equation (equation 4) and BRI equation (equation 8) have the best

agreement with the experimental results for the concrete shear strength. However, the BRI equation appears to be simpler and safer than Razaqpur equation. For BRI equation (equation 9), only 17 beams have V_{exp}/V_{calc} less than 1.0 compared to 31 beams for Razaqpur equation (equation 4).

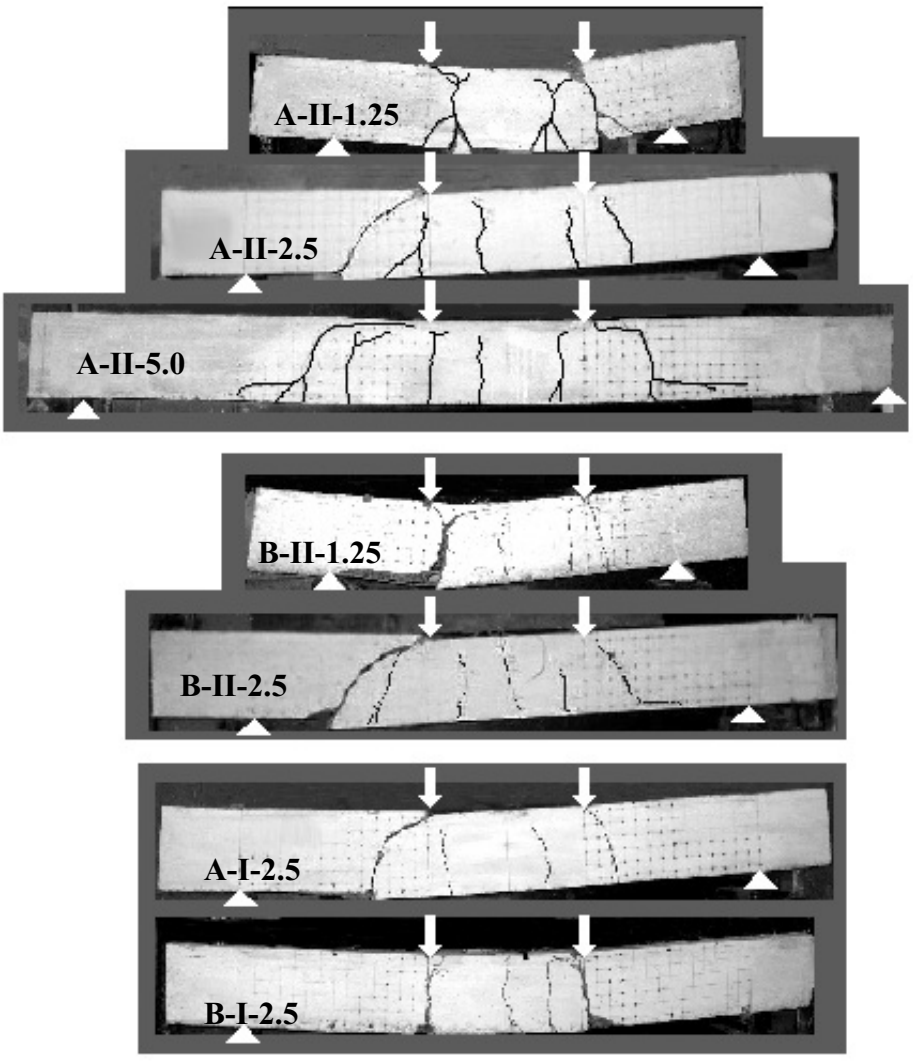

Figure 3. Cracking pattern of the tested beam specimens.

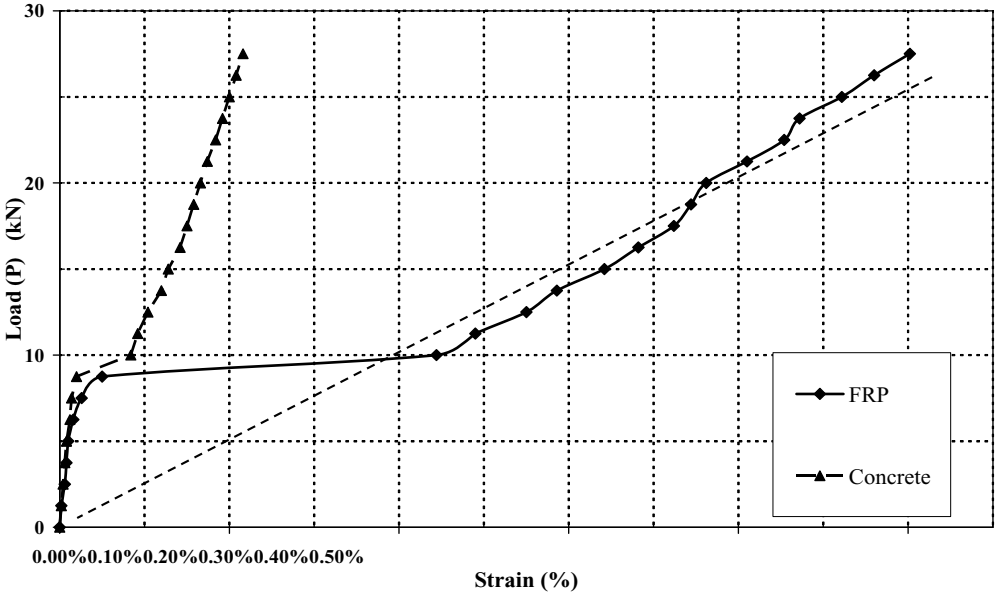

Figure 5. Measured strains in FRP and concrete for specimen B-II-2.5.

CONCLUSIONS

From the available experimental data and the results of the conducted experimental program, the following conclusions can be drawn:

1. The ACI equation for predicting concrete shear strength of members reinforced with FRP longitudinal reinforcement is very conservative.

2. The shear strength of concrete beams reinforced with FRP longitudinal bars is greatly affected by the ratio of $\rho_f / \rho_{f\,bal}$ in addition to concrete strength and the shear span to depth ratio.

3. The Japanese Building Research Institute BRI equation matches well with the available experimental data.

ABSTRACT

An overview of the many recent cases of roof collapse and the collapse of other portions of buildings in the United States and Canada is given. This paper discusses many of the recent cases of collapses of buildings or portions of buildings that usually get only local news coverage. In most cases roofs collapse under heavy snow loads, although some also fail under wind or rain loads. Many example cases are given based on information collected from local news coverage and other sources. In most cases, the collapse occurs in ordinary buildings and there are few, if any, serious injuries. In many cases the building gives the occupants some warning of collapse and people escape. One exception to the lack of injuries occurs when a wood deck fails. When a wood deck fails, the deck is usually loaded with people. Surprising, the frequency of collapse may be higher in schools and firehouses. Collapse of a portion of a school or a firehouse is upsetting to the public, even when there are no injuries.

INTRODUCTION

Structural collapse or other significant structural problems rarely occur. Many engineers, architects, and building designers are only exposed to a small number of structural failures during their career. Young engineers and students usually have not experienced any collapses or other failures. They usually have been exposed to information about only a few major structural collapses such as:

- the 1st Tacoma Narrows Bridge (Galloping Gertie) in 1940 as described by Robison
- the walkways at the Hyatt Regency Hotel in Kansas City in 1981 as discussed by Petroski
- the I-35 bridge collapse in Minneapolis as reported by National Transportation Safety Board

Although there is much to learn from these major failures, a better awareness of the more common structural failures adds perspective and importance to the common design, construction, inspection, and maintenance tasks.

SCOPE OF STUDY

The most common type of structural collapse is the collapse of a roof of a building. Although the paper title is: "When the Roof Collapses", the paper includes structural failures of floors, walls, and other structures. Some limits to the scope of the investigation are:

1. Only failures in the United States or Canada were considered. The construction standards, practices, and the building inventory in the United States and Canada are similar. The inclusion of Canada adds to the data of roof collapses due to heavy snow loads.
2. Failures due to severe events that buildings are not expected to resist without damage were excluded. This is to avoid a skew in the data by rare events that buildings are not designed to resist. Damage due to tornados, major hurricanes, major earthquakes, and floods were excluded. No major hurricanes or earthquake occurred during the period studied. Damage due to severe wind storms and heavy snow is included, because almost all buildings are expected to be designed for wind and snow loads (when applicable).
3. Failures due to fire were excluded. In some cases a structural collapse initiates a fire by breaking a gas line or by other means. When it is identified that a structural collapse caused the fire, the case is included.

Collapses that occur during construction were included. Other construction accidents not related to a structural collapse were excluded from this study. Since construction collapses usually occur before all structural elements are completely installed, they are not always considered to be structural failures. These cases are marked with the building age being set to "construction" (const.), so that they can be easily removed when needed in any statistics.

Buildings are not expected to last forever. If they are well maintained they can last for many decades. Structural failures where the age of the building appears to be a significant factor are marked as "old" or "historic". This is a judgment by the author and is usually not based on the knowledge of the actual building age or how well the building was maintained.

SOURCES OF INFORMATION

In most cases the source of information for the listed structural failures is local news media. The main research method used is to perform internet searches of news sites

using keywords related to structural collapse. Often multiple news sites are found for the same structural failure. Nearly all available sources are reviewed. In many cases these sources are no longer available a few weeks after initially posted on the internet. To deal with this problem, searches are performed once or twice a week. Relevant data is copied to local computer files for later review and analysis. Due to the large number of sources, references for all sources are not provided.

When forensic investigation reports are available, they are gathered and reviewed. In most cases, forensic investigation reports are not available to "outside parties". In many cases no professional forensic investigation occurs.

Since the source is most commonly news sites, important details needed to determine the cause of the failure are usually missing. In spite of the lack of detailed information, some summary knowledge is gained by the broad review of a large number of failures. Common problems can be identified. In some cases trends or patterns can be observed.

Some of the best insight into the scope, type, and likely cause of the collapse comes from the review of pictures (and sometimes, video) taken by others at the scene of the collapse. Only a few of the hundreds of pictures could be included in this paper.

One benefit of using open public sources is that the author (and the reader) is completely free to provide commentary without any obligation to the involved parties.

HOW MANY STRUCTURAL FAILURES OCCUR PER YEAR?

How many structural failures occur per year? I was once asked this question by my employer. After some efforts I found no reliable sources to help answer this question. Now, many years later, this paper provides a count of failures in the United States and Canada for the 2010 calendar year. Of course, one can only count what you know. Some failures have likely occurred that did not get any press or media coverage or were missed in the attempt to search for them. Thus, the count provided is a lower bound for a reasonable estimate of the actual number of failures. It seems likely that the actual number of failures is 10 to 50 percent higher than the number that is counted here.

STRUCTURAL FAILURES BEFORE THE 2010 YEAR

The process of recording structural failures started before 2010 began. The search process was inconsistent at first. This allowed the search technique to be perfected. Beginning in December 2009 an attempt was made to capture all available data for the winter snowfall period. It was later extended to capture all available data for the

year of 2010. Table 1 contains the results from this pre 2010 period with a infamous historical structural failure added for perspective.

Table 1. Incomplete record of structural failures before 2010

STRUCTURAL FAILURES FOR THE 2010 CALENDER YEAR

The process of searching for structural failures continued during the 2010 calendar year. It was expected that rate of failures would drop to a very low rate once the snow stopped falling. Although some decline occurred, a significant rate continued throughout the year. Table 2 shows summary results for 2010.

Table 2 shows that some types of failure occur more frequently and with effects that vary widely. Snow loads on roofs cause the greatest number of building failures, but

relatively few injuries and deaths. It appears that many roof collapses give the occupants warning and allow for escape. Even when an occupant is trapped under the roof, they are often not seriously injured.

Deck, porch, and balcony failures occur less often, but cause far more injuries. Luckily the injuries for deck porch, and balcony failures are usually not life threatening. This high rate of injury for deck, porch, and balcony failure is due to the fact that the weight of people is the major load, so the collapse usually occurs when the deck, porch, or balcony is full of people.

Failures due to rain loads rarely result in injuries. This is because the failure is usually not a complete roof collapse. When a roof failure occurs due to rain loads, it is likely due to poor drainage. Water accumulates on the roof. When the failure begins to occur a hole in the roof membrane develops, and the water on the roof rushes into the building. This unloads the roof structure and stops the collapse from progressing. Thus we get lots of water damage, but almost no injuries.

Collapses during building construction or renovation almost always cause people to fall or construction materials to fall onto people. Thus, construction collapses often have serious injuries and sometimes deaths.

Table 2. Summary results of structural failures for 2010

	# injured	# Dead	# bldg
Snow load on roofs	6	3	146
deck, porch, & balcony	133	1	38
rain load cases	0	0	27
wind load cases	1	2	16
collapse during construction	16	7	21
collapse with only dead load	25	7	94
floor collapse	29	0	6
other	4	0	2
Totals for 2010	214	20	350

Collapses that occur with only dead loads are a mixture of different types. Some occur in older buildings, often with masonry walls. Old buildings that are vacant seem to result in a disproportional number of cases. Lack of proper maintenance can lead to corrosion, decay, or other structural damage.

Some collapses with only dead load are ceiling collapses. These ceiling collapses sometime cause injury. Since there is no design live load for a suspended or other type of ceiling, a ceiling is always holding its full dead load. A construction defect or damage from water leakage will eventually cause a ceiling to collapse.

The third type of collapse with only dead load is a roof collapse with no roof live (snow or wind) load. It is surprising when a building suddenly collapses or sags for no apparent reason. This occurred several times in 2010.

Table 3 contains some selected records from the full list of structural failures recorded in the year 2010. A review of these records can provide a sense for the type of failures that occurred.

Table 3. Selected records of structural failures for 2010

BUILDING TYPES WITH HIGHER FREQUENCY OF COLLAPSE

Some building types appear to have a higher frequency of collapse. When considering the frequency, the number of collapses for a type of building needs to be compared with the total number of building of the same type. Numerical calculation of this type was not performed but the commonness of a building type was considered as part of the judgment.

Fabric covered building are not very common, but several collapses of this type were noticed. The collapses include both the structural frame support type and the air pressure supported type of fabric covered buildings.

Barns and other agricultural buildings had a large number of roof failures. This is not surprising because these building are commonly built to lower standards and have little review or inspection from building departments.

It is surprising that fire stations appear to have a higher frequency of roof failures. This is concerning since these facilities are needed during time of storms and other emergencies. The newer building codes require that fire stations be designed to higher standards than normal buildings. Most of the fire stations that collapsed in 2010 were likely built before these newer building codes were in effect.

Schools also had a high occurrence of roof failures. From the amount of media coverage of the problems at school buildings, there seems to be greater public concern when structural problems occur in schools compared to other buildings. Even school bus garages, which had a high frequency of collapses, caused public concern.

Houses had a low frequency of collapse when considering the very large number of houses in most communities. It may be useful to educate the public that most houses are safe, even in stormy weather.

In general structures with long clear spans had a higher frequency of collapse than smaller buildings or building with interior walls. This fact may be the major reason

that barns, fire stations, school gymnasiums, and school bus garages all have higher frequencies of collapse.

CONCLUSION

The number of structural failure in the United States has been documented for calendar year 2010. The number counted is 450. Since no count is perfect, the actual number is likely higher. The count is very low compared with the 100 million or higher buildings in the region.

ABSTRACT: The intent of the study is to incorporate discrete, short, mechanically deformed, small diameter steel fibers into high strength concrete ($f'_c > 69$ MPa) in an attempt to eliminate or reduce the need for steel rebar in concrete construction. This paper presents the rheological properties and behavior of high strength steel fiber reinforced (SFR) / self-consolidating (SFRSC) concrete mixture with different dosages of steel fibers, ranging from zero to 2% by volume in 1% increments. The effect of high range water reducing agent (HRWR) and viscosity modifying agent (VMA) on the fresh properties of SFRC/SCC are studied. Concrete mixtures include fly ash and silica fume. The fresh properties studied are: the flow-ability (spread diameter), the pass-ability (J-Ring and U-Box test) and fill-ability (V-Funnel test). The study shows that, the addition of steel fibers to the mixture results in the reduction of flow-ability, pass-ability, fill-ability and workability, which was mitigated through the adjustment of HRWR and VMA dosage.

1. INTRODUCTION:

The interest to minimize the use of longitudinal and transverse steel reinforcement in the construction of reinforced concrete structures and to reduce the structural weight has triggered the launch of this particular research. In areas such as beam-column joint, two way slab-column joints and heavily loaded columns, where considerable amount of transverse and longitudinal reinforcing steel are normally present, the required quantity of longitudinal reinforcing steel can be reduced greatly and in some cases eliminated if steel-fiber reinforcements coupled with high concrete strength are used. The desirability of high strength concrete is in the overall reduction in the weight of structures, the volume of concrete used in the construction, and the resulting beneficial environmental effects associated with reduction in weight and materials.

This research is the continuation of previous studies conducted at the Civil Engineering Department at University of Nevada, Las Vegas since 1997 (Ahmed, 2001; Ahmed and Ladkany, 2003; Ladkany and et al, 2005). 1% by volume fraction of one inch long steel-fiber and Styrene-Butadiene, rubber based polymer, were added to normal 27.6 MPa (4 ksi) concrete mixture to study the ductility behavior of steel-fiber and polymer concrete mixtures (Ahmed, 2001). High strength steel-fiber mixtures, with 0.3% of steel by volume, were studied for compressive and tensile strength with different combinations of admixtures and cement substitutes (Doli, 2007).

This research is conducted in two phases. In the first phase, results of which are discussed in this paper, the rheological properties of flow-able and/or self-consolidating high strength steel-fiber concrete are presented. The fresh properties of the FRC under consideration are: flow-ability, pass-ability and fill-ability of the mixture with various quantities of steel fibers by volume fraction added to the mixture. The current study investigates the effects of steel fibers and admixtures to the fresh properties of FRC. In addition to the above rheological properties, the research will also investigate the effect of steel fibers on: (a) the mixture's self-consolidating or flow-able behavior, (b) balling effect of the steel-fibers, and (c) the proportioning of water reducing, and viscosity modifying agents to obtain the desirable mixture that meets various ASTM requirements. The admixtures in use are: High Range Water Reducing Agent (HRWR), Viscosity Modifying Agent (VMA), fly ash and silica fume.

The second phase, which is not part of this paper, will deal with the study of shear, flexural and ductility behavior of FRC in relation to thin plates and shell structures.

2. RESEARCH SIGNIFICANCE

The purpose of the research is twofold. First, to observe the fresh properties of FRC mixture and verify if the self-consolidating properties of the mixture can be maintained at different levels of steel-fiber content, 0% to 2% by volume fractions. Second, to study the properties of fresh FRC mixtures at various levels of steel-fiber content with respect to the amount of admixtures, such as HRWR and VMA used. As the steel-fiber content in the concrete mixture increases the need to adjust admixtures dosage and/or w/c ratio becomes necessary.

3. EXPERIMENTAL PROCEDURES

Initially, a control mix, without steel fibers, that meets the fresh properties of self-consolidating concrete, described in section 3.3 below, was established. Maintaining the water-to-cement ratio constant, steel fibers, HRWR and /or VMA were added increasingly to get SCC properties of the FRC mixture. The steel fibers are added in

increments of 1% by volume fraction from 0 to 2%. Therefore, three types of concrete mixtures were studied.

3.1 Raw materials

Coarse and fine aggregates were obtained from a local quarry in Las Vegas, Nevada. Since the application of the concrete mixtures were ultimately to be used for thin plates and shells (about 25.4 mm thick), the size of the coarse aggregate was limited to nominal sizes of 9.53 mm (3/8") and #4. The oven-dry specific gravity and absorption of the coarse aggregate (ASTM C 128-07a) are 2.777 and 0.60%, respectively. Fine aggregate grading, with fineness modulus of 3.03, met the requirements of ASTM C33 grading limitations. The oven-dry specific gravity and absorption of the fine aggregate (ASTM C 128-07a) are 2.785 and 0.64%, respectively. Deleterious substances are substantially below the maximum allowable limits for both coarse and fine aggregates.

The amount of water-to-cement ratio and coarse-to-fine aggregate ratio were adjusted to suite the concrete mixture under consideration. Optimum coarse-to-fine aggregate ratio for FRC was found to be 44% to 56% (724:920 kg/m^3), respectively. The water-to-cement ratio was set at about 0.435 to meet both self consolidating properties and high strength concrete requirements.

ASTM C 150 Type V Portland cement 404 kg/m^3 (25.2 lb/ ft^3), which is widely used in the local area due to its resistance to sulfate and Class F fly ash, at 42.5% by weight of cement, meeting the requirements of ASTM C 618 were used. Silica fume, 7.5% by weight of cement, was also used.

The admixtures used were High Range Water Reducers (HRWR) and Viscosity Modifying Agent (VMA).

ASTM 820-90 Type II Deformed cut sheet carbon steel fibers with equivalent diameter of 0.584 mm (0.023 in) and aspect ratio, l/D, of 47:1 were used. The steel fibers have rectangular cross section of 0.406 x 0.838 x 19.05 mm (0.016 x 0.033 x ¾ in) and specific gravity of 7.85. The tensile strength of steel-fibers ranges between 379 to 763 MPa (55,000 to 111,000 psi).

3.2 Mixing procedures

Preparation of concrete ingredients and procedure of mixing concrete were conducted per ASTM C 192.

The mixer and other tools that came into contact with the concrete were dampened to prevent mixing water fluctuation. Coarse aggregates were mixed for two minutes with 1/3 of the mixing water and steel fibers. Fine aggregates were added to the mixer and

mixed for two minutes with 1/3 of mixing water and steel fibers. Lastly, the silica fume, fly ash and cement were added and mixed for two more minutes with the remaining 1/3 of mixing water and steel fibers. The admixtures, HRWRA and VMA, were added and the content mixed for three minutes followed by three minutes of rest and two more minutes of mixing, for a net mixing time of 14 minutes.

The mixer was stopped while the ingredients were loaded into it, with the exception of water and steel fibers.

3.3 Testing procedures

3.3.1 Flow-ability (slump flow and flow rate test)

The unconfined workability of SCC was measured using slump flow. In the procedure, a standard slump cone (upright or inverted) is filled with concrete and the cone is lifted vertically with no lateral or torsional motion to let the mixture flow. Slump flow is measured by taking the average of two perpendicular diameters of the flow. If the diameters differ by more than 50 mm (2”), the test is invalid and need to be repeated (ASTM C 1611, 2009). Slump is measured from the top of the test cone’s initial position to the top of the spread.

The time elapsed for flow to reach 20 inch diameter from the initial time of test cone lift is defined as the rate of flow (ASTM C 1611, 2009). Target flow rate for SCC is 5 seconds or less (ASTM C09.47, 2009).

3.3.2 Passing ability (J-Ring Test)

A similar set up as slump flow test except a J-Ring, circular ring with 16 #5 deformed bars, see Figure 1, is placed around the perimeter of the test cone before the lift. The J-Ring flow diameter is the average of the two perpendicular diameters measured. The difference between the slump flow and J-Ring flow determines the passing ability of the concrete mixture. A difference of 25 mm (1 in) shows good passing ability and a difference more than 50 mm (2 in) shows poor passing ability (ASTM C 1621,2009).

3.3.3 Filling ability (V-Funnel Test)

A V- shaped funnel, see Figure 2, is filled with concrete mixture, the bottom door is opened and the time passed for the content to clear the apparatus is recorded as V-Funnel flow time (t_v). V-Funnel flow time of 10 seconds or less shows good filling ability (ASTM C09.47, 2009).

Figure 1. J-Ring Apparatus

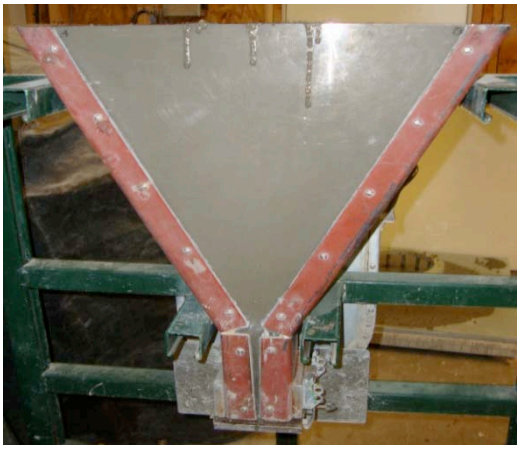

Figure 2. V-Funnel Apparatus

3.3.4 Filling and passing ability (U-Box Test)

A U-shaped box equipped with 3 #4 bars and a sliding door, Figure 3, is filled with the concrete mixture. The sliding door is lifted and the height of the mixture in the two chambers is measured. The difference in height, U-Box filling height, of 304.8 mm (12 in) or less indicates the mixture has good filling and passing ability (ASTM C09.47, 2009).

Figure 3. U-Box Apparatus.

4. RESULTS AND DISCUSSION

4.1 Effects of HRWR Agent on the FRC mixture

HRWR agent is used in our study to reduce the amount of mixing water and hence achieve high concrete compressive strength and to get a self-consolidating or flow-able concrete mixture as well. Table 1 show that the addition of HRWRA increases the slump flow (spread) diameter, slump and the chance of bleeding. The amount of HRWR needed also increases with the increase of steel-fiber content, for similar spread diameter of the mixture.

4.2 Effects of VMA on the FRC mixture

VMA enhances the deformability and uniformity of a mixture. VMA can be used to minimize aggregate piling, segregation and bleeding as the amount of water and/or HRWR in the mixture increases to obtain optimum mixture properties. The main drawback generally is that, VMA slows down the flow of the mixture hence, increasing the time of the flow rate (T_{50}).

Tests were conducted to determine the influence of VMA on the steel-fiber mixtures. An amount of 0.385 kg/m^3 (0.024 lb/ft^3), minimum manufacturer's recommendation, was added to the successful mixtures #1, #4 and #7 in Table 1, having 0%, 1% and 2% of steel volume fractions, respectively. Results in Table 2 show that the VMA shrinks the flow diameter by 15.2 mm (0.6 in) for 0%, 88.9 mm (3.5 in) for 1% and

an increase of 10.2 mm (0.4 in) for 2%. The flow rate (T_{50}) of the mixtures increased by 0, 8 and 5 sec for 0%, 1%, and 2%, respectively. However, bleeding of 12.7 mm (1/2 in) and 15.9 mm (5/8 in) were observed in 0% and 2% steel volume fraction mixtures, which explains the increase in spread diameter and flow rate of the mixtures.

It was concluded that VMA is not needed for mixtures indicated in Table 1, since the flow rate is increased and the slump flow (spread) decreases with some observed bleeding with the addition of VMA.

Table1. Mix dosages and fresh property results kg/m^3 (lb/ft^3)

Mix	HRWR kg (lb)	VMA Kg (lb)	Steel-Fiber % (lb)	Slump Flow mm (in)	Halo mm (in)	SLUMP mm (in)	T_{50} sec

4.3 Effects of Steel Fibers on the FRC mixture

From Table 1 it can be seen that, an addition of 1% steel fibers by volume has very little effect on the fresh properties of the FRC mixture. Fibers are also less noticeable during the mixing and testing process. However, the introduction of steel fibers to the concrete mixture reduces the workability, pass-ability, fill-ability, and flow-ability progressively as the fiber content increases to 2%. With the increase in steel-fiber volume fraction in the mixture, the workability and slump flow decreases but the flow rate and the need for more HRWR increases.

4.4 J-Ring Test Results

Results from J-Ring tests for mixture #1, #4 and #7 are shown in Table 3. The spread diameter differences were an increase of 9.4 mm (0.37 in), decrease of 22.4 mm (0.88 in) and 44.5 mm (1.75 in) for 0%, 1% and 2% steel-fiber volume fraction, respectively. For 0% steel-fiber the ring barrier made no difference. On the other hand, for 1% and 2% the diameter shrank by an amount of less than 50 mm (2 in),

maximum margin that is required for SCC mixture. Therefore, all three mixtures satisfied J-Ring test requirement. In general, the introduction of steel fibers into the mixtures reduces the spread diameter in the J-Ring test.

4.5 V-Funnel Test Results

V-Funnel test results in Table 3 show that, the time needed for a mixture to clear the funnel increased from 8 sec to 18 sec (125%) and 31 sec (287%) for 0%, 1% and 2% steel fiber mixture, respectively. It can be concluded that, the increase in steel-fiber volume fraction in the mixture decreases its fill-ability.

4.6 U-Box Test Results

The results in Table 3 show that the U-Box test requirements for SCC mixture are met for 0% and 1% steel volume fraction mixtures. However, the 2% mixture exhibited 63% higher than the maximum allowable U-Box filling height requirement.

Table 3. J-Ring, V-Funnel and U-Box Test results of mix #1, #4 & #7, kg/m^3 (lb/ft^3)

Mix	HRWR kg (lb)	VMA Kg (lb)	Steel-Fiber (%) (lb)	J-Ring Flow mm (in)	Slump Flow mm (in)	V – Funnel sec	U - Box H_1 - H_2 mm (in)
1	0.178 (0.392)	0	0 (0)	768.4 (30.25)	759.4 (29.9)	8	1.52 (0.06)
4	0.171 (0.376)	0	1 (5.00)	666.8 (26.25)	689.1 (27.13)	18	25.4 (1.00)
7	0.189 (0.416)	0	2 (10.00)	628.7 (24.75)	673.1 (26.5)	31	495.3 19.50

Table 4. Summary of results

Mix	Slump Flow > 482 mm (19 in)	J-Ring Flow ≤ 50 mm (2in)	V – Funnel Flow Time (≤ 5 sec)	U - Box Filling Height ≤ 305mm (12in)
1	Acceptable	Acceptable	Acceptable	Acceptable
4	Acceptable	Acceptable	Not Acceptable	Acceptable
7	Acceptable	Acceptable	Not Acceptable	Not Acceptable

5. CONCLUSION

Preparing SCC or flow-able Steel-fiber concrete is very sensitive and complicated process. Attempting to have high strength concrete, by reducing water-to-cement ratio, in addition to having SCC property makes the process even more complicated and laborious. Table 4 below, summarizes the results of the three mixtures without VMA, in relation to the test conducted and whether the mixture met the SCC requirements. It is shown that Mixture #1, with 0% steel-fiber volume fraction met all the requirements for SCC properties. But the other two mixes, 1% and 2%, fell short in one and two tests each, respectively. Some of the short falls can be remedied by adjusting the HRWRA and/or VMA dosage. If needed the water-to-cement ratio might even be increased to achieve the SCC behavior required, at the expense of concrete compression strength.

From the current experimental study, it can be concluded that, with the increase of steel-fiber volume fraction the required HRWRA increases. Ultimately, VMA and water- to-cement ratio need to be adjusted to get the SCC properties for 1% and 2% steel fiber mixtures.

ABSTRACT

Adhesive-bonded anchors are increasingly adopted as structural fasteners for connections to hardened concrete. The strength of these anchors relies on several factors such as geometric parameters and adhesive bond strength. Due to the complexity of the interaction of these factors, it is difficult to estimate their tensile capacity. Furthermore, these anchors have not yet been incorporated into the design provisions of ACI 318-08. This study aims at estimating the effect of different parameters on the tensile strength of concrete adhesive anchors in uncracked concrete using artificial neural networks (ANNs). The ANN model will be able to capture the complex relationship between the tensile strength of anchors and different parameters.

INTRODUCTION

In many applications, steel structural members are required to be connected to concrete. Accordingly, the use of concrete anchorage systems has increased. Anchors are categorized into two types based on the time of installation. The first type is the cast-in-place anchors, which are installed while concrete is placed. These anchors develop their load capacity through two mechanisms, direct adhesion to concrete along the surface and bearing through anchor surface deformations, a head or a hook. Over the past two decades the knowledge and design of cast-in-place anchors has become well know and established in ACI 318-08 Appendix D (ACI 318-08, 2008). The second anchorage type used is post-installed anchors in which anchors are installed in hardened concrete. This system is, in turn, divided into two categories: mechanical bonded anchors and adhesive anchors. Similar to cast-in place anchors, mechanical anchors develop their strength through the transfer of load to the concrete at the anchor head, while adhesive anchors develop their strength through an adhesive layer that bonds them to concrete along the entire surface (Cook *et al.*, 1998). Post-installed anchors have the versatility to be placed in any desired location after the concrete has hardened, which increases their simplicity and speed of construction. As a result, post-installed anchors are growing in popularity among contractors in the concrete industry especially in retrofitting applications.

Adhesive anchors are post-installed anchors that derive their strength from the chemical compound adhesion to the walls of the hole drilled in concrete and the steel anchor rod. Chemical compounds used include epoxy, cementitious material, polyester resin, and other similar types (ASTM E 488-96, 1996). Typically, the hole diameter is only about 10 to 25 percent larger than the diameter of the reinforcing bar or threaded rod (Cook *et al.*, 1998). Structural adhesives for this type of anchorage are available prepackaged in glass capsules, in dual-cartridge injection systems, or as two-component system requiring user proportioning (Cook *et al.*, 1998).

The difficulty in determining a sensible design approach for adhesive concrete anchors is corroborated by their diverse range of failure modes (Cook *et al.*, 1998). The aim of this paper is to use ANN modeling approach to investigate the effect of various design parameters on the tensile capacity of single adhesive anchors.

MODES OF FAILURE

Given the complexity of the parameters that affect adhesive concrete anchors, it is difficult to develop a universal design equation. The interaction of concrete/adhesive interface in conjunction with the steel/adhesive interface makes it extremely difficult to establish a model that evaluates both failure planes in a small space as such (Zamora *et al.*, 2003). Figure 1 shows different modes of failure for adhesive anchors which may become challenging to distinguish, since they can intermix. There are five typical modes of failure for adhesive anchorage systems as identified by Cook *et al.* (1998), as shown in Figure 1. Adhesive anchors with shallow embedment tend to exhibit the concrete cone pull-out mode. As the anchor embedment depth increases, a combined failure with a bond failure below a shallow concrete cone is usually observed (Cook *et al.*, 1998). The bond failure part can occur at adhesive/concrete or steel/adhesive interfaces and even a mixed mode bond failure maybe observed on different parts of the anchor (Cook *et al.*, 1998; Zamora *et al.*, 2003).

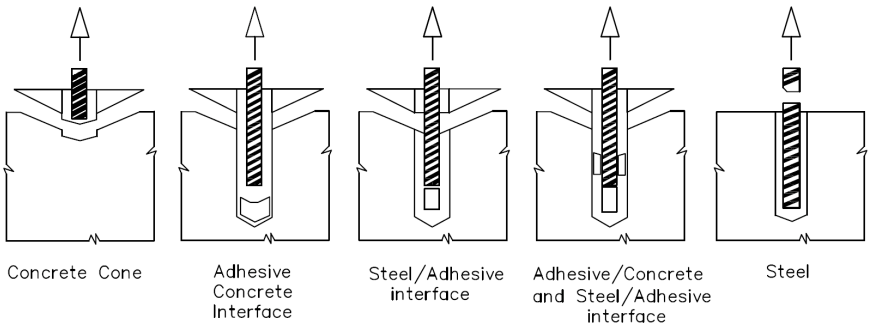

Figure 1. Typical failure modes of adhesive concrete anchors after Cook *et al.* (1998)

CURRENT DESIGN MODELS

For the purpose of comparative analysis, the current design models for adhesive concrete anchors are listed in the following section.

Concrete Cone Models

Concrete cone model was initially proposed by Eligehausen *et al.* (1984). The model is statistically derived based on multiple testing of a single adhesive type and anchors whose ratio of embedment depth to diameter is equal to nine ($h_{ef}/d = 9$). The ultimate predicted strength (N_U) of the anchor depends on the embedment depth and the concrete strength, but does not account for adhesive failure assuming a failure in a concrete cone mode. The model is presented by the following equation:

$$N_U = 0.92 h_{ef}^{\ 2} \sqrt{f_c} \tag{1}$$

where,

N_U = ultimate predicted strength of anchor (N)
h_{ef} = embedment depth (mm.)
f_c = 150 × 300 mm (6 × 12 in.) concrete cylinder compressive strength (MPa)

Uniform Bond Stress Model

The uniform bond stress model, presented in Eq. (3), is dependent on unique bond stress of the adhesive product, the diameter, and embedment length.

$$N_U = \tau \pi d h_{ef} \tag{2}$$

where,

N_U = ultimate predicted strength of anchor (N)
d = anchor diameter (mm)
τ = unique bond stress (MPa)
h_{ef} = embedment depth (mm)

Cook *et al.* (1998) indicate that while using the uniform bond stress model, the anchor diameter is most appropriate to use in Eq. (2) rather than the hole diameter. The bond stress along the embedment length of the anchor (τ) in Eq. (2) can be best represented through the uniform bond stress model, which is very simple to implement (Cook *et al.*, 1998).

Combined Cone/Bond Models

The combined concrete cone and bond stress models were proposed for adhesive anchors by Cook *et al.* (1998) and the Japan Concrete Institute (1994). For deeper embedment, a two term equation proposed by Cook *et al.* (1998) is used to combine the strength of the shallow cone with the bond strength. The cone depth is calculated using Eq. (3), and if it is smaller than the embedment depth, then the combined cone failure and bond failure are calculated in Eq. (5). If the embedment

depth is smaller than the depth of the concrete cone then Eq. (5) is to be used, as it is a concrete cone model as suggested by Eligehausen *et al.* (1984).

$$h_c = \frac{\tau\pi d}{1.84\sqrt{f_c}} \tag{3}$$

$$N_U = 0.92h^2{}_c\sqrt{f_c} + \pi\tau d(h_{ef} - h_c) \tag{4}$$

$$N_U = 0.92h_{ef}{}^2\sqrt{f_c} \tag{5}$$

where,

N_U = ultimate predicted strength of anchor (N)
d = anchor diameter (mm)
τ = unique bond stress (MPa)
h_{ef} = embedment depth (mm)
f_c = 150 × 300 mm concrete cylinder compressive strength (MPa)
h_c = depth of shallow concrete cone (mm)

Two interface bond model

The basis of this design model is differentiating between failure at the adhesive/concrete interface and failure at the steel/adhesive interface. Eq. (6) is appropriate for steel/adhesive interface failure, where the ultimate load depends on the bond stress evaluated at the steel/adhesive interface, the embedment depth, and anchor diameter. Similarly, Eq. (7) is for adhesive/concrete interface failure, where the ultimate load depends on the bond stress evaluated at the concrete/adhesive interface at a low concrete strength, the diameter of the hole, the embedment length, and the ratio of the square root of the concrete strength being considered to the square root of the low strength concrete used to establish τ_0.

$$N_U = \pi\tau dh_{ef} \tag{6}$$

$$N_U = \pi\tau_0 d_0 h_{ef}\Psi_c \tag{7}$$

where,

N_U = ultimate predicted strength of anchor (N)
d = anchor diameter (mm)
d_0 = hole diameter (mm)
τ = unique bond stress (MPa)
τ_0 = bond stress evaluated at hole diameter (MPa)
h_{ef} = embedment depth (mm)
f_c = 150 × 300 mm concrete cylinder compressive strength (MPa)
Ψ_c = 1.0 for products with little or no influence of concrete strength

ARTIFICIAL NEURAL NETWORK APPROACH

Artificial neural networks (ANN) are powerful computational tools inspired by the understanding and abstraction of the structure of biological neurons and the internal operation of the human brain (Haykin, 1994). ANN multi-layer perceptrons (MLP) are used extensively in engineering applications due to their ability to perform nonlinear transformations for functional approximations with given inputs in order to reach desired outputs. The value of neural networks relies in its ability to be trained through adaptive data driven approaches, and therefore the system is able to analyze, learn and capture complex or hidden relationships. MLP networks consist of multiple layers (an input layer, an output layer and one or more hidden layers). Each layer contains a number of processing elements (units) partially or fully connected to units in the consecutive layer. Connections between processing units are initially assigned random numerical values (weights) representing their strength. The main objective in building an artificial neural network-based model is to train specific network architecture to search for an optimum set of weights, for which the trained ANN can predict accurate values of outputs for a given set of inputs from within the range of the training data (Haykin, 1994). While the MLP networks trains the complex array of interconnected data, the training of network is driven by sufficient and relevant data to achieve optimum results. Further investigation of artificial neural networks is outside the scope of this paper. However, more details about how to construct, train and validate MLP networks are available elsewhere (Haykin, 1994; Rumelhart *et al.*, 1986).

EXPERIMENTAL WORLDWIDE DATABASE

Test reports on the behavior of adhesive anchors have been collected from experimental programs in Europe, USA, and Japan. From 36 reports, a database containing the results of 2,878 tests has been established. Currently the adhesive anchor database is maintained for ACI committee 355 by Professor Ronald A. Cook, Department of Civil Engineering, University of Florida, Gainesville. The database contains tensile and shear load testing in uncracked and cracked concrete with single anchors, groups of two anchors, and groups of four anchors. It distinguishes between confined and unconfined tests as well as between tests far from the concrete edge, tests near the concrete edge, and tests with close anchors spacing. Finally, the database differentiates adhesives by manufacturer as well as types such as epoxies, vinylesters, unsaturated polyesters, hybrid adhesives, and inorganic adhesives. Some tests indicate the temperature range at which the adhesive was cured. Currently, the International Code Council Evaluation Service (ICC-ES) AC-308, "Acceptance Criteria for Post-Installed Adhesive Anchors" (2005) along with ASTM E 488, "Standard Test Methods for Strength of Anchors in Concrete and Masonry Elements" (1996) and E 1512, "Standard Test Methods for Testing Bond Performance of Bonded Anchors" (1993) are the testing standards that manufacturers must follow to evaluate their adhesives for commercial use. The dimensions of the geometric properties of the anchorage system are recorded for each test in the concrete anchor database, along with qualitative identification of the failure mode that was observed as well as the quantitative tensile capacity at which the anchorage system failed. However, the tests in the 36 reports (1985-1994) that were used to establish the worldwide database were performed even before the release of the previous

evaluation criteria of ICBO ES AC-58 (1995) and the only available guidelines at that time were for expansion anchors ICBO ES AC-01 (1993). The purpose of the current ICC-ES AC-308, as stated in *Section 1.1* is to establish requirements for different manufactures post-installed adhesive anchors in concrete elements to be recognized in an ICC Evaluation Service, Inc. (2005). This product evaluation methodology allows adhesives from different manufactures to be consistently evaluated. Accordingly, engineers can use a unique bond stress for each product for design purposes.

SELECTION OF DATABASE

The success of establishing an ANN model is dependent on the amount and quality of information provided to train it as stated before. Therefore, the worldwide database was limited to unconfined, single adhesive anchors, far from edge loaded in tension in uncracked concrete with bond failure for the purpose of this study. Furthermore, tests which resulted in the yielding of steel were omitted since these specimens demonstrated sufficient bond between the borehole and adhesive as no bond failure was observed. The database used must be sufficiently large to enable the ANN to fully capture the effect of the considered design parameters on the tensile capacity of single adhesive anchors. The initial geometric and material design parameters that were used to establish and train the ANN were: the diameters of the anchor and the bore hole, the embedment depth of the anchor, the concrete strength and the bond index which is described in the following section. The selected design parameters have all been shown in previous studies and design models to be crucial in estimating the tensile capacity of adhesive anchors (Cook and Konz, 2001). Manufactures are required by the International Code Council Evaluation Service (ICC-ES) AC-308, *Section 2.1.20* "manufacturer's published installation" (2005) to specify the installation of, and condition of the borehole, as well as the curing temperature range at which the adhesive should be applied. Accordingly, the tests selected to train the ANN were in the standard ranges that adhesives would be cured (5°C - 30°C/41°F - 86°F). Previous research by Cook and Konz (2005) shows that inappropriate temperature and conditions of the borehole can have detrimental effects on the performance of the anchorage system, and hence temperatures that were outside the range listed were omitted.

The difficulty of identifying the failure mode is described in more detail by Zamora *et al.* (2003). They indicated that upon inspection of anchor after failure it is extremely difficult to identify if the failure was purely a cone failure, a result of effective adhesive bond, or rather a pull out failure, a result of ineffective adhesive bond (1998). Consequently, it is expected that the classification of the failure mode listed within the worldwide database is subjective nature. While the characteristics of the different failure modes are physically dissimilar yet their combination creates a difficulty in distinguishing a single prevailing mode of failure. For the purpose of this study only explicitly described bond failures were selected for the training the ANN in order to isolate the complex relationship between parameters that affect this mode of failure. Concrete cone failure has already been described by the Concrete Capacity Design (CCD) model by Fuchs *et al.* (1995). In order to properly and accurately train the network, duplicates within the testing data were carefully

eliminated in order to improve the training capability of the network. The duplicates that were found in the database were carefully reduced to a single test data point. If inconsistent values of tensile capacity were found, then the procedure discussed by ASTM E 488 (1996) was followed to eliminate these outliers. The tensile capacities that met the ASTM standard methodology were then averaged and the duplications of these tests were reduced to a single data point representing the general trend observed for that specific anchorage test. Duplicates were deemed to be points with similar geometric parameters (e.g. diameter of anchor, diameter of hole, embedment depth, and concrete strength). However, as discussed in by Cook and Konz (2001) and Meszaros (1999), adhesive bond strengths and consequently the tensile capacity of anchors are manufacturer dependent. Accordingly, tests with identical geometrics parameters yet different adhesive manufactures were not considered as duplicates. The resulting database contained *213* tests from the original worldwide database for training of the ANN model.

ANN MODEL

The ANN model implemented in this study was a single feed-forward back-propagation multi layered perceptron network that utilized a scaled gradient conjugant (SGC) function, contained within MatLAB, Neural Network Toolbox. The network was trained with 80% of the *213* data points while the remaining 20% was used to determine whether the network was appropriately trained and able to capture the relationship between the different input parameters and output. The architecture of the network, shown in Figure 2, was developed with five inputs: diameter of anchor (d), diameter of hole (d_o), embedment depth (h_{ef}), concrete strength (f_c), and an adhesive index, as well as a single output, tensile capacity (N). The inputs and outputs were then normalized to values between 0 and 1, in order for the SGC function to be compatible for training (Rumelhart *et al.*, 1986). To ensure that the operator of the network had no bias of selecting data for training or testing, all datasets were randomized previous to training. Accordingly, inputs were fed to the network through three hidden layers that utilized a tangent sigmoid transfer function. Each layer contained 8 neurons which separated the 5 inputs and output. An epoch or single pass of the data through the network created an error output, between the network's predicted output and desired output. Data is then passed through the network again in order to reduce the error between the network's predicted output and desired output. Subsequently, optimum training results were attained through 2000 epochs.

To train the data more thoroughly, an additional parameter, the adhesive index, was deemed necessary to represents the adhesive bond strength. Examining the ICC AC-308 reveals two main adhesive related issues: product type and anchor diameter. This is evident from ICC-ES AC-308 *Section 2.1.23* (2005), since different anchor diameters must be tested for each adhesive to determine strength of the adhesive at various anchor diameters. The common trend is that larger anchors have higher tensile capacity, but yet lower bond strength. Using these two design principles, the bond index was determined from the uniform bond strength model as suggested by Cook *et al.* (1998) and McVay *et al.* (1996). The bond index was

defined based on ICC-ES AC-308 and assigned as a number between 0 and 1 unique to each adhesive product and diameter size range as outlined by ICC-ES AC-308 and based on the available test data for that product over the diameter size range. A major advantage of the ANN approach is that as new adhesives are tested, their test data can be easily added to the network database.

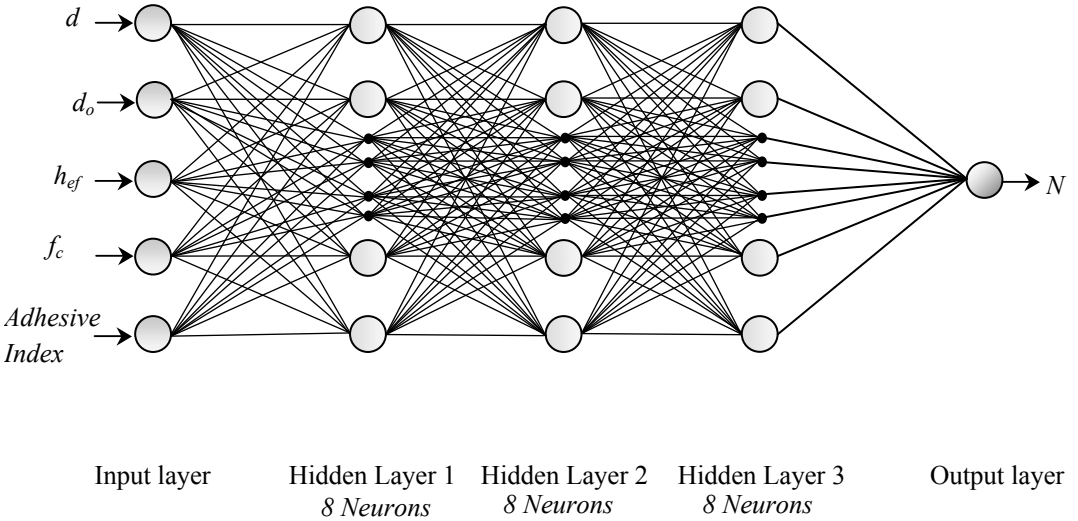

Figure 2. Architecture of the developed artificial neural network model

PARAMETRIC STUDY

Effect of Anchor Diameter on Tensile Capacity

Current ICC-ES AC-308 provisions provide evidence that tensile capacity increases as the anchor diameter increase (ICC-ES AC-308, 2005). This is reasonable since the bond surface area of the anchor ($\pi d h_{ef}$) increases linearly with the anchor diameter increase. Figure 3 displays a plot of the relation between anchor diameter and tensile capacity. It is shown that the increase is not linear despite the linear increase in bond area. Furthermore, as the anchor diameter increases the rate of the tensile capacity increase is reduced as shown in Figure 3.

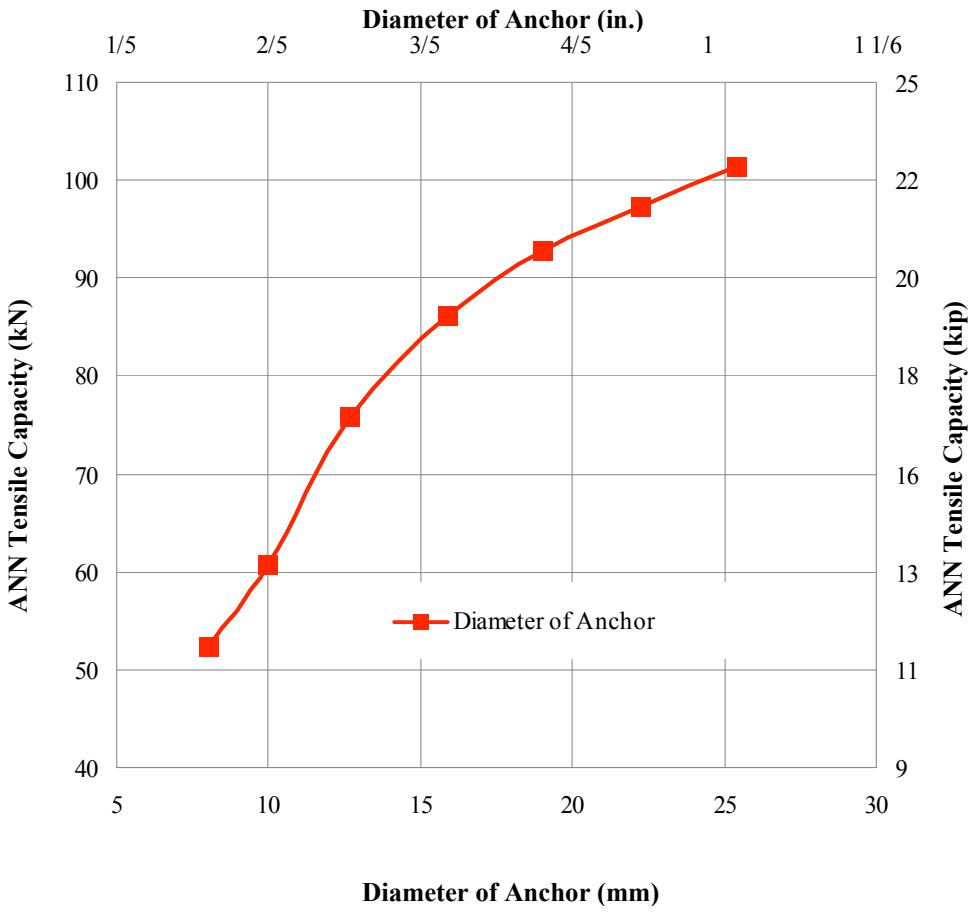

Figure 3. Effect of anchor diameter on tensile adhesive anchor capacity

Effect of Ratio of Anchor to Borehole Diameters on Tensile Capacity

The effect of the borehole diameter with respect to the tensile capacity is difficult to isolate and in many respects impractical since the annular gap is relative to the anchor diameter. Accordingly, the effect of the borehole diameter must be investigated through the borehole to anchor diameter ratio. The general trend from the database reveals typical ratios for borehole to anchor diameters in the range of 1.10 - 1.25 (Cook *et al.*, 1998). Concurrently, the parametric study examines more closely these ratios to determine the effect of this ratio on the tensile capacity of the anchor. The effect of this ratio on tensile capacity was studied for two bolt diameters ½ in. (12 mm) and 1 in. (25.4 mm). As illustrated in Figure 4, the tensile capacity increases with the increase in the borehole/anchor diameters ratio. This indicates that the tensile capacity increases with the increase in annular gap. For the 1 in. (25.4mm) diameter anchor, this increase was observed up to a d_0/d ratio of 1.25, as shown in Figure 4.

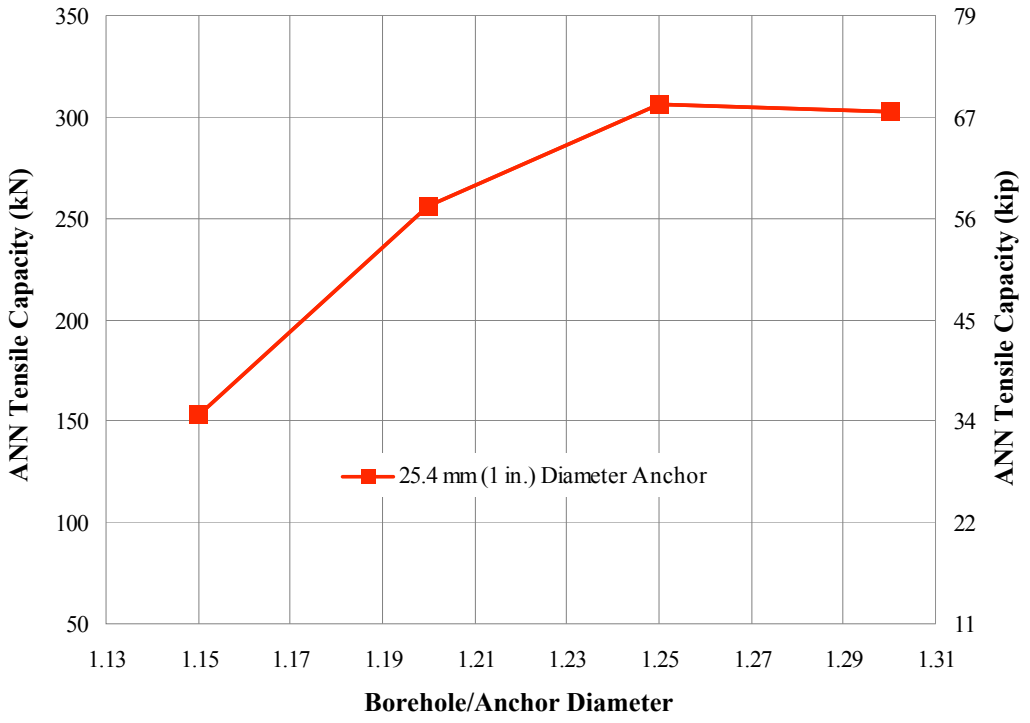

Figure 4. Effect of ratio of anchor diameter and borehole diameter on tensile adhesive anchor capacity (1 in/25.4 mm)

SUMMARY AND CONCLUSION

This study investigated the feasibility of using artificial neural networks as an approach to estimate the effect of several parameters on the tensile capacity of adhesive concrete anchors. The developed model was able to predict the effect of various parameters on the tensile capacity of adhesive anchors. The parametric study showed similar trends to those in the literature on adhesive anchors (ACI Cook *et al.*, 1993 and 1998; McVay *et al.*, 1996) in a quantitative manner. The ANN model can identify the optimum range of use for several parameters. The ANN model once established is readily available to input unique bond stresses that are evaluated for new adhesive products.

ACKNOWLEDGEMENTS

The authors wish to express their sincere appreciation to Dr. Ronald Cook of the University of Florida, ACI Committee 355 member that currently maintains and provided the worldwide database used in this study. Financial support was provided by the Western Alliance to Expand Student Opportunities (WASEO). The support of the Howard R. Hughes College of Engineering at the University of Nevada, Las Vegas is greatly appreciated.

ABSTRACT

The Aria Tower is the principal hotel and iconic centerpiece of the MGM Resorts International CityCenter Las Vegas mixed-use complex making its mark on the Nevada skyline. The Aria is designed in an elegant, sophisticated and contemporary architectural style with a floor plan based on interlocking arcs that is distinctly different from the linear, T, Y and X floor plans common to casino hotels. It also has three separate elevator cores with dedicated entry lobbies to provide guests with the experience of entering a smaller, exclusive hotel and avoiding long walks to their rooms. Visual massing of the hotel exterior is minimized by varying the heights of different building areas while fitting over 4 million square feet of hotel/casino spaces in up to 52 stories above ground and two stories below ground within the Federal Aviation Administration (FAA) height limitation of 600 feet. The unusual floor plan, separate cores and varied heights presented unique structural analysis and design challenges. This paper discusses the process and results for structural engineering of the Aria tower, including development of its "Core-Moment Frame" lateral system, its deep foundation interacting with caliche, and its unconventional post-tensioned (PT) slab system applied to a high rise building in a region of moderate seismicity. Guiding the project through turbulent economical times, completing the project on schedule, and achieving the coveted Green Building LEED (The Leadership in Energy and Environmental Design) Gold status were the results of the professionalism, dedication, commitment, and cooperation of the entire Aria Tower ownership, design and construction team.

INTRODUCTION

Aria Tower is the hotel/casino centerpiece of CityCenter, the grand urban development MGM Mirage (now MGM Resorts International) envisioned encompassing entertainment and luxury living within the same complex. That vision was made a reality over the past several years. CityCenter, at the heart of the Las Vegas entertainment district, is on 66 acres bounded by Las Vegas Boulevard, Frank Sinatra Drive along I-15, the existing Monte Carlo Casino and the existing Bellagio Casino to its East, West, South and North respectively. The complex consists of the Aria Tower hotel/casino, the Vdara hotel, the Mandarin Oriental hotel/residence, the

Veer East and Veer West residences, the Crystals shopping mall, a theater, the Harmon Tower and a Central Plant that powers the entire complex. See Figure 1.

Figure 1. Rendering of CityCenter, 2005

Ground breaking of the development took place in the spring of 2005 amid a construction boom in the area. At the peak of its construction, the development employed more than 8,000 trade workers, not counting technical professionals. The project was indisputably a major contributor to the local economy.

Centered within the development complex, the Aria Tower sits nearly 900 feet back from Las Vegas Boulevard. The 600 foot height of the 52 story tower just meets the FAA maximum building height limitation for the site and is one of the tallest buildings in Las Vegas. The tower has a base footprint of 120,000 square feet, with a gross building area of 4.5 million square feet, and a net area of 4.2 million square feet of hotel, casino, and retail spaces.

GEOMETRY AND BUILDING SYSTEM

Aria Tower floor plan geometry is based on two back-to-back overlapping arcs that create four wings merging at a central core area, resembling a butterfly with wings spread. Overall building massing was established considering aesthetics, views, hotel operations and the owner's target mix of hotel rooms and suites, so each of the four wings and the central core are at different heights. See Figure 2. In the upper half of the building, even the story heights vary by wing to create a range of guest room experiences. The West wing drops off progressively from Level 23 to Level 25. At Level 25 the central core stops, creating two independent towers above that point. The North and East wings form a V, with the East Wing terminating in stages from

Level 31 to Level 33 and the North Tower continuing upward. The South Tower stands alone and soars to the maximum height of the building. Tip to tip the Aria Tower floor plan extends 880 feet in the North-South direction and 480 feet in the East-West direction. The central core zone is 310 feet long and 120 feet across at its widest section. All wings are 70 feet wide with lengths varying from 120 feet to 250 feet.

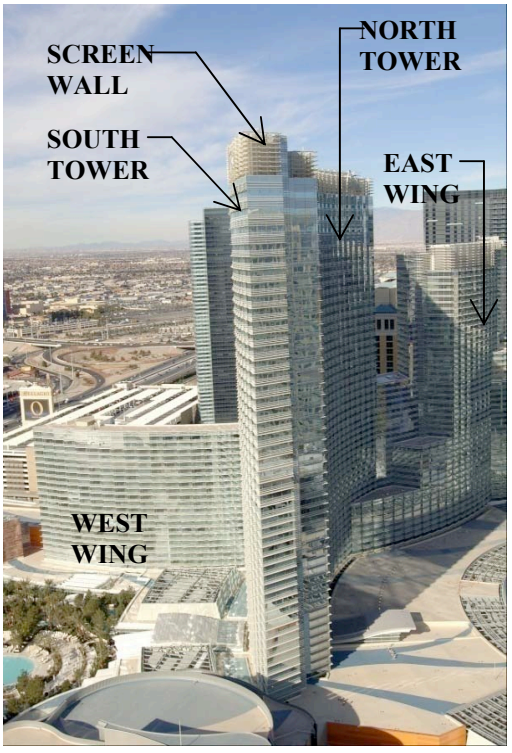

Figure 2. South Aerial View of Aria Tower- Looking North, 2009

Although based on smooth circular arcs, the hotel tower slab edges follow a sawtooth pattern with regular jogs. This edge mates with aluminum and glass façade panels with integral offsets to provide each guest room with an enhanced corner view. The façade articulation also creates exterior elevations that Cesar Pelli of Pelli Clarke Pelli Architects (PCPA) calls a "shimmering world of reflections" that may contain images of adjacent buildings, distant mountains or dramatic Las Vegas lights.

While functionally and aesthetically important, having multiple curved wings of varying heights posed several structural challenges. Wings may try to work separately or together under wind load, and move differently under seismic load. The curved geometry may affect building behavior. Wings of varying heights mean nonuniform mass distribution which can induce torsional effects. To address and minimize these issues, it was essential to establish a lateral system capable of providing stiffness of similar magnitude in every feasible direction to resist lateral forces and achieve the desired occupant comfort level. Additional considerations included building height constraints, usable floor area goals, construction schedules, material sources, bottom line costs, and intricate coordination with adjacent structures. After studying a variety of framing options, a cast-in-place concrete system was selected as most suitable for this application. The Aria Tower was to be a concrete system with shear wall cores, post-tensioned (PT) two way flat plate slabs, and long, narrow concrete perimeter columns aligned with walls between rooms. Completed Aria Tower construction included 250,000 cubic yards of concrete, 8,000 tons of mild steel reinforcement and 1,600 tons of post-tensioned (PT) cables totaling 1,200 miles - enough to nearly encircle the state of Nevada.

ARIA TOWER FOUNDATION

The sub-grade under the Tower consists of moderate to strongly cemented clayey gravel and sandy gravel laced with caliche, or hardened calcium carbonate deposits. The strongly cemented zone extends to a depth of 75 feet below grade, and is underlain by a saturated, under-consolidated, and very soft formation that varies in depth from 50 to 80 feet. Soil excavated for the two story basement would offset only a small fraction of the tower weight, and using a mat under the large tower footprint would result in high compressive stresses in the deep soft soil. The estimated settlement of 12 to 18 inches for a mat foundation was deemed unacceptably large. Therefore a deep foundation system using cast-in-place (CIP) concrete piles was recommended by geotechnical engineer GeoDesign as presented in Table 1.

Building/Location	Location/ Loading Condition	Min. Recommended Shaft Length (ft.)	Estimated Settlement (inches)
Aria Tower	Center Core	100	4
	South Tower	120	5
	North Tower	120	5
	West Wing	100	5
	East Wing	100	4
East Podium	30x90 Grid	70	4
	30x30 Grid	30	3
West Podium	30x30 Grid	50	3

Table 1. Estimated Settlement for Structures Supported on Drilled Shafts

To resist their gravity and overturning forces, the shear wall cores are supported on partial area mats 11 feet thick bearing on 48 inch diameter 8,000 psi concrete piles at least 120 feet long. The actual pile length was determined by field testing to obtain a minimum allowable axial capacity of 4,700 kips. Perimeter tower columns and adjacent podium columns are supported on pile caps bearing on smaller, shorter piles. The first Aria Tower pile was cast in January 2006. When the first Tower mat was cast on June 26, 2006 at the central core, Las Vegas Boulevard was closed from midnight to 8 AM as 550 concrete trucks delivered 5,520 cubic yards as a single pour. The massive concrete mat was continuously monitored for maximum temperature and for temperature differentials as it cured by using thermocouples installed at the top, center, and bottom of mat in six locations.

Upon completion of the Aria Tower and surrounding podium construction, the maximum settlement at tower core was measured at 3 ½ inches, and podium columns located at 70 feet from Tower core settled at 2 ½ inches. The settlements were well below the geotechnical estimates. The site was then locally re-graded to compensate for settlement by matching the as-built finished floor elevations.

LATERAL SYSTEM

Lateral stability of the Tower is provided by ordinary reinforced concrete shear walls located at the central core, at the two junctions where wings meet, and at the stair well on the tip of each wing. Average wall thickness is 24”, with a

maximum thickness of 36" at the central core base. This system was permitted by the governing code based on International Building Code[1] (IBC) 2000 for Seismic Design Category C. Coupling ('link') beams are only 16 inches deep on typical floors to satisfy aesthetic requirements of the ceiling profile transition in elevator lobbies. While such shallow beams can result in excessive flexibility, the cores of this building have long unbroken wall panels that improve stiffness and strength.

ETABS software developed by Computers & Structures, Inc. (CSI) was used to perform lateral analyses. CSI collaborated with TT in modifying, improving, and recalibrating the software throughout the Aria Tower design process to accommodate the unique and complex geometry. The contribution from CSI was invaluable to successful completion of the lateral analyses.

One complication arose in modeling methods. For overall building lateral analysis it is common to treat each floor as a rigid diaphragm. However, that approach had two drawbacks. First, at the time, the rigid diaphragm approach only permitted one diaphragm per plan, so it would incorrectly treat all the nodes at a level as sharing a common slab, even above the separation of wings at Level 25. Second, at every change in core geometry, a rigid diaphragm attempted to redistribute shear through transfer forces that were sudden, unrealistically large and impractical to design for. Consequently a "semi-rigid" diaphragm system was adopted: in-plane rigidity of the diaphragm was based on realistic slab stiffness values. Multiple runs bracketing potential properties for cracked and un-cracked sections and other variations confirmed that the transfer forces were relatively insensitive to the diaphragm values used. Floor plates and perimeter columns were included in the finite element model. As the 2D membrane floor plate elements in the standard semi-rigid model lacked the capacity to properly handle complex mass distribution, further studies concluded that shell element with 6 degrees of freedom was better suited to model the Aria Tower floor plates.

The inclusion of columns and floor plates as shell elements simplified gravity load distribution and building mass applications. It also resulted in through-slab transfer forces with values and distributions along core heights that are realistic, credible and constructible. While creating the comprehensive model required considerable effort, it proved worthwhile for flexibly responding to a continuous stream of requests for feasibility studies due to architectural, interior, and MEP changes. Since tower structural construction led issuance of the core and shell building permit by a year and half, the model offered favorable relief in its expeditious "re-modeling" process.

However, the approach required taking significant precautions as well. The out-of-plane stiffness of shell elements naturally created moment frames from the slab/column gravity system. Moment frame behavior could alter dynamic behavior when linked with the shear wall system. We made it clear that we were not providing a "Dual System", as defined in IBC[1] code, because that would further complicate the analysis and design. From the final model the slab/column frames provided a stiffness

contribution of 12%. This was small enough to have only a minor effect on the building period and on forces taken by the core walls. This justified designing the lateral system under an "Ordinary Shear Wall" classification.

Tower walls also lend lateral stability to the surrounding podium structures, including long span cantilevered east and west canopies, the entire north and east podiums, and part of the south and west Podiums. This was the natural result of avoiding architecturally undesirable seismic separation joints through the active lobby and casino areas and framing podium areas with steel to maximize clear spans and future alteration flexibility. Later versions of the lateral system model included the adjacent podium structures to better simulate podium mass contributions. This also afforded means to extract the resultant lateral forces for podium planning and design. Upon project completion, the mass contribution from the podium was 14% out of a combined total weight of 1.38 million kips. See Figures 3 and 4.

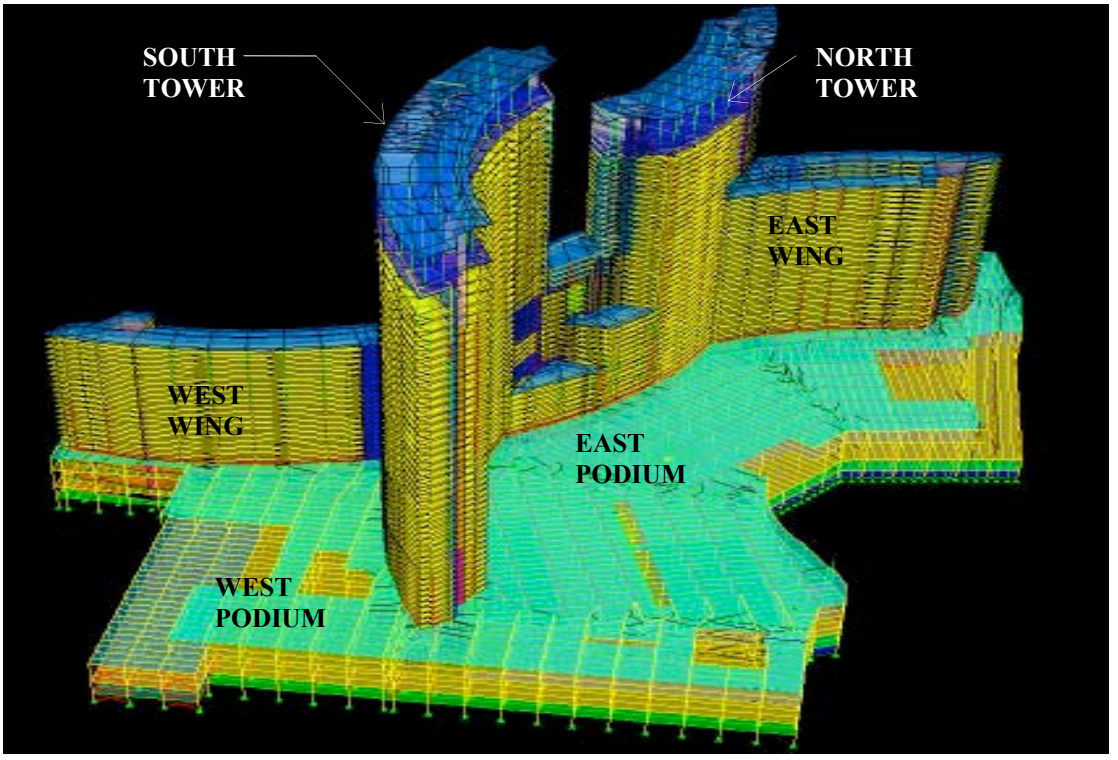

Figure 3. Isometric View of Finite Element ETABS Model of Aria Tower

Wind loads were provided by Rowan Williams Davis & Irwin Inc. (RWDI) based on wind tunnel test results. Recognizing the possibilities for wings to move independently, RWDI determined instantaneous wind forces using a High Frequency Pressure Integration model, where hundreds of pressure taps are monitored in real time. The resulting wind forces were applied at 6 points per floor - one each at the North, South, East, and West wings; and one at each side of the Central Core. To reflect the potential effects on the wings of complex air flows and vortex patterns, RWDI presented a wind load matrix of 170 cases in an assortment of direction and

magnitude combinations. Further combinations with gravity and seismic forces per IBC[1] code resulted in an impressive 200 load cases. So many load combinations applied to a massive finite element model strained the hardware and software built-in limitations, even after software patches and upgrades. To solve this limitation we eventually grouped load cases and analyzed them separately. An EXCEL file was developed to import and sort the results from various grouped analyses and determine the controlling cases. These cases were then applied to the model for final analyses.

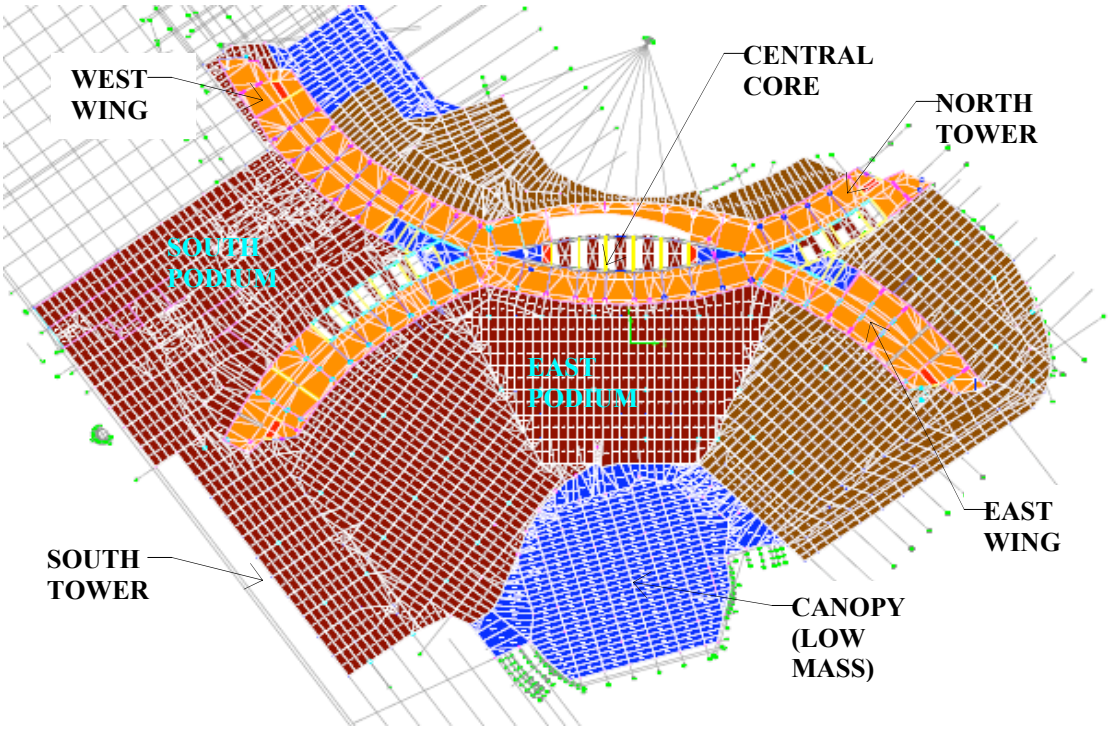

Figure 4. ETABS Model of Aria Tower with Attached Podium at Level 03

Seismic design was based on Modal Response Spectrum Analysis, using a specific response spectrum curve developed by GeoDesign for ground motions with a 2% probability of exceedance in 50 years. To achieve the design objective of balanced performance under seismic behavior, seismic forces were applied at mass centers of each wing along the principal axes of each wing/tower, and were also studied for the combined tower(s). The modal base shear calculated using the Complete Quadratic Combination (CQC) method was scaled up to match the equivalent static base shear. Member stiffness reductions were adjusted based on concrete stress levels from the analyses. The response spectrum and static analyses were then repeated for the new properties and iterated until convergence was reached. The analyses also took into account code-mandated accidental torsion, amplified torsional forces required due to plan irregularity, and amplification from the P-Δ effect.

The lateral system had a first-mode period of 4.62 seconds. Story drifts were well within the code recommended limits of 1.5% and 0.2% of story and building heights under seismic loads and wind load, respectively.

ASTM A1035 MMFX[2] steel was used to ease rebar congestion at critical shear wall end zones. While less ductile than conventional rebar, use of this steel was appropriate in ordinary concrete shear walls with low ductility demand. In addition, the American Concrete Institute[3] (ACI) placed an upper limit of 80 ksi on the yield strength of reinforcing steel, and a variance for higher strength was not granted by the County. As a result, even though the steel has a minimum yield value of 100 ksi, only 80 ksi was used in the design.

GRAVITY SYSTEM

Gravity loads are carried by two-way post-tensioned (PT) slabs supported by columns and shear walls. Exceptions were made at the tower roof, mechanical floors, casino floors, sky villas, and transition floors that have heavy loads, extensive floor openings, and/or interior planning not complete at the time of design. At the exceptional floors, conventionally reinforced two-way flat plate or one-way slab/beam systems were more suitable for their flexibility in responding to structural modifications. To account for the influence of building lateral system deformations on the slab/column frames, all associated gravity frames were designed and checked with appropriate load combinations that included forces from lateral analyses.

PT slabs were first analyzed by using strip models in ADAPT 2D software developed by ADAPT Corporation with the results exporting into its companion 3D finite element ADAPT Modeler for quantity optimization, stress evaluation and slab deflection assessment. See Figure 5. ADAPT Corporation collaborated with TT in modifying, improving and recalibrating their software throughout the tower design process. Their contribution was also invaluable to project completion.

A thickness/maximum span ratio of 1/48 was used per PCI[4] guidelines. While it is common to push for even thinner slabs, a 9 ½ inch thick PT slab was selected for its superior serviceability performance and comparable cost to thinner slabs. Preliminary studies demonstrated that in comparison with thinner slabs, the increase in concrete volume and foundation quantities were offset by savings in total PT and mild steel tonnage.

Neither ACI nor IBC discussed using unbonded PT tendons in resisting seismic force. However, PTI[5] observed that past experiences revealed excellent member performances with unbonded tendons in earthquakes. Hence an unbonded PT system was selected for the project considering the moderate Seismic Design Category C classification, favorable cost and ability to accommodate a tight construction schedule when compared to a bonded tendon system. Sufficient mild steel reinforcement was provided to resist at least 75% of the tensile force for both positive and negative moments at column faces from factored load combinations that included lateral load effects.

Banded tendons were placed in each wing in the transverse (radial) direction, with uniformly distributed tendons running in the longitudinal (circumferential) direction. The choice of tendon orientation addressed a concern that pre-stressing forces are ineffective acting parallel and adjacent to longitudinal stiff shear walls. By running the uniform tendons in this direction, most of the uniform tendons are farther from the shear walls and more effective in providing the desired two way action. Banding tendons in the transverse direction clustered the dead-end anchorages near cross walls and far from the complex and congested reinforcement of the shallow link beams.

The effective post-tensioning force was selected to balance 65% to 75% of the structural dead weight, while the remainder of flexural design moment is resisted by mild steel reinforcement. The design philosophy was to minimize PT based upon coordination with interior design and curtain wall consultants. The interior layout placed structurally undesirable floor penetrations in the vicinity of perimeter columns; the arrays of stud rails provided around these columns to meet punching shear strength requirements further congested areas already teeming with mild steel reinforcement and PT tendons; and the tendons must sweep to avoid openings. At the same time, façade panels with integral offsets at the sawtooth slab edge in front of perimeter columns require many more curtain wall anchorages/embedments, and some intrude into locations reserved for anchorage of banded PT tendons. After extensive cycles of coordination, both façade anchors and PT anchors were fit into the limited space. Minimizing the number of PT tendons alleviated anchorage congestion. In addition, having more than typical mild steel in PT slabs benefited slab ductility, improved redundancy, and provided the ultimate strength needed to resist load combinations including lateral load effects.

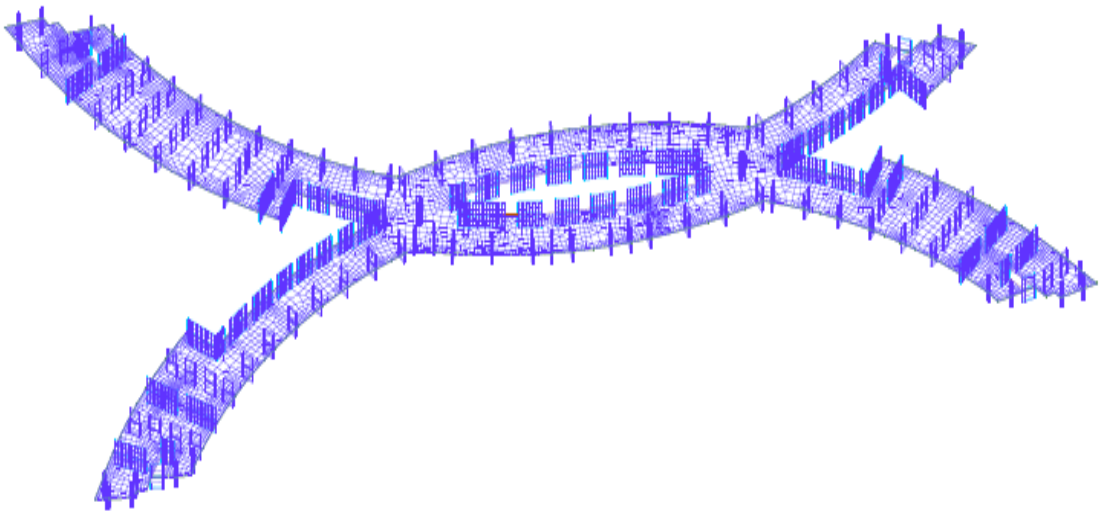

Figure 5. ADAPT 3D Model of Post-Tensioned Floor System

Long concrete structures in general and long PT structures in particular require attention to potential effects from restraint due to shortening. Elastic

shortening from PT precompression, long-term shrinkage and thermal strains must be considered. To address restraint between separate stiff cores, delayed-pour strips were located in the narrow slab 'neck' between the cores. Although the far ends of wings were relatively unrestrained against shortening, the contractor requested that additional pour strips be included in the design to suit concrete pour capacity and construction schedule. See Figure 6. The strips were left open for a minimum of 21 days after cable elongation was approved. These pour strips were critical to minimize the stresses induced by creep and shrinkage of the slabs bounded by stiff vertical elements. All pour strips were designed as simply supported drop-in slabs carried by a cantilevered slab at each side.

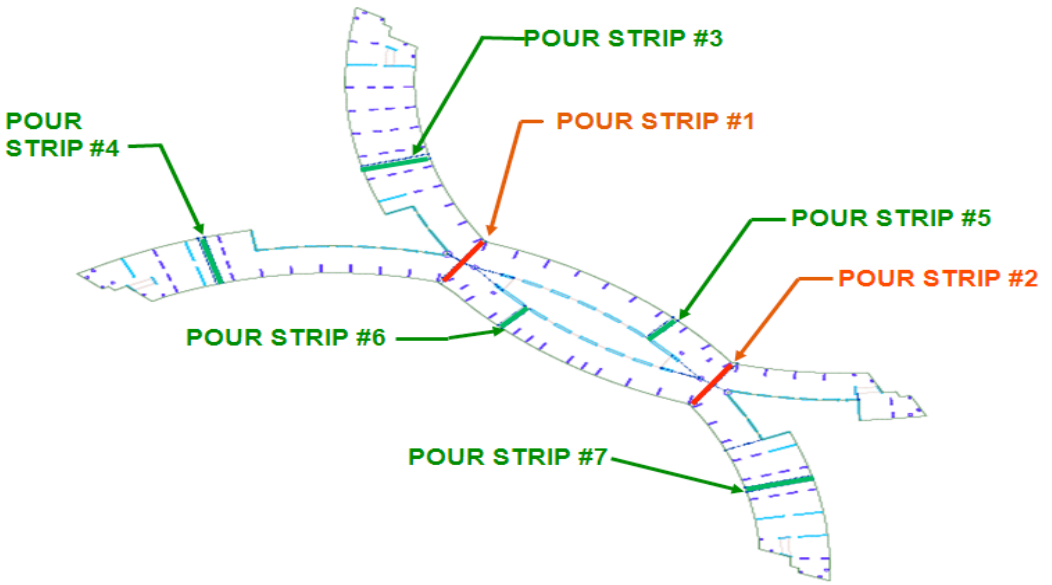

Figure 6. Pour Strip Locations

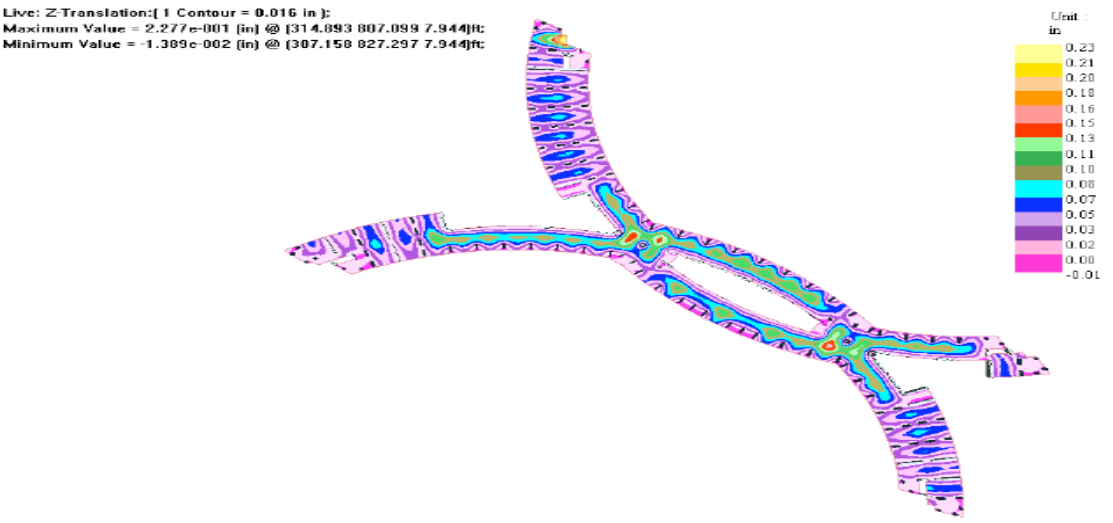

Figure 7. Slab Displacement under Live Load

For curtain wall support and curtain wall joint design it was important to control slab edge live load deflections as well as differential live load deflections between adjacent floors. Relative to adjacent column supports, the PT slab is anticipated to experience only 1/8 inch live load displacement at mid-span along the building perimeter. A maximum live load displacement of 1/4 inch occurs at the tips of 17 foot long cantilevered slabs. See Figure 7. The typical deflection to span ratio of 1/3,500 is well within stringent criteria for sensitive curtain wall installations.

Transfer girders are common occurrences throughout the building to suit different functions at different floors. Deep concrete beams up to two stories in height used as transfer girders were designed in accordance with the ACI[3] "Strut and Tie Model" procedure.

Columns were designed for forces from gravity loads and effects of lateral system deformations through appropriate factored load combinations. Functional changes demanded intricate column geometric shape changes throughout the tower. Columns near wing meeting points change shape numerous times along their height. Transformations that result in a shift in plan center of gravity, which are also common, required careful study for their impacts on column strength and lateral force transfer. At locations where a wing perimeter column above is interrupted by the corridor for a merging wing below, the interrupted column was 'hung' using bonded 150 ksi DYWIDAG pre-stressing thread bars with tightly controlled construction sequences.

SPECIAL FEATURES AND DISCUSSIONS

A tower roof screen wall is one of Aria Tower's distinguishing features. See Figure 2. It serves to conceal building maintenance cranes that facilitate window washing operations. The aluminum fin enclosures complement the reflective glass and aluminum curtain wall panels below. Closely spaced aluminum fins are cantilevered a maximum of 6 feet from back-up alumium frames supported by structural steel tube posts cantilevered up to 36 feet from roof structures. Behind the screen walls, two sets of window washing cranes were designed to operate simultaneously on tracks along the entire length of each tower. The tower cranes with 109 feet booms exert tremendous forces on structural supports in downward, upward, and torsional directions. For smooth crane operation, the deep concrete beams, girders, and pedestals designed to support the tracks were sized to restrict deflection to less than span/1,200 under service loads.

A water wall within the Aria Tower ground floor lobby was only a glimmer of a concept when lower floor construction began: water flowing down thin sheets of glass panels sloped at 7 degrees and suspended from two floors above in a 60 foot high space. To keep structural support as thin as the glass panel and its equally thin frame, a post-tensioned cable system was planned. This required all concrete elements to receive the water wall and associated mechanisms to be tuned to resist

substantial post-tensioning forces and limit deflection to a negligible value to minimize its effect on cable system performance. In 2009, Novum Corporation received the commision to design the water wall by using a stainless steel cable system. This water wall is indubitably one of the highlight features in the tower lobby.

Curved floor plans such as Aria Tower wings often perplex structural designers of post-tensioned systems. Should the tendons be curved or should they run straight? The first impression is that tendons placed along a curve will result in a transverse component perpendicular to the building curvature adding lateral force to the building system. On the contrary, if tendons curve to follow the floor plan curve there should be no net transverse force from the post-tensioning, and precompression stresses from the PT act uniformly. However, if building floor plan and tendons curve differently the force of 27 kips per tendon can have a significant impact on the lateral system and on in-plane forces in the slab itself. It should not be ignored.

Shrinkage and creep effects in tall concrete structures are of significance to building short term and long term serviceability. Differential axial strains on columns and shear walls were of particular interest to Aria Tower curtain wall construction and installation tolerances, as the façade runs along both columns and shear walls. We developed a proprietary program using Visual Basic in EXCEL to estimate cumulative effects based on Model B3 from report ACI 209R-92[6]. The design implemented differential shortening mitigation measures, including optimization of member geometries, reinforcing ratios, and concrete strengths. In addition, floor elevations included compensation at every 5 levels to help mitigate estimated future shrinkage and creep movements.

CONCLUSION

The journey of Aria Tower design and construction started in the spring of 2004, and ended with spectacular fireworks for its Grand Opening ceremony on the 19th of December, 2009. While subsequent events have swirled around CityCenter with drama worthy of Las Vegas, few have paused to reflect on the fact that this LEED Gold Aria Tower is not only iconic and visionary, but a symbol of Las Vegas's future direction: a feat in design, engineering, and construction completed on schedule with few glitches thanks to a successful team effort. Thornton Tomasetti (TT) is proud to have been a part of the design and construction team on a project with such ambitious goals including a vision for the future of Las Vegas, a highly compressed design and construction schedule, and integration with surrounding buildings. This accomplishment entailed collective efforts and a conscientious emphasis on team work and cooperation from all parties involved. Therefore, this article also pays tribute to Udom Hungspruke, project manager of TT, Pelli Clarke Pelli Architects (PCPA) as design architect; HKS Architects as production architect; Perini Construction as General Contractor; and Flack & Kurtz as MEP consultant. We also would like to thank Jonathan Neubauer, MECE, and Corey Guo, P.E. for their technical contributions.

ABSTRACT

Engineering structures such as wind turbines require continuous monitoring to ensure structural safety, to reduce the overall maintenance and repair costs and, ultimately, to achieve extended lifetimes and a greater economic viability. For that purpose, an automated SHM system for wind turbines has been developed and installed on a 500 kW wind turbine in Germany. During its operation, temporary malfunctions of the installed sensing units have been observed. These malfunctions, such as temporary sensor breakdowns which are well known from real-time SHM systems, might cause the loss of valuable monitoring data if not detected timely. A multi-agent system, which is capable of self-detecting system malfunctions and notifying the human individuals automatically, has been developed and integrated into the existing SHM system. The SHM system and its subsystem, the multi-agent system, have been in continuous operation since 2009. Since then, various malfunctions have automatically been detected and appropriate actions have been taken in a timely manner. As a result, the malfunctioning of the sensors did not lead to significant data loss, thus enhancing the quality of the SHM system.

INTRODUCTION

Degradation of engineering structures, increasing demands on structural safety and growing maintenance costs are emerging problems that are gaining attention in civil and environmental engineering. Engineering structures require continuous monitoring and frequent inspections in order to reliably assess their performance and safety, to provide timely maintenance support and to increase service life. This paper discusses the development and implementation of a self-managed monitoring system for a wind turbine structure. Wind turbines represent one of the most cost-effective sources of electrical power providing an environmentally friendly energy production. Accordingly, wind energy technology is fostered and large wind energy farms are being built in many countries. The world market for wind turbines has considerably

grown, for example, with approximately 16 GW of new capacity added worldwide in the first half of year 2010 (WWEA 2010).

The necessity of applying innovative structural monitoring systems has been recognized over the past several years. Wind turbine monitoring is considered worthy of substantial investments and supports by governments (BMJ 2009, MIWF 2009). Considerable efforts are currently being undertaken to design SHM systems for wind turbines. Novel sensing technologies and sophisticated monitoring techniques are being developed and applied to wind turbines (Jüngert 2008, Lading *et al.* 2002, Sutherland *et al*. 1994, Rolfes *et al*. 2007). However, robust software platforms designed to facilitate data interrogation, data archiving and automated execution of monitoring tasks have received little attention.

In a previous research project (Hartmann and Höffer 2010), a decentralized real-time SHM system for remote monitoring of wind turbines has been designed, implemented and installed on a 500 kW wind turbine in Germany. The decentralized SHM system integrates different information technologies and provides automated data acquisition, storage and interrogation functionalities. In addition, the SHM system provides remote access to the monitoring data including flexible data visualization and data export mechanisms. During the operation of the SHM system, it has been observed that temporary malfunctions occurred affecting the performance and the reliability of the SHM system. The causes for such malfunctions, well-known from real-time SHM systems, are manifold, e.g. communication problems when using long-distance lines, temporary power blackouts that affect the computer systems or simply hardware problems of the data acquisition units (DAUs) due to extreme weather conditions.

Evidently, if not detected timely the malfunctions might cause the loss of valuable monitoring data. A multi-agent system, which is designed to detect malfunctions automatically and to immediately send out alerts for corrective actions, has been developed and integrated into the existing SHM system. Multi-agent software technology allows creating modular and extensible decentralized systems based on cooperating software agents, which are self-contained computational entities capable of autonomously carrying out monitoring tasks, such as detecting DAU malfunctions, generating alert messages and sending notifications. Each software agent is designed for solving one single task. With a certain degree of flexibility and autonomy, a software agent can decide on its own which actions are appropriate to solve its task and which other cooperative agents are to be requested for assistance to achieve a specific goal. A multi-agent system is scalable and can be easily extended or modified by adding further specialized software agents.

This paper presents a multi-agent system designed for structural health monitoring applications. First, a decentralized real-time SHM system installed on the wind turbine in Germany is described. The design and implementation of the multi-agent system and its integration with the existing SHM system are discussed. Examples are presented to demonstrate the practicability and the reliability of the multi-agent system, which has been in continuous operation since 2009.

A DECENTRALIZED REAL-TIME SHM SYSTEM FOR WIND TURBINES

A decentralized real-time SHM system is designed and prototypically implemented on an Enercon E-40 wind turbine located in Dortmund (Germany) to continuously assess its performance and operational conditions. As shown in Fig. 1, the SHM system consists of a hardware monitoring subsystem M_1 and a software monitoring subsystem M_2. Installed in the observed wind turbine, the hardware subsystem M_1 includes an array of sensors connected to data acquisition units, which are controlled by a computer located on-site in the structure. Remotely connected to the hardware subsystem, the software subsystem M_2 consists of software modules that are designed to autonomously execute crucial monitoring tasks, such as storing and converting the collected data sets. Both subsystems are briefly described in the following.

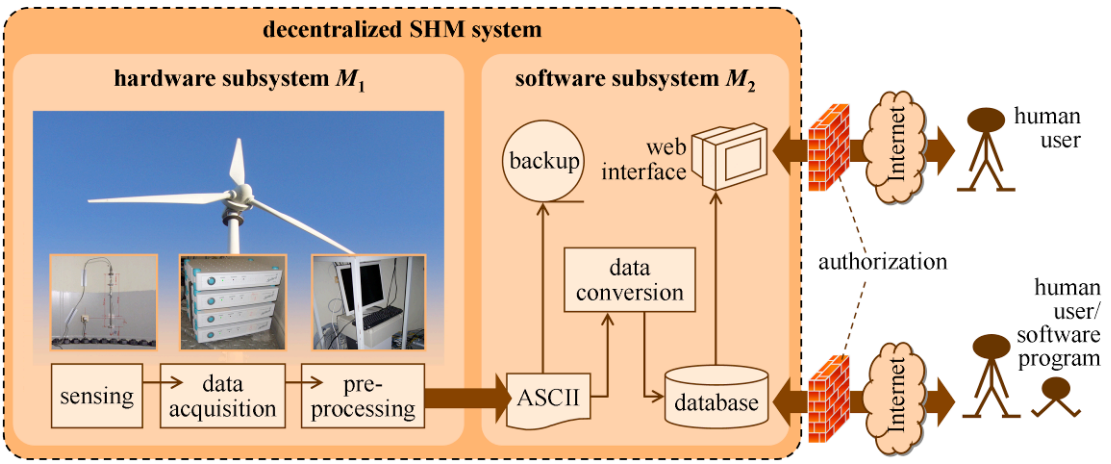

Figure 1. Architecture of the SHM system.

Hardware subsystem

The hardware subsystem M_1 collects structural and environmental data for assessing the conditions of the wind turbine. To this end, the wind turbine is instrumented with sensors that are installed both inside and outside the steel shaft as well as on the foundation of the structure. The sensors are controlled by data acquisition units which are connected to a computer located in the wind turbine.

As shown in Fig. 2, six inductive displacement transducers, type HBM-W5K, are mounted at two different levels inside the shaft. The displacement transducers are complemented by Pt100 resistance temperature detectors to account for temperature influences on the displacement measurements. Additional temperature sensors are placed at two other levels in and outside the wind turbine to measure the temperature gradient of the wind turbine shaft. For the temperature data acquisition, three 4-channel Picotech RTD input modules PT-104 are installed and, through RS232 to USB interface converters, connected to the computer located in the wind turbine.

Six three-dimensional PCB-3713D1FD3G piezoelectric accelerometers, manufactured by PCB Piezotronics, are placed at five levels in the wind turbine shaft. At the foundation of the wind turbine, three single-axis PCB-393B12 piezoelectric

seismic ICP accelerometers are installed. For acquiring wind information, a Metek USA-1 ultrasonic anemometer is mounted on a telescopic mast near the wind turbine. Fig. 2 shows the instrumentation of the wind turbine, exemplarily illustrating the interior of the shaft at the level of 21.3 m as well as the anemometer installed.

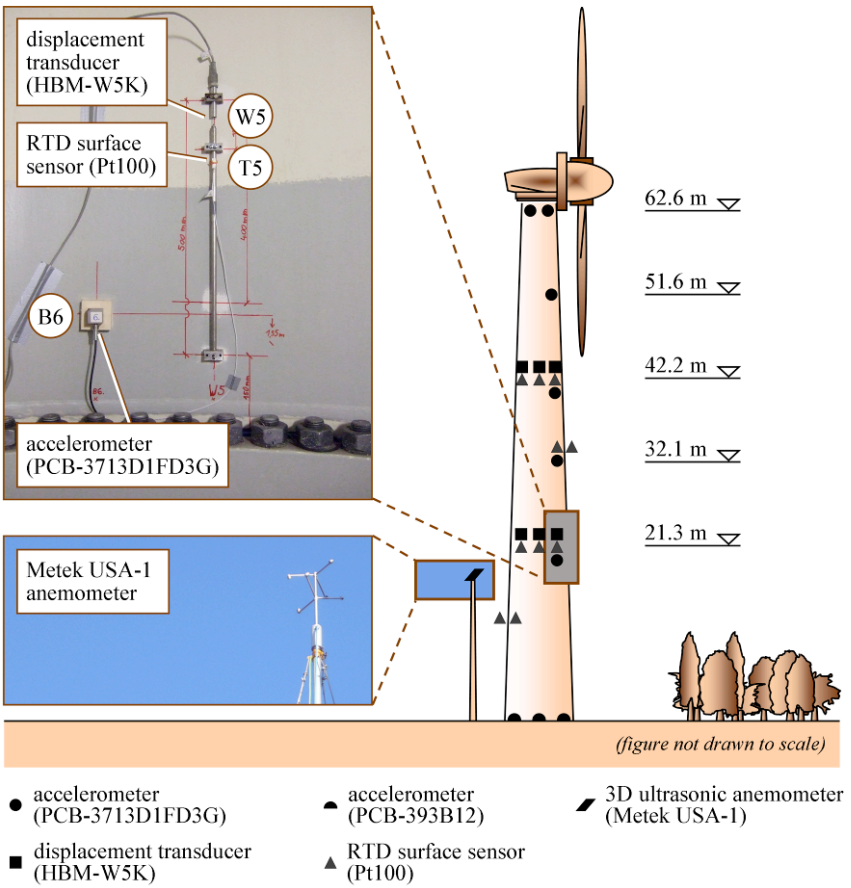

Figure 2. Instrumentation of the wind turbine (hardware subsystem).

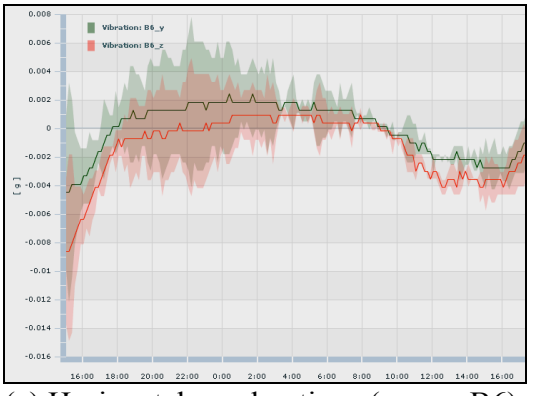
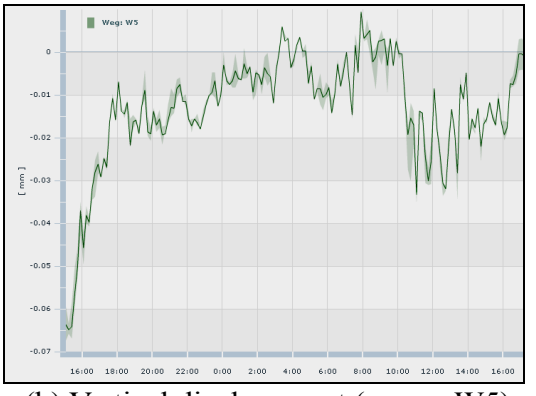


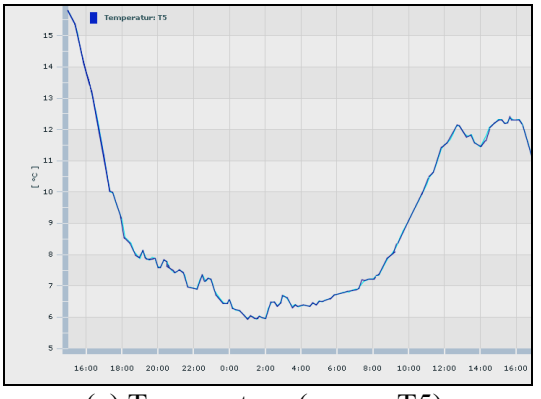
Software subsystem

The data collected and pre-processed by the hardware subsystem M_1 is forwarded to the software subsystem M_2 using a permanently installed DSL connection. The purpose of the software subsystem is to perform data archival and data processing tasks such as condensing, converting and storing of the acquired data sets. Furthermore, the subsystem is design to allow authorized users to remotely access the SHM system independent of their geographical location. The subsystem M_2 comprises (a) server systems for on-line data synchronization, data conversion and data transmission, (b) RAID-based storage systems for periodic backups, and (c) a MySQL database system for persistent data storage. A web-based interface is available for remotely accessing and visualizing the monitoring data.

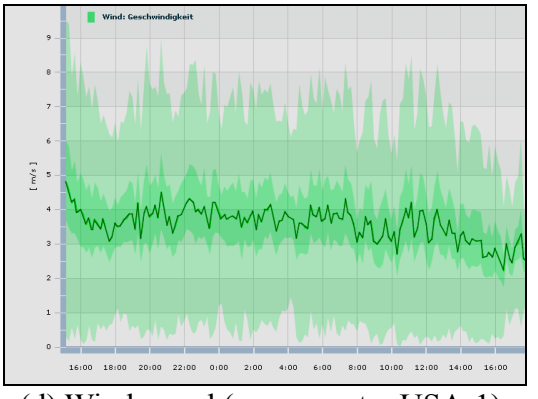


Remote access to the data is provided in two ways: through a web interface and through a direct database connection. The web interface offers GUIs for remotely

visualizing, exporting and analyzing the monitoring data. Through the database connection, the monitoring data can be directly accessed by software applications such as MATLAB and other tools.



To illustrate the remote access to the SHM system using the web interface, Fig. 3 shows a user's GUI for visualizing wind turbine data, collected on October 22, 2010, in near real-time. In Fig. 3a, a typical acceleration time history is displayed, collected by accelerometer B6 shown in Fig. 2 at the level of 21.3 m. Fig. 3b, 3c and 3d show, respectively, the displacement time histories (collected by sensor W5), temperature data (acquired by displacement transducer T5,) and wind speed (recorded by the anemometer). Besides remotely visualizing the sensor data, the user can analyze the sensor data with embedded functionalities provided by the web interface.



(a) Horizontal accelerations (sensor B6).

(b) Vertical displacement (sensor W5).

(c) Temperature (sensor T5).

(d) Wind speed (anemometer USA-1).

Figure 3. Data sets remotely accessed via the web interface provided by the SHM system (collected on October 22, 2010, during one day).

Malfunctions observed during operation

A typical malfunction of a temperature DAU, observed during operation of the SHM system is elucidated in Fig. 4. As can be seen from Fig. 4, the temperature DAU malfunction is implicitly indicated by anomalies within the data sets collected by the DAUs themselves. A malfunction, or cause for alert, that is characterized by a large number of identical measurements due to an internal system crash of the DAU at time

t_0 is shown in Fig. 4. As a result of the malfunction occured, the DAU cannot record and store the actual temperature measurements. Instead, the last normally collected value (sensed right before the occurrence of the malfunction) is stored repeatedly by the DAU.

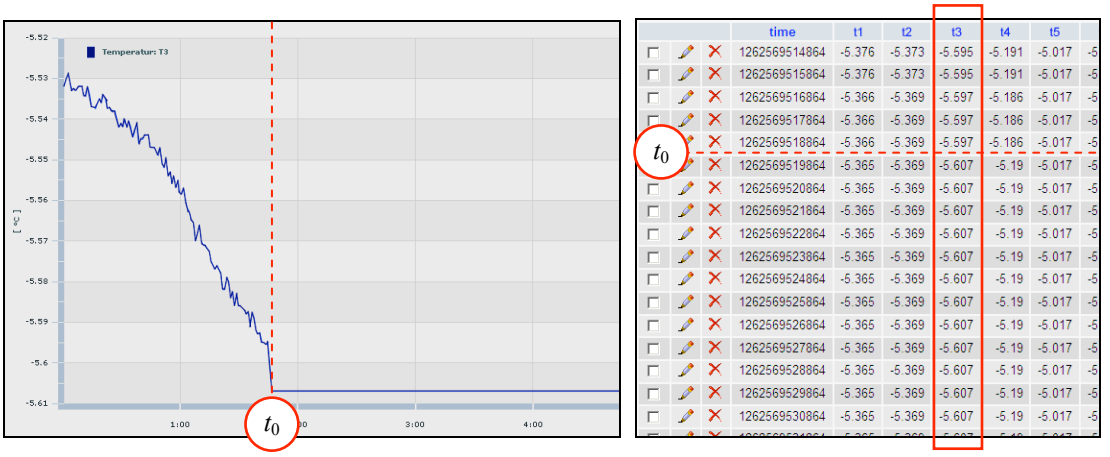


Figure 4. Visual and numerical representation of a DAU malfunction illustrated by temperature sensor T3 through the web interface (left) and the direct database connection (right).

A MULTI-AGENT SYSTEM FOR AUTONOMOUS MALFUNCTION DETECTION

The purpose of the multi-agent system, which is integrated into the SHM system, is to detect malfunctions in the DAUs automatically and to inform the responsible individuals immediately about the defects so that the affected DAUs can be restarted remotely or replaced in a timely manner. The agent-based paradigm has been chosen as a technological basis for the implementation of the self-detection and self-management functions. A software agent can flexibly carry out its autonomous actions and cooperatively communicate and work with other agents. Software agents are characterized by a number of properties (Wooldridge and Jennings 1995):

- **autonomy**: agents operate without any direct intervention by humans and exhibit control over their actions
- **social ability**: agents interact with other agents (and possibly humans) via agent-communication languages
- **reactivity**: agents perceive their environment (for example, the physical world or a SHM system) and respond to the changes that occur in the environment
- **pro-activeness**: agents do not simply act in response to their environment, but they are able to take initiative and to apply goal-directed behavior

The developed multi-agent system comprises a set of collaborating software agents implemented to accomplish the tasks required for malfunction detection. First,

the multi-agent system hosts two special agents, namely the "Agent Management System (AMS) agent" and the "Directory Facilitator (DF) agent". The AMS agent is responsible for the overall management actions, including creating and terminating other agents. The DF agent implements a yellow page service, allowing the agents to advertise their services as well as to look up other agents that offer the services needed to cooperatively accomplish a specific monitoring task. The AMS and DF agents together provide the overall configuration description of the multi-agent system. Furthermore, an "interrogator agent", implemented for analyzing the monitoring data with respect to malfunctions, and a "mail agent" for sending notifications to the responsible individuals are included in the multi-agent system.

Data interrogator agent

The interrogator agent analyzes the sensor data collected by the DAUs to detect malfunctions. As in the example described earlier, one malfunctioning symptom for a temperature DAU can be characterized by a large number of identical measurements. To detect such an anomaly, the interrogator agent at certain time intervals extracts and analyzes the temperature data sets stored in the centralized MySQL database. A set of configuration files (specifying interrogation parameters, database URL, database driver, sensor specification, scheduled interrogation intervals, etc.) is pre-defined in the multi-agent system (Smarsly *et al.* 2010).

The connection to the database being part of the software subsystem M_2 is realized through a programming interface based on the Java Database Connectivity (JDBC). JDBC is an industry standard for database-independent connectivity between Java applications, such as the software agents considered here, and various database systems. The security of database requests and data transmissions are provided by the database system, i.e. the MySQL database, which requires password and username as well as secure drivers to be specified by the agent.

Email notification agent

Upon detecting a malfunction, responsible individuals are immediately notified. On behalf of the interrogator agent, notifications are issued by the mail agent via an agent-based email messaging service in a two-step process. In the first step, the mail agent collects all relevant data from the monitoring system, which is necessary for composing the emails. The mail agent creates the emails using the information about the observed anomaly that are provided by the interrogator agent. Metadata, such as addresses of the recipients or the email server to be used, are acquired for the automated emailing; these metadata are stored in configuration files located in the multi-agent system. In other words, the email content is created based on the anomaly information received from the interrogator agent and the email header is automatically created based on the metadata obtained by the mail agent from the configuration files resided in the multi-agent system. Once the emails are composed, they are sent by the mail agent to the email clients (the individuals responsible for the malfunctioning devices). Secure email messages are ensured by username- and

password-based authentications that the mail agent, like a human user, needs to specify when trying to access the mail server.

Decentralization and extensibility

One distinct advantage of the agent-based approach is that the software system can be easily extended to accommodate additional functions. For example, self-detections of other types of malfunctions (that are not characterized by a large number of identical values) or interrogations of other measurement data (such as acceleration data) can be implemented as additional specialized agents that are integrated into the multi-agent system. Also, damage detection algorithms, such as fast Fourier transforms or autoregressive models, can be included into the multi-agent system as software agents. Software packages, such as MATLAB, can be integrated into the multi-agent system by "wrapping" the particular software package as an agent.

Software agents can be distributed over several computers and geographically situated at different locations. Communications between distributed agents can be carried out through agent messages via computer networks, such as the Internet. Additional agents can be launched remotely to perform specific structural monitoring functions as long as they are registered to the multi-agent system.

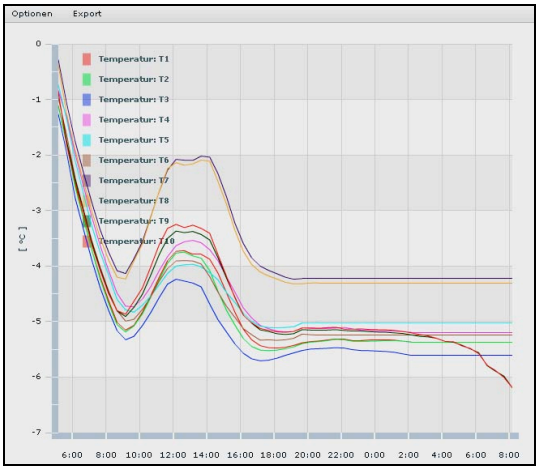
To ensure extensibility and interoperability, the multi-agent system is implemented in compliance with the specifications issued by the Foundation for Intelligent Physical Agents (FIPA). FIPA, the IEEE Computer Society standards organization for agents and multi-agent systems, promotes agent-based technology, interoperability of agent applications and the interoperability with other technologies. The FIPA agent communication specifications, for example, ensure a common understanding of two or more communicating agents based on the FIPA Agent Communication Language (ACL) as used for the communication within multi-agent systems (FIPA 2002).

VALIDATION OF THE MULTI-AGENT SYSTEM

The multi-agent system has been integrated into the existing SHM system to monitor the temperature DAUs instrumented on the wind turbine. The SHM system and the multi-agent system are installed at different geographical locations as follows:

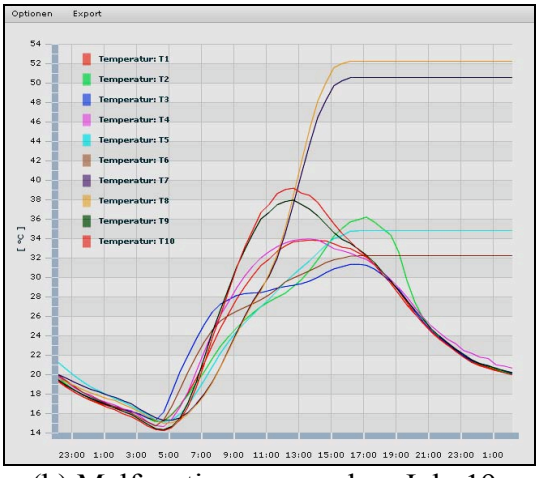
- The hardware subsystem M_1 (including sensors, DAUs and on-site computer) is installed with the wind turbine located in Dortmund (Germany).
- The components of the software subsystem M_2, including the MySQL database system, reside on different computers at the Institute for Computational Engineering at the Ruhr-University Bochum (Germany).
- For the validation tests, the multi-agent system is distributively located at different institutes: The interrogator agent and the mail agent for detecting malfunctions and generating alerts are located at Stanford University (USA) while the email server, used by the mail agent at Stanford University, is situated at the Ruhr-University Bochum.

For detection of malfunctions in the temperature DAUs, the interrogator agent scans the collected data sets, based on experience, for 150 consecutive identical values. Fig. 5 shows two malfunctions, detected from the data sets collected by the temperature DAUs in January, 2010 (Fig. 5a), and in July, 2010, (Fig. 5b). These malfunctions are characterized by a large number of identical measurements, which, as a result of a DAU-internal system crash, are repeatedly stored by the DAU instead of regular measurements.



Once a malfunction is detected, the multi-agent system generates an alert to notify the authorized users immediately about the malfunction so that appropriate measures can be taken in order to avoid the loss of valuable monitoring data. In detail, the interrogator agent requests the mail agent to inform the responsible users via email about the malfunction discovered. As a result, the mail agent generates an email to submit it to the recipients as specified in the multi-agent system's configuration files. As shown in Fig. 5c, the email content includes detailed information on the detected malfunction and is generated using the analysis results provided by the interrogator agent. The email header is assembled based on the information taken from the configuration files.

SUMMARY AND CONCLUSIONS



In this paper, a multi-agent system for the autonomous detection of SHM system malfunctions has been presented. The multi-agent system has been integrated into an existing decentralized SHM system for real-time monitoring of a 500 kW wind turbine in Germany. Since its initial deployment in December, 2009, the multi-agent system is in continuous operation and has reliably detected all malfunctions of the temperature data acquisition units of the SHM system[1]. Furthermore, the multi-agent system has immediately notified the technicians by email, whereupon the affected data acquisition units were remotely restarted by the technicians in a timely fashion. Consequently, considerable amounts of valuable sensor data, which could otherwise be lost as in conventional SHM systems, were saved and are available for assessing the performance and operational conditions of the wind turbine.

Due to its adaptability and modularity, the multi-agent system can be easily extended and integrated with other existing SHM systems. Software agents and the multi-agent system can be installed on any computers at any locations away from the SHM system. Treated as software agents, different algorithms for malfunction detection and monitoring functions can easily be added into the multi-agent system. In summary, this research has successfully demonstrated that the multi-agent software paradigm can be advantageously deployed for long-term structural health monitoring practice under real-world conditions.

[1] For long-term operation, the multi-agent system has been installed at the Institute for Computational Engineering in Bochum.

ABSTRACT

Civil infrastructures are generally a country's most expensive investment, and concrete is the most widely used material in the construction of civil infrastructures. During a structure's service life, concrete ages and deteriorates, leading to substantial loss of structural integrity and potentially resulting in catastrophic disasters such as highway bridge collapses. A solution to prevent such occurrences, is the use of Structural Health Monitoring (SHM) technology for Smart Concrete structures. Smart Concrete is concrete reinforced with Carbon Nanofibers (CNF). CNF concrete has many structural benefits. CNF restricts the growth of micro cracks in addition to yielding higher strength and ductility. Additionally, test results indicate a relationship between electrical resistance and concrete strain. A series of RC columns were built and tested under a reversed cyclic loading using CNF as a SHM device. The SHM device detected and assessed the level of damage in the RC columns, providing a real-time health monitoring system for the structure's overall integrity.

INTRODUCTION

The use of fibers to reinforce brittle materials can be traced back to ancient times when straw was added to mud bricks. The modern development of the use of fibers in construction began in the 1960s with the addition of steel fiber to reinforced concrete structures. This was closely followed by the addition of polymeric fibers, glass fibers and carbon fibers in the 1970s, 80s and 90s, respectively (Li 2002).

Fibers improve brittle materials such as concrete by enhancing tensile strength, ductility and toughness (Shah and Naaman 1976). In concrete, they do this by arresting cracks. The cracking process within concrete begins with the onset of isolated nanocracks. These nanocracks grow together to form localized microcracks, which in turn grow together to form macrocracks. These macrocracks widen to form cracks visible with the naked eye. Fibers arrest these cracks by forming bridges across them. With increasing tensile stress, a bond failure eventually occurs, and the fiber will pull out of the concrete allowing the crack to widen. An ideal concrete in terms of strength, ductility and toughness would include nano, micro and macrofibers; however, this concrete is not currently economically feasible.

Fiber research in concrete construction is an ongoing field and the use of carbon nanofibers (CNF) was examined in this study. The addition of CNF to concrete has many advantageous mechanical and electrical properties. In addition to increased strength and ductility, which is found in all fiber-reinforced concretes, CNF concrete (CNFC) exhibits increased conductivity (Chen and Chung 1993, Li, Xiao, et al. 2004, Li, Zhang and Ou 2006, Li, Zhang and Ou 2007). Because of the tunnel conductivity effect, CNFC exhibits properties necessary for strain monitoring and electromagnetic interference (EMI) shielding. Short-fiber composites were found to be a new class of strain sensor based on the concept of short electrically conducting fiber pull-out that accompanies slight and reversible crack opening. The electrical conductivity of the fibers enables the DC electrical resistivity of the composites to change in response to strain damage or temperature, allowing sensing (Chen and Chung 1996, Chung 1995, Chung 2000, Xiao, et al. 2003). The most difficult issue presented during CNFC production is dispersion of the CNF. Well dispersed CNF results in uniform calcium-silicate-hydrate (CSH) gel formation (Chung 2005). It was discovered that CNF disperses better in self-consolidating concrete (SCC) (Gao, Strum and Mo 2009), so a shear-critical self-consolidating carbon nanofiber concrete (SCCNFC) column was built and tested under a reversed cyclic load. The structural behavior of the column was examined in addition to the self-sensing ability of the SCCNFC. The results were compared to the structural and self-sensing ability of a self-consolidating reinforced concrete (SCRC) specimen that did not contain CNF. It was found that a Smart Concrete containing CNF is capable of self-Structural Health Monitoring.

CARBON NANOFIBER CEMENT-BASED MATERIALS AS A STRAIN SENSOR

The beginning of carbon nanofiber composites began with the discovery of the carbon nanotube (CNT) in the late 1980s (Lau and Hui 2002). CNT are over 100 times stronger than steel and only one-sixth of the weight in addition to demonstrating high thermal and electrical conductivities (Lau and Hui 2002). These properties make CNT extremely attractive for engineering materials.

CNT and carbon nanofibers (CNF) are very similar. CNF consist of grapheme layers arranged as stacks of cones, cups or plates to create a cylindrical nanostructure. CNT consist of grapheme layers wrapped into perfect cylinders. CNF are easier to construct than CNT (Ngo, et al. 2006).

Since the 1990s, researchers have been adding CNF to cement paste (containing no aggregate), mortar (containing fine aggregate) and concrete (containing fine and coarse aggregate) (Chen and Chung 1996, Chung 2000). The addition of CNF to cement-based materials has many advantageous mechanical and electrical properties including increased strength, ductility and conductivity (Chen and Chung 1993, Li, Xiao, et al. 2004, Li, Zhang and Ou 2006, Li, Zhang and Ou 2007).

Strain sensing is a function necessary for smart structures. There are two types of strain sensing, reversible and irreversible. The measurement of irreversible strain allows structural health monitoring, while the sensing of reversible strain permits dynamic load monitoring. Structural health monitoring is the process of implementing a damage detection and characterization strategy for engineering structures. Dynamic load monitoring can detect loads on structures as they are applied and removed in real time. These are important technologies because they gauge the ability of a structure to perform its intended function aging, degradation or disasters. Typically, monitoring reversible strain is more difficult because it can only be

monitored in real time. Additionally, reversible strain tends to be smaller than irreversible strain (Chen and Chung 1996).

Sensing refers to the ability to provide and electrical or optical response to a stress or strain. Chen and Chung (1996) give the following requirements for a structural sensor:

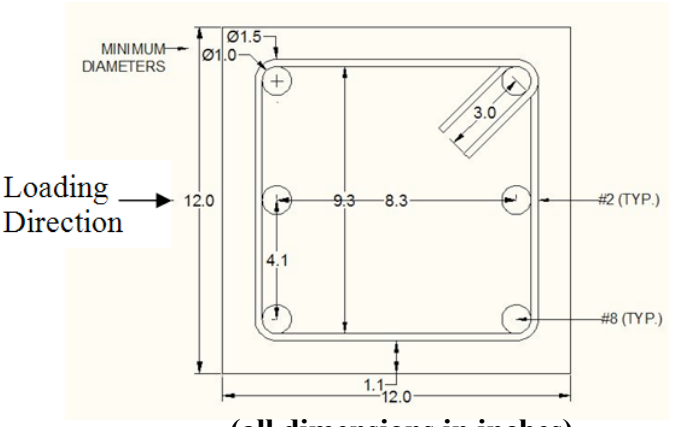
(a) Wide strain/stress range of detection (from small strains up to failure)
(b) Response being reversible upon stimulus removal (necessary for repeated use of the sensor)
(c) Ease of measuring the response (without the need of expensive peripheral equipment)
(d) Presence of the sensor having no bad effect on the structural properties of the structure
(e) Chemical stability and durability
(f) Low cost

Current commonly used sensors include strain gages, optical fibers and piezoelectric sensors, which all suffer from high cost, poor durability and the need for expensive peripheral equipment including electronics and lasers. Because of this, the use of sensors in civil structures is uncommon (Chen and Chung 1996). CNFC could become a better option as a strain sensor because points (a) through (e) are applicable. CNF are currently fairly expensive; however, technology may provide a way to make them more cheaply in the future.

CNFC exhibits properties necessary for reversible strain monitoring and electromagnetic interference (EMI) shielding. Short-fiber composites were found to be a new class of strain sensor based on the concept of short electrically conducting fiber pull-out that accompanies slight and reversible crack opening. For a CNF composite to have strain sensing ability, the fibers must be more conducting than the matrix in which they are embedded, of diameter smaller than the crack length, and well dispersed. Their orientations can be random, and they do not have to touch one another (Chung 1995, Chen and Chung 1996). The electrical conductivity of the fibers enables the DC electrical resistivity of the composites to change in response to strain damage or temperature, allowing sensing (Chen and Chung 1996, Chung 1995, Chung 2000, Xiao, et al. 2003, Gao, Strum and Mo 2009).

DISPERSION OF CARBON NANOFIBERS IN CONCRETE

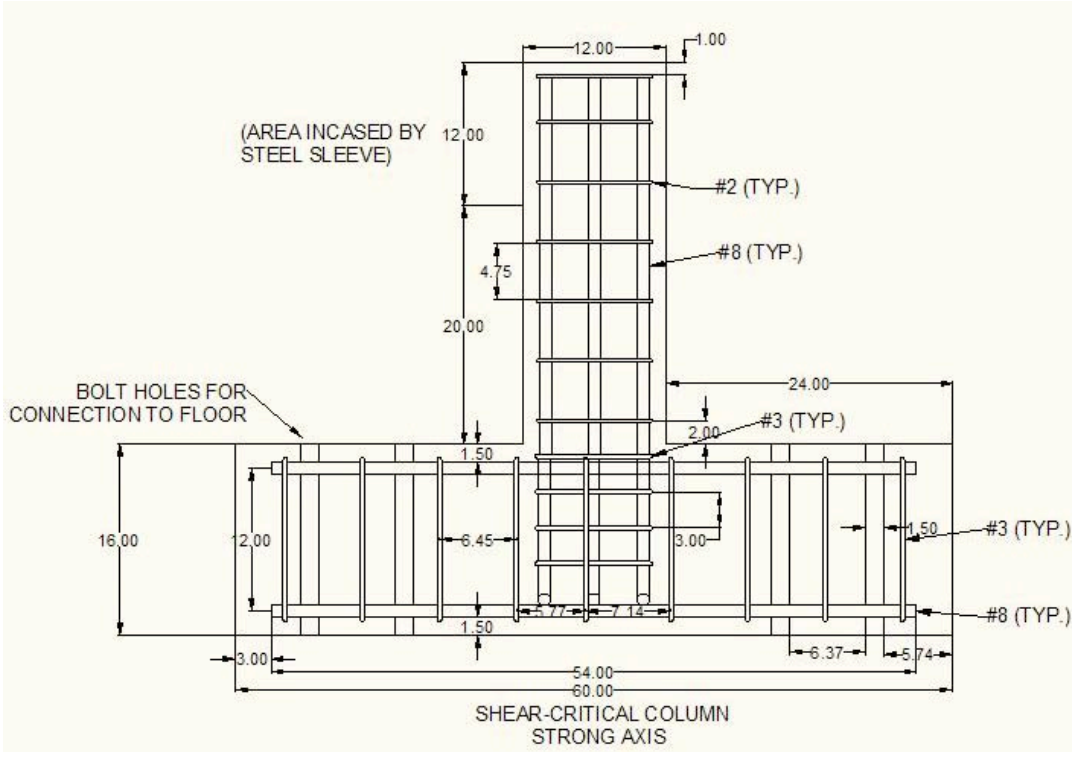
The most difficult issue presented during CNFC production is dispersion of the CNF. Well dispersed CNF results in uniform calcium-silicate-hydrate (CSH) gel formation, which improves the structural and electrical properties of the concrete (Chung 2005). It was discovered that CNF disperse better in self-consolidating concrete (SCC) (Gao, Strum and Mo 2009). Mixing CNF into SCC creates self-consolidating carbon nanofiber concrete (SCCNFC). Self-consolidating concrete (SCC) is highly flowable, non-segregating concrete that can spread into place, fill the formwork, and encapsulate the reinforcement without any mechanical consolidation (ACI 318 2008).



The mixing procedure used for the SCCNFC was used by Gao et al. at the University of Houston (UH) (2009). UH suggested the following procedure:

(a) Blend the CNF, HRWR and enough water to create a homogeneous liquid using laboratory-grade blenderss for three minutes.
(b) Mix the coarse aggregate, sand and cement in a mixer and mix for three minutes.
(c) Add the CNF mixture to the mixer with any additional water.

A SCCNFC column was built and tested under a reversed cyclic load. The structural behavior of the column was examined in addition to the self-sensing ability of the concrete. The results were compared to the structural and self-sensing ability of a SCRC specimens.



TEST SPECIMENS

Both column cross-sections were 304.8 mm (12 in.) square and contained six #8 rebar (Fig. 1). This percentage of longitudinal steel was 3.27% by volume of concrete. The columns contained #2 stirrups with a spacing of 120.7 mm (4.75 in.) providing transverse reinforcement of 0.287% by volume of concrete. Since the columns were designed to be shear critical, the maximum reinforcement spacing was chosen based on the ACI 318 specifications. The columns were 507 mm (20 in.) in height, which results in an aspect ratio of 1.7. Each of the columns was rigidly connected to similar foundations. See Figs. 2 for the elevation view of the columns and foundations.

(all dimensions in inches)

Fig. 1 Cross-Section of SCRC and SCCNFC Columns

(all dimensions in inches)

Fig. 2 Elevation View of the Strong Axis of the Shear-Critical SCRC and SCCNFC Columns and Foundations

MATERIALS

The properties of the materials used for the mixes were as follows:

(a) Cement: The cement used in all mixtures was ASTM Type III Portland cement.
(b) Fly Ash: Class F fly ash was used for the SCRC mix.
(c) Coarse Aggregate: Crushed limestore with a maximum diameter of ¾" was used in the SCCNFC column. River rock with a maximum diameter of ¾" was used in the SCRC column.
(d) Fine Aggregate: Natural river sand with a fineness modulus of 2.71 was used in all mixes.
(e) High –Range Water Reducer (HRWR): Glenium® 3200HES was used in the SCCNFC column and Glenium® 3400 HES was used in the SCRC. Both chemicals were polycarboxylate admixtures from BASF Chemical Co.
(f) Viscosity Modifying Agent (VMA): RHEOMAC® VMA 450 was used in the specimens and also supplied by BASF Chemical Co.
(g) Carbon Nanofibers: Pyrograf Products, Inc. PR-19-XT-LHT-OX fibers were used in this study. The specific gravity of the fibers was 0.0742. The diameter of the fibers was 149 nm (5.87e-6 in.) and the length was 19 μm (7.48e-4 in.) resulting in an aspect ratio of 128.

MIX PROPORTIONS

Table 1 Mix Proportions in kg/m^3 (lb/yd^3) of Concrete

Material	SCRC Mix	SCCNFC Mix
Cement	446 (752)	457 (771)
Fly Ash (Class F)	299 (504)	-
Fine Aggregate	937 (1580)	898 (1514)
Coarse Aggregate (Limestone)	-	859 (1448)
Coarse Aggregate (River Rock)	491 (827)	-
Water	224 (377)	182 (307)
Glenium® 3400HES	2.81 (4.73)	-
Glenium® 7700HES	-	2.34 (3.94)
REHEOMAC® VMA 450	5.69 (9.59)	-
Carbon Nanofibers	-	3.23 (5.45)

The mix proportions can be seen in Table 1. It was discovered that CNF has an optimal dosage of approximately 1% by volume. In order for CNF to have advantageous properties within concrete, it must be well dispersed. Increased CNF dosages increase concrete properties up to the point where the CNF begin to attract one another and clump. This occurs at dosages higher than 1% by volume (Gao, Strum and Mo 2009).

CONCRETE SENSOR SETUP

One goal of testing the SCCNFC column was to prove that concrete containing CNF can be used as a sensor. The electrical properties of the concrete had to be tested, so wire meshes were constructed and embedded in each of the columns. The wire meshes were made of 12.7 mm (1/2 in.) hardware cloth with 14 gauge copper wire soldered to it. The wire extended outside of the column. Fig. 3 shows one of the wire meshes. The meshes were placed in the column as shown in Fig. 4. The meshes could not touch the rebar in the column because the electrical

properties of the concrete, not the steel, needed to be tested. Fig. 5 shows the installation of the meshes. Fig. 6 shows the wire connected to the mesh protruding from the column.

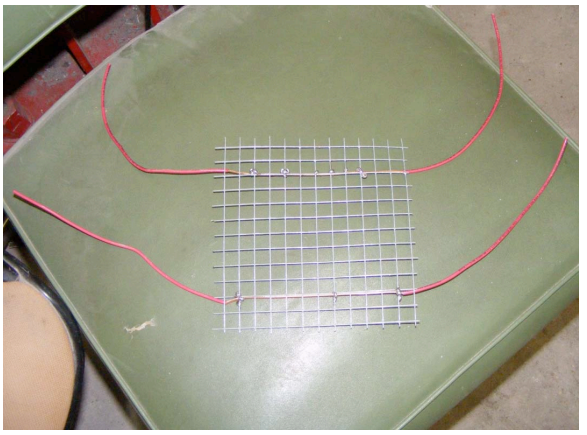


Fig. 3 Wire Mesh

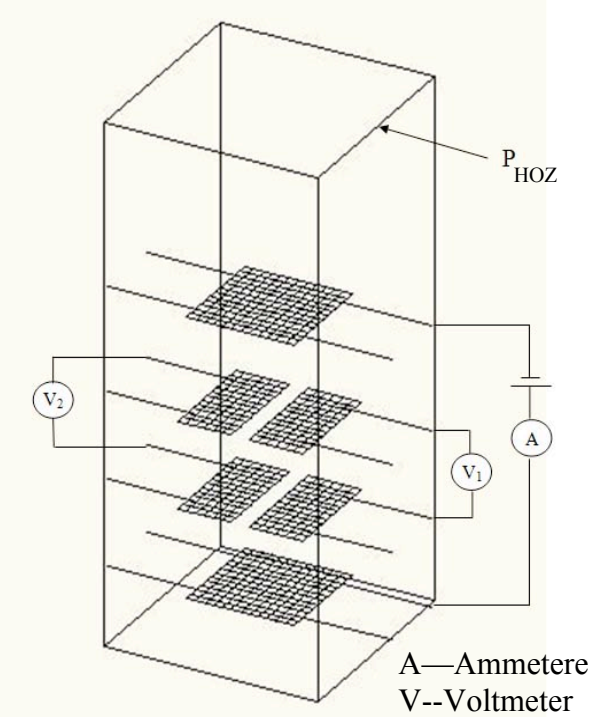

Fig. 4 Wire Mesh Placement Diagram (Four Probe Method)

Fig. 5 Wire Mesh Installation

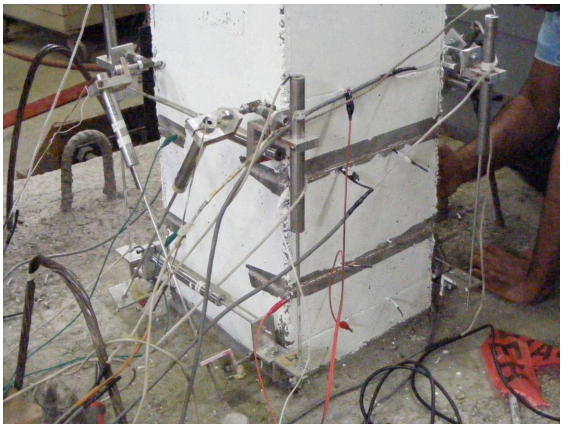

Fig. 6 Wires Connected to Meshes Protruding from Column

To measure the electrical properties of the concrete, the voltage and current were measured using a four-probe method as seen in Fig. 4. A power supply was attached to the top mesh that provided a current of approximately 31 V DC. An ammeter was attached to the bottom mesh and connected back to the power supply to complete a circuit. The current measured by the ammeter was recorded continuously during the tests by hand. Additional voltmeters were attached to the two middle meshes on both the north and south sides of the

column to measure voltage. The voltage readings were also recorded continuously during the tests by hand.

SENSOR SETUP

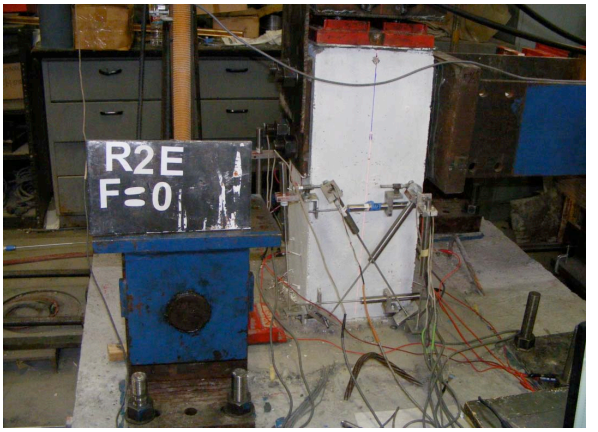

Fig. 7 LVDT Rosette

Linear voltage displacement transducer (LVDT) rosettes were placed on the east and west side of each column to measure the strain in the concrete. Fig. 7 shows one of these LVDT rosettes. LVDTs were placed on the foundation to measure any foundation slippage. Additionally, LVDTs were placed at the top of the column to measure the column displacement. One of these LVDTs was used to control the actuator, Therefore, a closed-loop displacement control was used to test the column more precisely after post-yielding. This was necessary to grasp accurately the ductility of the column after yielding of main flexural rebars occurred. The other LVDT was used to record displacement values. These can be seen in Fig. 11. Data from the LVDTs was continuously monitored and stored by the HBM Spider-8 Data Acquisition System.

TEST SETUP

Fig. 8 Test Setup

During the testing, the columns were subjected to constant vertical axial loading equal to 10% of their axial capacity and horizontal reversed-cyclic loading until failure. Fig. 8 shows the test setup including the horizontal actuator, vertical load jack, support system, column and data acquisition systems. The 649 kN (146 kip) capacity actuator was bolted to a steel beam, which was bolted to a rigid vertical steel frame. Each column was connected to the strong floor by 16-31.75 mm (1.25 in.) diameter all-thread steel rods that went through the foundation. A steel plate was placed around each group of four rods, mortared to the concrete surface and nuts were screwed onto the plates to hold the foundation flush against the strong floor. Additional bracing bolted to the strong floor was placed on the north and south sides of the column's foundation along the loading directions.

The axial loading system consisted of many pieces. When applying the system, first a lead sheet was placed on top of the column, followed by a four-ball roller. A steel plate was placed on top of the roller followed by a jack. A steel beam was put on top of the jack. All-thread rods were connected to the beam and hinges that were connected to the foundation and strong floor. Axial load was applied to the column through adding pressure to the jack.

LOAD PROGRAM

Table 2 Concrete Compressive Strength in MPa (ksi) and Axial Load in kN (kips) for Each Specimen

Axial Load kN (kips)	518 (116)	389 (87.4)
Days of Curing	6	8

The first step of the load program was to apply an axial load that would remain constant during the course of the test. The axial load equaled one-tenth of each of the columns calculated axial capacity. This was calculated using an unfactored interaction diagram. The axial capacity is dependent on the compressive strength of the concrete (f_c), so the axial force varied for each specimen. See Table 2 for the concrete compressive strength and axial load for each of the two columns.

After the axial load was applied, a reversed-cyclic load was added using a 649 kN (146 kip) capacity actuator. The intended load path was to use force control to complete two cycles each of ±89 kN (20 k), two cycles each of ±178 kN (40 k), two cycles each of ±267 kN (60 k). A positive force denotes a push by the actuator while a negative force represents a pull by the actuator. At the point of the yielding of the longitudinal steel, the test would switch to displacement control and complete two cycles each at a displacement ductility of 2, 3, 4, etc. Once failure occurred, the column was pushed in displacement control to try to obtain a descending branch on the load versus displacement curve.

TEST RESULTS

The load path followed for the SCRC column specimen can be seen in Fig. 9 with the first cracks, switch to displacement control and failure marked. The first crack on the south side of the column occurred at -178 kN (-40 k). The first shear crack formed on the column during the first -178 kN (-40 k) cycle at -178 kN (-40 k) on the west side. The column failed in shear and crushing of concrete at 276 kN (62 k). The west side of the column exhibited crushing of the concrete struts with large shear cracks. The east side exhibited local crushing at the actuator connection. The maximum displacement at the top of the column (drift) was 12.7 mm (0.50 in.). Fig. 10 shows the west side of the column after failure. Fig. 11 shows the load versus displacement curve for the test.

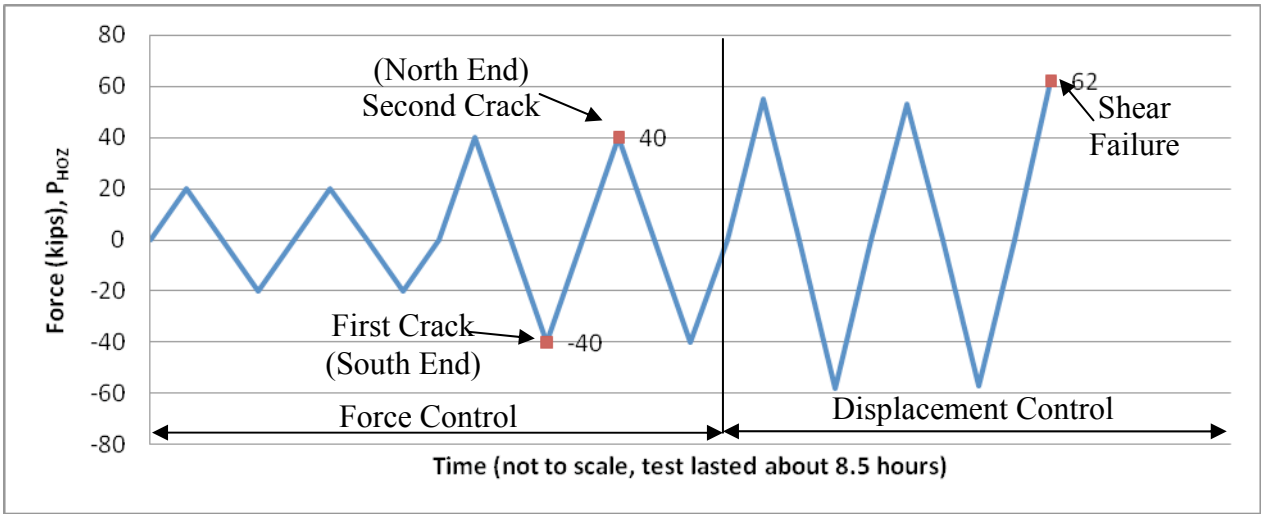

Fig. 9 SCRC Column Load Path

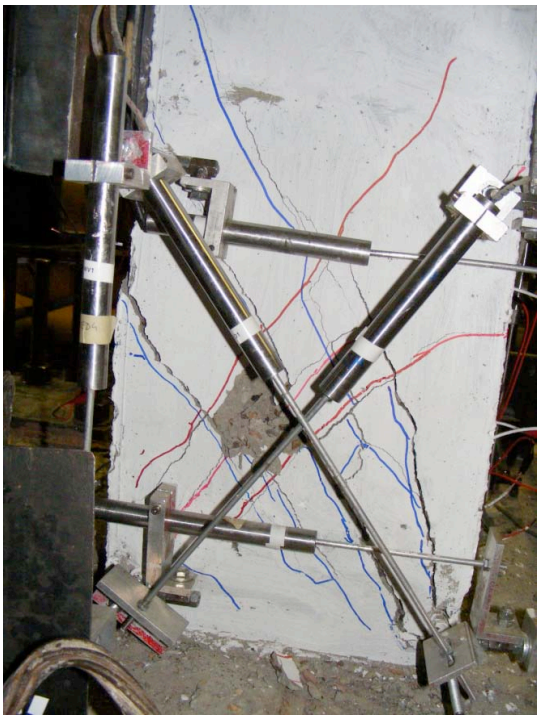

Fig. 10 West Side of SCRC Column After Failure

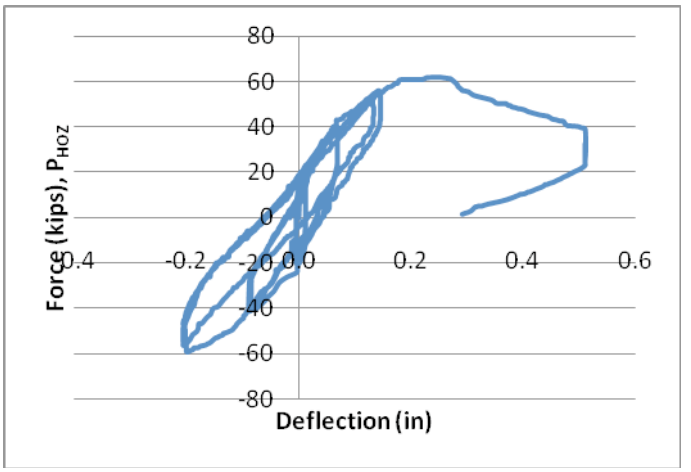

Fig. 11 SCRC Column Force vs. Displacement Curve

The actual load path followed for the SCCNFC column can be seen in Fig. 12. The pump shut down during the test, and the actuator unloaded during the fifth cycle of the test. The pump was turned back on and the test resumed. The first flexural crack formed on the column at 160 kN (36 k) on the east, west and north sides. The second flexural crack formed on the east, west and south sides at a load of -158 kN (-35.6 k). The column failed in the combined modes of shear and concrete crushing at 298 kN (67 k) on the west side of the column. The maximum displacement was 10.16 mm (0.4 in.). Fig. 13 shows the west side of the column after failure. Fig. 14 shows the load versus displacement curve for the test.

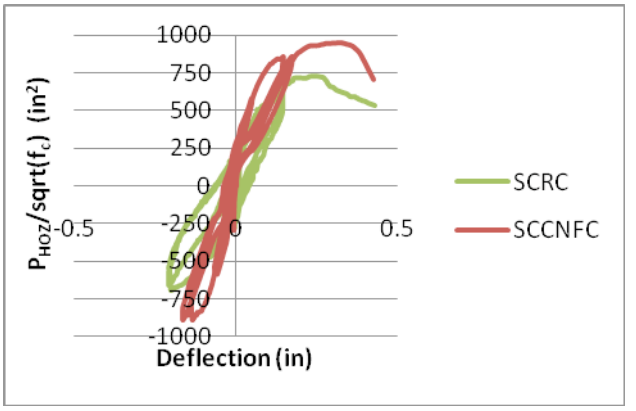

Fig. 15 Force vs. Displacement Curves for all Specimens

COMPARISON OF STRUCTURAL BEHAVIOR OF COLUMNS

Fig. 15 shows a normalized force versus displacement curve for all of the specimens. Since all of the columns had the same dimensions, the horizontal load (P_{HOZ}) was normalized by dividing by the square root of the compressive strength of the concrete. By examining the figure, it is evident that the SCCNFC column failed at higher loads and with larger deflection than the SCRC column. Additionally, the SCCNFC column was much stiffer than the SCRC column and exhibited a higher energy dissipation. A definite yielding of longitudinal steel occurred in both the SCRC and SCCNFC columns. Figs. 10 and 13 show the crack patterns of the SCRC and SCCNFC columns, respectively. The compression struts are easily visible in both the SCRC and SCCNFC columns.

SELF-SENSING ABILITY OF SCCNFC

During each of the column tests, the electrical resistance was determined to check the self-sensing ability of the concrete. To measure the electrical properties of the concrete, the voltage and current were measured as depicted in Fig. 4 using the meshes described. A DC power supply was attached to the top mesh that provided a constant voltage of about 31 V. A voltmeter was attached to the bottom mesh and connected back to the power supply to complete a circuit. The current measured by the ammeter was recorded continuously during the tests. Additional voltmeters were attached to the two middle meshes on both the north and south sides

of the column to measure voltage. The voltage readings were also recorded continuously during the tests. To determine the electrical resistance, Ohm's law was used.

The electrical readings showed a great correlation between the peaks in the applied horizontal force, strain and resistance plots for the SCCNFC column and little correlation between the resistance plots and the force or strain plots for the SCRC column. Fig. 16 shows the relationship between the SCRC column's horizontal force, LVDT strain and electrival resistance versus time on the north side of the column. As shown by the grey vertical lines, there is no relationship between the peaks and valleys in the electrical resistance and the load or strain on the north side of the column.

Fig. 17 shows relationship between the SCCNFC column's horizontal force, LVDT strain and electrical resistance versus time on the north side of column. As shown by the grey vertical lines, there is a very good correlation between the force, strain and resistance. On the north side of the column, the peaks and valleys matched up until the point that the column was greatly damaged.

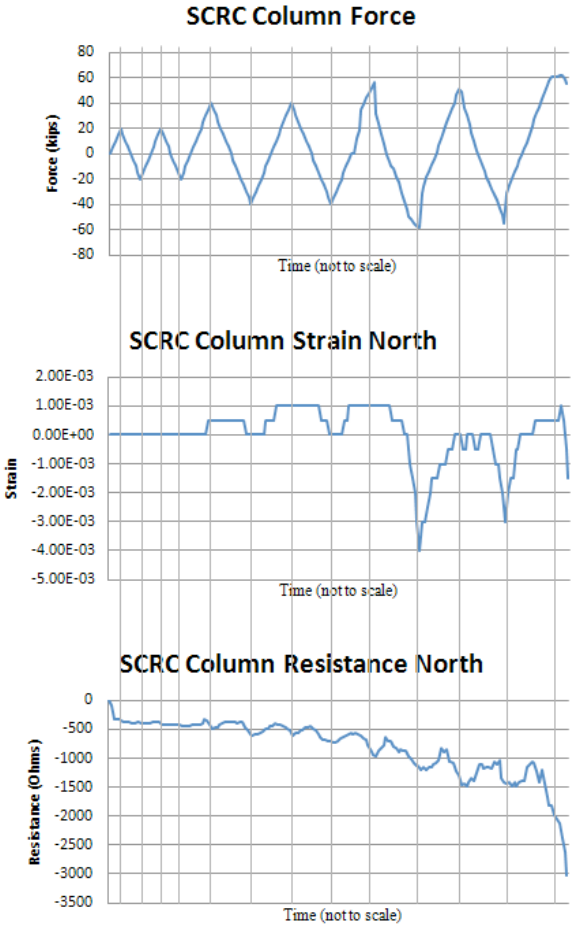

Fig. 16 SCRC Column Comparison of Horizontal Force, LVDT Strain and Electrical Resistance on North Side

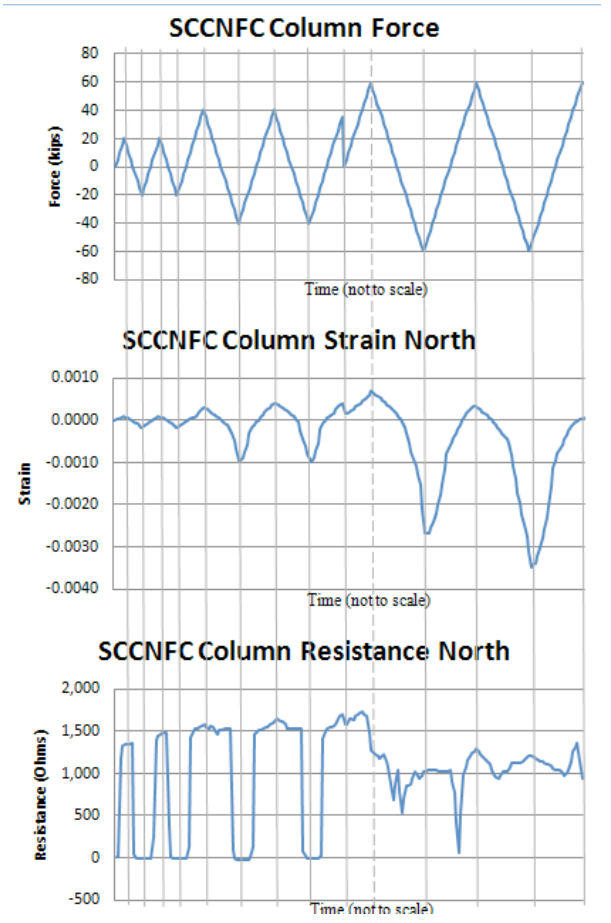

Fig. 17 SCCNFC Column Comparison of Horizontal Force, LVDT Strain and Electrical Resistance on North Side

Because of the strong correlation found between the horizontal force, LVDT strain and electrical resistance verses time graphs for the SCCNFC column, the electrical resistance

variation (ERV) was calculated and compared to the deflection at the top of the column. ERV is the measured electrical resistance minus the initially measured electrical resistance quantity divided by the initially measured electrical resistance. Fig. 18 shows the relationship between the ERV and deflection at the top of the column for the first five cycles of the test. Yielding occurred in the fifth cycle. The envelope shown in Fig. 18 represents the damage in the column measured by the SCCNFC. It is obvious from Fig. 18 that the column shows major damage at approximately a deflection of 2.03 mm (0.08 in.). This corresponds to the steel yielding in the SCCNFC column. This proves that SCCNFC can be used as a type of self-Structural Health Monitoring system.

CONCLUSIONS

Self-consolidating concrete with carbon nanofibers in shear critical columns was investigated and the performance was compared to a conventional self-consolidating reinforced concrete column. This research studied the test results of the two columns tested under reversed-cyclic loads. The columns consist of a traditionally reinforced concrete (SCRC) column that serves as a control specimen and a self-consolidating carbon nanofiber concrete (SCCNFC) column. The objectives of the experiments include studying the structural behavior of the materials and examining the self-sensing abilities of the concretes. The following points detail the research findings and conclusions drawn from those findings:

(1) Highly workable and stable self-consolidation concrete (SCC) can be made from locally available construction materials and can maintain its workability and stability with the addition of fibers. The SCC mixes tested during this research had satisfactory workability and were found suitable for application in short columns. SCC greatly increases the ease of column construction.

(2) The addition of carbon nanofibers (CNF) to concrete increases the strength and ductility of a column.

(3) SCCNFC can be used as a reversible strain sensor. The peaks and valleys in the electrical resistance readings of the concrete match the peaks and valleys of the applied force and the strain in the concrete. The SCRC specimen did not have corresponding strain and electrical resistance values. It was found that concrete structures containing well-dispersed CNF in an appropriate dosage is capable of self-Structural Health Monitoring.

ABSTRACT

Structural sensing and dynamic monitoring of critical infrastructure is essential to maintain the ageing critical infrastructure of US. To this end various sensing mechanisms and innovations have been used in the recent past such as strain sensors, accelerometers etc. Measurement of strain gives first hand information about the state of stresses in a structure. The effectiveness of multiwalled carbon nanotube (MWCNT) films as strain sensors has been demonstrated by the authors (Vemuru et al. 2009) and other researchers. In this paper the real time dynamic response of MWCNT polystyrene nanocomposite thin film sensors is studied and experimental results presented of both its dynamic response as well as its response to temperature. Experimental results demonstrate a linear response from the MWCNT nanocomposite. Further electromechanical properties observed are completely reversible and stable. The temperature response of the nanocomposite film is also studied experimentally and results presented. It is demonstrated that the nanocomposite thin films monitors the strain very effectively and can be used as a multifunctional material in civil, mechanical and aerospace applications.

Introduction

Carbon nanotubes (CNTs) first discovered by Ijiima (Iijima 1991) exhibit a remarkable combination of electrical, mechanical and thermal properties ((P. M. Ajayan 1999; Baughman et al. 2002)). The combination of these properties makes CNTs ideal filler materials in nanocomposites. The past decade witnessed large advances in the CNT filler based nanocomposite research. Among the bevy of host polymer matrices it has been observed that hydrocarbon polymers such as polystyrene (PS), polypropylene or polyethylene render the nanocomposites with mechanical properties significantly higher than those of other polymer composites (Fernández-Sánchez et al. 2009).

Schadler et al. (Schadler et al. 1998)observed a shift in the raman peaks in multiwalled carbon nanotube (MWCNT) - epoxy composites when subjected to tensile or compressive loading. Tombler et al. (Tombler et al. 2000) highlight the reversible electromechanical properties of a single walled carbon nanotube (SWCNT) upon deformation using an AFM tip. Semet et al. (Semet et al. 2005) observe a reversible change in the nonlinear conductance of a MWCNT upon being bent longitudinally. Experiments by Jang et al. (Jang et al. 2008) revealed reversible electrical resistance change when individual an MWCNT was strained to a value less than or equal to its elastic limit. Also the change in resistance of the nanotube deformed within its elastic limit corresponds well with the applied strain. All these studies correspond to the piezoresistive characteristics of nanotubes at the nanoscale.

Studies by Dharap et al. (Prasad Dharap et al. 2004) and Li et al. (Z. Li et al. 2004) marked the first attempts done to utilize the piezoelectric properties of CNTs at the nanoscale for strain sensing applications at the macroscale. Using a SWCNT buckypaper they observe a linear change in the voltage response across the film using contact based measurements (electrical measurements using four point probe) (Prasad Dharap et al. 2004) and non contact based measurements (observing a shift in the peak of G band of Raman spectrum) (Z. Li et al. 2004). In both the studies, it was observed that the change in the response observed corresponded with strain linearly. The macroscale strain sensing properties were studied for MWCNTs using MWCNT-buckypaper ((Vemuru et al. 2009; X Li et al. 2008)) and similar behavior was observed.

In this study the mechanical characteristics of multiwalled carbon nanotube PS/MWCNT nanocomposite thin films is studied in detail. The electromechanical response of the nanocomposite thin films under static loading is studied by attaching the film to a brass specimen and subjecting the brass specimen to axial strain in a hydraulic machine for static testing. The electromechanical response of thin film under dynamic loading is studied by attaching the film to a flexible aluminum beam and studying its free vibration response. Finally the electrical response of the film to temperature changes is also studied by attaching the film to Teflon and heating it.

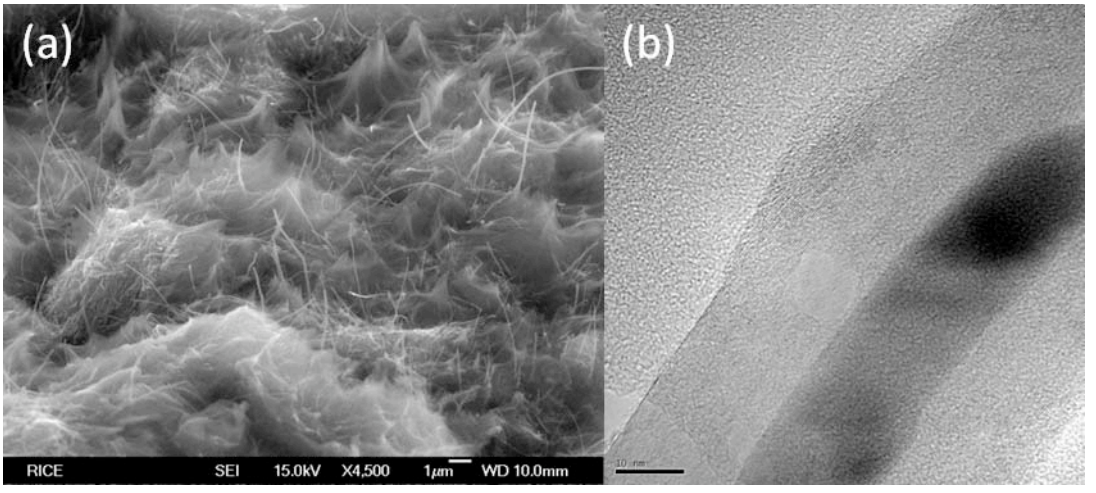

Figure 1: (a) SEM image of PS/MWCNT film (b) TEM image of a MWCNT in the polymer

Preparation of PS/MWCNT nanocomposite films

The purified multiwall carbon nanotubes were prepared by spray pyrolysis method using xylene & ferrocene as a carbon source and catalyst materials respectively. CNTs were functionalized by treating them with a mixture of nitric acid (HNO_3) and sulphuric acid ($H_2 SO_4$) in 3:1 ratio followed by ultrasonication at 42 KHz & stirring at 90^0 C for 3 hrs. To minimize the aggregation of functionalized CNTs in the nanocomposite, they were treated with toluene solution containing a nonionic surfactant, Polyethylene glycol (PEG, Molecular weight is 600), followed by ultrasonication in a sonic bath for 2 hr. The PS used in this work has molecular weight of 100,000. The required amounts of processed CNTs were mixed with PS solution in toluene and the resulting mixture is stirred for 2 hrs resulting in a homogeneous mix. The obtained solutions of composite is taken onto a flat plate and dried at room temperature for about 12 hrs forming

flexible PS/MWCNT composite film. Using the above mentioned technique uniform flexible thin nanocomposite films of 0, 0.5, 1, 3, 5, 6, 8 & 10 wt% CNTs were obtained.

Strain sensing

Experimental Setup

For dynamic loading nanocomposite film was attached to a flexible aluminum beam using vacuum bonding technique. To ensure perfect bonding and subsequent strain transfer the bonding is done using vacuum bonding technique for duration of 12 hours. A four point probe is formed by depositing leads of equal thickness equally spaced on the film by sputter coating technique. Wires are attached to the silver leads using silver epoxy. Electrical measurements from the sample are achieved using a Keithley 2400 sensitive digital source meter (with a measurement precision of ±1 μV or ± 10 pA). The electrical measurements from the nanocomposite film are presented as it is without the use of any analog or digital filters. A strain gage is attached to the same beam for comparison purposes. The aluminum beam is arranged as a cantilever and nanocomposite film and strain sensor are attached close to the support and the tip of the beam is deflected and allowed to vibrate freely. The PS/MWCNT thin film is insulated from the surface of the brass specimen using a thin coat of epoxy. The applied strain to the brass specimen is measured directly using a strain gage attached onto the surface of this insulating epoxy layer on the brass specimen. The strain measurements are performed using National Instruments Bridge module (NI 9237) all strain measurements are taken at a sampling frequency of 2000 Hz.

For static strain measurements, a thin film of PS/MWCNT nanocomposite is attached to a brass specimen (cross section 0.25 inch × 2.0 inch) with epoxy. Electrical contact is attained by depositing silver leads onto the thin film by sputter coating. The brass specimen is subjected to axial load in a hydraulic MTS testing apparatus with a maximum capable load of 100 Kips.

Results and Discussions

Thin film electromechanical characteristics

By applying an input voltage of 0.25 V (the choice of the input voltage is done to ensure that the output current from the nanocomposite film is limited to a value less than 1 mA) the film is subjected to strain by application of mechanical load to the brass specimen to which the film is attached.

The gage factor of the thin film is given by the formula

$$GF = \frac{\frac{\Delta R}{R_o}}{\varepsilon} = \frac{\frac{V}{i_f} - \frac{V}{i_o}}{\varepsilon \times \frac{V}{i_o}} = \frac{i_o - i_f}{\varepsilon \times i_f}$$

Gage factors of PS-MWCNT films at different wt% of CNTs in them can be gauged from figure 2. Using the above formula the gage factor of the 10 %wt PS/MWCNT film is calculated as 1.49. The measured gage factor is less in comparison to the gage factor of commercial strain gages (about 2). However from the response of 6% wt PS/MWCNT film is calculated as 3.28. This observation confirms with earlier literature where researchers have reported that an increase in wt% of CNT fillers leads to reduction of the gage factor of nanocomposite sensors. Table 1 summarizes the gage factors of the PS-MWCNT films with different wt% content of CNTs.

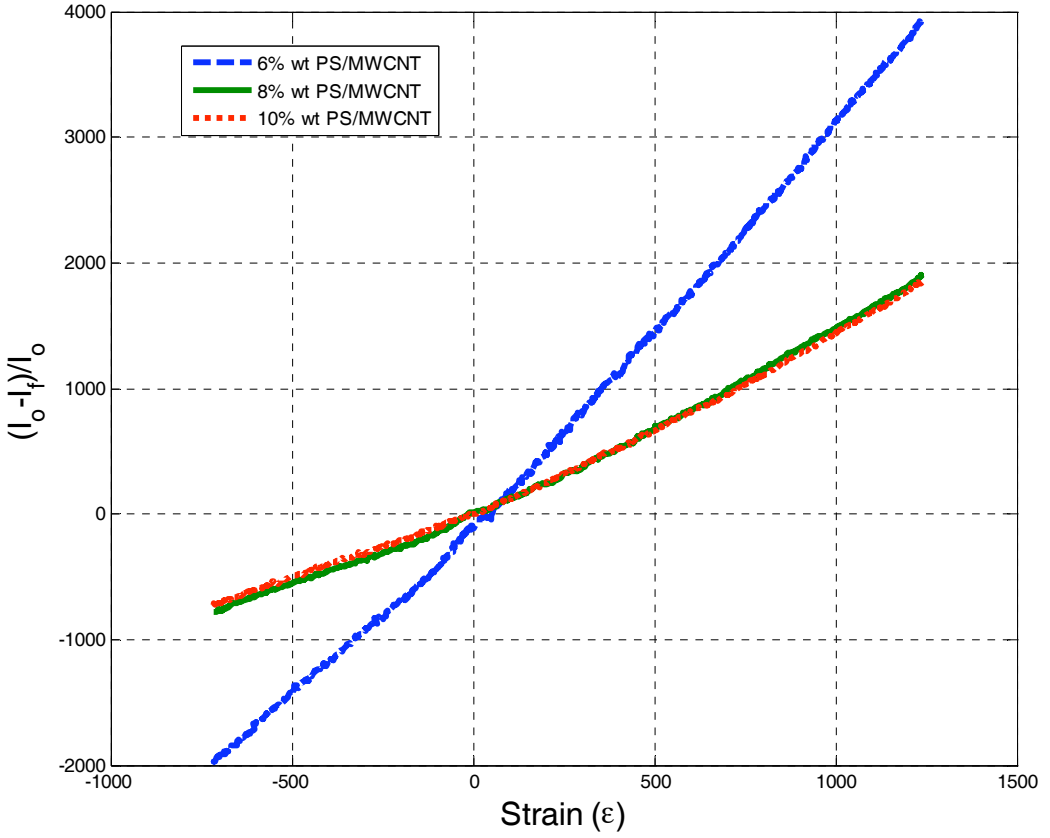

Figure 2: Plot of normalized current response as a function of strain for different % wt content of MWCNTs in the PS-MWCNT nanocomposite films.

CNT wt%	6%	8%	10%
Tension	3.28	1.55	1.49
Compression	2.55	1.04	0.99

Table 1: Gage factors of the PS-MWCNT films with differing % wt of MWCNTs in them for compression and tension

Dynamic Strain Measurement

Several such cycles of free vibrations are recorded and presented in Figure 3. It can be seen that the current response of the sensor is excellent and corresponds closely with the readings obtained from strain gage. The zoomed in superimposed plots of normalized current response and strain readings of different free vibration cycles show in more detail how closely the current response tracks the applied strain. The nanocomposite film further exhibits very good return to pre loading conditions at the end of each set of vibrations. The dynamic strain response characteristics of the nanocomposite film show its potential for SHM.

Temperature Measurement

For temperature measurements nanocomposite film was attached to a Teflon strip using epoxy. The nanocomposite film was heated using a heater and electrical measurements were taken using a four point probe with input voltage of 0.25V as the temperature across the film was varied from 23.5 ^{o}C to 58 ^{o}C and allowed to gradually cool to room temperature. The temperature change across the film is measured using a type K thermocouple in conjunction with a fluke multimeter. The film showed an excellent response to temperature change and the current response as shown in figure 4. It can be seen from the compared normalized response and temperature as the film is heated the change in the resistance of film corresponds clearly with increasing temperature. However the film and the thermocouple exhibit different rates of cooling as can be seen from the way the current responses of the film differs from the temperature decrease of the thermocouple.

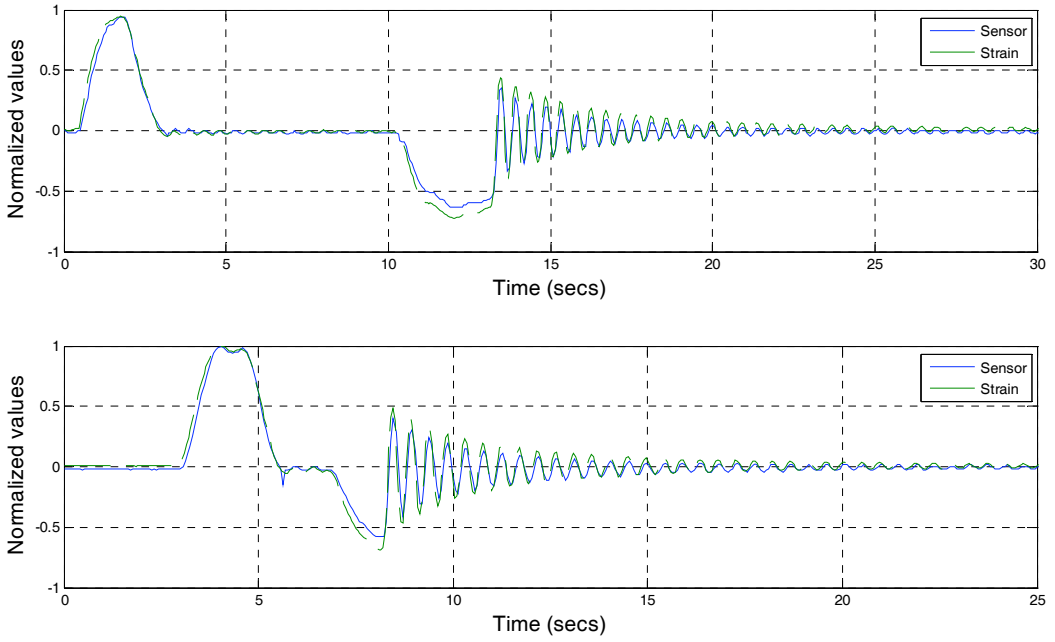

Figure 3: Plot of current response and strain from the free vibration response of a flexible aluminum beam

Conclusions

In this study the electromechanical properties of nanocomposites films made from polystyrene and MWCNTs is thoroughly investigated and the strain sensing behavior of these films is studied in detail. The nanocomposite films show excellent noise free electromechanical response to applied strain both in compression as well as tension. The response of the film was studied under static loading and it corresponded linearly with applied strain. Further the response observed was completely reversible and returned to preloading conditions upon load removal. The sensitivity of the nanocomposite films was studied under different concentrations (by % wt) of MWCNTs in them and it was observed that the increasing concentration of nanotubes led to a reduction in the film sensitivity. The PS-MWCNT films exhibits excellent strain sensing characteristics for both static and dynamic strain measurements and shows great potential for health monitoring

applications. The PS-MWCNT film also exhibit very good sensitivity to temperature changes as is evident from the experimental results.

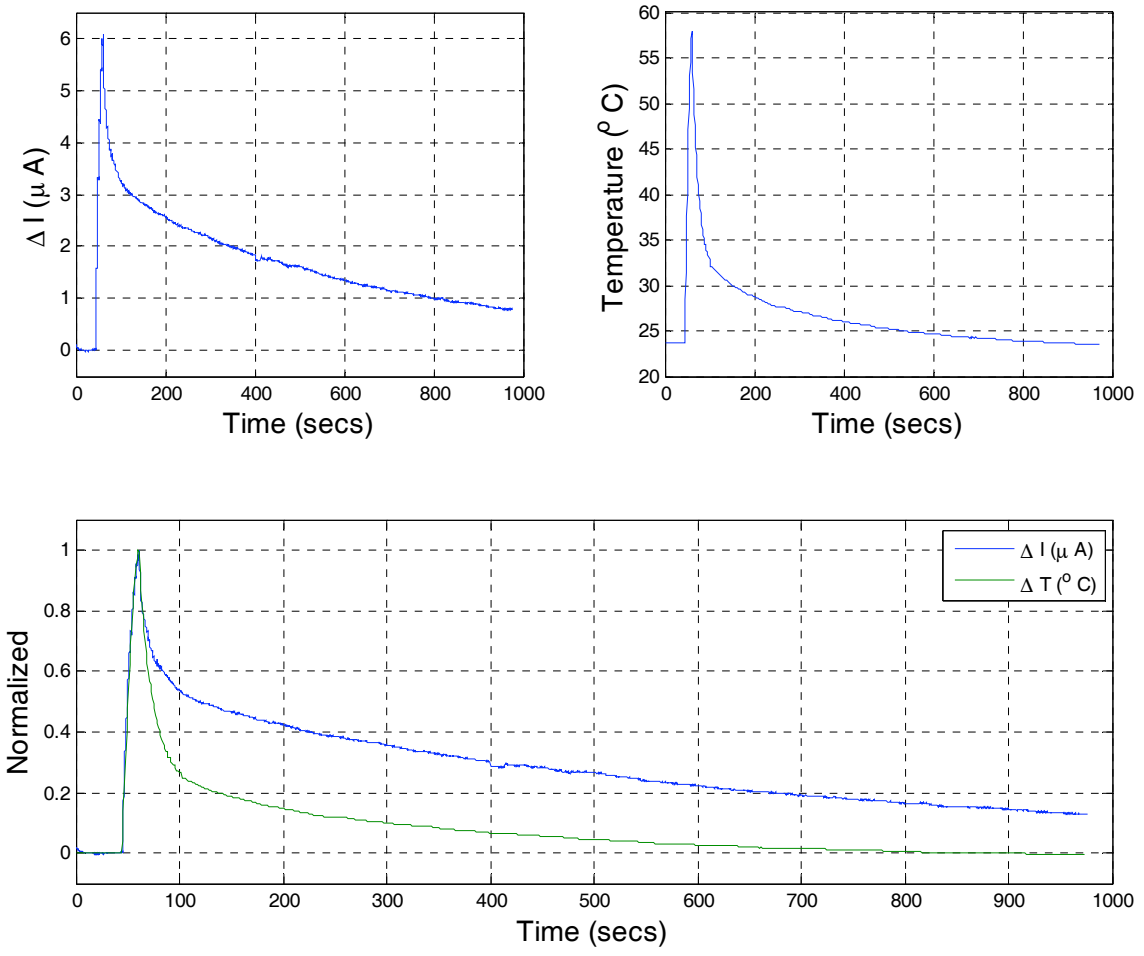

Figure 4: Plot of current response and temperature change across the film as it is heated from 23.5 oC to 58 oC and allowed to gradually cool to room temperature

ABSTRACT

For structures located in a moderately or highly aggressive environment, multiple environmental and mechanical stressors lead to deterioration of structural performance and, therefore, create maintenance issues. Such deterioration will reduce the service life of structures. The main purpose of this paper is to discuss a methodology previously proposed by the writers for the evaluation of long-term seismic reliability of reinforced concrete (RC) bridge piers in a marine environment and present new results. This methodology consists of three steps: (1) investigate the relationship between material deterioration and structural performance on an experimental basis; (2) consider both the seismic hazard and the hazard associated with marine environment; and (3) perform an analysis of the long-term seismic performance of RC bridge piers in an aggressive marine environment.

INTRODUCTION

Several recent studies deal with the seismic reliability of concrete structures located in earthquake prone regions and aggressive environments (Choe et al. 2008, Coronelli and Gambarova 2004, Ghosh and Padgett 2010, Li et al. 2009, and Simon et al. 2010). However, these studies used a very simple structural model in the evaluation of both seismic capacity and demand. Experimental studies on RC columns with chloride-induced corrosion of steel reinforcement subjected to cyclic loading include: Yamamoto and Kobayashi 2006, Oyado 2007, and Kato et al. 2004, 2005. These studies reported that the numerical model to evaluate the relationship between the load and displacement of corroded RC component needs to consider (a) the reduction of steel bar volumes, (b) cracking of concrete cover due to the expansion of corrosion products, (c) bond degradation between concrete and steel, and (d) non-uniformity of corrosion along the steel bars in RC columns. Since performing the structural analysis only considering the reduced steel rebar cross-section is an oversimplification for evaluating the relationship between load

and displacement of deteriorating RC components, the numerical methods must be improved in order to capture the effect of corrosion on the seismic capacity and demand as reported in previous experimental results. Based on the experimental results of RC specimens with corrosion subjected to cyclic loading, the analytical method to evaluate the relationship between the lateral load and displacement of RC bridge piers and to predict the displacement at the onset of buckling of the longitudinal rebars has to be provided.

For long-term reliability estimation, the steel weight loss $C_w(t)$ at t years after construction is needed. In a marine environment, $C_w(t)$ is affected by many factors such as distance from coastline and wind speed. This study uses the procedure to calculate $C_w(t)$ based on the probabilistic hazard curves associated with airborne chlorides (Akiyama et al. 2009 and 2010a). The effect of differences in marine environment on the long-term reliability could be quantified.

The main purpose of this paper is to discuss a methodology previously proposed by the writers for the evaluation of long-term seismic reliability of reinforced concrete (RC) bridge piers in a marine environment and to present new results.

PROCEDURE TO CALCULATE THE SEISMIC RELIABILITY: A BRIEF REVIEW

Akiyama et al. (2010b) presented the basic equations to estimate the long-term seismic reliability of RC structures in earthquake prone region and a marine environment. This procedure is summarized in this section.

During a given time interval T, the cumulative-time failure probability p_f of a bridge pier subjected to both seismic hazard and hazard associated with airborne chlorides is

$$p_f = 1 - \left(1 - p_{fa}(1)\right) \cdot \left(1 - p_{fa}(2)\right) \cdots \left(1 - p_{fa}(t = T)\right) \tag{1}$$

$$p_{fa}(t) = \int_0^{100} \int_0^{\infty} -\frac{dp_0(\gamma)}{d\gamma} \cdot P\left[D_e \geq C_a \middle| \Gamma = \gamma, C_w = c_w(t)\right] \cdot f\left(c_w(t)\right) d\gamma \, dc_w \tag{2}$$

where $p_0(\gamma)$= the annual probability that the seismic intensity, Γ, at a specific site would exceed a value γ; $P\left[D_e \geq C_a \middle| \Gamma = \gamma, C_w = c_w(t)\right]$ = conditional probability of the seismic demand D_e exceeding the seismic capacity C_a conditioned upon the seismic intensity γ and steel weight loss c_w (t); and $f\left(c_w(t)\right)$ = probabilistic density function, PDF of $c_w(t)$.

RC column with sufficient ties subjected to cyclic loading exhibits ductile behavior and the load-carrying capacity decreases after the onset of buckling of longitudinal rebars. Therefore, the onset of buckling of longitudinal rebars is defined as the ultimate limit state of RC column in the seismic design specification (Japan Road Association 2002). Naito et al. (2010) proposed the displacement ductility evaluation methods of concrete-encased steel columns based on the buckling analysis of longitudinal rebars and concrete-encased steel in plastic hinge. Their model used

in the buckling analysis considered the prevention forces of ties and cover concrete, R_w and R_c, for lateral deformation of longitudinal rebar.

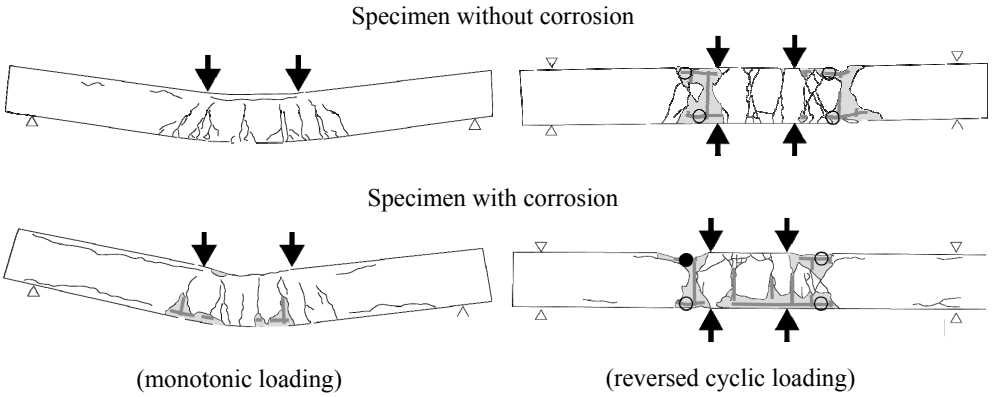

Figure 1. Specimens with and without corrosion after monotonic or cyclic loading (based on information provided by Kobayashi (2006) to the first author)

Kobayashi (2006) investigated the effect of steel corrosion on the seismic capacity and hysteresis loop of RC beams. Figure 1 shows the appearance of RC beams with and without corrosion after monotonic and cyclic loading. Kobayashi (2006) showed that after the cyclic loading, RC beams suffered severe spalling of cover concrete within constant-moment region. This spalling was caused by the steel corrosion products and corrosion cracks that led to debonding between the cover concrete and rebar. From these experimental results of corroded RC component, the expansion of corrosion products could reduce the prevention force R_c. R_c is modified from original equation proposed by Naito et al. (2010) to minimize the differences between computational and experimental displacement (Yamamoto and Kobayashi 2006, Oyado 2007, and Kato et al. 2004 and 2005) at the onset of rebar buckling of corroded RC specimens subjected to cyclic loading. RC bridge pier is modeled as single degree of freedom in nonlinear time history analyses to calculate the seismic demand. Degrading elasto-plastic model (e.g., Takeda model 1970), which could evaluate the nonlinear response behavior of the RC component subjected to cyclic loading, is used as hysteresis rule.

PDF of steel weight loss $c_w(t)$ needs to be calculated in Eqn. (2). Steel weight loss depends on time after construction, hazard associated with airborne chloride, concrete strength and quality, and structural details such as concrete cover and diameter of rebar. Akiyama et al. (2009 and 2010a) presented the procedure to calculate the steel weight loss. Hazard assessment associated with airborne chloride was established based on seismic probabilistic hazard assessment (Kameda and Nojima 1988). The results of hazard assessment associated with airborne chlorides depend on the ratio of sea wind (defined as the percentage of time during one day when the wind is blowing form sea toward land), wind speed in the location analyzed,

and distance from coastline. The probability that C_{air} at a specific site will exceed an assigned value c_{air} is

$$q_s(c_{air}) = \int_0^\infty \int_0^\infty P(C_{air} > c_{air} | u, r) \cdot f_u(u) \cdot f_r(r)\, du dr \quad (3)$$

where $f_u(u)$ and $f_r(r)$ = PDFs of wind speed u and ratio of sea wind r, respectively; and $P(C_{air} > c_{air} | u, r)$ = probability of the event $C_{air} > c_{air}$ given u and r.

LONG-TERM SEISMIC RELIABILITY OF RC BRIDGE PIERS IN A MARINE ENVIRONMENT

The elevation and cross-section of the bridge pier analyzed in this study is shown in Fig. 2. This bridge pier was designed according to the seismic design specification in Japan (Japan Road Association 2002). Specified concrete strength is 24 MPa and concrete cover is 90 mm. In this specification, minimum concrete cover shall be 90 mm and corrosion-resistant coated rebar shall be used, if concrete structure is located in very aggressive marine environment and the distance from coastline is less than 0.1 km.

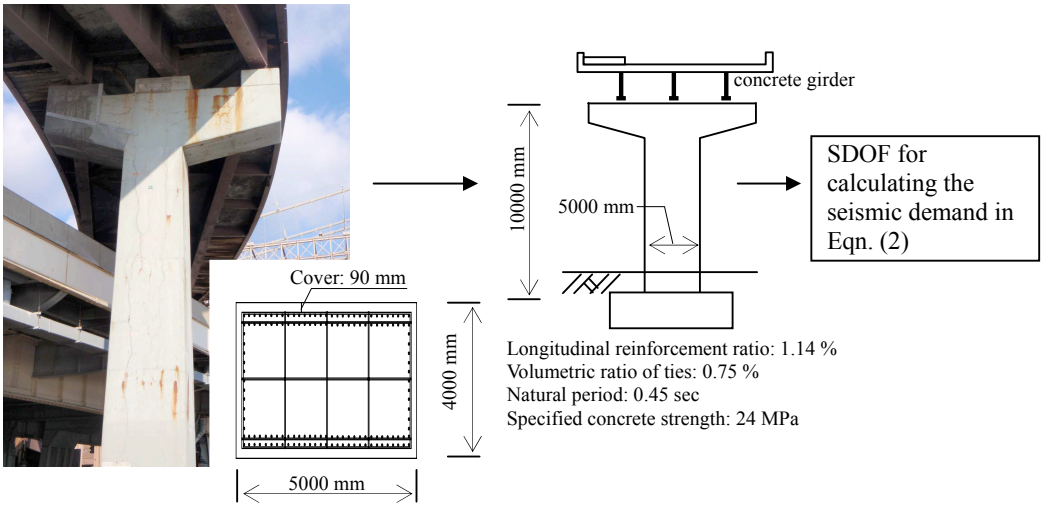

Figure 2. RC bridge pier analyzed

For illustrative purpose, it is assumed that the bridge pier is located in Niigata city and the distance d from coast line is 0.1 km. Seismic hazard curve (National Research Institute for Earth and Disaster Prevention 2010) and hazard curve associated with airborne chloride are shown in Fig. 3. Figure 4 shows the relationship between cumulative-time failure probability and time after construction of RC bridge pier. To examine the effect of corrosion on the failure probability, cumulative-time failure probabilities without deterioration are also shown. As indicated in Fig. 4, concrete cover of 90 mm is not enough to protect the rebar from

airborne chloride attack. This can make the difference between the cumulative-time failure probability associated with both seismic and airborne chloride hazards and that associated with seismic hazard alone. It should be noted that even though the design specification by Japan Road Association (2002) require that coated rebars are used for RC structures in very aggressive marine environment, RC bridge pier shown in Fig. 2 has non-coated rebars.

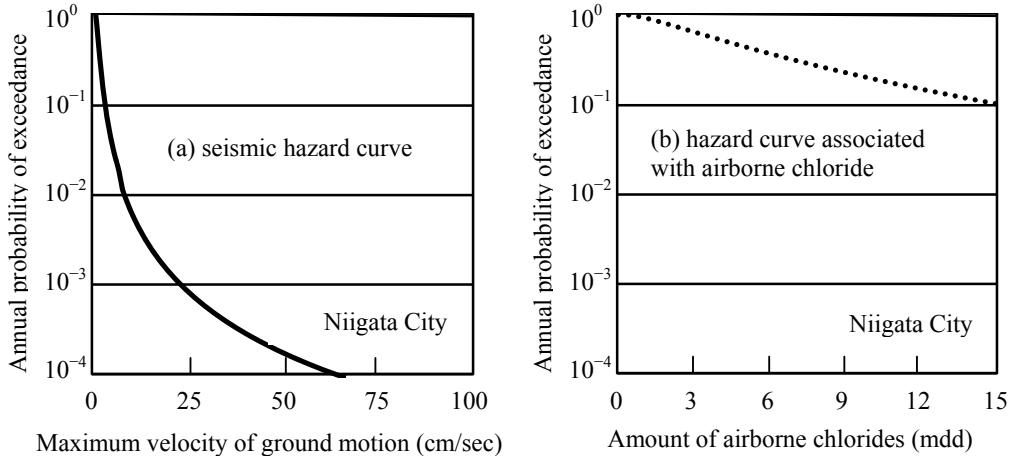

Figure 3. Seismic and airborne chloride hazard curves

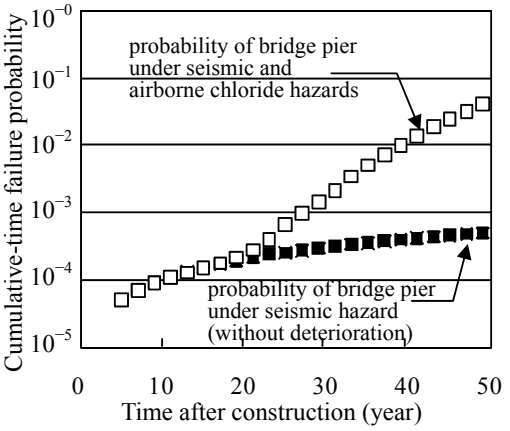

Figure 4. Relationship between time and cumulative-time failure probability

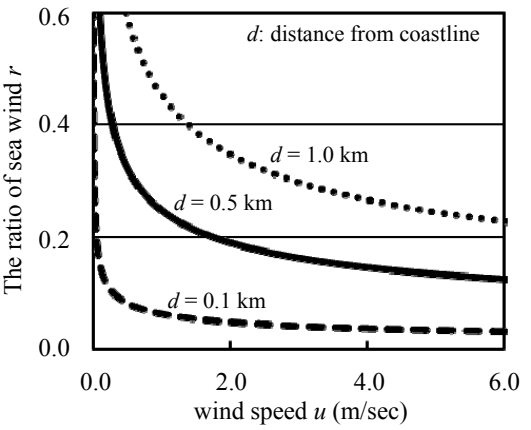

Figure 5. r versus u for several values of d to prevent the deterioration of seismic performance

The difference between the cumulative-time failure probability associated with both seismic and airborne chloride hazards and that associated with seismic hazard alone depends on marine environment. The marine environment required to take into consideration the effect of corrosion on seismic performance is identified using

$$\frac{\beta_{corrosion}}{\beta_{w/o_corrosion}} = \varepsilon_a \tag{4}$$

$$\text{where} \quad \beta_{corrosion} = -\Phi(p_{f2}(u, r, d, T = 50 \text{ years})) \tag{5}$$

$$\beta_{w/o_corrosion} = -\Phi(p_{f1}(T = 50 \text{ years})) \tag{6}$$

$\beta_{corrosion}$ = reliability index associated with probability p_{f2}; $\beta_{w/o_corrosion}$ = reliability index associated with probability p_{f1}; p_{f2} = probability associated with Eqn. (1) considering both seismic and airborne chloride hazards, p_{f1} = probability associated with Eqn. (1) considering seismic hazard alone, Φ = cumulative distribution function of the standard normal variable.

p_{f2} depends on u, r and d used in Eqn. (3). When RC structure is far from coastline, $\beta_{corrosion}$ is almost equal to $\beta_{w/o_corrosion}$. However, when d is less than 1.0 km, the difference between $\beta_{corrosion}$ and $\beta_{w/o_corrosion}$ depends on the combination of the mean values of u and r as shown in Fig. 5. It is assumed in Fig. 5 that (a) bridge pier analyzed has the structural details shown in Fig. 2; and (b) ε_a is 0.90. Since the mean values of u and r in Niigata City are 3.69 m/sec and 0.344, respectively, concrete cover must be larger than 90 mm if d is less than 1.0 km. When the mean values of u and r are provided from meteorological data and the distance from coastline is given, it could be determined from Fig. 5 whether or not the effect of corrosion on the seismic performance is investigated.

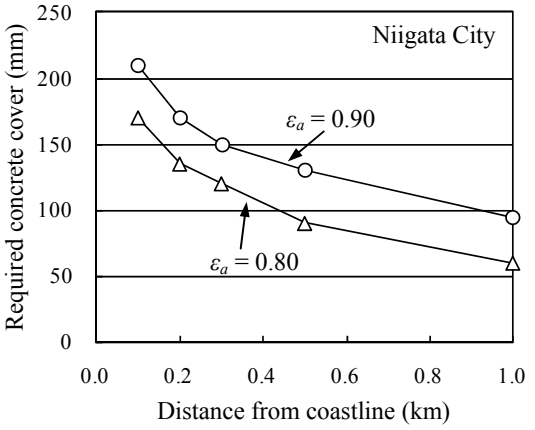

Figure 6. Required concrete cover to prevent the deterioration of seismic performance of RC bridge pier in Niigata City

Figure 6 shows the relationship between distance from coastline and required concrete cover of RC bridge pier in Niigata City to satisfy Eqn. (4) when ε_a is 0.9 or 0.8. In very aggressive environment such as Niigata City, RC components must have an extremely large concrete cover to prevent the deterioration of seismic performance from corrosion. One of the ways to protect RC structures without increasing concrete cover is to use corrosion-resistance coated rebars or stainless rebars. It has been suggested that expected reductions in maintenance and repair costs and the extension of service life can justify their use on a life-cycle cost basis

(e.g., Val and Stewart 2003). Further research is needed on the seismic reliability of RC structures in a marine environment in connection with life-cycle maintenance and optimization (Frangopol and Liu 2007).

CONCLUSIONS

1. For the long-term assessment of RC structures located in a marine environment and earthquake prone regions, the effect of corrosion due to airborne chlorides on the seismic capacity need to be taken into consideration. A computational procedure to integrate the probabilistic hazard associated with airborne chlorides into long-term seismic reliability assessment of RC bridge piers was presented.
2. In very aggressive marine environment, the possible use of corrosion-resistance coated rebars or stainless rebars must be studied based on the life-cycle maintenance and optimization concepts and methods.

ABSTRACT

This study presents a stochastic method to optimize the inspection of reinforced concrete structures subjected to chloride penetration. The strategy is oriented to find the time interval between two consecutive inspections that (1) minimize the costs of inspection, preventive and corrective repair; and (2) ensure a given level of safety. The optimal interval is therefore determined by using stochastic processes and decision theory. The chloride penetration phenomenon is represented by a Markov chain whose transition matrix is determined from simulations.

INTRODUCTION

Civil infrastructure deteriorates with time mainly as a result of environmental factors. Infrastructure deterioration may be progressive (e.g., as a result of chloride ingress), it may result from sudden events (shocks e.g., earthquakes) or as a combination of both. The cost-efficient design, management and operation of these systems depend, to a large extent, on the assumptions and quality of the deterioration models used for the analysis. Nowadays, design and management of infrastructure must consider economical, social and environmental constrains to reduce environmental impact, optimize resource allocation and decrease waste generation. This new tendency of design and management must also consider all the phenomena which affect the performance of structures. For RC structures, corrosion induced by chloride ingress generates important damage after 10 or 20 years of service (Rosquoet *et al.*, 2006). Consequently, its inspection and maintenance are essential to ensure an optimal level of serviceability and safety during its lifespan.

The purpose of this paper is to develop a method to optimize the intervals of inspection of reinforced concrete structures subjected to chloride penetration. An optimal inspection interval minimizes the costs of inspection, preventive or corrective repair and failure. The method of optimization takes as starting point the work of Sheils *et al.* (2010) and is presented in the following section. Afterwards, the discussion focuses on the estimation of the transition matrices from a comprehensive model of chloride penetration and the cost modeling. Finally, the proposed methodology is illustrated with a numerical example.

STRATEGY OF INSPECTION AND MAINTENANCE

General description. Inspection can be carried out by using destructive and non-destructive methods. This study refers to RC structures subjected to chloride ingress and focuses on inspection/maintenance of major infrastructure such as ports and bridges. The requirements for the strategy of inspection/maintenance were defined within the framework of the European project FUI (2007-2010) MAREO[1] with the collaboration of public agencies, construction companies and research centers. In the strategy of inspection/maintenance considered herein, inspection is undertaken by analyzing the concentration of chlorides at the cover depth on concrete cores (destructive method). Afterwards, depending on inspection results, the repair technique consists of rebuilding the polluted concrete cover. The advantage of the proposed approach is that preventive repair ensures optimal levels of serviceability and safety during the lifespan of the project.

Inspection model. This approach requires that the structure is inspected periodically; i.e., every Δt years. The purpose of these inspections is to establish the real chloride concentration at the cover depth, C. This parameter provides information about the probability of corrosion initiation, and therefore, can be used by the owner/operator to decide if the structure must be repaired or not. The experimental test to determine the chloride profiles is based on the AFREM procedure (RILEM, 2002). Bonnet et al., (2009) found that there are significant differences between "theoretical" and "measured" chloride profiles. To take into account the influence of errors in measurement, the difference between measured $\hat{C}$ and real C values is usually modeled by considering a noise η as follows:

$$\hat{C} = C + \eta \qquad [1]$$

It is supposed herein that the noise is independent of the real chloride concentration because there are several sources of error influencing the results of the inspection. This assumption has been validated from a series of measurements on metallic harbor structures (Schoefs et al. 2009).

Errors in measurement can lead to under or overestimations of chloride content, and consequently, to make erroneous decisions increasing the probability of failure or producing over-costs. From a probabilistic point of view, two measures can be defined to quantify these events:

- Probability of Good Assessment (PGA): determines the probability of detecting an event (crack, defect, concentration, etc.) given that it exists:
$$\text{PGA} = P\left(\hat{C} \geq C_{rep} \middle| \hat{C} \geq C_{rep}\right) \qquad [2]$$
- Probability of Wrong Assessment (PWA): establishes the probability of detecting an event given that it does not exist:
$$\text{PWA} = P\left(\hat{C} \geq C_{rep} \middle| \hat{C} < C_{rep}\right) \qquad [3]$$

[1]. Maintenance and REpair of concrete coastal structures: risk-based Optimization (MAREO) Project

where C_{rep} represents the repair threshold. The equations presented above assume that the noise and the signal follow a normal distribution –i.e. N[μ_η, σ_η] and N[μ_C, σ_C].

Repair model. Chloride penetration into concrete may cause structural failure when no repair is carried out. The repair criterion considers that the polluted concrete is rebuilt when the chloride concentration measured during the inspection reaches a threshold value C_{th}. According to Duracrete (2000), the threshold value C_{th} can be modeled by a normal distribution N[$\mu_{C_{th}}$, $\sigma_{C_{th}}$]. Thus, the probability of corrosion initiation between the inspection intervals can be estimated as:

$$p_f = \Phi\left(\frac{C-\mu_{C_{th}}}{\sigma_{C_{th}}}\right) \quad [4]$$

TRANSITION MATRICES FOR MODELING CHLORIDE INGRESS

A discrete-time Markov process can be used for prediction by knowing the current state of a system. Towards this aim, the space of the variable of interest is discretized into M states. The Markov process is thus used to determine the probability that an event belongs to a state j knowing that in a preceding state it belonged to a state i. This probability, noted as a_{ij}=P(X_{t+1}= j | X_t =i), is called "transition probability". It is considered herein that a_{ij} is independent of t. The transition probabilities can be grouped in a matrix of size M×M called transition matrix **P**. According to the Chapman-Kolmogorov equations, by knowing an initial state, the probabilities of belonging to other states after t transitions, **q**(t), are (Ross, 2004):

$$\mathbf{q}(t) = \mathbf{q}_{ini}\mathbf{P}^t \quad [5]$$

where the vector $\mathbf{q}_{ini}$ contains the probabilities of belonging to the states at an initial time –i.e., t =0. In this study, the variable of interest is the concentration of chlorides at the cover depth, C, which controls corrosion initiation. Therefore, the Markov processes can be used to estimate the probability that C is in a given state at a given time. If it is supposed that after construction t=0 the concentration of chlorides at the cover depth is zero. Consequently, all the concentrations belong to the first state, $\mathbf{q}_{ini}$ becomes $\mathbf{q}_{ini}$=[1, 0, 0, … ,0] and equation [5] provides a vector containing the probabilities of belonging to a state j at time t, **q**(t).

In several applications of Markov chains, the transition matrix is obtained from experimental data or expert judgment. However, given that the rate of chloride ingress into concrete is slow and that chloride ingress is influenced by several parameters (environment, material properties, etc.), it is proposed herein to numerically estimate **q**(t). The following sections will describe the adopted probabilistic model of chloride penetration and the method proposed to estimate the transition matrix.

Chloride ingress model. Chloride ingress into concrete is controlled by a complex interaction between physical and chemical mechanisms that have been commonly modeled as a diffusion phenomenon. However, in this paper a more comprehensive

model is proposed; it considers the interaction between: (1) chloride penetration, (2) diffusion of moisture; and (3) heat transfer. The description of the formulation of the model is beyond the scope of this paper but can be found in Bastidas-Arteaga *et al.*, (2011).

The management of uncertainties considers, first, the random variables presented in Table 1. The criteria for determining the characteristics of the random variables are dicussed in (Bastidas-Arteaga *et al.*, 2011). Taking into account the non-linearity and the complexity of the system of partial differential equations used to model chloride penetration, Monte Carlo simulations and Latin Hypercube sampling are employed herein.

Table 1. Probabilistic parameters of the random variables

Variable	Units	Distribution	Mean	COV
– Reference chloride diffusion coefficient, $D_{c,ref}$	m^2/s	log-normal	$3 \cdot 10^{-11}$	0.20
– Activation energy of the chloride diffusion process, U_c	kJ/mol	beta on [32;44.6]	41.8	0.10
– Aging factor, m		beta on [0;1]	0.15	0.30
– Reference humidity diffusion coefficient, $D_{h,ref}$	m^2/s	log-normal	$3 \cdot 10^{-10}$	0.20
– Parameter representing the ratio $D_{h,min}/D_{h,max}$, α_0		beta on [0.025;0.1]	0.05	0.20
– Parameter characterizing the spread of the drop in D_h, n		beta on [6;16]	11	0.10
– Thermal conductivity of concrete, λ	W/(m°C)	beta on [1.4;3.6]	2.5	0.20
– Specific heat capacity of concrete, c_q	J/(kg°C)	beta on [840;1170]	1000	0.10
– Density of concrete, ρ_c	kg/m^3	Normal	2400	0.04

Estimation of the transition matrix from simulations. Transition matrices are estimated from Monte Carlo simulations of the probabilistic model of chloride penetration. In each simulation, the chloride concentration at cover depth during time is recorded. In all simulations, the frequency of belonging to a given state is determined. Thus, the probability of belonging to a state j at time t is obtained from:

$$\hat{q}_j(t) = \frac{n_o(t)}{N} \qquad [6]$$

where $n_0(t)$ is the number of observations in the state j measured at time t and N is the number of simulations. Table 2 presents the possible states of the system and its corresponding boundaries (minimum and maximum); note that each state corresponds to a chloride concentration C. Taking into account this discretization, Figure 1 shows the variation in time of the probability of belonging to the last state i=10 ($\hat{q}(t)$) obtained from Monte Carlo simulations.

Table 2. States used for discretizing the problem.

State i	1	2	3	4	5	6	7	8	9	10
C minimum (kg/m^3)	0.0	0.4	0.8	1.2	1.6	2.0	2.4	2.8	3.2	3.6
C maximum (kg/m^3)	0.4	0.8	1.2	1.6	2.0	2.4	2.8	3.2	3.6	4.0

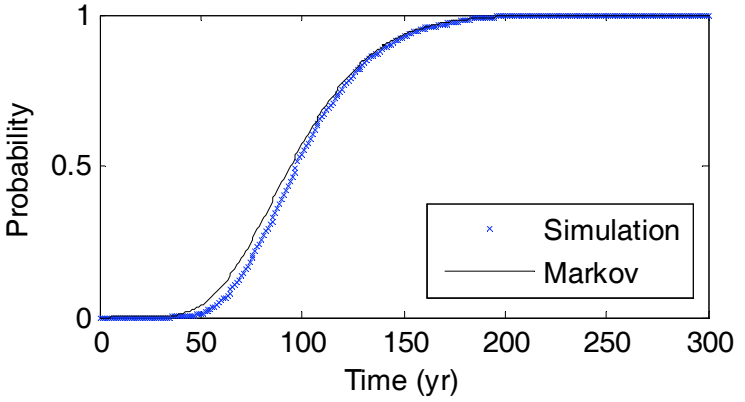

Figure 1. Comparison between the probabilities computed from Monte Carlo simulations and Markov model for the last state.

Once the probabilities $\hat{q}(t)$ have been estimated, several methods can be used to compute the transition probabilities. The major difficulty in the assessment of **P** lies in the number of parameters a_{ij} to estimate. Various studies consider a Markov matrix with two parameters for state (Pappas *et al.*, 2001, Roelfstra *et al.*, 2004). In this case, the transition probabilities can be estimated from a non-linear regression. However, complex stochastic phenomena cannot be modeled by a transition matrix with two transition probabilities per state (Roelfstra *et al.* 2004). To solve this problem, the proposed method searches the values a_{ij} that minimize the difference between the probabilities estimated from simulations and the obtained from the Markov model (equation [5]). Since the kinematics of the time-dependent evolution of each state is similar, there are *M* functions to minimize:

$$\begin{cases} \min_{\mathbf{a}} \max_{\mathbf{F}} \mathbf{F}(\mathbf{a}) = \left(f_1(\mathbf{a}), f_2(\mathbf{a}), \ldots, f_M(\mathbf{a})\right)^T \\ \text{s.c.} \quad a_{ij} \geq 0 \quad \text{et} \quad \sum_{j=0}^{\infty} a_{ij} = 1 \end{cases} \qquad [7]$$

where **a** is a vector containing the transition probabilities (optimization parameters) and:

$$f_j(\mathbf{a}) = \sum_{t=0}^{t_{ana}} \left| \hat{q}_j(t) - q_j(t, \mathbf{a}) \right| \qquad [8]$$

where t_{ana} represents the analysis period used to perform the adjustment. This multi-objective optimization problem has been solved by using the "optimization toolbox" of Matlab©. The selected optimization method minimizes the maximum value of a set of multi-variable functions from an initial value.

COST ANALYSIS

Two kinds of costs are usually considered in cost analysis: *agency* and *user* costs. Agency costs encompass the direct costs incurred by the owner/operator during the life-cycle including initial construction costs and costs associated with inspection,

repair, rehabilitation, replacement and disposal. User costs represent the inconvenience and expenses incurred by users due to traffic disruption such as travel delay costs, ship operating costs and accident costs. According to Thoft-Christensen (2009), user costs should be included in the analysis to formulate a comprehensive strategy of maintenance management of infrastructure. However, given that the information to estimate user costs is hard to establish and find; this work is only based on agency costs.

In this study the direct costs incurred by the agency include only costs associated with maintenance (inspection, preventive repair, corrective repair and failure). The initial construction costs are not included in the analysis because it is assumed that it would be the same for all maintenance alternatives. Since it is not possible to determine the final use of the structure at the end of the life-cycle (deconstruction or demolition), the residual (or salvage) value is also not considered. This study considers costs estimated with standard and intergenerational discounting.

In life-cycle cost analysis, the expected value of the total present value life-cycle cost E[C_T] is computed as:

$$E[C_T] = \sum_{j=0}^{m} E\left[C_j(t)\right] W(t); \text{for } t \le T_t \qquad [9]$$

where m is the total number of interventions carried out within the time interval [0,T_t], $C_j(t)$ is the j^{th} expenditure at time t (for instance in years), T_t is the life-cycle length and $W(t)$ is the weight used to discount $C_j(t)$ to the present value. $C_j(t)$ depends on the properties of the original and repair materials; and on the characteristics of the maintenance strategy (i.e., inspection interval, inspection quality, repair threshold, etc.). The costs of inspection C_I, preventive repair C_{pr} and corrective repair C_{cr} are simply calculated as a fraction of the initial cost of construction C_0 as:

$$C_I = C_0 k_I \qquad [10]$$

$$C_{pr} = C_0 k_{pr} \qquad [11]$$

$$C_{cr} = C_0 k_{cr} \qquad [12]$$

where k_I, k_{pr} and k_{cr} are weights used to compute the costs of inspection, preventive and corrective repair as a fraction of C_0, respectively.In conventional discounting, the standard discount weight can be expressed as:

$$W_s(t) = 1/(1 + r_s)^t \qquad [13]$$

where r_s is the standard discount rate. Sumalia and Walters (2005) and Prager and Shertzer (2006) derived an intergenerational discount weight for computing net benefits from the use of environmental resources. In their formulation, they treat the benefits as accruing to the current generation (at standard discount rates) plus to each of the annual increments of new stakeholders who will have entered the stakeholder population by that future year divided by the generation length, G. Consequently, the intergenerational discounting $W_I(t)$ can be estimated as (Sumalia and Walters, 2005):

$$W_I(t) = W_s(t) + \frac{W_c(t-1)}{(1+r_I)G}\left[\frac{1-\Delta^t}{1-\Delta}\right] \quad [14]$$

where r_I is the intergenerational discount rate computed on an annual basis and $\Delta = (1+r_s)/(1+r_I)$.

NUMERICAL EXAMPLE

Problem description. This example aims to determine an inspection interval that optimizes the maintenance costs of RC structures. Consider a structure placed in a marine environment with temperature ranging from 5 to 25 ºC and with relative humidity between 0.6 and 0.8. The stochastic climate model is described in (Bastidas-Arteaga et al., 2011). The structure is exposed to an average environmental chloride concentration C_{env}=6 kg/m^3. This concentration corresponds to the boundary between high and severe corrosive environments (Weyers, 1994). According Duracrete, (2000), C_{env} is modeled as a stochastic process generated by independent numbers following a log-normal (log-normal noise) with a coefficient of variation of 0.2. To simplify the study, it is assumed that the repair material has the same characteristics that the construction material.

The determination of an optimal inspection interval is very sensitive to the cost models. Therefore, to obtain realistic results, the inspection, preventive repair and corrective repair coefficients (i.e., k_I, k_{pr} and k_{cr}) were defined taking into account the average expenditures for these items incurred by the port of Nantes Saint-Nazaire, France. These coefficients are presented in Table 3 and are used to estimate the costs of inspection, preventive and corrective repair on the basis of an initial construction cost of 1000 units. Given that it is supposed that repair is preventive, there is no failure cost and these coefficients are lower than 1. Whereas the coefficient of preventive repair only considers the cost related to cover rebuilding, the coefficient of corrective repair includes besides the costs of structural strengthening. Table 3 also includes the numerical values used to model inspection and repair.

Table 3. Parameters used in the numerical example

Parameter	value
Noise of the measurement, η, km/m^3	0.30
Standard deviation of noise, σ_η, km/m^3	0.50
Repair threshold, C_{rep}, km/m^3	0.10
Threshold chloride concentration, C_{th}, km/m^3	2.00
Standard deviation of C_{th}, σ_{Cth} , km/m^3	0.40
Initial cost of construction, C_0	1,000
Inspection coefficient, k_I	0.005
Preventive repair coefficient, k_{pr}	0.15
Corrective repair coefficient, k_{cr}	0.30
Discount rate, r_s	5%
Discount rate per generation , r_I	3%
Generation length, G	25 yr
Life-cycle length, T_t	100 yr

Results. To estimate the Markov matrix, the problem is discretized into M = 10 states. The matrix **P** was obtained from 10,000 simulations for a concrete cover of 5cm.

Figure 1 compares the probability of belonging to the state 10 estimated by both simulations and the Markov model. Note that the phenomenon is well represented by the estimated **P**.

Figure 2 presents the expected times to preventive and corrective repair as a function of the length of the inspection interval. These results were obtained from the Markovian approach for a given repair technique to rebuild the concrete cover (formed concrete). As expected, the time to preventive repair, t_{pr}, is lower when the structure is periodically inspected. On the contrary, less inspection implies that the time to corrective repair, t_{cr}, decreases. These times will be used to determine the optimum inspection interval that minimizes costs. To simplify the computation, the results of simulation are adjusted to two analytical functions that will allow us to estimate t_{pr} and t_{cr} in terms of the length of the inspection interval Δt_I (Figure 2).

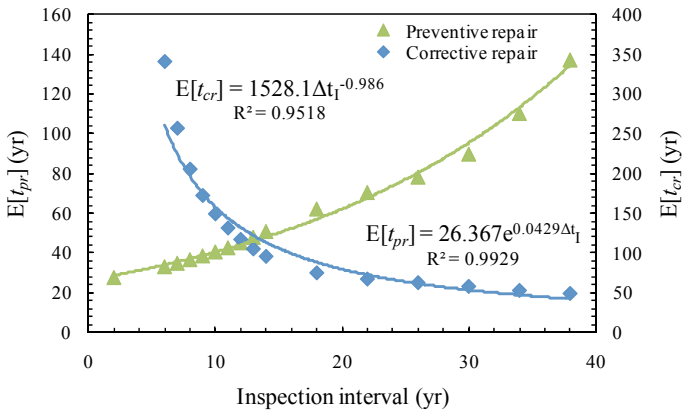

Figure 2. Determination of the expected value of the times to preventive and corrective repair

Figure 3 presents the expected costs for three cases: standard discounting, intergenerational discounting and without discounting. An intergenerational discount rate of r_I = 3% (per generation) was used. The total cost is discriminated into the costs of inspection, preventive and corrective repair. It is observed in all cases that the costs of inspection and preventive repair decrease and the cost of corrective repair increases for larger inspection intervals. This behavior is explained by the fact that when the inspection interval is greater, most inspections detect the component's failure. On the contrary, when the structure is inspected regularly, repair is preventive, and therefore, the corrective repair expenditures diminish.

The results showed that the expected total cost is optimal when the structure is inspected every 20 years for the standard discounting case and every 15 years for the intergenerational case. However, the optimum expected cost is different for all cases because the future flows for the intergenerational and undiscounted cases are important in comparison to the standard case for the life-cycle length T_t. The differences between the optimum inspection intervals imply that the intergenerational and undiscounted cases give more importance to preventive maintenance.

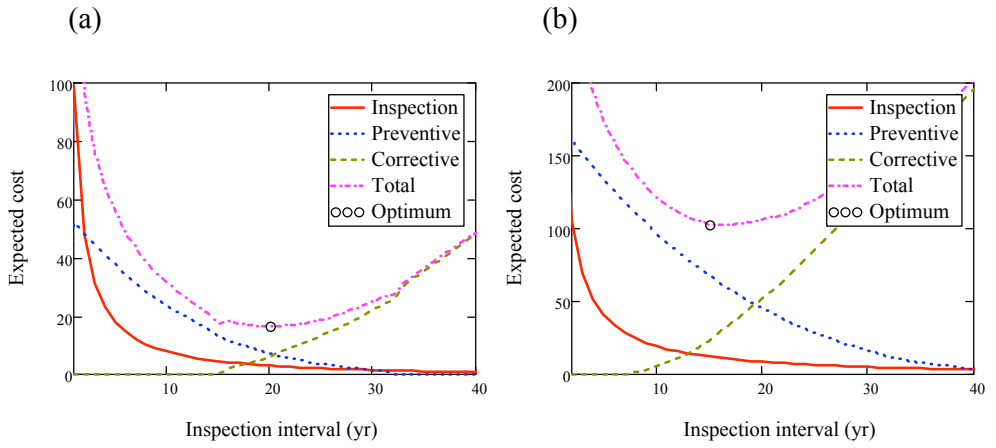

Figure 3. Expected costs for the cases (a) standard and (b) intergenerational discounting

The discount rate per generation can be defined in different ways. For instance Sumalia and Walters (2005) state that the simplest way to fix r_I is to select a value equal to the standard discount rate. It can also be defined from a discussion with the community or it can be used the internal rate of return for educating people to the Ph.D. level in a given country. The influence of this parameter on the length of the optimum inspection interval and on the total expected cost is studied in Table 4. Therefore, for small discount rates per generation, the structure should be inspected more frequently and the total expected cost is larger. On the contrary, when $r_I \rightarrow \infty$, the optimum result converges to the result obtained when intergenerational discounting is neglected.

Table 4. Influence of r_i on the optimum inspection interval and on the total expected costs

r_I (%)	Optimum Δt_I (yr)	Total expected cost
3	15	102.5
5	19	53.8
10	20	26.6
20	20	19.2
∞	20	16.6

CONCLUSIONS

This paper presents a stochastic method for optimizing the inspection/repair of RC structures subjected to chloride penetration. The inspection technique measures the concentration of chlorides at the cover depth. Afterwards, based on the inspection results, the structure is repaired by replacing the polluted concrete with new material. The inspection/maintenance strategy chosen is modeled using decision theory and Markov processes. It is also proposed a methodology for determining the transition matrix from simulations of a chloride penetration model. The proposed method is

illustrated with an example where it is showed that there is an inspection interval that minimizes the costs of inspection, preventive and corrective repair.

Abstract

A structural risk evaluation methodology is introduced in this paper for the offshore platforms against major hazard events (hurricanes and earthquakes) during the operating life of the platforms. The primary objective is to evaluate the risk level from the major hazard events to identify possible risk reduction solutions. Firstly a non-linear progressive collapse analysis approach is presented to investigate the platform capacity to resist the loads imposed by major hazard events. The structural reliability method is then proposed to estimate the probability of platform failure under major hazard events. The platform failure limit state function is defined in terms of hazard loads and platform capacity. Uncertainties are included in the parameters associated with hazard loads and platform capacity. Finally the platform failure consequence and the probability of platform failure are combined to determine the platform risk associated with the major hazard events. Case studies are presented to illustrate the application of the developed structural risk evaluation approach.

Keywords: Offshore platforms; Structural risk evaluation; Major accidental events

1 INTRODUCTION

Offshore platforms are subjected to major accidental events, such as hurricanes, earthquakes, fires, explosions, dropped objects and vessel impacts, during the operating life of the platforms. Oil production from an offshore platform may be stopped because of a major accident event if the platform or some parts of the platform fail during the accidental event. In 2008 Hurricanes Gustav and Ike resulted in a total of 60 platforms being destroyed and 31 structures with extensive damaged (Kaiser and Yu 2010). The industry's evaluation of recent hurricanes in the Gulf of Mexico indicates that the hurricane 100-year return period event is substantially higher than that presently provided in API RP 2A 21st edition (2008). Thus, the criteria related to a reduced return period during the design phase results in an increase to the operating risk of offshore platforms. A large number (over 100) of fixed offshore platforms has been installed in seismically-active regions all over the world (Asgarian and Agheshlui, 2009). As new regions with the potential for significant seismic activity are now beginning to be developed, methods are needed to assist in the design of the structures which will be placed in those regions. In addition, geological studies have identified the potential for increased seismic activity in regions once believed to be far removed from seismic hazard. Offshore structures within these regions are in need of assessment for earthquake loads or re-assessment for increased earthquake loads. These facts underline the importance of the structural risk evaluation of offshore platforms against major accidental events.

A number of investigators have discussed the structural reliability of platforms subjected to major hazard loadings. Botelho et al. (1994) calculated the failure probability of ST130 "A" platform in the Gulf of Mexico during Hurricane Andrew. Gebara et al. (2000) and Jha et al. (2000) studied the effect of sea floor subsidence on the platform failure probability on three jacket platforms in the North Sea. Heredia-Zavoni et al. (2004) carried out a structural reliability assessment of deck elevations subjected to storm wave loading for fixed platforms in the Bay of Campeche. Dier et al. (2001) developed a reliability analysis methodology for jacket platforms in the North Sea. Ronalds et al. (2003) investigated the structural reliability of a generic caisson under storm overload in the Australian North West Shelf. Park et al. (2010) evaluated the effect of uncertainties of dynamic forces and structural properties on the reliability of the offshore platform using Monte Carlo Simulation (MCS). Nadim and Gudmestad (1994) studied the reliability of an oil production system at the Statfjord Field in the North Sea. However, to date very limited work has been reported on the structural risk evaluation of offshore platforms against major accidental events.

This paper presents a comprehensive structural risk evaluation approach for the offshore fixed platforms against hurricanes and earthquakes. Firstly a non-linear progressive collapse analysis approach is presented to investigate the platform capacity to resist the loads imposed by major hazard events. The structural reliability method is then used to estimate the probability of platform failure under major hazard events. The platform failure limit state function is defined in terms of hazard loads and platform capacity. Uncertainties are included in the parameters associated with hazard loads and platform capacity. The platform failure consequence and the probability of platform failure are combined to determine the platform risk associated with the major hazard events. The risk mitigation measures that could reduce the risks are briefly discussed.

Finally case studies are presented to illustrate the application of the developed structural risk evaluation approach.

2 STRUCTURAL RISK EVALUATION

2.1 Nonlinear Progressive Collapse Analysis

The platform capacity is generally determined from a nonlinear progressive collapse analysis, in which hazard loads are applied progressively until the platform collapses. Nonlinear analysis takes into consideration the non-linear effects of individual component behavior, including non-linear material behavior as well as the non-linear deflection of the structural components and system. Nonlinear progressive collapse analysis also allows the load redistribution from over-utilized members. Platform failure is generally defined as formation of a limiting mechanism in the platform structure or foundation. As the hazard loads are progressively increased during the nonlinear progressive collapse analysis, non-linear events such as member buckling and yielding, joint plasticity, and pile pullout or plunging are monitored, which is used to detect the formation of a limiting mechanism in the structure or foundation.

During a nonlinear progressive collapse analysis, the loadings are generally applied in two steps. The first step consists of the platform's dead weight and topsides loads. In the second step, the hazard loads are ramped up progressively until platform failure is reached. The platform capacity can be characterized in terms of the load factor, which is defined as the ratio of the platform's ultimate hazard load carrying capacity to nominal design load, e.g. 100-year storm lateral loading for hurricane evaluation and 10,000-year seismic loading for earthquake evaluation.

The structural model of a platform consists of the jacket, topsides, piles, foundation, conductors and miscellaneous platform appurtenances, reflecting the platform's as-is condition by accounting for known damage, deterioration and modification based on platform inspection records. The jacket structure is modeled as a space frame, in which tubular beam elements are used to model the jacket structural members. Non-linear joint characteristics are included in the model to check the capacity of each brace-chord intersection at the tubular joints. Jacket appurtenances that are exposed to wave and current loading are included in the model, either explicitly or implicitly by enhancing the hydrodynamic coefficients of the primary jacket members the appurtenances are attached to. All primary members on the topsides structures are included in the structural model to represent the topsides stiffness. The foundation model consists of non-linear beam-column elements to represent the piles with the soil being modeled with non-linear springs which represent the non-linear pile-soil interaction.

2.2 Structural Risk Evaluation

The platform risk is defined as the product of the probability of platform failure (likelihood of failure) and the consequence of failure based on a risk matrix. Risk matrix provides a traceable framework for explicit consideration of the frequency and consequences of hazards. A risk matrix uses a matrix dividing the dimensions of failure probability and consequence into typically 3 to 6 categories. Different operators may

have different risk matrix driven by company policy. Figure 1 presents a risk categorization matrix example. The consequence of platform failure considers life-safety consequence, environmental consequence and business loss/disruption.

Consequence of Failure				
	High	Medium Risk	High Risk	High Risk
	Medium	Low Risk	Medium Risk	High Risk
	Low	Low Risk	Low Risk	Medium Risk
		Low	Medium	High
		Likelihood of Failure		

Figure 1. Risk Matrix Example

The structural reliability analysis is used to estimate the probability of platform failure under major hazard events. During the platform reliability analysis, a platform is modeled in terms of two basic sub-systems: one representing jacket including foundation and the other representing topsides. The platform fails if either the jacket sub-system or the deck sub-system fails. The platform system reliability analysis models the two correlated sub-systems as a system in series.

The limit state function for estimating the failure probability is defined as

$$g(X) = R - S \tag{1}$$

where, R is a random variable describing the platform capacity (resistance) and S is the total hazard load. The uncertainty in the platform capacity considers the variability in the material properties such as yield strength, dimensional tolerances, platform condition and foundation. $g(X)$ defines a failure criterion that is a function of all random variables X. Failure occurs when the load S exceeds the capacity R or when $g(X) < 0$.

With the establishment of a limit state function, the annual probability of failure is defined by the expression:

$$P_f = \int_0^\infty \left(1 - F_S(x)\right) \cdot f_R(x) \cdot dx \tag{2}$$

where, P_f is the annual probability of failure, F_S is the cumulative distribution function (CDF) for the environmental load S, and f_R is the probability density function (PDF) for the capacity R.

The probability of failure can be calculated using the Rackwitz-Fiessler FORM (first order reliability method). In this method, the probability of failure is estimated using first order approximation to the limit state at the design point. Non-normal distribution random variables are transformed to equivalent normal distribution variables. The Newton-type recursive formula is used to iteratively search the most probable point (MPP) of failure in the limit state surface. The probability of failure is calculated as $P_f = \Phi(-\beta)$, where β is reliability index and $\Phi(\cdot)$ is the cumulative distribution function of a standard normal variable.

Risk of failure during an accidental event can be mitigated by a number of methods. All are likely to have significant cost and/or operational impact. Some hurricane mitigation alternative currently being implemented by operators in the Gulf of Mexico include:

- Raising of the deck above the wave crest
- Strengthening of the jacket structure
- Reduction of loading on the structure through the removal of unused wells, boat landings or other appurtenances to the jacket.
- Reduction in platform failure consequence.

2.3 Hurricane Structural Reliability Analysis

The platform failure probability against hurricane events is normally calculated for up to 8 wave approach directions (4 orthogonal directions and 4 diagonal directions). Failure in each direction is treated as a failure element, and the multiple direction failure forms a series system for reliability calculations. For platforms that experience storm waves from a dominant approach direction, probability of failure may be calculated for the dominant direction only.

The limit state function for estimating the failure probability is defined as

$$g(X) = R - S = R - L - W \tag{3}$$

where L is a random variable describing the wave and current load on the platform, and W is wind load on the platform.

By calculating the wave and current loads for a number of storms with different return periods, the wave and current load can be expressed as a function of wave height using regression analysis. The wave and current load characteristics change when the wave crest reaches the bottom of steel of the lowest deck of the topsides. For the regression of wave and current load as a function of wave height, two different functional forms are selected for wave and current load before and after deck inundation. The wave and current load L has the functional form

$$\begin{cases} L = C_1 \cdot H_m^{C_2} & H_m < H_d \\ L = \left[C_1 + C_3\left(H_m - H_d\right)\right] \cdot H_m^{C_2} & H_m \geq H_d \end{cases} \tag{4}$$

where H_d is the maximum wave height which results in a wave crest just hitting the underside of lowest deck of topsides, H_m is a random variable describing the annual

maximum wave height, C_1 is a random variable that characterizes the load uncertainty on the jacket system, C_2 is the exponent in the load-wave height relationship, and C_3 is a random variable that characterizes the uncertainty in the wave-in-deck loads.

For hurricane failure mode the topsides weight might have little effect so the uncertainty in topsides weight was excluded from the reliability calculation in this study. However, in the case that there is significant uncertainty in the topsides weight, the topsides weight should also be considered as a random variable.

2.4 Seismic Structural Reliability Analysis

Modeling of the structure, seismic action input and analysis of a structural dynamic response are three key issues for earthquake assessment. The validity of seismic analysis results depends on not only a proper model of the structure and a high-precision method adopted in the analysis, but also the earthquake loading parameters. In this study, a demand calculation procedure utilizing response spectrum analysis (RSA) has been implemented for the purposes of calculating load demands on the offshore structure. The seismic demand is expressed as maximum base shear force, and the capacity of the structure is expressed in terms of ultimate strength of the platform.

Detailed seismic reliability analysis of an offshore platform is quite involved. The random variables include the resistance of the structural components, the load characteristics, and any other random variable that may influence the performance (Nadim and Gudmestad, 1994). In the present study, a simplified model for the limit state function is assumed as

$$g(X) = R - S = R - \frac{(DD + LL)S_a}{r} \tag{5}$$

where S is the earthquake load in terms of maximum base shear, DD is a random variable describing the total dead load of the offshore platform, LL is a random variable characterizing the reduced live loads, S_a is a random variable that characterizes the design spectral at the fundamental frequency of the platform, and r is the response modification factor estimated utilizing response spectrum analysis.

For seismic failure mode the lateral inertia load had significant effect so the uncertainty in topsides weight was included in the reliability calculation in this study.

3 CASE STUDY

A case study for a 4-leg fixed steel jacket platform is presented to illustrate the application of the developed structural risk evaluation approach. The three-dimensional structural model has been created in USFOS program as shown in Figure 2.

3.1 Hurricane Risk Assessment

The non-linear progressive collapse analyses (pushover analyses) were performed using the USFOS program, resulting in a minimum reserve strength ratio (RSR) of 3.83 when subjected to a 100-year storm wave from platform's diagonal direction. It implies that the platform can resist 3.83 times of the load imposed by the 100-year return period storm. Pushover analyses also showed the collapse of the platform was caused by a

failure mechanism formed within the jacket by brace buckling and yielding. No significant non-linearities were observed in the piles or deck legs.

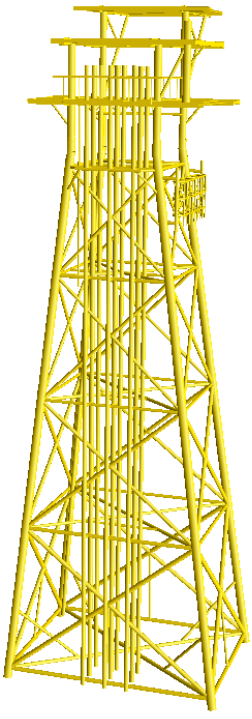

Figure 2. Platform structural model

A metocean study has been carried out using hind-casting techniques to determine the frequency of hurricane events with different magnitudes for the platform location. The significant wave height H_s in storms was fitted using a Weibull distribution. Mean value and standard deviation of H_s are given as

$$\mu_H = \gamma + \eta\Gamma\left(\frac{1}{\beta}+1\right) \tag{6}$$

$$\sigma_H = \eta\sqrt{\Gamma\left(\frac{2}{\beta}+1\right)-\Gamma^2\left(\frac{1}{\beta}+1\right)} \tag{7}$$

where β, η and γ are Weibull distribution parameters: β = 1.1687, η = 2.0970 and γ = 3.8624. The annual probability of exceedance of significant wave height was found by describing the frequency of occurrence of storms as a Poisson process. The annual probability of exceedance of H_s is given as

$$P_e(H) = 1 - \exp\left[-\lambda \exp\left[-\left((H-\gamma)/\eta\right)^{\beta}\right]\right] \tag{8}$$

where λ is a storm rate defined as $\lambda = N_{storms} / T_{hindcast}$, N_{storms} is the number of storms in the hindcast record, and $T_{hindcast}$ is the duration of the hindcast (years).

The regression of maximum wave height H_m as a function of H_s gives $H_m = 1.887 H_s^{0.951}$. Multiple USFOS runs were performed for a number of wave heights to generate wave loads. Coefficients C_1, C_2 and C_3 in Eq. (4) were determined by simultaneously fitting the curve in both regions above and below H_d using the regression method. The regression of wave load to wave height yielded the parametric relationship of wave load as a function of wave height. Relationship between the wave height and wave/current load is plotted in Figure 3.

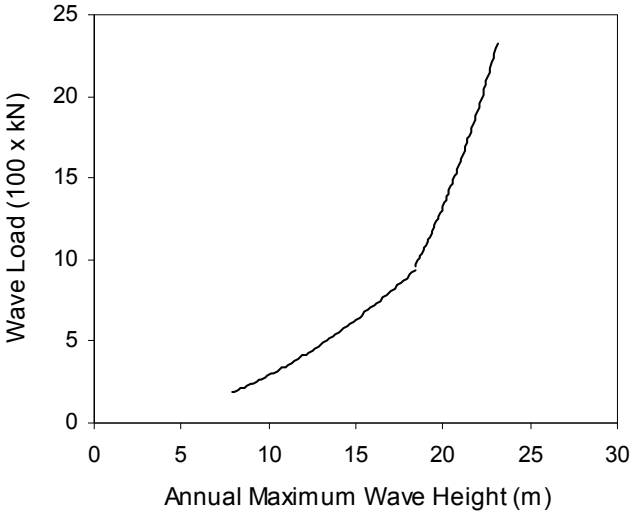

Figure 3. Wave load characteristics

The platform capacity R is assumed to have a lognormal distribution with a coefficient of variation of 0.15 as in PMB report (1996). The coefficient C_1 is assumed as a lognormal random variable with a coefficient of variation of 0.1 as in PMB report (1996). Given the large variability in the wave-in-deck forces, the coefficient C_3 is assumed as a lognormal random variable with a coefficient of variation of 0.35 as recommended by API RP 2A. Table 1 summarizes the random variables used in the reliability analysis and provides a description of the distribution types and coefficients of variation (CoV).

For the platform location, the dominant approach direction of the extreme waves is at the platform's diagonal direction. In this study only the annual failure probability for the diagonal wave direction was considered. The annual probability of platform failure has been calculated using FORM method. The platform has annual probability of failure of 1.438×10^{-4}.

The annual probability of platform failure and the consequence of failure are combined to determine the overall platform risk associated with hurricane hazard based on a risk matrix in Figure 1. The platform has medium failure consequence. The platform has medium likelihood of failure. The risk evaluation indicates that the platform is medium risk for the hurricane hazard.

Random Variable	Distribution	Mean Value	CoV
Platform Capacity, *R* (kips)	Lognormal	4,002	0.15 for jacket 0.20 for foundation
Annual Significant Wave height, *Hs* (ft)	Weibull	per formula (6)	per formula (7)
Coefficient C_1	Lognormal	0.809	0.10
Coefficient C_3	Lognormal	0.033	0.35

Table 1. Random variables for hurricane risk evaluation

3.2 Earthquake Risk Assessment

The design guidelines of the Norwegian Petroleum Directorate require that fixed offshore installations on the Norwegian Continental Shelf should withstand an earthquake event with annual occurrence probability of 10^{-4} (Norwegian Petroleum Directorate, 1992). The annual probability failure for the offshore platform in the platform location is estimated given that the design earthquake with an annual occurrence of 10^{-4} takes place in the field. Table 2 and Figure 4 show the response spectrum of the site specific horizontal motion with 5% damping for the 10^{-4} / year earthquake event.

The non-linear progressive collapse analyses (pushover analyses) were performed using the USFOS program, resulting in a minimum load factor of 8.07 when subjected to a 10^{-4} / year earthquake event. It implies that the platform can resist 8.07 times of the load imposed by the 10^{-4} / year earthquake event.

The calculated fundamental period of the platform is 2.90 seconds and the design spectral response acceleration, at the fundamental period, is 0.097g. A coefficient of variation of 0.30 is assumed for the design spectral response acceleration as shown in Figure 3. The uncertainties of the dead weight and live loads of the structure are considered in the analysis. For design of conventional offshore structures, a normal distribution with a coefficient of variation of 0.13 and 0.14 are recommended for the dead load and the live loads, respectively (Skjong et al. 1995). The uncertainty in the dead load of the offshore platforms is normally considered to be small due to control of weights during design and fabrication. However, the assumed coefficient variation includes uncertainties resulting from the structural analysis in addition to the uncertainty of the load.

Finally, r, the response modification factor is found to be 0.9 by employing the response spectrum analysis. The random variables, mean values and coefficient variables (COV) for the random variables with their statistical distribution functions are summarized in Table 3.

Utilizing FORM method, the annual probability of failure for the platform is found to be 2% given that the 10^{-4} / year earthquake event takes place in the field. The annual probability of platform failure and the consequence of failure are combined to determine the overall platform risk associated with earthquake hazard based on a risk matrix in Figure 1. The platform has medium failure consequence. The platform has medium likelihood of failure. The risk evaluation indicates that the platform is medium risk for the earthquake hazard.

Frequency(Hz)	Sa (g)		COV
	Mean	Stdv

4 CONCLUSION

A comprehensive structural risk evaluation approach has been presented for offshore fixed platforms against major hazard events. Non-linear progressive collapse analysis is used to calculate the platform capacity characterized in terms of the platform's load factor. The probability of platform failure is estimated from the structural reliability analysis. The platform failure consequence and the probability of platform failure are combined to determine the platform risk level associated with the major accidental events. Case studies have illustrated the effectiveness of the developed structural risk evaluation approach. This paper only covers the risk evaluation of hurricanes and earthquakes. The writers are conducting an ongoing research for the development of the risk evaluation approach for other accidental events such as fires and blasts, vessel impacts and dropped objects.

ABSTRACT:

Bridge infrastructure faces both continued aging and deterioration throughout its lifetime, as well as potential exposure to natural hazards such as earthquakes in hazard prone regions. Consequential damage requires increased monetary investments, energy spent on subsequent repair/replacement, as well as carbon dioxide (CO_2) emissions associated with the manufacture/transport of repair materials. This paper will derive and compare estimates of three important metrics associated with the life cycle performance of aging bridges given seismic exposure, namely, life cycle cost, embodied energy and associated CO_2 emissions. A case study is presented for a representative multi-span simply supported (MSSS) concrete girder bridge to evaluate the life cycle sustainability metrics of the corroded bridge system given uncertain performance and repair under lifetime exposure to seismic hazards. The results underscore the importance of capturing the effects of time dependent structural deterioration when conducting life cycle analysis of bridges based on different indicators. The proposed framework is also anticipated to help guide the selection of optimal rehabilitation or retrofit measures for bridge infrastructure based on target sustainability metrics related to life cycle cost, energy usage, and harmful emissions.

1. INTRODUCTION

Within the context of this study, sustainable development is defined as "development which continues to effectively serve public needs despite numerous physical threats to its performance and while promoting limited environmental, social, and economic strains as a result of its existence" (Padgett, Ghosh et al. 2009). This concept is of growing interest within the field of infrastructure and structural engineering due to its potential to promote harmony amongst physical and natural systems. Since infrastructure continues to age and deteriorate throughout its life, and is also exposed to a variety of natural hazards, its degradation or potential damage during natural hazards results in money, energy, and CO_2 expenditures from repairs or replacements performed. These consequences, although not comprehensive in nature, are examples of metrics of the sustainability of built infrastructure.

Quantitative methods of sustainable analyses facilitate engineering sustainable infrastructure by providing engineers with a "more rational decision making [method

by means of]…decisive indicators, trade-offs, and weighting sensitivities" (Sahely, Kennedy et al. 2005). However, most of the measures of sustainability which presently exist for evaluating infrastructure are qualitative (Dorf 2001; Dasgupta and Tam 2005; Jeon and Amekudzi 2005; Litman 2008). Traditional life cycle assessments (LCA) of infrastructure focus on evaluating engineering metrics which have existed for many years and are generally limited to structural performance outcomes (Frangopol 1999; Thoft 2009). By neglecting sustainable metrics such as embodied energy and CO_2 emissions as well as risk from natural hazards such as earthquakes, these LCA methodologies fail to consider factors related to the environmental impacts of the structure throughout its life (Engineers 1999). If the interaction between the structure and environment along with sustainability indicators are taken into account in the process, the life cycle cost (LCC) of the structure will ultimately decrease (Furuta, Katayama et al. 2005; Ugwu, Kumaraswamy et al. 2005).

One aspect of promoting sustainable infrastructure includes the assessment and minimization of energy use, resource depletion, and emissions. This study provides a framework to quantify the life cycle performance of seismically vulnerable aging bridges on the basis of cost, embodied energy expenditure and CO_2 emissions attributed to seismic repairs and replacements. This approach to quantifying bridge infrastructure performance on the basis of non-traditional metrics can help to provide insight into the relationship between natural hazards and infrastructure sustainability, considering uncertainty in exposure, physical performance, and repair action. The results highlight the vulnerable components and likely repair methods that hinder the sustainability of the system and can guide the selection of optimal rehabilitation or replacement measures for bridges.

2. SEISMIC LCA OF SUSTAINABILITY METRICS FOR BRIDGE INFRASTRUCTURE: SCOPE, METHODOLOGY, AND FORMULATION

2.1 *Scope of Study and Estimates of Embodied Energy and CO_2 Emissions*

One definition for embodied energy is "total energy expended for harvesting, transporting, processing, packaging, and installing the (infrastructure) material" (Pearce 2004). Embodied CO_2 emissions of materials is carbon dioxide released which "reflect[s] the specific inputs of ingredients and energy sources and the CO_2 emissions associated with them"(Alcorn 2001). Though several other definitions exist for these terms (Engineers 1999; Alcorn 2003; Venkatarama Reddy 2004; Long 2007; Padgett, Ghosh et al. 2009), there is little variation. Inconsistencies among the various CO_2 and embodied energy coefficients which do exist ensue primarily from the difference in scope of parameters included in the derivations of these coefficients.

Within this study, the life cycle analysis will be defined to include the cost, embodied energy expenditure, and CO_2 emissions from material and labor utilized in different seismic repairs/replacements throughout the life of the aging bridge analyzed. Aging and seismic risk have been integrated in this analysis in order to evaluate the effectiveness of the structure to continue to "serve public needs despite numerous physical threats to its performance" (Padgett, Ghosh et al. 2009)—which is within the boundaries of sustainably built infrastructure. Figure 1 displays the scope

of total embodied energy and CO_2 emission considered in this study. Items not within the red-dashed box are beyond the scope of the current study, but reflect additional contributions to energy and emissions that may be considered in broader life cycle analyses. The total embodied energy expenditure and CO_2 emissions are taken as the sum of the contributions from material and crew. Data required in order to calculate total embodied energy expenditure and CO_2 emissions from labor and material utilized in various seismic repairs/replacements at a specific time during the life of an aging bridge in a seismic zone includes: geometry of bridge, repairs/replacements for bridges exposed to seismic events, quantity of material utilized in repairs, days required to complete repairs, embodied energy/CO_2 emission coefficients for materials and workers.

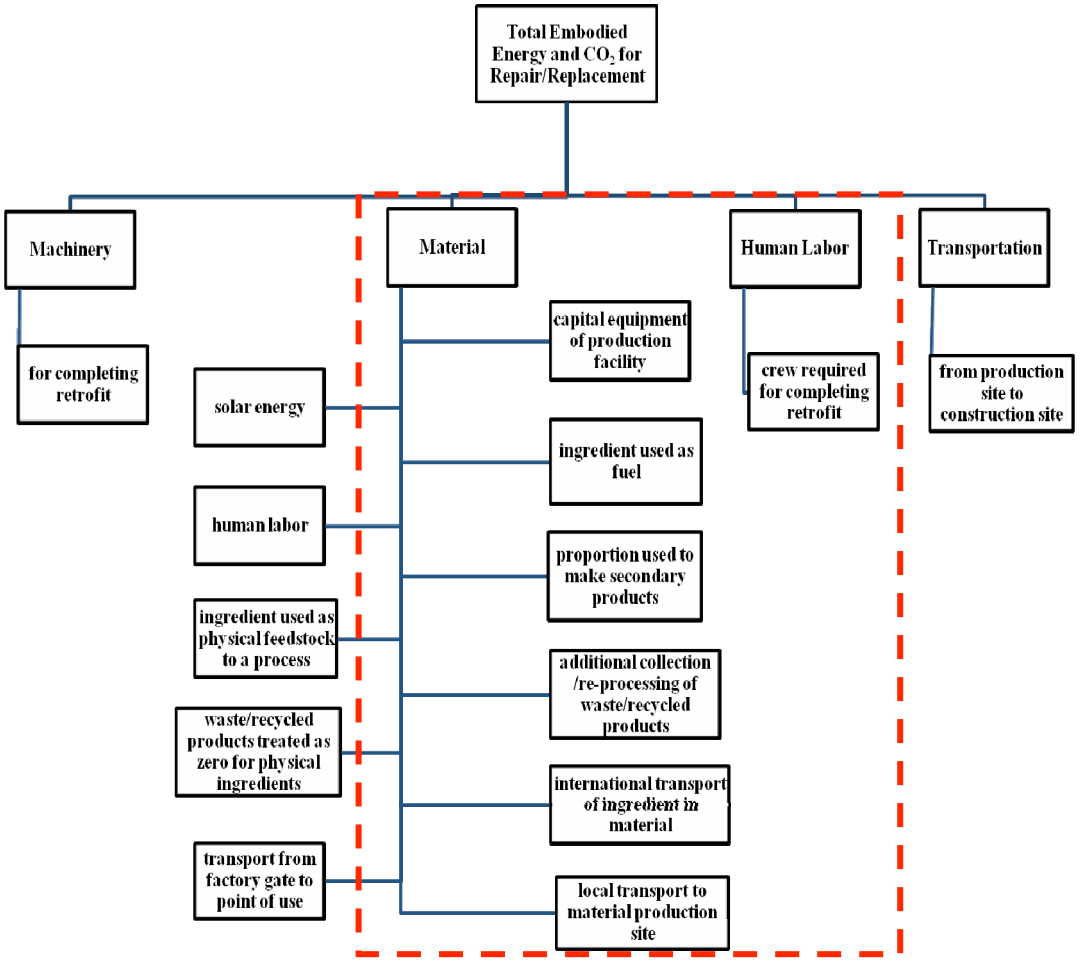

Figure 1: Embodied Energy and CO_2 Emissions Scope of Study

In order to preserve consistency in scope of LCA conducted, the proposed framework utilizes coefficients derived by the Centre for Building Performance Research (CPBR) in collaboration with Building Research Association of New Zealand (BRANZ) (Alcorn 2003) for calculations concerning both embodied energy and embodied CO_2 for construction materials. The metric of embodied energy is measured in units of energy per unit volume (MJ/m^3) and CO_2 coefficients in units of

mass per unit volume (kg/m^3). Table 1 shows values of coefficients for materials used in bridge repair or construction procedures.

Table1: Embodied Energy and CO_2 Coefficients for Materials used in repairs

Material	Embodied energy coefficient MJ/m^3	Embodied CO_2 emission coefficient Kg/m^3
Epoxy (polystyrene)	1401	59.9
Concrete (30MPa)	2762	376
Grout	3496	496
Steel (structural)	245757	9749
Polymer wrap	202650	1030
Stainless steel	613535	44747
Rubber (natural latex)	62100	16478

To increase the scope and accuracy of these sustainability metric estimates, contributions from human labor—which is not accounted for by the CPBR in their coefficient derivations—is included in this study. Although sources from which CO_2 emission coefficients and embodied energy coefficients for human labor are attained are different, the variables required—such as length of work day and age/gender of worker— in order to calculate these coefficients for each worker remain the same. To calculate estimates for labor required to complete seismic repair procedures, the size of the construction crew and number of days required to complete a specific repair are taken from the RS Means Building Construction Cost Data book (RSMeansCo. 2008). For repairs not listed, procedures from similar activities are utilized. Embodied energy and CO_2 emissions corresponding to a crew performing repairs are calculated by multiplying crew size, days required to complete a specific repair, and embodied energy/CO_2 emission of a worker (RSMeansCo. 2008). Total energy expenditure during construction work for an average male adult (18- 30 years old) in an 8 hour work day (1 hour lunch break) is taken to be approximately 5.75 MJ/day per worker (Haggarty, Valencia et al. 1997). Estimation of kilograms of CO_2 emitted per day per worker considers an average adult respiration rate of 16 breaths per minute (Clinics 2005) and grams of CO_2 per breath to be 0.037 grams of CO_2 per breath (Center 1998) per worker. Kilograms of CO_2 emitted is then given by: *(Breaths/minute) * (60 minutes/hour) * (hours/day) * (g CO_2/breath) * (0.001 kg/g) = kg of CO_2/ day per worker*. This results in an approximate 0.28416 kg of CO_2/day emitted per worker. As seen in Figure 1, machinery utilized in repair and transportation to site are not considered in estimate calculations, however future work will integrate these factors.

2.2 *Formulation of Aging Bridge Sustainability LCA*

Recent research developed LCC model based on a non-homogeneous Poisson process (Ghosh and Padgett 2010), which is extended herein to asses life cycle embodied energy and CO_2 emission estimates by integrating the embodied energy and CO_2 emission coefficients discussed in the previous section. This model is specifically

applied to assess the performance of an aging bridge subjected to earthquake exposure, thereby relating lifetime natural hazard performance to metrics of structural sustainability. Given a constant annual earthquake occurrence rate at the bridge site, the annual rate of occurrence of a particular damage state i for a bridge component m at time t can be as a non-homogeneous Poisson process given by $\lambda_{i,m}(t) = \nu P_{i,m}(t)$ where, ν is the constant site specific earthquake occurrence rate and $P_{i,m}(t)$ is the annual probability of exceedance of damage state i for the m^{th} bridge component at time t. Following this assumption, the time between the beginning of exposure of the bridge to earthquakes ($t = 0$), and the occurrence of first failure ($t = \tau$), is an exponentially distributed random variable with the probability density function (PDF), $f_\tau(t)$ given by

$$f_\tau(t) = \lambda_{i,m}(t) e^{-\int_0^t \lambda_{i,m}(t)dt} \tag{1}$$

Additionally, let E_{i,m_t} be defined as the quantity of the sustainability metric in question (embodied energy or CO_2 emissions), corresponding to damage state i to restore the bridge component m to its original full functionality at time *t*.

Assuming the value of the metric in restoring the structure at time *t* is the same as its present day repair metric value— that is $E_{i,m_t} = E_{i,m_0} = E_{i,m}$ — the expected seismic life cycle value for any sustainability metric (LCSM) can be calculated as

$$E\left[SLCSM_{i,m}\right] = \left[\sum_{t=1}^{T} P(E_{i,m_t}).E_{i,m}\right] \tag{2}$$

where $P(E_{i,m_t})$ is the probability of incurring energy expenditure, carbon dioxide emission, or any other metric. $E_{i,m}$ at time t can be replaced by the probability density function of the time elapsed from beginning of exposure to hazard occurrence but in the discrete space. This concept can be further extended to aggregate over *n* distinct damage states and multiple repair strategies using the theorem of total probability to arrive at expected seismic LCSM as

$$E[SLCSM_m] = \sum_{i=1}^{n}\sum_{t=1}^{T}\sum_{j=1}^{J} \lambda_{i,m}(t) e^{-\sum_{t=1}^{t=T}\lambda_{i,m}(t)} P\left(E_{i,m,j}\right)E_{i,m,j} \tag{3}$$

where $P\left(E_{i,m,j}\right)$ is the probability of adopting the j^{th} repair strategy, which has an associated sustainability metric value $E_{i,m,j}$, and J is the total number of viable repair options. In preceding equations, the mean annual rate of failure, $\lambda_{i,m}(t)$, due to occurrence of a particular damage state i can be approximated by the annual probability of damage due to damage state i as (Melchers 1999)

$$\lambda_{i,m}(t) = PA_{i,m}(t) - PA_{i+1,m}(t) \tag{4}$$

where $PA_{i,m}(t)$ is the annual probability of exceedance of damage state i at time t for m^{th} bridge component and is evaluated by convolving the fragility curve with the seismic hazard curve. To estimate probabilities of exceeding different damage states, the use of risk assessment techniques incorporating time dependent bridge fragility curves is employed. Further details on constructing such seismic fragility curves for bridges as well as deterioration mechanisms for bridge components can be found elsewhere (Ghosh and Padgett 2010). To show the effects of deterioration on component vulnerabilities, Figure 2 shows how the fragility curves for moderate damage state for reinforced concrete (RC) columns of the MSSS concrete girder bridge change over time along the service life of the bridge. Parameters of time dependent fragility curves are then used in combination with CO_2 and embodied energy estimates for various seismic repair procedures to arrive at life cycle estimates following the above formulation. Material embodied energy and CO_2 estimates for each repair action including material and labor are adopted as discussed in the previous section.

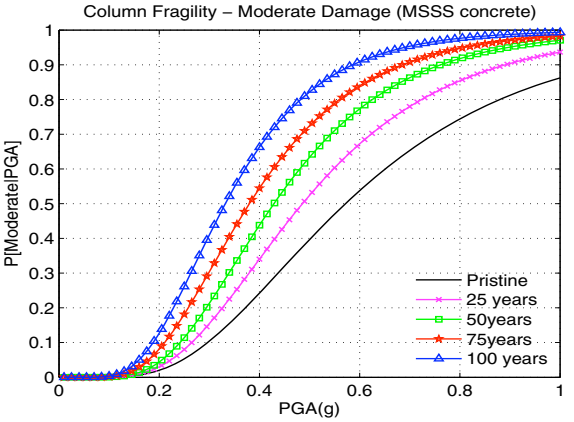

Figure 2: Fragility Curves for Deteriorating Bridge Columns at Different Points in Time Along Service Life

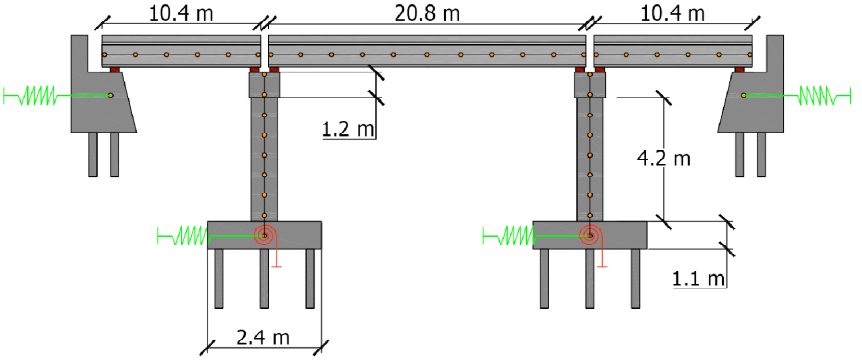
3. CASE STUDY RESULTS AND DISCUSSION

3.1 *Resulting Embodied Energy, Cost, and CO_2 Estimates of Aging Bridge*

The framework is demonstrated with a multi-span simply supported concrete (MSSS Concrete) girder bridge located in Tennessee. Geometry for the bridge is shown in Figure 3 below. This bridge type has been previously identified by researchers (Nielson 2005) as being seismically vulnerable due to inadequate seismic detailing such as poorly confined RC columns, inadequate transverse reinforcement, and 'walking out' of bearings from under the girders during large deformations following seismic events. Additionally, the reinforcing steel in the concrete columns and the bridge bearings are prone to aging and deterioration mechanisms. Such mechanisms include corrosion of reinforcing steel in columns and bearing dowel bars along with increase in stiffness of bearing pads due to thermal oxidation.

The life cycle analysis quantifying total expected value of embodied energy (LCEE) and CO_2 (LCCD) is carried out for both pristine and aging MSSS Concrete bridge models with an assumed 75 year service life. The expected present value of

cost (LCC) is calculated following the method presented in (Ghosh and Padgett 2010) with an assumed discount ratio of 3%. While fragility parameters for the pristine bridge are assumed not to change with time, the aging bridge estimates are performed using the concept of time evolving fragility curves. Life cycle estimates of these three sustainability metrics are quantified for both pristine and deteriorating bridges in order to demonstrate the importance of considering aging within an LCA due to the great parameter underestimations resulting from its negligence.



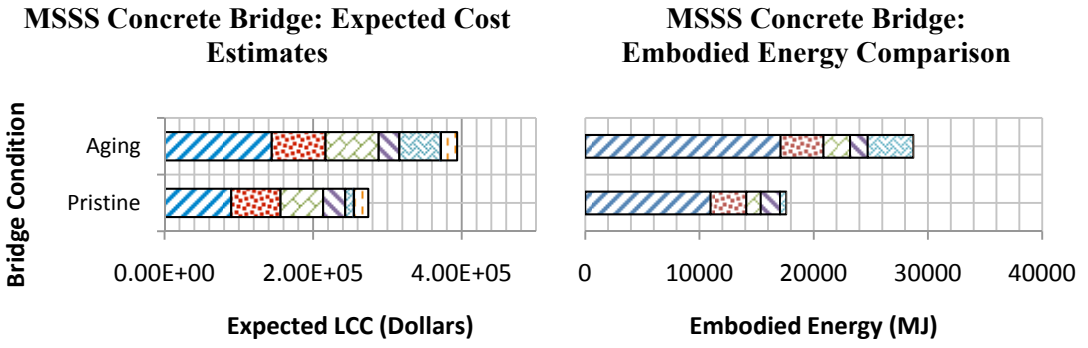


Figure 3: Case Study MSSS Concrete Bridge

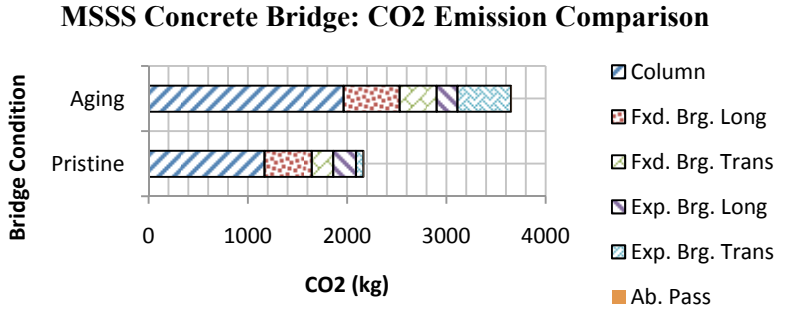

Resulting LCA estimates of cost, embodied energy, and CO_2 for both bridge cases are compared and tabulated in Figures 4 (a) to (c) respectively. Additionally, these figures present the contribution of different bridge components to the life cycle estimate of the three metrics. Columns, fixed longitudinal bearings, and fixed transverse bearings contribute the most to all three metric estimates. To avoid such large contributions from these aging components, priority should be given to retrofit/upgrade the components in order to improve their lateral resistance to damage under seismic loading. Doing so can potentially reduce resulting metric estimates. Figures 4 (a) to (c) demonstrate that neglecting aging/deterioration result in 31% underestimation of life cycle cost, 40% underestimation of embodied energy, and 40% underestimation of CO_2 values throughout the service life of the bridge.. These results underline the importance of incorporating the effects of structural degradation mechanisms into life cycle analyses when quantifying sustainable performance in the face of natural hazards such as earthquakes.

4.2. *Contribution from Repair Procedures to Life Cycle Embodied Energy and CO_2*

The different repair procedures considered within this study have varying relative contributions to both total expected value of seismic life cycle embodied energy and CO_2. Repair procedures which involve major replacements—such as demolishing and replacing a bridge or its column—are anticipated to consume and emit the greatest amount of embodied energy and CO_2 due to the scale of the repairs; however the likelihood of damage occurring requiring these major replacements may not be as large. Contributions from major repair/replacement procedures to total expected value, after integrating fragility, hazard potential, and probability of repair given certain level of damage, are tabulated in Tables 2 below.

4(a) 4(b)

4(c)

Figure 4: (a) Expected LCC Values, (b) Expected LCEE Values, (c) Expected LCCD Values

Table 2: Contribution of Major Repair/Replacement Procedures to Expected Value of Life Cycle Embodied Energy and CO_2 Emissions

Repair Procedure	Bridge Condition	Embodied Energy, MJ (% Contribution)	CO_2, kg (% Contribution)
Column replacement	Pristine	4029 (23%)	538 (25%)
	Aging	5114 (18%)	683 (19%)
Fixed bearing replacement	Pristine	3161 (18%)	485 (22%)
	Aging	3793 (13%)	574 (16%)
Expansion bearing replacement	Pristine	1270 (7%)	220 (10%)
	Aging	2378 (8%)	385 (11%)
Demolish and replace bridge	Pristine	6505 (37%)	869 (40%)
	Aging	14551 (51%)	1943 (53%)

The total embodied energy and CO_2 emissions can be reduced by altering the approach for major repair procedures if viable or mitigating the potential damage to the structure requiring these major repairs. However, due to localized-minor repairs being performed in a more frequent and common manner (as compared to major repairs), improving the sustainability of localized-minor repairs can have a significant

impact on the expected value of these life cycle performance metrics. Localized repair procedures—such as grouting and wrapping—contributing the most to total expected life cycle embodied energy and CO_2 emissions estimates after integrating fragility, hazard potential, and probability of a repair given certain level of damage, are shown in Figure 5 for the aging bridge model. These procedures are the repair methods that most likely hinder the sustainability of the system and should be addressed by using a different alternative to these repairs if possible in order to reduce emissions and energy and hence improve sustainability.

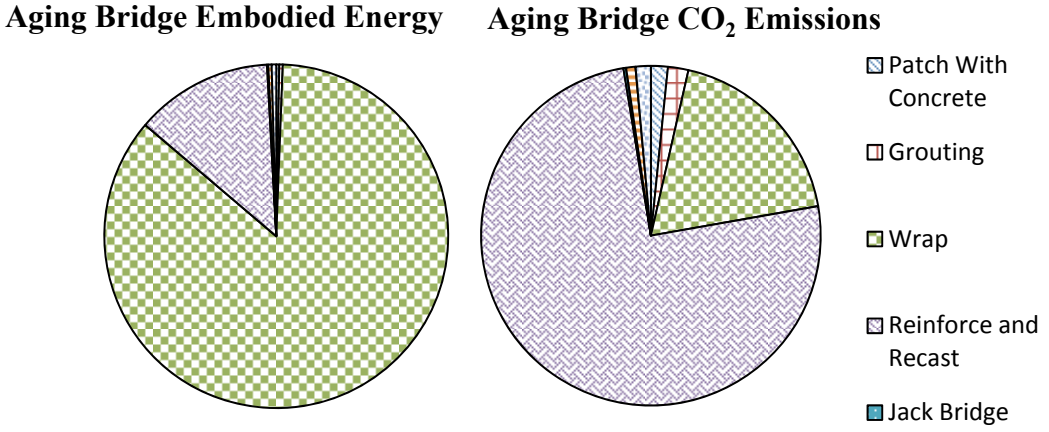

Figure 5: Contribution of Localized Repair Procedures to LCEE and LCCD

4.3 *Testing Sensitivity of Sustainability Metrics to Remaining Service Life*

Sensitivity of total expected embodied energy and CO_2 emission quantities, as well as total expected present values of cost, to remaining service life of a bridge for both aging and pristine models is also assessed. Results are shown in Figures 6 (a) to (c) for all three metrics. The sensitivity results reveal that changes in remaining service life have a considerable effect on all three metric life cycle estimates corresponding to the aging bridge as compared to the pristine bridge. For example, with 25 years of remaining service life, the expected LCC, LCEE, and LCCD for the aging bridge model is 130%, 198% and 216% higher for each metric respectively as compared to the pristine bridge. Additionally as remaining service life of a bridge increases, the expected value of the sustainability metrics also increase as anticipated. Therefore structures with longer service lives may be priorities to upgrade for enhancing long term sustainability.

Even though totals for all sustainability metrics increase for both aging and pristine bridge models as remaining life increases, it is observed that relative difference (percent change) between the two models actually decrease with increasing service life. That is relative difference is greatest at the smallest remaining service life. Results also show that aging affects CO_2 totals the most, followed by embodied energy, and cost. This design or upgrade that mitigates potential deterioration or corrosion susceptibility can have the greatest influence on reducing expected CO_2 emissions. Overall, the relative importance that decision-maker or stakeholders place

upon the sustainability metrics should dictation their weighting in a framework for prioritizing mitigation actions to promote structural sustainability in the face of natural hazards.

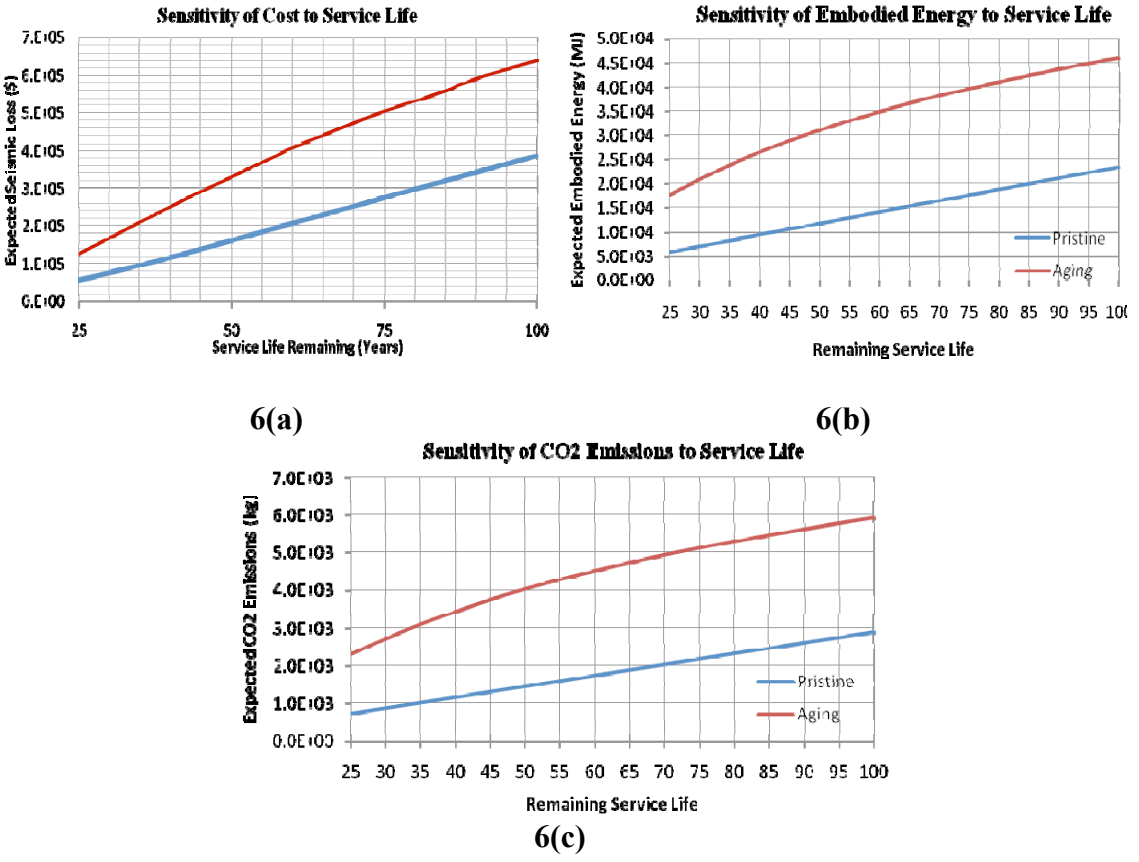

Figure 6: (a) Sensitivity of LCC, (b) Sensitivity of LCEE, (c) Sensitivity of LCCD Estimates

5. CONCLUSIONS

A framework for the estimation of the expected present value of seismic life cycle cost and total expected seismic life cycle embodied energy and carbon dioxide quantities for an aging/deteriorating bridge is presented in this study in order to highlight the critical links between concepts of sustainable engineering and consideration of extreme events. A non-homogeneous Poisson process is adopted in the LCA to capture the effects of aging and deterioration in the seismic life cycle analysis of sustainability metrics. This approach integrates three sustainability metrics—cost, embodied energy, and carbon dioxide—into the life cycle analysis of a structure, two of which (energy and CO_2) are usually disregarded in LCA's for structures exposed to natural hazards. Given increasing environmental challenges and efforts to improve the harmony amongst the built and natural environment, the importance of incorporating and quantifying sustainability metrics beyond cost has become critical.

Through results from the case study on the MSSS Concrete bridge located in Tennessee, it can be seen that taking into account the degradation of a bridge can result in significant differences in the seismic life cycle cost, embodied energy, and CO_2 estimates. Additionally this framework aids in prioritizing bridges which require seismic repairs or replacements based on the sustainability metrics of cost, embodied energy, and CO_2. Although major repair methods contribute the largest percentages to total expected cost, embodied energy, and CO_2, attention should be given to local component repairs due to their higher likelihood or frequency of performance. The findings highlight repair actions for which alternative, more sustainable, methods should be explored as well as vulnerable bridge components for which improving the resistance to damage under seismic loading can significantly affect the resulting cost, emissions or energy expenditures.

Future work will focus on incorporating additional sustainability metrics which extend into other areas of the triple bottom line indicators (environmental, social, and economics), including other phases of a structure's life, as well as extending the boundaries of each metric's totals. Opportunities also exist to explore the discounting of emissions and energy for an equivalent present value analysis of all sustainability metrics, as conducted for the life-cycle cost analysis. Finally, these metrics can be used to directly assess and compare alternative maintenance, design, or retrofit actions for structures exposed to deterioration threats and seismic hazards.

ABSTRACT

A proposed probabilistic framework for performance-based durability engineering is motivated by the successful implementation of the Pacific Earthquake Engineering Research Center's framework for performance-based earthquake engineering. Both approaches combine several stages of analysis linked through a limited set of "pinch point" variables, which allows modeling flexibility. The analysis extends to the computation of information useful to decision makers, and can also provide sensitivity analysis of the modeling stages to be used to direct future research. The major stages, variables, datasets, and models to be used are outlined with corrosion in reinforced concrete as the cause of deterioration.

INTRODUCTION

A durability framework is proposed in accordance with the interest in the engineering community and the SEI-ASCE Technical Council on Life-Cycle Performance, Safety, Reliability and Risk of Structural Systems in the prediction of structural performance over a lifetime of deterioration. Guided by performance-based earthquake engineering (PBEE), the proposed performance-based durability engineering (PBDE) framework has the potential to drive innovation in both research and practice just as the introduction of PBEE's methodology led to improvements in structural analysis and loss estimation. Recently developed models have the ability to predict the onset and propagation of deterioration for a variety of structure types and hazards. Predicting the interaction between traditionally-defined hazards, such as seismic loads, and agents of material or structural degradation is challenging, but new models from research offer great potential in this field. The predictions of performance under deterioration are valuable in themselves and their implementation in a probabilistic framework that provides useful decision information has at this time not been carried out systematically, and is expected to provide increased value.

Background

The Pacific Earthquake Engineering Research (PEER) Center aimed to address uncertainty in structural risk and reliability using a transparent, probabilistic methodology in developing performance-based earthquake engineering. In advancing the PEER framework, researchers and practitioners have succeeded in creating the necessary models and data to evaluate seismic risk in this manner, and to use the results of the framework to make more rational choices in structural design and renovation [1]. While this work is ongoing, analysis tools for nonlinear seismic response and building component fragility curves have been developed and improved through new research and collaboration, after testbed simulations identified parts of the framework with large impact on decision variables. These improvements have reduced some aspects of modeling uncertainty, and have subsequently been incorporated into simplified methods for practicing engineers.

PEER's PBEE methodology is an extension of nuclear risk simulation, linking together the results of four areas of earthquake-related research to allow calculation of recurrence rates at each stage of the analysis [2]. Hazard analysis is used to determine an intensity measure (IM), structural analysis to determine engineering demand parameters (EDP) and damage measures (DM), and risk analysis to predict decision variables such as loss, downtime, and casualties. Each stage of analysis may require complex modeling, but only a few "pinch point" variables are passed between stages, allowing each stage of the analysis to be uncoupled. Uncertainty is incorporated through the intensity measure hazard curve by selection of ground motion "records," through uncertainty in relations between engineering demand parameter (e.g. story drift) and damage measures, as well as through probabilistic loss curves. Convolution of probabilities of exceedence through the PEER equation allows the prediction of rates of exceeding a particular value of a decision variable.

$$\nu_{DV}(DV>dv)=\iiint G_{DV}(DV>dv|DM>dm)dG_{DM}(DM>dm|EDP>edp)dG_{EDP}(EDP>edp|IM>im)d\lambda_{IM}(IM>im)$$

Motivation

The development of a new framework for PBDE is motivated by interest in more explicit consideration of structural durability in design and by the adoption of PBEE in the engineering community. Although probabilistic aspects and modeling stages must differ from those used in PBEE, the methodology of defining analysis "pinch points" where a few variables are passed from one stage of analysis to the next can be used to develop an analogous framework for PBDE.

Structural deterioration due to environmental effects occurs because of a variety of interacting, complex mechanisms. While modeling multiple causes of deterioration is an eventual goal of this research project, the selection of a simpler "testbed" mechanism is necessary to demonstrate the methodology of the proposed framework. The mechanism should be selected on the basis of interest to decision makers due to large losses or safety threats, and to researchers developing deterioration models. Transportation infrastructure offers a class of structures where such deterioration is of interest, and the wide availability of models for steel corrosion in reinforced concrete has led to the selection of this cause of degradation as the testbed mechanism.

Predicting corrosion initiation and propagation in reinforced concrete is very challenging, as is determining effects on structural behavior and reliability. The complexity, need for validation of research models, and large economic losses make this mechanism an important trial case for PBDE.

This paper expands upon a previous outline of the main models, pinch points, and variables required to develop a PBDE framework for chloride-induced corrosion [3]. Four stages of analysis are defined, with reference to existing models to be used in each stage, as well as identification of areas in which more data or models are required. Upon successful demonstration of the utility of the proposed PBDE framework for chloride-induced corrosion in reinforced concrete, the framework will be extended first to other causes of corrosion, such as carbonation, and then to other degradation mechanisms. These might include scour, pounding, or freeze-thaw degradation in concrete and masonry, or degradation mechanisms for other materials, such as rot in timber structures.

Existing Durability and Deterioration Frameworks

Many researchers and practitioners have proposed frameworks for analyzing corrosion-related structural deterioration. These generally divide into three main categories: design criteria for acceptable service-related performance; reliability analysis for serviceability and ultimate limit states; and maintenance optimization.

Design Frameworks

The intent to design structures that satisfy minimum acceptable levels of durability has led to the creation of several codes and frameworks for performance-based design for durability. In addition to US efforts such as the new SEI-ASCE Technical Council on Life-Cycle Performance, Safety, Reliability and Risk of Structural Systems, which intends to develop guidelines for durability, and ACI Life-365 [4], councils and working groups in Europe and Japan have proposed durability frameworks. These include fib's *Bulletin 34 Model Code for Service Life Design* [5], RILEM's DuraCrete model [6], and work by JSCE-331 [7]. These frameworks tend to employ empirical degradation models, and output probabilistic service life predictions. Because they are for the most part designed for use in industry, simplicity tends to be valued over the user's ability to replace parts of the model with their own preferred models. While estimates of service life are valuable, the analysis rarely extends to predicted costs, downtime, or environmental impacts.

Reliability Frameworks

Reliability analyses of corroding structures have been performed by many researchers, including Thoft-Christensen [8], Enright and Frangopol [9], Vu and Stewart [10], and Li and Melchers [11], among others. Many of these assessments have also included sensitivity analysis to identify variables with large impact on the structural reliability, and corrosion rate, steel yield strength, and cover depth have frequently been identified as variables of importance. Spatial correlation of variables such as surface chloride concentration has been found by some studies, e.g. Vu and Stewart [10], to have a large effect on corrosion initiation and reduction in structural

capacity. Previous studies have used several different types of reliability analysis, e.g. FORM and Monte Carlo, and varying characterization of the stochastic variables and definition of end of service-life, but some generalizations about the reliability-based approaches are possible. All results are highly dependent on the models used to predict chloride ingress, corrosion initiation, and corrosion propagation. In some cases, the use of effective Fickian diffusion and assumptions about constant, uniform corrosion rates may lead to inaccuracies in predictions of service life [12, 13]. Additionally, as with the design codes, information on repair costs or observable damage such as crack widths is not always available, and would be helpful to owners and operators.

Maintenance Optimization Methods

Many methods exist for determining optimal repair timing with regard to cost or other constraints such as level of service. Bridge Management Systems (BMS) like Pontis track deterioration of bridge components based on commonly recognized "CoRe" elements. Future deterioration is predicted by component type and environmental conditions using Markov chains [14]. NCHRP Report 590 uses a multi-objective optimization scheme for BMS, and other optimization schemes can become very complex [15]. However, the Markov models used for optimization may not be appropriate for all types of environmental conditions, and the user or decision maker may require information that is not easily accessible from a program like Pontis.

Summary of Existing Methods and Limitations Addressed by this Research

Design, reliability, and maintenance optimization approaches share a few limitations. The main limitation, though not characteristic of every approach, is the difficulty in computing output data that would include a variety of information useful to decision makers. Other limitations are lack of generality due to analysis assumptions and the inability to replace certain models with the analyst's preferred models. Complexity is a limitation of certain frameworks, and is also a limitation of the framework proposed here. The proposed methodology does offer a comprehensive approach, transparency and flexibility in modeling, and clear, practical decision information. Efforts in the PBEE community, such as ATC 58, have used advanced research efforts to develop simpler design approaches, and it is a long term goal of this project to develop a similar simplified version of PBDE. The framework and methodology proposed here is expected to complement other methods for designing durable structures and analyzing the course and effects of deterioration.

PROPOSED PBDE FRAMEWORK

General Description of Phases

The PBDE analysis is broken up into four phases, which pass a limited number of "pinch point" variables to the next phase, shown in Figure 1. This allows the analysis phases to be decoupled, which enhances flexibility in the choice of model for each phase. The first phase, (1) exposure analysis takes information about the location of the site to determine exposure conditions, which might include temperature, humidity, and loads. Variability in these conditions is taken into account by the

computation of exposure "records." Phase (2), deterioration analysis, relates these conditions to structural and material degradation. This phase may require the use of sub-models, or can be modeled in a fully-coupled sense. The damage measures determined by deterioration analysis capture data that can be observed or detected by inspectors, such as crack widths. These damage measures are then related to specific repair actions by repair analysis, phase (3). In phase (4), impact analysis, an inventory of the materials and means required for a specific repair is used to calculate costs, closure or "downtime" for repair, and environmental impacts, through life cycle impact assessment. These impacts, along with safety assessment using system reliability theory, are termed "decision information." At the conclusion of the PBDE assessment, curves of the probability of values of a particular type of decision information are calculated over the time period of analysis, presumably the service life of the structure. These curves can then be used choose maintenance timing, repair schemes, or select an alternative among competing designs.

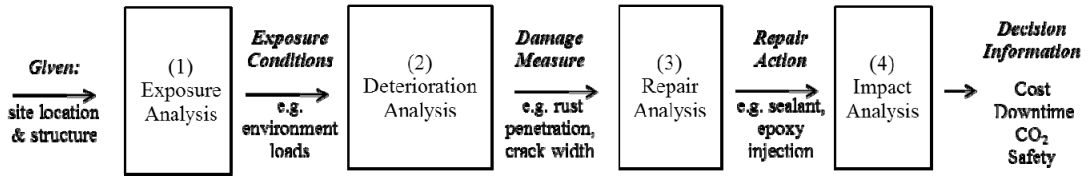

Figure 1: PBDE analysis flow

When chloride-induced corrosion in reinforced concrete is chosen as the deterioration mechanism, it is possible to specify which pinch points will be used in the analysis. Most models for deterioration will require surface chloride concentrations as an environmental condition (EC), as well as information on relative humidity and loading. Practical damage measures (DM) for a corroding structure are chloride ingress, corrosion current, and crack width. Repair actions (RA) include application of sealant, epoxy injection of cracks, removal of concrete cover with sandblasting of corroded rebar, and use of cathodic protection. Impacts of interest would be cost and downtime for maintenance actions, and environmental impacts of the repairs.

Incorporation of Probabilistic Aspects

A major advantage of this framework is the ability to incorporate uncertainty in exposure, similar to how uncertainty in seismic hazard drives PBEE. However, while earthquake occurrence is generally modeled as a Poisson process, the time-varying nature of exposure sources and deterioration requires a different probabilistic treatment. Additionally, the desire to identify particular repair actions for a component, rather than the need for "repair" causes complications. While deterioration is only conditional (in a probabilistic sense) on exposure, and impact is only conditional on repair, the conditioning between exposure, deterioration, and repair is less clear-cut, as the particular repair action and timing will influence future deterioration. A probabilistic framework for probability of exceedence, with substantial similarity to the PEER PBEE equation, has been proposed, but may require implicit repair analysis to avoid some of the aforementioned issues.

$$G_{DI}(DI>di, t)=\iiint G_{DI}(DI>di \mid RA>ra, t)dG_{RA}(R\ ra \mid DM>dm, t)dG_{DM}(DM>dm \mid EC>ec, t)\ dG_{EC}(EC>ec)$$

An alternative approach, widely used in the reliability literature, is to perform Monte Carlo simulation using an input environmental condition "record" and tracking the lifetime deterioration, repair, and decision information for each record. This approach can also accommodate uncertain structural and material parameters, which in other approaches would likely require the use of a response surface or post-analysis adjustment of output curves. The major downside to this approach is the large number of simulations required, which can be very computationally expensive. Alterations to the Monte Carlo method, such as importance sampling, may reduce the amount of computations required. Regardless of the method used to incorporate uncertainty, the end result of the analysis is a distribution of the decision information at all points in time, which can then be collapsed to simpler forms, such as expected values and variances, if desired.

Discretization of Structure

Before analysis can proceed the structure must be discretized into components and sub-components. This discretization is motivated by the need to allow for spatial variation in exposure conditions and material properties at a smaller length-scale and by the recognition that damage measure significance and repair actions vary by component type. For example, crack width limitations are different for concrete decks and bents. Thus at a minimum the structure must be broken down into component types: columns or bents, girders, decks, joints, abutments, and so forth. Choosing the subdivisions based on CoRe elements used in US bridge inspection is a sensible modeling choice. Further spatial subdivision may be performed when necessary. Once the structural discretization is complete the PBDE analysis can commence.

PBDE ANALYSIS PHASES

Phase (1): Exposure Analysis

Exposure conditions are environments (e.g. temperature, humidity, concentrations of chemical species) or loads (e.g. live, earthquake, wind) that cause transient or long-term effects on the structure. The selection of which exposure conditions require modeling is determined by the selected deterioration models, which may require very little (e.g. only surface chloride concentration) or a large quantity of data (e.g. histories of chlorides, temperature, humidity, and loads over the structure lifetime). Thus exposure analysis may be as simple as simulation of random variables based on distributions found in literature or through observation of the site, or may require more complex modeling of the site layout, structural geometry, prevailing wind conditions, and sources of airborne or direct chloride deposition.

There are many sources of these conditions available in the literature, from surveys of existing structures, empirical studies, and analytical models of chloride deposition. Stochastic descriptors for seasonal climatic conditions are generally available from national data sources, such as the National Climatic Data Center [16]. These descriptors can then be used to simulate records of ambient conditions. Surveys and

studies of chloride deposition from marine air, reviewed in Meira, et al. [17], provide ranges of deposition based on wind speed, distance from the coast, and height. While this data may not cover all conditions, it should suffice in many cases. Deposition for deicing salts may be found in research related to the DuraCrete project, among other sources [6]. Research proposed by Lindvall intends to develop analytical models for deposition based on distance from roadway and surface geometry, and could be used in a more complex study if required [18]. It is therefore concluded that current data sources and models will be sufficient to allow for testbed simulation using the PBDE framework for a well-selected site.

Phase (2): Deterioration Analysis

Deterioration analysis for corrosion in reinforced concrete requires simulation of five aspects of corrosion and deterioration, as shown in Figure 2. This simulation may be performed by a single program, such as, among others, DuCOM [19]. Alternately, a series of different models may be used to allow for increased flexibility in modeling all of the interconnected phases of deterioration. Thus, a simple model might track ingress through Fick's second law of diffusion using effective diffusion coefficients and surface chloride concentrations, and predict initiation using a critical chloride concentration or threshold. The resulting corrosion rate might be determined stochastically, and the effects of cracking, bond slip, and other damage mechanisms ignored. This would allow the export of corrosion rate or current and bar area loss as damage measures, as well as the reduction in section structural capacity for impact analysis. This approach has been very frequently used, e.g. by Ting and Nowak [20], and can yield very good results when effective corrosion parameters are available, and conditions are such that a change in conditions or corrosion rates are not anticipated. An example of this might be corrosion in a fully-submerged structure.

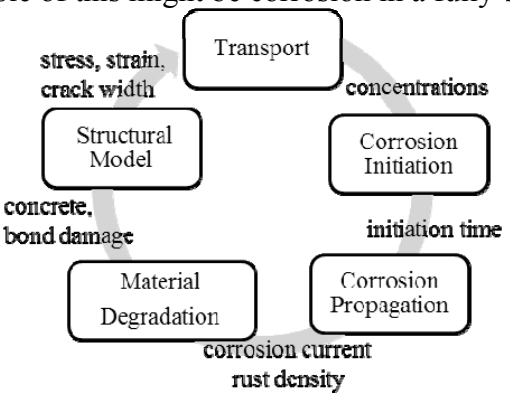

Figure 2: Deterioration Analysis stages

On the other hand, this treatment does not completely capture the phenomenological behavior of corrosion in reinforced concrete, and may not accurately predict damage in cases where exposure and structural geometry is more complex. Thus the most complex treatment would require three-dimensional finite element or finite volume simulation of the structure, with use of coupled partial differential equations governing temperature, moisture, chloride, and oxygen transport, electropotential, stress, and cracking. Such a comprehensive model is available in DuCOM, as previously stated, but sub-models such as that developed by Kemper, et al. for ingress

[21] and Michel, et al. for corrosion propagation [22] might also be adopted for some aspects of the analysis cycle. Cracking due to corrosion propagation has very complex effects on the course of future deterioration, but formulations of transport in cracked media can be used in the finite element method to capture this phenomenon [23]. Use of these complex models requires many input parameters, and may result in issues with convergence and long run-times. This approach is therefore more likely to be used in research and for new structures where simpler methods are not expected to yield accurate results, due to exposure severity or geometric complexity.

When multiple hazards are considered, certain methods of deterioration analysis become more or less attractive. The very complex finite volume and finite element models discussed may not be the ideal models to use when a full suite of nonlinear response histories are required for PBEE assessment using the PEER methodology. In this case fiber models may be a better option, paired with simpler models for chloride ingress and corrosion initiation and propagation. A scenario-specific analysis might allow for the use of the more complex models.

Phase (3): Repair Analysis

Repair analysis uses the observable or detectable damage measures to select a reasonable repair action. Two main methods for choosing a repair action have been proposed: fragility curves like those used in PBEE; and decision or logic trees. Fragility curves have the benefit of incorporating the uncertain relation between damage and repair explicitly. However, because damage states and repair actions do not have a one-to-one mapping (e.g. both large crack widths and detection of a high corrosion current might lead to removal of concrete cover and sandblasting) joint distributions for damage measures and repair actions must be used to avoid "double-counting." This joint behavior will be difficult to model, given the generally slow rate of deterioration and repair and resulting lack of large datasets. Alternately, decision trees make the probabilistic aspects less transparent, but are capable of sorting out the damage measures in such a way that prevents double-counting of the probability of a repair action. While review of existing repair actions chosen through BMS can help populate the logic trees, solicitation of expert opinion from bridge and maintenance inspectors will provide preliminary data for modeling.

Future changes to the AASHTO Bridge Element Inspection Manual will increase the precision of data available on the U.S. national bridge inventory [24]. Inspectors will record both the severity and spatial extent of a certain type of damage, which can then be used to assign probabilities in a logic tree. For example, inspection of a concrete deck would record the presence of cracking, spalls, and efflorescence, their severity, and their quantity. While it will take many years to develop a statistically significant sample of actual damage measures and repair actions, this data source will provide future empirical evidence to complement expert opinion [25].

The separation of damage severity and spatial effects suggests another complication in repair analysis: the "decision" of when the repair takes places, and what components of a set of like components will be repaired. A repair analysis that leads to 93% of the deck surface area being repaired at one time, or bents repaired one at a

time for several years running is insensible. The use of a spatial threshold for repair (e.g. if >80% of a component class is affected, apply the repair to the entire class in that time step) should help to alleviate this problem. This adds a more prescriptive or deterministic aspect to the repair analysis, as the repair timing and extent become less uncertain. However, the practical advantages of the approach are expected to outweigh the potential drawbacks. Additionally, the thresholds could be modeled as stochastic parameters in a Monte Carlo-style simulation, which would reintroduce a suitable level of uncertainty. A repair analysis using a combination of local damage measures, logic trees and spatial thresholds is expected to be the best choice for the form of repair analysis, although other methods of analysis will be studied.

Phase (4): Impact Analysis

Impact analysis is separated into two main categories: those that rely on a repair inventory (cost, downtime, and environmental impacts), and safety or structural reliability, which is computed directly from deterioration analysis. For best results, the repair inventory should be tailored to the particular materials and methods used by the owner or operator. The inventory will be created based on a combination of expert opinion and review of construction documents for actual repairs. It is envisioned that a general inventory will be created, which can then be modified by the analyst to reflect operator preferences.

Each item or process in the inventory (e.g. concrete, sandblasting equipment) must then be linked in unit form to curves for cost, downtime, and environmental impacts. Material costs can be found in, for example, contract cost data provided by state departments of transportation [26], and should reflect variance in bid prices through a probabilistic distribution. Downtime curves are slightly more difficult to obtain, as the aggregation of the time for each unit of repair action (e.g. 1 m^2 of sealant applied) must represent the relative fraction of the total repair time, including setup and breakdown. Preliminary data will again come from review of construction documents. Finally, the methods of life cycle impact assessment (LCIA) are used to analyze the environmental impacts of repair materials and methods. Commercial codes such as SimaPro [27], as well as ongoing research projects [28], link unit inventories of materials and processes to impacts like greenhouse gas emissions, carcinogens, and energy use, and can therefore can be readily linked to output from repair analysis. Uncertainty must also be accommodated in this phase, as, for example, the greenhouse gas emissions of a cement plant or a generator vary by plant and manufacturer. Incorporation of uncertainty in cost, downtime, and environmental impacts given repair action, when convolved with the repair hazard curve, yields the desired exceedence curves for the decision information.

For multihazard analysis structural safety or reliability may be of more interest. As reviewed previously, this field is very well-developed, and many methods exist for computing the probability of "failure," in this case violation of the ultimate limit state. One method is the use of time dependent reliability theory based on upcrossing, as the required time-varying distributions for load and capacity are readily available from the input data for exposure analysis and the output of deterioration analysis. However, this gives only failure from overloading, whereas the probability of failure

from extreme load cases might be of greater interest. Due to the combination of variability in exposure condition/deterioration/repair simulations and in extreme loads (e.g. ground motions, storm surges), this sort of analysis may be better performed using a Monte Carlo approach.

FUTURE WORK

Clearly much work remains to develop and validate the proposed framework. Efforts will first focus on implementing selected deterioration models within the framework, and validating their predictions on controlled laboratory studies of corroding structural members available from literature. Sensitivity analyses will determine which input variables and assumptions have large effects on the accuracy of the predicted deterioration and on decision information. An actual structure will then be selected as a testbed case on the basis of available data for exposure conditions, inspection and maintenance, and knowledge of repair practices. A repair and impact inventory will be developed for this structure, and the decision tree between damage and repair will be developed through review of maintenance records and expert opinion. The PBDE assessment will then be performed using a variety of different models and assumptions to validate the method.

CONCLUSION

A framework for performance-based durability engineering has been proposed after the successful implementation of the PEER Center's performance-based earthquake engineering framework. The approach presented differs from existing frameworks for durability in its use of a sequence of separate analysis stages and "pinch point" variables to provide modeling flexibility. This flexibility allows the assessment of the impact of modeling choices and assumptions, and can provide feedback to researchers. Additionally, the inclusion of impact analysis allows the calculation of decision information useful to owners and operators. Existing models and datasets identified will allow for future testbed simulation to demonstrate how the framework is implemented for archetype structures. It is hoped that the further development of this framework will foster collaboration on new research and design methods, as did the development of performance-based earthquake engineering.

ACKNOWLEDGEMENTS

This research is being conducted under the support of a National Science Foundation Fellowship, a Stanford Graduate Fellowship, and the John A. Blume Earthquake Engineering Center.

ABSTRACT

The devastation inflicted on civil infrastructure by natural disasters has the potential to result in numerous deaths and huge economic losses. Natural hazards such as hurricanes, earthquakes, floods, and tornadoes have led to extreme property damage and the loss of many lives. While the occurrence of these hazards is beyond our control, novel structural engineering approaches to design and construction have the ability to reduce their consequences. Structures along the coast are particularly susceptible to a variety of natural hazards. Coastal construction practices, however, as they exist today, may not be sufficient to resist their extreme loads. Design and construction in a coastal environment must consider the effects of multiple hazards concurrently rather than focusing on each hazard in isolation. Multi-hazard engineering strategies can be incorporated into design to enhance the inherent resilience and improve the robustness of structures. Current design approaches also lack a probabilistic backbone that can be used to relate specific structural performances with different hazard intensities. Performance-based engineering (PBE) allows for a structure to be designed for specified levels of performance under particular hazard scenarios. Currently, arbitrary importance factors are integrated into design to account for uncertainties in hazards and their loads. In comparison, PBE uses direct analysis procedures to predict the performance of a building under hazard loads over the entire life of the structure. The probabilistic basis of PBE allows future changes in hazard frequencies and intensities due to global climate change to be taken into account. An integration of multi-hazard engineering with PBE promises to significantly improve structural reliability for a wide range of loading scenarios. A possible methodology for assessing response of structures in coastal environments vulnerable to winds, storm surge, tsunamis, and earthquakes is presented.

INTRODUCTION

Structures along the coast are susceptible to several natural hazards, including hurricanes, tsunamis, and earthquakes. Current coastal construction practices, however, may not be sufficient to resist the extreme loads caused by these hazards. Until now, the design of structures has been too focused on treating single hazards in isolation and must be broadened to include the capacity to resist multiple hazards. A

multi-hazard approach takes into account the design strategies for various hazards concurrently within a balanced all-inclusive design (Bruneau 2007; Kafali 2008; Potra and Simiu 2009; Ellingwood et al. 2004; Li and Ellingwood 2009). To further increase the robustness of design and construction in areas vulnerable to several natural hazards, performance-based engineering (PBE) can be combined with multi-hazard engineering. PBE allows for a structure to be designed for specific levels of performance under particular hazard scenarios (FEMA 1997; FEMA 2000; Augusti and Ciampoli 2008; Ellingwood 2008). Therefore, instead of considering code minimums during design and construction for each individual hazard, different levels of structural performance can be achieved based on building function or requirements of building owners. Currently, arbitrary importance factors are integrated into design procedures to account for uncertainties in hazards and their loads (Ellingwood 2008). In comparison, PBE uses direct analysis procedures to predict the performance of a building under multiple hazard scenarios over the entire life of the structure.

Multi-hazard engineering and PBE can be integrated into a framework for the design of structures in coastal areas. The first step in the framework is to define the individual and combined hazards, model the hazards and specific events, and characterize the loads (Thompson and Cardone 1996; Vickery et al. 2000; Jelesnianski et al. 1992; Ellingwood et al. 2004). Monte Carlo based procedures can be used to simulate the independent and combined hazards occurring over the lifetime of the structure (e.g., Shinozuka 1972; Kareem 2008). In this manner, the estimated loads to which a structure will be subjected over its lifetime are determined. Next, the fragility of the structure over a range of loading scenarios is determined. A system fragility analysis is used together with PBE to yield the responses of the structure to the hazards (Kareem 1987; Shinozuka et al. 2000; Wen and Ellingwood 2005). A comprehensive risk-based analysis procedure can then be used to determine whether the responses, which are directly related to the damages, are acceptable over the full range of the different events (e.g., Ellingwood 2008). If the responses are unacceptable, it may be necessary to iterate on the design until the responses over the range of loading scenarios are acceptable.

The probabilistic nature of the method presented herein is particularly important considering the many sources of uncertainty in the analysis. In order to achieve reasonable results and therefore make the proper risk-based decisions, uncertainty in the number of events and their characteristics and intensities, uncertainty in the loads that are acting upon the structures, and uncertainty in the system response must all be considered. In addition, possible changes in the frequency and characteristics of events due to climate change can also be taken into account (Webster et al. 2005; Knutson and Tuleya 2008; Emanuel et al. 2008). Proper consideration of the hazards and consequences, including their uncertainties, within the framework allows resources to be allocated in the most efficient and effective manner. Reduction of overall risk and enhanced robustness without significant increase in cost is the goal of the approach introduced herein.

MULTI-HAZARD ENGINEERING

A multi-hazard engineering approach has the potential to reduce the capacity for dynamic loads to inflict significant damage on structures by considering the

multiple hazards with which a structure may be faced in all aspects of design and construction (Kafali 2008; Ellingwood et al. 2004). Robust design features are chosen such that they enhance performance when considering several individual hazards or the combined loading from two hazards. For the case in which two hazards are present at a site, three types of events must be considered, two hazards occurring individually and events in which both hazards are occurring concurrently. Therefore, the more hazards that are present at a site, the more complicated is their treatment. Fortunately, the analysis and design frameworks for each of the individual hazards are often similar and, therefore, can be combined without much difficulty, as shown in subsequent sections.

Design of coastal structures for hurricanes is inherently a multi-hazard engineering problem. Hurricanes often cause storm surge and waves as well as severe wind. Current methodologies design for each of these hazards independently, without consideration of their combinations. Therefore, the most extreme load conditions may not be considered. Coupling a storm surge model with a hurricane simulation model, however, yields more realistic information on both the flood and wind hazards in a specified area (Huang 1999).

Multi-hazard engineering in its most advanced state will involve the individual and combined modeling of each of the hazards present. Simulations can then be used to fully describe the hazard environment at the site. These models, however, can be computationally expensive and are often not realistic for use when considering large return periods and thus many simulations. At a simpler level, the multi-hazard paradigm can be implemented such that a suite of hazards, both independent and concurrent, are considered and an envelope of the demands induced by the hazards are used for final design. This method, however, can lead to inefficient, and thus suboptimal, designs. HAZUS-MH, developed by the Federal Emergency Management Agency (FEMA), models potential losses from earthquakes, floods, and hurricanes (FEMA 2006a; FEMA 2006b; FEMA 2006c). The ability to estimate impacts from multiple hazards present in a region allows decisions to more easily be made considering allocation of resources and mitigation options.

PERFORMANCE-BASED ENGINEERING

The PBE paradigm has been popular in earthquake engineering and, more recently, it has been extended to blast engineering (ICBO 1997; FEMA 1997; FEMA 2000; FEMA 2004; Hamburger and Whittaker 2003). Although PBE has been informally practiced in wind engineering for decades, its framework is being evaluated for formal adoption. Building codes are intended solely to prevent substantial loss of life or collapse in major hazard events. Therefore, significant damage may be sustained by the structures during events that are considered to have probabilities as high as a 2% annually. While it is not economically practical to design structures to resist the most extreme loads without sustaining damage, the amount of damage sustained for different hazard intensities can be controlled using PBE. Arbitrary safety factors associated with minimum design requirements can be replaced by PBE in an effort to achieve a balance between cost of construction and performance of the structure. PBE necessitates the accurate prediction of response of a structure over a range of natural hazards and intensities that the structure is likely to face over its lifetime. The three main steps of PBE include proper estimation of the hazard(s), evaluation of the vulnerability of the structure to these hazard(s), and

accurate determination of the consequences of the hazard(s) at the system level (Tang et al. 2008). While an understanding of the response of the structural performance at the component level is important, ultimately the system-level behaviors are used as the performance descriptors used to determine the performance levels.

The performance descriptors for individual and concurrent hazards can be chosen such that the performance levels can be set in a straightforward manner. For example, in seismic PBE, interstory drift is often chosen as a performance descriptor (Li and Ellingwood 2007). The probability of exceedance of certain drift ratios are associated with immediate occupancy, life safety, and collapse prevention. Other proposed performance descriptors include flood depth as compared to first floor height of the structure, breach of windows and other openings, and amount of damage to roofing panels. These performance descriptors can then be related to performance levels which are then associated with the hazard intensities.

The quantitative performance descriptors are related to limit states and ultimately qualitative performance levels. The performance levels specified by FEMA (1997) for earthquakes, as mentioned above, are immediate occupancy, life safety, and collapse prevention. Immediate occupancy means limited structural damage has occurred and there is low threat to life safety. Life safety means the structure suffered significant damage but there is low risk of collapse. Collapse prevention means the building is likely to experience partial or total collapse but will continue to carry the gravity load demands for a period of time immediately following the earthquake. While these seismic-based performance levels are a good starting point, additional performance levels are necessary when considering a suite of hazards and their combinations. For example, occupant comfort may be added due to wind/hurricane considerations. Acceptable performance levels are set by the owners and designers for the particular location, type of structure, and use of structure. For example, a lifeline structure, such as a hospital should have immediate occupancy after high intensity, low probability events. The desired performance levels may also be linked to monetary cost. A business may prefer to spend more money up front in the design and construction of the structure rather than risk days or weeks of downtime after high intensity events. The performance levels may be determined by limit states which may be strength related or cost related. This flexibility inherent in PBE is not possible with current code based design.

This paper seeks to extend the probabilistic foundation of PBE to account for multiple hazards present in a coastal environment. Enhancing building design using a PBE approach may increase initial construction costs but long-term savings may easily outweigh the initial investment. In addition, the building owners and occupants are able to choose how the structure will perform over the full range of hazards to which the structure will likely be subjected (Tang et al. 2008). An extension of a PBE framework that considers multiple hazards is outlined below in an effort to show the many advantages of these approaches to engineering design.

DESIGN AND ANALYSIS FRAMEWORK

Figure 1 outlines a proposed framework for performance-based design and analysis of structures in a multi-hazard environment. Each step of this framework is detailed in subsequent sections.

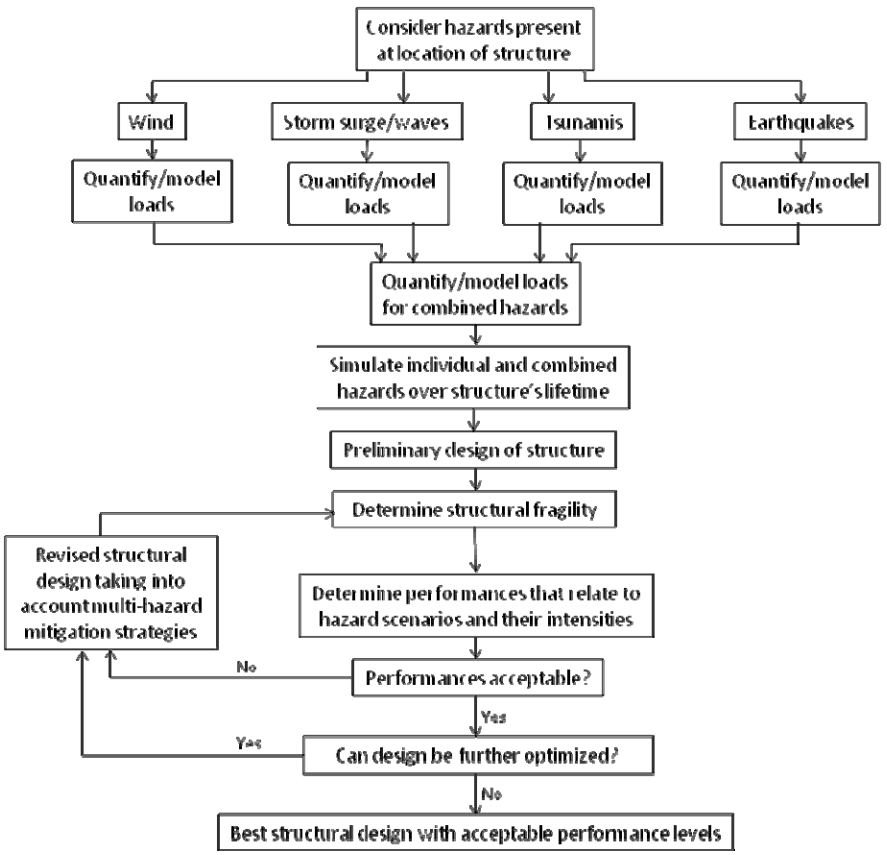

Figure 1. Design and analysis framework for combined multi-hazard engineering and PBE.

Model the hazards present. The risks that are specific to a structure's site are determined and the site is analyzed based on location and previous history. In coastal construction, our focus herein, the natural hazards with which a structure may be faced are narrowed to include storm surge/waves, tsunamis, earthquakes, and wind. Stochastic modeling of the individual and combined loads associated with all hazards present at a location is the important first step. Computationally expensive as well as simplified models are available for the individual as well as the combined loads.

The wind hazard present at a site is often expressed by a maximum wind speed probability distribution that is appropriate for the location, exposure, and elevation of the site. The location determines whether the site is vulnerable to hurricane winds and/or winds associated with extratropical storms. Since our focus is coastal construction, hurricanes are used to determine the extreme wind environment (Thompson and Cardone 1996; Vickery et al. 2000). The modeling of hurricane winds can be complicated depending on how much detail is included. Monte Carlo simulation (MCS) is employed to generate thousands of hurricanes with varying storm sizes, tracks, intensities, and locations to generate probabilities of occurrence of hurricanes in a particular location and the probability distributions of the maximum wind speeds. Historical hurricane data is used to develop probability distributions of the hurricane parameters from which the MCS random variables are drawn (Kafali 2008). Single and multiple point models derived from spectral density functions are used to characterize the fluctuating wind components, which are then combined with the mean wind velocities determined via simulation. Huang et al. (2001) also uses

simulation techniques to characterize the wind environment, but uses more complex wind models derived from previous models by Batts et al. (1980) and Georgiou (1985). The five parameters of focus in this methodology are annual occurrence rate, minimum approach distance, approach angle, central pressure difference, radius of maximum wind speed, and translation velocity (Huang 1999). Once again historical hurricane data is used to develop the probability distributions of the parameters used by MCS. Variations of these parameters in time and correlations between the parameters are also taken into account as the hurricane is moved along its path. For example, central pressure difference is modeled as a Weibull distribution with mean and standard deviation determined for the location of interest. The central pressure difference, however, decreases as the hurricane moves over land. This wind modeling method yields accurate maximum surface wind speeds for a particular site.

Storm surge can be a major source of damage during a hurricane depending on the storm characteristics and the location. Storm surge is water that is forced toward the shore by hurricane winds. Proper modeling of storm surge is important for accurate determination of coastal areas susceptible to flooding. Surge depth, velocity, and duration are the key parameters necessary for complete modeling of storm surge loads. In addition, surface waves superimposed on the storm surge are important since the wave action on a structure can lead to very different loads than those caused by flooding. The primary parameters necessary for modeling hurricane induced storm surge include central pressure difference, storm size, translational velocity of storm, shelf width, bottom slope, and peakedness of storm wind speed distribution (Irish et al. 2008). Some modeling approaches for storm surge make significant simplifications, while other, more complicated, methods take into account all these parameters in significant detail. For example, hurricane inundation can be simulated using the hydrodynamic model ADCIRC (Advanced CIRCulation). ADCIRC is a finite-element, depth integrated model that takes into account storm surge developed due to tides, wind forcing, and ocean wave forcing (Westerink et al. 1992). ADCIRC uses actual wind fields for forcing when available. For predicting storm surge from hypothetical storms, however, simplified wind models are used. ADCIRC does not model the nearshore wave environment. Therefore, ADCIRC can be coupled with the Steady State Spectral Wave (STWAVE) model (Resio 1987) or the Simulating Waves Nearshore (SWAN) model (Booij et al. 1999) to gain a complete understanding of the storm surge and waves present at a site location. In addition, a Pierson-Moskowitz spectrum has been used to determine the waves to be superimposed on the storm surge using the mean wind speed (Kafali 2008). A much simpler method for storm surge prediction has been developed by the National Weather Service and is known as SLOSH (Sea, Lake, and Overland Surges from Hurricanes) (Jelesnianski et al. 1992). SLOSH can estimate storm surge flooding for a given category, forward speed, direction, and location. SLOSH uses simplified parametric wind models to produce surface stresses, which drive the water onto the shore. SLOSH does not include tides, ocean waves, or wind-driven waves. SLOSH may also be coupled with STWAVE or SWAN with some success. In its simplest form, storm surge modeling can be derived from FEMA flood maps associated with the National Flood Insurance Program (NFIP). These flood maps can be used to determine probabilistic flood depths for a structure over its lifetime. The above storm surge/wave modeling methodologies can be used together with ASCE7-05 procedures to quantify the hydrostatic forces from inundation, the hydrodynamic forces from water velocity, the breaking wave forces, and the buoyant forces.

Tsunami forces are similar to those associated with storm surge and can be modeled in much the same way. Hydrostatic, hydrodynamic, and buoyant forces are the cause of most of the destruction from tsunamis. The occurrences of the driving mechanisms for tsunamis, subduction zone earthquakes, sea floor landslides, or volcanic activity, however, are more difficult to predict. The rare occurrence of tsunamis has also hindered development of realistic occurrence and propagation models. Short term tsunami models, however, have been developed by the NOAA Center for Tsunami Research (NCTR) and simulation models are currently being created by a NEES project known as TSUNAMOS at Oregon State University. Inundation forecasts are available through NOAA NCTR based on Method of Splitting Tsunami (MOST) models. MOST is used for the generation of a tsunami by an earthquake, propagation of the tsunami, and subsequent inundation of dry land (Titov and González 1997). MOST is the basis of the Short-term Inundation Forecast for Tsunamis (SIFT) tool, also developed by NCTR. SIFT provides tsunami forecasts quickly and accurately using tsunami propagation simulations after a tsunami generating event has occurred (Gica et al. 2008). SIFT also incorporates data collected by deep water buoys and features site specific inundation forecasts. TSUNAMOS seeks to improve current tsunami models by including 3D breaking waves, improving bathymetric and topographic features in tsunami prone regions, and integrating experimental and full-scale data (NEESR-SG 2007). Once the inundation depths and velocities have been determined via modeling, ASCE7-05 procedures can be used to approximate the forces with which structures will be faced.

Earthquake modeling has been researched extensively over the past several decades. The models available range from very complex to very simple. At the highest levels, stochastic methods are used to generate earthquakes using empirical spectra or spectra based on physical models (Housner and Jennings 1964; O'Connor and Ellingwood 1992; Boore 2003; Kafali 2008). While the earthquake time series generated by the spectra may not resemble actual earthquakes that have occurred or may occur at the site, essential characteristics of the ground motion are captured. An ensemble of seismic acceleration time histories can be used to fully characterize the earthquake environment at the site. Similarly, a suite of actual ground motions at the site or similar sites can be used. At the most simple level, the USGS provides mean yearly rates for combinations of earthquake magnitude and source to site distances that can be related to probable damage states for different types of structures (USGS 2009). These values are also useful when combined with the stochastic and kinematic models. The spectra chosen to generate the time histories are often dependent on the magnitudes and source to site distances associated with different recurrence intervals.

The multi-hazard paradigm necessitates consideration of combined hazard loads. As mentioned above, hurricanes consist of multiple hazards that are directly related to each other. The central pressure difference of the hurricane determines the intensity of the storm, which determines wind speeds as well as potential storm surge depths. Therefore, hurricane wind speeds, storm surge depths, and wave heights should all be modeled together. The difficulty, however, becomes combining models such that they are still computationally efficient. A storm hazard model known as The Arbiter of Storms (TAOS) seeks to achieve this by extending the SLOSH model to include realistic wind estimates and waves (Watson 1995). Tsunamis and earthquakes can also be multi-hazard events. A future goal of the NEES TSUNAMOS simulator is to combine TSUNAMOS with OpenSees, well-known earthquake engineering

software (NEESR-SG 2007). Further development in the combined modeling of hazards is necessary in order to make multi-hazard engineering feasible.

Once models for the individual and combined hazards have been determined and validated it is necessary to simulate random arrival times of the hazards at a site over a structure's lifetime. Figure 2 depicts the potential occurrence of hazards, both combined and individual, over the lifetime of a structure. Simulation procedures not only specify the random arrival times of the events but also their random properties (e.g., Kafali 2008). Event arrivals and intensities of individual hazards can be modeled as a Poisson process (e.g., Huang 1999; Kafali 2008). Then the characteristics of the events once the intensities are known can be specified using MCS. The simulation procedures for event arrivals and characteristics take into account the temporal and spatial uncertainty of the hazards. The characteristics can be simulated from probability density functions associated with the different parameters of the events (Kafali 2008).

The uncertainties associated with global climate change and its potential effects on hurricanes can also be incorporated. Future global warming may cause the sea level to rise and hurricanes to intensify (Webster et al. 2005; Knutson and Tuleya 2008; Emanuel et al. 2008). These possible changes can be taken into account during hazard characterization. For example, mean sea level within ADCIRC can be adjusted for sea level rise (Mousavi et al. 2010). Similarly, adjustments of hurricane intensities can easily be made using simple equations relating sea surface temperature rises and intensity rises (Knutson and Tuleya 2008). Therefore, hazard modeling in a probabilistic framework can easily include predicted changes in overall hazards or specific characteristics of the hazards.

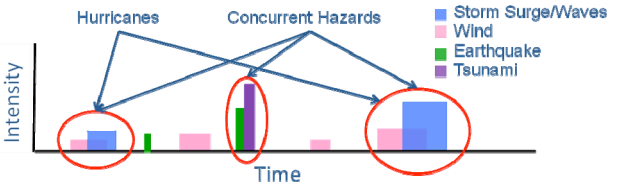

Figure 2. Stochastic modeling of the individual and combined hazards present at a location over the lifetime of the structure.

Determine fragility. Once the hazards have been defined and the loads for all the scenarios are characterized using the tools above, the structural fragilities associated with the range of hazards and intensities are determined. Fragility curves are the result of the combination of the vulnerability of the structure and the hazard loads and are typically assumed as a two-parameter lognormal distribution function. System fragility is the conditional probability that the structural response exceeds a damage state given a hazard intensity. The damage states correspond to defined limit states which are related to the performance levels. For example, a seismic fragility curve may be defined by the exceedance of different interstory drift limit states. Defined limit states (e.g., 1%, 2%, 3% drift ratios) correspond to performance levels such as immediate occupancy, life safety, or collapse prevention. In this manner, system fragility is plotted against the parameters characterizing the natural hazards, i. e., interstory drift, maximum wind speeds, storm surge depth, etc. A variety of empirical and analytical methods can be used to generate fragility curves that range from the very simple to the very complicated. A few of these methods will be discussed below.

One of the most simple, but most attractive, options for fragility analysis involves the use of damage functions already available from FEMA in HAZUS-MH. These damage functions correspond to different building ages, structural types, and exposure categories. They were created through direct comparison between the hazard loads and empirically or analytically derived resistance parameters. The functions are related solely to the intensity of the hazards. Therefore, the full time histories are not necessary for this fragility analysis. For example, the exposure, building age, and structure type would determine which fragility curve would be considered and only the maximum wind speeds would be necessary to determine the damage. Similarly, the source-to-site distance and location would determine the fragility curve to be considered but only the magnitudes of the earthquakes would be necessary to determine the damage. The damage suffered by a structure throughout its lifetime due to the suite of hazards simulated above can be used to estimate the monetary loss over a specific period of time. Determination of whether the extent of damage as well as the losses are acceptable will be explained below. While this approach to fragility analysis is convenient, a number of assumptions are made that can cause the results to be inaccurate.

Empirical fragility curves can also be developed in a straightforward manner as in Shinozuka et al. (2000). This approach, however, is often not possible since damage data must be available for a large number of similar structures affected by the same intensity hazard. This has been possible in seismic fragility analysis because damage to a number of similar structures can be used after a specific event, such as the 1995 Kobe earthquake. The curves are developed by integrating damage state information with the intensity measure (e.g., peak ground acceleration for earthquakes). Several curves can be defined that are associated with different performance levels. This method is not considered further for this framework, however, since we are considering hypothetical hazard scenarios in the future.

Analytical fragility curves may be used when empirical fragility curves cannot be determined (Shinozuka 2000). Generated time histories with specified intensity parameters are used for the hazard loads. These time histories are available via simulations as discussed in the previous section. A finite-element code such as SAP 2000 or ETABS can then be used to simulate the damage due to the different time histories. These damages can then be used to determine the damage states associated with different hazard intensities. Extensions and modifications of this general framework are typically used for the development of fragility curves.

Wen and Ellingwood (2005) use a similar method to assess the vulnerability of structures to different hazards. System response to the generated time histories are determined using single-degree-of-freedom oscillators that represent each mode. Maximum responses due to the different modes are then combined using Square Root Sum of Squares (SRSS). The results from the simplified systems can then be used to develop probabilistic demand curves.

Establish acceptable performance levels. A risk analysis approach is used to determine acceptable damages for different events throughout the lifetime of the structure. Together, the building owner, occupants, and design engineers can determine acceptable probabilities that the structure enters different damage states given a range of load scenarios (Kafali 2008). For example, given a low intensity, high probability scenario the structure should likely undergo no damage. For high intensity, low probability events the structure may undergo moderate to extensive

damage. A cost/benefit analysis couched in a risk based framework is performed to understand the likelihood of specific hazard events as well as potential consequences. Since resources are not endless, it is important to determine how best to design the structure to resist hazards and reduce the consequences with what is available.

Optimization of the design of the structure is performed by iterating through this basic procedure in order to determine the best possible structural design that utilizes the best selection of complementary multi-hazard mitigation strategies. The goal is to minimize risk while still avoiding inefficient and costly construction. Optimization will occur until the acceptable performance levels have been met in the most cost-efficient manner. Optimization may involve changes to the design that are as simple as raising the grade level or adding hurricane straps to the roof or as complicated as adjusting the orientation of the entire structure or considering different structural materials. The final goal of the structural design is a structure that has a total life-cycle cost that is a minimum but the system maintains the specified performance levels during potential hazards. The presentation will include a detailed example of the framework presented here.

CONCLUDING REMARKS

Continued development of coastal areas without consideration of the range of natural hazards, and the benefits and consequences of measures taken to mitigate them, will undoubtedly result in future storm and flood damages, and increased public expenditures for post-storm response and recovery. PBE combined with multi-hazard engineering has the promise to provide a cost-effective and efficient design for a structure subjected to loads from multiple hazards. Multi-hazard mitigation aims to use available resources most effectively to design safe structures that are able to withstand a range of natural hazards. Common practice in design currently considers each hazard separately and combines these designs in a non-optimal manner. The most effective overall solution can be created by considering the portfolio of expected threats to a location and putting together a versatile design. Performance-based engineering offers the optimal framework for creating the best engineering design considering uncertainty in demands and capacities. This paper introduces a basic design framework that combines multi-hazard and performance-based engineering.

ABSTRACT

The seismic performance of structural systems exposed to aggressive environments has to be considered time-variant. Current capacity design criteria are time-invariant and do not account for the interaction with environmental hazards. In fact, for aging systems the energy-dissipating collapse mode may vary over time due to a reduction of both strength and curvature ductility of critical cross-sections where plastic hinges may occur during a seismic event. In this study the lifetime seismic performance of concrete structures is investigated in both probabilistic and deterministic terms. Static and dynamic non linear analyses are carried out on a three-story concrete frame to evaluate the effects of damage on the time evolution of seismic performance indicators. The results show the important role of a life-cycle approach for both seismic assessment of existing structures and seismic design of new structures.

INTRODUCTION

In seismic design of concrete frame systems a collapse mechanism involving the maximum number of story is required to optimize the seismic performance. The optimal failure mechanism can be selected based on a capacity design with strong columns and weak beams (Pauley and Priestley 1992, CEN-EN 1998-1 2004). This approach is time-invariant and do not account for the interaction with environmental hazards. In fact, for concrete structures the diffusive attack from external aggressive agents, like sulfate and chloride, can take place and lead to deterioration of concrete and corrosion of reinforcement (CEB 1992). Such kind of damage can significantly reduce local strength and ductility and modify, in this way, the failure mechanism (Biondini and Frangopol 2008) and the corresponding seismic performance during the structural lifetime (Biondini *et al.* 2011, Akiyama *et al.* 2011). As a consequence, capacity design criteria should be properly calibrated to consider the severity of environmental exposure and the required structural lifetime (Biondini *et al.* 2008, 2011, Berto *et al.* 2009, Akiyama and Frangopol 2010, Rao *et al.* 2010). The effects of chloride induced corrosion of steel reinforcement on the lifetime seismic performance of concrete structures are investigated in this study. A probabilistic approach is adopted to take into account the uncertainties involved in the diffusion and corrosion processes (Enright and Frangopol 1998, *fib* 2006). The lifetime nonlinear structural analyses are carried out by using a general method for concrete structures in aggressive environments (Biondini *et al.* 2004). Two cross-sections with different shape ratio and reinforcement layout are considered to show that concrete

members designed to have the same initial performance and durability threshold parameters, such as concrete cover and quality of the materials, may exhibit different strength and ductility over time depending on geometrical characteristics of the cross-section (Biondini and Frangopol 2010). The time-variant performance of the critical cross-sections of members is analyzed in terms of bending moment versus curvature relationships. These results are implemented in a structural model based on lumped plasticity beam elements (Carr 2006). Static and dynamic non linear analyses are carried out on a three-story concrete frame to evaluate the effects of damage on the time evolution of seismic performance. The results show that the reduction of strength and ductility of concrete members leads to reduced seismic performance of the structural system and confirm the important role of a life-cycle approach for both seismic assessment of existing structures and seismic design of new structures.

TIME-VARIANT PERFORMANCE OF CONCRETE CROSS-SECTIONS

Case study. Cross-sectional analyses are carried out in order to describe the aging phenomena of concrete elements under chloride diffusive attack. The two cross-sections shown in Figure 1 are considered. These cross-sections have been designed so to have the same resistant bending moment $M_{R0} \cong 620$kNm and curvature ductility $\mu_\chi \cong 20$, by assuming material strengths $f_c = 30$MPa for concrete and $f_s = 430$MPa for steel, strain limits $\varepsilon_{cu} = 0.35\%$ for concrete and $\varepsilon_{su} = 6.00\%$ for steel, and concrete cover $c = 40$mm. The effects of confinement are taken into account by assuming the concrete ultimate strain as a function of the stirrup mechanical ratio ω_w (CEB 1985):

$$\varepsilon_{cu}^{*} = \varepsilon_{cu} + 0.05 \cdot \omega_w$$

Cross-section **1**
8 Φ22mm
Stirrups Φ8/75mm

Cross-section **2**
10 Φ16mm
Stirrups Φ8/75mm

Figure 1. Cross-sections and location of the aggressive agent.

The diffusion process. The cross-sections shown in Figure 1 are exposed to the diffusive attack of chlorides along one side (bottom side in Figure 1). This situation is typical of members placed along the perimeter of buildings with the external surface exposed to aggressive atmosphere. Since most observations indicate that transport of chlorides in concrete is diffusion controlled (Bertolini *et al.* 2003), the diffusive process is described by using the following limit state equation based on Fick's one-dimensional model (*fib* 2006):

$$C(x=c,t)=C_0+(C_{S,\Delta x}-C_0)\cdot\left[1-erf\frac{c-\Delta x}{2\cdot\sqrt{D_{app,C}\cdot t}}\right]=C_{crit}$$

where the actual chloride concentration $C(x = c, t)$ at the depth c of the reinforcing steel at time t is compared to the critical chloride concentration C_{crit} which defines the initiation of the corrosion process; C_0 is the initial chloride content of the concrete, assumed equal zero in the following; Δx is the depth of the convection zone, *i.e.* the concrete layer up to which the process of chloride penetration differs from Fick's model, assumed equal zero in this study; $C_{S,\Delta x}$ is the chloride content at depth Δx and time t; $D_{app,C}$ is the apparent coefficient of chloride diffusion, which is evaluated as follows (*fib* 2006):

$$D_{app,C}=D_{RCM,0}\cdot A(t)$$

where $D_{RCM,0}$ is the chloride migration coefficient, and $A(t)$ is a function considering "aging" according to the following formula (*fib* 2006):

$$A(t)=\left(\frac{t_0}{t}\right)^a$$

where t_0 = 28 days = 0.0767 years is the reference initial time.

The diffusion process is described in probabilistic terms assuming the random variables, distribution type, mean μ and standard deviation σ, listed in Table 1 (*fib* 2006). Based on this model, a probabilistic analysis is carried out by Monte Carlo simulation. The probability density functions (PDFs) of chloride concentration at cover depth c and time steps t = 10, 25, 50 years are shown in Figure 2 with reference to a sample size of 50,000 simulations.

Based on the Fick's limit state equation, the PDF of the initiation time t_i for propagation of steel bar corrosion can also be evaluated as shown in Figure 3 (Enright and Frangopol 1998). A lognormal distribution with mean μ = 9.24 years and standard deviation σ = 4.66 years appears to be a good estimate of the actual distribution for the corrosion initiation time (Figure 3, continuous line).

Table 1. Probability distributions and their parameters (*fib* 2006).

Random Variable	Distribution Type	μ	σ
Concrete cover, c [mm]	Normal (*)	40	8
Aging exponent, a [-]	Beta (b_{min} = 0.0; b_{max} = 1.0) (#)	0.3	0.12
Chloride content at depth Δx, $C_{s,\Delta x}$ [wt.%/c]	Normal (*)	3	$0.3\cdot\mu$
Chloride migration coefficient, $D_{RCM,0}$ [m^2/s]	Normal (*)	$15.8\cdot10^{-12}$	$0.2\cdot\mu$
Critical chloride content, C_{crit} [wt.%/c]	Beta (b_{min} = 0.2; b_{max} = 2.0) (#)	0.6	0.15

(*) Truncated distributions.

(#) b_{min} = lower bound, and b_{max} = upper bound of beta distributions.

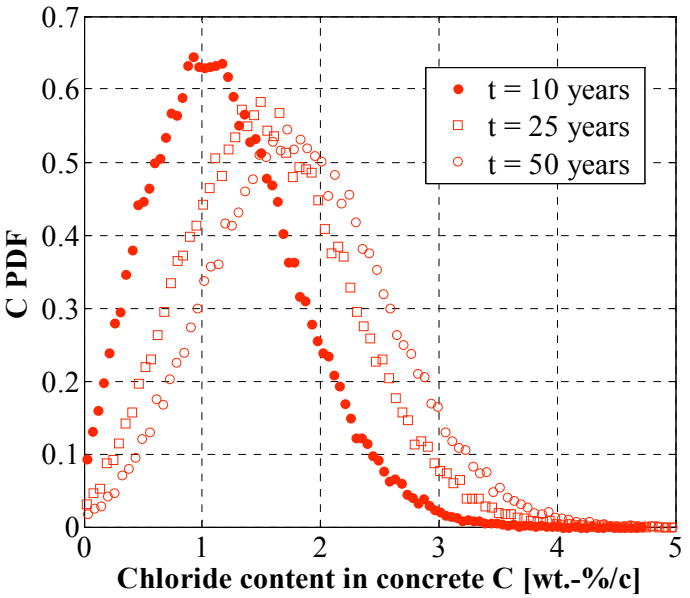

Figure 2. Probability distributions of chloride content in concrete $C(x, t)$ at cover depth $x = c = 40$mm and time steps $t = 10, 25, 50$ years.

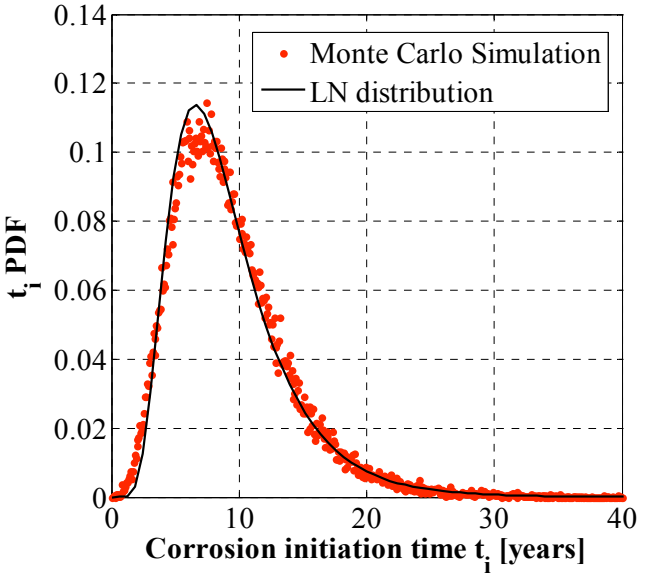

Figure 3. Probability density function of corrosion initiation time t_i.

Damage modeling. The chloride attack induces a corrosion process with reduction of the area of the reinforcing bars. The corrosion penetration P_x is evaluated as follows:

$$P_x = r_{corr} \cdot t_p$$

where r_{corr} is the corrosion rate and $t_p = (t - t_i)$ is the propagation time. Considering uniform corrosion, the reduction in the diameter of a corroding reinforcing bar at time t can be estimated as follows (Berto *et al.* 2009):

$$D(t) = D(0) - P_x .$$

On the basis of correlations between chloride content and corrosion current density in concrete (Bertolini 2003, Liu & Weyers 1998, Thoft-Christensen 1998), a linear relationship between rate of corrosion r_{corr}, in the range 0 to 200μm/year, and chloride content, in the range of 0-3%, is assumed in this study. The time-variant mean value μ of rebar diameter $D(t)$ with respect to the nominal diameter $D(0)$, and the relative coefficient of variation $\delta = \sigma/\mu$, are shown in Figure 4 over a 50 year lifetime.

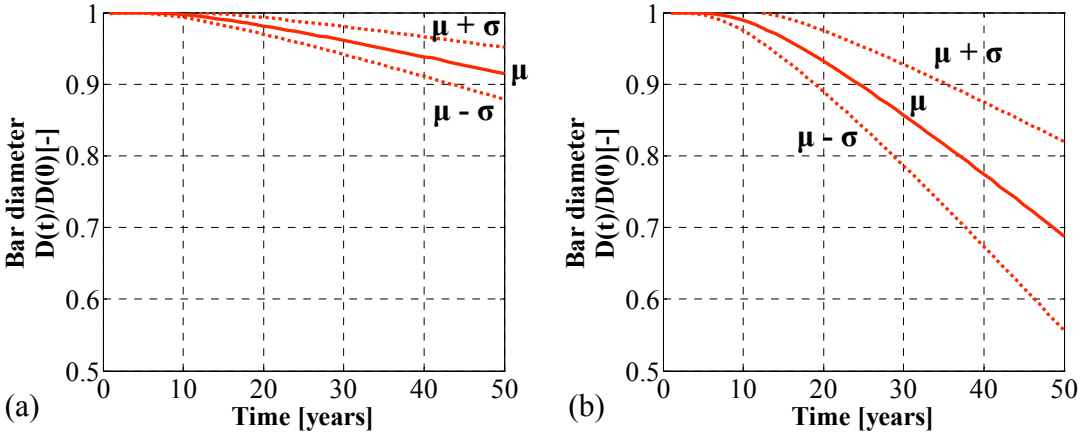

Figure 4. Time evolution of steel bar diameter (a) $D(0)$ = 22mm and (b) $D(0)$ = 16mm: mean (continuous line) and one standard deviation (dotted lines).

Lifetime performance indicators. The time-variant structural performance is evaluated in terms of resistant bending moment $M_R = M_R(t)$ and curvature ductility $\mu_\chi = \mu_\chi(t)$. The performance deterioration is mainly due to the corrosion of the bars closer to the exposed surface. The material strengths f_c and f_y are assumed as lognormally distributed random variables, considering the nominal values as mean values and by assuming 5MPa and 30MPa as standard deviation values for concrete and steel, respectively.

Figures 5 and 6 shows the results of a Monte Carlo simulation in terms of time evolution of the statistical parameters of resistant bending moment $M_R(t)$ and curvature ductility μ_χ, respectively, for the two cross-sections shown in Figure 1. It is noted that cross-section 2 shows a greater reduction in terms of strength than cross-section 1, since the effects of steel reinforcement corrosion are more significant for small bar diameters, as shown in Figure 4.

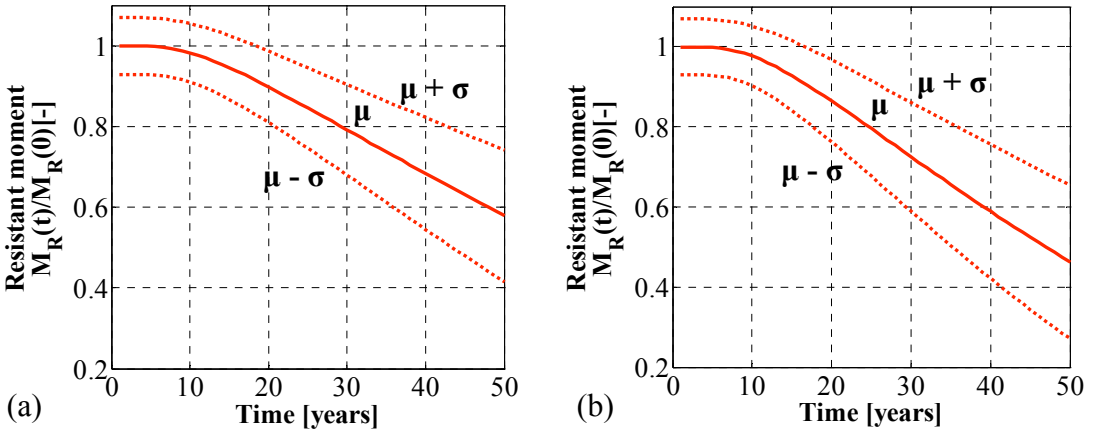

Figure 5. Time evolution of the resistant bending moment $M_R(t)$ of (a) cross-section 1 and (b) cross section 2 (Figure 1): mean μ (continuous line), and standard deviation σ from the mean (dotted lines).

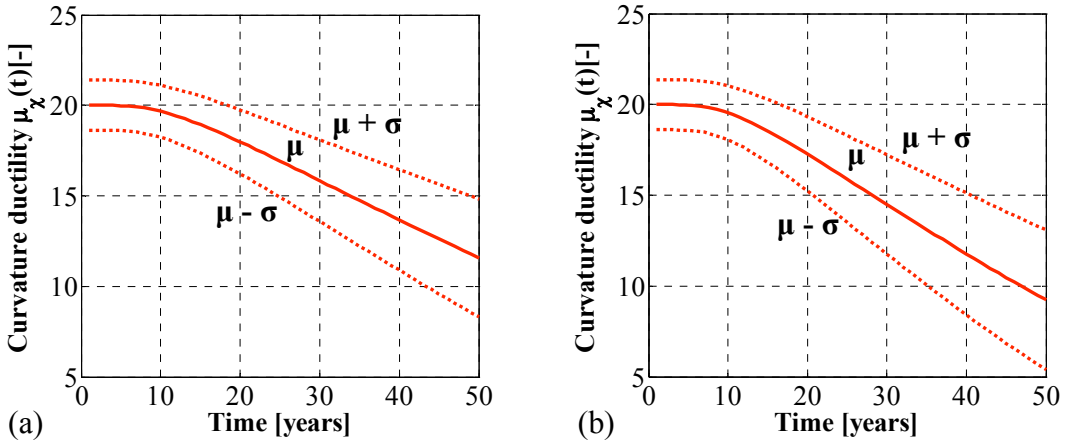

Figure 6. Time evolution of curvature ductility μ_χ of (a) cross-section 1 and (b) cross section 2 (Figure 1): mean μ (continuous line), and standard deviation σ from the mean (dotted lines).

LIFETIME SEISMIC PERFORMANCE OF CONCRETE FRAMES

Case study. The 2D three-story precast concrete frame shown in Figure 7 is considered (Biondini *et al.* 2011). The beams have span l = 8.0m and rectangular section 0.5×0.8m. The columns have inter-story height h = 4.0m. Two different cases are analyzed by considering the two column cross-sections shown in Figure 1. An axial load N_1 = 250kN, due to both dead and live loads, is applied at each story to the columns. Cast-in-situ moment resisting beam-to-column connections are adopted to emulate the structural behavior of monolithic frames. The connections are designed according to capacity design criteria, *i.e.* "strong column-weak beam", by assuming for beams a suitable over-strength ratio γ_c in terms of design resistant bending moments M_{Rd}:

$$\gamma_c = \frac{\left|M_{Rd}^{columns}\right|}{\left|M_{Rd}^{beams}\right|}$$

Two cases are investigated by assuming γ_c = 1.1 and γ_c = 1.3, as suggested by European seismic codes (CEN-EN 1998-1 2004) for structures with low ductility class and high ductility class, respectively. It is assumed that the lifetime material degradation affects the columns only, and that the chloride attack is on the external edge of the columns (Figure 1). The resistant bending moments of the beams are listed in Table 2.

The structure is modeled with elastic beam-type elements and with lumped inelastic rotational springs to simulate the non-linear behavior due to the formation of plastic hinges. For both columns and beams, a linear elastic element with inelastic rotational springs at the ends where formation of plastic hinges is expected, are adopted, as shown in Figure 7.

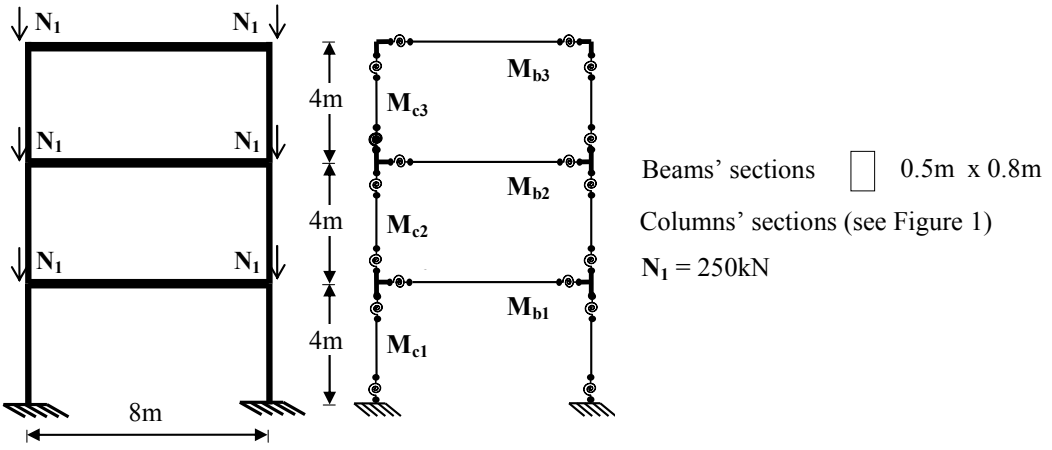

Figure 7. Modeling of the three-storey concrete frame.

Table 2. Resistant bending moments of the beams.

	M_{b1} [kNm]	M_{b2} [kNm]	M_{b3} [kNm]
Low ductility	1127.9	985.6	457.1
High ductility	954.4	834.0	386.8

Lifetime overstrength factor. Based on the reduction of column resistant bending moment $M_R(t)$ shown in Figure 5, the time evolution of the overstrength factor γ_c at the first floor is evaluated in probabilistic terms for both the low ductility and the high ductility frame (Figure 8). A change of collapse mechanism may occur for γ_c < 1, since the capacity design criterion of "strong column-weak beam" no longer holds. With reference to the mean values of the factor γ_c, for the low ductility frame a change of collapse mechanism may occur using both cross-section 1 and cross-section 2 after about 20-30 years of lifetime. For the high ductility frame, the condition γ_c < 1 occurs for cross section 2 only after about 45 years of lifetime.

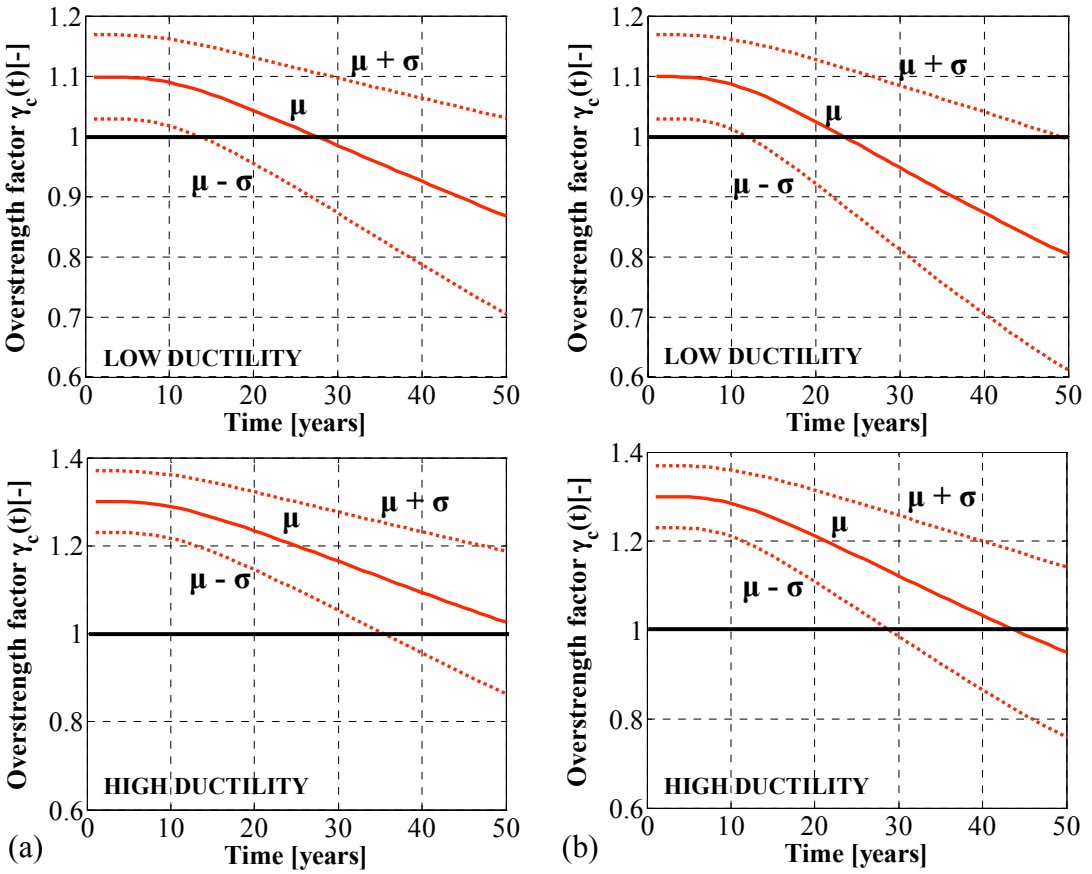

Figure 8. Time evolution of overstrength factor γ_c for low ductility and high ductility frame with (a) cross-section 1 and (b) cross-section 2: mean (continuous line) and one standard deviation from the mean (dotted lines).

Static nonlinear analysis. The lifetime seismic performance of the structural frame system shown in Figure 7 is investigated by static nonlinear analysis. The time-variant performance of the critical cross-sections of members in terms of bending moment versus curvature relationships is implemented in a structural model based on lumped plasticity beam elements (Carr 2006). The analysis is carried out under a linear distribution of horizontal forces by increasing the intensity of the applied loads up to failure. The results obtained for the low ductility frame with column cross-section 1 are discussed in the following. Figure 9 shows these results in terms of total base shear F versus top displacement Δ. A significant reduction of the total base shear strength is obtained over the structural lifetime. Moreover, a significant reduction of the ultimate displacement and hence of the displacement ductility is obtained over time. In fact, as expected, due to the reduction of bending moment capacity of the columns, a change of collapse mechanism occurs moving from a typical "beam sway" to a "column sway" mechanism.

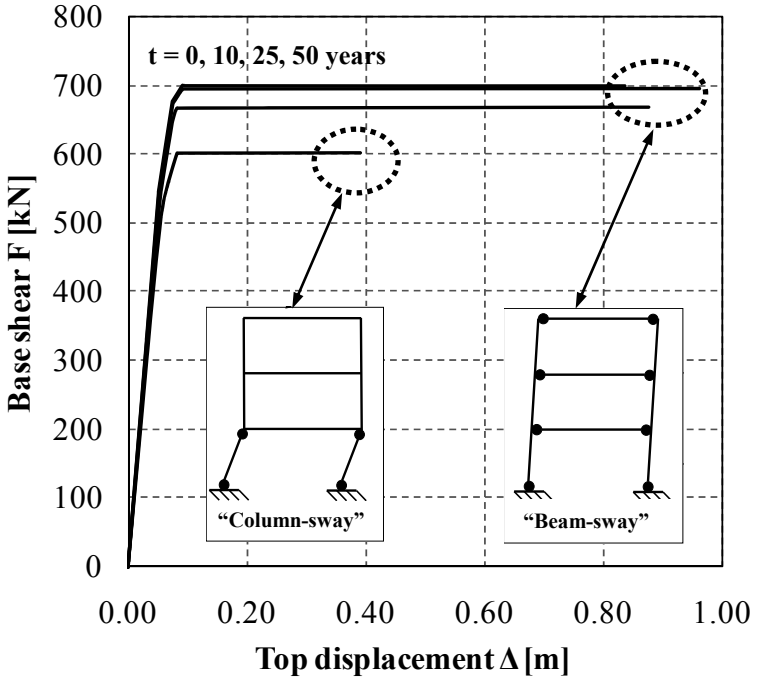

Figure 9. Time evolution of base shear *F* vs. top displacement *Δ*.

Dynamic nonlinear analysis. Time history dynamic nonlinear analyses are carried out for the low ductility frame with column cross-section 1 using the ensemble of ten earthquake records listed in Table 3 (Pampanin *et al.* 2002). These records are scaled to match Eurocode 8 design response spectrum for soil class B and peak ground acceleration PGA = 0.54*g* (CEN-EN 1998-1 2004). Figure 10 shows the lifetime evolution of the mean values of the maximum story displacements and inter-story drifts. The mean values of residual displacements and inter-story drifts after the seismic excitations are listed in Table 4. It is noted that the stiffness and strength reduction at cross-sectional leads to an increase of displacements and drifts over time. This could affects the seismic performance at the damage limit state, with damage of the non-structural elements. On the contrary, story shear forces decrease over time due to the reduced strength of columns, as shown in Figure 11.

Table 3. Characteristics of seismic records (Pampanin *et al.* 2002).

Earthquake record	Year	Station	Soil Type	Scaling Factor	Scaled PGA [g]

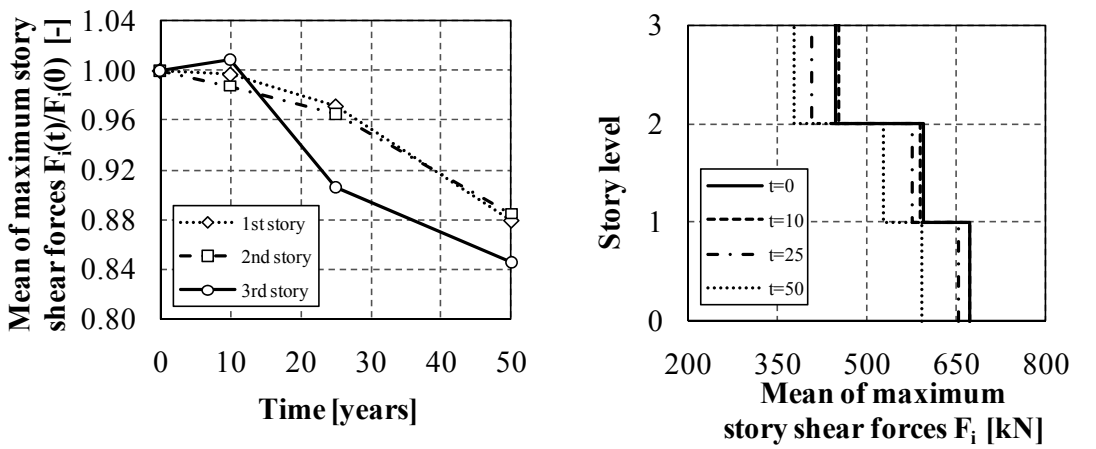

Figure 11. Time evolution of the mean values of the maximum shear forces F_i at each story *i*.

CONCLUSIONS

The effects of chloride induced corrosion of steel reinforcement on the lifetime seismic performance of concrete structures have been investigated. It has been shown that concrete members having the same initial performance and durability threshold parameters, such as concrete cover and quality of the materials, may exhibit different strength and ductility over time depending on geometrical characteristics of the cross-section. Moreover, it has been found that the reduction of stiffness, strength and ductility of concrete members involves a deterioration of the seismic performance of the structural system, with increasing displacement/drift demand and reduction of the seismic capacity over time. These results confirm the importance to take the interaction between seismic and corrosion hazards into account and emphasize the need of a life-cycle approach to seismic assessment of existing structures and seismic design of new structures.

The Role of Critical Infrastructure in Community Resilience to Disasters

Scott B. Miles, Ph.D.[1]

[1]Resilience Institute, Department of Environmental Studies, Western Washington University, 516 High St, MS 9085 Bellingham, WA 98225. scott.miles@wwu.edu

ABSTRACT

This paper issues a call to improve the conceptual underpinnings of community resilience to disasters as it relates to critical infrastructure. It is argued that, broadly, infrastructure is the combination of both capital and services. Loss and recovery, and thus resilience, of infrastructure do not make practical sense without consideration of both. Specifically, infrastructure is characterized by its relationship to other infrastructure, agents, possible disruptions, possible interventions, jurisdictions and markets. Based on this and previous development work related to the resilience simulation model ResilUS, the beginnings of a new conceptual model are proposed. The comprehensive nature of the model suggests it is appropriate for planning purposes. The conceptual model provides opportunities for advancing ResilUS, specifically, and infrastructure and community resilience research and planning broadly. It facilitates the creation of a database schema for infrastructure loss and restoration and its impact on indicators of community resilience. Population of this schema will push understanding of community resilience and facilitate the development of better tools for supporting resilience planning.

INTRODUCTION

While resilience is still a contested concept, particularly related to communities and disasters, the contestation suggests perceived utility by a wide range of practitioners and scholars. There are many definitions of resilience. However, whether the topic is psychology, physics, engineering, or disasters, there is essential agreement around the capacity to handle and bounce back from stress – anyhow each of those goals are specifically defined or achieved. For community resilience to disasters (or disruptions in general), critical infrastructure resilience, specifically, is a core issue and arguably, a required capacity for the broader goal. Infrastructure, it is argued here, is the combination of both capitals (physical assets) and services derived from those capitals. Critical infrastructure resilience to disasters has gained considerable attention recently, but the conceptual models of infrastructure, resilience to disasters, and the connection between the two are underdeveloped. Without more robust conceptual models, empirical research, computational modeling, and community resilience capacity building is hindered. As an aside, the debate of what infrastructure is "critical" is not a focus of this paper, though is touched on briefly, and so the adjective is not used further.

Many conceptual models of infrastructure resilience, of the few specific ones in the literature, take a narrow focus. Often the focus is on structural, technical or functional aspects of the system. In doing so, the concept in many instances won't match peoples' needs or expectation for performance of infrastructure in response to disruption as they relate to their livelihoods and well being. Few are likely to consider, for example, that disrupted water infrastructure has been restored if the ruptured pipes are repaired but no potable water comes out of the tap. A telephone company will not bounce back from severed lines, if there is not enough demand for their service after repairs are made. If collapsed transmission towers are replaced but trained SCADA operators are not available to manage electrical distribution, customers probably won't consider their electricity provider as having recovered. A bridge damaged by a particular seismic intensity and built back to a lower seismic design load wouldn't be perceived as resilient to the same or greater hazard by engineers and planners. A final example might be a jurisdiction that ignores population growth needs for increased wastewater treatment capacity or redundancy, resulting in untreated discharge during a large storm event.

These contrived examples intimate that infrastructure and community resilience are influenced, and, as argued in this paper, specifically defined by a wide range of elements. These elements include at minimum the following: 1) the capital it relies on, 2) the services it is expected to provide, 3) the actors involved in its operation and management, 4) the disruptions it is designed for, 5) the resilience interventions that are possible, 6) demand from markets for it, and 7) the capacity of groups with authority over or responsibility for it. By developing a broader and deeper conception of infrastructure a wider range of community resilience interventions are possible.

The paper continues with a description of a conceptual model developed in part by the author to provide a point of departure for this call for the development of better conceptual models. The conceptual model provided the foundations for developing the community resilience simulation model ResilUS. The third section describes a greatly expanded conceptual model based on the ResilUS foundations as an artifact for further discussion and development. The paper concludes by redoubling the call for improved conceptual models of critical infrastructure resilience and a suggestion for future work on the conceptual model presented here, and more broadly.

RESILUS CONCEPTUAL MODEL

The work described here builds upon the conceptual foundations of ResilUS, a prototype simulation model of community resilience to disasters (Miles and Chang, 2011; Miles and Chang, 2007; Miles and Chang, 2006; Miles and Chang, 2003). ResilUS has two distinct versions, with evolution of both the conceptual and computational models. The complete specification (including citations, which are left out due to space constraints) of the first version is detailed in Miles and Chang (2004), the second in Miles and Chang (2006). The proposed conceptual model described in this paper is thus the beginning of a third evolution. It builds on the previous version, while integrating other contributions from the literature. The second version of the ResilUS conceptual model is described briefly to provide contrast with the proposed model and insight into possible elements that can be carried over.

ResilUS represents socio-economic agents – households and businesses – within particular neighborhoods, which are contained within a broader community (Figure 1). ResilUS represents damage and recovery associated with a hazard event to three elements of community capital – economic, human (or, for businesses, individual), and technological, which is limited to buildings and lifelines – transportation network, electrical network, water network and critical facilities.

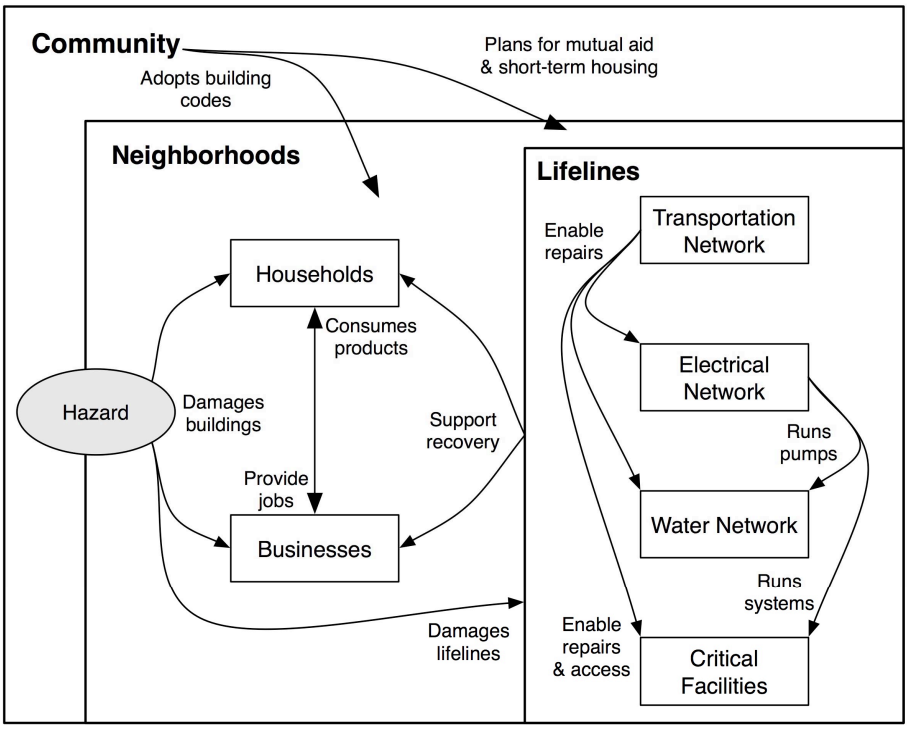

Figure 1. Simplified conceptual model of ResilUS.

ResilUS relies on two generic indicators of resilience – 1) ability to perform and 2) opportunity to perform associated with each hierarchical scale (community, neighborhood, agent). As stated above, the essence of resilience is avoiding loss and achieving recovery resulting from a disruption or hazard event. Figure 2 illustrates these two components of resilience. Resilience, of agents, infrastructure, or communities, is measured in terms of some indicator of performance (e.g., level of service, building stock, income, or gross regional product). A community's capacity to minimize the initial loss is referred to as robustness (Bruneau et al., 2003). As indicated in Figure 2, rapidity – the capacity to recover rapidly – comprises a second important metric of resilience (Bruneau et al., 2003).

Without a disaster, a resilience indicator will have some "normal" path with respect to time (Figure 2, Path A). In the event of a hazard event, the recovery time-path makes a great difference in accumulated loss, cascading effects, and, thus, well being. The indicator level may exceed pre-disruption performance (Path B) due to interventions such as effective recovery planning, mutual aid, or building back better. The indicator level may return to pre-disruption performance (Path C) or permanent losses may be suffered, resulting in a lower equilibrium (Path D). Most importantly, Figure 2 raises

the issue of how recovery is defined. Recovery can be defined based on a comparison between indicator time-paths "with" and "without" disaster or between "before" and "after." The former definition requires modeling what would have happened to the resilience indicator without the disaster; thus, the latter definition is simpler conceptually and computationally. In reality, community recovery is typically characterized by qualitative changes, adaptation, and restructuring, so that conditions don't return to pre-disaster states or merge with a no-disaster time-path. Currently, ResilUS models recovery as a return to pre-disaster conditions or levels (Path C).

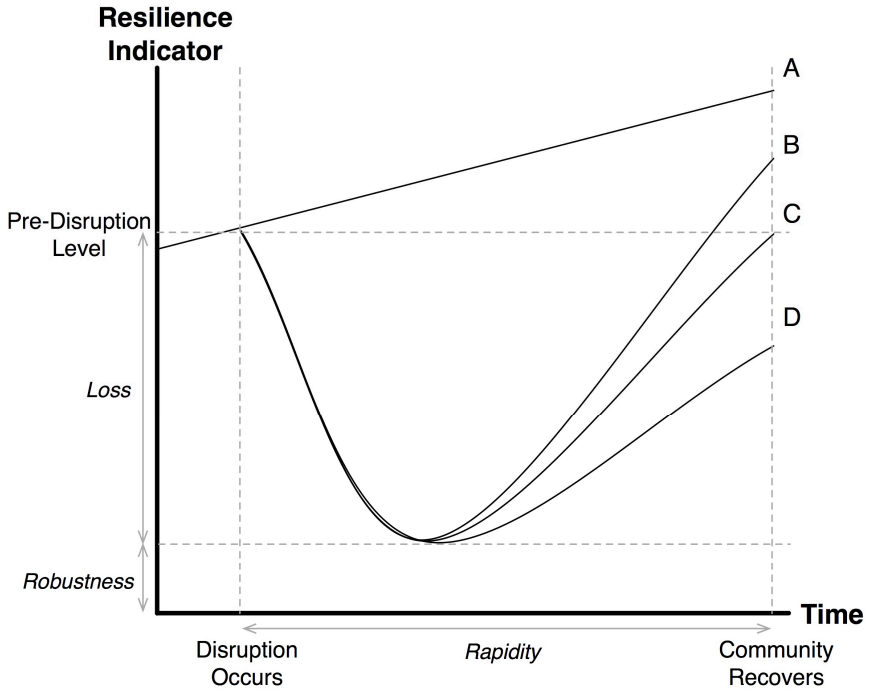

Figure 2. Schematic of community disaster loss and recovery – resilience.

The indicator of the ability to perform for households in ResilUS is represented by household health. Among other variables, health is directly influenced by availability of critical facilities and serviceability of shelter (either their own residence or short-term housing). Shelter serviceability is influenced by residence reconstruction and availability of lifeline services. Reconstruction time is influenced by the size (single-family vs. multi-family) of the respective building in addition to the construction capacity in the community. Reconstruction can only begin after inspections have been completed in the neighborhood, which is influenced by the quality of the preparedness plan, the recovery capacity of the community, and the recovery priority given to the neighborhood. Health influences a household's ability to pay off any incurred debt. ResilUS represents whether a household owns their residence. If they do not, they do not incur debt with respect to any reconstruction loans. The opportunity to perform is represented by employment level in their neighborhood and broader community. Employment influences a household's opportunity to pay off any

incurred debt. Debt is one of the main influences of whether a household is forced to leave their residence, neighborhood or community.

For businesses, the ability to perform is represented by a businesses' capacity to be productive (not necessarily economic productivity or throughput). The service level of a business's physical facility influences this capacity, which is in turn influenced by a combination of reconstruction and service restoration. Reconstruction time is influenced by the complexity or size of the respective facility, in addition to the construction capacity in the community. Again, reconstruction can only begin after inspections have been completed. The ability to perform is also influenced by community-wide health levels of households, the transportation network reconstruction level within the neighborhood, if the business's sector is locally oriented, or throughout the community if the sector is export-oriented. A business's ability to perform influences its ability to pay down incurred debt. Businesses do not incur debt from reconstruction loans if they do not own their facility. The opportunity to perform is represented by the demand for a business's product or services. Recovery of demand is influenced by some proportion of household debt within the respective neighborhood or the entire community, depending on the business's size. Demand influences a business's opportunity to pay down incurred debt, which in turn influences whether the business fails.

Whether an agent (household or business) is able to reconstruct their residence or facility is influenced by their financial resources – the sum of insurance, reconstruction loans, disaster aid in the form of grants, and pre-event savings. If the agent owns their building or facility, the maximum level of financial resources is implicitly related to the value of the building or facility.

Lifelines (infrastructure) are represented as a set of components (technological capital), with each component having attributes of construction age, maintenance level, component type, and degree of structural mitigation. Currently the model conceptually equates service restoration and component reconstruction. The time in which a particular lifeline component is reconstructed is influenced by the particular type of component (e.g., transformer vs. power line) and the infrastructure resources available in the neighborhood. These resources are influenced by the construction capacity in the community, quality of the preparedness plan, quality of mutual aid agreement the recovery capacity of the community, and the neighborhood's priority.

NEW CONCEPTUAL MODEL OF INFRASTRUCTURE AND COMMUNITY RESILIENCE

The previous section's description of the current conceptual model of ResilUS provides a useful starting point for developing a more encompassing, detailed, and integrated representation of the linkages between infrastructure and community resilience associated with disasters and other disruptions. While the proposed conceptual model can serve as a blueprint for improvement of ResilUS, its ultimate value is in spurring additional contributions to it, implementations of it towards an array of effective tools for fostering resilience, and alternatives to it. The proposed model is not fully integrated with many details of the ResilUS model. The contrasts

between the two models are clear, so much as there are conceived, but whether previous elements are carried over is far from settled and is not specifically described.

Figure 3 provides an overview of the proposed conceptual model. It describes general relationships within a community related to four components of resilience – community capital, services, agent well being, and community identity. The model starts on the left depicting the means and progresses to the right as evolving ends. In other words, infrastructure (the combination of capitals and services) is the means to the ends of agent well being and community identity (Monstadt, 2009; Little, 1999).

Capital refers to a stock of assets used to create or obtain additional assets and derive services. This concept applies to many types of assets including financial, ecological and social (Putnam, 2001; Daly, 1997). Community capital refers to any asset, whether corporeal or not, that a community requires for well being and identity (Fey et al., 2006). The classification and distinction of community capital vary in the literature. Here, six types of community capital are proposed for representing community resilience: human, social economic, political, natural, and technological.

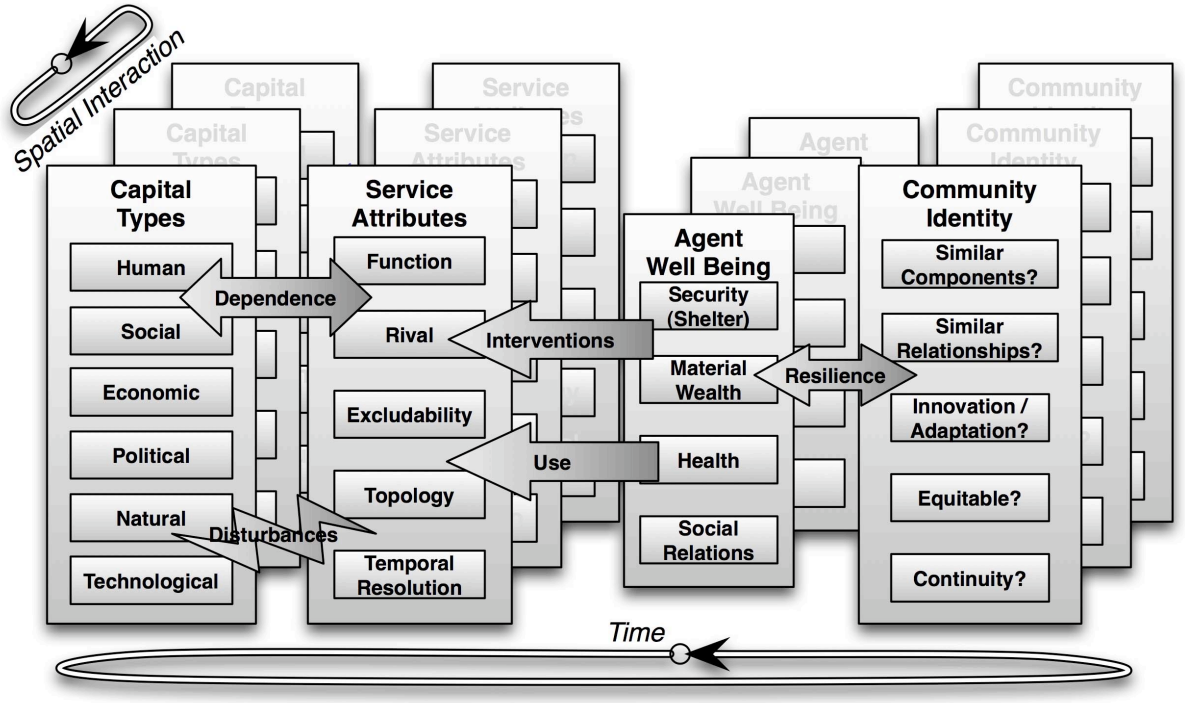

Figure 3. Overview of CRI conceptual model.

Well being and capital are linked by a complex set of relationships with mediating services, which produce waste (Costanza, 2000). The most significant relationships between capitals and community resilience are associated with provision and use of services, and by extension the avoidance of and recovery from disruption of these services. Services are measurable flows or perishable goods provided by or consumed by an agent. Social networks are a set of relationships of varying degree and characteristic to other agents, including markets for businesses. Different services require different types of capital (Olewiler, 2006; Millenium Assessment, 2005;

Olewiler, 2004; de Groot et al., 2002; Costanza et al., 1997). Services have attributes of rivalrousness and excludability, which influence the degree to which they are available to agents (Fisher et al., 2009; Frischman, 2005). Services have a distance from an agent, as well as a topological connection (or not), based on the location of the related capitals and agents (Fisher et al., 2009). Disturbance of services occur in various ways, primarily associated with damage to or loss of some capital (or service requiring that capital) (Beier et al., 2008). Disturbances are events with spatially varying intensity that have the potential to damage capital and/or disrupt services. Various interventions can be taken to protect, maintain, restore and substitute services, though this might manifest at the capital level. Interventions are pre-defined actions, plans, or protocols enacted by an agent. Services that cannot be substituted for are critical services; the capitals required for those services are critical capitals; the pairing of critical services and capital is critical infrastructure (Brand, 2009).

Well-being is associated with agents – individuals to any type of group or organizations. Capitals are accountable stocks that are managed, built, spent, or utilized by an agent. Agents are actors that have some relative degree of power at any scale, for example to use services, provide services, or take interventions. The constituents of well being are material wealth, health, social relations, and freedom (Leemans, 2009). The concept of freedom is provisionally considered out of the scope of this model. Well-being for agents is derived through a complex set of relationships with infrastructure and other agents within their community.

A community is any aggregation of agents that can refer to themselves as "members." This means that community is about identity and that a resilient community is one that can maintain some level of identity with respect to member agents (Pendall et al., 2007; Gillson, 2009). Different sets of conditions (e.g., different locations or topological connections) are associated with different possible states or thresholds between states. Identity is associated with a lack of change or similarity in components and relationships required to derive well being. This can also be extended to issues of equity and continuity. This all exists and occurs within and throughout time and space. It may take time for capital damage to result in any change in community identity; changes in one neighborhood or community may have effects in another neighborhood or community, the magnitude of which likely attenuates with increasing distance and scale.

There are seven proposed object classes (defined elements with attributes and functional capacity) for the conceptual model: agents, capitals, disturbances, interventions, jurisdictions, services, and social networks. These are fundamental, at minimum, to characterize infrastructure and community resilience. The relationships between these seven object classes are illustrated in Figure 4.

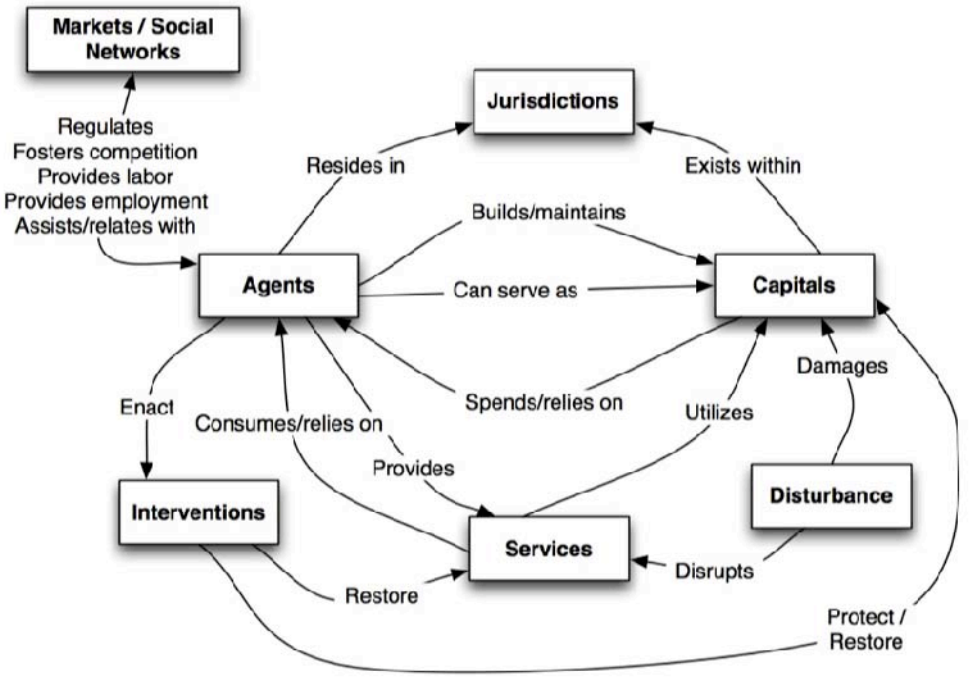

Figure 4. Functional relationships between proposed objects in a new conceptual model of community resilience.

Each object class shares a common set of attributes and actions (functions), which have not been fully specified to date, but will have some similarities with the current ResilUS conceptual model. Sub-classes of each have additional attributes, attribute values, and/or actions that make them distinct (e.g., pipe network vs. fiber optic network). An agent and its resilience is defined by 1) jurisdiction its required capitals and services are contained by, 2) the capital it has or relies on, 3) the services it provides, 4) the services it uses, 5) the markets that demand its services, 6) the possible disturbance it is vulnerable to, and 7) the interventions it can take and how they are implemented. (Jurisdictions are an entity associated with one or more boundaries that governs and/or contains agents.) Similarly, the universe of possible infrastructure types (sub-classes) and its resilience is defined by the logical combinations of the possible jurisdictions, capitals, services, agents, disturbances, and interactions. This topological definition is true for the other objects, as well.

Figure 5 illustrates how agents suffer loss and achieve recovery across both space and time, depending on the condition of community capital and the levels of services they depend on. Agents exist in some location at some point in time with some level of well being (attribute). Agent well being varies with time because of varying levels of required services, which in turn vary based on the conditions of necessary capitals .A disturbance event in a particular location (e.g., a neighborhood) can alter the agent's well being time-space-path because of service loss perhaps related capital damage. Service levels outside of the location are likely to be better, depending on scale effects and distance. This means that some agents may improve their well being by moving locations (either within the community or outside of the community), substituting services, or adapting to a state without those services.

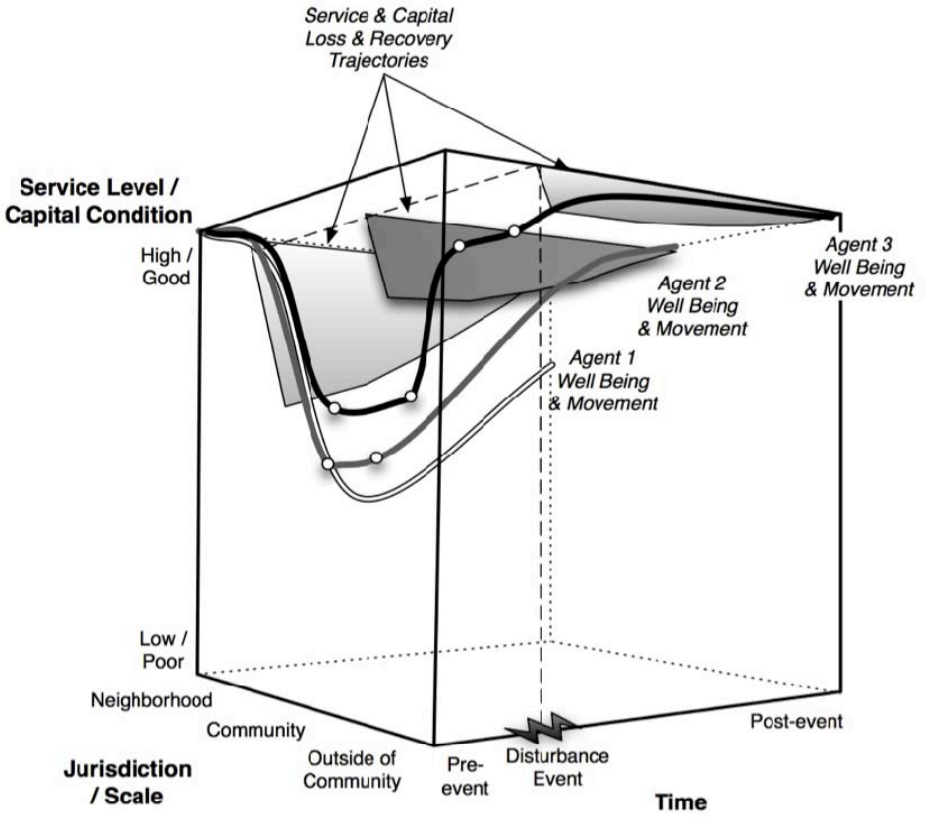

Figure 5. Agent resilience across space and time, as influenced by community capital condition and levels of services. The solid polygons represent resilience time-space-paths for infrastructure (capitals and services), while the lines represent time-space-paths for agents resilience. Points along the time-space-long indicate movement in space.

CONCLUSION

This paper has issued a call for other researchers and practitioners to improve the conceptual underpinnings of community resilience to disasters as this important topic specifically relates to infrastructure. It is argued that, broadly, infrastructure is the combination of both capital and services. Loss and recovery, and thus resilience, of infrastructure do not make practical sense without consideration of both. Infrastructure in the context of community resilience to disasters is defined by the relationship to other infrastructure, agents, possible disruptions, possible interventions, jurisdictions and markets. Based on this and previous work related to ResilUS, the beginnings of a new conceptual model have been proposed.

The comprehensive nature of ResiliUS and the proposed conceptual model make it appropriate for planning and awareness purposes. Many professionals – including emergency managers, but also extending to elected officials, urban planners, and the like – make decisions that intentionally or unintentionally influence community resilience. Yet many are unfamiliar with the research literature on factors that influence resilience. The conceptual model could be used to help educate these

stakeholders about empirical findings from disaster studies (e.g., what types of businesses have the most difficulty recovering from certain infrastructure disruption).

Such a conceptual model is daunting for implementation but can provide significant opportunities for advancing ResilUS, specifically, and infrastructure and community resilience research and planning more broadly. The conceptual model facilitates the creation of a database schema for infrastructure loss and restoration across time and space and its impact on indicators of community resilience. Population of this schema with time-series data collected from various size and types of events by researchers will push our empirical understanding. Analysis of such data will provide valuable insight regarding policies and plans to reduce infrastructure service disruption and the impacts of that loss on communities. It will also facilitate the development of new and better computational tools for supporting resilience planning.

ABSTRACT

This paper proposes a three-stage framework to analyze the smart grid resilience. In each stage, a series of resilience improvement strategies are introduced to realize the smart grids, and appropriate metrics are also identified and then combined to establish an annual resilience metric. Taking the power transmission grid in Harris County, Texas USA as case study, this paper establishes an original power grid model and several smart grid models to compare the effectiveness of resilience improvement strategies in different stages. Results show that the annual resilience of the smart grid with all three-stage improvements increases 0.035% compared to the original grid. Although the improvement is small in magnitude due to the high reliability of real power grids, it may save hundreds of millions of dollars. This framework can provide insights to design resilient smart infrastructure systems and retrofit present ones.

INTRODUCTION

Economic prosperity, national security, and public health and safety cannot be achieved without the continuous reliable operation of electric power grids. The concept of smart grid has been proposed to solve optimization, reliability and resilience problems existing in traditional grids (Roncero 2008; Pothamsetty and Malik 2009; Kothari et al. 2010; Garrity 2008; Suter and Werner 2009). The novel ideas and challenges in the realization of smart grids has attracted multi-disciplinary researchers and led to several technical and strategic studies in the past few years, including visions of the whole smart grid, from generation, to transmission and distribution, implementation and realization of smart grids, and applications of some specific technologies, such as energy storage and smart metering(National Energy Technology Laboratory 2008; Amin 2005; U. S. Department of Energy 2003; U. S. Department of Energy 2008; Lightner and Widergren 2010; Metke and Ekl 2010). Among these studies, there are few contributions on the resilience modeling and simulation of the smart grids, although resilience is an adequate property to describe power grid performance and quality of service under distinct operation conditions, and it synthesizes other concepts such as vulnerability, robustness, reliability, and recoverability.

Regarding the definitions of resilience, they vary by discipline and application. The ecologist Holling (1973) defined resilience at the system level as “a measure of the persistence of systems and of their ability to absorb change and disturbance and still maintain the same relationships between populations or state variables”. The U. S. Department of Homeland Security (2006) conceptualized resilience as “the capacity of an asset, system, or

network to maintain its function during or to recover from a terrorist attack or other incident". Also, the Multidisciplinary Center for Earthquake Engineering Research (MCEER) defined resilience as "the ability of the system to reduce the chances of shock, to absorb a shock if it occurs (abrupt reduction of performance) and to recover quickly after a shock (re-establish normal performance)" (Bruneau et al. 2003). In addition, Vugrin et al. (2010) proposed the definition of system resilience as "Given the occurrence of a particular disruptive event (or set of events), the resilience of a system to that event (or events) is the ability to efficiently reduce both the magnitude and duration of the deviation from targeted system performance levels". To sum up these definitions, resilience includes the aspects of resisting, absorbing and recovering from changing conditions.

To qualitatively or quantitatively analyze system resilience, researchers have proposed different methods. The MCEER proposed a conceptual framework to list three constituent features of a resilient system (Bruneau et al. 2003): low failure probability, low level of impacts, and high speed of recovery. Combining the MCEER's resilience metric, input-output models, and structural fragilities, Reed et al. (2009) introduced a simple methodology to evaluate engineering resilience and interdependency for subsystems of a multi-system networked infrastructure system under extreme natural hazard events. Other studies include Vugrin et al. (2010), who reasoned that system resilience should consider not only systemic impact which was defined as the difference between a targeted system performance level and an actual system performance following a disruptive event, but also the recovery cost.

Among these studies, Bruneau's works and Reed's works did not consider the aspect of recovery cost, and Vugrin's studies ignored the factor of "failure probability". In addition, they all defined the resilience under a specific disruptive event, which does not sufficiently reflect the ability of resisting changing conditions. Based on these existing definitions and studies on resilience, this paper introduces a three-stage resilience analysis framework, where resilience measures the ability of the system to resist, absorb and recover from one or many types of disruptive events, without aiming at a particular disturbance scenario.

The paper firstly introduces the three-stage resilience analysis framework. A series of resilience improvement strategies are proposed to realize smart grids. Then, taking the power transmission network in Harris County, Texas as an example, an original power grid model and several smart grid models are established to compute their resilience and compare the effectiveness of resilience improvement strategies in different stages. Finally, it offers the conclusions from this study and includes directions for future research.

THREE-STAGE RESILIENCE ANALYSIS FRRAMEWORK

This paper defines the resilience as the ability of the system to resist, absorb and recover from one or many types of disruptive events. To propose a framework for the resilience analysis, this section firstly introduces the system performance response process following a disruptive event, as shown in Figure 1. Under normal operation the system performance level is at 100%. However, when an initial failure occurs at point A, the damage propagates and the performance level drops to a certain value I, where 1-I is the maximum impact level. During or after damage propagation, an undesirable system state is detected and recovery resources are dispatched. After a period of recovery time, the system reaches a new steady state performance level at point B, which may be better or worse than its original state.

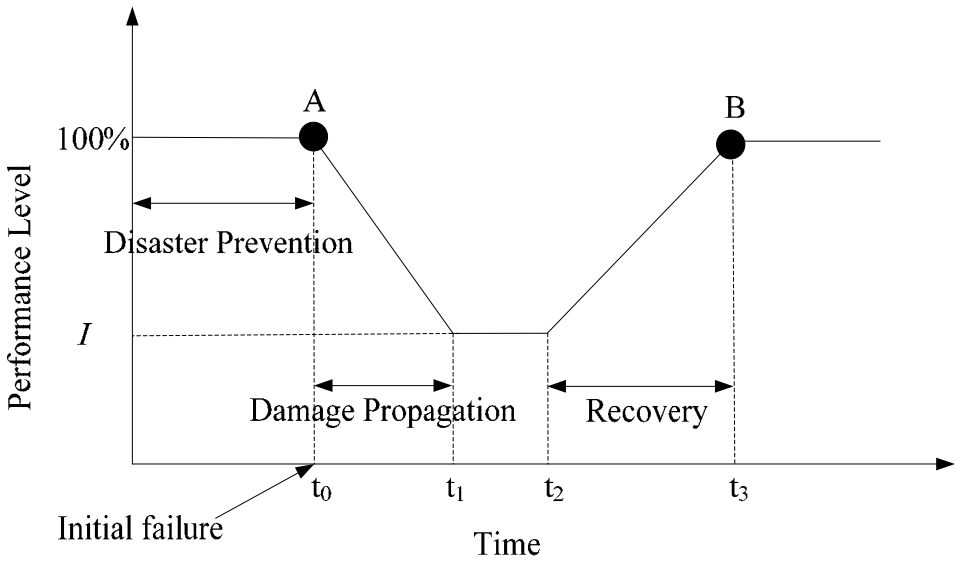

Figure 1: The performance response curve of a system following a disruptive event

Three stages

The performance response process in Figure 1 can be divided into three different stages. The first stage is the disaster prevention stage from the normal operation to the onset of initial failure; the second stage is the damage propagation process after the initial failures; the third stage is the recovery process during which resources are allocated to restore the system. These three stages can respectively reflect the ability of the system to resist, absorb and recover from disruptive events. This ability is just the definition of resilience. Hence, this paper explores resilience in three stages:

The first stage mainly reflects the system's resistant capacity. It is the ability of the system to prevent failures or reduce the initial failure scales (the number of initial failed components). In MCEER's seismic framework (Bruneau et al. 2003), as the seismic occurrence cannot be controlled, resistant capacity is only strengthened through reducing the component failure probabilities, which also means the reduction of initial failure scales. But under some hazard types such as human-related and organization-related failures, their occurrence frequencies can be reduced through various ways. The reduction of the expected hazard frequency also improves the resistant capacity. Hence, instead of the "failure probability" in MCEER's seismic framework, "expected hazard frequency" and "initial failure scales" together describe the resistant capacity and are taken as the resilience indexes in the first stage of the proposed framework.

The second stage mainly reflects the absorptive capacity. It is the degree to which the system can absorb the impact of initial failures and minimize the consequences by themselves. In this stage, the maximum impact level (the value 1-*I* in Figure 1) is used to measure the absorptive capacity and regarded as the resilience index in the second stage.

The third stage mainly reflects the restorative capacity. It is the ability of the system to be repaired quickly and effectively. Recovery time and recovery cost together represent the restoration capacity and characterize the resilience in the third stage.

Resilience improvement strategies

The three system capacities in different stages together determine the system resilience. To improve resilience, this paper identifies a series of strategies per each stage, which are also the ways to realize the smart grids. The main strategies are summarized in Table 1.

Table 1: Main strategies to realize the smart grid per each stage

Stage	Resilience Indexes	Resilience Improvement Strategies
First Stage	Expected hazard frequency; Initial failure scale;	• Identifying and hardening key components • Learning and Improving from previous accidents • Sensing and monitoring in real time and visualizing clearly • Improving decision support platform, staff training, cultures and organizations
Second Stage	Maximum Impact level;	• Adjusting infrastructure topology • Designing redundancy • Self-healing and self-adapting
Third Stage	Recovery time; Recovery cost;	• Improving situational awareness and decision support platform • Increasing available recovery resources • Establishing efficient communication channels and coordination

In the first stage, apart from the listed methods, there are still many other approaches to enhance the resistant capacity, such as adequate training, optimized decision support platforms and several other cultural and organizational factors, which can be all used to realize the smart grids. In the following case study, this paper only considers the random failures. To establish a smart grid model in the first stage, the new system is assumed to have reduced frequency of random failures due to using accident causation methods and adopting real-time monitoring for early warning.

In the second stage, there are also some other approaches to reduce the maximum impact level, but they vary per system type and tend to be more difficult to identify because they often rely upon the ingenuity of people faced with adversity (Vugrin et al. 2010). In the following case study, to establish a smart grid model in the second stage, the new system is supposed to have improved absorptive capacity due to the deployment of energy storages or emergency generators for a proportion of power load substations.

In the following case study, to establish a smart power grid model in the third stage, the new system is supposed to have improved recovery capacity due to improved situational awareness and availability of a decision support platform so that the recovery response is more rapid and the recovery sequences are optimized.

Resilience Metric

Combining the above resilience indexes, this subsection proposes a system-level metric to quantify the resilience. As the expected hazard frequency is one of the resilience indexes,

this paper introduces a time-dependent annual resilience metric. Under a specific disruptive event, the area between the actual performance curve and the targeted performance curve is affected by three resilience indexes: initial failure scales (affecting the maximum impact level 1-*I*), the maximum impact level (1-*I*) and the recovery time. So this paper takes this area (named "impact area" here) as a key parameter in the formulation of the resilience metric.

For a disruptive event with the hazard type h and initial hazard intensity $q^h \in [q_L^h, q_U^h]$, there is a probability distribution $\varphi^h(q^h)$ when events materialize at time t_0. With the amount of recovery resources R, denote the expected restoration curve (performance curve during the recovery process) by $P(t, q^h, R)$ and assume the system is totally restored at time $t_E(q^h, R)$. If the targeted performance curve during the recovery process is represented by $NP(t)$ and the expected hazard frequency is f^h, then the annual impact area (AIA) is expressed as follows:

$$AIA^h(R) = f^h \int_{q_L^h}^{q_U^h} \int_{t=t_0}^{t_E(q^h,R)} (P(t,q^h,R) - NP(t))\varphi(q^h)dtdq^h \tag{2-1}$$

The integral part of the equation (2-1) gives the expected impact area under a disruptive event with any possible intensity q^h, which when weighted by the expected frequency of the failure events f^h leads to the annual impact area. Then, the annual resilience (AR) metric is computed as follow:

$$AR^h(R) = \frac{\int_0^T NP(t)dt - AIA^h(R)}{\int_0^T NP(t)dt} \tag{2-2}$$

Normalizing the difference between the annual targeted performance area (the denominator) and the annual impact area leads to the annual resilience metric. T is the time interval of a year, and its specific value is determined by the unit of t in the performance curve. For example, if t is provided in a daily scale then T=365.

As equations (2-1) and (2-2) include the "recovery cost" (described by R), the expected hazard frequency (f^h) and the "impact area" (affected by the other three resilience indexes), the proposed resilience metric completely integrates the five resilience indexes in Table 1. Additionally, to obtain a global resilience metric under multiple hazard types, main hazard types should be identified so that the global resilience metric $GAR(R)$ is proposed as follows:

$$GAR(R) = \frac{\int_0^T NP(t)dt - \sum_{h=1}^{H} AIA^h(R)}{\int_0^T NP(t)dt} \tag{2-3}$$

Where H is the number of main hazard types. This paper only consider one type of hazards, so H=1 and the equations (2-2) and (2-3) are identical. However, if multiple hazards have been identified and modeled, the proposed framework can also calculate the global resilience according to equation (2-3).

CASE STUDY

This section takes the power transmission grid in Harris County, Texas USA as an

example to simulate its resilience and discuss its resilience improvements. The original power transmission system data is obtained from Platts (Platts 2009). Its geographical representation is shown in Figure 2, while the basic topological and geographical characteristics are illustrated in Table 2. The average degree aligns well with published values of 2.67 for the Western States power grid off the Rocky Mountains (Watts 2004).

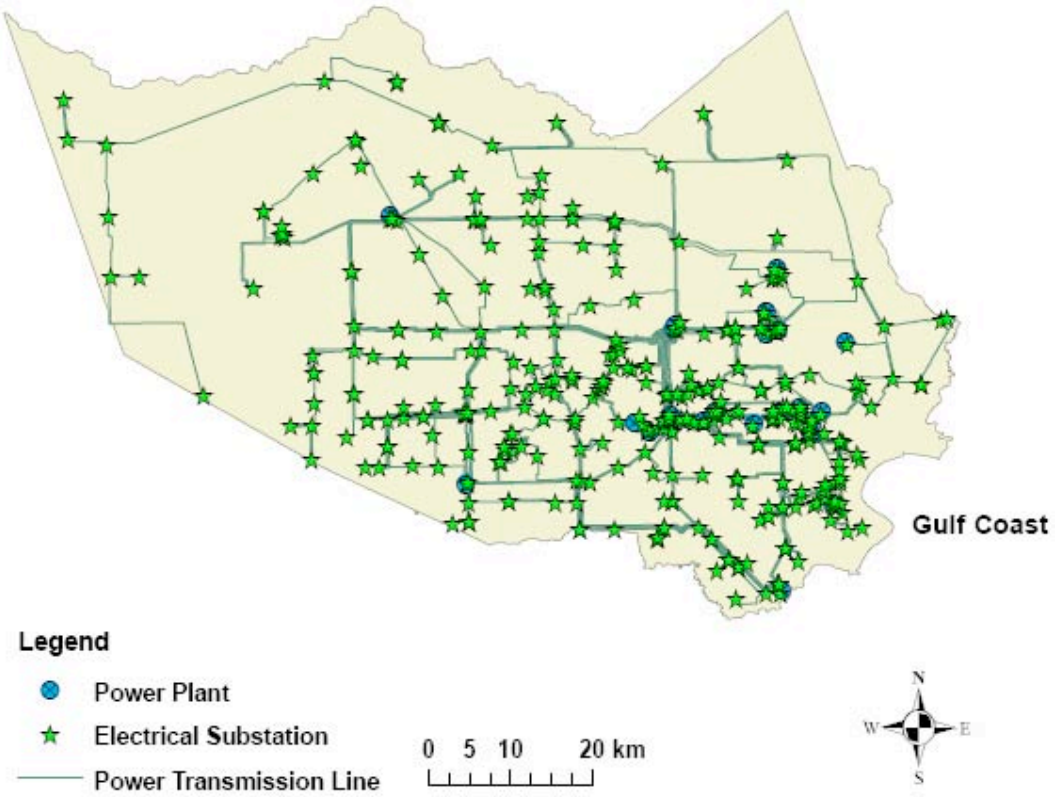

Figure 2: A geographical representation of the power transmission grid in Harris County, Texas

Table 2: Topological and geographical characteristics of the power transmission grid in Harris County, Texas

Number of nodes	Number of links	Average degree	Total edge length
417	551	2.64	2144.5km

Hazard modeling

To illustrate the proposed framework, this paper only considers random failures (h=1). To model random failures, available historical data are used to describe its frequency and the distribution of the hazard intensity (the number of initial failed components). Nationwide historical outage data includes failure records from all hazard types including some infrequent and high-consequences failures, such as hurricane, earthquake, which can cause extensive initial failures. However, due to their relative small frequency, they only slightly affect the distribution of the hazard intensity under random failures. In addition, this paper only considers forced or automatic outages because planned outages are known in advance.

An Institute of Electrical and Electronics Engineers (IEEE) survey of US and Canadian overhead transmission line outages for 230kV (Adler et al 1994) showed that the forced transmission line outage rate for 230kV was 1.25 per 100 kilometers-year (2.0 per 100 miles-year) averaged from 1965 to 1985. Among the 5 901 forced line outages, there were 3 692 (3 692/5 901=0.63) independent failure events and the number of *initial* outage lines in each event is well approximated by a power law with exponent -3.75 (Chen and McCalley 2005). Also, a particular data set recorded by a North American utility over a period of ten years showed that among 8 864 automatic line outages there were 5 227 (5 227/8 864=0.59) independent events, while the number of *initial* outage lines in each event was well approximated by a power law with approximate exponent -3.71 (Dobson and Carreras 2010).

The practical power-law character of the initial failures conflicts with the previous modeling of random failures by only an identical time-dependent failure probability for each component (Dobson et al. 2001; Anghel et al. 2007), which leads to a Poisson distribution of the initial failed components (hazard intensity). Hence, instead of simply using the "time-dependent failure probability", this paper takes the expected hazard frequency (the expected number of failure events per year) and the power-law distribution of initial failed components (hazard intensity) to model random failures.

According to the previous data, given the total transmission line length, the number of forced transmission outage for Harris County per year is computed by multiplying the average failure rate 1.25 per 100 kilometers-year, while the number of independent outage events is determined through a scale factor equal to 0.6. This leads the expected frequency of the "random failures" equals to 19. The distribution of *initial* failure intensity q^1 is assumed to satisfy a power law with exponent -3.7 as follows: $\Pr(q^1 = x) = 0.905x^{-3.7}$, $1 \le x \le 8$, where x is the number of initial failed lines that can lead to cascading outages. The range limitation of x describes the empirical small portion of initial failed components under random failures, and helps excluding the failure events from the infrequent and high-consequences failures subset.

Original grid and smart Grids

To analyze the effectiveness of resilience improvement strategies in each stage, this paper introduces an original power grid model and several smart grid models. To model the power transmission system response under a disruptive event, due to unavailability of power injection and line susceptance data, this paper uses a complex network betweenness model. Betweenness is a proxy for the amount of current passing through network elements, and it is computed as the number of shortest paths that pass through every node when connecting generators with load substations. A disruptive event can cause the failure of some power substations and alter the network topology, which further changes all substation betweenness scores. If a substation betweenness exceeds its maximum capacity defined as the product of its initial betweenness and a tolerance parameter (*tp*), this substation fails operationally. This model has been used to analyze the cascading failure process of many real power transmission grids, such as the North American Power Grid (Kinney et al. 2005), the Italian Electric Power Grid (Crutitti et al. 2004), and the IEEE 118 and 300 bus test systems (Dueñas-Osorio and Vemuru 2009).

To calculate the annual resilience metric, the key is to obtain restoration curves under different hazard intensities q^1 and different amounts of recovery resources R. To mainly discuss the effectiveness of different resilience improvement strategies, this paper doesn't consider the variety of resource types and the dynamic resource mobilization process, so R is simply modeled by a single value as an approximation of the reality. Also, for simplicity, each damaged component is assumed to require one unit of recovery resources. Figure 3 gives the flow chart to simulate the restoration curve $P(t, q^1, R)$ under given q^1 and R. The detailed set of procedures is illustrated as follows:

1. Calculate the initial node loads (betweenenss) and node capacities.
2. Simulate random failures under a given hazard intensity. Determine the number of initial failed component q^1 according to the power-law distribution, then randomly select q^1 lines to be failed and assign each failed line with the repair time, which is the sum of a variable ε satisfying uniform distribution [0, 3h] and a variable η satisfying exponential distribution with mean value 5h (The parameter settings are based on Anghel et al. (2007)). The variable ε describes the traffic time for dispatching resources and η is the time to restore the failed components.
3. Remove the failed components from the network and recalculate the node loads.
4. Find the failed components with loads exceeding their capacities. If failed components exist, assign them with the repair time, which is still assumed to be the sum of ε and η, and then go to step 3; otherwise, go to step 5.
5. Calculate the performance metric (the proportion of normal operating nodes is taken as the metric in this paper), whose value is also the maximum impact level. Mark the time t as t=0, which is the start time of the restoration curve. This paper assumes the damage propagation is instantaneous and ignored due to the rapid power flow. Hence, at the time 0, the performance level sharply decreases to the maximum impact level from the normal performance level.
6. Move forward the time t=t + response time, where response time is the time for failure detections and restoration decisions.
7. Allocate the recovery resources R to the unrestored components according to the recovery sequences (the time order to restore the failed components).
8. Move forward the time t=t+1.
9. Find the restored components with their repair time reaching the set values. If restored components exist, release the recovery resources and reallocate them to unrestored components, and then go to step 10; otherwise, and go to step 8.
10. Reconnect the restored components, and calculate the new network loads. If it leads to new overloaded nodes, cancel the reconnections, go to step 8; otherwise, go to step 11.
11. Get the new network topology, record the simulation time and calculate the performance metric.
12. Assess whether all components have been restored. If it is true, go to step 13; otherwise, go to step 8;
13. Plot the restoration curve under the given hazard intensity.

Repeat the procedures from 1-13 for 500 times to obtain the expected restoration curve under given q^1 and R. Based on the flow chart in Figure 3, some details of the original power

grid model and the smart grid models in each stage are introduced as follows:

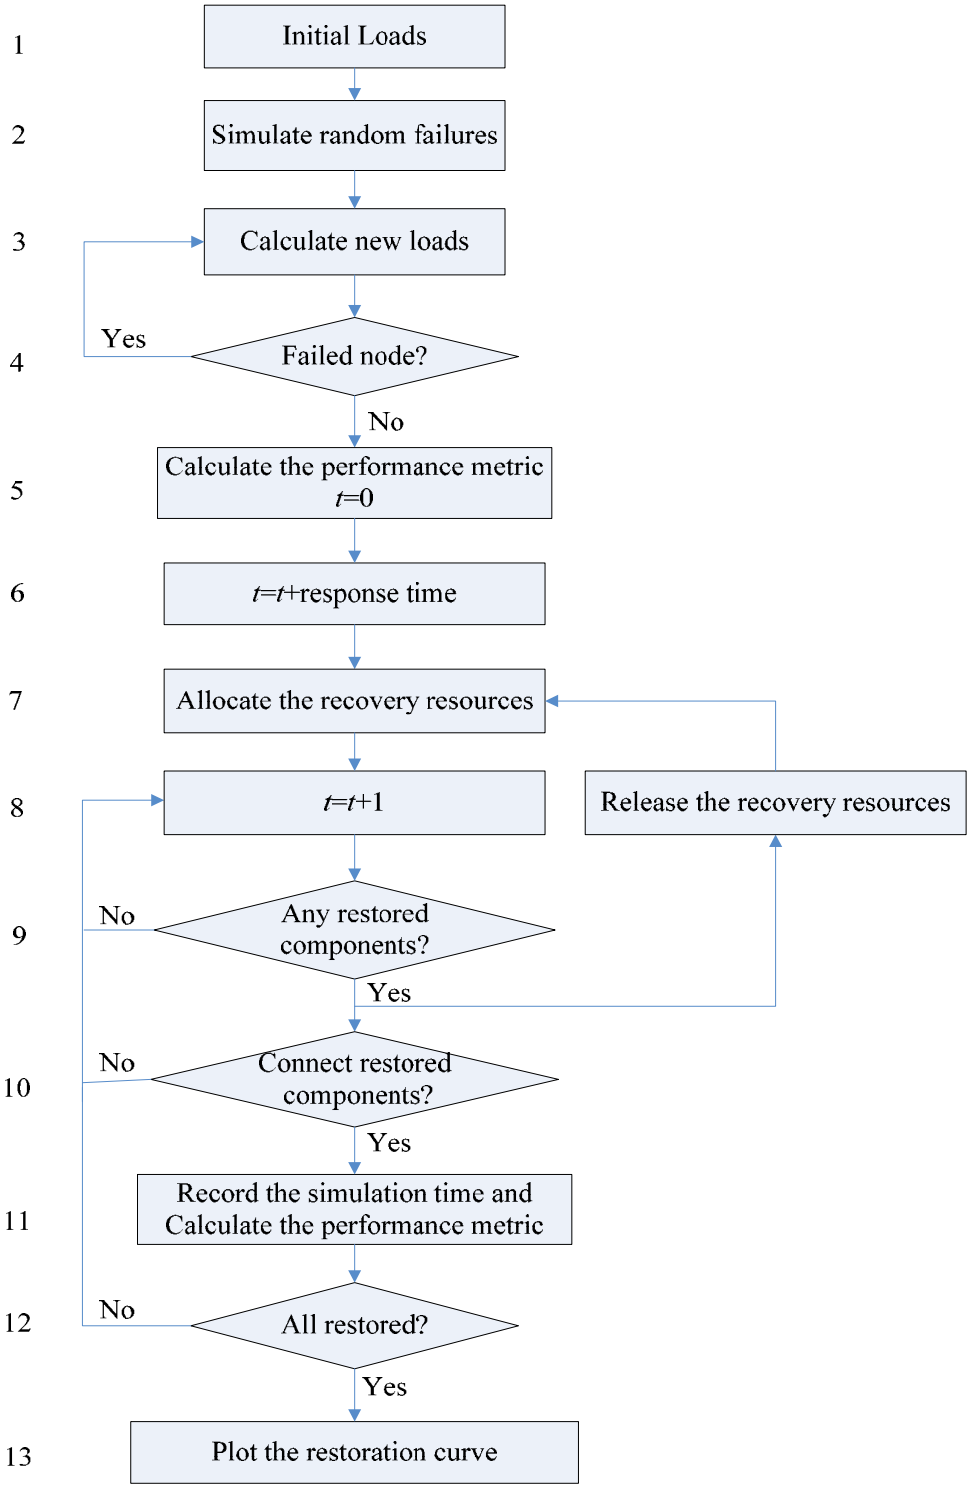

Figure 3: Flow chart to simulate restoration curves

In the first stage, compared with the original power grid, the smart grid has reduced frequency of random failures from 19 to 17.

In the second stage, compared with the original power grid, the smart grid is deployed

with energy storages or emergency generators for 10% critical substations as an approximation of the reality to illustrate the framework. These substations are identified according to their maximum topological degrees, and can still work normally for a period of time (assume 24 hours as an approximation of the reality) after their failures.

In the third stage, compared with the original power grid, the smart grid has shorter recovery response time and better recovery sequences. For the original power grid, the response time is 4h and the recovery sequences are determined randomly. These parameter settings are based on practical experiences from the power companies (Centerpoint Energy 2008). The failures are usually reported by inefficient channels, such as phones by customers. This leads to large delay for failure detections by operators and also incomplete information on all existing failures, which makes the recovery sequences are not optimized and usually based on the time order of the reports of the failures. Hence, this paper models the recovery sequences by random sequences as an approximation of the reality. For the smart grid, the response time is only 1h and the recovery sequences are selected according to the maximum node and link betweenness. The larger the component betweenness, the closer its topological distance (shortest path length) with the generators, and its priority restoration is heightened.

According to above assumptions, this paper considers five system cases to analyze and compare the effectiveness of the offered improvement strategies in different stages. Case 0: the original grid; Case 1: the smart grid with resilience improvement in stage 1. Case 2: the smart grid with resilience improvement in stage 2; Case 3: the smart grid with resilience improvement in stage 3; Case 4: the smart grid with resilience improvement in all three stages.

Simulation Results

This subsection analyzes the annual resilience of five system cases and compares the effectiveness of different resilience improvement strategies.

Restoration curve

For any fixed amount of recovery resources, the restoration curve is simulated under any given hazard intensity. When the amount of recovery resources is 30, Figure 4 shows typical simulation results under 3 initial failed links.

Case 1 enhances the resistant capacity to have reduced frequency of random failures. Its restoration curve is overlapped with the original grid (Case 0). This is because the restoration curve is to aim at the specific disruptive event, and cannot present the effects of the frequency of these events.

Case 2 improves the absorptive capacities to have energy storage units or emergency generators for critical substations (redundancies). Its restoration curve shows the decreased maximum impact level and the enhanced curve during the redundant periods (24 hours or 1 day). After depleting the redundant capacities, its performance level decreases to be the same as that of the original grid.

Case 3 improves the restorative capacity to have rapid recovery responses and better recovery sequences (betweenness-based). The restoration curve clearly shows the effectiveness of prompt responses, components start to be restored after 1 h but it is 4h for the original grid. The effectiveness of better recovery sequences is clearly shown in the Figure.

The recovery speed (the slope of the restoration curve) increases, and the impact area decreases considerably.

Finally, when all three-stage improvement strategies work together (Case 4), the impact area reduces by almost 50% compared with that of the original grid. Adopting better recovery sequences contributes the most to the resilience improvement.

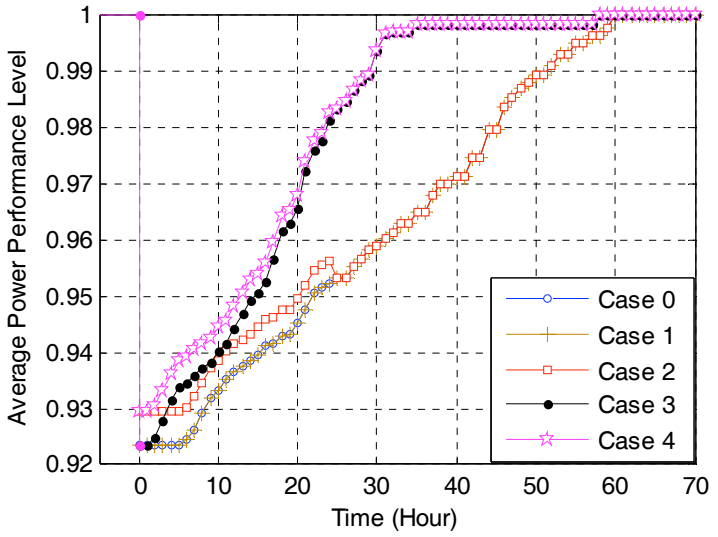

Figure 4: Expected restoration curves under 3 initial failed lines and 30 units of recovery resources.

Annual resilience

For any fixed amount of recovery resources, according to the restoration curves in Figure 4, the impact area is calculated. Further, taking the expected hazard frequency and the distribution of the initial failure intensity into consideration, the annual impact area is computed, and then the annual resilience is calculated according to Equation (2-2). Figure 5 shows the results.

With the increase of the amount of the recovery resources (R), the annual resilience increases for each case, and finally reaches a steady value. Deploying redundancies is the least effective strategy (Case 2) due to the small redundant capacities. Adopting better recovery sequences (betweenness-based sequence) (Case 3) is the most effective strategy, particularly under limited recovery resources. Specially, when the amount of recovery resources is only 10 units, the improvement magnitude (relative to Case 0) of the annual resilience of the system Case 3 is 25 times that of Case 2 and 4.4 times that for Case 1. Under sufficient resources, the improvement magnitude becomes smaller and it is only 2.7 times that for Case 2 and 1.6 times that for Case 1. If taking the cost of different strategies and the budget limitations into consideration, the proposed analysis framework can provide the way to find the most effective strategy to improve the resilience.

When the three-stage improvement strategies work together, the improvement magnitude relative to the original power grid is only 0.035%. It is small, but the saved economic loss may be significant. This is because if substituting the number of normal operating nodes by the number of customers without outage, the annual resilience metric is

tantamount to a power reliability metric used in the industry---the Average Service Availability Index (ASAI), which is the ratio of the total number of customer hours that service was available during a given time period to the total customer hours demanded. The reliability of the U.S. power grid (the total line length of the transmission grid is 300,000km) is 99.97%, and the 0.03% unreliability can cost the economy $150 billion every year (NIST white papers 2010). The length of power transmission grid in Harris County is 2144.5km, according to the length ratio (2144.5/300 000=0.007), small improvements of the annual resilience may still save hundreds of millions of dollars.

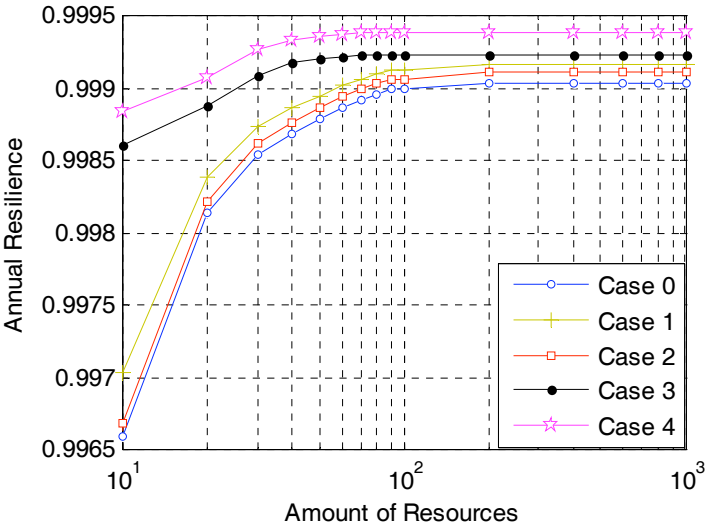

Figure 5: Annual resilience as a function of the amount of recovery resources for different system cases.

CONCLUSIONS

This paper proposes a three-stage framework to analyze the smart grid resilience. Taking the power transmission grid in Harris County, Texas as an example, this paper establishes an original power grid model and several smart grid models to compute their resilience and compare the effectiveness of the improvement strategies in different stages. Results include that under limit availability of recovery resources, adopting better recovery sequences (betweenness-based) is the most effective strategy. Under sufficient availability of recovery resources, reducing failure frequency, deploying with redundancies and rapid recovery response are all effective. The annual resilience of the smart grid with all three-stage improvements increases 0.035% compared to the original grid. The improvement magnitude is small, but it may save hundreds of millions of dollars.

Details in the proposed framework should be studied further and complemented in the future. First, this paper only considers one hazard type, identifying other hazard types, such as hurricane hazards, and then to calculate the global resilience will be the future direction. Second, as there are many performance metrics, such as connectivity, maximum flow and energy served, various resilience metrics can be formulated to reflect system resilience from different aspects. Second, this paper only considers a few resilience improvement strategies

in the case study, while other strategies (mentioned in Table 1) together with their estimated cost can be explored to find the optimum retrofit strategy under limited budget.

Conceptual and Analytical Differences between Resiliency and Reliability for Seismic Hazards

Ross B. Corotis[1], F.ASCE, NAE, PE

[1]Department of Civil, Environmental and Architectural Engineering, University of Colorado at Boulder, 428 UCB, Boulder, CO 80309-0428; PH (303) 735-0539; FAX (303) 492-7317; email: Corotis@colorado.edu

ABSTRACT

A distinction is made between the reliability of a structural system and its resilience. The former is generally measured probabilistically, evaluated by means of computer algorithms capable of handling multiple failure modes, and forms the basis of design codes. Resilience must incorporate the time history of performance following significant disturbance, include imprecise definitions and evaluations, and reflect the effects of system performance (physical, economic, social and political) on the community served. Reliability analysis, including code calibration, has generally been the purview of structural engineering risk professionals. Resilience, on the other hand, should integrate community input on the degree of inconvenience and time trajectory of recovery, even incorporating concepts of sustainability. Resilience must often use generalized uncertainty, including fuzzy logic, to transform societal goals into metrics, and recognize sensitivity to sources of uncertainty in terms of acceptance of diminished performance. At a minimum, this requires keeping epistemic and aleatory uncertainty separate.

INTRODUCTION

There are many different definitions of resiliency that have become popular within the last few years. A workable one developed five years ago by the U.S. Subcommittee on Disaster Reduction (2005) is as follows:

> "The capacity of a system, community or society potentially exposed to hazards to adapt, by resisting or changing in order to reach and maintain an acceptable level of functioning and structure. This is determined by the degree to which the social system is capable of organizing itself to increase this capacity for learning from past disasters for better future protection and to improve risk reduction measures."

The Subcommittee on Disaster Reduction goes on to say, "Disaster-resilient communities experience minimum disruption to life and economy after a hazard event has passed." A simpler definition of resilience was proposed a year later by the U.S. Department of Homeland Security (2006):

> The capability of an asset, system or network to maintain its function or recover from a terrorist attack or any other incident."

Other definitions of resilience refer to mitigating risk and containing the effects of incidents, including recovery activities and social disruption. Some (San Francisco Planning and Urban Research Association, 2009) even address the issue of the ability of communities to govern after a disaster, including following existing building codes and providing basic infrastructure services, including the ability for people to move about. This last study sets a time goal of weeks for basic services and a few years for a re-established normality.

Resilience will be defined in this paper as the capability of a system to maintain acceptable levels of service in the face of shock, misfortune or significant disturbance, or to recover within an appropriate period of time. This concept is quite distinct from reliability. Reliability is a probabilistically-based measure of the ability of a system to perform its required functions under specified conditions and periods of time.

In order to pursue a quantitative analysis of resilience, it is first necessary to quantify such linguistic terms as *acceptable* service, *appropriate* recovery and *shock*. It is then necessary to move beyond the probabilistic principles that form the basis of reliability analysis and recognize the need to incorporate concepts of generalized uncertainty, including imprecise probabilities and linguistic and fuzzy logic. In addition, assessment of resilience depends on reliability, or functionality *of the system*, and, crucially, focuses on the requirements *of the community served* and the ability to meet these requirements throughout the recovery trajectory. Incorporating the full recovery time history of the community functionalities is an important aspect of resiliency.

Some aspects related to resiliency that are worthy of additional consideration include the development of multiple levels of resilience, related to different degrees of severity of events, and the balance between mitigation and preparedness. Worthy of note is the fact that resiliency encompasses performance in the post-disaster period, while risk and reliability focus on measures such as expected economic loss, mortality and morbidity. Often resilience also incorporates the setting of goals and the development of plans and processes.

At its foundation, the role of infrastructure systems is to enable society to perform its economic, social, cultural, political, mobility, communications and quality of life functions (Tierney et al., 2001; Kahneman and Tversky, 2000). Resiliency must address the capability of systems to provide acceptable levels of service in the face of

impending threats, including extreme events such as earthquakes or other hazards. The understanding of service level resiliencies and impact on community function lays the basis for new decision support methodologies (Corotis, 2007).

STRUCTURAL RELIABILITY

Over the past 40 years the field of structural reliability has matured to the point where efficient computer algorithms are available to evaluate the reliability of structural systems with multiple, correlated failure modes (Bucher and Bourgund, 1990; Der Kiureghian et al, 2006). Concomitantly, design codes have incorporated probabilistically-based load and resistance factor formats based on first and second order reliability methods.

Despite the terminology of strength design and the advancements in seismic engineering of considering modal behavior, current design approach procedures still reduce to member-by-member proportioning without sensitivity of the selected design to failure modes, or certainly their impact on the overall integrity or functionality of the structure. Research on systems analysis and progressive collapse have improved detailing for structural performance (Ellingwood, 2006), but still wanting is direct integral incorporation of the sustainability of the structure in the light of planned and unforeseen loads. Recent research reported by Nishijima and Faber (2009) addresses sustainability in a general engineering decision analysis framework.

RESILIENCE AND RELIABILITY

The concept of structural resilience must be integrated into reliability analysis such that the whole approach to structural seismic design becomes one of the tradeoff of investment in the structure with its sustainability for its intended purpose. Even beyond that, the integrity of the structure in terms of its role in the resilience of the community itself is incorporated in a heuristic fashion (ATC, 1991). Inherent in such an approach is the sensitivity of the performance of the structure to such issues as epistemic uncertainty in the load environment, including low probability high consequence events, and even black swans, or seismic events not directly considered in the design (Taleb, 2010). Even in seismically active regions, current design is based on examining multiple load combinations, and designing each element for its "most critical" combination. Lacking has been the sensitivity of the final design to alternatives, for example unexpected deviations in flood or wind loads on a structure whose final design has been dominated by an assumed earthquake load.

Community resiliency is affected by the performance of coupled infrastructure systems (*Infrastructure Resiliency Guide*, 2007; Teirney and Bruneau, 2007). The basic concept of resiliency is illustrated in Figure 1 (in which the projected trajectory, for the sake of simplicity, is shown as a straight line). For various specific and measurable activities of a community (such as economic production level, access to critical facilities, cultural events and housing starts), the performance will be traced as a function of individual and coupled infrastructure systems along with associated

incidences. As Figure 1 illustrates, each activity will be immediately affected by a particular incident, after which the recovery of the infrastructures and the resiliency of the community will create a unique recovery trajectory. The area below the dashed line and above the actual activity curve represents an integrated measure of activity loss to the community, complicated by the fact that after the recovery the activity level may be higher or lower than the pre-event trajectory. It is clear from this comprehensive approach that the expertise required for deriving resiliency measures needs to be cross-disciplinary, combining engineering theory, mathematical modeling and social/behavioral science aspects (*Critical Thinking: Moving from Infrastructure Protection to Infrastructure Resilience*, 2007). The activity represented in Figure 1 could be economic, but it could also be the level of a utility service.

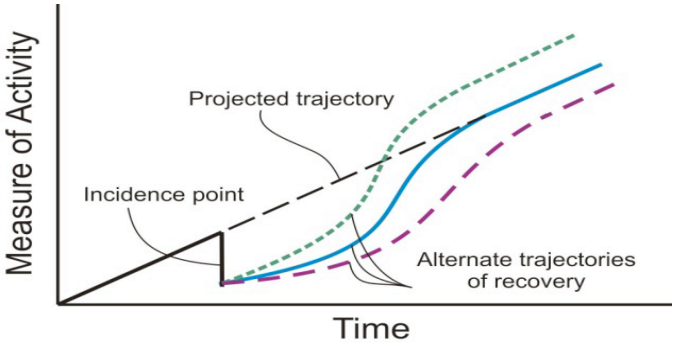

Figure 1. Community activity and recovery over time

Strategies to address resiliency following extraordinary events can be expected to range from constituent system and component upgrades and redundancy provisions, to coupling-decoupling strategies and de-rating actions to ameliorate stress on susceptible infrastructure elements, and even to enhanced situational awareness and preparedness training. Techniques for dealing with events such as shock, misfortune or significant disturbance cannot be limited to the usual approaches to systems reliability or risk assessment. Indeed, such events are often referred to as black swans, and by their very nature are unknowable and therefore unquantifiable in detail. This does not mean, however, that systems and procedures cannot be developed to prepare for and ameliorate losses following such events. As Taleb (2010) in his book specifically on black swans says, "We do not understand the future – but that is not necessarily bad news. We could plan *bearing in mind such limitations*." Even without explicit knowledge of event occurrence probability, forward thinking approaches to system resilience can help to mitigate adverse community impacts.

RESILIENCE AND COMMUNITY INPUT

One of the key differences in developing strategies for resilience in the face of unusual events is the necessity of more extensive incorporation of public involvement and political decision making. Indeed, while there is the need for better communication from the science and engineering community to the broader community, a successful roadmap for investment into more resilient infrastructure

systems requires a much more participatory approach. One of the reasons for this is that people in general behave as if events further into the future are less likely to occur, even if they have the same probability of occurrence as those in the near term (Smithson, 2008). Smithson goes on to point out that, "Professionals, politicians and risk managers must also contend with stakeholder perceptions of uncertainty and the competing interests." Therefore, projects advancing the knowledge of resiliency must be cognizant of this unique dependency between science and society. The situation is well stated by Pidgeon (2008): "Establishing a workable consensus is not merely a matter of educating the public about expert knowledge. Input from the public is valued for its contribution to 'social rationality,' which encompasses matters of preference, culture, values and ethics. Representations can indeed be anchored in probability and consequence, but at times also accommodate culture, context, politics and values [leading to] two-way analytic-deliberative processes." The time has come for a deeper understanding and collaboration between the structural engineering profession and the behavioral and social science discipline in assuming a broader perspective and responsibility for communicating the performance and limitations of the built environment to the public at large, as well as taking a central role in discussions of societal choices and trade-offs (Corotis and Enarson, 2007; Tierney, 2006). Significant advancement in the field of earthquake engineering has recently been developed in this area, including the Great Southern California Shakeout (Wald et al, 2008) and PAGER for the USGS (Porter, 2008).

A challenge for resiliency that must be addressed is that of the possibility of irrational distortion of decision-making when discussing issues of unforeseen hazards. Smithson (2008) points out that, "The core concern is whether risk communication produces (in)appropriate intensification or (in)appropriate attenuation of public risk fears." Even without such distortion, it is important to understand that the rationality understood by technologists is not the same as the rationality that drives political decisions (Corotis, 2005). Furler (2008) notes that political leaders "are focused primarily on managing…in such a way as to ensure the government retains office at the next election." This can be stated even more succinctly: "Politicians sell certainty. Science lives off doubt." (The Economist, 2009).

STRUCTURE RELIABILITY, ROBUSTNESS AND CODE DESIGN

The ASCE Standard (ASCE, 2010) has been a national leader in transforming probabilistic safety concepts into codified form for seismic design. The goal of building codes has been the protection of life safety, by ensuring either the survival of a building or at least a level of performance that promotes life protection and safe evacuation. Codes focus on the performance of individual structures and of life safety, but often do not represent comprehensively community conditions prevailing at the occurrence of earthquakes (or hurricanes, floods, tornadoes, or other natural hazards).

The concept of varying importance of individual structures already exists in codes, but the primary considerations in the selection of an importance category are the potential number of people at risk within the structure, the role of the structure in

disaster response, and the potential for the release of hazardous materials. In the ASCE Standard (ASCE, 2010) the importance category is used for the design of structures to resist earthquakes and other natural hazards, and the concept should be extended to consider the safe evacuation of people from buildings and the effect of continued functioning or non-functioning of the building. Standards and codes currently in use do not take into account the importance of structures with respect to community capacity to withstand the shocks of natural disasters or community vitality in the aftermath of disasters (Ellingwood et al, 1993).

It is also important to understand the relationship of how buildings are actually used, and with what significance for hazard mitigation, emergency preparedness, and disaster response and recovery. Beyond the stated purpose considered in structural design, there are often multiple uses and informal uses throughout a building's history that may greatly alter the impact on a community to damage or loss of a building (Corotis, 2002; Wen, 2001). Loss of a building's instrumental or operational value is self-evident but loss of social or symbolic value also affects the surrounding community. These considerations might, but do not presently, help determine land use planning, siting of buildings, relative safety of buildings implicit in existing building codes, and priorities for retrofitting projects.

The widely accepted approach to structural reliability is based on the methods developed by the Joint Committee on Structural Safety (JCSS, 2008; Faber et al, 2007). In this framework, the direct risk is given by

$$R_D = \sum_{k=1}^{n_{EXP}} \sum_{l=1}^{n_{CSTA}} p(C_l / EX_k) C_D(C_l) p(EX_k) \quad (1)$$

In which $\boldsymbol{R}_D$ is the risk due to direct consequences, n_{EXP} and n_{CSTA} are the number of exposure events and constituent damage states, respectively, $p(C_l/EX_k)$ is the probability of damage to constituent C_l given exposure to hazard event k, and $C_D(C_l)$ is the direct consequence for constituent C_l.

Considerations of resilience must consider the indirect structural risk, which is given by the following formula

$$R_{ID} = \sum_{k=1}^{n_{EXP}} \sum_{l=1}^{n_{CSTA}} \sum_{m=1}^{n_{SSTA}} C_{ID}(S_m, C_D(C_l)) p(S_m / C_l, EX_k) p(C_l / EX_k) p(EX_k) \quad (2)$$

In which n_{SSTA} is the number of different indirect consequence states associated with each constituent, and $C_{ID}(Sm, C_D)$ is the indirect consequence for state Sm for constituent C_l.

ALTERNATIVE MEASURES OF UNCERTAINTY

In the context of resiliency the traditional probabilistic and statistic-based models of likelihood and possibility are not in themselves sufficient to deal with the uncertainty inherent in resilience for shock, misfortune or significant disturbance. Instead, the concepts of generalized uncertainty are necessary (Klir, 2006). The situation at the

heart of resiliency is that theorized by Kasperson (2008): "But where highly complex systems with extensive connectivity and interaction exist …alternative approaches to coping with uncertainty must be found [that include] newer, more holistic and integrative assessment." One of the cornerstones for advancement in resiliency analysis is the further development and application of the principles of generalized uncertainty. Classical probability theory is very powerful and can address many situations in the decision rhetoric, but must be built upon further to address resiliency. When combined with utility theory, probability forms the basis of optimal decision theory, developed over 50 years ago (von Neumann and Morgenstern, 1944) and refined by Haimes (2004).

For practical societal decisions, it has been convenient to distinguish various sources of uncertainty, recognizing that a deeper understanding can be obtained by not combining all sources of uncertainty into one probability measure. For this reason, hazards analysis should distinguish between epistemic and aleatory uncertainty, reflecting such distinctions as inherent randomness, parameter uncertainty, and even model approximations and shortcomings (Corotis, 2003; Ellingwood, 2001). For many sociological applications of uncertainty it has been necessary to extend classical probability theory to fuzzy logic, incorporating linguistic variability. For other cases, the use of subjective probability, which pre-dates frequentist definitions but was out of favor for many decades, is necessary to capture uncertainty (Vick, 2002). Yet these modifications of classical probability theory still often fail to represent the total degree of uncertainty in many practical situations. When converting linguistic information into uncertainty measures, it is necessary to introduced generalized measures, or imprecise probabilities (Klir, 2006).

This introduction of imprecise probabilities allows the use, for instance, of multiple joint distributions when only the marginal distributions of the variables are known from observation. The identification and propagation of sources of uncertainty are necessary to quantify resiliency of structural infrastructure via metrics of community activity, relating the consequences of performance of structures during seismic events. The extrapolation of such approaches as probabilistic methods, fuzzy logic and imprecise probabilities is yet to be fully explored for both generic and real systems in the context of interdependent urban infrastructures' ability to absorb shock, service the community, and restore activity. The characterization of uncertainty in infrastructure resilience metrics is anticipated to be critical.

STRUCTURAL RESILIENCE AS A TIME-VARYING PROCESS

The concept of structural resilience can only be considered comprehensive when characterizing the performance of the structure over time when subjected to unforeseen events. Metrics are needed for the performance of a structure with respect to intended functions under realistic alternative environments (Tao et al, 1995; Wang et al, 1995; Taleb, 2010.

As described in an opening section, structural (as well as community) resilience must be evaluated in a pre-posterior fashion as a time-evolving response to the demands of the environment. In the case of structural function, it is necessary to define the essential functions of buildings, and not just their occupancy for design code purposes. In addition to considering alternate uses as well as possible changes over the lifetime of the structure, it is important to recognize that short and long term objectives of recovery of activities following a disaster are often distinct (Graham, 2007).

Considering the time period following a disaster, the first three days are usually focused on emergency response, and the first week on adding emergency shelter and the beginning of infrastructure service functions. The first month continues the restoration of infrastructure services and provision of shelter, adding oversight of market forces and protection against disease. In the following few months services should be completely restored and businesses returning to normal operation. Also during this period shelter should become of a more long-term nature and extended to commercial enterprises. During the remaining time of that first year the community should look to future resilience, including the adoption of enhanced development plans and procedures. After that, development should implement the plans for resilience and mitigation. This schedule is being developed for earthquake disasters in the United States, and clearly has application for resilience with respect to both natural and intentional hazards.

FUTURE AREAS OF INVESTIGATION

Below are descriptions of three areas where further development of theory is needed to quantify resilience in the face of seismic threats.

- Development of policy innovations that relate the rationalities of political decision making with the low probability, high consequence events associated with seismic hazards and intentional acts of terrorism. Life cycle analysis must be combined with risk perception models incorporating hazards-based social psychology (pertinent references: Slovic, 2000, 2004; Hammel and Corotis, 2007).

- Resiliency-enhancing strategies that create innovative practices for prioritizing a hierarchy of sequential needs for system recovery following an earthquake. Comparison between techniques based on probability/statistics measures and those associated with generalized uncertainty are important (pertinent references: Klir, 2006; McNeill, 2008).

- Quantification of business disruption and economic impacts after service losses due to earthquakes can build on work done by the Applied Technology Council for earthquakes (ATC, 1991), but must be expanded both in terms of regional economic as well as social impacts.

CONCLUSIONS

This brief paper has sought to distinguish structural reliability from resilience. Central differences relate to event modeling, outcome evaluation and uncertainty assessment. More importantly perhaps are the concepts of functionality impact on society, decision making inclusivity, and temporally integrated multiple loss measure.

ABSTRACT

The concept of Disaster Resilience has received considerable attention in recent years and it is increasingly used as an approach for understanding the dynamics of natural disaster systems. The goal of this paper has two distinct tasks: (i) conduct a literature survey analyzing asset-based approaches for defining and measuring disaster resilience for physical infrastructures that is one of the seven dimensions of the PEOPLES Resilience Framework; (ii) identify the gaps between asset-based approaches and community-scale approaches. It is offered an overview of the models developed in literature to quantify resilience and performances of electric power, water, wastewater and natural gas utilities; communication companies and transportation networks as well as health care facilities. Discussion will be added related to strengths and weakness on how these approaches could facilitate the comparison of alternative resilience options/strategies and measure the speed with which disruptions can be overcome and community functions restored.
A new geographic approach will be introduced to measure community resilience, focusing on spatial, temporal scale of resilience.

INTRODUCTION

Resilience is clearly becoming increasingly important for modern societies as states come to accept that they cannot prevent every risk from being realized, but rather must learn to adapt and manage risks in a way that minimizes impact on human and other systems.
While studies on the disaster resilience of technical systems have been undertaken for quite some time, the societal aspects and the inclusion of various and multiple types of extreme events are new developments. In this regard, countries and states around the world are increasingly debating ways to enhance community resilience. At this time, there is no explicit set of procedures in the existing literature that suggests how to quantify resilience in the context of multiple hazards, how to compare communities with one another in terms of their resilience, or how to determine whether individual communities are moving in the direction of becoming more resilient in the face of various hazards. Considerable research has been accomplished to assess

direct and indirect losses attributable to earthquakes, and to estimate the reduction of these losses as a result of specific actions, policies, or scenarios. However, the notion of resilience suggests a much broader framework than the reduction of monetary losses alone. Equally important, in addition to focusing on the losses produced by multiple hazards, research must also address the ways in which specific pre- and post-event measures and strategies can prevent and contain losses (Bruneau et al, 2003). Resilience (R) is defined as a function indicating the capability to sustain a level of functionality or performance for a given building, bridge, lifeline networks, or community, over a period defined as the control time T_{LC} that is usually decided by owners, or society (usually is the life cycle, life span of the system etc.). Resilience is defined graphically as the normalized shaded area underneath the functionality function of a system, defined as *Q(t)*. *Q(t)* is a non stationary stochastic process and each ensemble is a piecewise continuous function as the one shown in Figure 1 (Cimellaro et al. 2010):

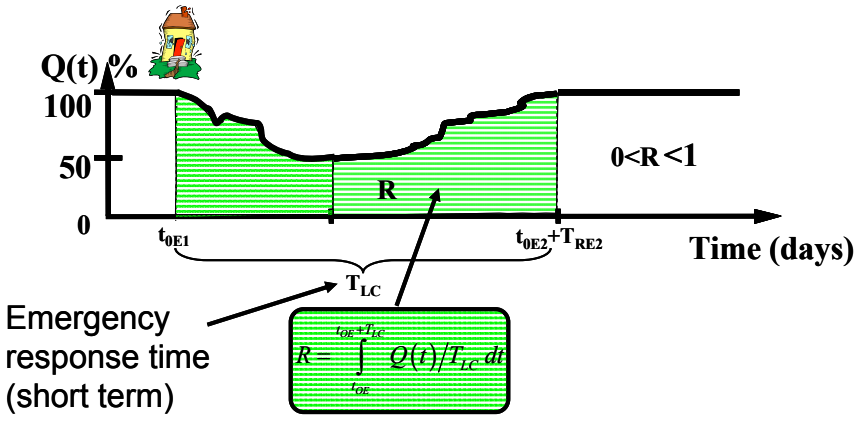

Figure 1 Schematic Representation of Community Resilience

Disaster resilience is often divided between technological units and social systems. On a small scale, when considering critical infrastructures, the focus is mainly on technological aspects. On a greater scale, when considering an entire community, the focus is broadened to include the interplay of multiple systems – human, environmental, and others – which together add up to ensure the functioning of a society. At the community level, the human component is central, because in the case of a major disruptive event, resilience depends first on the actions of people operating at the individual and neighborhood scale. Community resilience also depends heavily on the actions of different levels of government and its agencies at the local and regional scales when a disruptive extreme event occurs.

In order to emphasize the primary role of the human system in community sustainability, the acronym "PEOPLES" have been used This nomenclature highlights both the physical and environmental assets as well as the socio-economic-political/organizational aspects of a particular community. The PEOPLES Resilience Framework is built on and expands previous research at MCEER linking several previously identified resilience dimensions (technical, organizational, societal, and economic) and resilience properties (r4: robustness, redundancy, resourcefulness, and rapidity). PEOPLES incorporates MCEER's widely accepted definitions of service functionality, its components (assets, services, demographics) and the parameters influencing their integrity and resilience.

The PEOPLES Resilience Framework defines components of functionality shown in Figure 2 using a geospatial-temporal distribution within its influence boundaries. Interdependencies

between and among these components are key for determining the resilience of communities. PEOPLES enables the use of various community resilience indices that integrate over space and time the system functionality and services of a community in a landscape setting. In this particular dimension, historical and continuously gathered information through remote sensing and Geographic Information Systems (GIS) will play a major role in assessing the resilience of all integrated systems and feed a predictive resilience model. Resilience can be considered as a dynamic quantity that changes over time and across space. It can be applied to engineering, economic, social, and institutional infrastructures, and it can use various geographic scales. To be able to expand the assessment of resilience to a community and landscape perspective, the PEOPLES Resilience Framework is based on basic community organizational units at a local (neighborhoods, villages, towns or cities) and regional scale (counties/parishes, regions, or states) (see Figure 2).

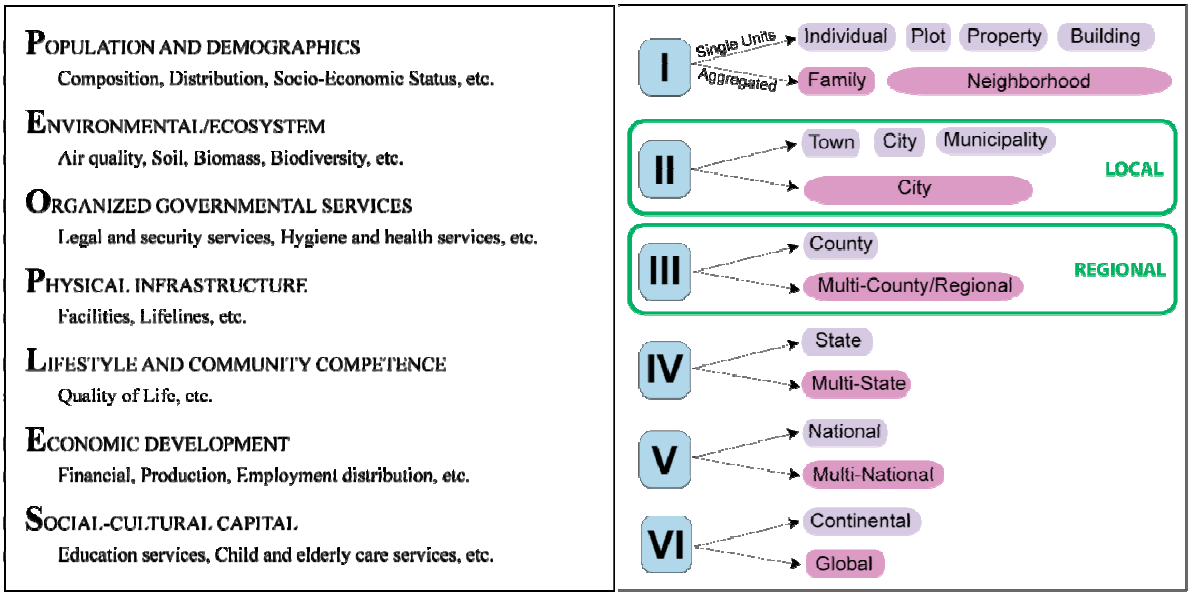

Figure 2 The PEOPLES Resilience Framework and their Geographic Scales

The goal of this paper is to focus only on the physical infrastructure dimension of the PEOPLES framework identifying the different performance measures of the different components.

PHYSICAL INFRASTRUCTURE DIMENSION

The physical infrastructure dimension incorporates both facilities and lifelines. Within the category of facilities, we include housing, commercial facilities, and cultural facilities. Within the category of lifelines, we include food supply, health care, utilities, transportation, and communication networks (Figure 3).

a) Facilities	ii) Health Care
i) Residential	(1) Acute Care
(1) Housing Units	(2) Long-Term Acute Care
(2) Shelters	(3) Primary Care
ii) Commercial	(4) Psychiatric

(1) Distribution Facilities (2) Hotels - Accommodations (3) Manufacturing Facilities (4) Office Buildings iii) Cultural (1) Entertainment Venues (2) Museums (3) Religious Institutions (4) Schools (5) Sports/Recreation Venues **b) Lifelines** i) Communications (1) Internet (2) Phones (3) TV (4) Radio (5) Postal	(5) Specialty iii) Food Supply iv) Utilities (1) Electrical (2) Fuel/Gas/Energy (3) Waste (4) Water v) Transportation (1) Aviation (2) Bridges (3) Highways (4) Railways (5) Transit (6) Vehicles (7) Waterways

Figure 3 List of subcomponents of the PHYSICAL INFRASTRUCTURE dimension of the PEOPLES framework

Eulerian indicators for facilities and lifelines

For residential, commercial and cultural facilities it is possible to use point location indicators such as physical damage indicators and using the analogy with fluid mechanics, these indicators can also be called Eulerian indicators, because they describe the performance of each component at a given location. Some facilities due to their malfunction can also cause indirect damage such as commercial distribution facilities, religious institutions, schools etc. Therefore for these facilities their influence area needs to be considered evaluating the number of users that will not receive service over the total number of users that received service before the extreme event.

When considering residential housing units (1) a good indicator of resilience to extreme events is also the ratio between the vacancy rates for rental housing and the housing stock not rated as substandard or hazardous (Tierney 2009). This indicator is however affected by the damage state of the housing units, so it is representative if all housing units are opportunely retrofitted.

Point location indicators can also be used when considering the other group of physical infrastructures, the lifelines for communication, food supply and utilities lifelines (electric, water, gas etc.). In this case the indicators are defined as percentage of households receiving service at a given location.

Indicators for communication networks

In terms of communication networks, key indicators may include the sufficiency of procedures for communicating with the public and addressing the public's need for accurate information following disasters, adequacy of linkages between official and unofficial information sources, and adequacy of ties between emergency management entities and mass media serving diverse populations (Tierney 2009).

Indicators for health care facilities

In term of health care facilities, a key indicator is the waiting time (WT) that is the time that the patient needs to wait in the hospital before receiving service (Cimellaro et al, 2010b,c). Other models are also available in literature and are summarized in the following table. Further details about key indicators for this dimension can be found in the MCEER report (Cimellaro et al. 2009).

KEY INDICATORS OF THE TRANSPORTATION SYSTEM

Among physical infrastructures special attention should be given to the transportation system. When considering road network in the past, lot of attention has been given to the damage of individual bridge structures, while indicators measuring the performance of the overall transportation system should be considered.

Lagrangian Indicators

Eulerian indicators can be used for lifelines such as water, electric power, natural gas, and telecommunications, where performance can be readily measured by the percentage of households in the study area that have lost lifeline service. However this approach cannot be used for transportation systems, because transportation service is consumed by an individual user across the network, rather than at a point location, therefore using the analogy of fluid mechanics the indices that better describe the performance are the so called lagrangian indicators that describe the performance of a user that move across the network. For example they belong to this group indicators based on the original destination (OD) nodes (e.g. Bocchini and Frangopol, 2011) and on the network connectivity analysis (CA) (Chang and Nojima, 2001).
In term of transportation system there are many key indicators available in literature, therefore it is necessary to distinguish between normal and critical operating conditions. Many indicators can be found describing the performance of the road network in normal operating conditions, while a few can be found to evaluate performances after extreme events as shown in Table 1.

Normal operating condition indicators	Extreme event indicators
Average road user costs	Total length of highway open L (Chang and Nojima, 2001);
Travel time as measure of level of satisfaction	Total distance-based accessibility D (Chang and Nojima, 2001);
Number of fatalities as measure of user risk	Bocchini and Frangopol (2011)
Overhead percentage (fixed costs/total costs) as indicator of road administration's cost-effectiveness	REDARS (Werner et al. 2006)
Roughness (IRI is widely used indicator) related to pave-ment quality, travel cost and user satisfaction	
States of bridges	
Satisfaction with the road system as indicator of road users overall satisfaction	
…	

Table 1 Key indicators divided by normal and critical operating conditions (not exhaustive)

Each of these extreme events indexes is estimated as the ratio of post-earthquake to pre-earthquake conditions and ranges from 0 (system non-functional) to 1 (system fully functional).
Among all it is worthed to focus on the extreme event indicators that are of interest for the PEOPLES framework therefore some of the most relevant and simple to understand are summarized below.

The indicator *L* (Chang and Nojima, 2001) reflects the length *x* of highway in the network that is open to traffic at any point in time *t*, and is defined as a ratio to the pre-earthquake length open $\bar{x}$:

$$L(t) = \frac{x(t)}{\bar{x}} \tag{1}$$

The limit of this indicator is that it is basd only on the extend of damage. A second indicator *D* is based on minimum network travel distances and thus takes into account both the extent and the location of damage. It attempts to measure changes in accessibility at all nodes on the network:

$$D(t) = \frac{f - A(t)}{f - 1} \tag{2}$$

where

$$A(t) = \frac{\sum_i \sum_j d_{i,j}(t)}{\sum_i \sum_j \bar{d}_{i,j}} \qquad 1 \le A \le f \tag{3}$$

with *f*=effective distance multiplier for link closure; *A*=total network accessibility ratio; $d_{i,j}$=minimum travel distance between nodes *i* and *j* on damaged network; $\bar{d}_{i,j}$=minimum travel distance between nodes *i* and *j* on intact network.

Recently Bocchin and Frangopol (2011) developed an index for the functionality of a bridge network. The index is based on the assumption that the time to cover the length of a highway segment is assumed to be the sum of two parts: (i) the time spent on the highway; (ii) the time spent on detour routes. These hypotheses are consequential to the assumption that for every (partially) closed bridge there is at least one possible detour route to bypass the damaged bridge. These detours cause a delay due to the necessity to change the path and to the limited capacity of local routes.

$$Q(t) = 100 \cdot \frac{\Gamma(t) - \Gamma^0}{\Gamma^{100} - \Gamma^0} \tag{4}$$

where

$$\Gamma(t) = \frac{1}{\gamma_t \cdot TTT(t) + \gamma_D \cdot TTD(t)} \tag{5}$$

$TTT(t) = \sum_{i \in I} \sum_{j \in J} f_{ij}(t) \cdot c_{ij}$ is the Total Travel Time; $TTD(t) = \sum_{i \in I} \sum_{j \in J} f_{ij}(t) \cdot d_{ij}$ is the total travel distance; γ_T=is a balancing factor (cost) associated with the time spent by the network users, γ_D=is a similar factor related to length. f_{ij} = is the traffic transiting over the highway segment between nodes *i* and *j*; *i* is the set of nodes of the network and *j* is the subset of nodes connected to node *i*; c_{ij}=is the time required to cover segment *i–j* with traffic flow f (t); d_{ij} =is the length of highway segment *i–j*.

Seismic Risk Analysis for transportation system (REDARS)

Another interesting methodology for measuring the global road network performance after earthquakes is implemented in REDARS (Risks from Earthquake DAmage to Roadway Systems) that is a multi-disciplinary tool for seismic risk analysis (SRA) of highway systems (Werner et al., 2006). Once defined the region of interest the seismic hazard is evaluated and the resulting damage states for each component of the system considering damage extend, type and location. How each component's damage will be repaired, including its repair costs, downtimes, and time-dependent traffic states (i.e., its ability to carry traffic as the repairs proceed over time after the earthquake). Next, REDARS incorporates these traffic states into a highway-network link-node model, in order to form a set of system-states that reflect the extent and spatial distribution of link closures at various times after the earthquake. It applies network analysis procedures to each system-state, in order to estimate how these closures affect system-wide travel times and traffic flows. Finally, REDARS estimates corresponding economic losses and increases in travel times to/from key locations or along key lifeline routes. These steps can be applied for a single earthquake and no uncertainties (deterministic analysis) or for multiple earthquakes and simulations in which uncertainties in earthquake occurrence and in estimates of seismic hazards and component damage are considered (probabilistic analysis).

INTEGRATING FUNCTIONALITIES OF PEOPLES FRAMEWORK

Within the *PEOPLES Resilience Framework,* each dimension and/or service and its indicators or terms of functionality will be represented with a GIS layer of the area of interest (Figure 4). Each dimension of the framework can be represented by a combination of sub-dimensions (or layers), each having spatial-temporal dependent functionalities, each representing a subcomponent. For example the physical infrastructure layer shown in Figure 4 can be subdivided into layers representing the housing, transportation, electric power, water, sewage, communications, etc.
In Figure 4, Q_{HOU} = functionality of the housing units in the community; Q_{TRA}= functionality of the transportation network; Q_{ELE}= functionality of electric power system; Q_{H2O}= functionality of the water system; Q_{COM}= functionality of the communication network; Q_{SEW}= functionality of the sewage system; all terms are function of the location (**r**) and of the time (**t**). This list of functionality terms that is inserted within the physical infrastructure is not exhaustive. Additional terms can be added, such as functionality of schools, dams, fire stations, oil and natural gas systems, emergency centers, etc. For each layer, is possible to define a *resilience index contour map* after integrating the functionality for the control time (T_{LC}) period.

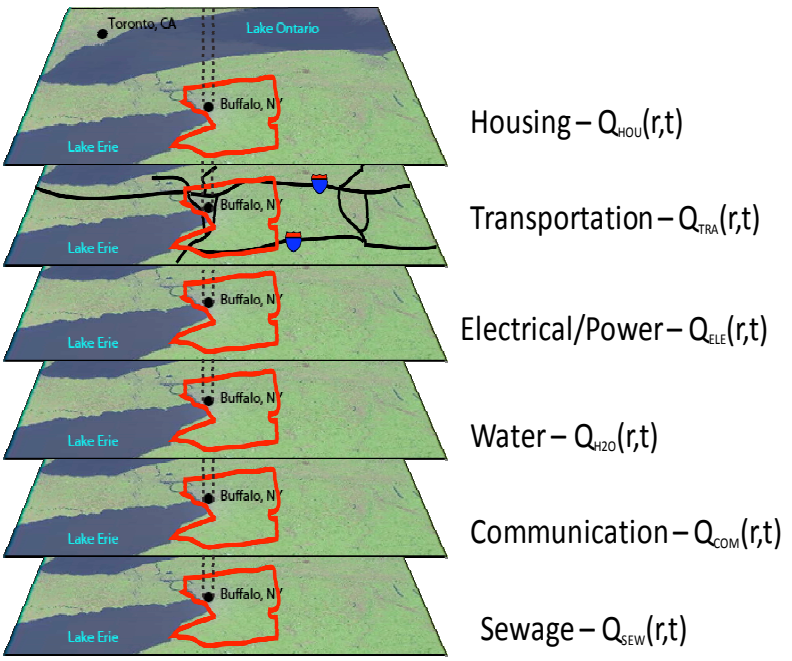

Figure 4 Schematic representation of Physical Infrastructure Functionality Maps

Region of interest

The spatial distribution of functionalities in each dimensional layer is also specific to the area of influence of the network of lifelines that it represents. For example the highway network and the electric grid have different boundaries as well as the areas served by the water system and by the communication system. These areas of influence are not the same for each layer and they can be national, regional or local, dependent on the service provided. Multiple community resilience indices, *Ri*, for each component, i, or a single combined index, R, would be dependent on a defined temporal and geographic size or scale defined by community boundaries. The community will include in its boundaries an entire network, or several networks, but most likely will include only parts of the larger national or regional networks. Therefore in determining resilience, first, the boundaries of the region of interest should be defined. Geographic Information Systems (GIS) are increasingly being used to map vulnerability, and to better understand how various phenomena (hydrological, meteorological, geophysical, social, political and economic) effect human populations. The region of interest is further divided in grid cells and inside each cell, r, a definition of functionality Qi(r,t) at a given time instant, t, is given for each dimension (Figure 5). For example, if the community resilience index of the electric power network has to be calculated for a given region, first the definition of functionality Q_{ELE} needs to be defined, for example as

$$Q_{ELE}(\mathbf{r},t) = \frac{N_{CP}(\mathbf{r},t)}{N_C(\mathbf{r},t)} \quad (1)$$

where N_{CP}=number of households receiving power in the grid cell and N_C= total number of households in the grid cell.

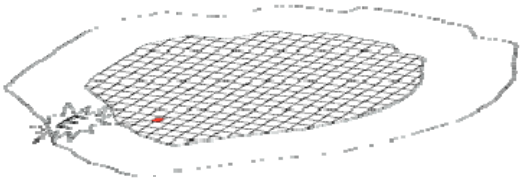

Figure 5 Example of region of interest divided in grid cells

Then, after evaluating the functionality $Q_{ELE}(\mathbf{r},t)$ in each grid cell for the entire period of control, T_{LC}, different ways of representing the data are available.

Resilience maps

At every instant t_0 a given functionality maps $Q_{ELE}(\mathbf{r},t_0)$ (or contour plots) can be plotted over the region of interest. These maps can be used during the entire recovery process, especially in the days immediately after the extreme events and they can be updated on regular basis for example. They can be used to direct resources and personnel toward the zones more affected by the extreme event in the region. At different time periods defined also by the control time, T_{LC}, it is possible integrate the functionality for the given control time and calculate the resilience at each location **r**.

$$R_{ELE}(\mathbf{r}) = \int_{t_{OE}}^{t_{OE}+T_{LC}} Q_{ELE}(\mathbf{r},t)/T_{LC}\,dt \tag{2}$$

Then the resilience indices can be used to develop the resilience maps in the form of contour plots. These maps can be used as information during the entire recovery process, or during any given control period. At the end of the emergency period they give you a status on the level of achieved resiliency of the component/dimension in the aftermath of the extreme event.

Finaly, a global **community resilience index for the specific dimension** (*electric power system* in the example below) can be provided by double integrating over the entire region, r_{LC}, and the control period, T_{LC}..

$$R_{ELE} = \int_{\mathbf{r}_{LC}(t)} R_{ELE}(\mathbf{r})\,dr = \int_{\mathbf{r}_{LC}(t)} \int_{T_{LC}(t)} Q_{ELE}(\mathbf{r},t)/T_{LC}\,dtdr \tag{3}$$

All equations above are presented for the functionality of the electric power network, only, but formulation can be easily extended to all components/dimensions.

Community Resilience indices

When a global resilience index is required to assess the entire community, as a result of all components and dimensions, this index can be obtained using the total functionality $Q_{TOT}(r,t)$, that combines the different dimensions, so the final community resilience index is given by:

$$R = \int_{\mathbf{r}_{LC}(t)} R(\mathbf{r})\,dr = \int_{\mathbf{r}_{LC}(t)} \int_{T_{LC}(t)} Q_{TOT}(\mathbf{r},t)/T_{LC}\,dtdr \quad (4)$$

where Q_{TOT}(r,t) is the global functionality that is a function of time and space and combines all functionality terms considered; r_{LC} is the region of interest that can change with time; t is the time parameter; T_{LC}= control time that can change through the time.

Interdependencies

All resilience dimensions and their respective indices to measure their performances are interdependent (Figure 6).

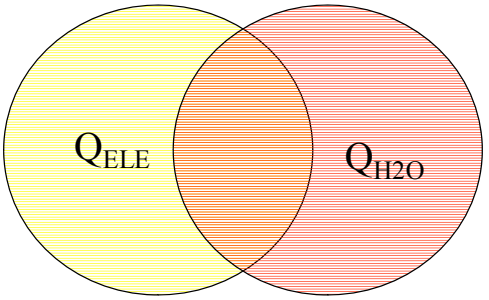

Figure 6 Interdependencies among different functionalities

A simple way of combining different functionalities is using the analogy with the probability axiom of arbitrary events therefore the global definition of functionality is given by

$$Q_{TOT} = \sum_{j=1}^{n} Q_j - \sum_{i=1}^{n}\sum_{j=2}^{n} Q_i Q_J + \sum_{i=1}^{n}\sum_{j=2}^{n}\sum_{k=3}^{n} (Q_i Q_j Q_k) - \ldots + (-1)^{n-1} \sum_{i=1}^{n}\sum_{j=2}^{n}\sum_{k=3}^{n} \ldots\ldots \sum_{l=n-1}^{n} (Q_i Q_j Q_k \ldots Q_l Q_n) \quad (5)$$

It is obvious that not all functionalities might have the same weight; therefore the global functionality can be determined using the mathematical expectation denoted by $E\{Q(\mathbf{r},t)\}$ that is defined by

$$Q_{TOT} = E\{Q(\mathbf{r},t)\} = \sum_{i=1}^{n} p_i(\mathbf{r},t)\,Q_i(\mathbf{r},t) \quad (6)$$

where n is the number of dimensions considered relevant in the functionality, $p_i(r,t)$=priority (probability) factors; Q_i=functionality associated to a given dimension of PEOPLE framework. Notable, for the total system functionality, the number of dimensions can be maximum seven (n=7) as indicated in the PEOPLES framework. However, the same formulation (recurrence formula), with suitable adjustment of the meaning of the indices, applies to the total functionality of a single component/dimension such as the physical infrastructure, or the organizational system, thus allowing to determine the resilience index of just that component/dimension.

The formulation suggested above provides the base for further development of the resilience indices for various locations using a probability framework while considering inherent uncertainties in the systems.

REMARKS AND CONCLUSIONS

The paper conducts a literature survey analyzing asset-based approaches for defining and measuring disaster resilience for physical infrastructures that is one of the seven dimensions of the PEOPLES Resilience Framework. It is offered an overview of the most relevant models developed in literature to quantify resilience and performances of electric power, water, wastewater and natural gas utilities; communication companies and transportation networks as well as health care facilities. A new geographic approach is introduced to measure community resilience, focusing on spatial, temporal scale of resilience. System community resilience measures can provide a very useful tool for mitigation of multiple hazards such as earthquakes and are important for several reasons:

1. They enable comparisons of system conditions across disaster events in different regions.
2. They allow comparisons across scenario disaster events for a single study region, and with a rapid development can be used for pre-event mitigation planning.
3. They may also facilitate discussions of what levels of risk and potential loss are acceptable or unacceptable.
4. They can be used in efficient post-disaster restoration strategies by prioritizing damage repair optimizing system performance.
5. They be implemented for estimating economic impacts for emergency response and recovery planning.

ABSTRACT

The process of community recovery in the aftermath of a disaster is complex, long lasting, resource intensive, and poorly understood. Insights described here result from an ongoing project that aims to monitor, quantify, and evaluate the process of post-disaster recovery for two events, Hurricane Charley (2004, Charlotte County and Punta Gorda, Florida) and Hurricane Katrina (2005, Harrison County and Biloxi, Mississippi). A mixed-methods approach using statistical data, interviews, and remote sensing-derived data is applied in an effort to understand as well as monitor, measure and evaluate the recovery process and its outcomes. Observations associated with the post-disaster course of moving residents from temporary to transitional, and ultimately permanent housing serves as the focus for this paper. This work represents a discrete portion of a multi-sector project where Economic, Environmental, Housing/Infrastructure, and Social elements of community recovery are explored. Understanding community recovery can inform community resilience-building strategies.

INTRODUCTION

Post-disaster recovery efforts often require many years, enormous resources, and define the character of the affected communities for an extended period of time. Nevertheless, recovery is cited as the most poorly understood phase of the disaster cycle (e.g., Berke and Beatley, 1997; Haas et al., 1977; Mileti, 1999; Olshansky, 2005; Rubin et al., 1985). An improved understanding of recovery could promote recovery planning and community resilience prior to a disaster as well as management following a disaster. An important first step in advancing the

understanding of post-disaster recovery is improving the ability to measure, monitor, and evaluate it. In fact, participants at a meeting of the aid community identified an urgent need for basic and applied research into the long-term recovery process, noting in particular the *lack of a standard, independent and replicable approach by which progress made during the relief and recovery phases can be measured, monitored and evaluated against existing guidelines* (Shelter, 2006). In recent years, supported by organizations including DfiD, ECHO and USAID, aid agencies have devoted considerable effort to developing guidelines for the emergency relief and recovery processes (e.g., Corsellis and Vitale 2004, Sphere 2004. Currently, governments and relief organizations evaluate their programs in an *ad hoc* manner, without a systematic approach or standardized criteria. The goal of this research is to develop a systematic approach for identifying evidence of post-disaster recovery through a unique fusion of multi-source data. In doing so, and by examining the post-disaster landscape over time, one aim of this research is to comment on wider community resilience for several post-hurricane scenarios.

Post-disaster recovery is a complex physical, social, economic, environmental, and political process (Phillips, 2009). Given the importance of recovery, limitations of previous research on it, and new technological opportunities, this project aims to develop innovative methods for systematically and quantitatively measuring, monitoring and evaluating post-disaster recovery through a unique integration of multi-source data. Two study areas support the methodological development, focusing on communities in southwest Florida impacted by 2004 Hurricane Charley, with validation of the method using areas in Mississippi affected by 2005 Hurricane Katrina. The project is producing unique comprehensive recovery datasets, including new remote sensing-based and previously underutilized statistical data, together with interview and expert judgment data. This paper establishes a methodological framework for assessing recovery that complements existing theoretical and practically-based metrics and models, and established recovery assessment techniques. The paper discusses methods that synergistically exploit qualitative and quantitative information, enhancing the value of both and facilitating a deeper understanding of the complex nature of recovery.

Resilience is equally complex, to define, to promote, and to sustain. Gaps exist in the implementation of resiliency concepts within community development and emergency planning activities (Paton and Johnston, 2006). The experiences and realities of long-term recovery can serve as a resource to communities that are attempting to build their internal capacity to absorb or adapt to a disruption or disaster event. This research aims to harness the opportunity to learn from communities who have long-term disaster experience, and so there is much potential to apply recovery lessons to facilitate resilience-building efforts.

New methods for acquiring and analyzing recovery data can provide diverse benefits to those who manage, fund, and study disaster recovery: This can empower communities and provide evidence to support their experiences of the recovery process. It can open a new source of dialogue and discourse that could have practical

repercussions for the creation of resilient communities, for the distribution of aid and resources. It also facilitates theoretical discussions on the potential identification of different types of recovery, dependent on their initial conditions and key decisions post-disaster. Further, by augmenting existing ways of empirically measuring recovery, the project advances the state-of-the-art in post-disaster recovery studies and supports the continuing development of a theory of post-disaster recovery.

This paper demonstrates the development of methods to assess recovery. Described through the use of exemplars that highlight a single sector of recovery - temporary housing – we demonstrate how the recovery can be better understood through the use of multi-source data. We provide an overview of the use of remote sensing and field interviews carried out in one study area. These exemplars provide an insight into how the fusion of diverse information sources are being used in the wider research project to aid evaluation of recovery and resilience.

STUDY EVENTS AND LOCATIONS

Given the complexities of post-disaster recovery, diversity of disaster impacts, and differential rates of recovery, this project includes two study events, Hurricanes Charley and Katrina, two counties, Charlotte County Florida and Harrison County Mississippi, and two municipalities within the study counties, Punta Gorda, Florida (Figure 1) and Biloxi, Mississippi (Figure 2). The purpose of this multiple event and multi-location approach is to mitigate place- and event-specific effects on recovery and to support development of findings that are scale, place and event independent.

Charlotte County and Punta Gorda, Florida

Hurricane Charley made landfall with the eye passing directly over the city of Punta Gorda, Florida at 16:45 EDT on Friday, August 13, 2004. Charley was a fast moving storm that brought 150 mph sustained winds, 8in of rainfall, and a 7 foot storm surge to the study area (Pasch et al., 2005). Charley changed direction and unexpectedly headed toward Punta Gorda, making landfall as a Category 4 storm.

Harrison County and City of Biloxi, Mississippi

Hurricane Katrina made its final Gulf Coast landfall on Monday, August 29, 2005 at the mouth of the Pearl River, close to the Louisiana/Mississippi state boundary, as a Category 3 storm. At landfall, sustained winds of up to 120mph impacted the Mississippi coast including the study area (Faulkner et al. 2007). The storm surge, which ranged from 24-28 feet along the coast, contributed significantly to losses along the Mississippi Gulf Coast (Farris 2007). This surge was complemented by 10-12 inches of rainfall between August 24 and August 30 (Grauman et al. 2005).

DATA AND METHODS

A mixed-methods approach fused interviews and survey instruments with statistical data and satellite imagery/aerial photography in order to develop a comprehensive picture of the recovery process operating in our study locations. In the aftermath of a disaster, record keeping and reporting requirements (housing permits for example) are often suspended for a discrete period of time to remove impediments to repair and recovery. By combining diverse and complementary data sources, the aim of this research is to provide self-validating approach to measure and evaluate recovery efforts.

Remote Sensing Imagery

Remotely-sensed images were sourced from several sources for both study areas. For Punta Gorda and Charlotte County, aerial orthophotographs with a spatial resolution of 1 foot were sourced from the Southwest Florida Water Management District (SWFWMD), captured in January of each year, for 2004-2009. These were combined with Quickbird-02 satellite imagery captured before and after Hurricane Charley (23 March 2004, 14 and 19 August 2004), with spatial resolution of 60cm for the pansharpened product. The imagery for the second study site of Mississippi were collected from several state and local agencies for 2005-2008. Field validation information was collected during site visits to Florida and Mississippi in January and October 2010, respectively. This entailed collecting GPS-registered video and photo data (using the VIEWS^{TM} system; ImageCat, Inc. 2010) for every street in the study areas, providing a snap-shot of the recovery progress in each location. Similar VIEWS^{TM} footage had been captured within days of both Hurricane Charley and Katrina, and has been used for validation of much of the image analysis in the wider research project.

Several manual and semi-automated methods were adopted during the project to analyze the multi-temporal remotely-sensed imagery, producing datasets pertaining to *Housing, Environmental* and *Economic* sectors. Much of this work is still in progress at time of publication. However, as an exemplar, this paper provides an overview of the analysis of a large concentration of temporary shelters (*Housing* sector), on Airport Road, 3 miles east of central Punta Gorda.

Analysis of temporary shelters, Punta Gorda FL.

Using the multi-temporal imagery provided by SWFWMD, a presence/absence analysis was performed to quantify the changes in availability of temporary housing. This required the generation of point information for each unit of manufactured housing sited on the lot that the imagery showed to be vacant prior to the storm. Each housing unit (confirmed during field visits as FEMA-supplied trailers) was identified by a point in a GIS, and given attributes indicating its presence or absence in a series of images, acquired at a one year intervals for 2005, 2006 and 2007. As the numbers changed over time as temporary shelters came and went, the presence or absence of

trailers in the imagery was recorded. This also enabled the estimation of the total area used for temporary housing over time, based on the boundaries of the site.

Considering the normal specifications for these types of housing units (FEMA trailers), and allowing for an average capacity of three occupants, it was possible to estimate the occupation of the camp over time. This assumed that the presence of the shelter in the imagery also meant the shelter was occupied.

Field Visit Interview Data

Field work in study locations not only provided key contextual information of study areas and ground validation of remote sensing imagery analysis, but also interviews were carried out to provide experiential data and an opportunity for communities to help explain patterns found in statistical and imagery analysis. Research teams traveled to Port Charlotte and Punta Gorda (Charlotte County, Florida) on two occasions, in August 2009 and in January 2010. The first visit coincided with an *Extreme Makeover* community celebration marking the fifth anniversary of Charley's landfall. This provided an opportunity to interview residents regarding the pace and perceived milestones in the community recovery process. A total of 114 residents shared experiences and opinions of recovery across time and space. Interviews with three agencies and organizations who took the lead in recovery efforts, provided background and overview information as well as facilitating introductions to key individuals/organizations. This information supported the second field visit in January, 2010. During this visit, in-depth interviews were conducted with over two dozen organizations/agencies. These agencies/organizations included city, county and regional scales, as well as spanned housing, emergency management, planning, transportation, infrastructure and housing, economic and social welfare sectors. Similar field reconnaissance, ground validation, and interviewing took place in October 2010 for the Mississippi study area. In this case, city, county and state organizations and agencies were interview targets, with specific focus on the economic, environment and housing sectors. In total three dozen interviews were completed.

OBSERVATIONS AND FINDINGS

Temporary Housing

The image analysis of the concentration of FEMA-provided shelters in Punta Gorda showed that before Hurricane Charley, the site was a vacant, vegetated lot. By January 2005, in an area of 0.287 km^2, 552 housing units had been established in regular blocks containing 6-14 individual units (Figure 3), accounting for an estimated population of 1656. The number of units was reduced to 369 by January 2006 (population = 1107, and to 11 in January 2007 (population = 33; Figure 4). By 2008, all trailers had been removed and the site had been cleared to make way for permanent administrative units, including the new Charlotte County Fire and Emergency Services Center. By the field visit in 2010, there were no traces of the

temporary shelters on the site. Figure 5 shows the transition of part of the site from 2005-07.

Imagery was not available in the time between the storm and January 2005, therefore the exact date that the temporary housing area was established can only be estimated from imagery alone. The limitation of image sampling rate is a common factor when using remotely-sensed data, which can be reduced through the collection of additional images in this interim time period, or through fusion of ancillary datasets.

Figure 3. Presence of Temporary Housing Units in Punta Gorda, January 2005 (imagery courtesy of SWFWMD)

Although this exemplar has been shown to describe the transition of multiple families into and out of temporary shelters, often transitional trailers are situated next to damaged homes and residences. In a wider, multi-temporal study of housing for the whole of Punta Gorda (under review for publication), many trailers were identified on private properties, and stayed *in situ* until repairs or rebuilding was completed. These particular temporary shelters from FEMA have been a useful and identifiable proxy for monitoring transitional populations from remotely-sensed data.

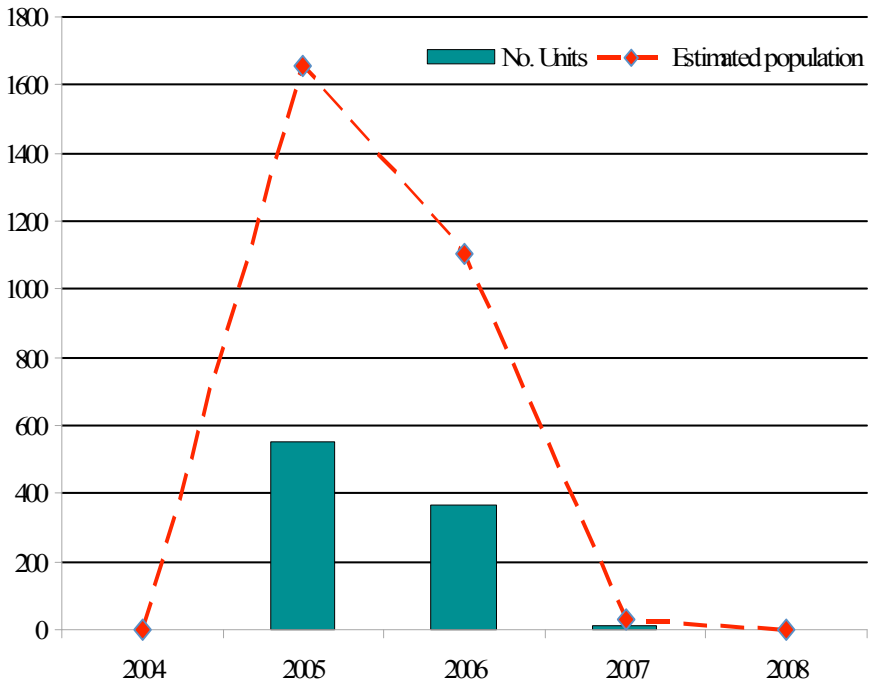

Figure 4. Quantification of temporary housing units in Punta Gorda: 2004-08. All data derived from SWFWMD orthophotographs.

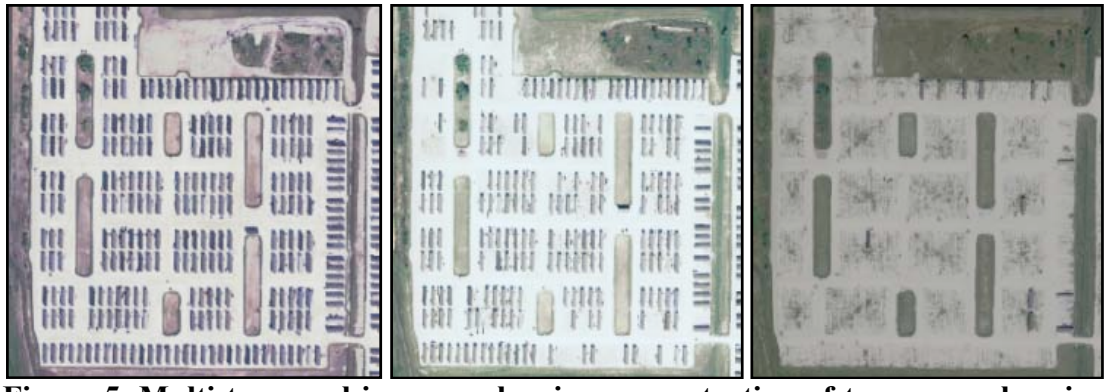

Figure 5. Multi-temporal imagery showing concentration of temporary housing in Punta Gorda. (left-right: 2005, 06, 07). Imagery courtesy of SWFWMD.

During interviews in Florida the topic of FEMA temporary shelters was discussed in all meetings. Travel-trailers and other temporary shelters (whether from FEMA or another source) generally fell into two categories – those situated at or near a resident's original address, and those situated in parks/camps removed from a resident's property. Community non-governmental organizations expressed concern about the consequences of positioning temporary housing parks/camps in a remote location. While a large area was available and utilities were installed expeditiously, residents living in the facility were far removed from aid distribution centers,

employment opportunities, and daycare facilities. The unintended consequences of the remote location were ultimately mitigated by transportation facilities provided to residents of the temporary shelter.

Concerns were expressed to the field teams, not over the timing that temporary shelter was available, but at the length of time that availability extended. Interviewees commented that it was difficult to move families from temporary to permanent housing, and as such, temporary housing units stayed much longer than had originally been envisioned. Without clear limitations on occupancy, abuse of the temporary shelters was described; both in terms of populations impacted by Hurricane Charley, but also by individuals who moved to the area specifically to reside in the temporary housing after the storm. The assumption of full occupancy used in the described remote sensing analysis was valid as there were attempts to remove the trailers as soon as occupants left to avoid informal occupancy of these units. Residents and agencies both stated that in many cases across the city, low-income families ultimately moved away from the community and from the state of Florida.

Similar concerns about temporary housing were expressed in the second study. In Harrison County, MS, residents and agencies both described the need to have a plan for mobile homes to be strictly temporary and not linger and become established as a permanent park or second homes at private addresses. Particularly in areas were zoning requirements are flexible, officials suggested that plans for phasing out temporary housing are critical.

The issue of occupancy and how it changes over time (i.e. the sequence of multiple families in one structure with time), is one example of where the fusion of image analysis with interviews and statistical data can provide a full picture of post-disaster recovery. Analysis of remote sensing data provides valuable data from which to monitor, measure and evaluate post-disaster recovery. When combined with contextual information provided by ancillary documents, key-informant interviews, and surveys of residents, an explanation of the patterns observed through image analysis emerges. Understanding the unintended consequences of decisions, such as the location and functionality of facilities, and how this changes over time, provides a set of lessons learned that can inform future decisions as well as aiding other communities manage their own long-term community recovery in a disaster's aftermath.

CONCLUSIONS

Understanding the ways that community recovery in the aftermath of a disaster unfolds with time, the pace, the decision-making, pitfalls, and lessons learned all combine to provide a unique source of input and validation for the community resilience-building activities that communities engage in. A community (or business or individual) who constructs and maintains resilience will (or should) recover more efficiently, equitably, and sustainably than less resilient places. In that sense, lessons learned regarding recovery can inform resilience building decisions and resilience

measurement criteria. The goal of this paper has been to highlight observations that are potentially generalizable and provide evidence of key elements of resilience. Using exemplars to highlight a unique and multi-source data fusion, the focus has explicitly been on temporary shelter and the intent is that recommendations derived from these observations would be complemented with recommendations related to other sectors of community (economic, environment, infrastructure, and social/demographic sectors).

A. Pre-disaster plans for siting and removing temporary shelters (tents to trailers) enhance community resilience and promote disaster recovery.
B. Pre-disaster plans for repairing/rebuilding low-income housing are critical to ensuring that middle and low income residents are able to return to their communities. A resilient community may or may not be one where demographic shifts result from disaster pressures, but a resilient community recovers in an equitable way when the causes and consequences of such social disruption and change are considered prior to the disaster event.
C. Rental costs and property values fluctuate substantially in the immediate, short-term and long-term aftermath of a disaster; resilient communities identify and address the causes and consequences of such fluctuations.
D. Resilient communities recognize that disasters pose opportunities to address community goals.

ACKNOWLEDGEMENTS

The authors would like to acknowledge all residents and leaders who volunteered to share their recovery experiences with our project team. Field visits and analysis were supported by an enthusiastic team of students and support staff, including Dana Rathfon (U. Delaware), Katie Correll and Mia Murray (U. Memphis), Marleen de Ruiter (U. British Columbia), and Matthew Honey (ImageCat Ltd).

ABSTRACT

This paper deals with the concept of "resilience" and proposes its use as optimization criterion for the rehabilitation of a transportation network subject to earthquake. The most earthquake damage prone components of a transportation network are certainly its bridges; therefore, the proposed approach focuses on bridge rehabilitation interventions.

The design variables of the optimization problem are the application times and durations of the interventions on bridges of the network. These durations are determined by the amount of funding invested on each bridge. Hence, the proposed methodology provides the optimal rehabilitation schedule and cost breakdown for all the bridges of the network.

A numerical application is presented to illustrate the proposed approach and to show its capabilities.

INTRODUCTION

After the occurrence of an extreme event, such as an earthquake, that heavily damages a transportation network, the rehabilitation interventions should be prioritized so that the overall serviceability of the network is restored as soon as possible. In fact, the emergency response and the economic and social recovery of the region affected by the extreme event strongly depend on the condition of the transportation infrastructure. The most used indicator to quantify the promptness and effectiveness of the restoration is resilience (Bruneau *et al*. 2003). This indicator is defined as the integral over time of the serviceability and, therefore, measures the ability to restore quickly the original network performance level (Cimellaro *et al*. 2010).

Bocchini and Frangopol (2011a) proposed a computational framework based on multi-objective optimization for the post-event rehabilitation of bridges along a

highway segment. This paper is an extension of their approach to the case of transportation networks. The two objectives of the optimization are the maximization of the transportation network resilience and the minimization of the total rehabilitation cost. The design variables of the problem are the starting time and the pace of the rehabilitation actions (i.e., damage rehabilitation rates) on the various bridges of the transportation network. Several constraints can be added to the optimization problem. For instance, a maximum total cost can be set, or the number of simultaneous interventions can be limited. Since the two objectives of the optimization are conflicting, the result is not a single solution, but a Pareto optimal set of solutions, among which the decision makers can choose one, based on economic and engineering judgment. The numerical solution of the problem is achieved by means of bi-objective genetic algorithms (Goldberg 1989), which are an optimization tool that does not require a closed form expression of the objective functions to compute the Pareto front (Deb 2001).

The use of this technique for the assisted decision making can drive and significantly enhance the infrastructure recovery process during the critical months that follow the occurrence of an extreme event. A numerical application to a realistic transportation network confirms the effectiveness of the proposed technique. Finally, it should be noted that even if the procedure and the numerical example are presented referring to the case of earthquake damage, the proposed technique is applicable in the case of any other extreme event as well.

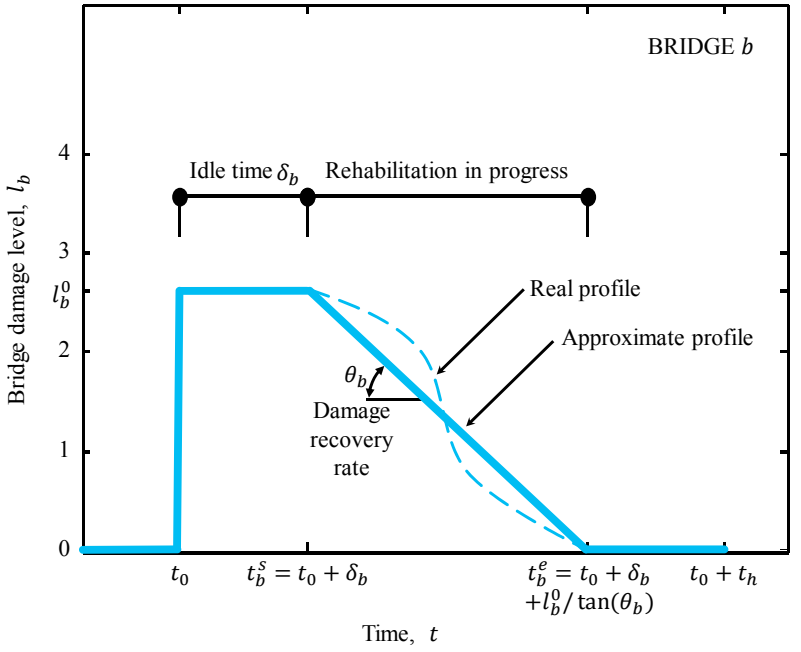

Figure 1. Bridge rehabilitation model and design variables.

BRIDGE REHABILITATION

As already mentioned, the design variables of the problem are associated with the bridge rehabilitation procedure. In particular, for each bridge b they are (i) the idle time δ_b between the occurrence of the extreme event and the beginning of the

rehabilitation activities, and (ii) the damage recovery rate θ_b. In a network with N_B bridges, the number of design variables is $2N_B$. Figure 1 provides a representation of the bridge rehabilitation process and illustrates graphically the meaning of the design variables (i.e., δ_b and θ_b). The real rehabilitation path can have a shape that is very difficult to predict. Therefore, considering also the large amount of uncertainties involved in the problem at hand, the damage recovery is approximated with a linear function.

The bridge damage level $l_b(t)$ affects the functionality of the bridge, in terms of its ability to carry traffic flows. For instance, when the damage level is at least moderate ($l_b \geq 2$), the bridge in unsafe and should be prudentially closed to traffic. Therefore, its functionality is null. The functionality of the bridge is modeled by the variable $q_b(t)$. Table 1 shows that for high damage levels, $q_b = 0$. If the damage is between minor and moderate ($1 \leq l_b < 2$) the bridge can be partially open to traffic, but its capacity should be limited. In fact, opening only some lanes the parts of the structure more affected by damage can be protected and the overall traffic loads can be reduced. This leads to a partial reduction of the bridge functionality (e.g., $q_b = 0.5$). When the rehabilitation activities start on a bridge that has damage in this range (from minor to moderate), additional lanes have to be closed and the bridge is likely to be out of service. If a bridge has only very minor damages ($0 \leq l_b < 1$), the rehabilitation activities require a partial reduction of the traffic flow capacity. However, while the rehabilitation works are not in progress, the bridge is fully open to traffic. Table 1 summarizes the bridge states and the bridge functionality for various damage levels. More accurate value of q_b can be assessed for specific bridges and types of damage.

Table 1. Bridge functionality.

Damage level	Rehabilitation in progress	Bridge state	Functionality q_b
$2 \leq l_b \leq 4$	Yes	Out of service	0
$2 \leq l_b \leq 4$	No	Out of service	0
$1 \leq l_b < 2$	Yes	Out of service	0
$1 \leq l_b < 2$	No	Partially in service	0.5
$0 \leq l_b < 1$	Yes	Partially in service	0.5
$0 \leq l_b < 1$	No	In service	1

TRANSPORTATION NETWORK RESILIENCE ASSESSMENT

A possible analytical definition of resilience is

$$R = \frac{\int_{t_0}^{t_0+t_h} Q(t)\mathrm{d}t}{t_h} \tag{1}$$

where t_0 denotes the instant in which the earthquake occurs, t_h is the investigated time horizon, and $Q(t)$ is an indicator of the "functionality" (or "serviceability") level of the considered infrastructure. In Figure 2 a graphical representation of the meaning of resilience is provided. For a fixed extreme event and time horizon (t_0 and t_h), resilience is the ratio between the shaded area under the functionality (i.e., the integral

at the numerator) and the total area (i.e., $100\% \cdot t_h = t_h$). Figure 2 shows that the functionality can also decrease during the rehabilitation process. In fact, when interventions start on bridges, they often require a temporary reduction of the functionality (e.g., a partial closure of a bridge for the work in progress). The definition of resilience in Eq. (1) takes into account all the effects of this kind.

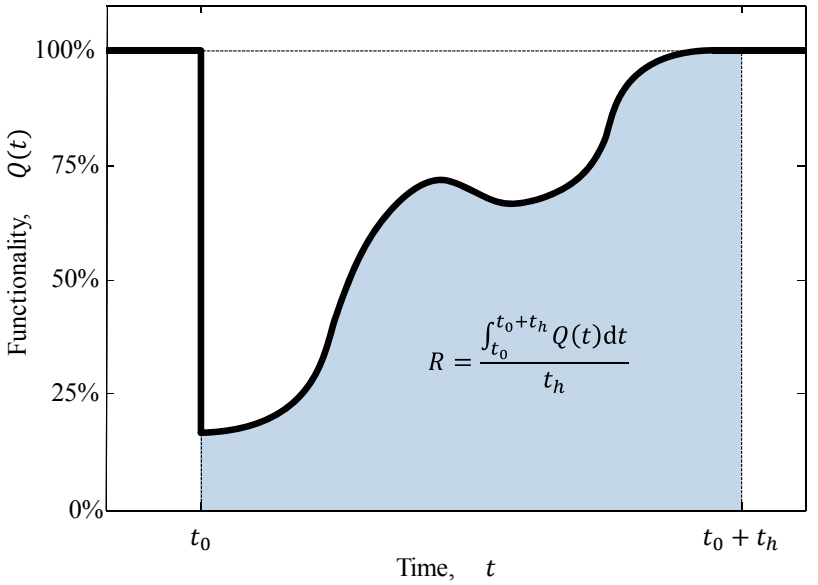

Figure 2. Definition of resilience and relationship with functionality.

Eq. (1) clearly states that the concept of resilience is based on the concept of functionality. For a transportation network, several functionality indicators have been proposed in the literature. In this paper, the performance of the network is measured as a function of the total travel time spent (TTT) and total travel distance covered (TTD) by all the users that start they trip in a predefined time frame (Bocchini and Frangopol 2011a):

$$Q(t) = \frac{\Gamma(t) - \Gamma^0}{\Gamma^{100} - \Gamma^0}\ ; \qquad Q(t)\epsilon[0,1] \subset R \tag{2}$$

$$\Gamma(t) = \frac{1}{\gamma_T \cdot TTT(t) + \gamma_D \cdot TTD(t)}\ ; \qquad \Gamma(t)\epsilon R^+ \tag{3}$$

where γ_T is a balancing factor (cost) associated with the time spent by the network users and measured in min^{-1}; γ_D is a similar factor associated with the distance traveled and measured in km^{-1}; Γ^0 and Γ^{100} are the values attained by the network performance indicator Γ in the special cases when all the bridges are out of service and in service, respectively. The quantities $TTT(t)$ and $TTD(t)$ are computed solving the complete traffic distribution and assignment problem (Bocchini and Frangopol 2011b).

The traffic flow capacity of each highway segment is affected by the functionality of the bridges that carry it, as provided in Table 1. In particular, the following model is used (Bocchini and Frangopol 2011a):

$$c_{ij} = c_{ij}^{e}\left[1 + \alpha\left(\frac{f_{ij}}{f_{ij}^{e}}\right)^{\beta}\right] \tag{4}$$

where c_{ij} is the time spent by a driver to go from node i of the network to node j; c_{ij}^{e} is the time spent to cover the same segment at free flow, considering also the limited capacity of the damaged bridges; f_{ij} is the traffic flow (number of vehicles per hour) on segment i-j; f_{ij}^{e} is the traffic flow capacity of segment i-j, considering the detrimental impact of closed or partially closed bridges; and α and β are parameters of the model. For a more detailed description of the effect of the bridge functionality on the traffic flow, the reader is referred to Bocchini and Frangopol (2011a).

FORMULATION OF THE PROBLEM

The problem is formulated as a bi-objective optimization. The first objective is the maximization of the network resilience over the investigated time horizon. The value of R is provided by Eq. (1), where the network functionality over time is computed through traffic flow analyses. The second objective is the minimization of the total present rehabilitation cost. This cost is a function of the time of rehabilitation (since it considers the discount rate of money) and the damage recovery rate (since a faster rehabilitation requires more resources). The following total present cost model can be adopted (adapted from Bocchini and Frangopol 2011a):

$$C = \sum_{b=1}^{N_B}\left[\int_{t_b^s(\delta_b)}^{t_b^e(\delta_b,\theta_b,l_b^0)} \frac{k_b \cdot \tan(\theta_b)}{(1+r)^t}\,\mathrm{d}t\right] \tag{5}$$

where subscript b runs over the bridges; $t_b^s(\delta_b)$ and $t_b^e(\delta_b, \theta_b, l_b^0)$ are the time at which the rehabilitation starts and ends on bridge b, respectively; k_b is the reference rehabilitation cost of bridge b, which can be assessed as one fourth of its total cost; and r is the annual discount rate of money.

As mentioned previously, the design variables are the idle time before the initiation of the rehabilitation δ_b and the damage recovery rate θ_b, presented in Figure 1. The first set of design variables is subject to the obvious constraint $0 \le \delta_b \le t_h$. The damage recovery rate is assumed to be constrained as well. In fact it is assumed that the recovery rate cannot be pushed by any means beyond a certain limit θ_{max}. Moreover, to exclude too slow interventions from the search domain, since they are certainly non convenient, it is also imposed that $\theta_b \ge \theta_{min}$. A constraint is also imposed on the maximum cost $C \le C_{max}$. Finally, an additional constraint is introduced in this paper. It requires that the number of simultaneous interventions N_{SI} on the bridges of the network never exceeds a prescribed value N_{SImax}. This

constraint reflects the fact that the number of large construction companies that can work in an area (especially an area that experienced an extreme event) is limited. If the maximum number of simultaneous interventions is small (e.g., half of the number of bridges) this constraint limits very significantly the domain of feasible solutions. The formulation of the optimization problem is summarized in Table 2.

Table 2. Problem formulation.

Given:	network topology;
(input)	traffic data;
	road capacities;
	secondary detour routes characteristics;
	bridge locations;
	approximate rehabilitation costs;
	discount rate of money;
	l_b^0 (post-event damage level for bridge b) $\quad \forall\, b = 1,2,\dots,N_B$;
find:	δ_b (idle time for bridge b) $\quad \forall\, b = 1,2,\dots,N$;
(design variables)	θ_b (damage recovery rate for bridge b) $\quad \forall\, b = 1,2,\dots,N_B$;
so that:	$R = maximum$;
(objectives)	$C = minimum$;
subject to:	$0 \le \delta_b \le t_h$, $\quad \forall\, b = 1,2,\dots,N_b$;
(constraints)	$\theta_{min} \le \theta_b \le \theta_{max}$, $\quad \forall\, b = 1,2,\dots,N_b$;
	$C \le C_{max}$;
	$N_{SI}(t) \le N_{SImax}$, $\quad \forall t \in [t_0, t_0 + t_h]$.

The optimization problem is solved using multi-objective genetic algorithms. At the end of the optimization, a Pareto front of solutions is provided. Each of these solutions consists in the values of δ_b and θ_b for all the bridges of the network. Therefore, each solution describes a global rehabilitation plan in terms of schedule of interventions, damage recovery rate and, in turn, cost breakdown among the various bridges. All the Pareto solutions are optimal, meaning that for each one of them it is not possible to find another solution that improves an objective without worsening the other. Decision makers choose the optimal solution that seems the most appropriate for the specific scenario under consideration.

NUMERICAL EXAMPLE

Description of the problem. A bridge network located in the Lehigh Valley, Pennsylvania, is considered for a numerical application. For illustrative purpose, a very rare earthquake with magnitude 7 and hypocenter 10 km deep is assumed to damage the bridges of the network. The value of l_b^0 is computed performing a series of fragility analyses associated with four damage states with the program HAZUS-MH MR4 (DHS 2009) and taking the expected value of the damage (Bocchini and Frangopol 2011b). The location of the epicenter, the transportation network layout, the location of the bridges, and the associated earthquake damages are shown in Figure 3. Nodes 1 and 4 represent the cities of Allentown and Easton, respectively,

while nodes 2 and 6 collect traffic from the northern and southern parts of the city of Bethlehem. Nodes 3 and 5 are highway junctions. Data on the characteristics of the nodes and of the highway segments are provided in Bocchini and Frangopol (2011b). Data associated with bridges and detour routes are collected in Table 3. The detour time is computed based on the detour length provided by the National Bridge Inventory (FHWA 2009). The detour capacity is estimated as 1500 cars/hour for the entire network, depending on the characteristics of the region (medium population density, urban) and the number of lanes of the secondary routes. The representative restoration cost is computed as one fourth of the bridge cost, as provided by the database of HAZUS.

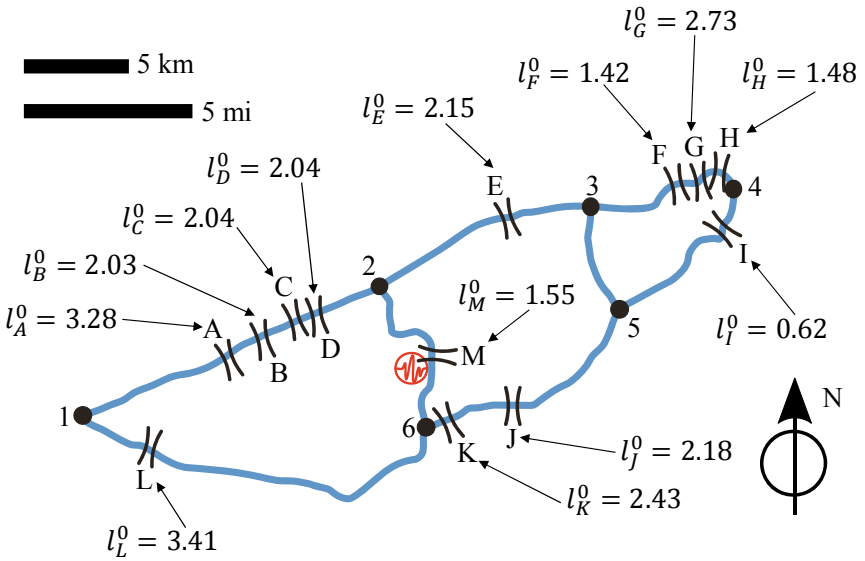

Figure 3. Layout of the network, location of the epicenter, and expected damage levels.

Table 3. Bridge characteristics.

Bridge	Detour time [minutes]	Detour capacity [cars/hour]	k_b [$]
A	12	1500	885,000
B	10	1500	889,000
C	12	1500	1,773,000
D	12	1500	1,345,000
E	26	1500	925,000
F	10	1500	731,000
G	10	1500	1,752,000
H	10	1500	731,000
I	32	1500	1,165,000
J	26	1500	3,873,000
K	16	1500	621,000
L	16	1500	928,000
M	10	1500	4,088,000

The investigated time horizon is 24 months; admissible damage recovery rates are between 0.58 and 5.67 damage recovered per year (equivalent to slopes between 30^o and 80^o in Figure 1); the maximum number of simultaneous interventions is 6; the annual discount rate of money is 5%; the maximum cost of the rehabilitations is \$8,000,000; and the parameters γ_T and γ_D are $2 \cdot 10^{-7}$ min^{-1} and $6.21 \cdot 10^{-8}$ km^{-1}, respectively.

Results of the analysis. In 1896.9 minutes, genetic algorithms running on a personal computer produced in 2006 with a single-core 3.4GHz CPU and 2GB of RAM completed 100 generations made by 400 individuals each. The resulting Pareto front is plotted in Figure 4.

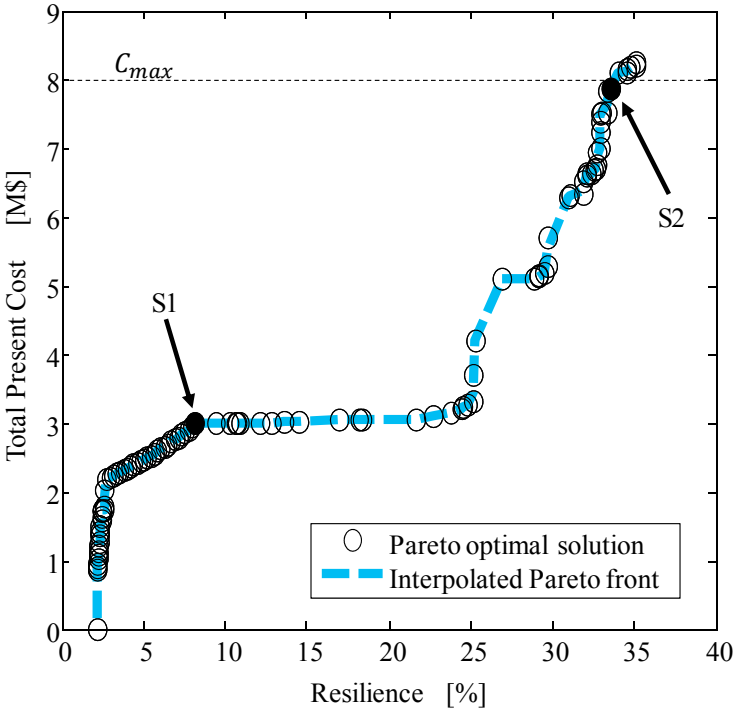

Figure 4. Pareto front of optimal solutions.

The solution indicated in Figure 4 as S1 prescribes interventions only on the critical bridge L, which is heavily damaged and affects the large volume of traffic that departs from and is headed to node 1 (Allentown). For this reason, $\delta_L = 0$, while for all the other bridges $\delta_b = t_h$. This solution is relatively inexpensive (\$2,980,000) because it affects only one bridge, but provides a value of resilience that is very limited (8.2%). The group of solutions on the left of S1 are very similar to S1, but with a slightly larger value of δ_L. Hence, the resilience that they provide is a little lower, but also the cost is lower, due to the annual discount rate of money.

The cost associated with solution S2 in Figure 4 is the closest to C_{max} . Solution S2 prescribes interventions on bridges E and L immediately, on bridge H after approximately 6 months, and on bridge B after one year. Figure 5a shows the rehabilitation schedules and the damage recovery rates (i.e., the design variables)

associated with this solution. Figure 5b presents the time-dependent network functionality. The ratio between the shaded area and the total area is the resilience associated with S2. Even though only four out of 13 damaged bridges are rehabilitated, at the end of the investigated time horizon the functionality of the network is restored to 51.6% of its original value. Figure 5c shows the cumulative cost of the interventions discounted at t_0.

It should be noticed that the strict constraints on the maximum number of simultaneous interventions and on the available funding have determined that none of the optimal solutions allows to completely restore the original network functionality. In a real scenario, this type of analysis should be used for the immediate emergency response after the occurrence of an earthquake. For the complete restoration of an infrastructure network subject to this level of damage, more resources and a longer time horizon must be considered.

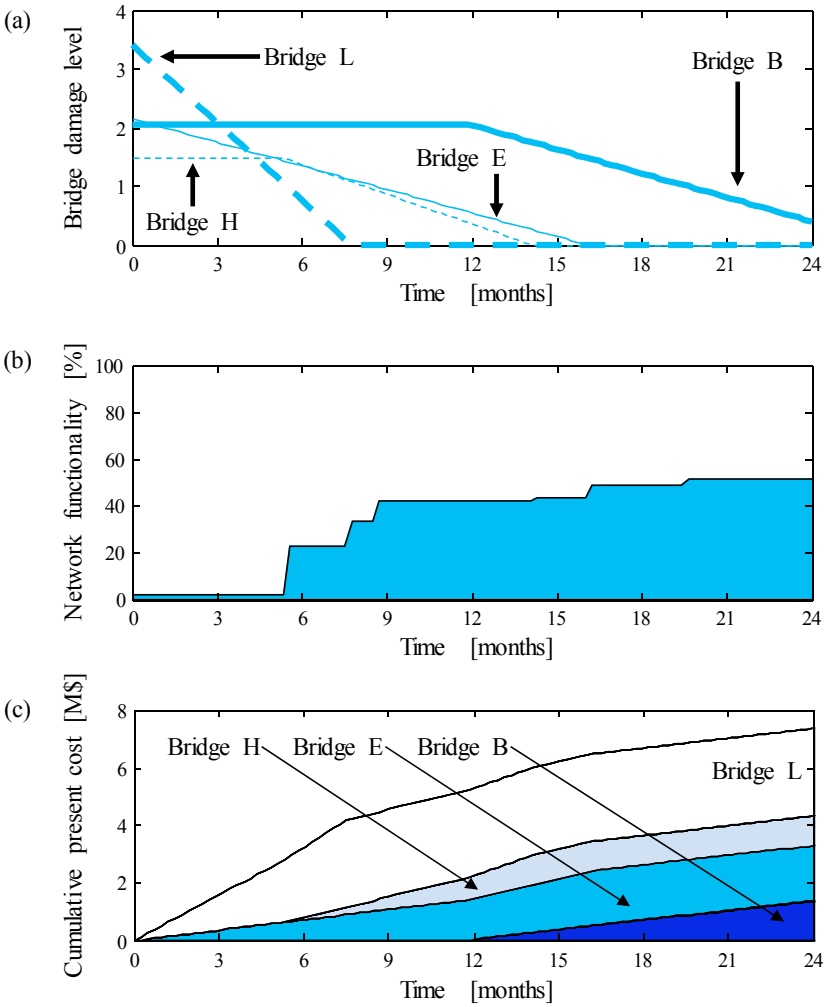

Figure 5. Rehabilitation plan associated with solution S2: (a) schedule of the rehabilitations, damage recovery rates, and damage level profiles for the bridges that are rehabilitated; (b) evolution of the network functionality and resilience (shaded area); (c) cumulative present cost of the rehabilitations.

Discussion of results. The CPU time required by the solution indicates that with any modern computer this type of computation is perfectly feasible, even in the case of complex bridge networks. The computational effort can be further reduced as follows. Approximately 97.5% of the time is used for the repeated solution of the traffic assignment and distribution problem (performed several millions times per run). The proposed procedure already builds a lookup table automatically during its execution (i.e., it stores the results of the network analysis for each bridge configuration that it investigates). This way, every time it is already available, the code retrieves the network functionality associated with a certain bridge configuration, rather than computing it again. Network owners or managers can run the code and make it build the lookup table for the set of most probable bridge configurations. In this way, in case of an extreme event, the execution of the optimization would be extremely fast. Figure 6 shows a dramatic reduction of the CPU time along the generations used by genetic algorithms. Indeed, this reduction is mostly due to the fact that the latest generations could take advantage of a more complete lookup table built along the execution.

The proposed technique automatically identifies the bridges that need to be rehabilitated first and the optimal damage recovery rates (i.e., the best cost breakdown) in order to quickly restore the original network functionality.

The new constraint introduced on the maximum number of simultaneous interventions forces the technique to select only a subset of bridges. For this example, the constraint on N_{SI} turned out to be the one that affected the most the Pareto front. In fact, in the last generation, 39% of the candidate solutions were discarded because they did not satisfy this constraint.

Since the time horizon is short (two years) the effect of the annual discount rate of money is very limited, even if a very high value was selected (5%).

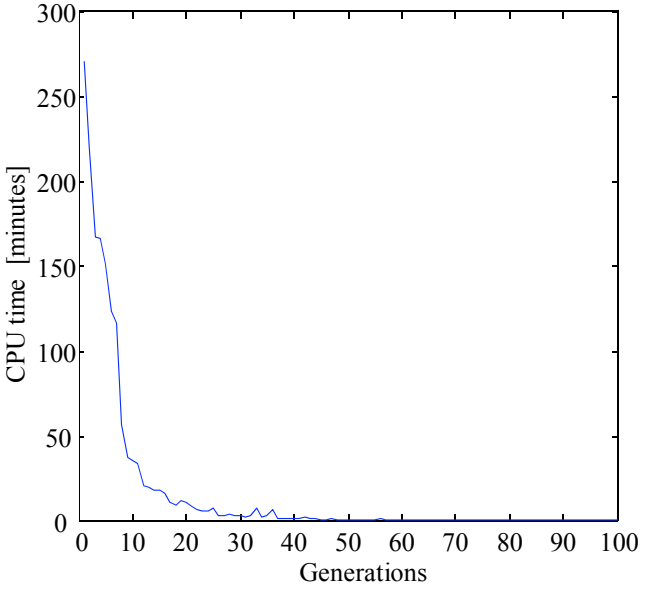

Figure 6. CPU time per generation (single-core PC produced in 2006).

CONCLUDING REMARKS

A methodology has been presented for the use of resilience as optimization criterion for the rehabilitation of bridges belonging to a transportation network subject to earthquake. This methodology provides a Pareto front of schedules and damage recovery rates for the rehabilitation interventions that maximize the network resilience and minimize the cost of interventions. The proposed approach assists decision makers to enhance the disaster management and the recovery of the region.

With respect to other techniques addressing similar issues, the one proposed in this paper extends the applicability to complex transportation networks. This is achieved through the solution of the complete traffic assignment and distribution problem. Moreover, a new constraint on the maximum number of simultaneous interventions has been introduced.

The time required for the analysis depends on the complexity of the network, on the original damage level of the bridges, and on the constraints that are imposed. The presented numerical example shows that the technique is applicable to the investigated network and the CPU time required is kept feasible by the use of genetic algorithms and the lookup table technique (Bocchini and Frangopol 2010a). It is expected that even for more complex bridge networks, the computational effort remains affordable.

ABSTRACT

This experimental study focuses on investigating the feasibility of using shape memory alloy (SMA) spiral to conduct emergency repairs on severely damaged reinforced concrete (RC) bridge piers. The studied repair technique can be implemented in less than 24 hours and hence can be used to rapidly restore the functionality of lifeline bridges that are severely damaged by an earthquake. The proposed repair technique can also ensure the safety and structural integrity of important bridges against strong aftershocks. Unlike other repair techniques such as composite jackets, which utilize the concept of passive confinement, this proposed technique relies on the concept of concrete *active confinement* to enhance the strength and ductility of severely damaged concrete. Research has shown that active confinement is a more superior confinement technique to passive confinement; however, with conventional materials, its fast application on-site in case of an emergency could be a challenge. This study presents an easy and fast method to apply active confinement using SMAs. The thermally activated shape recovery feature of SMAs is used to apply the active confining pressure at the damaged locations. To examine the proposed technique, two 1/3-scale RC columns which were severely damaged are repaired using SMA spirals and retested. The damage sustained by the two columns is localized primarily at the column base (i.e. at the plastic hinge zone), which is typical in seismically damaged slender columns. The damages in both columns are in the form of concrete cover spalling, concrete core crushing, and buckling and rupture of at least one of the longitudinal rebars. The repaired columns are tested under quasi-static cyclic loading. The results are compared with those of the as-built columns. The experimental results show that the repaired columns have fully restored their lateral stiffness, strength and hysteretic energy dissipation capability. The results of this study clearly illustrate the effectiveness of the proposed technique for emergency repair applications.

INTRODUCTION

There is a continuous need for developing rapid and robust emergency structural repair methodologies for ensuring the safety of our societies from natural hazards such as earthquakes. In order to mitigate the impacts of such hazards on our societies,

one approach is to secure critical life-line structures against possible damages and malfunction. When life-line bridges are severely damaged, the functionality of the entire transportation network is impacted, thus delaying emergency response teams from taking a swift action. In many cases, severely damaged reinforced concrete (RC) columns supporting life–line bridges have jeopardized safety and functionality of the bridges. Therefore, this paper focuses on addressing the emergency repair of severely damaged RC bridge columns.

The majority of the repair techniques currently at hand suggest the use of either fiber reinforced polymer (FRP) sheets or concrete jackets. One of the recent studies that explored the use of carbon-FRP (CFRP) sheets to repair already damaged columns was conducted by Vosooghi et al. (2008). Prior to this study there was another study that focused on using prefabricated FRP composite straps for seismic damage repair of circular and rectangular columns (Saadatmanesh et al. 1997). These studies reported improvements in the strength and ductility of the repaired columns. However, a major challenge when using FRP sheets for rapid repair is the time required for the resin to cure under ambient climate conditions which could extend up to a week or more. On the other hand, some studies attempted the use of concrete jackets for repair (Bett et al. 1988; Fukuyama et al. 2000; Lehman et al. 2001). The results of the research were satisfactory; however, this technique also requires considerable labor and time, which will impose significant delays in the opening of damaged bridges. Therefore, this paper focuses on presenting and investigating experimentally a new rapid repair technique for severely damaged RC columns using shape memory alloy (SMA) spirals. The new technique is designed specifically for emergency situations, and thus will help in restoring the functionality of severely damaged structures in less than 24 hours. Two damaged RC columns were repaired and tested under quasi-static cyclic loads.

REPAIR TECHNIQUE USING SMA SPIRALS

Utilizing the recovery stress of prestrained SMA spirals associated with the shape memory phenomenon of SMA is the key point of the new repair technique. As wrapping the damaged region of the RC column with the prestrained SMA spirals and providing the spirals with high enough temperature, an active confining pressure is applied in the form of hoop stress on the damaged region of the column, and the active confining pressure contributes to restore the strength and flexural ductility of the damaged column.

For this particular application, approximately 6%-prestrained SMA wires in a martensite phase by manufacturer were used. It is important to maintain the active confining pressure even at a wide range of ambient temperature for its service life. Therefore, an alloy whose thermal hysteresis is wide enough has to be used, and the ternary NiTiNb alloy was selected in this study for that reason. The thermal hysteresis width of NiTiNb is typically around 130 ^{o}C, with its martensite start temperature (M_s) being approximately -50 ^{o}C (Duerig et al. 1990). Figure 1 depicts schematic of a wide hysteresis SMA with the expected range of ambient temperature. Since the expected range of ambient temperatures is greater than M_s, the alloy should remain in the austenite phase when the ambient temperature drops down after heating.

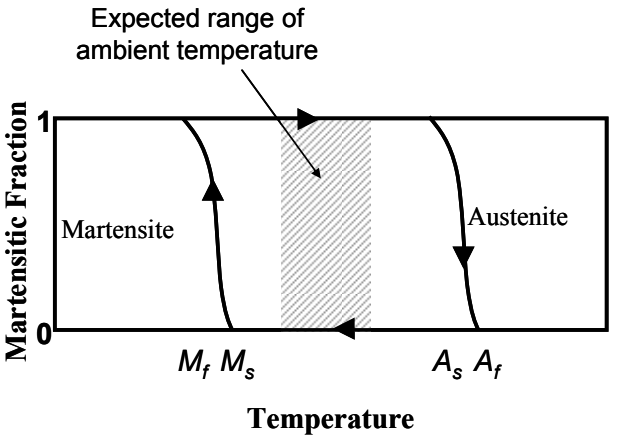

Figure 1. Martensitic fraction vs. temperature of a SMA with wide thermal hysteresis.

In an earlier study by the authors, thermo-mechanical tests on the NiTiNb wires were conducted (Shin and Andrawes, 2010a). From the experimental tests, the stabilized recovery stress of SMA was recorded as 459.9 MPa even at room temperature (16 ^{o}C) after the temperature of SMA wire was heated approximately up to 200 ^{o}C. This stable recovery stress was continually exploited in this study to apply the active confining pressure as a rapid repair technique to restore damaged columns' strength and flexural ductility.

The proposed repair technique consists of the following steps: (1) removing loose concrete, (2) straightening and/or coupling any buckled or ruptured longitudinal reinforcing bars, (3) injecting epoxy into concrete cracks, (4) applying quick-setting cement-based mortar to replace the removed concrete, (5) wrapping the damaged portion with the prestrained SMA wire in the form of a spiral, and heating the SMA spiral by using a fire torch or by passing an electric current.

SPECIMENS DESCRIPTION AND DAMAGE HISTORY

As-built Specimens

Two reduced scale (1/3-scale) single-cantilever RC columns were repaired with the proposed technique using SMA spirals, and tested under quasi-static lateral cyclic loading. The damaged columns in a previous study conducted by the authors (Shin and Andrawes, 2010b) were used. One of the columns (C1) was damaged under an incrementally increasing displacement-controlled lateral cyclic load, while the other column (C2) was damaged accidentally due to an error in the control system which caused the column to fail under excessive monotonic load. Figure 2 shows details of the as-built columns and the steel reinforcing rebars. The effective height of the column was 1270 mm, and the diameter of the cross section of the column was 254 mm with 25.4 mm clear cover. The dimensions of the footing were 1168 mm x 1168 mm x 406 mm. Eight No.4 (13 mm diameter) reinforcing bars were used for the longitudinal reinforcements, while No. 2 (6 mm diameter) transverse ties were placed every 102 mm for the transverse reinforcement. The average compressive strength of

the concrete was 40 MPa at the day of testing. Figure 3 shows the load protocol adopted in the tests.

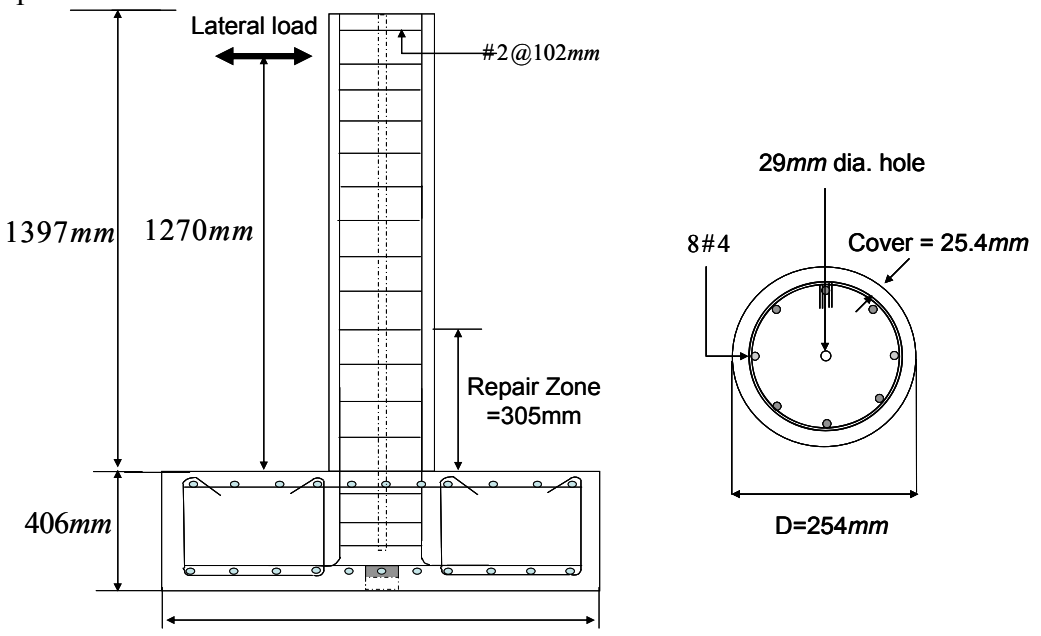

Figure 2. Elevation and cross section of as-built columns.

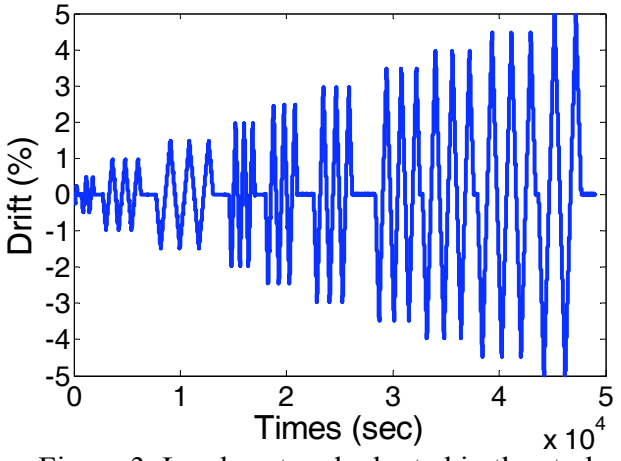

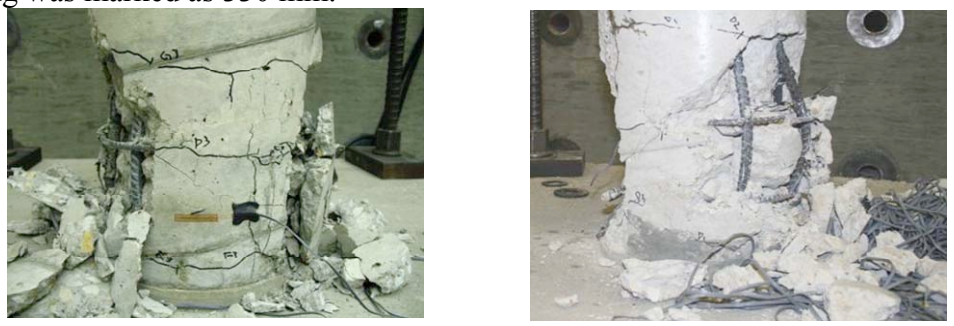

Figure 3. Load protocol adopted in the study.

Behavior and Damage of As-built Column C1

When column C1 reached the 1.5% drift ratio, the longitudinal reinforcing bars started yielding, and the average maximum strength was recorded as 34.0 KN. Also, at the drift ratio of 3.5%, cover concrete had spalled significantly, after which, the core concrete and the two longitudinal bars located near the extreme fibers started crushing and buckling, respectively. When the column reached 4.2%-drift, one of its longitudinal rebars ruptured, which resulted in the degradation of the strength abruptly by 23%. The maximum drift the column experienced was 5%-drift ratio. Figure 3.a shows a picture of the damaged C1 column. The damage of the column consisted of: 1) crushed cover and core concrete on both sides of the column, 2) one ruptured and five buckled longitudinal reinforcing bars, and 3) excessive opening of

transverse reinforcement. The height of the formed plastic region from the top of the footing was marked as 330 mm.

(a) C1 (b) C2

Figure 3. Damage sustained by columns C1 (a) and C2 (b).

Behavior and Damage of As-built Column C2

It was planned for Column C2 to be tested under the same cyclic load protocol used for the column C1. However, at a drift ratio of 1.5%, the hydraulic actuator went out of control exerting a maximum drift ratio of about 7% on the specimen in one direction. Due to the accident encountered during testing, no data was recorded after the 1.5% drift. Figure 3.b shows a picture of the damaged specimen under the excessive monotonic loading. Since the column failed primarily under the monotonic loading in one direction, the concrete at one side was completely crushed, while at the other side, the concrete was cracked due to excessive tension. Therefore the damage of the column c2 was unsymmetrical while the damage of the column C1 was symmetrical. In addition, since column C2 was not subjected to significant cyclic loading at high drift ratios as column C1, the reinforcing bars of column C2 had buckled without experiencing any ruptures. The height of the damaged plastic region was marked as 330 mm.

REPAIRED SPECIMENS

In order to repair the two damaged columns and restore the functionalities of the columns in less than 24 hours, a five-step repair process had been taken. Each step of the repair process was illustrated in figure 4. First, crushed and loose pieces of concrete were removed from the damaged region of the columns, and the steel reinforcing bars were exposed. Figure 4.a shows the concrete surface of column C1 after removing the crushed concrete. Second, slightly buckled longitudinal reinforcing bars were straightened, and the ruptured bars were connected using rebar couplers (figure 4.b). As noted earlier, only one reinforcing bar was ruptured and needed coupling in column C1. For column C2, however, no longitudinal rebars were ruptured, but three of the rebars buckled severely after being damaged by the excessive monotonic loading. To adjust these severely buckled rebars, it required to cut the bars, and reconnect them with couplers. Third, pressurized epoxy was injected to fill the cracks of the concrete in this repair process (figure 4.c.). Steps one through

(a) Concrete removal

(b) Steel adjustment

(c) Epoxy injection

(e) Heating SMA spirals

(f) Repaired column

Figure 4. Pictures of the five-step emergency repair process.

three took approximately three hours. Forth, the damaged region was filled with quick-setting mortar (figure 4.d). The nominal compressive strength of the mortar under controlled environmental conditions at an age of 24 hours was 31.0 MPa. To examine the strength of the mortar in the laboratory environment where the columns were tested, three 76 mm x 152 mm cylinders were cast using the quick-setting mortar and tested after 24 hours. The strength of the cylinders was found to be 21 MPa, which is 53% of the compressive strength of the concrete used in casting the as-built columns. While curing the mortar, the fifth step of the repair process proceeded. The columns were wrapped with the SMA spirals at the repaired region (i.e. 330 mm

from the column base) with 25mm pitch spacing, and heated using a fire torch as shown in figure 4.e. Figure 4.f shows a picture of the repaired column after the completion of the repair process. It took approximately 24 hours from the first step of repair process until the onset of the column testing. However, it is important to note that the whole repair process from the first step to the fifth step was completed in less than 15 hours.

TEST-SETUP

Figure 5 shows schematic of the test setup used in this study. The columns were subjected to quasi-static lateral cyclic loading protocol similar to the one previously shown in figure 3. A 445 KN servo-controlled hydraulic actuator with a stroke of ± 254 mm was used to apply the lateral loading at the effective height of 1270mm. The constant axial force was applied on the column during the test, and it was maintained as 116 KN, which represented 5% of the gross section compressive strength of the as-built columns. A 445 KN hydraulic actuator was used to apply the axial force, and a load cell was mounted on the top of the column, and the load cell was anchored to a 15.2 mm-diameter seven wire steel strand located at the center of the column. Additionally, to measure the net displacements of the column, four Linear Variable Differential Transformers (LVDTs) were installed Three LVDTs were placed between the floor and the footing to capture the rotation of the footing and its displacement relative to the floor. The last LVDT was installed to measure the relative displacement between the reaction wall and the actuator's steel and concrete blocks.

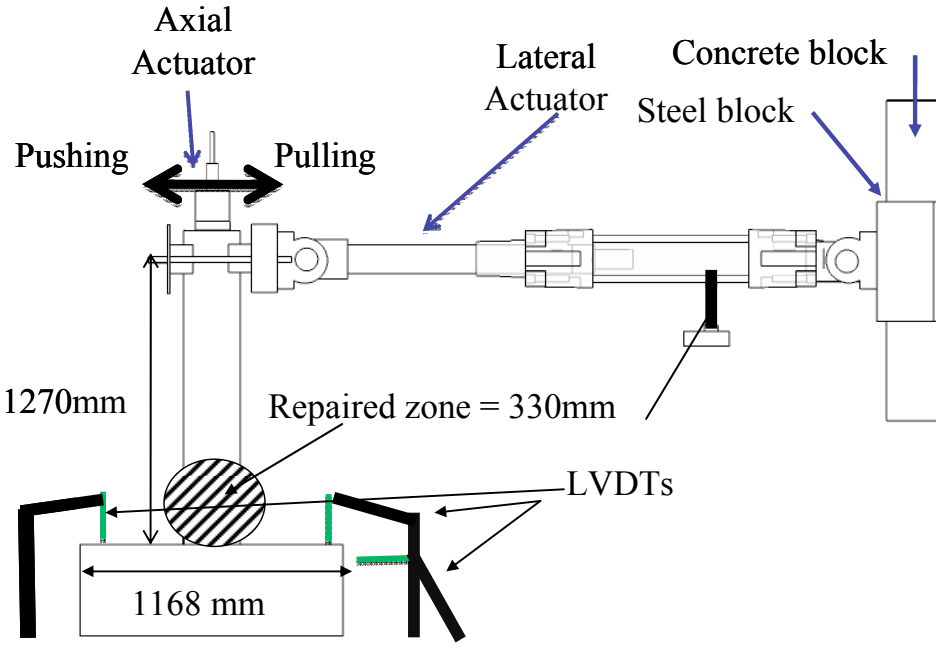

Figure 5. Schematic of the test set-up

TEST RESULTS

Column C1

Figure 6 shows a comparison between the lateral force versus displacement relationships of the as-built and the repaired C1 column. The repaired column started yielding at a drift ratio of 0.7%, and the average maximum strength recorded under pushing and pulling was 34.2 KN. At a drift ratio of 2%, the strength of the repaired column dropped abruptly by 28% due to the rupture of one of the longitudinal reinforcing bars. In the succeeding cycle, another rebar was ruptured, which resulted in reducing the strength to 52% of its maximum strength. Based on the comparison between the average strengths of the repaired and as-built columns, it was concluded that the emergency repair technique using SMA spirals performed on the severely damaged column was capable to fully restore the as-built column's lateral strength. Furthermore, the average initial stiffness of the repaired column was found to be 3.4 KN/mm, which is 54% higher than that of the as-built column and 930% higher than the residual (secant) stiffness of the damaged column.

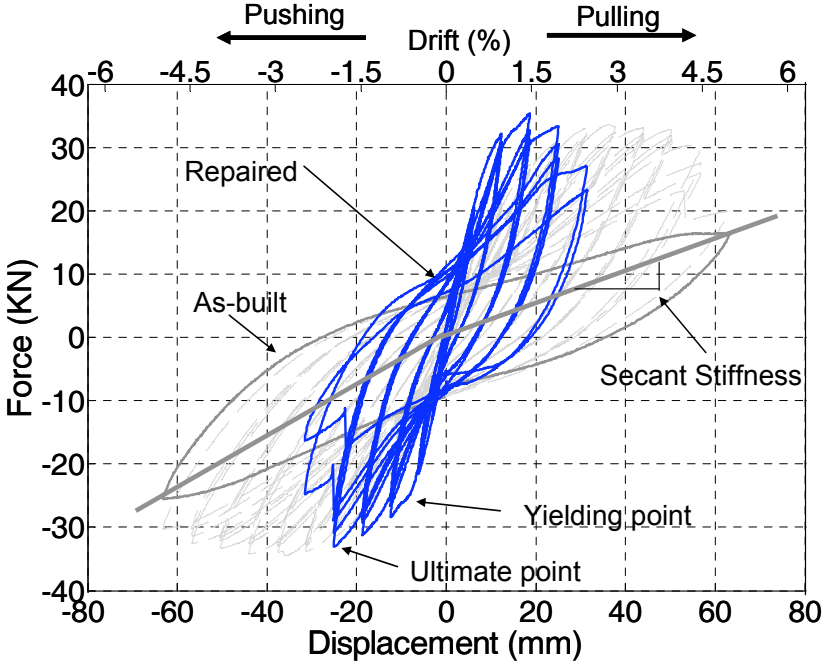

Figure 6. Comparison between the cyclic force vs. displacement relationships of the as-built (dashed line) and the repaired (solid line) C1 column.

Column C2

Figure 7 shows a comparison of the lateral force versus displacement relationship between the as-built and the repaired column C2. The repaired column started yielding at a drift ratio of 0.6%, and the maximum strength recorded was 41.3 KN at 1.5% drift ratio. The cyclic behavior of the repaired column C2 was unsymmetrical, and the lateral strength of the column degraded gradually, instead of showing an

sudden drop unlike the repaired column C1. The slippage of the coupled rebars located on one side of the repaired column during testing was identified as a main reason for the unsymmetrical behavior of the repaired column C2 after the completion of the test. The failure of the couplers to fully connect the rebars resulted in a reduced strength of the rebars, which led to significantly less strength for the column when "Pushed" (see figure 7). On the other hand, when the column was "Pulled", it showed satisfactory behavior since the rebars resisting tension were relatively in fair condition and only sustained minimal damage during the first round of testing. Assessing the behavior of the column when pulled, one can observe that the strength of the repaired column exceeded that of the as-built column by 21% (based on the predicted maximum strength of the as-built column, 34.5 KN). Also, the average initial stiffness of the repaired column in both pulling and pushing directions was 4.2 KN/mm, which exceeded the initial stiffness of the as-built column by 47%.

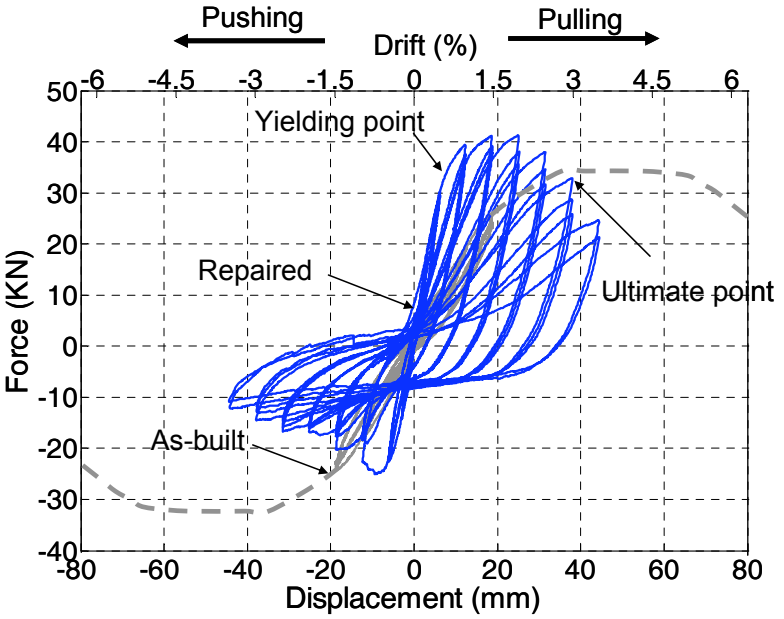

Figure 8. Comparison between the force vs. displacement relationships of the as-built (dashed line) and the repaired (solid line) C2 column.

CONCLUSIONS

This paper presented a new emergency repair technique for severely damaged RC columns using prestrained SMA spirals. The thermally-triggered recovery stress of prestrained SMAs was used to exert large external active confining pressure on the concrete at the repaired region of the damaged column in a short time. Two reduced scale (1/3-scale) RC single cantilever columns (C1 and C2) that were severely damaged in a previous study were repaired using the new repair technique, and retested under quasi-static lateral cyclic loading. The repair process of each column was conducted in less than 15 hours and the columns were tested in less than 24 hours. Test results revealed that the lateral strengths and the initial stiffness of both repaired columns were fully restored or even enhanced, It is important to note that the

recovered properties of the repaired columns are mainly attributed to the ability of the SMA spirals to apply and maintain active confining pressure on the damaged region of the columns, which increased the strength of the already damaged concrete and delayed its damage by increasing its ultimate strain. Finally, this paper showed that the proposed repair technique is effective and could be implemented successfully in a short time and thus could be used in emergency situations to maintain or restore the functionality of damaged lifeline structures.

ABSTRACT

This study compares the performance of two smart isolation systems that utilize superelastic shape memory alloys (SMAs) for seismic protection of isolated bridges during strong earthquakes. The first isolation system is an SMA/rubber-based (SRB) isolation system and consists of a laminated rubber bearing that decouples the superstructure from the bridge piers and an SMA device that provides additional energy dissipation and re-centering capacity. The second isolation system, named as superelastic-friction base isolator (S-FBI), combines the superelastic SMAs with a flat steel-Teflon bearing rather than a laminated rubber bearing. Seismic energy equations of a bridge structure with SMA-based isolation systems are established by absolute and relative energy balance formulations. Nonlinear time history analyses are performed in order to assess the effectiveness of the isolation systems and compare their performance. The program RspMatch2005 is employed to generate spectrum compatible ground motions that are used in dynamic time history analyses of the isolated bridge. The results indicate that SRB isolation system produces higher seismic input energy, recoverable energy and base shears as compared to the S-FBI system. Also, it is shown that combining superelastic SMAs with a sliding bearing rather than rubber bearing significantly reduce the amount of the required SMA material.

INTRODUCTION

Strong earthquakes can be considered as the most significant and possibly most frequent natural hazard that causes damage to the bridge structures. Severe damages or complete collapses have been observed in numerous bridges during the past earthquakes. Since the bridges are lifelines of the transportation network, damaged bridges within the highway system cause an increase in travel time and distance. Therefore, indirect economic loss can reach to significant levels besides the direct loss resulting from bridge damage (Enke *et al*., 2008). To reduce the damaging effects of earthquakes on bridge structures, there have been intensive research efforts in the field of structural engineering over the past decades. Several innovative design strategies have been developed and employed to improve response of bridges

subjected to seismic loads. Among them, seismic isolation has been most commonly used method to minimize the damaging effects of strong ground motions.

Seismic isolation aims to reduce earthquake energy that enters to the structure by providing flexible interfaces which decouple the support of a structure from the horizontal motions of the ground. For seismically isolated bridges, the isolation bearings are placed between the superstructure and the top of the substructure (the piers and abutments). Under service loading, they behave as a conventional bridge bearing. During an earthquake loading, the seismic isolation (i) reduces the lateral forces in the superstructure by elongating the fundamental period of the structure and dissipating energy and (ii) concentrates the lateral displacements at the isolation level, i.e. limits the structural deformations of the piers. A variety of devices including rubber isolation systems that combine laminated rubber bearings and some mechanical dampers as well as sliding-type isolation systems that filter out earthquake forces via the discontinuous sliding interfaces have been developed and used for seismic isolation.

To improve the response of isolated structures, several researchers have proposed smart isolation systems which combine smart materials with conventional bearings. Shape memory alloys (SMAs) are a unique class of metal alloys that have the ability to recover extensive deformations upon removal of the external load. Superelastic SMAs display hysteretic energy dissipation capacity and have substantial resistance to fatigue and corrosion. Due their appealing characteristics, superelastic SMAs have been considered as an isolation component by a number of researchers to develop a smart isolation system. Wilde *et al.* (2000) proposed a base isolation system that is composed of a laminated rubber bearings and an SMA device for protecting elevated highway bridges from the hazard of earthquakes. Ozbulut and Hurlebaus (2010a) studied the performance of a superelastic-friction base isolator (S-FBI) that combines a flat sliding bearing and a superelastic SMA device. They identified the optimum design parameters of the S-FBI system for seismic protection of bridges against near-field earthquakes. As an alternative to conventional rubber isolators, Ozbulut and Hurlebaus (2010b) evaluated the performance of a smart rubber bearing system with shape memory alloys. In particular, they explored the effectiveness of SMA/rubber-based (SRB) isolation systems in mitigating response of the bridge structures subjected to near-field earthquakes by performing a sensitivity analysis. Although both the S-FBI system and SRB system have been found to be an effective isolation system when their design parameters are judiciously selected, further work is needed to compare the efficiency of these two SMA-based isolation systems.

Energy-based concepts have been considerably used in the earthquake resistant design of structures since an energy-based design method was introduced by Housner (1956) in the mid 1950s. The basic idea in the energy-based design is that the *energy demand* during a seismic excitation should be less than the *energy supply* of a structural system. In view of energy-based concepts, in seismic isolation, the goal is to reduce the seismic input energy to the system and dissipate the input energy through damping mechanisms. Therefore, an optimal isolation system should minimize the energy transmitted to the structure while dissipating the most of the energy through nonlinear hysteretic deformations in the isolation device with only a

small amount of left energy that can cause damage on the main structural system (Austin and Lin, 2004).

The goal of this study is to assess and compare the effectiveness of two different SMA-based isolation systems, namely the S-FBI system and SRB isolation system by conducting nonlinear time history analyses with energy balance assessment. First, the energy balance equations are formulated for an isolated bridge structure. Both absolute and relative energy formulations are considered and the relevance of using them for the seismic evaluation of structures subjected to various earthquakes is discussed. Then, the efficacies of the S-FBI system and SRB isolation system for seismic protection of bridges are assessed by conducting nonlinear time history analyses.

MODELING OF ISOLATED BRIDGE AND SELECTED GROUND MOTIONS

A three-span continuous bridge is selected for the numerical simulations (Wang *et al*., 1998). The deck of the bridge has a mass of 771.1×10^3 kg, and the mass of each pier is 39.3×10^3 kg. The bridge has a total length of 90 m, and each pier is 8 m tall. The moment of inertia of piers and Young's modulus of elasticity are given as 0.64 m^4 and 20.67×10^9 N/m^2, respectively. The fundamental period of non-isolated bridge is 0.45 s. Since the isolation systems installed at the abutment and pier have similar characteristics and therefore, the seismic response of the bridge at the abutment and pier have the same trend, only an internal span is modeled.

Figure 1 shows a two-degree-of-freedom model of the isolated bridge with the S-FBI system and SRB system. The S-FBI system combines a superelastic SMA device with a flat steel-Teflon bearing, whereas the SRB isolation system combines the SMA device with a laminated rubber bearing rather than a sliding bearing. The SMA device simply consists of multiple loops of superelastic NiTi wires wrapped around low-friction wheels. The pier is assumed to remain linear-elastic and modeled with a linear spring and dashpot. The restoring force of the S-FBI system is given as

$$F_{SFBI} = F_f + F_{SMA}, \tag{1}$$

where F_f and F_{SMA} denote the frictional resistance force of the steel-Teflon sliding bearings and the nonlinear force of the SMA device, respectively. A hysteretic model is used to simulate the force of the sliding bearings (Constantinou *et al*., 1990). The frictional force at a sliding interface is given by

$$F_f = \mu W Z \tag{2}$$

where μ represents the coefficient of friction, W is the normal load carried by the bearing interface, and Z is a hysteretic dimensionless quantity computed from following equation

$$Y\dot{Z} + \gamma|\dot{u}_b||Z||Z|^{n-1} + \beta\dot{u}_b|Z|^n - \dot{u}_b = 0\,, \tag{3}$$

where Y is the yield displacement of the sliding bearing chosen as 0.0005 m and, γ, β, and n are dimensionless parameters that control the shape of the hysteretic curve and have the values of 0.9, 0.1 and 1, respectively.

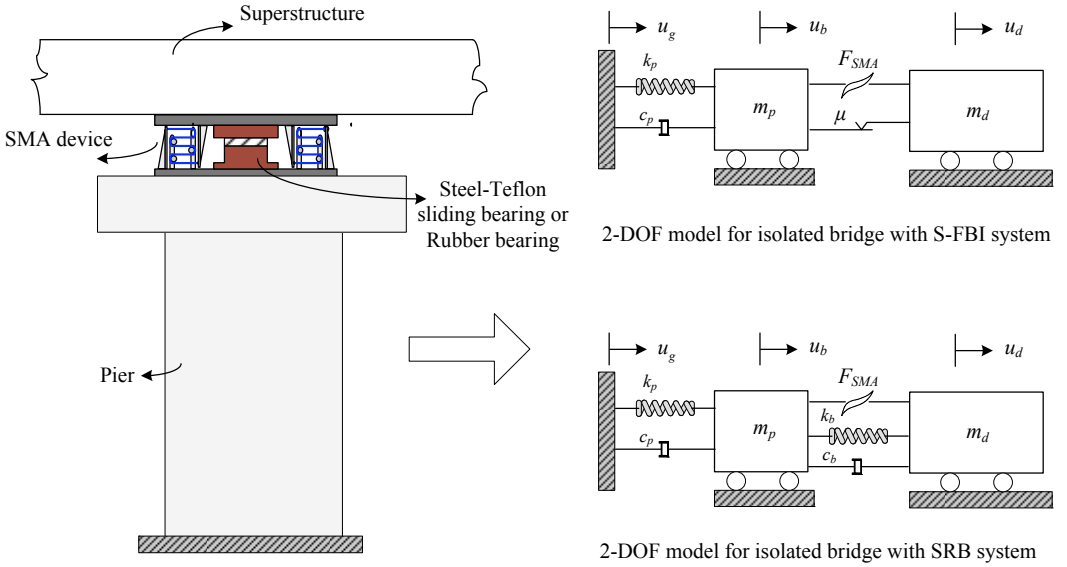

Figure 1. Model of isolated bridge structure

A neuro-fuzzy model developed by Ozbulut and Hurlebaus (2010c) is used to simulate the force-deformation behavior of the SMA device. Neuro-fuzzy modeling refers creating a fuzzy inference system (FIS) that is trained by a learning algorithm based on neural networks. The FIS maps an input space to an output space by means of fuzzy if-then rules. Adaptive neuro-fuzzy inference system (ANFIS) is a soft computing approach that employs neural network strategies to develop a fuzzy inference system whose parameters cannot be predetermined. Ozbulut and Hurlebaus (2010c) used the ANFIS to create a model of superelastic SMA wires and the details in regard to the neuro-fuzzy model of the NiTi wires can be found in their work.

The restoring force developed in the SRB isolation system is given by

$$F_{SRB} = c_b \dot{u}_b + k_b u_b + F_{SMA} \tag{4}$$

where c_b and k_b are the viscous damping and initial stiffness of the laminated rubber bearing, respectively; $\dot{u}_b$ and u_b are the velocity and deformation of the bearing, respectively; and F_{SMA} is the force of the SMA device.

Four ground motion records, namely, 1940 El Centro, 1992 Landers, 1992 Erzincan, 1999 Kocaeli are selected as seismic loading. Note that the 1940 El Centro record resembles a typical far-field ground motion; the 1992 Landers and 1992 Erzincan records are near-field ground motions characterized by forward directivity and the 1999 Kocaeli record is a near-field earthquake with fling effect. Near-field earthquakes are characterized by long period and large- velocity pulses. While the near-field records with forward directivity have double-sided velocity pulses, fling motions are characterized by a unidirectional large amplitude velocity pulse.

The program RSPMatch 2005 is used to modify selected time histories so that their response spectra are compatible with the selected target spectrum. A response spectrum constructed as per the International Building Code (2000) for a site in

southern California, assuming firm rock conditions is selected as the target spectrum (Malhotra *et al*., 2003). Figure 2 shows the target response spectrum used in the analysis and response spectra of selected ground motions for 5% damping level before and after spectral matching.

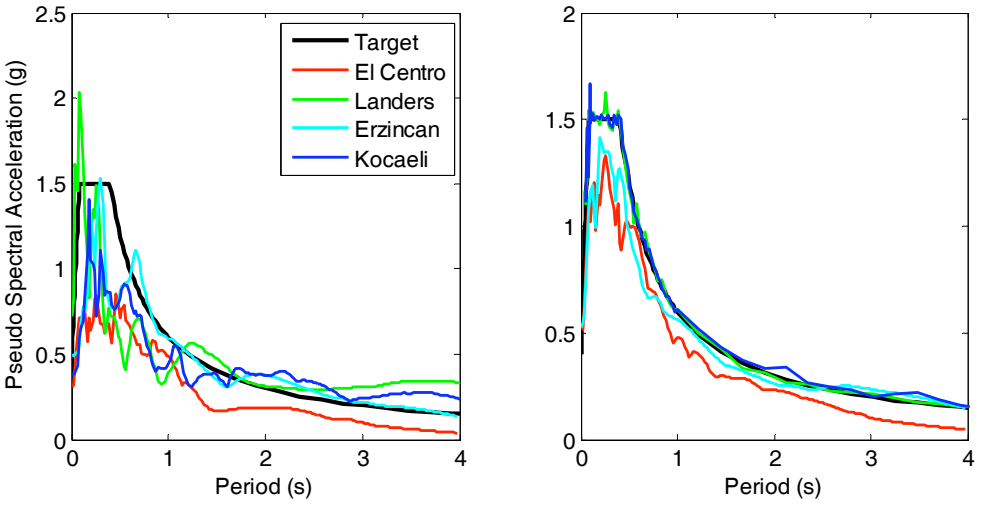

Figure 2. Model of isolated bridge structure

SEISMIC INPUT ENERGY FORMULATIONS FOR AN ISOLATED BRIDGE

In previous studies, in order to quantify the energy imparted to the structures, the absolute energy equation was used by some researchers (Park and Otsuka, 1999; Takewaki, 2004), while the relative energy formulation (Fajfar and Vidic, 1994; Ordaz *et al.* 2003) was employed by others. Kalkan and Kunnath (2008) investigated the relevance of using absolute and relative energy formulation in seismic evaluation of structures that are subjected to near-field ground motions. They found that the difference between absolute and relative energy input to structural systems during near-field earthquakes is much larger than that of in the case of far-field earthquakes. They suggested that selection of appropriate energy measure for near-field earthquakes should be based on the shape and period of the dominant pulse in the ground motion record and the vibration properties of the structural system. It was noted that arbitrarily using absolute or relative energy definitions for near-field ground motions can result in overlooking significant information.

The absolute energy balance equation of an isolated bridge modeled as two-degrees-of-freedom system can be written as

$$\frac{1}{2}\{\dot{u}_t\}^T\mathbf{M}\{\dot{u}_t\}+\int_0^t\{\dot{u}\}^T\mathbf{C}\mathrm{d}\{u\}+\int_0^t\mathbf{F}[u,\dot{u}]\mathrm{d}\{u\}=\int_0^t\{m\}^T\{\ddot{u}_t\}\mathrm{d}u_g(\tau) \qquad (5)$$

where $\{u_t\}$is the vector of absolute displacements of the system, $\{u\}$is the vector of relative displacements of the system, $\mathbf{M}$ = (2×2) diagonal mass matrix, $\mathbf{C}$ = (2×2) damping matrix, and $\mathbf{F}[u,\dot{u}]$= (2×1) vector of restoring forces, $\{m\}$= (2×1) vector of lumped masses and u_g is the ground displacement. Equation (5) can be simply expressed as

$$E_K + E_\xi + E_A = E_I \,, \tag{6}$$

where

$$E_K = \frac{1}{2}\{\dot{u}_t\}^T \mathbf{M}\{\dot{u}_t\} \tag{7}$$

$$E_\xi = \int_0^t \{\dot{u}\}^T \mathbf{C}\mathrm{d}\{u\} = \int_0^t \{\dot{u}\}^T \mathbf{C}\{\dot{u}\}\mathrm{d}\tau \tag{8}$$

$$E_A = \int_0^t \mathbf{F}[u,\dot{u}]\mathrm{d}\{u\} = \int_0^t \{\dot{u}\}^T \mathbf{F}[u,\dot{u}]\mathrm{d}\tau \tag{9}$$

$$E_I = \int_0^t \{m\}^T \{\ddot{u}_t\}\mathrm{d}u_g(\tau) = \int_0^t \{m\}^T \{\ddot{u}_t\}\dot{u}_g \mathrm{d}\tau \tag{10}$$

Here, E_K denotes the absolute kinetic energy, E_ξ is the damping energy, E_A is the absorbed energy, which is composed of the recoverable elastic strain energy E_S and the irrecoverable hysteretic energy E_H and, E_I represents the absolute input energy.

Similiarly, the relative energy equation for the isolated bridge can be written as follows

$$\frac{1}{2}\{\dot{u}\}^T \mathbf{M}\{\dot{u}\} + \int_0^t \{\dot{u}\}^T \mathbf{C}\mathrm{d}\{u\} + \int_0^t \mathbf{F}[u,\dot{u}]\mathrm{d}\{u\} = -\int_0^t \ddot{u}_g \{m\}^T \mathrm{d}\{u\} \tag{11}$$

or

$$E_K^{'} + E_\xi + E_A = E_I^{'} \,, \tag{12}$$

where

$$E_K^{'} = \frac{1}{2}\{\dot{u}\}^T \mathbf{M}\{\dot{u}\} \tag{13}$$

$$E_I^{'} = -\int_0^t \ddot{u}_g \{m\}^T \mathrm{d}\{u\} = -\int_0^t \{m\}^T \{\dot{u}\}\ddot{u}_g \mathrm{d}\tau \tag{14}$$

The difference between absolute and relative energy formulations is essentially the difference in the kinetic energy terms and can be computed as

$$E_I - E_I^{'} = E_K - E_K^{'} = \frac{1}{2}\{\dot{u}_t\}^T \mathbf{M}\{\dot{u}_t\} - \frac{1}{2}\{\dot{u}\}^T \mathbf{M}\{\dot{u}\} \tag{15}$$

Note that the definition of E_ξ and E_A is the same for both absolute and relative energy formulation.

In order to illustrate the difference in absolute and relative energy input to a structure during a typical far-field and near-field earthquake, Figure 3 energy response history of the non-isolated bridge subjected to a far-field (1940 El Centro) and a near-field (1992 Kocaeli) ground motion. It can be seen that the two different energy formulations result in similar input energy response histories for far field earthquake and input energy gradually builds up and reaches to a maximum near the end of the ground motion. In contrast, for near-field earthquakes, instantaneous energy spikes that have considerably larger values than the energy accumulated at the end are present in the response time history. The values of absolute and relative input energy differ significantly during these energy spikes. Therefore, both absolute and

relative energy balance formulations are considered to evaluate the energy response of the isolated bridge with SMA-based isolations systems subjected to different earthquakes in the next section.

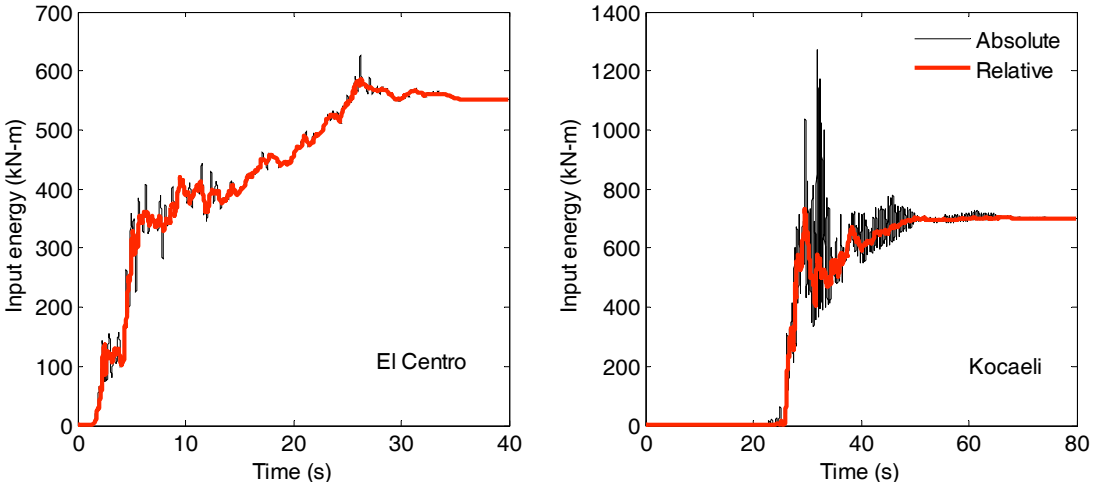

Figure 3. Input energy time histories for a typical far-field and near-field earthquake

NUMERICAL STUDY

In this section, an energy-based methodology is used to compare the performances of the S-FBI system and the SRB isolation system for protecting bridge structures against various earthquakes. Figure 4 shows idealized force-deformation curve of an SMA device. In the figure, F_y and u_y represent forward transformation force and displacement of the SMA device; k_{SMA} and αk_{SMA} denote initial and post transformation stiffness of the device, respectively. For the NiTi wire considered in this study, α, which represents the ratio of post transformation stiffness and initial stiffness of the SMA device, is observed to be 0.1 and the forward transformation strain of SMA wire ε_y is about 1%. Here, the forward transformation displacement u_y and the normalized forward transformation strength of the SMA device F_o which is defined as, $F_o = F_y / W_d$ where W_d is the weight of the bridge deck are selected to characterize the SMA device of the smart isolation systems. Note that once u_y and F_y are given, the geometric dimensions of the SMA elements can be computed from

$$u_y = \varepsilon_y \cdot L_{SMA}$$
$$k_{SMA} = \frac{F_y}{u_y} = \frac{A_{SMA} \cdot E_{SMA}}{L_{SMA}}, \tag{16}$$

where E_{SMA}, A_{SMA} and L_{SMA} are the Young's modulus, cross-sectional area and length of the SMA wires, respectively.

Based on the findings of the work of Ozbulut and Hurlebaus (2010b), an optimal SRB isolation system is designed with the parameters of u_y = 40 mm and F_o = 0.20 for the SMA device and k_b = 25 kN/cm and 2% viscous damping ratio for the laminated rubber bearing. The optimum design parameters for the S-FBI system are

adopted from Ozbulut and Hurlebaus (2010a). For the S-FBI system, the flat sliding bearings has a friction coefficient of 0.10 and the parameters of the SMA device are u_y = 30 mm and F_o = 0. 06. Note that for the above design parameters, the volume of the SMA wires used in the S-FBI system is 70% less than the volume of the SMA material employed in the SRB isolation system.

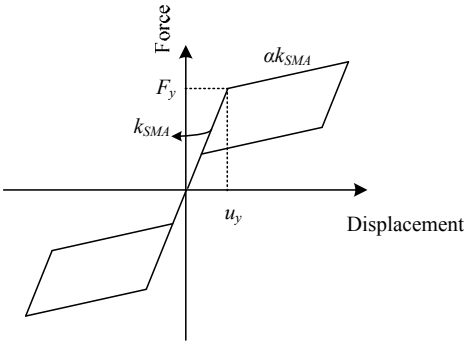

Figure 4. Idealized force-deformation curve of SMA device

Figure 5 through Figure 8 shows the time histories of the various response quantities for the isolated bridges subjected to El Centro, Landers, Erzincan and Kocaeli earthquakes, respectively. In particular, the time histories of input energy and recoverable energy (kinetic energy + strain energy) for absolute and relative energy balance formulations as well as the time histories of the deck drift and base shear normalized by the weight of the deck are plotted in each figure.

It can be seen that absolute and relative input energy are very similar and cumulatively increase and reach a maximum at the end of the motion for both the SFBI and SRB isolation systems for El Centro earthquake. However, for near-field earthquakes, energy spikes are observed especially in the absolute input energy at the early stages of the excitation. Specifically, Kocaeli earthquake produces considerably high absolute instantaneous energy spikes for both isolation systems. It should be noted that peak input energy, either computed through absolute or relative energy formulations, is smaller for the S-FBI system compared to the SRB system for all excitation cases.

When the time histories of recoverable energy transmitted to the bridge structure are compared, it can be seen that there is a substantial reduction in recoverable energy, which is the cause of damage in the structure, for the S-FBI system in comparison with that of the SRB system. This is observed for all excitation cases and irrespective of absolute or relative energy formulation except the Kocaeli earthquake, where the S-FBI system has larger recoverable energy for relative energy formulation. This is due to the fact that the force transmitted to the superstructure by the S-FBI system is considerable smaller than that by the SRB system, which will be shown later.

From the time-histories of the deck drift, it can be seen that the S-FBI system reduce the peak deck drift considerably more than the SRB system when the isolated bridges subjected to El Centro and Kocaeli earthquakes, while both systems produce similar peak deck drift in the case of Landers and Erzincan excitations. However, note that the SRB isolation system damps out the vibrations over longer time. The S-

FBI system also has consistently smaller peak base shear for the considered earthquakes.

Figure 9 illustrates the energy absorbed by the subcomponents of SMA-based isolation systems, i.e., the rubber and steel-Teflon bearings and the SMA device for the S-FBI system and the SRB isolation system subjected to different earthquakes. It can be seen that the energy is dissipated mainly by the SMA device for the SRB isolation system whereas the SMA device serves as a re-centering component in the S-FBI system and the energy is dissipated through friction in the sliding surface for the S-FBI system.

CONCLUSION

This study compares the performances of two different SMA-based isolation systems, namely S-FBI system and SRB isolation system by conducting nonlinear time history analyses with energy balance assessment. First, absolute and relative energy balance equations are derived for an isolated bridge. Then, a numerical study is performed to compare the response of a three-span isolated bridge structure with an S-FBI system and that of an SRB isolation system.

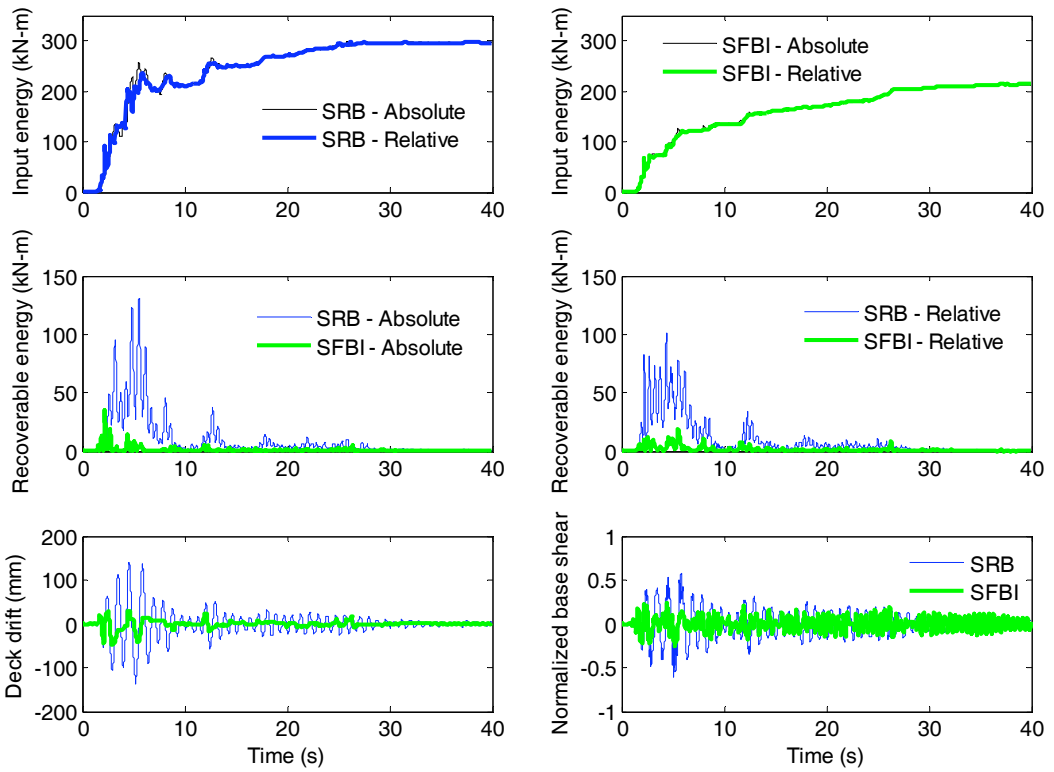

Figure 5. Time histories of various response quantities for El Centro earthquake

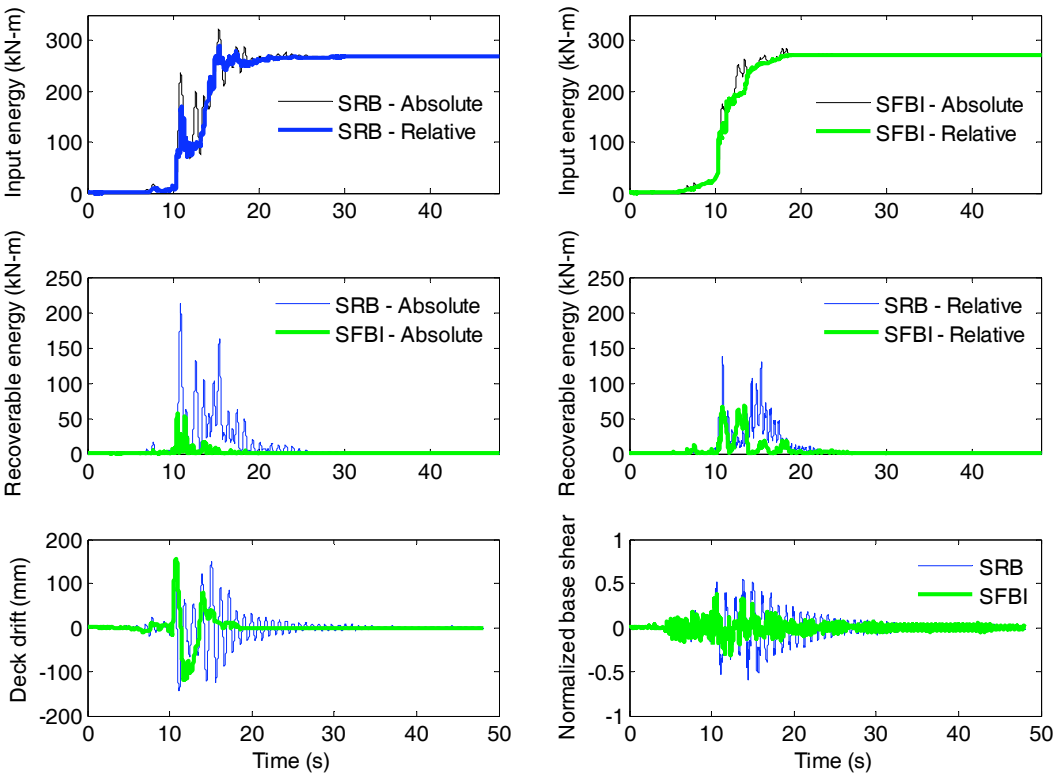

Figure 6. Time histories of various response quantities for Landers earthquake

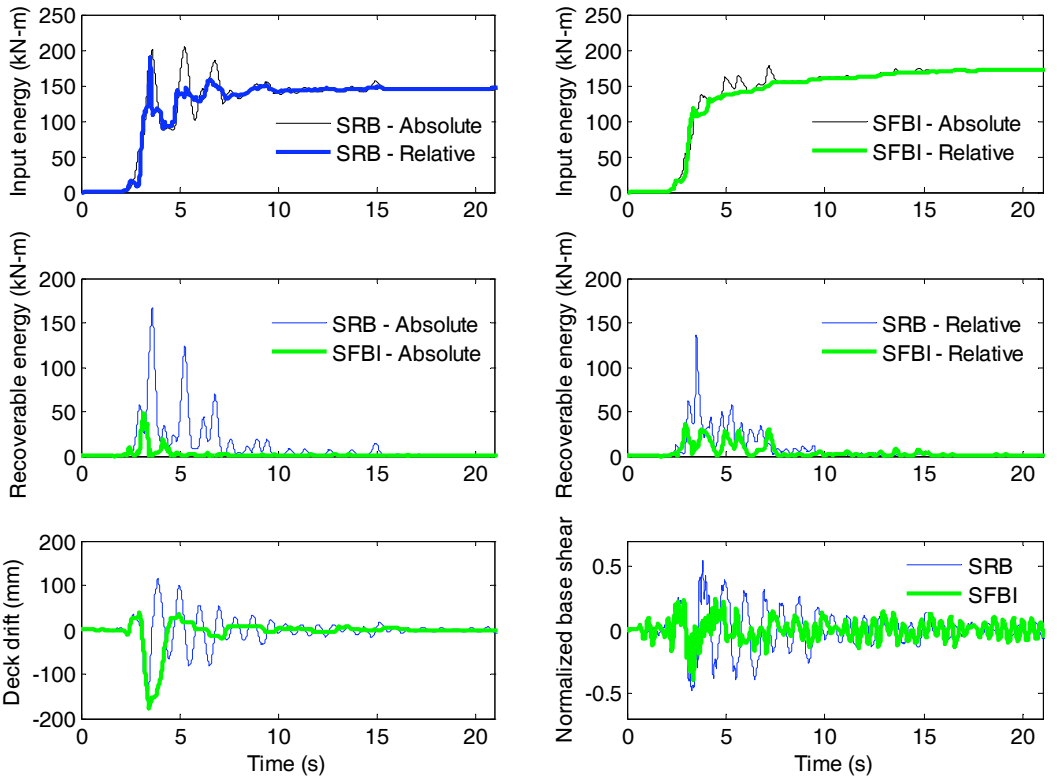

Figure 7. Time histories of various response quantities for Erzincan earthquake

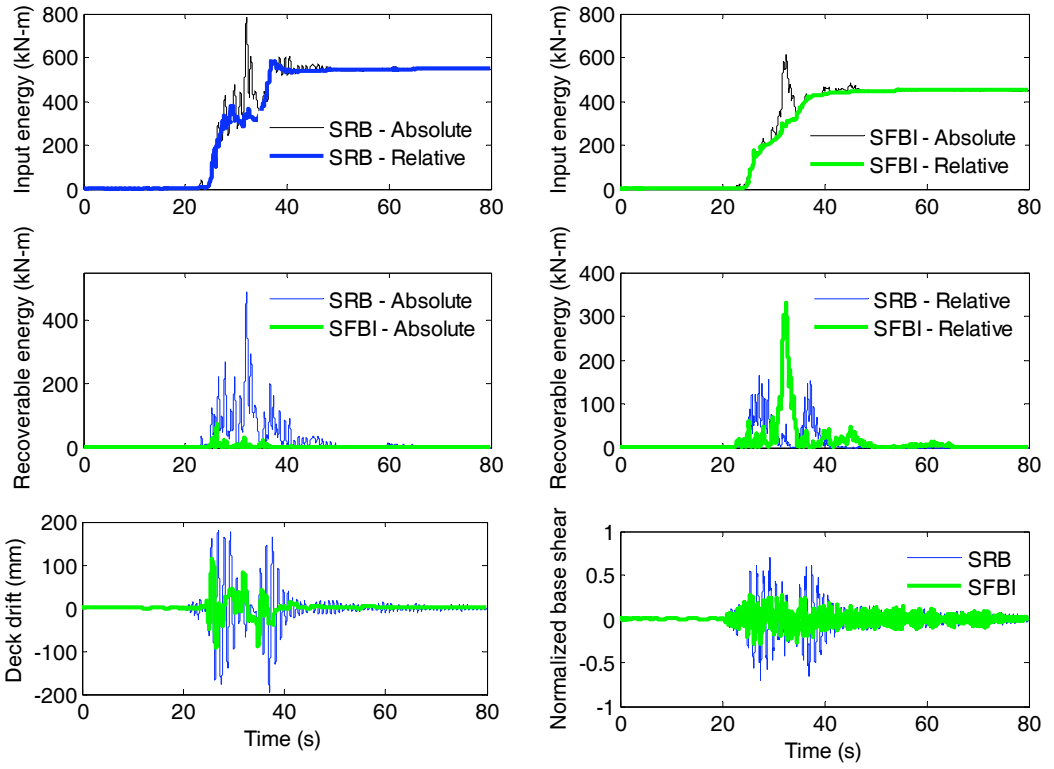

Figure 8. Time histories of various response quantities for Kocaeli earthquake

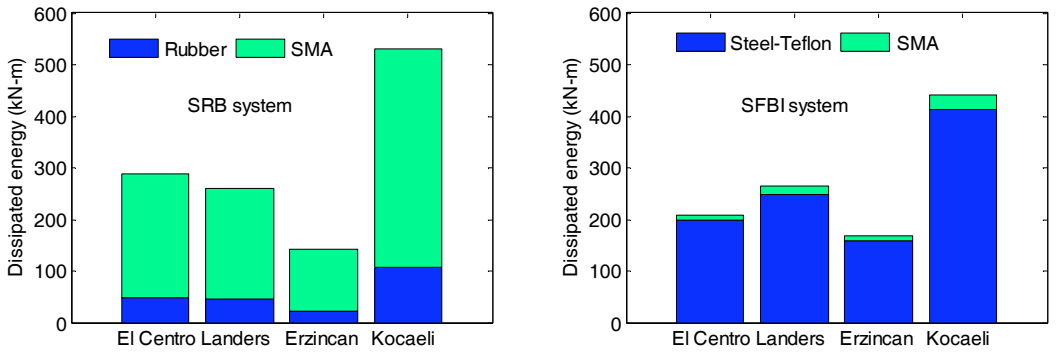

Figure 9. Energy dissipated by the subcomponents of the S-FBI and SRB isolation systems

It is found that the bridge structure isolated by either the SRB isolation system or the S-FBI system can effectively limit the peak deck drift response for considered excitations. However, it is noted that the peak base shear exhibits higher values in the case of the SRB isolation system. It is also observed that the S-FBI system attracts smaller quantities of input energy than the SRB system. It is shown that the energy is mainly dissipated by the SMA components for the SRB isolation system. On the other hand, the energy dissipation in the S-FBI system is through friction, while the SMA component of the isolation system serves as a re-centering device. Since the energy dissipation in the SRB isolation system almost solely relies on the hysteretic behavior of SMAs, and, the energy dissipation capabilities of the superelastic SMAs are limited, larger amount of SMA material is required for the SRB isolation system.

To be more specific, the S-FBI system employs superelastic SMA wires that are 70% less in volume as compared to those used in the SRB isolation system.

Noting that the high cost of the SMA is mostly cited as one of the main barriers that preclude the use of SMAs in a full-scale seismic application and considering superior structural response of the S-FBI system, it can be concluded that the S-FBI system which combines SMAs with flat sliding bearings has more favorable properties than the SRB isolation system which consists of a laminated rubber bearing and an SMA device.

Abstract

Failure of expansion joints is a leading cause of damage to bridge superstructures. Cohesive and/or adhesive failure of joint sealant material facilitates decay of the structures beneath it. The objective of this study is to develop a novel smart joint sealant to self-heal cohesive damage and eliminate adhesive failure of expansion joints. This sealant will be a shape memory polymer (SMP) based syntactic foam material. A key feature of this sealant is that it utilizes the shape memory functionality for the purpose of self-healing damage. In particular, internal cracks can be narrowed or fully closed by confined shape recovery of the smart sealant. Also, the sealant can be programmed to consistently and autonomously apply a compressive stress to the edge of the concrete deck and restrict the upward expansion, so that adhesive failure or debonding can be eliminated and a smooth joint can be maintained. In this study, a shape memory polymer (SMP) based syntactic foam sealant was prepared by dispersing 40% by volume of glass microballoons into a SMP matrix. After curing, this foam sealant was first programmed under 2-D stress condition (compression in longitudinal direction and tension in transverse direction) by a specially designed 2-D test fixture and then freely recovered. The effect of the prestress levels and the number of programming-recovery cycles on the thermomechanical behavior and shape fixity and shape recovery ratios, was investigated. The potential of this sealant for eliminating adhesive failure and healing cohesive damage was discussed.

1. Introduction

Expansion joints are weak links in bridge decks or concrete pavements. Expansion joint failure is a leading cause for structural damage to bridge

superstructures. Various types of sealants have been utilized to seal expansion joints in bridge decks and pavements. These sealants are typically hot-poured, cold-poured, or preformed. A comprehensive review of the existing sealants used in concrete pavements has shown that the failure of these sealants is dominated by adhesive failure and cohesive failure besides aging (Odum and Attoh, 2008).

Damage related to poorly performing expansion joints in bridge decks in the United States amounts to hundreds of millions of dollars each year. A survey conducted by the Federal Highway Administration indicated that, in a five-year evaluation period, over 60% of the expansion joints were leaking water and the remaining 40% were experiencing problems that would shorten their service life (Fincher 1983; Wallbank 1989). Joint failure remains an unsolved problem in the transportation community.

Due to the critical role played by joints in bridge decks and pavements, joint sealant has been a topic of intensive research for many years. Various factors that cause the failure of sealed joints have been identified (Price, 1984; Lee, 1994; Chang and Lee, 2002). The most frequently used types of sealed joints in the United States include, but are not limited to, (1) Field-poured silicone and polymer modified asphalt joints; (2) Compression seal joints; (3) Strip seal joints; (4) Polymer modified asphalt plug joint system; (5) Inflatable neoprene joints; and (6) Modular joint sealing system. According to some recent surveys of practical experiences (Chang and Lee, 2002; NCHRP#319, 2003), each type of sealant has its own pros and cons. Recently, a new silicone foam based seal material was developed for field-poured sealant (Malla, 2007). One advantage of this new material is its high ductility. Since the accommodation to movement of field-poured sealant is realized through the high ductility of sealant under both tension and compression, the adhesion to the concrete edge and cohesion in sealant itself are critical. However, one problem of the normal foam sealant used for compression seal joint is the loss of compression over time. It was reported that large sustained compressive movements force air out of the seal material (gas leakage) (Malla, 2007), which may not recover when the joint expands, and thus causes compression loss in the compression seal joint under cyclic loading.

Another problem of foam sealant is the filling of the open cells (void) with water in the foam sealant after long-term service. This problem can accelerate and magnify due to micro-cracking and damage caused by thermal stress and traffic load. In the field, the bond between the sealant and concrete can be weakened by the presence of moisture at bond interface. Such moisture deteriorated bond is especially vulnerable to tension stress (Ouyang and Wan, 2008), and thus leads to adhesive failure at the bond interface. When sealants serve in dry conditions, the presence of tension stress due to deck's movement

normally causes cohesive failure within sealant materials (Odum and Attoh, 2008). Additionally, a problem with solid sealants is that they are squeezed out of the joint when the expansion joint narrows due to the thermal expansion of the structural elements.

Shape memory polymer (SMP) is a new member of the family of shape memory materials. It has been found that SMPs can be deformed and fixed into a temporary shape and recover their original permanent shape only on exposure to external stimuli such as heat, light, magnetic field, etc. (Koerner et al., 2004; Lendlein et al., 2005; Mohr et al., 2006). The driving force for shape recovery is the conformational entropy of the molecular segments in terms of micro-Brownian thermal motion. Thermodynamically, the molecular segments experience a change from a temporary and ordered configuration to its random and coiled configuration during the shape recovery process. Since this process is accompanied by an increase in entropy, it is an autonomous process.

A recent development in SMPs is the use of confined shape recovery for the purpose of self-healing structural-length scale damage. Li and John investigated the concept for SMP based syntactic foam to repeatedly heal impact damage (Li and John, 2008). Later, it has been proved that SMP based syntactic foam can be used in grid stiffened SMP based syntactic foam cored sandwich and 3-D woven fabric reinforced SMP based syntactic foam panel for repeatedly and efficiently heal impact damage (John and Li, 2010; Nji and Li, 2010a). Most recently, a two-step close-then-heal self-healing scheme has been proposed by Li and Nettles (2010) and Xu and Li (2010), and elucidated by Li and Uppu (2010). This is a scheme by mimicking self-healing of biological systems such as human skin. This concept has been experimentally validated by Nji and Li (2010b), which shows that this system can heal structural-length scale damage repeatedly, efficiently, timely, molecularly, and almost autonomously.

We believe that an ideal sealant should be able to apply a consistent compressive stress to the concrete wall so that adhesive failure can be avoided. Also, the sealant needs to maintain in the groove when the groove narrows due to thermal expansion of the concrete. Additionally, the sealant should prevent water from seeping into it and also have self-healing capabilities so that cohesive failure can be healed. To this end, we propose to use shape memory polymer based syntactic foam as a sealant for expansion joint. First, the foam sealant can be programmed or trained by a 2-D stress condition: compression in the longitudinal (horizontal or traffic direction) and tension in transverse or vertical direction; see Figure. 1 (a). When the foam sealant is installed at the lowest temperature the sealant will experience, the sealant will always apply a compressive stress to the concrete wall; see Figure. 1 (b). When the temperature rises, the compressive

stress applied to the sealant will increase, which further ensures that the sealant applies a compressive stress to the concrete wall and adhesive failure can be avoided. Also, because the stiffness of the SMP based sealant reduces as temperature rises, the compressive stress will not become excessive such that compressive failure of the concrete occurs. However, the squeezing out problem dominates due to Poisson's ratio effect. With SMP based sealant and the special 2-D training, this problem can be solved because the rising temperature will trigger the shape recovery process of the sealant, which makes the sealant contracts in vertical direction. If properly trained, the Poisson's effect (squeezing out) and shape recovery effect (contracting) can be balanced and the sealant may maintain at the same level; see Figure. 1 (c). When temperature drops, the shape recovery stops and the sealant returns to Figure. 1 (b). As discussed by Li and Uppu (2010), each compressively constrained shape recovery completes a new cycle of programming. It is thus believed that this sealant will be able to experience many such cycles without failure.

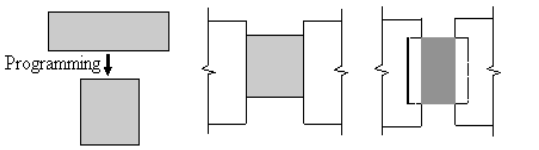

Figure 1. Work principle of SMP based syntactic foam sealant.

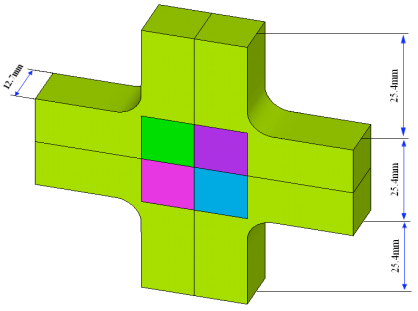
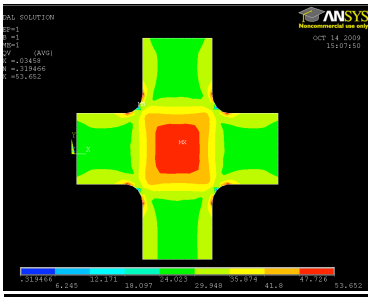
In order to solve the problem of water damage, we propose to use close-celled foam instead of open-celled foam. Therefore, we believe that a SMP based syntactic foam trained by 2-D programming (compression in one direction and tension in the transverse direction) would be a viable alternative as a sealant for expansion joint. The purpose of this study is to experimentally investigate the 2-D programming and shape recovery of a SMP based syntactic foam sealant.

2 Experimentation



2.1 Raw materials

The syntactic foam consists of hollow glass microspheres dispersed in a shape memory polymer matrix. The polymer is a styrene based thermoset SMP resin system (T_g= 62^{o}C) sold commercially by CRG Industries under the name Veriflex®. The glass microballoons (hollow spheres) were purchased from Potters Industries (Q-CEL6014: 85μm average outer diameter, effective density of 0.14 g/cm^3, maximum working pressure of 1.73MPa, and 0.8μm wall thickness). These raw materials have been used previously for the smart syntactic foam (Li and Nettles, 2010; Nji and Li, 2010a).



2.2 Biaxial specimen preparation

The SMP based syntactic foam sealant consists of hollow glass

microballoons and SMP matrix, which was fabricated by dispersing 40% by volume of microballoons into the SMP resin. The microspheres were added to the resin while slowly stirring the mixture to minimize air bubbles in the resin. The microspheres were added in multiple steps to avoid agglomeration. After dispersion, a hardening agent was added and the mixture was mixed for 10 min. The composite was poured into a 229×229×12.7 mm steel mold and placed in a vacuum chamber at 40kPa for 20 min in order to remove any air pockets introduced during the mixing process. Based on our previous study (Li and Nettles, 2010), the curing cycle was 79°C for 24h, 107°C for 3h, and 121°C for 9h. After curing, the sealant panel was de-molded and was machined into biaxial specimens for programming and further testing. The cruciform specimen dimensions were given in Figure. 2 (a). With such a dimension, the central square is roughly under a 2-D stress condition as validated by a finite element analysis; see Figure. 2 (b).

(a) A schematic diagram of biaxial specimen dimensions

(b) von Mises stress distribution in the specimen (there is a piece of square material (red color) at the center of the specimen (about 25.4mm by 25.4mm) that is subjected to a uniform 2-D stress condition)

Figure 2. Cruciform specimen for 2-D programming.

2.3 2-D programming of biaxial specimen

In order to make the polymer smart, it usually subjects to a typical three-step thermomechanical cycle called programming (Li and John, 2008). The energy that is restored with shape recovery is a growing function of the energy supplied during the deformation at a high temperature (Miaudet et al., 2007). The

SMP based foam sealant can be programmed to consistently and autonomously apply a compressive stress to the edges of the concrete deck/pavement regardless of the environmental conditions (expansion or contraction) of the expansion joint. This feature ensures that the debonding problem can be avoided by preventing tensile stress from occurring at the interface.

After machining the cruciform foam sealant specimen, two small steel tabs were fixed by using strong glue along the edge of the central square (uniform 2-D stress condition as shown in Figure. 2 (b)) on to one side surface of the specimen (one in the vertical and the other in the horizontal direction) to measure the displacement of the two directions (see Figure. 3(a)). Then the cruciform specimen was introduced into the truss-form fixture and the bolts were tightened to grip the four arms of the specimen, with each arm by 12.7mm (as shown in Figure. 3(b)). The truss fixture can transform 1-D compression into 2-D loading (vertical compression and horizontal tension) by directly applying compressive load to the top and bottom nodes of the truss fixture. The ratio of the vertical load and horizontal load can be adjusted by changing the length of the members of the truss fixture. Finally the temperature was monitored with the help of thermocouples connected to a Yokagawa DC100 data acquisition system.

According to the previous study (Li and Nettles, 2010), the glass transition region of the foam is 63.69–76.19^{o}C with a glass transition temperature of T_g = 70.50^{o}C. In order to perform efficient programming and shape recovery tests, we chose 79^{o}C as a testing temperature since it is just above the upper limit of the T_g region in the foam. We started with putting the device into a chamber and heating up to 79^{o}C and holding for about 25 minutes, and then retightening the bolts to clamp the sample better because the specimen became soft at 79^{o}C. After retightening, place the set-up back into the chamber and install two linear variable differential transducers (LVDT) in conjunction with the two pre-attached tabs in the vertical and horizontal direction, respectively (see Figure. 3(c)). Also install the weight-bearing rod to the top node of the truss fixture and reheat the system up to 79 ^{o}C for another 20 minutes for temperature equilibration.

Immediately following, a load was applied onto the rod by hand. This loading method caused the sample into compression condition in the vertical direction and tension condition in the horizontal direction. Approximately 20 min were allowed for the deformation to stabilize. This completed the first step (pre-strain) of the programming. In the next step (cooling), the heating was first stopped, and the chamber was kept closed and the system was allowed to naturally cool for 8-10h to room temperature while maintaining the applied load constant. The strain gauges and LVDT tracked the shape changes of the specimen during this cooling step. Because of creep and contraction during cooling, the strain was

continuously increased until the temperature reached room temperature. Then the specimen was unloaded. This completed the 2-D thermo-mechanical programming or shape fixity process of the cruciform foam sealant.

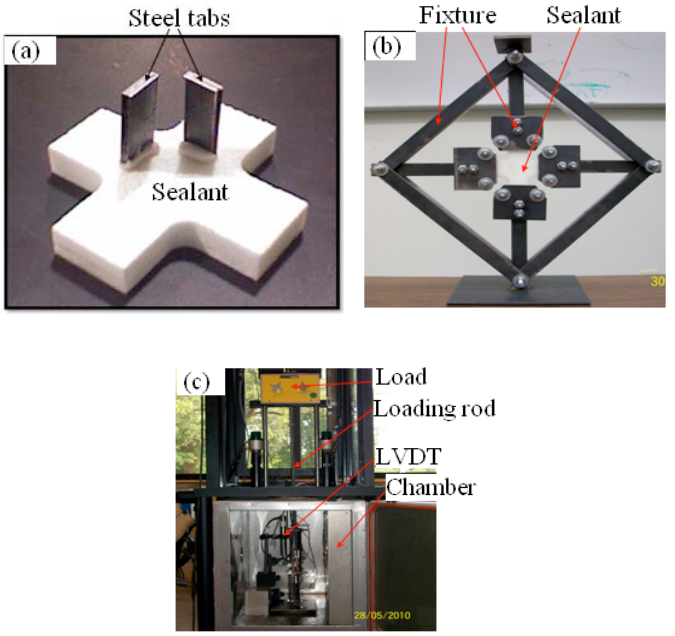


Figure 3. Programming setup and testing method of cruciform foam sealant specimen.

After completing the specimen programming, the core area of the programmed cruciform specimens was machined to four smaller cube specimens with an edge length of 12.7mm (see Figure. 4) for further shape recovery testing. In Figure 4, Orientation-1 is subject to compressive prestress; Orientation-2 is subject to tensile prestress; and Orientation-3 is free of stress.

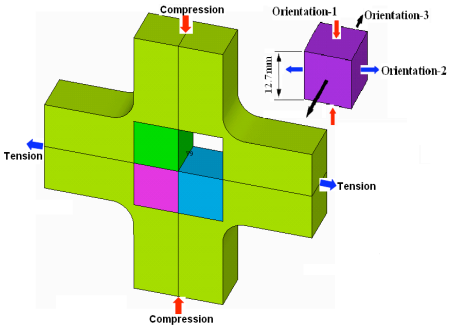

Figure 4. A schematic diagram of the preparation for programmed sealant specimen.

In order to evaluate the effect of prestress level on the thermomechanical behavior, four compressive prestress levels in the vertical direction were used. They were 168.3kPa, 207.7kPa, 247.6kPa, and 300.7kPa, respectively. Because of

the symmetry of the truss fixture and the specimen, the tensile prestress in the horizontal direction was the same as the corresponding vertical compressive prestress. In addition, some specimens with 300.7kPa prestress experienced 10 thermomechanical cycles to evaluate the functional stability of the foam sealant.

2.4 2-D shape recovery of biaxial specimens

2-D free-shape recovery started after the completion of the programming by using the same heating chamber and LVDT system. The chamber was heated up quickly from room temperature to 49^{o}C and allowed to soak for 20 min. Then the heating was continued again at an average heating rate of 0.3^{o}C/min until 77^{o}C. After 7 minutes, the heating was ramped quickly to 79 ^{o}C and holding for 30 minutes. This completed the 2-D free shape recovery.

3. Results and Discussion

3.1 Thermomechanical behavior of biaxial specimens

Figure 5 shows the typical strain evolution during the entire thermomechanical cycle subjected to various prestress levels. Similar to previous 1-D stress controlled programming and free shape recovery (Li and Nettles, 2010), each direction (compression in the vertical direction and tension in the horizontal direction) shows similar four-step thermomechanical behavior. From Figure 5, the thermomechanical cycle includes four steps: Step1 (loading), Step 2 (cooling while holding the load constant), Step 3 (unloading), and Step 4 (recovery). The small spikes are due to manual control of the testing setup.

Based on Figure 5 (a) and (b), the shape fixity ratio and shape recovery ratio are obtained. The shape fixity ratio is 95.6%, 96.7%, 98.6%, and 99.2% for the four prestress levels, respectively. The corresponding shape recovery ratio is 97.3%, 95.4%, 94.1%, and 91.6%. It is clear that as the prestress level increases, the shape recovery ratio decreases. This is understandable because higher prestress may cause some damage to the foam (such as crushing of microspheres), which is unrecoverable during shape recovery. For the shape fixity, with the increase in the prestress, the foam sealant specimen becomes denser and stiffer, resulting in a smaller springback and higher shape fixity.

From Figure 5 (c), the horizontal and vertical strain after 10 thermomechanical cycles is close to the strain development of the first thermomechanical cycle. The shape fixity ratio is 98.5 %, and the shape recovery ratio is 88.3%. It is noted that the shape fixity ratio is slightly higher, and the shape recovery ratio is slightly lower than that in the first thermomechanical cycle under the same prestress level (300.7KPa). This is because more unrecoverable damages are accumulated during each additional thermomechanical cycle, which lead to the decrease in shape recovery ratio and increase in shape fixity ratio.

However, this change is shape recovery ratio and shape fixity ratio is comparatively small. Therefore, the shape recovery functionality of this foam sealant is stable and sustainable.

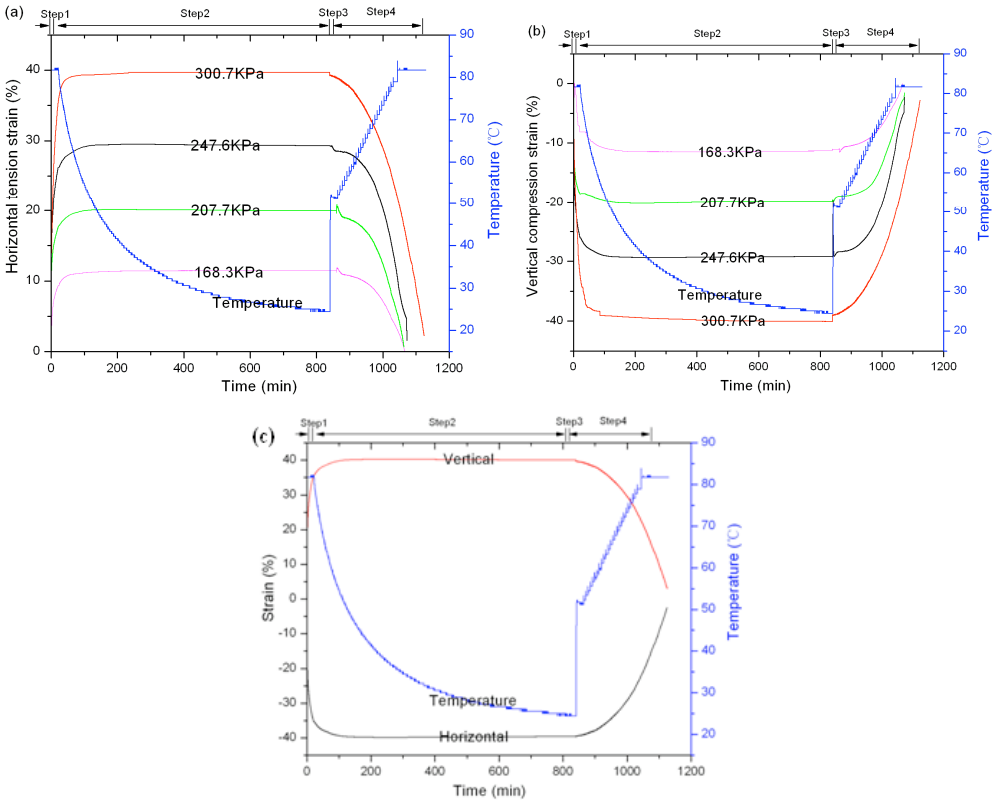

Figure 5. (a) Horizontal and (b) Vertical strain of the cruciform sealant sample under various stress levels during programming and recovery (Steps 1-3 represent programming and Step 4 represents free shape recovery) and (c) Horizontal and vertical strain of the 10th thermo-mechanical cycle under the prestress level of 300.7kPa.

To visualize the programming and recovery process, Figure 6 shows the original and programmed cruciform foam sealant specimen and its recovery process under various temperatures. During Step 1 and Step 2 of the programming, the 2-D stress condition causes the orientation of the macromolecular chains of SMP aligns along both vertical and horizontal directions. This leads to a decrease in entropy of the material system in the programming process (Hossein et al., 2007; Jalil and Hossein, 2005). Meanwhile, some microspheres may be bent or buckled, and the deformed microspheres or crushed debris are aligned in the tension orientation due to the compression in the transverse direction. Furthermore, a wrinkle-like pattern can be seen with the naked eye on the stretched specimen surface along both directions, as shown in Figure 6 (b). This reflects the 2-D stress conditions. It is believed that the central square of the

cruciform foam sealant specimen is changed from isotropy to anisotropy. From Figure 6 (c-f), the recovery rates in horizontal and vertical directions are faster when the temperature is up to T_g, which is consistent with strain development shown in Figure 5. Additionally, the recovery process occurs in both directions simultaneously, which is important for the sealant in expansion joints to expand in the horizontal direction and contract in the vertical direction without distortion. It is beneficial to achieve the design purpose of smart foam sealant proposed in this study.

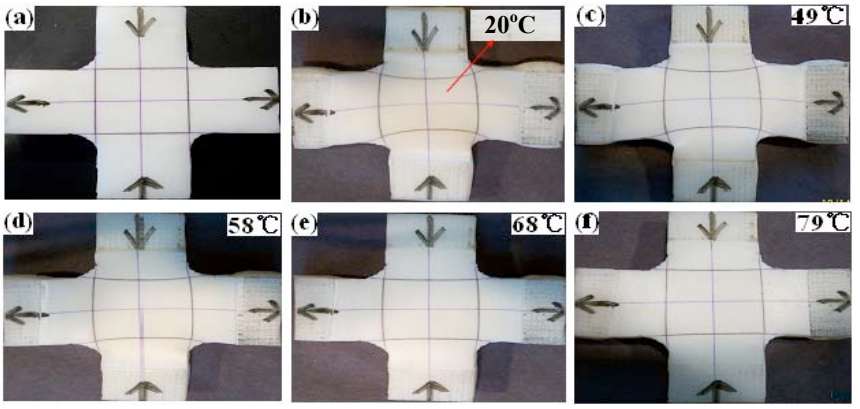

Figure 6. (a) Original and (b) programmed cruciform foam sealant specimen and (c-f) its recovery process under various temperatures.

4. Conclusion

Based on the comprehensive tests, the following conclusions are obtained:

(1) A special 2-D programming method for SMP based foam sealant is developed. The foam sealant has good shape memory functionality under the 2-D stress condition. The 2-D programming method may cause the sealant to transform into anisotropy from isotropy.

(2) The 2-D programming method has a potential to solve squeezing-out problem of the foam sealant when the expansion joint narrows. The number of thermomechanical cycles has a slight effect on thermomechanical behavior of the foam sealant, indicating good stability of the shape memory functionality of the foam sealant.

INTRODUCTION

The ASCE SEI Committee on Disproportionate Collapse Standards and Guidance is developing a guidance document for design against disproportionate collapse of structures. A Terminology and Procedures Sub-Committee was created to focus on definitions of terms and to develop a conceptual framework. The Sub-Committee prepared a draft that was discussed and accepted in principle by the Committee at its meeting on 13 May 2010. The draft is published here in its latest but shortened version for rapid dissemination and discussion. The complete draft is available on request.

The draft starts with a comprehensive and consistent set of definitions of relevant terms such as collapse resistance, robustness, vulnerability, exposure, direct design, indirect design, threat-specific design, non-threat-specific design, and many more, which up to now have not been consistently defined and used. These definitions are strongly cross-referenced and a hierarchical system of interrelated definitions thus emerges. On this basis, a conceptual framework of design criteria comprising design requirements, design objectives, design methods, and verification procedures is developed. This framework will serve as the outline for the Committee's design guidance document. Specific content for a number of sections and an appendix still need to be developed by dedicated Sub-Committees (SC). These tasks are clearly defined by the framework.

The draft consists of recommendations and commentary. In the following, recommendations are set in normal font and commentary in italics. The section numbering of the draft is substantial to cross-referencing and thus retained. Specific content still to be developed by dedicated Sub-Committees is indicated in brackets. Numbers given in tables are intended to illustrate the possible final content of these tables and to stimulate discussion. They should be understood as placeholders for the final content to be specified by the respective Sub-Committee.

TERMINOLOGY AND PROCEDURES SUB-COMMITTEE DRAFT

1 Scope

These recommendations concern the design for the prevention of disproportionate collapse of structures. A performance-based framework of design criteria comprising design requirements, design objectives, design methods, and verification procedures is given. It applies to the design of new structures and the retrofit design of existing structures. *In general, the design criteria are specified on a project-by-project basis by the parties involved in and affected by a given project. This specification can be based on the provisions presented here as long as they are applicable. If not, other applicable provisions can be used. (...)*

2 Definitions

2.1 Abnormal event. An event that is unforeseeable or occurs with very low probability and is not considered in the ordinary design of a structure. *This term refers to the abnormal conditions that might actually occur. In contrast, the abnormal conditions assumed in the design against disproportionate collapse are called hazard scenarios (see Sect. 5.2).*

2.2 Action. A condition that affects a structure and can be characterized by physical quantities. *In most cases, actions are applied loads or imposed deformations or displacements. However, the definition also includes heat action (fire) and corrosive action. Abnormal events and hazard scenarios may or may not result in actions.*

2.3 Alternative load paths. Alternative paths for a load to be transferred from a point of application to a point of resistance. Enable a redistribution of forces originally carried by failed components thus preventing a failure from spreading. *Providing alternative load paths is one of the design methods (see Sect. 2.10, 6.1, and 6.5).*

2.4 Authorities. The Authorities are the construction authorities that hold jurisdiction over the structure in question.

2.5 Client. The Client is understood here to be the collective of the owner of the structure and all the parties affected by its possible collapse. *The need to include affected parties derives from the indirect consequences of a collapse. For a storage structure filled with hazardous material, important bridges and tunnels, and other lifeline structures, for instance, possible indirect consequences are an impairment of public infrastructure and of civil and national defense. Examples of affected parties are military authorities, external local authorities, utility companies, concessionaires, financial institutions, and insurance companies. Defining the collective will of the Client can require an administrative or political decision on a national or international level.*

2.6 Collapse resistance. Insensitivity to abnormal events. A structure is collapse resistant if abnormal events do not lead to disproportionate collapse. A precise definition requires reference to specified design objectives: a structure is collapse resistant if the hazard scenarios affecting the structure do not lead to an extent of damage that violates the performance objectives. The hazard scenarios affecting the structure, referred to in this definition, do not include hazard scenarios averted by event control. *Collapse resistance is a property that depends on the structure and the abnormal events. A robust structure is collapse resistant because an initial damage does not spread disproportionately (see Sect. 2.34). A non-robust structure can be made*

collapse resistant by reducing its vulnerability to prevent or lessen initial damage (see Sect. 2.42). See also Figure 2. A disproportionate collapse can be prevented by providing collapse resistance or by reducing the exposure (event control).

2.7 Consequences. The consequences of the collapse of a structure. *Being all-embracing, this term refers to the sum of all direct and indirect losses resulting from a collapse (see Sect. 4.3). (...)*

2.8 Continuity. Continuous connectivity between structural components. *Extraordinary load-transfer mechanisms, such as catenary action, can be enabled by continuity. In this way, the redundancy and robustness of a structure can be increased. However, an increase of robustness can also be achieved by a break of continuity at segment borders.*

2.9 Design criteria. The design criteria form the framework of performance-based design. They consist of design requirements, design objectives, design methods, and verification procedures. *(...)*

2.10 Design methods. Methods that aim at preventing disproportionate collapse of a structure. *(...)*

2.11 Design objectives. Design objectives are the basis of direct design. They comprise hazard scenarios, performance objectives, and applicable combinations of actions and safety factors. *(...)*

2.12 Design requirements. Specification of whether design against disproportionate collapse is required for a structure and, if yes, specification of the level of requirements on design objectives, design methods, and verification procedures. *(...)*

2.13 Direct design. The terms direct and indirect design categorize approaches for designing collapse-resistant structures: (a) direct design aims at explicitly ensuring collapse resistance by demonstrating that the structure meets specified performance objectives when specified hazard scenarios occur and affect the structure; (b) indirect design aims at increasing the collapse resistance of a structure implicitly by incorporating consensus-approved design features; this is done by applying prescriptive design rules and thus without explicit consideration of hazard scenarios and without demonstrating that performance objectives are met. *(...) Protection, increased local resistance, alternative load paths, and segmentation (i.e. the structural methods, see Sect. 2.39) can be implemented within a direct or indirect design approach.*

2.14 Disproportionate collapse. A collapse that is characterized by a pronounced disproportion between a relatively minor event and the ensuing collapse of a major part or the whole of a structure. A precise definition requires reference to specified design objectives: a collapse is disproportionate if the hazard scenarios lead to an extent of damage that violates the performance objectives. *The terms disproportionate collapse and progressive collapse are often used interchangeably because disproportionate collapse often occurs in a progressive manner and progressive collapse can be disproportionate. Disproportionate collapse is the more appropriate term in the context of design and performance because a precise definition of disproportionate requires specified design objectives. The term progressive collapse is more suitable when referring to the physical phenomenon and mechanism of collapse (see Sect. 2.30).*

2.15 Ductility. The ability of a structural component or structure to sustain large plastic deformations without rupture. *Ductility can increase the redundancy and robustness of a structure. However, an increase of robustness can also be achieved by non-ductile behavior at segment borders.*

2.16 Engineer. The Engineer is the person or entity responsible for the design of the structure and of any external structural measures of protection.

2.17 Event control. Reducing the probability of occurrence and the intensity of abnormal events through non-structural measures. *Event control is one of the design methods (see Sect. 2.10, 6.1, and 6.2).*

2.18 Exposure. The exposure results from the abnormal events that possibly affect a structure during construction and lifetime and are not considered in ordinary structural design. *The exposure of a structure is one of the conditions from which the design requirements are derived (see Sect. 4). The disproportionate collapse of a structure can be prevented by reducing its exposure which in turn can be achieved by event control (see Sect. 2.17). See also Figure 2.*

2.19 Hazard scenarios. The abnormal conditions to be assumed in design to occur during construction and lifetime of a structure. *The hazard scenarios are specified as part of the design objectives (see Sect. 5).*

2.20 Increased local resistance. An increase (or confirmation of adequacy) of local structural resistance. Aims at preventing or reducing initial damage that could otherwise lead to disproportionate collapse. *Providing increased local resistance is one of the design methods (see Sect. 2.10, 6.1 and 6.4). Within direct design, this is called specific local resistance (see Sect. 2.38). Within indirect design, this is called prescribed local resistance (see Sect. 2.28).*

2.21 Indirect design. See Sect. 2.13.

2.22 Initial damage. The damage to a structure that can be ascribed directly to an abnormal event (without resorting to the response of the structure as a whole) or a notional damage as determined from the hazard scenarios. *An initial damage results in a reduction (sectional weakening) or a complete loss (component failure) of the load-carrying capacity of a part of the structure. It is usually locally limited.*

2.23 Integrity. (…) *The term general structural integrity has been defined as the property of being able "to sustain local damage with the structural system as a whole remaining stable and not being damaged to an extent disproportionate to the original local damage" [1]. This corresponds to the term robustness as defined in Sect. 2.34. However, the term integrity is used only occasionally to denote this particular meaning. Furthermore, it could also be defined in a different manner more in line with general usage, namely as the wholeness and intactness of a structure. Integrity would thus refer to the state of a structure and not to its behavior. It is therefore recommended to discontinue the usage of the term integrity in the firstly mentioned sense and to use the term robustness instead.*

2.24 Key element. A structural component (or a part of the structure) that meets two conditions: (a) it is not larger than the structural part assumed to initially fail as determined from the hazard scenarios; (b) its failure entails further damage that violates the performance objectives. *Examples of possible key elements are a building column, a pier of a continuous bridge, a cable in a cable-supported structure, an individual anchor of an anchored retaining wall, certain areas of the subsoil, and components of temporary bracing or shoring during construction.*

2.25 Non-structural methods. See Sect. 2.39.

2.26 Non-threat-specific design. See Sect. 2.40.

2.27 Performance objectives. The acceptable response of a structure to hazard scenarios. *The performance objectives are specified as part of the design objectives (see Sect. 5).*

2.28 Prescribed local resistance. A local increase of structural resistance implemented as an indirect design measure. *Prescribed local resistance is the indirect-design version of the design method increased local resistance described in Sect. 2.20. Instead of prescribed local resistance, the term enhanced local resistance has occasionally been used in the past.*

2.29 Prescriptive design rules. Consensus-approved features of indirect design (…) codified in standards and guidelines or specified for a particular project. *See Sect. 6.8.*

2.30 Progressive collapse. A collapse that commences with the failure of one or a few structural components and then progresses over successively affected other components. *See Sect. 2.14. There are various types of progressive collapse that differ with respect to the mechanism of collapse and the propagating action such as pancake-type collapse, zipper-type collapse, domino-type collapse, (...) and mixed-type collapse. Different kinds of structures can be susceptible to different types of progressive collapse. (...)*

2.32 Protection. Mitigating the effect of abnormal events through external structural measures. Aims at preventing or reducing initial damage that could otherwise lead to disproportionate collapse. *Providing protection is one of the design methods (see Sect. 2.10, 6.1, and 6.3).*

2.33 Redundancy. Availability of alternative load paths. *See Sect. 2.3. Redundancy is one possibility to enhance robustness. Both terms denote different properties of the structure though and should be clearly distinguished.*

2.34 Robustness. Insensitivity to initial damage. A structure is robust if an initial damage does not lead to disproportionate collapse. A precise definition requires reference to specified design objectives: a structure is robust if an initial damage as determined from the hazard scenarios does not lead to an extent of damage that violates the performance objectives. *Robustness is a property that depends on the structure and the location and amount of initial damage. If the initial damage is specified as a notional damage, its cause is immaterial and robustness becomes a purely structural property. This is in contrast to a broader definition of robustness – as it is given, for instance, in Eurocode 1 [2] – that refers to abnormal events. Such a broader conception is close to the term collapse resistance defined in 2.6. A robust structure is collapse resistant but not vice-versa (see Sect. 2.6). Robustness can be achieved by alternative load paths (see Sect. 2.3) or segmentation (see Sect. 2.36). See also Figure 2.*

2.35 Segment border. A border of a segment of a structure at which a failure within the segment is isolated from the remaining structure and thus brought to a halt. *See Sect. 2.36 and Sect. 6.6.*

2.36 Segmentation. Segmenting a structure by dedicated segment borders to isolate a failure that occurs in a segment within that segment thus preventing a failure from spreading. *Segmentation is one of the design methods (see Sect. 2.10, 6.1, and 6.6). Instead of segmentation, the term compartmentation (or compartmentalization) has occasionally been used in the past. (...)*

2.37 Significance. The significance of a structure is determined by the consequences of its collapse. *The significance of a structure is one of the conditions from which the design requirements are derived (see Sect. 4).*

2.38 Specific local resistance. A local increase of structural resistance implemented as a direct design measure. *Specific local resistance is the direct-design version of the design method increased local resistance described in Sect. 2.20.*

2.39 Structural methods. Structural methods aim at preventing a disproportionate collapse through the structural design of the structure itself (internal methods) or of external structural measures of protection, thus enhancing collapse resistance. In contrast, non-structural methods aim at preventing abnormal events from affecting a structure, thus reducing the exposure, without requiring a structural design for this purpose. *Protection, increased local resistance, alternative load paths, and segmentation are structural methods. Event control is a non-structural method. Structural methods can be implemented within a direct or indirect design approach (see Sect. 6.7 and 6.8).*

2.40 Threat-specific design. The terms threat-specific and non-threat-specific design categorize the manner hazard scenarios are specified: (a) threat-specific design is based on specific threats that possibly occur (specific abnormal events); (b) non-threat-specific design is based on the assumption of notional actions or notional damage. *Direct design can be based on threat-specific or non-threat-specific hazard scenarios. Indirect design is not based on hazard scenarios and therefore is neither threat-specific nor non-threat-specific (see Sect. 6.8). (...)*

2.41 Verification procedures. Procedures for demonstrating that specified performance objectives are met when specified hazard scenarios occur. Used in the context of direct design and event control. *The verification procedures are specified as part of the design criteria (see Sect. 3 and 7).*

2.42 Vulnerability. Susceptibility of a structure to suffer initial damage when affected by abnormal events. *This definition is based on Ref. [3] according to which vulnerability accounts for the direct consequences of an abnormal event, which are related to the component behavior. A structure can be made collapse resistant (see Sect. 2.6) by reducing its vulnerability which in turn can be achieved by protection (see Sect. 2.32) or increased local resistance (see Sect. 2.20). See also Figure 2.*

3 Design criteria

3.1 General. The design criteria form the framework of performance-based design against disproportionate collapse. They consist of design requirements, design objectives, design methods, and verification procedures. *(...) The framework suggested here is illustrated in Figure 1.*

3.2 Specification of design criteria. In general, the design criteria are specified on a project-by-project basis by the Client and the Engineer and approved by the Authorities as further detailed below. This specification can be based on the provisions of Sect. 4 to 7 if applicable. If not, other applicable provisions can be used. (…) *Due to the complexity and diversity inherent in major structures, a project-related specification of design criteria is required for such structures. Such a specification entails a decision-making process possibly supported by specialist consultants. In some cases, the design criteria can be established on the basis of a classification of structures. Such a classification is outlined below. It is anticipated, however, that a generally binding specification of design criteria on the basis of a classification of structures will at best be possible for small to medium-sized structures. Some of the design criteria listed here have been codified for specific types of structures: Eurocode 1 [2], General Services Administration guidelines for federal office buildings [4], Unified Facilities Criteria for Department of Defense projects [5], Approved Document A of the UK Building Regulations [6], Post-Tensioning Institute recommendations for stay cable design, testing and installation [7].*

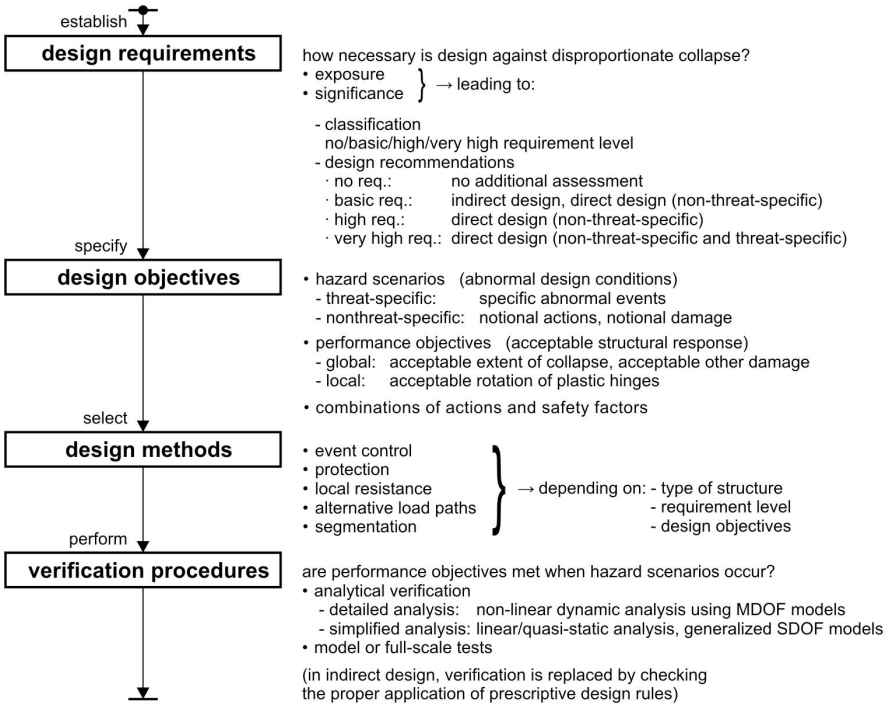

Figure 1: Framework for design against disproportionate collapse

4 Design requirements

4.1 General. The design requirements specify whether design against disproportionate collapse is required for a structure. If such a design is required, they can specify the level of requirements on design objectives, design methods, and verification methods. The design requirements are usually based on the exposure and the significance of a structure. *In view of cost effectiveness, design against disproportionate collapse will not be required for every structure. It is suggested that the following four levels of requirements be distinguished: no requirements, basic requirements, high requirements, and very high requirements.*

4.2 Exposure. The exposure results from the threats that possibly affect a structure during its construction and lifetime. In the context of disproportionate collapse, only the threats not considered in the ordinary design of a structure are of interest. When they occur they are called abnormal events. *(...) A list and classification of possible abnormal events is given in Table 1 (...).*

4.3 Significance. The significance of a structure is determined by the consequences of its collapse. *The consequences of a collapse are the sum of all direct and indirect losses. They go beyond the immediate human and material losses and include indirect consequences such as impairment of public infrastructure and of civil and national defense. (...)*

4.4 Specification of design requirements. The design requirements are specified by the Client and approved by the Authorities. This specification can be based on the classification suggested in Table 3 if applicable or on other applicable provisions. *Structures can be classified according to their exposure and significance. The resulting classes of structures can be linked to levels of requirements. Such a classification*

Table 1: List and classification of abnormal events

Faults			Errors
External		Immanent	
Man-made (accidental/intentional)	Environmental		
Impact (car, train, ship, aircraft)	Earthquake	Lack of strength	Design errors
Explosion (gas, explosives)	Extreme wind forces	Cracks	Construction errors
Fire	Heavy snow fall		Usage errors
Excessive loading (live load)	Floods (scour)		

[To be revised and completed by the Requirements and Objectives Sub-Committee]

Table 2: List and classification of consequences
[To be drafted by the Requirements and Objectives Sub-Committee]

Table 3: Classification of structures and design requirements

Basis of classification	Classification of structures	Examples of structures	Requirement level
Significance low	Structures whose failure does not result in major human or material losses	Buildings rarely occupied by humans; Short bridges on secondary roads	1 – No requirements
Significance medium	Structures whose failure results in limited human or material losses	Buildings with up to 50 occupants; Bridges and tunnels of up to 100 m length and up to four lanes	2 – Basic requirements
Exposure or significance high	Structures which are highly exposed or whose failure results in major human or material losses	Embassy and military buildings. Structures and clusters of structures with up to 1000 occupants; Bridges and tunnels of up to 1000 m length and up to six lanes	3 – High requirements
Exposure and significance high	Structures which are highly exposed and whose failure results in major human or material losses	Lifeline structures; Buildings in which hazardous products are stored or processed; Structures and clusters of structures with more than 1000 occupants; Bridges and tunnels of more than 1000 m length or more than six lanes	4 – Very high requirements

[To be revised and completed by the Requirements and Objectives Sub-Committee]

is suggested in Table 3. (...) Specifying design requirements is not intrinsically an engineering problem. It can be supported by professionals but must reflect the will of (...) Client and Authorities. Therefore, the classification suggested in Table 3 is a non-binding orientation guidance. (...)

5 Design objectives

5.1 General. Design objectives are the basis of direct design. They comprise hazard scenarios, performance objectives, and applicable combinations of actions and safety factors.

5.2 Hazard scenarios. The hazard scenarios are the abnormal conditions to be assumed in the design to occur during the construction and lifetime of a structure. They can be specified as specific abnormal events, as notional actions or as notional damage. Notional damage is typically specified as cases of initial local failure. *In threat-specific design, the hazard scenarios are specific abnormal events. In non-threat-specific design, they are notional actions or notional damage.*

The abnormal conditions possibly affecting a structure can differ substantially from project to project. Therefore, it is difficult to specify the hazard scenarios in a standardized manner. (…) Threat-specific design requires the identification and quantification of all threats possibly affecting the structure and the ensuing effects on it. These input data are likely to be incomplete and imprecise because some threats remain unpredictable. Threat-specific design, if used, should therefore be complemented by elements of non-threat-specific design, in particular by the assumption of notional damage. For the same reason, preference should normally be given to non-threat-specific design, possibly complemented by elements of threat-specific design. With respect to notional damage, the applicable design methods are limited to alternative load paths and segmentation (see Sect. 6). (…)

5.3 Performance objectives. The performance objectives are the acceptable response of a structure to the hazard scenarios. (…) *The performance objectives can be defined on a global level, that is, as acceptable extent of collapse and acceptable other damage, or on a local level, for instance, as acceptable rotation of plastic hinges. Other damage includes damage to the non-collapsed remaining structure, damage to the surroundings, and indirect losses resulting from an impairment of public infrastructure and of civil and national defense. (…) Global performance objectives are generally more meaningful. Local performance objectives can serve as simplified and substitute criteria for achieving global objectives. (…)*

5.4 Combinations of actions and safety factors. The combinations of actions and safety factors to be applied in analytical verifications pertaining to direct design must be specified. *In ordinary design, this specification is mathematically derived from the requirement to achieve a uniform level of safety. This is not currently possible in the context of disproportionate collapse. A reasonable level of safety can nevertheless be achieved by using reasonable combinations of actions and safety factors. It is suggested that the actions determined from the hazard scenarios and actions resulting from an initial damage be combined with dead load, live load, and environmental loads. (…) It is suggested that stricter safety factors be required when disproportionate collapse is intended to be prevented by specific local resistance (see Sect. 6.4).*

5.5 Sets of design objectives. The design objectives can be specified as sets or functions of interrelated data. *When the design objectives are specified as more than one set of data, the performance objectives can be specified differently for hazard scenarios of different kind or extent. Such dependency can be expressed by a number of sets of design objectives or by functional relationships. (…)*

5.6 Specification of design objectives. The design objectives are specified by the Client and approved by the Authorities. This specification can be based on the provisions suggested in Tables 4, 5, and 6 if applicable or on other applicable provisions. The hazard scenarios shall not be specified against the advice of the Engineer. *The design objectives can be established depending on the level of requirements. Corresponding design objectives are suggested in Tables 4, 5, and 6. (…) The level of requirement in these tables can be determined from the classification of structures suggested in Table 3 if applicable. (…)*

Table 4: Hazard scenarios depending on the level of requirements
[To be revised and completed by the Requirements and Objectives Sub-Committee]

Table 5: Performance objectives depending on the level of requirements

Requirement level	Acceptable extent of collapse	Acceptable other damage
2 – Basic requirements	10 % of the structure in terms of masses, volumes, or floor area (in buildings).	A cost equivalent of 10 % of the construction costs of the structure.
3 – High requirements	10 % of the structure in terms of masses, volumes, or floor area (in buildings).	A cost equivalent of 10 % of the construction costs of the structure but not more than USD 20 M.
4 – Very high requirements	5 % of the structure in terms of masses, volumes, or floor area (in buildings).	A cost equivalent of 5 % of the construction costs of the structure but not more than USD 20 M.

[To be revised and completed by the Requirements and Objectives Sub-Committee.]

Table 6: Combinations of actions and safety factors depending on the level of requirements

Requirement level	Design method	Combinations of actions and load safety factors	Resistance safety factors
2 – Basic requirements	Specific local resistance	1.3 HSA + 1.1 IDA + (0.95 or 1.1) DL + 0.7 LL + 0.2 EL	Concrete: 0,65 Steel: 0,9
	Alternative load paths, Segmentation	1.1 HSA + 1.1 IDA + (0.95 or 1.1) DL + 0.7 LL + 0.2 EL	Concrete: 0,7 Steel: 0,95
3 – High requirements	Specific local resistance	1.5 HSA + 1.1 IDA + (0.95 or 1.1) DL + 0.7 LL + 0.2 EL	Concrete: 0,65 Steel: 0,9
	Alternative load paths, Segmentation	1.2 HSA + 1.1 IDA + (0.95 or 1.1) DL + 0.7 LL + 0.2 EL	Concrete: 0,7 Steel: 0,95
4 – Very high requirements	Specific local resistance	1.7 HSA +1.3 IDA + (0.9 or 1.3) DL + 1,0 LL + 0.3 EL	Concrete: 0,6 Steel: 0,85
	Alternative load paths, Segmentation	1.3 HSA + 1.3 IDA + (0.9 or 1.3) DL + 1,0 LL + 0.3 EL	Concrete: 0,65 Steel: 0,9

HSA = actions determined from hazard scenarios; IDA = actions resulting from initial damage; DL = dead load; LL = live load; EL = environmental load; (see Sect. 5.4 for further explanations)

[To be revised and completed by the Requirements and Objectives Sub-Committee.]

6 Design methods

6.1 General. Design methods are methods that aim at preventing disproportionate collapse of a structure. The available design methods are event control and protection, which are external methods, and increased local resistance, alternative load paths, and segmentation, which are internal methods. Event control is a non-structural method, whereas protection and the internal methods are structural methods. Structural methods can be implemented within a direct or indirect design approach. *Internal methods apply to the design of the structure itself. External methods do not directly apply to the design of the structure itself. (…) The classification of design methods suggested here is illustrated in Figure 2.*

6.2 Event control. Event control reduces the probability of occurrence and the intensity of abnormal events through non-structural measures. *Event control reduces the exposure of a structure. The kind of abnormal event to be controlled must be anticipated for implementing event control. It is thus a threat-specific method. Examples of event control are the control of public access to the structure, the enforcement of standoff distances, aerial surveillance, and anti-aircraft defense. (…)*

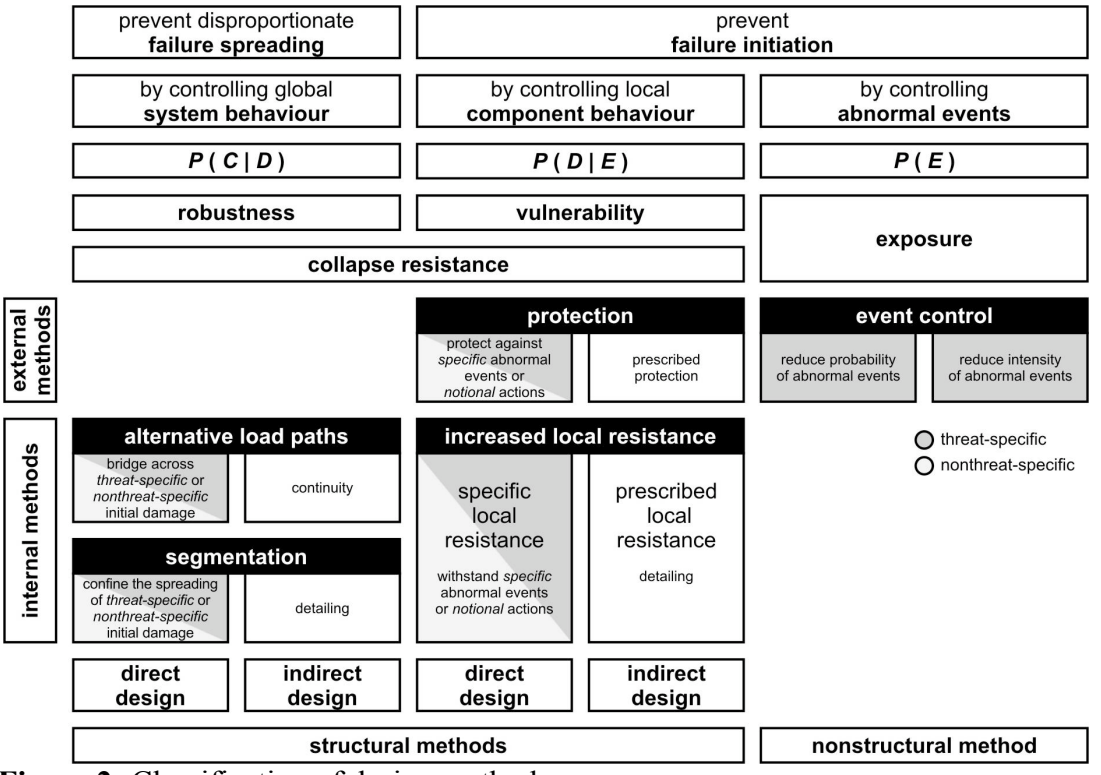

Figure 2: Classification of design methods

6.3 Protection. Protection mitigates the effect of abnormal events through external structural measures. It aims at preventing or reducing initial damage that could otherwise lead to disproportionate collapse. *Protection reduces the vulnerability of a structure. It usually focuses on the key elements of a structure. External structural measures of protection are additional auxiliary components or structures as long as they are not components of the load-transfer system of the structure being protected. Examples of protection are barriers, walls, and dams that resist and shield from impact and blast.*

6.4 Increased local resistance. The local structural resistance is increased or confirmed to be adequate by this design method. It aims at preventing or reducing initial damage that could otherwise lead to disproportionate collapse. Within direct design, this method is called specific local resistance. Within indirect design, this method is called prescribed local resistance. *Increased local resistance reduces the vulnerability of a structure. This method usually focuses on its key elements. (...) Providing specific local resistance is based on specified hazard scenarios. These can be specific abnormal events not averted by event control (threat-specific) or notional actions (nonthreat-specific). In either case, these input data are possibly imprecise. Furthermore, the failure of any one key element is likely to lead to immediate disproportionate collapse (contrary to the failure of an alternative load path or a segment border). It is therefore suggested that an increased margin of safety be required when disproportionate collapse is intended to be prevented by specific local resistance. (...)*

6.5 Alternative load paths. Alternative load paths provide alternatives for a load to be transferred from a point of application to a point of resistance. They enable a redistribution of forces originally carried by failed components and thus prevent a failure

from spreading. *Alternative load paths enhance the robustness of a structure. Alternative load paths can form through ordinary or extraordinary load-transfer mechanisms. (…) Alternative load paths can be added by increasing continuity, strength, and ductility.*

6.6 Segmentation. A structure is divided into segments by dedicated segment borders. This allows a failure that occurs in a segment to be isolated within that segment and thus to prevent a failure from spreading. *Segmentation enhances the robustness of a structure. Segment borders can produce their isolating effect by three different modes of effectiveness: (a) by accommodating large forces, that is, by high local resistance; (b) by accommodating large deformations and displacements, that is, by eliminating continuity or reducing stiffness; (c) by accommodating large forces and large displacements at the same time, which can be achieved by high ductility and results in large energy dissipation capacity. (…)*

6.7 Direct design. Direct design aims at explicitly ensuring collapse resistance by demonstrating that specified performance objectives are met when specified hazard scenarios occur and affect the structure. *For structures of high exposure or significance, direct design is preferable to indirect design. It takes into account the diversity and complexity emerging in structures and ensures collapse resistance in a reasonably reliable, verifiable, and economical manner.*

6.8 Indirect design. Indirect design aims at implicitly increasing the collapse resistance of a structure by incorporating consensus-approved structural design features. This is done without explicit consideration of hazard scenarios and without demonstrating that performance objectives are met. Such features can be codified in standards and guidelines or specified for a particular project, both as prescriptive design rules. *The verification effort required in direct design may become disproportionate for structures of low or medium significance. If therefore direct design is not used, a certain degree of collapse resistance by using indirect design may still be desired. The prescriptive design rules codified so far are detailing rules that intend to provide tension ties, to enable catenary action, or to provide ductility in building structures. These measures aim at providing increased local resistance or alternative load paths. If potential alternative load paths are not provided with the strength required for a redistribution of forces, a failure spreading is possibly not prevented but promoted. Therefore, prescriptive design rules aiming at providing alternative load paths should be applied only to structures strictly within the scope of the applicable provisions or when their safety has been approved otherwise. Prescriptive design rules for specific and specified types of structures are suggested in an Appendix [to be drafted by the Indirect Design Sub-Committee].*

6.9 Combination of design methods. (…) *The design methods can be combined in different ways and for different purposes. (…)*

6.10 Specification of design methods. The structural design methods are selected by the Engineer and approved by the Authorities. This selection can be based on the provisions suggested in Table 7 if applicable or on other applicable provisions. The complementary or alternative use of event control requires adequate professional and organizational support for reliably implementing such non-structural measures and the explicit consent of the Client, the Engineer, and the Authorities. *The applicable structural design methods, including the respective design approaches, can be specified depending on the level of requirements. Such a specification is suggested in Table 7. (…)*

Table 7: Specification of structural design methods

Requirement level	**Design approaches**	(…)
2 – Basic requirements	Indirect design (prescriptive design rules);	
	Direct design (based on non-threat-specific hazard scenarios	(…)
3 – High requirements	Direct design (based on non-threat-specific hazard scenarios possibly complemented by threat-specific hazard scenarios)	(…)
4 – Very high requirements	Direct design (based on non-threat-specific hazard scenarios complemented by threat-specific hazard scenarios)	(…)

[To be revised by the Requirements and Objectives SC and the Direct Design SC]

7 Verification procedures

7.1 General. Verification procedures are used to demonstrate that specified performance objectives are met when specified hazard scenarios occur. They are used in the context of direct design and event control. In an analytical verification, the analysis including the modeling of hazard scenarios, structure, measures of protection, and event control should be sufficiently detailed. (…) *Verification is usually performed by analysis. In particular cases, it can be performed by model or full-scale tests. In indirect design, verification is replaced by checking the proper application of prescriptive design rules.*

7.2 Detailed analysis. The required level of detail is generally high. *An analytical verification generally requires non-linear dynamic analysis allowing for large displacements and non-linear material behavior, and using multi-degree-of-freedom models.*

7.3 Simplified analysis. In some cases, simplified analysis can be used. *Simplification, where admissible, resorts to linear analysis, quasi-static analysis, and generalized single-degree-of-freedom models. Simplified analysis can be sufficient if the failure spreading does not involve impact loading. This is not usually the case for structures susceptible to pancake-type collapse (...). [To be revised and completed by the Direct Design Sub-Committee.]*

7.4 Specification of verification procedures. The verification procedures are selected by the Engineer and approved by the Authorities. *It is suggested that generally detailed analysis be required. Simplified analysis can be allowed on the basis of further research into the relationship between type of structure, type of progressive collapse (...), and type of structural response. [To be revised and completed by the Direct Design Sub-Committee.]*

8 Documentation

8.1 General. The design criteria and the structural analysis and design with respect to disproportionate collapse shall be documented as necessary for design checking, construction, structure management, and emergency response. *(...)*

8.2 Construction documents. Key elements, identified during and remaining after design, that exist in the various construction stages and in the completed structure shall be stated in the construction documents. *The initial failure of any remaining key element is likely to lead to disproportionate collapse. To make such initial failure less probable, structural design and construction (including soil investigation) should meet enhanced requirements when key elements are concerned. In design, this is reflected by the design methods event control, protection, and increased local re-*

sistance. In construction, this is ensured by enhanced quality and safety requirements. The key elements should be stated in the construction documents to enable the Client and the Authorities to specify and to enforce such enhanced construction requirements. The components of temporary works can be key elements. The design of such components is within the scope of these Recommendations.

8.3 Building safety provisions. The design criteria shall also be documented as part of the building safety provisions (…). This documentation shall include a commentary that provides efficient guidance to structure management, users, and emergency response personnel in the case of an abnormal event. *The commentary should include, for instance, the size and location of initial damage that can safely be tolerated by the structure without leading to disproportionate collapse. (...)*

CONCLUSIONS

A draft has been presented that will serve as the outline for the design guidance document to be developed by the ASCE SEI Committee on Disproportionate Collapse Standards and Guidance. It contains a comprehensive set of definitions of terms relevant to disproportionate collapse of structures and, on this basis, a conceptual framework of design criteria encompassing the entire design process. Specific content for a number of sections and tables and an appendix still needs to be developed. This will be done by the Requirements and Objectives Sub-Committee, the Direct Design Sub-Committee, and the Indirect Design Sub-Committee. The scope of these Sub-Committees is defined by the conceptual framework presented here.

A Framework for Optimizing Civil Infrastructure Resiliency

ABSTRACT

Civil infrastructure systems are complex networks of tightly coupled, interdependent subsystems that involve many factors and system constraints. Their resiliency is critical for the proper functioning of society during and following extreme events such as hurricanes and earthquakes. The goal of this paper is to outline the formulation of a framework that provides strategies for increased resiliency. These strategies will be expressed in a common rule-based form of "If-Then" statements. A rule-based model is flexible and can incorporate social performance measures in addition to traditional metrics. The rule-based model also has the capability to reflect the performance of interdependent networks of multiple systems. These rules may be formulated in a manner so as to be incorporated in a multi-objective optimization algorithm that can improve system performance. A brief example of the proposed framework is provided.

INTRODUCTION

Civil infrastructure systems are considered the foundation of a properly functioning society. The constituent subsystems include power delivery, transportation systems such as roadways, and utilities such as water supply. The resiliency of such systems depends not only upon the physical aspects of the systems but the community in which they are located. As defined by MCEER[1] [Bruneau et al. (2003)], *resiliency* for infrastructure systems has the dimensions of *robustness*, *resourcefulness*, *redundancy* and *rapidity*. Although many of these dimensions may be evaluated as technically-based functions of the physical systems such as fragilities, some implicitly include the social and organizational aspects of the community in which the infrastructure exists. For example, *resourcefulness* is a function of both physical resources and the abilities of the community members to respond to and recover from disaster events. Relating the social and organizational "abilities" and traits to the technical functions involving physical systems is extremely challenging.

[1] Multidisciplinary Center for Extreme Event Research, University of New York at Buffalo, NY.

Cimellaro et al. (2009) developed a metamodel for hospital organizational recovery post-earthquake that incorporated uncertainties and interdependencies of transportation roadways, structural performance, and the quality of care at health care facilities. In our approach, we implement a rule-based method to capture the organizational aspects of recovery. These aspects are based upon a system of rules derived both pre and post event for post-disaster recovery from technical sources as well as social strategies consciously or unconsciously developed by community members. Indeed, the rule-based format allows for the introduction of complex community social dynamics determined through surveys and other tools.

In the US, post-disaster emergency response efforts are traditionally designed with a top-down approach designated as "command and control" [e.g., DHS (2009)] while many participants within affected systems approach their response from a less structured bottom-up approach. Figure 1 illustrates this response situation. Communication in both directions is crucial to an effective response. Bridging the gap between these two approaches can provide a framework for a decision support system that best synergizes the command and control with the community-based social systems.

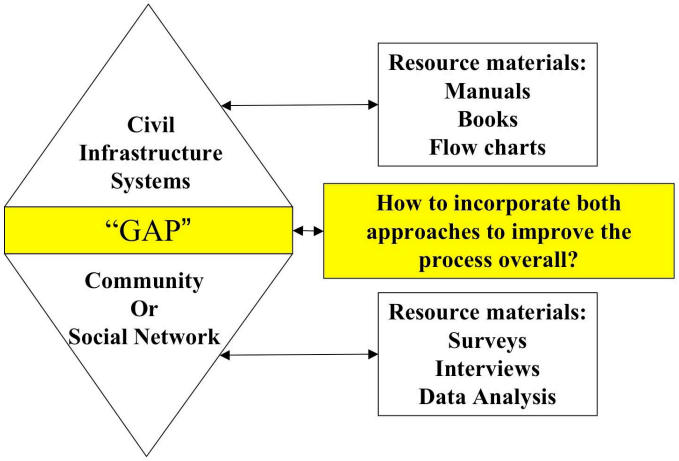

Figure 1. Perspectives of emergency response approaches to management post-event.

In order to build our framework, we must incorporate aspects of systems engineering, social science, optimization and civil engineering. The relevant aspects of these are outlined in the next section.

BACKGROUND.

An interdependent model of civil infrastructure resiliency is comprised of multiple dimensions that include post-event community-based social performance measures and multi-criteria optimization of complex systems based upon rules. Each of these will be defined and outlined in this section before our proposed framework is presented.

Civil Infrastructure Systems.

"Civil infrastructure" is defined in this context as "interconnected lifelines". "Lifelines" are networks that provide for the proper functioning of modern society, such as electric power delivery, transportation systems and water supply. The present networked infrastructure developed in an ad-hoc manner through varying stages of technological innovation without consideration for the interconnected behavior. Individual aging lifelines such roadways continue to decline [ASCE (2009)]. Figure 2 illustrates the system of systems discussed in this paper.

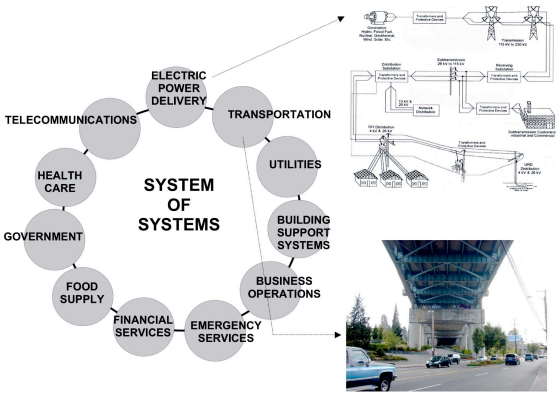

Figure 2. The system of systems that describe the civil infrastructure.

Our network model is derived from the eleven-system interdependent infrastructure as postulated by Chang et al. (2005). The eleven systems $S_1,...S_{11}$ are denoted by index values as follows:

$$\begin{Bmatrix} S_1 \\ S_2 \\ S_3 \\ S_4 \\ S_5 \\ S_6 \\ S_7 \\ S_8 \\ S_9 \\ S_{10} \\ S_{11} \end{Bmatrix} = \begin{Bmatrix} \text{Electric power delivery, with subsystems distribution, transmission and generation.} \\ \text{Transportation, with subsystems air travel, roadways, fueling, transit, rail, water and port facilities.} \\ \text{Utilities, with subsystems water supply, sewage treatment, sanitation.} \\ \text{Building Support Systems, with subsystems HVAC, elevators, security and plumbing.} \\ \text{Business Operations, with subsystems computer systems, hotels, insurance and gaming.} \\ \text{Emergency Services, with subsystems 911, ambulance, fire, police and shelters.} \\ \text{Financial Systems, with subsystems of ATM, banks, credit cards and stock exchange.} \\ \text{Food Supply, with subsystems of distribution, storage, preparation and production.} \\ \text{Government, with subsystems of offices and services;} \\ \text{Health Care, with subsystems of hospitals and public health.} \\ \text{Telecommunications, with subsystems of cable, cellular, Internet, landlines and media.} \end{Bmatrix} \quad (1)$$

Rule-based Optimization.

Complex systems have complicated rules that describe their operation and performance. Instead of using a traditional optimization model with closed form mathematical equations, we apply a recently developed multi-objective interacting particle algorithm that operates directly on If-Then logic rules [Mete and Zabinsky (2010) and Mete (2010)].

In traditional approaches, mathematical modeling must be implemented to create linear or non-linear functions to characterize the real system. The If-Then approach allows users to create and modify the rules that represent the operational or

performance metrics of the system. Mete and Zabinsky (2010) developed an algorithm that operates directly on the rules and produces estimates of the Pareto optimal solutions. The methodology has been applied successfully to scheduling and resource allocation problems defined by business rules [Mete, 2010].

The primary advantage of a rule-based approach is that it employs the natural language of users and is similar to the human cognitive process [Giarratano and Riley (2005); Newell and Simon (1972)]. A popular type of expert systems, rule-based systems, have been successfully implemented for true/false evaluations, such as credit eligibility [Hu and Ansell (2007)]. The current methodology also requires optimization in order to constrain the solution with imposed rules.

In the definition of the problem, the rules are classified as "hard" or "soft". Hard rules provide boundaries so that all solutions must satisfy them. Soft rules represent preferences for the solution. Hard rules are analogous to constraints and soft rules are analogous to *goal programming* in traditional modeling approaches, which result in multiple objectives. Hard rules have true or false (binary) outputs that indicate feasibility of a solution, whereas soft rules have measurable outputs and quantify the degree to which the rule is satisfied. If a soft rule is not completely satisfied, a penalty function *"f"* is assessed.

Mathematically, the defined variables are mapped into Euclidean space where the variables may be real or integer-valued. Variables are associated with solutions that are evaluated for feasibility with hard rules and degree of satisfaction by soft rules. This formulation provides a framework for stochastic optimization. If x is a solution and $f_1,\ldots,f_m$ denote the degree of satisfying soft rules $1,\ldots,m$, respectively, the mathematical problem is

$$\begin{aligned} &\text{minimize: } f_1(x), f_2(x), \ldots, f_m(x) \\ &\text{subject to: } \textit{hard rules} \end{aligned} \tag{2}$$

The functions $f_1,\ldots, f_m$ are smallest when the soft rules are satisfied and larger when they are not. They act as penalty functions. The main flow of the Multi-objective Rule-based Interactive System is presented in figure 3 [Mete (2010)]. The concept is that a group of users may interact through the decision support system to develop hard and soft rules that accurately account for operation and performance of the network of infrastructures. This would facilitate incorporating rules from the top-down command and control structure as well as rules from community-based systems that relate individual responses in various solutions. The rules may also provide interdependency relationships between infrastructures.

When solutions are added to the estimated Pareto optimal list, the decision-makers can discuss the alternatives to come to solutions to implement. If needed, the rules can be modified as the decision-makers explore the impact of non-dominated solutions on the various performance metrics and understand the consequential tradeoffs.

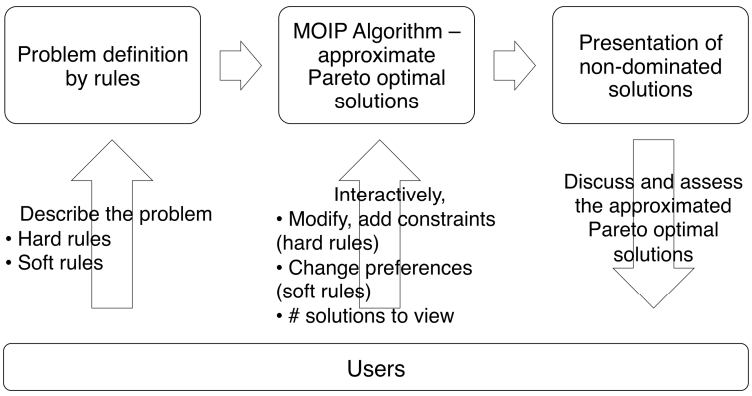

Figure 3. Flow of Multi-objective Rule-based Interactive System. Based on [Mete (2010)].

The multi-objective interacting particle (MOIP) algorithm is used for optimization directly on rules. This algorithm is a combination of a simulated annealing type algorithm and a population-based algorithm (such as genetic algorithms). The MOIP algorithm is inspired by theoretical results from physics that allow us to provide some convergence results. Details on the MOIP algorithm are provided in Mete (2010) and Mete and Zabinsky (2010). Candidate solutions are generated and checked by the hard and soft rules that lead to an estimated Pareto optimal list.

Social Performance Metrics.

The resourcefulness of communities in recovery and response efforts varies as can be evidenced from recent events such as the aftermath of communities in Haiti and New Zealand following major earthquakes. Predictions of community behavior are challenging. The information we seek is ill-defined and highly dependent on the characteristics of the groups seeking assistance. In order to provide models of social behavior post-event, survey instruments traditionally employed in other scenarios such as driver attitudes and behavior in roadway activities may be used [e.g., Donmez et al. (2006)]. To examine various subgroups, stated preferences for resources need to be captured using techniques such as those employed by Ng, Barfield, and Mannering (1998). The surveys will need to address individual's capabilities and limitations within the network [Dickie and Boyle (2009)]. In investigating the attitudes of individuals, we will attempt to answer the following questions:

- How are social groups defined for the community under investigation?
- What resources are required by various social groups post-event and for how long?
- Do individuals act as directed by local, state or federal government?
- Are individuals more closely organized by extended family and neighborhood groups or by governmental institutions?
- What roles do religious organizations and community centers play?
- What preferences are stated for seeking shelter and assistance?

Knowledge gleaned from the surveys will be embedded into the rules of the MOIP system.

FRAMEWORK APPLICATION.

As an example, we outline the approach for an earthquake scenario in the Puget Sound region of the Pacific Northwest. We assume that a magnitude 6.8 deep focus event has occurred. Decisions for roadway restoration by Seattle Department of Transportation [SDOT] and Washington State Department of Transportation [WSDOT] include the following:

- Assess the spatial extent of damage
- Identify if additional resources beyond the local capability will be necessary
- Set priorities for bridge inspection
- Allocate crews and equipment
- Decide road closures and openings

Example rules related to these decisions are listed as follows:

Hard Rules:

- All roads closed in affected areas until crew approves.
- Personnel must be available for rerouting traffic.
- Allocated crews require specific equipment.

Soft Rules:

- Route crews on shortest path if possible.
- Allocate full crews if possible.
- Prioritize bridge inspection on driver behavior.
- Incorporate driver behavior in traffic rerouting.

In the civil infrastructure recovery problem, many rules are derived from preparedness plans. As an example, a solution, x, could be the scheduling and assignment of teams and equipment to locations where the roadway (lifeline) needs to be restored. Hard rules can include the necessity to use equipment, whose operation depends on operator availability. Further, it is necessary to ensure that no equipment is allocated to two places at any given time.

The soft rules relate to rules for ideal situations as well as alternative solutions. For example, it may be ideal to have a three-person team at the site to inspect and open roadways. However, a two-person team can be feasible, but it would take additional time; that is, there is a penalty, f_1, incurred. Another soft rule could encompass the ideal origin-to-destination route. The ideal route would transport equipment and operators to the site the quickest, but an alternate route is feasibility with additional time (penalty, f_2).

The social performance metrics will form the basis for other soft rules. For example, there may be a need to restore traffic to locations not easily identified in the command-control approach. Some individuals find comfort in places that are more familiar such a church, temple, or neighborhood community centers. The information gathered from the survey will provide insights on the likelihood that they will seek shelter at a location not already identified in the top-down approach. The ideal place to restore traffic will be identified as the highest priority by the majority of survey

respondents. It is also recognized that there may not be easy access to some of these locations and hence, an alternative location based on the next highest priority location will be targeted for restoration. However, the penalty of the alternative location is the number of people that can actually be reached (f_3).

It is also likely that subgroups of the population will use only certain facilities. For example, the elderly may be more likely to seek shelter in a faith-based organization while those younger to middle-aged may be more likely to travel to the community center. These differences in subgroups will also need to be accounted for in the algorithm.

Sample Solutions.

The recovery of lifelines is usually characterized by a resilience metric, *Q(t),* or quality. When *Q(t)* equals 100 percent, the lifeline is operating at full capacity. At *Q(t)* equal to zero, the lifeline is not operating at all. Intermediate values of system performance are in-between these two values. We compare a base case scenario (our roadway recovery without MOIP) with two different MOIP solutions in Figure 4.

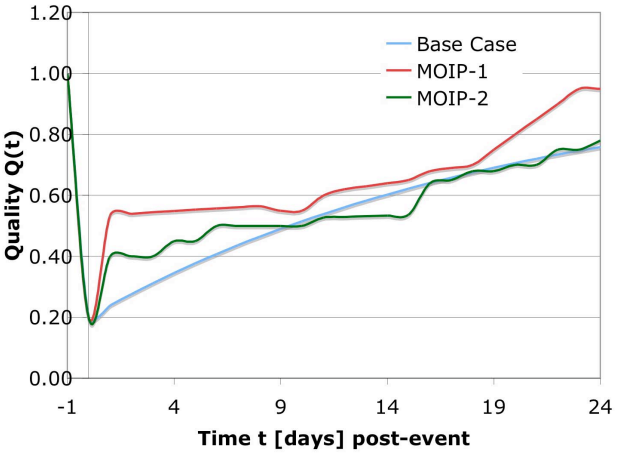

Figure 4. Comparison of *Q(t)* functions.

It is anticipated that the MOIP solutions will provide more rapid recovery. Differences among the recovery functions may be evaluated by decision-makers to improve resource allocation and possibly infrastructure design. Finally, because there are *Q(t)* functions for each system S_i as given in Eqn. (1), and these systems are interdependent [e.g. Reed et al. (2009)], we propose the use of a radar resiliency plot for all eleven systems, at regular time intervals, to assess the recovery of the entire infrastructure system. An example is given in Figure 5 for one time interval.

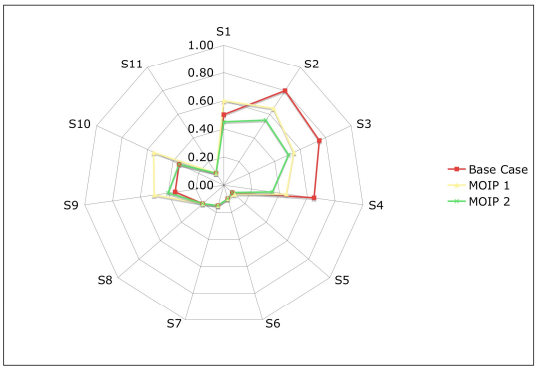

Figure 5. Radar resiliency plot for one time interval.

SUMMARY AND CONCLUSIONS.

We have outlined an alternative approach denoted as "rule-based MOIP" to modeling post-disaster decision-making regarding emergency response and recovery of civil infrastructure systems. Hard and soft rules incorporate constraints and preferences. MOIP provides quantitative information for discussion of mutual interests at the top level of emergency management. It has the potential to transform the process. Improved design of CIS and resource allocation post-event are possible through the application of the proposed methodology.

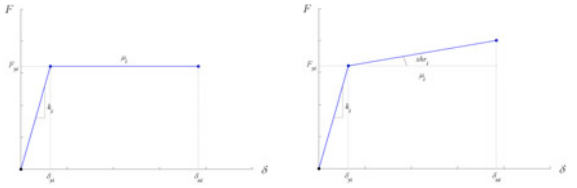
ABSTRACT

This paper aims at presenting an innovative approach for an optimised/full-controlled seismic design of structures which combines recent contributions in the field of earthquake engineering and overcomes the traditional design approach leading to the identification of the characteristics of the lateral-resisting system capable of satisfying multiple seismic performance objectives. In this respect, it is fundamental the total conceptual separation between the structural systems resisting to vertical and horizontal loads. With reference to both (1) a braced pendular frame structure and (2) a shear-type frame system coupled with a lateral-resisting element (such as a reinforced concrete core or a bracing system), the approach here presented identifies the characteristics (strength, stiffness, ductility, energy-absorption) of the system resisting to horizontal loads which enables to satisfy prescribed seismic performance objectives. This is achieved through the identification of an objectives curve, in the Force-Displacement diagram, of the mechanical characteristics of the structure. The lateral-resisting system is obtained by means of (1) special braces in the case of the braced pendular frame structure and (2) special connection elements in the case of the shear-type system coupled with a lateral-resisting element.

1. INTRODUCTION

The design of building structures capable of providing given seismic performances represents a difficult task due to the complex characterization of the seismic action (not a single action but a set of possible actions of different strength and probability of occurrence) and of the structural response. Many recent contributions in the field of seismic engineering have opened up new possibilities for the structural engineer in terms of conceiving and dimensioning a structural system which offers predetermined seismic performances. Skipping all details, these recent contributions may be summarized as follows: (i) the PBSD approach (SEAOC Vision 2000 1995, Bertero and Bertero 2002) formalized the need of satisfying a multiplicity of performance objectives, (ii) the Direct Displacement-Based Design (DDBD) (Priestley et al. 2007) introduced the displacement analysis as a tool for seismic design of structures and (iii) the wide use of protection devices and techniques (e.g. unbounded braces, dampers (Soong and Dargush 1997, Christopoulos and Filiatrault 2006), seismic isolators (Kelly 1997)) allowed the mitigation of the seismic effects on the structures and strongly suggested the conceptual separation between the structural systems resisting to vertical and horizontal loads.

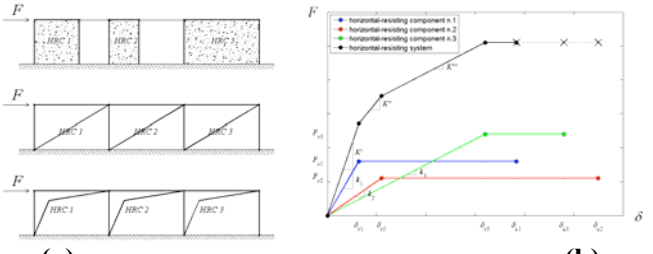
This paper (i) presents a design approach for a full-controlled seismic design of structures which combines these recent contributions and overcomes the traditional



one, and (ii) proposes a special solution for lateral-resisting systems capable of multiple seismic performances constituted by specifically developed "calibrated-shape devices".

2. IDEA AND NEW ASPECTS OF THE PROPOSED DESIGN APPROACH

The basic idea behind the design approach here proposed lies in the identification of the characteristics (strength, stiffness, ductility, energy-absorption) of the structural system resisting to horizontal loads which enables to satisfy a multiplicity of seismic performance objectives, as required by the PBSD and as already faced in other research works (Liu et al. 2004), by adapting and exploiting the complete DDBD approach (Xue and Chen 2003).



In general, the horizontal-resisting system (hereafter referred to as HRS) of a given building structure can be seen as composed of a series of single horizontal-resisting elements (hereafter referred to as "horizontal-resisting components", HRC), working together. The mechanical characterization of each component (being either a shear wall, a bracing system or other) of the horizontal-resisting system necessarily requires to capture both its elastic and inelastic behaviour. Without loss of generality, the mechanical characterization of each elementary component can be assumed to be an elastic-perfectly plastic one or a bilinear one with hardening, as represented in Figure 1 (a) and (b), respectively. The independent parameters, which are necessary to fully characterize the HRC behavior, are only four and they are stiffness, strength, ductility and strain hardening ratio. For sake of simplicity, in order to present the basic ideas of the design approach here proposed, in the following parts of this paper, the elastic-perfectly plastic model (strain hardening ratio = 0) has been assumed.

The mechanical characterization of the whole horizontal-resisting system (Figure 2b), as composed of the n horizontal-resisting components working in parallel (Figure 2a), can be directly obtained by adding the mechanical characterization of each single component.

(a) **(b)**

Figure 1: F - δ constitutive law of the *i*-th HRC. (a) Elastic-perfectly plastic model; (b) Bilinear model with hardening.

(a) **(b)**

Figure 2. (a) Different SDOF structural systems, each one composed of three homogenous horizontal-resisting components. (b) F - δ constitutive law of a

HRS composed of three HRCs, as obtained combining the constitutive laws of the single HRCs.

The new aspects of this design approach lie:
- in a sound and active combination of the most recent contributions in the field of the earthquake engineering (PBSD, DDBD and protection systems),
- in the total "*separation*" between the structural system resisting to vertical loads ("vertical-resisting system") and the structural system resisting to horizontal loads ("horizontal-resisting system"),
- in the development of a special solution for the horizontal-resisting system based upon the smart use of peculiar devices which are specifically calibrated in their shape to satisfy multiple performance objectives.

3. THE PROPOSED DESIGN APPROACH

The previous considerations, which show how a backbone F-δ curve can be developed and controlled acting on each single HRC, can be collected and formalized in a 3-Phases seismic design approach which is aimed at identifying the characteristics of the structural system resisting to horizontal loads which enables to directly satisfy given seismic performance objectives (without recurring to any trial-error processes). The approach is composed of the following 3-phases:
- Phase 1: starting from selected seismic performance objectives, identification of the F-δ objectives curve of the structural system to be designed;
- Phase 2: development of "calibrated-shape devices" which are capable of satisfying the selected performance objectives when used either (i) as special braces in the case of a pendular frame structure or (ii) as special connections in the case of a frame coupled with a lateral-resisting element;
- Phase 3: verification, by means of appropriate time-history analyses, of the seismic performances achieved.

The approach is illustrated in the following part of the paper with reference to two applicative examples, as developed with reference to:
1) a braced pendular frame structure, and
2) a shear-type frame system coupled with a lateral-resisting element (such as a reinforced concrete core or a steel bracing system).

4. FIRST APPLICATIVE EXAMPLE

The first applicative example is carried out with reference to a building structure composed of seven-storey pendular steel frames (for sake of simplicity it is here assumed that there is no transmission of bending moments at the column-beam connections). The building plan is 36 x 18 m, inter-storey height is 3.5 m and the total building mass is $4.54 \cdot 10^6$ kg. The building is assumed to be located in Bologna (Italy) on D.M. 14/01/2008 soil type C and on topographic surface S1. It is designed to meet the D.M. 14/01/2008 provisions.

The structure is characterized by the separation between the vertical-resisting system (beams and columns) and the horizontal-resisting system (special bracing system). The vertical-resisting system is sized to support just the vertical loads. The horizontal-resisting system is designed to display a controlled inelastic behaviour at the ground level and to behave elastically from the second storey up. It is composed

of: (1) special bracing elements, named “calibrated-shape devices” placed between the ground storey and the first storey, (2) traditional diagonal bracing elements from the second storey up. The horizontal-resisting system, placed between the ground and the first storey, is calibrated, within a Performance-Based Seismic Design approach, to satisfy a multiplicity of performance objectives through the identification of a "objectives curve", in the Force-Displacement diagram, of the mechanical characteristics of the structure. The horizontal-resisting elements from the second storey up can be designed through a capacity design approach and will not be considered in the following analyses. Figure 3 shows the geometry of one of the two perimeter pendular steel frames in both the North-South (NS) and the East-West (EW) directions.

The seismic behaviour of the building along each direction may be schematised as the one of a SDOF system characterized by a mass corresponding to that of the whole superstructure (second storey up) and by the lateral force-displacement relationship controlled by the HRSs composed of 8 HRCs along both the NS and the EW directions, respectively, together with the little contribution to the lateral resistance provided by the vertical-resisting systems. In the following part of the paper, for sake of conciseness, only the seismic behaviour of the building along the NS direction will be considered.

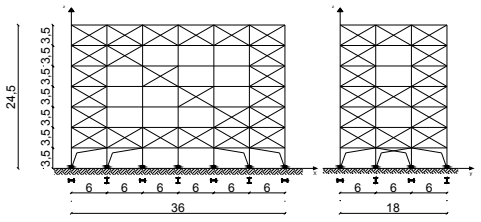


Figure 3. Schematic representation of the building structure considered.

4.1 Identification of the F-δ Objectives curve (Phase 1)

The selected performance objectives

With the aim of obtaining a desired behaviour for the structure at hand and designing the horizontal-resisting system, we imposed the following Basic Objectives as defined in the Vision 2000 document:

1) First Performance Objective (PO1): defined as a coupling of the Fully Operational performance level with the Frequent Earthquake Design Level;
2) Second Performance Objective (PO2): defined as a coupling of the Operational performance level with the Occasional Earthquake Design Level;
3) Third Performance Objective (PO3): defined as a coupling of the Life Safe performance level with the Rare Earthquake Design Level.

Objectives Curve in the force-displacements diagram

Imposing on the considered structure the previous performance objectives (making use of the tools of the typical Priestley’s DDBD approach, such as the identification of the seismic demands by equating equivalent viscous damping and reading off an effective period from highly-damper displacement spectra), we have obtained the *objectives curve* in the Force-Displacements diagram, for the city of Bologna, for D.M. 14/01/2008 soil type C and for topographic surface S1. For sake of conciseness, it is here only represented in graphical form in Figure 4, which

illustrates the target points for an optimised/controlled seismic behaviour of the structure (performance objectives PO1, PO2, PO3). As illustrative example, as far as PO1 is concerned, F_{PO1} = 4.41 MN, δ_{PO1} = 1.75 cm and $K_{PO1} = K_{target}$ = 253790kN/m.

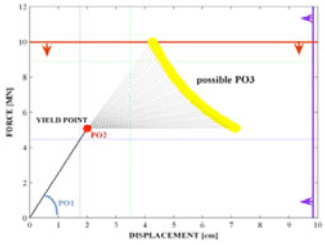

Figure 4. *Objectives curve* in the Force-Displacements diagram.

4.2 Identification of the characteristics of each single horizontal-resisting component (Phase 2)

In this section, the physical characteristics of the horizontal-resisting system are obtained taking into account also the mechanical properties along the horizontal direction of the vertical-resisting system.

Lateral stiffness of the vertical-resisting system

For the case-study at hand, the lateral stiffness (initial inclination of the force-displacement relationship) of the vertical-resisting system, as composed by 28 equal HEA300 columns (14 of which placed to act in weak direction and 14 of which in strong direction), is computed as:

$$K_{VRS} = \sum_{i=1}^{28} k_i = \sum_{i=1}^{14} 1.6\frac{EJ_y}{h^3} + \sum_{i=1}^{14} 1.6\frac{EJ_x}{h^3} = 80060\frac{\text{kN}}{\text{m}} \quad (1)$$

where E = 210000 MPa (Young modulus), J is the moment of inertia along the considered direction (J_y =19380cm^4 and J_x =58220cm^4), and h = 3.5 m (inter-storey height). The stiffness coefficient 1.6 derives from the specific static scheme corresponding to pendular columns which are constrained to move together, along the X-direction, in the upper stories due to the presence of traditional diagonal bracing elements. Figure 5 shows the contribution to the lateral resistance provided by the vertical-resisting system, together with the *objectives curve*, in the Force-Displacement diagram. It is possible to note that the vertical-resisting system alone is not able to satisfy the performance objects imposed.

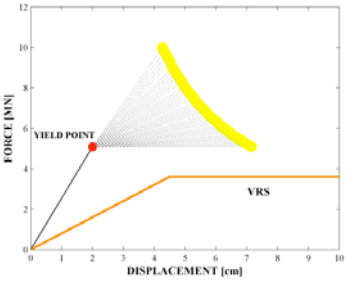

Figure 5 Vertical-resisting system F-δ diagram on the *objectives curve*

Lateral stiffness of the horizontal-resisting system

Without modifying the lateral stiffness of the vertical-resisting system, we assign the part of the lateral stiffness, required for satisfying the performance objectives, to

the horizontal-resisting system placed between the ground and the first storey. Figure 6 shows the "objectives curve" of each HRC. It is obtained subtracting from the structure "objectives curve" the lateral contribution of the vertical-resisting system and dividing by the total numbers of horizontal-resisting components which compose the horizontal-resisting system along the considered direction. Let us indicate the lateral stiffness of the horizontal-resisting system with ΔK or K_{HRS}:

$$\Delta K = K_{\text{HRS}} = K_{\text{Target}} - K_{\text{VRS}} = 173730 \ \frac{\text{kN}}{\text{m}} \tag{2}$$

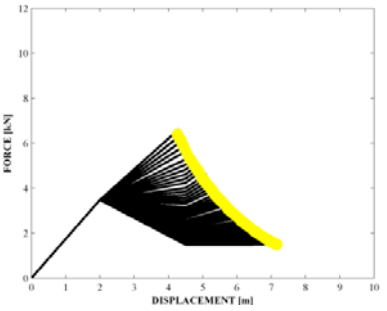

Figure 6 "Objectives curve" of each couple of HRCs.

Design of the linear mechanical/geometrical characteristics of the calibrated-shape device

The lateral stiffness of each couple of horizontal-resisting components (one brace in compression + one brace in tension) is 1/4 of the lateral stiffness of the horizontal-resisting system (there are four Calibrated-shape devices on each face of the building in North-South direction):

$$K_{\text{2HRC}} = \frac{K_{\text{HRS}}}{4} = 43440 \ \frac{\text{kN}}{\text{m}} \tag{3}$$

Figure 7 shows the generic couple of calibrated-shape devices.

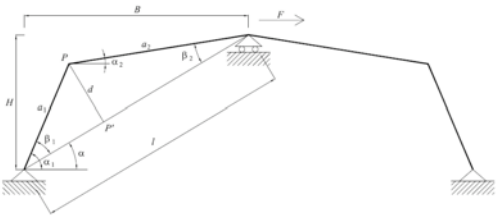

Figure 7 Generic couple of two calibrated-shape devices.

The Virtual Works Principle gives the lateral stiffness of the single crescent shaped brace as follows:

$$\frac{K_{\text{2HRC}}}{2} = \frac{3EJ\cos^2\alpha}{d^2 \cdot (a_1 + a_2)} \tag{4}$$

Where E is the steel Young Modulus; J is the inertia moment of the HRC's cross section; α is the inclination of the portal's diagonal; d is the distance of the knee point, P, from the portal diagonal; $a_1 + a_2$ is the length of the calibrated-shape device.

The first equation for sizing the single crescent shaped brace can be found imposing the equality between Eq. (3) and Eq. (4):

$$\frac{J}{d^2} = \frac{(K_{2HRC}/2)\cdot(a_1 + a_2)}{3E\cos^2\alpha} \quad \textit{(5)}$$

The structure first yield displacement, $_{y1}$, is also the single horizontal-resisting component first yield displacement. So, when each crescent shaped brace has reached its first yield displacement, the bending moment in the most stressed section reaches the first yielding moment, M_y.

The maximum bending moment at point P is given by:

$$M_P = \frac{F}{\cos\alpha}\cdot d \quad \textit{(6)}$$

The first yielding moment is given by:

$$M_y = f_y \cdot W_{el} \quad \textit{(7)}$$

where f_y is the steel yielding tension ($f_y = 275$ MPa) and W_{el} the section modulus of the HRC's cross section.

The second equation for sizing the single crescent shaped brace can be found imposing the equality between Eq. (6) and Eq. (7):

$$\frac{W_{el}}{d} = \frac{(F_{y1,\,2HRC}/2)}{\cos\alpha}\cdot\frac{1}{f_y} \quad \textit{(8)}$$

where h is the height of the cross section and $F_{y1,\,2HRC}/2$ is the first yielding force of each couple of HRCs.

The number of the unknown quantities (J, W_{el}, d) is greater than the number of the equation, hence it is necessary to fix one of the three unknown quantity.

Fixing d = 1 m, we obtain $J = 33414$ cm^4 and $W_{el} = 1789$ cm^3. At this point, several cross-sections may be found with these prescribed values of J and W_{el}. As illustrative examples, the following two cross-sections can be taken into account:

- ***rectangular cross-section characterised by h = 35 cm and b = 9.5 cm ($J = 33943$ cm^4 and $W_{el} = 1940$ cm^3);***
- ***HEB 340 profile modified (t_w=1.3cm, t_f =2.5cm) ($J = 36656$ cm^4 and $W_{el} = 2160$ cm^3).***

In the following section, for sake of brevity, only the "effective" constitutive law of the rectangular cross-section has been reported as obtained by an accurate push-over analysis.

Design of the non-linear mechanical characteristics of the calibrated-shape device

Provided that there are different possibilities regarding the second non-linear branch of the objectives curve (the satisfaction of the PO3 does not lead to a unique objectives curve, but many different solutions may be feasible), the constitutive law of each couple of HRCs has been numerically obtained (Figure 8a) with a non-linear static push-over analysis (displacement control) and then checked with respect to the possibilities of the objectives curve. The couple of braces has been modelled in the STRAUS7 version 2.2.3 package using 2D plane-stress plate elements with the typical stress-strain curve for mild steel material (S275), considering both mechanical and geometrical non-linearities.

Figure 8b shows the constitutive law of each couple of HRCs as reported above the *objectives curve*, together with the contribution of the single column of the vertical-resisting system, which may be considered negligible. Inspection of Figure

8a also indicates that the system is far from the ultimate displacement capacities of both the columns (128 cm) and the calibrated-shape devices (larger than 40 cm). It is clear that the single couple is able to satisfy the performance objective, consequently, also the structure should be able to satisfy the imposed performance objectives. This will be verified in next Phase 3. From Figure 8b, it can be noted that the imposed (designed) displacement under the Rare Earthquake is equal to 4.6 cm.

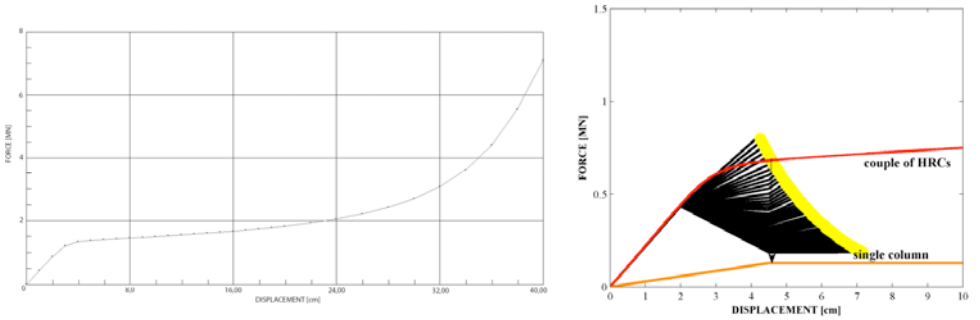

Figure 8. (a) Constitutive law of each couple of HRCs. (b) The constitutive law and the *objectives curve* of each couple of HRCs.

4.3 Analysis and verification (Phase 3)

In this phase, the analysis of the structure so obtained is carried out to verify if the actual structural behaviour is congruent with the expected/imposed performances. A plane model of the structure has been realized using the SAP2000 v14 package, and each crescent shaped brace has been modelled with a synthetic non-linear link element, characterised by a reasonable schematization of the sophisticated constitutive law obtained in the previous Phase 2.

Non-linear time-history dynamic analysis have then been developed on the structural model, using as earthquake ground motions, two groups of seven accelerograms. The first group is composed of seven accelerograms which are overall compatible with the design spectrum of the Italian code corresponding to the Frequent Earthquake. The second group is composed of seven accelerograms which are overall compatible with the design spectrum of the Italian code corresponding to the Rare Earthquake. The accelerograms have been obtained using the program REXEL v 2.2 (beta) (Iervolino 2008). Tables 1 (a) and (b) show the maximum displacements of the first storey caused by the seven accelerograms corresponding to the Frequent Earthquake and by the seven accelerograms corresponding to the Rare Earthquake, respectively. In these tables the average values of the these displacements are also reported. The average values of the displacements of the first storey represent the average displacement demand required by the earthquakes. Comparing the average value of the displacement demand with the value of the displacement demand imposed in Phase 1 for each performance objective, it is possible to note that the value are almost the same (1.76 cm vs. 1.75 cm, and 5.34 cm vs. 5 cm).

Table 1. Maximum displacements and average value of the first storey caused by the seven accelerograms corresponding to the (a) Frequent Earthquake, (b) Rare Earthquake.

5. SECOND APPLICATIVE EXAMPLE

The second applicative example is carried out with reference to a building structure composed of five-storey steel shear-type frames coupled with a lateral-resisting element (i.e. a r.c. wall). The connection between the frame and the lateral-resisting element is realized through the spread placement of hysteretic dissipative devices (therefore referred as HDDs) at each floor of the structure (Figure 9). The building plan is 36 x 18 m, inter-storey height is 3.5 m and the total building mass is $5.40 \cdot 10^6$ kg. The building is assumed to be located in Bologna (Italy) on D.M. 14/01/2008 soil type C and on topographic surface S1. It is designed to meet the D.M. 14/01/2008 provisions.

The structure is characterized by the separation between the vertical-resisting system (beams and columns) and the horizontal-resisting system (r.c. walls of the core). The vertical-resisting system is sized to support just the vertical loads whilst the lateral-resisting element is sized to support just the horizontal loads. The HDDs are calibrated, within a Performance-Based Seismic Design approach, to satisfy a multiplicity of performance objectives through the identification of a "objectives curve", in the Force-Displacement diagram, of the mechanical characteristics of the structure.

In this second case, the seismic behaviour of the building along each direction may be schematised as the one of a MDOF system.

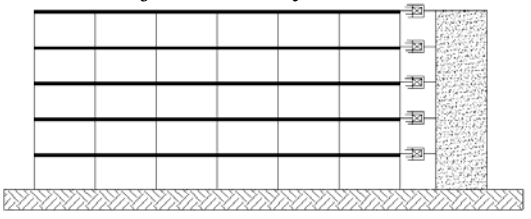

Figure 9. Schematic representation of the building structure considered.

5.1 Identification of the F-δ Objectives curve (Phase 1)

As far as the identification of the F-δ objectives curve (Phase 1) is concerned, the same Basic Objectives have been imposed on the considered structure to obtain the *objectives curve* in the Force-Displacements diagram.

5.2 Identification of the characteristics of each single horizontal-resisting component (Phase 2)

Since the structure at hand is a MDOF system, the HDDs should be calibrated along the height of the building. A tri-linear constitutive law is imposed for each HDD according to the following procedure:

1. Step 1: identification of the total stiffness which the lateral-resisting system should provide to the structure for satisfying the imposed performance objectives;
2. Step 2: distribution of the stiffness of each HDD along the height of the structure;
3. Step 3: identification of the yielding force of each HDD;
4. Step 4: selection of the slope of the second post-yielding branch, of the slope of the third hardening branch, and of the ultimate displacement.

Step 1: identification of the total stiffness for the HDD

The following criterion has been envisaged to obtain a reasonable total stiffness. The total stiffness is evaluated through the equation (9) accounting for the stiffness of the device placed on the first floor, $k_{d,floor1,new}$. This latter is evaluated multiplying the floor stiffness of the shear-type frame, $k_{p,floor,old}$, by a coefficient corresponding to the maximum ratio between the maximum inter-storey drift calculated from the linear analysis ($\max(id)_{floor}$) and the displacement corresponding to PO1, δ_{PO1}, or the elastic displacement of the structure, δ_{el}:

$$k_{d,floor1,new} = k_{p,floor,old} \cdot \max\left(\frac{\max(id)_{floor}}{\delta_{PO1}}, \frac{\max(id)_{floor}}{\delta_{el}} \right) \quad \textbf{(9)}$$

Step 2: distribution of the stiffness of each HDD along the height of the structure

For the distribution of the stiffness of each HDD along the height of the structure different criteria have been envisaged and analysed:

- Criterion 1: transformation of a *n*-DOF system (where *n* is the number of floors) in one made up of *n* unrelated SDOF systems characterized by the same stiffness:

$$k_d = \frac{4\pi^2 m_{floor}}{T_{Frequent}^2} \quad \textbf{(10)}$$

  where $k_{d,i}$ is the stiffness of the *i*-th device (where $k_{d,1} = k_{d,2} = ... = k_{d,i} = ... = k_{d,N}$), m_{floor} is the mass of the floor (which is assumed to be the same for each floor), $T_{Frequent}$ is the period of the whole structure corresponding to the initial imposed stiffness.
- Criterion 2: calibration of the stiffness of the *i*-th device based of the *i*-th shear floor (evaluated through a linear modal analysis) of the shear-type frame; in this case the stiffness of the devices varies from floor to floor:

$$k_{d,i} = \frac{T_i}{\delta_{PO1}} \quad \textbf{(11)}$$

  where $k_{d,i}$ is the stiffness of the *i*-th device, δ_{PO1} is the imposed displacement at PO1.
- Criterion 3: iteration carried out upon Criterion 2 which stops when the variation of the group of stiffness between two consecutive is negligible;

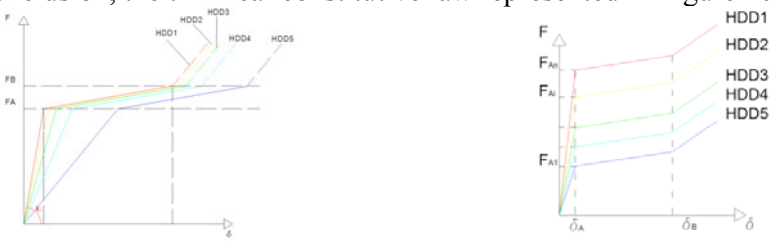
- Criterion 4: transformation of *n*-DOF system in one made up of *n*-linked SDOF systems. This conception is able to consider the shear contribute of overhanging floors.
- Criterion 5: optimization of the initial stiffness through Genetic Algorithms.

On the basis of the results obtained, the best methodology has been identified in Criterion 3, and, for design purpose, it has been deduced the following simplified formula: the relative values of the storey stiffnesses are roughly positioned on a line described by:

$$i_r,2 = \frac{i}{S(n)}; \quad S(n) = \sum_{i=1}^{n} i = \frac{n \cdot (n+1)}{2} \qquad \textit{(12)}$$

where n is the number of floors and i is the floor index (floors are numbered in a crescent order from the top to the bottom).

Step 3: identification of the yielding force of each HDD



Two criteria have been envisaged to identify the yielding force of each device:

1. the first one considers the same yielding force for all the devices (the yielding force of the device placed on the first floor has been chosen);
2. the second one considers the same yielding displacement for all the devices (the yielding displacement corresponding to the PO1 has been chosen).

Step 4: selection of the slope of the second post-yielding branch, of the slope of the third hardening branch, and of the ultimate displacement

The slope of the second post-yielding branch is defined as the 3% of the initial stiffness of each device, in order to limit the forces on the structural elements. The slope of the third hardening branch is defined as the 50% of the initial stiffness of each device. The ultimate displacement is defined on the basis of the PO3.

In conclusion, the tri-linear constitutive law represented in Figure 10 is obtained.

(a) **(b)**

Figure 10. Constitutive law of HDDs (a) same yielding force and (b) same yielding displacement.

5.3 Analysis and verification (Phase 3)

A plane model of the structure has been realized using the SAP2000 v14 package, and each connection element has been modelled with a synthetic non-linear link element, characterised by a constitutive law obtained in the previous Phase 2. Non-linear time-history dynamic analysis have then been developed on the structural model with the same earthquake ground motions used in the previous example.

Figure 11 displays the on the *objectives curve* of the first floor the results obtained through the non linear analysis.

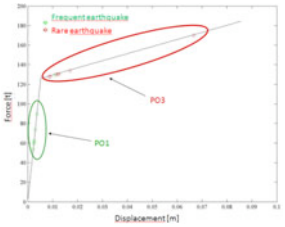


Figure 11. Verification of the seismic performances of the HDDs. *Objectives curve* for the first floor and results of the non-linear time-history analysis.

6. CONCLUSIONS

This paper presents an innovative seismic design approach which allows to exploit at their best all the potentialities offered by both the PBSD framework and the DDBD methodologies.

This approach, which has been applied to the case studies of a (1) moment-resisting frame structure and (2) shear-type frame system coupled with a lateral-resisting element, leads to the identification of the characteristics of the (1) structural system resisting to horizontal loads (special calibrated-shape braces) in the first case-study and (2) special connection elements in the second case-study, which enable to satisfy given seismic performance objectives. This is achieved by considering a total conceptual separation between the structural systems resisting to vertical and horizontal loads and by the use of peculiar calibrated-shape devices as horizontal-resisting system.

ACKNOWLEGEMENTS

Financial supports of Department of Civil Protection (Reluis 2010-2013 Grant – Thematic Area 2, Research line 3, Task 2: “Development and analysis of new technologies for the seismic retrofit”) is gratefully acknowledged.

The authors gratefully acknowledge Maria Cristina Todisco for her contribution in the development of the second case-study.

ABSTRACT

This paper focuses on blast vulnerability assessment of concrete masonry infill walls retrofitted with nano particle reinforced polyurea. Quarter scale model concrete masonry infill walls made of scaled down brick units were retrofitted with Polyhedral Oligomeric Silsesquioxane (POSS) reinforced polyurea and subjected to a pre-adjusted airblast pressure and impulse in the ERDC Blast Load Simulator facility. A computationally-efficient model was built using an explicit hydrocode called ANSYS AUTODYN to replicate with reasonable accuracy the behavior of retrofitted infill walls subjected to blast loads. A series of finite element analysis was conducted. The focus was to study the effect of some factors such as boundary conditions, thickness and arrangement of retrofitted layers, and ductility of retrofitted materials on the behavior of the system during and after blast. Results from blast experiments showed that POSS reinforced polyurea significantly enhanced the performance of masonry walls sustaining blast load. The finite element parametric evaluation results show that for the case of retrofitting with elastomeric materials it is better to apply the retrofit at the back side since this will be associated with no failure, when compared to front side retrofit, and a larger deflection (e.g. more energy dissipation) when compared with two side retrofit with a smaller amount of material.

1. INTRODUCTION

Conventional building components are highly vulnerable to terrorist bomb attack. One of the greatest threats from blast loading is the fragmentation–pieces from walls, windows, equipment, or vehicles flying at such high speeds that they can result in extensive injury or death. Un-reinforced masonry (URM) walls have low resistance to out-of-plane blast loadings due to low flexural capacity and brittle mode failure. These problems lead to a critical need to develop effective retrofitting techniques to improve the load carrying capacity of such members to resist blast loads. Good amount of work had been done on using elastomeric materials as a retrofit technique. Johnson, et al (2005) conducted a series of static and dynamic experiments to investigate the potential benefits of using both reinforced and unreinforced elastomeric materials to retrofit hollow, unreinforced, concrete masonry walls. The static experimental results demonstrated an increase in the ultimate flexural resistance of the retrofitted CMU walls. And it supported the idea that the polyurea spray-on materials did significantly increase the stiffness of the reinforced polyureas as compared to the unreinforced ones. Dynamic results showed that the unreinforced polyureas did add minor additional flexural resistance to the hollow unreinforced CMU wall, whereas the addition of reinforcement to the polyurea retrofit system significantly increased the flexural resistance of the CMU walls. Davidson, et al (2004) used full-scale

explosive tests to determine the effectiveness of using sprayed-on polymers to improve blast resistance of unreinforced masonry walls. They concluded that a sprayed-on polymer retrofit approach to strengthening masonry walls against blast loads was an effective technique. Davidson, et al (2005) experimentally and numerically studied damage and failure mechanisms of polymer reinforced concrete masonry walls subjected to blast loadings. They observed that a thin elastomeric coating on the interior face of the wall can be effective in minimizing the fragmentation and potential for collapse of unreinforced concrete masonry walls resulting from a blast. They also found that the elongation capacity was more important for damage reduction than having a high stiffness, so an effective balance between stiffness and elongation potential was required. Finite element results indicated that a spray-on polymer reinforcement approach can be effective in reducing the vulnerability of unreinforced CMU walls subjected to blast loading. Eamon, et al. (2004) analyzed CMUs subjected to blast pressure using the Finite Element Method. Their model had the ability to replicate experimental results with good agreement, generally matching the failure shape, the location of break lines, and the size and the number of primary pieces of debris. In order to protect the nation's infra structure one need to employ the best available materials. When existing materials cannot deliver the performance, it is important to design new material. Recent interest in the use of polymer based composite materials in infrastructure applications requires further improvements in blast resistance of these materials. The main objectives of this study are to investigate the ability of nano particle reinforced polymers to protect masonry infill wall against blast loading, and to study the effect of some factors like boundary conditions, thickness and arrangement of retrofitted layers, and ductility of retrofitted materials on the behavior of the system during and after blast.

2. DESCRIPTION OF MATERIALS USED

Polyhedral Oligomeric Silsesquioxane (POSS) reinforced polymers were used in the current research to protect masonry walls against blast loads. The polymer used in was polyurea Line-XS 350 produced by Protective Coatings Inc.

2.1. Material Properties

The static stress-strain behavior of POSS reinforced polyurea was determined by performing standard direct tension tests using a Servo-hydraulic Material Test Systems (MTS) machine on coupons cut from large panels. Important mechanical properties such as modulus of elasticity, tensile strength, and strain at failure were obtained directly from the generated curve. Table 1 lists the average modulus of elasticity, ultimate tensile strength, and strain at failure. Figure 1 shows typical stress-strain curves for one tested specimen.

Table 1: POSS reinforced polyurea mechanical properties

Modulus of Elasticity (MPa)	210.56
Ultimate Strength (MPa)	13.81
Strain at Rupture (%)	116

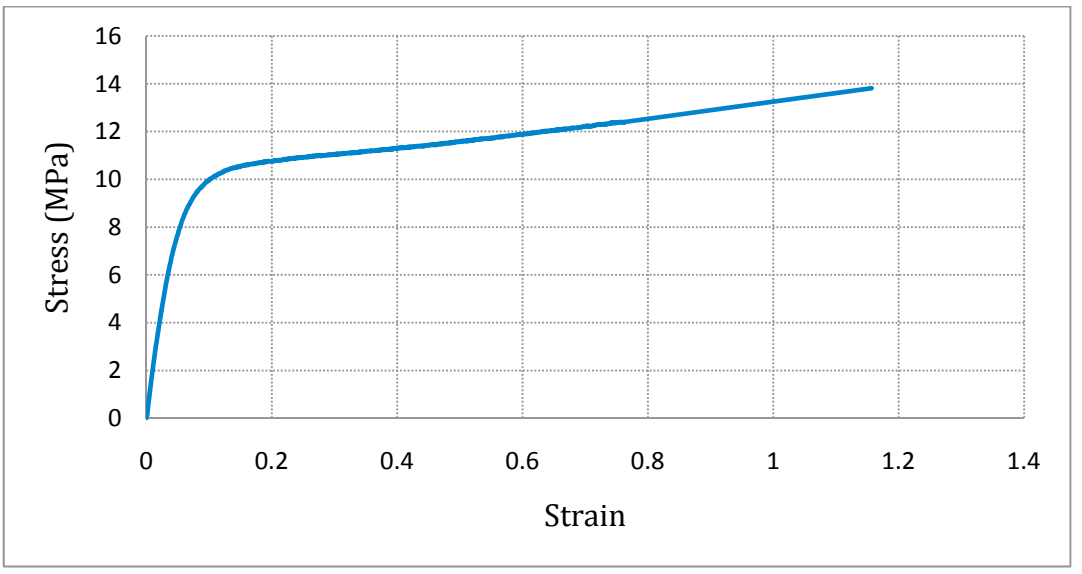

Figure 1: Typical stress-strain behavior for POSS reinforced polyurea under quasi-static tensile loading

Limited number of tensile dynamic testing was performed for POSS reinforced polyurea being used in this research using SHPB in order to compare the high strain rate response to quasi-static response. The results are shown in Figure2.

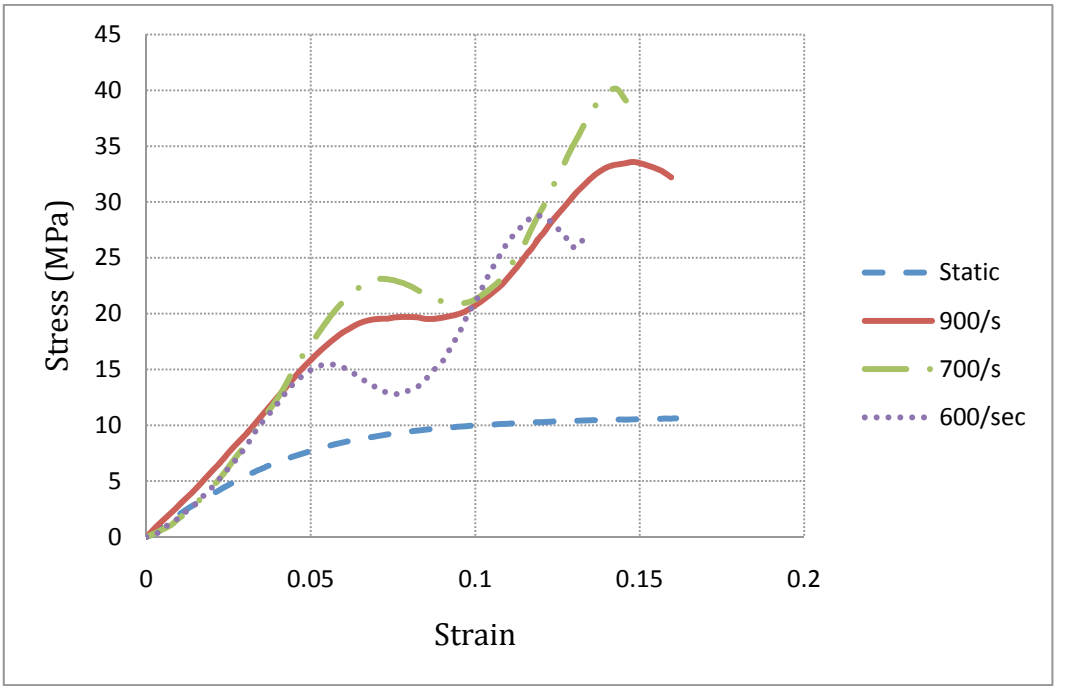

Figure 2: Stress-strain relation for POSS reinforced polyurea under dynamic tensile loading (SHPB)

3. EXPERIMENTAL WORK

Quarter scale model walls made of scaled down brick units (Figure3) were used to investigate the response of POSS reinforced polyurea retrofitted CMU panels subjected to air blast loading produced by Blast Load Simulator (BLS). The average mass of brick units was 252 gm. The walls were fully grouted with approximately 16 blocks tall and 12 blocks wide as shown in Figure3 below. The wall was casted in a steel frame with dowels at top and bottom to simulate simply supported conditions and free boundary conditions at left and right. The average unconfined compressive strength and density of the mortar were 15.9 MPa and 1.700 kg/m^3, respectively, and the average unconfined compressive strength and density of the grout were 15.9 MPa and 1.800 kg/m^3 respectively. The walls were tested at the US Army Engineer Research and Development Center (ERDC) using the blast simulator (Figure4).

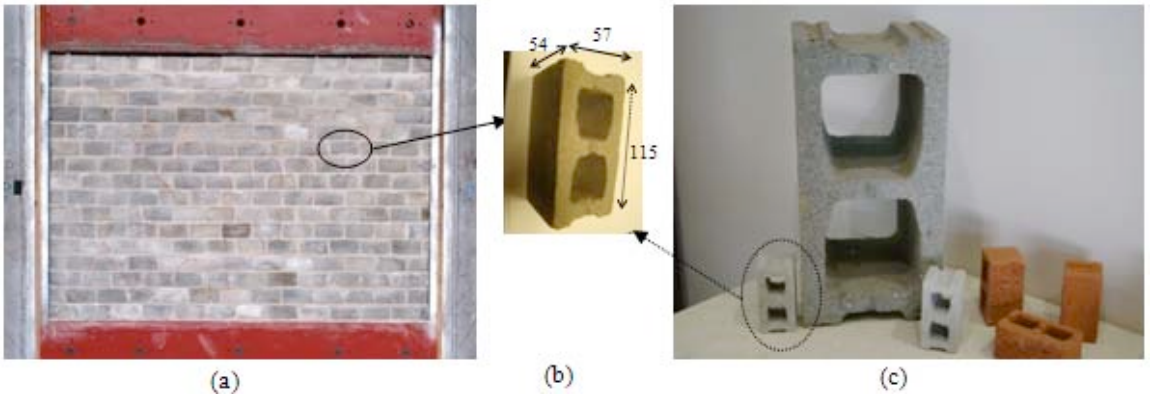

Figure 3: Masonry wall panel (b) Concrete masonry unit brick (all dimensions in mm) (c) Comparison between full scales and scaled down dimensions of masonry unit

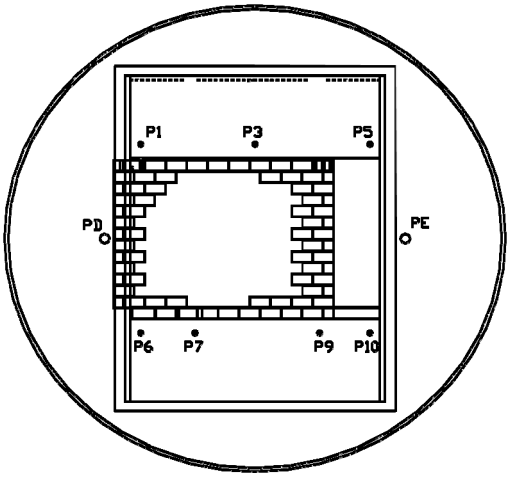
Figure 4: Blast simulator at ERDC, Vicksburg, MS



3.1. Experimental Setup

Spraying technique was used to apply POSS reinforced polyurea to the back (interior face) of the CMU infill walls (Figure5). This technique was used because of the fast reaction between the polyurea resin and the *cyanates* hardener. The walls were sprayed back and forth three times. Retrofitted layer thickness was observed to be 1.8mm.

Figure 5: Spray-on retrofitted material

A pre-adjusted air blast pressure and impulse were applied to each wall. Nine pressure sensors mounted on the steel loading frame were used to collect pressure time history (Figure6). Typical pressure time history and calculated impulse time history are shown in Figure 7.

Figure 6: Locations of pressure sensors and typical peak pressure values

It was noted that, for all cases, there was an initial rise to a peak reflected pressure (compression pressure wave) followed by a decay to zero pressure and then a negative phase (suction pressure wave). Therefore, if a wall system can be retrofitted adequately to resist the initial compression pressure wave, then it can be allowed to fail on the opposite side (non occupant side) when subjected to the negative pressure wave. Average values of reflected pressure and impulse subjected to the wall were observed to be 218.91 kPa and 494.35 kPa.ms respectively.

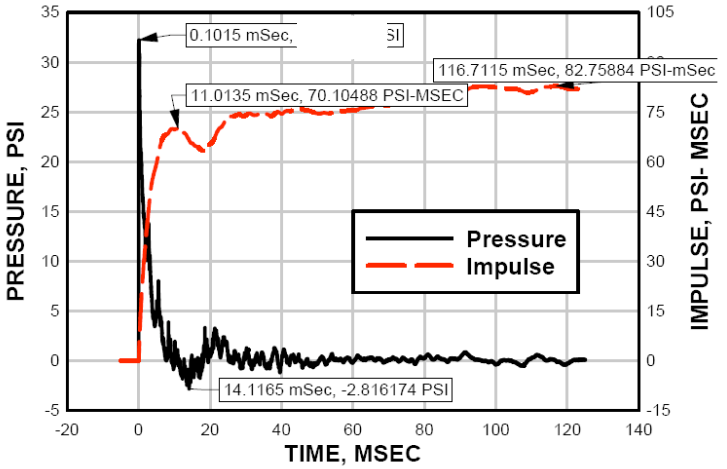

Figure 7: Typical pressure-time history and associated impulse time history obtained using pressure Sensor.

3.2.Experimental Investigation

Wall retrofitted with POSS reinforced polyurea had hairline shear and horizontal crack at blast peak pressure of 218.91 kPa. Shear damage was observed at the top left corner of the wall at the same peak pressure. The results showed that the addition of POSS reinforcement to the polyurea retrofit system increased the flexural resistance of the CMU INFILL wall significantly. However, the retrofit helped the whole panel to have no damage (Figure8).

Figure 8: Wall #3 (a) Back view after the blast event (b) Front view after the blast event

4. COMPUTATIONAL MODELING

To study the effect of blast loads on CMU infill walls and to understand the behavior of these structures under previously noted loading conditions, a number of experiments is required to get enough data that allow the researchers to analyze clearly and process the results. Unfortunately, the expense involved in blast experiments limits the number of tests that are predictable at a given time. Alternative methods as substitutes for actual experimentation had to be sought. The focus of this part of the study is to develop a computationally-efficient model that can replicate with reasonable accuracy the behavior of retrofitted CMU infill wall subjected to blast loads.

Finite Element (FE) models provide cost and time effective solutions compared to the experimental alternative. A finite Element model was built into this research to predict the experiments as mentioned previously. Due to time and cost constraints of the research program, development of a specific finite element analysis code for this project was not feasible. Therefore, ANSYS AUTODYN, an explicit hydrocode that used finite difference, finite volume, and finite element techniques to solve a wide variety of non-linear dynamic problems in solids, fluids, gases, and their interactions, was used to model and analyze the Nano Reinforced Elastomeric Materials retrofitted masonry walls subjected to blast loading.

4.1. Finite Element Configuration and Mesh

The importance of the computational modeling was measured by the ability of the finite element model to replicate with reasonable accuracy the experimental behavior of the system. Therefore, the same 16 blocks tall and 12 blocks wide CMU infill walls used in the experimental work were modeled using finite element software called AUTODYN. Each retrofitted wall was represented by 8670 Lagrangian cells, 3840 of which were filled with masonry material to represent the bricks; 2440 were filled with the mortar material bonding the bricks together; with remainder represented the retrofitted material. Figure9 shows the geometry and the mesh of the walls.

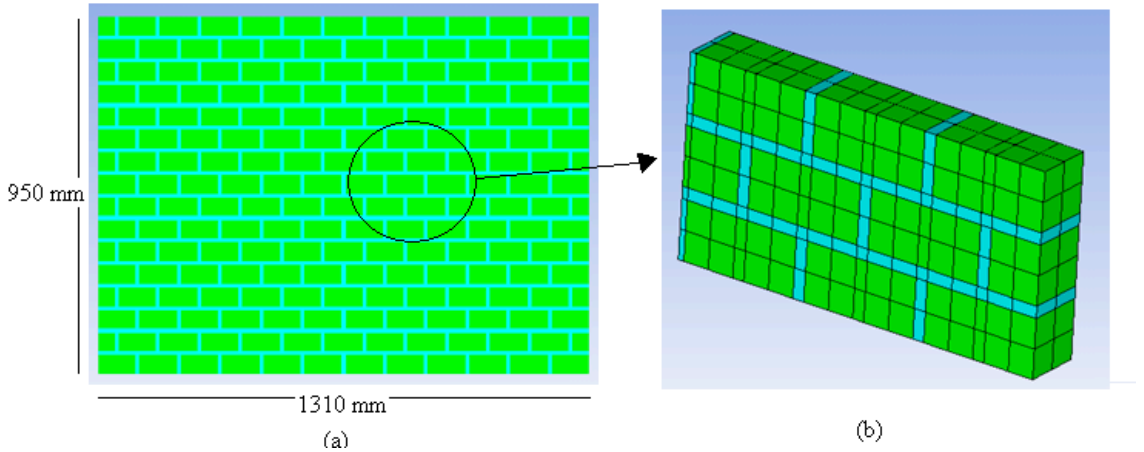

Figure 9: (a) Wall geometry (b) F.E. mesh

4.2. Material Modeling

To model a new material in AUTODYN, the parameters of equation of state (EOS), strength model, and failure model should already be defined.

Unreinforced masonry

The response of masonry under shock loading is a complex phenomenon. A variety of constitutive models for the dynamic and static response of masonry have been proposed over the years. In this research, Porous equation of state (EOS), Drucker-Prager strength model, and Hydrodynamic tensile failure (P_{min}) model were used to represent the unreinforced masonry. These models are discussed in detail in AUTODYN theory manual.

Mortar

Compaction equation of state (EOS), Mo Granular strength model, and Hydrodynamic tensile failure (P_{min}) model were used to represent the mortar.

POSS

A real EOS should be defined for these new elastomeric materials; however, due to the low pressure level introduced by blast waves, a linear equation of state works as a start for this study. Equation 10 shows the linear EOS used to model all three retrofitted materials,

$$P = K\mu \tag{10}$$

Whereas, K is the material bulk modulus; μ is volumetric strain as given by Equation 11; ρ is the material density; and ρ_o is the reference density.

$$\mu = \frac{\rho}{\rho_o} - 1 \tag{11}$$

Johnson-Cook Strength Model and Principal Strain Failure Criterion were used to model these materials. All material models used in this research are summarized in Table 2. More details are available in AUTODYN Theory Manual.

Table 2: Material models

Material	EOS	Strength Model	Failure Model
Masonry	Porous	Drucker-Prager	Hydrodynamic tensile failure (P_{min})
Mortar	Compaction	Mo Granular	Hydrodynamic tensile failure (P_{min})
Polyurea with POSS	Linear	Johnson-Cook	Plastic strain
E-glass/ Epoxy	Puff	Von Mises	Hydrodynamic tensile failure (P_{min})

4.3. Finite Element Results and Discussion

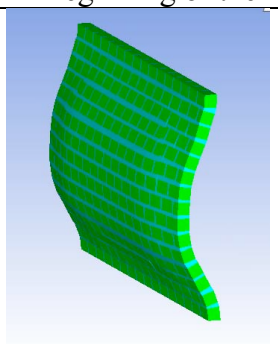
Un-retrofitted wall (Base Line)

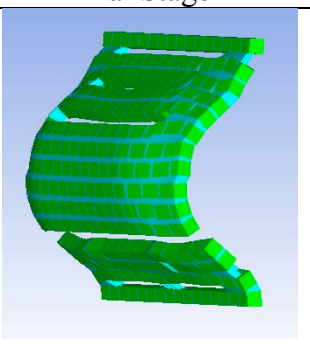
Results of FEA showed a maximum midpoint deflection of 95 mm and maximum debris velocity of 6.834 m/s as compared to a maximum midpoint deflection of 86 mm and a maximum debris velocity of 5.91 m/s obtained experimentally (Table 5). FEA experiments likewise showed that the wall failed in four main segments, and that all debris was captured by the retrofit material. Table 3 shows good agreement between experimental and numerical deformation shapes at the time of maximum deflection and at the end of the test.

POSS reinforced polyurea retrofitted wall

Results of FEA showed a maximum midpoint deflection of 112 mm as compared to a maximum midpoint deflection of 95.65 mm obtained experimentally (Table 5). The wall did not fail in either experiment or FEA. Table 4 shows good agreement between experimental and numerical deformation shapes at time of maximum deflection and at the end of the test.

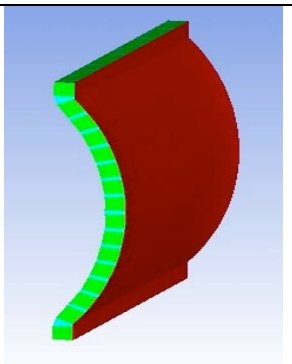
Table 3: Numerical and experimental results comparison for the case of un-retrofitted CMU infill wall

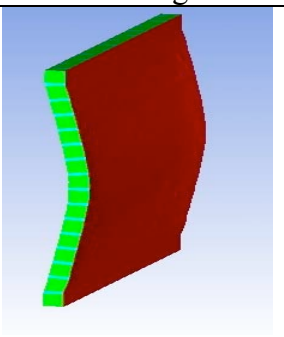




Beginning of the Failure	Final Stage	
		Numerical results obtained using AUTODYN hydrodynamic code
		Experimental results obtained using BLS

Table 4: Numerical and experimental results comparison for the case of CMU infill wall retrofitted with POSS reinforced polyurea





Maximum deflection	final stage	
		Numerical results obtained using AUTODYN hydrodynamic code
		Experimental results obtained using BLS

Table 5: Midpoint deflection and debris velocity

Wall	Maximum Midpoint deflection (mm)		Maximum debris velocity m/s	
	Experiments	Finite element	Experiments	Finite element
Un-retrofitted wall	86.0	95.0	5.9	6.8
Retrofitted wall	95.7	112.0	N.A	N.A.

5. PARAMETRIC EVALUATIONS

To get complete and better understanding of the behavior of retrofitted CMU infill wall under blast loading, a series of finite element analysis was conducted. The focus was to study the effect of some factors such as boundary conditions, thickness and arrangement of retrofitted layers, and ductility of retrofitted materials on the behavior of the system during and after blast.

5.1. Effect of Boundary Conditions

Two types of boundary conditions were applied to the top and bottom of the wall: simply supported (S.S.) and fixed. All retrofitting was applied at the back side of the wall. To neglect the thickness effect, thickness of retrofit layer was kept constant at 1.8mm for all simulations. Same finite element model in the previous section was used here. The effect of the boundary conditions was clear in the results. Using simply supported boundaries allowed the wall to deflect much more than fixed boundaries (Figure10). Both walls did not fail.

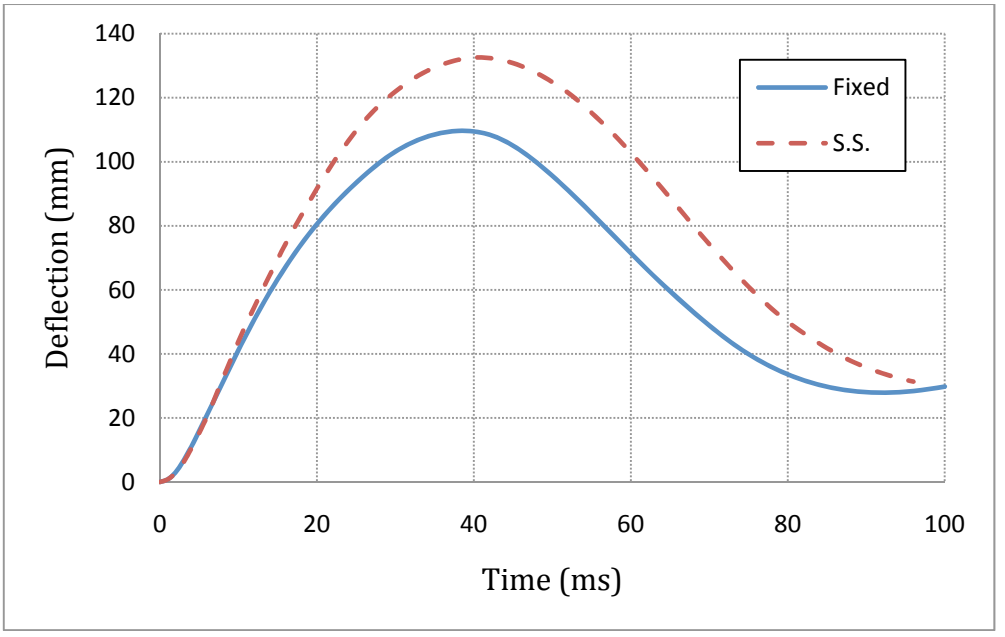


Figure 10: Midpoint deflection of retrofitted CMU infill wall with different B.C. under blast loading

The maximum deflection was observed to be 133mm and 110mm for the case of simply supported and fixed boundaries, respectively. By allowing the retrofitted wall to deform, more energy will be absorbed by the system as shown in Figure 11. The more energy absorbed the less

reaction forces transmitted to the beams and columns (Figure 12) where the energy will be dissipate to deform the panel, to destroy the wall itself, or to separate the retrofitted layer from the wall.

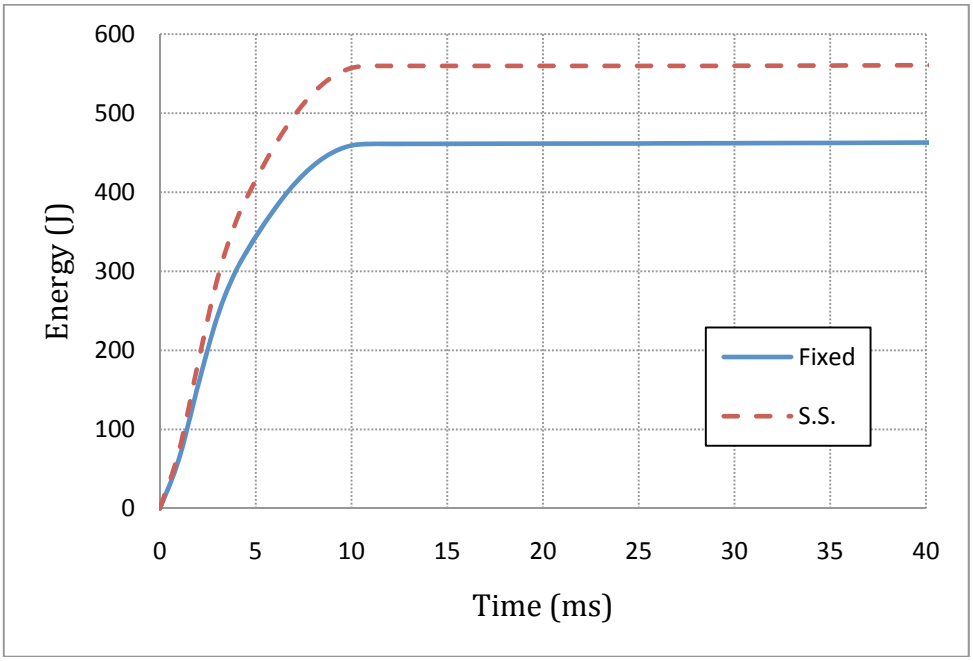

Figure 11: Energy absorbed by retrofitted CMU infill wall with different B.C. under blast loading

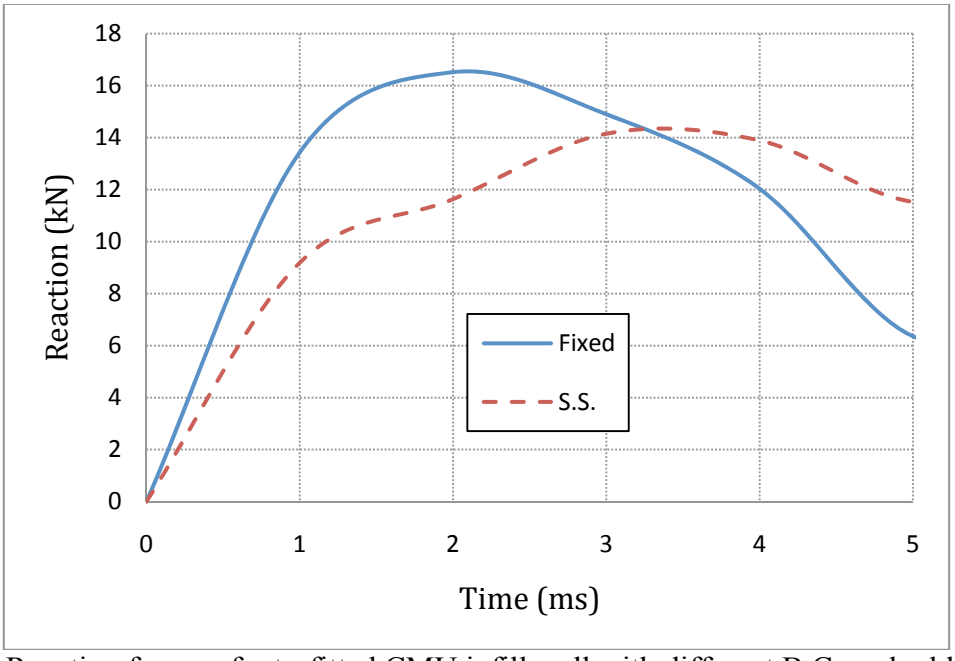

Figure 12: Reaction forces of retrofitted CMU infill wall with different B.C. under blast loading

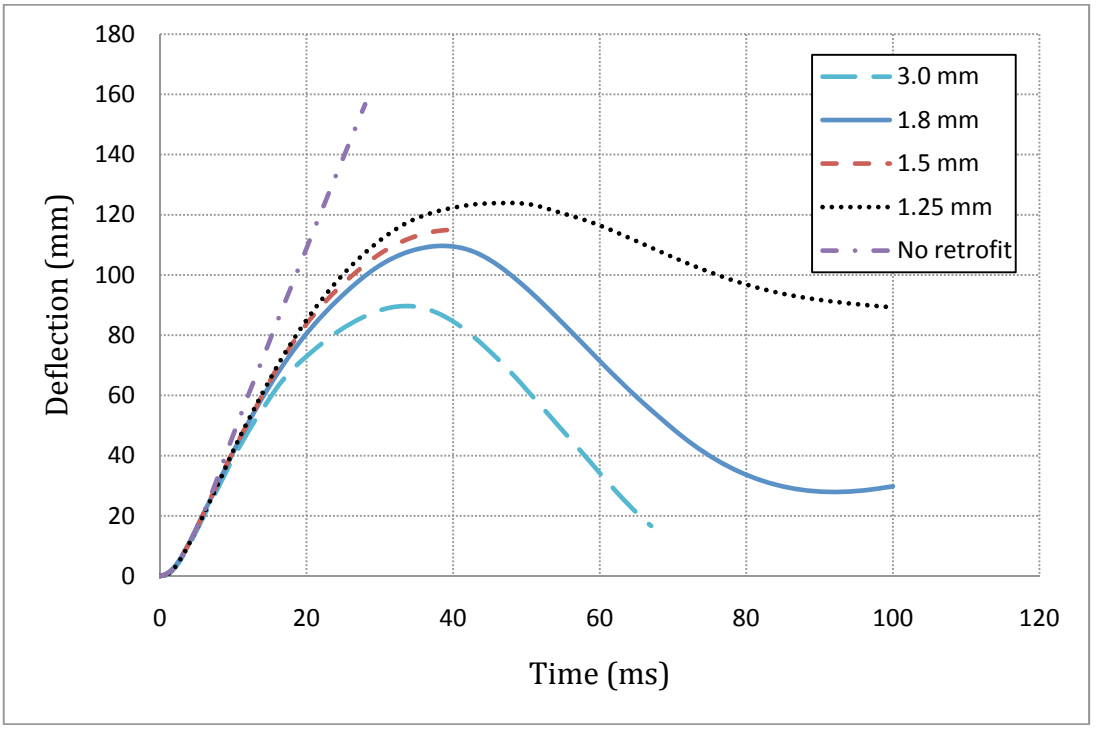
5.2. *Effect of Retrofitted Layer Thickness*

In order to study the effect of retrofitted layer thickness, the wall was coated with POSS reinforced polyurea with various thicknesses; 1.25mm, 1.5mm, 1.8m, and 3.0mm. All retrofitting was applied at the back side of the wall. The top and the bottom of the wall were fixed, while the two sides were left free for all simulations. The results show that the less thickness the more deformation due to blast until the wall failed when it was coated with 1.25 mm POSS reinforced polyurea at the opposite side of the blast (Figure 13).



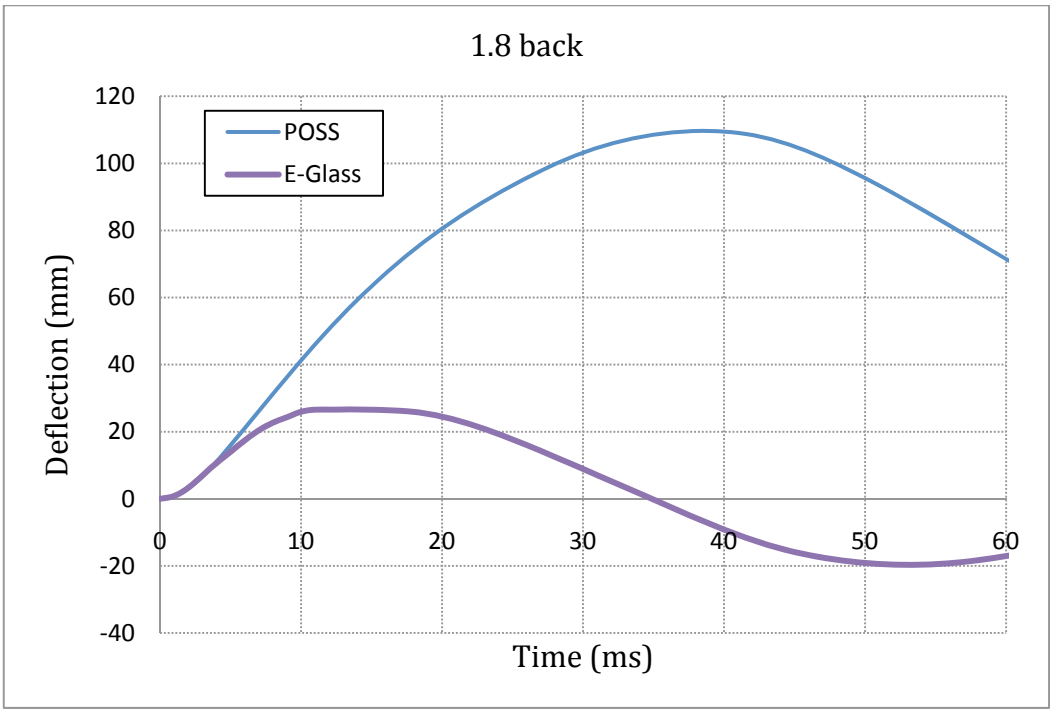


Figure 13: Midpoint deflection of retrofitted CMU infill wall with various coating thicknesses under blast loading

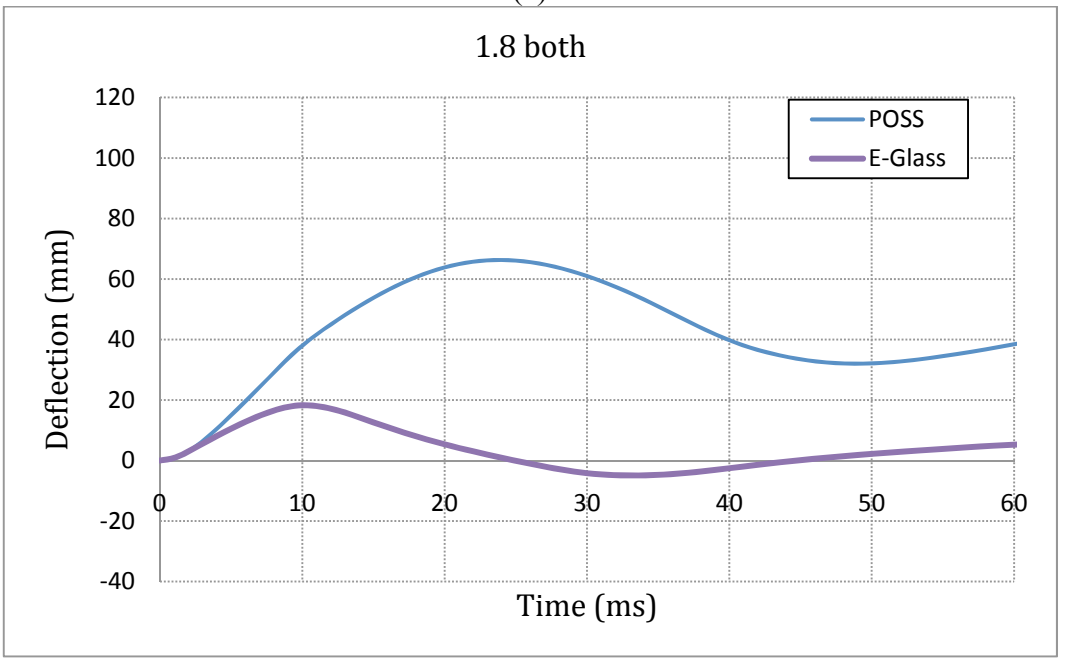
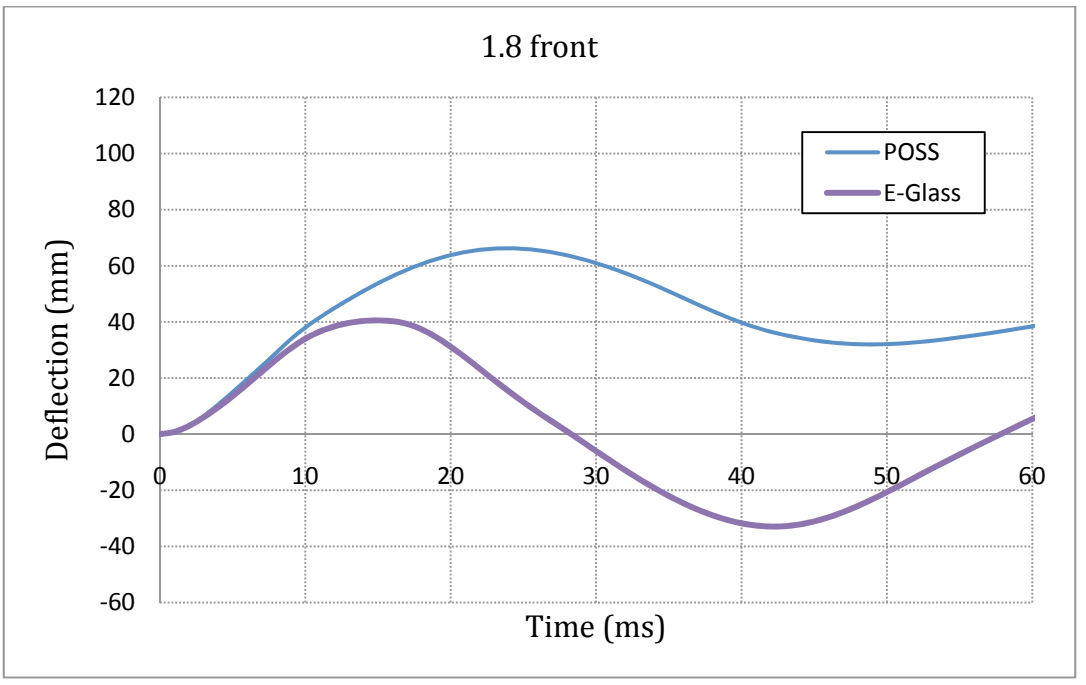


5.3. *Hybrid Retrofitting System*

In order to investigate the ability of using hybrid retrofitting system, one can play with the arrangement of retrofit layers and the ductility of retrofitted materials. A series of finite element analysis was conducted on different retrofit scenarios (back retrofit, front retrofit, and both sides retrofit) for two extreme cases of retrofit materials: rigid (E glass- epoxy) and relatively softer materials (POSS reinforced polyurea). To neglect the thickness effect, thickness of retrofit layer was kept constant at 1.8mm for all cases. The results (Figure 14 and Table 6) show that for the case of retrofitting with elastomeric materials it is better to apply the retrofit at the back side since this will be associated with no failure, when compared to front side retrofit, and a larger deflection (e.g. more energy dissipation) when compared with two side retrofit with a smaller amount of material. In the case of retrofitting with rigid materials, it was also observed that applying the retrofit at the back side was the best scenario.



In order to evaluate effect of wall retrofitting on structural elements (e.g. columns and beams), reaction forces were compared for two extreme retrofit cases. The results of FEA parametric evaluation (Figure 15) showed that retrofitting with rigid material will result in a higher reaction force. This means a higher possibility of failure beams and columns, which leads to failure of the whole structure.

Type of Retrofit	At max. deflection	Final stage	Max. deflection (mm)
Blast Side (POSS)			Failed
Blast Side (Glass-Epoxy)			Failed
Back Side (POSS)			110
Back Side (Glass-Epoxy)			27
Both Sides (POSS)			66
Both Side (Glass-Epoxy)			18

6. CONCLUSION

This study focused on blast vulnerability assessment of concrete masonry infill walls retrofitted with nano particle reinforced polyurea. Quarter scale model concrete masonry infill walls made of scaled down brick units were retrofitted with Polyhedral Oligomeric Silsesquioxane (POSS) reinforced polyurea and subjected to a pre-adjusted airblast pressure and impulse in the ERDC Blast Load Simulator facility. A computationally-efficient model was built using an explicit hydrocode called ANSYS AUTODYN to replicate with reasonable accuracy the behavior of retrofitted infill walls subjected to blast loads. Finite element parametric evaluation was conducted to study the effect of boundary conditions, thickness and arrangement of retrofitted layers, and ductility of retrofitted materials on the behavior of the system during and after blast. Results from blast experiments showed that POSS reinforced polyurea significantly enhanced the performance of masonry walls sustaining blast load. The parametric evaluation results show that for the case of retrofitting with elastomeric materials it is better to apply the retrofit at the back side since this will be associated with no failure, when compared to front side retrofit, and a larger deflection (e.g. more energy dissipation) when compared with two side retrofit with a smaller amount of material.

7. ACKNOWLEDGEMENT

This work was partially supported by the funding received under a subcontract from the Department of Homeland Security-Sponsored Southeast Region Research Initiative (SERRI) at the Department of Energy's Oak Ridge National Laboratory, USA. The preparation of the XGnP reinforced polyurea and the consultation on material properties provided by Dr. Larry Drzal of Michigan State University and XG Sciences is deeply appreciated. The preparation of POSS reinforced polyurea and consultation provided by Drs. Joe Lichtenhan and Bruce Fu of Hybrid Plastics is also gratefully acknowledged.

ABSTRACT

ASCE 4, "*Seismic Analysis of Safety-Related Nuclear Structures and Commentary*," was first issued in 1986. It was expanded, revised and re-issued in 1998. The second revision of the standard will soon be completed by the Working Group on Revision of ASCE 4, which is part of the ASCE Committee for Dynamic Analysis of Nuclear Structures.

This standard provides prescriptive criteria for the analysis of safety-related (Seismic Category I) structures, systems and components (SSCs). It is designed to be used in conjunction with ASCE-43/SEI 43-05, "Seismic Design Criteria for Structures, Systems and Components in Nuclear Facilities." It addresses all aspects of seismic analysis: site response, modeling, and analysis for all types of SSCs. The standard also provides guidance on Quality Assurance requirements and Peer Review needs. Taken together, ASCE4 and ASCE/SEI43-05 may be adapted by federal agencies such as the U.S. Nuclear Regulatory Commission and the U.S. Department of Energy as the minimum expected seismic analysis and design requirements for nuclear facilities.

This overview paper highlights the proposed changes to the ASCE 4-98 Standard proposed by the Working Group. These changes, if adapted, will become effective following consensus balloting and public comment of the proposed changes.

CHANGES TO THE CONTENTS AND FORMAT

There were many changes suggested to the content and also to the format of the document as summarized below:

- A multistep method of analysis which is commonly used in current practice was added. In this approach an initial analysis is conducted to determine the global structural response. Then, using the global response parameters, a detailed analysis is performed for structural and subsystem design.

- Nonlinear response analysis methods using time history and response spectrum methods as well as the nonlinear static analysis are now included in the standard.

- The 4-98 Standard does not prescribe the minimum number of time-histories to be used for dynamic analysis when time-history methods are used. The revised standard provides new criteria

- Criteria for the analysis of sliding and rocking analysis of unanchored components are not presented in ASCE 4-98. A new section is suggested for components and structures using approximate methods. These subjects are presented in ASCE//SEI 43-05 and are now included in ASCE 4.

- The section on Seismic-Isolated Structures was completely revised to bring in the current methods used by practitioners.

- The 4-98 Standard is reorganized to provide sections and subsections using 2 or 3 or 4-digit numbering system. This reorganization is expected to facilitate the use of the document.

- The ASCE 4-98 S first presented the "requirements" and then the "commentary." The proposed revision brings the commentary after each section or subsection. Depending on the need, commentary is provided immediately after the requirements section for each 2-, 3-, or 4-digit section.

- References are updated extensively and those that cannot be obtained through university libraries are deleted. The references are given as part of the commentary after each chapter; again to facilitate use the standard.

GOAL OF THE STANDARD

The overall goal of this standard is to produce a targeted level of seismic demand, conditional on the design basis ground motion occurring, that, when used with code capacities from the design standard, ASCE/SEI 43-05, the resulting design will achieve both of the following:

1. Less than about a 1% probability of unacceptable performance for the Design Basis Earthquake (DBE) ground motion, and:

2. Less than about a 10% probability of unacceptable performance for a ground motion equal to 150% of the DBE.

The 150% is a design check to assure acceptable behavior of the SSC at this level of earthquake. It should not be confused with the term "beyond design basis earthquake."

Commentary to ASCE/SEI 43-05 (Ref. 1) shows that the above performance goals will be met if the demand and capacity calculations are carried out to achieve the following:

1. Demand is determined at about 80% chance of not being exceeded for the specified input response spectrum. Consequently, the requirements of this

standard are set to produce demand estimates at 80% non-exceedance level; whether deterministic or probabilistic analysis methods are used. It should be noted that, for certain special structures (in Chapter 7) where greater uncertainty may exist due to highly variable properties, additional conservatism is incorporated into the analysis process to preclude underestimation of responses.

2. Design capacity is calculated at about 98% exceedance probability. Use of code capacity equations (with minimum specified strengths and code strength reduction factors) will result at about 98% exceedance probability (Ref. 1).

There have been a limited number of comparative studies between deterministic and probabilistic seismic analyses (Refs. 2 to 4). References 2 and 3 concluded that following the provisions of this standard will indeed provide demands that are reasonably close to the 80% non-exceedance level. Ref. 4 reached a similar conclusion except that under certain conditions the deterministic responses were below the probabilistically determined 80% non-exceedance level. It is expected that more studies will be carried out to further define the requirements with which 80% non-exceedance level can be assured.

Based on the current standard of knowledge, it is recommended that the updated ASCE 4 be used together with ASCE/SEI 43-05 (and the design codes specified in that standard) to achieve an acceptable level of conservatism in design.

SITE RESPONSE ANALYSIS

Modern probabilistic seismic hazard assessments are required for use in the design of most nuclear facilities. The probabilistic seismic hazard assessment will provide a mean horizontal and vertical Uniform Hazard Response Spectra (UHRS) at known annual frequencies of exceedance. Using the UHRS, performance-based, smoothed Design Response Spectra (DRS) are developed as input for the design of the facility (Ref. 1). DRS may be at the surface (DRS_S) or at the building foundation level as in-layer spectra (DRS_{FI}).

When time history analyses are to be used, sets of input motions to be used for subsequent conditioning shall be based on actual earthquake recordings (two horizontal and one vertical). Three options are proposed for time history analyses of structures:

1. A single time-history set (2H+1V) may be used provided that the 5% damped spectra produced by the conditioned records match or envelop the target spectra. In addition, the calculated spectra at 2% and 20% damping must exceed 90% of the respective target spectra.

2. Alternatively, three time-history sets that match the target spectrum at 5% damping may be used in which case the design is based on maximum responses.

3. The third alternative is to use five or more time-history sets in which case the design is based on the average response from the suite.

The above requirements are for linear time history analyses. For nonlinear time history analyses, a minimum of three time-history sets are required. If less than 7 time-history sets are used, the peak maximum component response is used for design. If 7 or more time-history sets are used, the median component response may be used for design.

SOIL-STRUCTURE INTERACTION (SSI) ANALYSIS

Soil-structure interaction (SSI) is expanded from ASCE 4-98 significantly. The proposed standard requires that SSI analyses be performed for all nuclear structures not supported by rock or rock-like foundation material. At sites with a shear wave velocity of 8000 ft/sec or greater at low shear strains, a fixed-base analysis is acceptable. Effects of mat foundation flexibility need not be included in the global response analysis for typical shear wall structures.

In general, the SSI analyses should account for the nonlinear behavior of the soil, uncertainties in soil properties and structure-to-structure interaction. Variation in the soil properties can be addressed by repeating the analyses for upper bound, median and lower bound soil stiffness cases and then enveloping the resulting responses. Alternately, probabilistic SSI analyses may be performed from which the 80^{th} percentile response may be extracted. The structure model to be used in the SSI analysis may be the detailed model used for determining the design forces and displacements or a simplified model. In the latter case, sufficient studies should be carried out to ensure the simplified model is truly representative of the detailed model. Embedment effects shall also be taken into consideration as they may affect the response characteristics of the system.

In recent years, wave incoherency has been shown to be an important factor in SSI analyses, particularly in the high frequency range and at stiff soil sites. Seismic wave incoherency arises from the horizontal spatial variation of both horizontal and vertical ground motions. Incoherency effects reduce the translational motions of the foundation but may produce foundation rotational motions.

Subsurface material properties significantly affect the seismic response of the structure. Therefore, accurate determination of the material properties by field and laboratory testing is important. The most important material properties to be determined are shear modulus and damping, as a function soil strain. Other properties that are needed in analyses include material unit weight and Poisson's ratio.

SSI analysis can be performed using the direct method or the sub-structuring method. In the direct method, the boundaries of the soil-structure model and the input motions at these boundaries are defined. With boundary input motions, soil-structure system is analyzed directly to determine the responses at any point in the system.

In recent years, sub-structuring methods have been more commonly used for the SSI analysis. A brief description of the two widely used sub-structuring methods follows:

1. A continuum mechanics approach in which the soil profile is modeled as semi-infinite layers overlying the half space. Free-field motions are defined at the "control" points. Interaction problem is solved using Green's functions. The primary example in this category is the CLASSI computer code.

2. Frequency-domain solution using a 2 or 3D finite element model. In this group the most frequently used computer code is System for Analysis of Soil-Structure Interaction (SASSI).

The standard also permits a probabilistic approach to develop seismic responses of the soil-structure system. In this method the range of parameters that define the soil and structural properties are defined. A series of SSI analyses are performed and responses at the 80% percentile level are calculated.

The proposed changes to ASCE 4-98 are intended to capture all the recent developments in SSI methods. The adaption of the proposed changes will help to provide a consistent application of SSI techniques in the design of nuclear facilities.

MODELING OF STRUCTURES AND SYSTEMS

Modeling used for the dynamic response of civil structures continues to evolve and become more complex. Today, structural models of one hundred thousand degrees of freedom or more are commonly used in nuclear projects. The emphasis is on the finite element analyses using a variety of computer codes which may have widely varying capabilities. Both linear and nonlinear analyses are routinely performed.

The standard focuses on aspects of modeling that will lead to accurate analytical solutions. Since different structural models are often used, their purposes should be clearly defined and the underlying assumptions should be explicitly stated. In developing the seismic analysis model, the frequency range of interest (the earthquake input amplified region and the building and soil response frequencies) should be carefully considered. The model for seismic analysis should be sufficiently refined to capture the high frequency content of the input motion; the model should be able to transmit motions up to 50 Hz. Lumped mass stick models that have been used in the past are no longer considered adequate for seismic analysis in the high frequency range.

There are many parameters that need consideration to produce a good model to obtain reasonably accurate solutions. These include: element types to be used, mesh sizes, types of analyses, material properties, significance of nonlinear behavior, modeling of mass, damping in seismic analysis and so on. The standard provides guidance on defining these parameters in practical applications.

The standard will also require explicit consideration of "response parameters of interest." If the purpose is to develop In-Structure Response Spectra (ISRS), the results should be accurate up to 100 Hz. The points at which ISRS are needed should be modeled accurately. On the other hand, if the purpose is to determine the seismic design forces, the model should permit capturing of important responses, such as forces or moments at the base of a wall. Since out-of-plane bending of slabs is important, the standard will require adequate number of elements in each direction to capture the bending moments. Unless a specific study is carried out, slabs should have eight elements along the long side and six elements along the short side.

In multi-step analysis, compatibility of the seismic analysis model with the detailed model that may be used in subsequent analyses must be demonstrated. This demonstration should include not only comparison of the design forces but also the ISRS at critical locations.

The decoupling criterion has been clarified; coupling of a subsystem with the primary structure is required when the values of key design parameters from the coupled model are more than 10% higher than those from the uncoupled model.

The standard provides additional guidance for the analyst in modeling reinforced concrete elements. When modeling reinforced concrete sections the analyst must choose whether to model the sections as gross, cracked, or somewhere in-between depending on the expected stress level in the structural element during earthquake response. The general consensus of the Working Group was that the assumption of uncracked (gross) properties is acceptable for in-plane responses for both walls and diaphragms. For out-of-plane responses, cracked section properties should be used for slabs if cracking is expected under the gravity loads. Out of plane response of walls must be evaluated from preliminary seismic evaluations to assess cracking potential. There are different assumptions for the cracked section properties, ranging from $0.7I_g$ to $0.5I_g$ in different standards. Analysts will need to carefully evaluate the demand-capacity ratios prior to making an assumption regarding the modeling of stiffness. Additional commentary is added to the standard to guide the analyst with making this decision.

ANALYSIS METHODS

The major change in the analysis chapter of the revised standard is the elimination of most of the equations. It was reasoned that these equations are found in many readily available references (books and papers) and repeating them in the standard would not serve a useful purpose. Therefore, the focus was on the methodology and criteria to be used in the analyses. The references for this chapter were carefully reviewed and many of them were removed due to difficulty in obtaining them. New references were added to provide background information in the recent developments in analyses approaches.

There were few changes in the sections on time history and response spectrum analyses (RSA). Both methods can be used to determine the seismic responses for design and ISRS for subsystem design.

The section on multistep analysis has been extensively revised. The requirements for the initial analysis in which the gross response of the structure is determined are defined. The standard permits the subsequent analyses to be static or dynamic (both RS and TH analyses).

For determining the total response due to the three components of an earthquake, the standard allows the use of the square-root-of-the-sum-of-squares (SRSS) method or the 100-40-40 rule (also termed the factor method), consistent with U.S. NRC Regulatory Guide 1.92 (Ref. 5). In the factor method, permutation of responses from each direction (considering signs) generally results in 24 spatial response combinations. The design is then carried out for all these combinations. When a single parameter is dominant in design, the results from SRSS and the factor method are essentially the same. However, when multiple design parameters are involved, the differences can be quite significant. The factor method generally results in more realistic designs. The SRSS method can be overly conservative.

As an example, consider a shear wall oriented in the north-south direction with seismic responses for four design parameters, P=axial load, V=shear, M_{ip}=in-plane moment, M_{op}=out-of-plane moment. Assume that responses for these parameters have been obtained from dynamic analysis as shown in Table 1. (Note: for simplicity the signs are ignored in this example.)

The first three rows in the table show the calculated responses due to seismic input in each direction. The fourth row is the SRSS combination results and these values would be used in design. The next three rows give the design values using the factor method. All three rows obtained from the factor method would be used in design.

As can be seen from the table, the most severe design condition is produced by the SRSS method. This is the case when each response parameter is dominated by a particular earthquake direction. On the other hand, the design resulting from each of the three factor method combinations will be less demanding, and the final design will be more realistic as each of these spatial response combinations are likely to occur.

A recent development has further complicated the issue. On some projects, reviewers have contended that, after obtaining the spatial combination results, the design should be based on the maximums of each parameter, regardless of the combinations that produced each maximum. The last row (factored-enveloped) in the table shows the resulting design condition. This is inconsistent with the goal of seismic design which is to use the parameters that are most likely to occur simultaneously.

Review of the table indicates that the SRSS design values are close to the factored-enveloped numbers. This suggests that the design parameters as calculated by the SRSS method are also unlikely to occur simultaneously.

Table 1. Example of Design Parameters using the SRSS and Factor Methods

Seismic Load	P, kips	V, kips	M_{ip}, ft-k	M_{op}, ft-k	Comment
N-S Earthquake	0	500	10000	100	
E-W Earthquake	0	30	500	500	
Ver Earthquake	400	0	0	0	
SRSS	400	501	10012	510	SRSS design
Factored 1: 100+40+40	160	512	10200	300	Consistent factor method design cases
Factored 2: 40+100+40	160	230	4500	540	
Factored 3: 40+40+100	400	212	4200	240	
Factored-enveloped	400	512	10200	540	Inconsistent factor method

SPECIAL STRUCTURES

SSCs with unique features that require special analytical approaches for seismic response determination have been collected in Chapter 7. Sections of Chapter 7 include:

- Buried pipes and conduits,
- Earth-retaining walls,
- Above ground vertical cylindrical tanks,
- Distribution system,
- Sliding and rocking of unanchored rigid bodies, and
- Seismically isolated structures.

There have not been many changes in the section on buried pipes and conduits, as there have not been significant new developments in the state of practice. One significant improvement is that a recommended value for the apparent shear wave velocity is provided for use in assessing pipe strains.

For earth-retaining walls, including the buried walls of safety-related concrete structures, new methods of analyses have been developed since the last edition. SSI analyses can now be used directly to obtain the soil pressures on the walls. On the

other hand, classical methods for flexible and rigid walls are still being used in the industry. A new method that combines the response from SSI analysis with an analytical approach for determining seismic-induced wall pressures has been introduced. This section now includes all these methods and provides specific guidance to the user.

Above-ground vertical cylindrical tanks have also been the subject of many studies. The section on these tanks was updated to include the state-of-the-art methods of both horizontal and vertical responses.

In ASCE 4-98 the only distribution system that was addressed extensively was the raceway systems. The proposed edition will include treatment of piping and pipe supports, tubing, ductwork as well as raceways. The expanded treatment of the distribution systems was reviewed by specialists in the industry to capture the industry experience.

Criteria for the analysis of unanchored components and structures are not included in ASCE 4-98. This revision proposes criteria consistent with ASCE/SEI 43-05. The committee proposes that the criteria be removed from ASCE/SEI 43-05 in subsequent revisions, and be retained in ASCE/SEI 4

The section on seismically isolated nuclear structures has been completely revised. The main advantage of seismic isolation is the reduced seismic response in the horizontal direction. Nuclear safety-related structures are stiff, with fundamental horizontal frequencies in the range of 2-10 Hz. The design response spectra may have their peak spectral accelerations also in the same range, thus maximizing the horizontal responses. Base isolation can bring the fundamental frequency below 1 Hz (typically around 0.3 Hz), thus significantly reducing the seismic response and hence the demand on systems and components. Unfortunately, these benefits are not readily available in the vertical direction; but the magnitude of the issue can be reduced by creative layout of the systems and components.

The standard covers three types of seismic isolators that are considered as viable alternatives for nuclear safety-related structures:

1. Low-damping elastomeric bearings,
2. Lead-rubber elastomeric bearings, and
3. Sliding bearings with restoring forces provided by gravity.

The standard addresses environmental and operating conditions, isolator performance, and modeling and analyses requirements. Multiple nonlinear analyses are required to determine the demands at the 80% exceedance level, consistent with the basic philosophy of the standard.

CONCLUSIONS

The American Society of Civil Engineers, Codes and Standards Committee has required that the ASCE Standards be updated on a tri-annual basis, unless special exceptions are granted. A proposed revision to ASCE 4-98 is working its way through the standards process by the Dynamic Analysis of Nuclear Structures working group. The proposed revision to ASCE 4-98, if adapted, will bring the state-of-the-art engineering practices to the design community for use in the design of the next generation of nuclear facilities. This overview has led to the following conclusions:

- The proposed revision standard is vastly improved in terms of extent and depth of the topics covered. It also reflects closely the current state of practice.
- As a result, the volume of the document is increased by more than two-fold.
- The proposed revision is expected to be a key document for the nuclear industry, hopefully eliminating (at least reducing) the contentious positions between the practitioners and the regulators.
- To that end, it is hoped that the new document will be endorsed by the regulators in its entirety
- Notwithstanding the above optimistic viewpoint, the proposed standard still lacks guidance on some analysis needs of designers of nuclear structures subjected to earthquakes Authoritative guidance on additional topics will go a long way toward designing better nuclear facilities while increasing the public confidence in the engineering of these facilities. Some of the topics that are being considered for inclusion in the next revision include:
    - Analyses of cranes,
    - Fragility calculations,
    - Seismic 2/1 evaluations.

    Others could conceivably be added to the above list to extend the reach and appeal of this standard worldwide.

ACKNOWLEDGEMENTS

The authors are grateful all members of the ASCE Working Group who have contributed to this document as volunteers for many years. The authors would also like to thank Bechtel Corporation which has generously supported earlier drafts of the revised standard for many years.

Abstract

Parameters of interest in the seismic analysis of liquid-containing tanks include reaction forces, slosh heights, and peak wall pressures. Numerous references including Section 7.4 of ASCE 4 have simplified expressions for wall pressures, overturning moments, and slosh heights for tanks with excess freeboard. For tanks with insufficient freeboard, less guidance is available. As an example, ASCE 4 requires that if tanks have insufficient freeboard, the liquid level must be lowered or the tank roof and wall must be designed to withstand the impact of the sloshing fluid. However, ASCE 4 does not provide specific guidance on evaluating the impact of liquid with the tank roof.

The present study evaluates seismically induced fluid-structure interaction in flat-top and domed tanks with insufficient freeboard using the explicit finite element program MSC.Dytran®[2] and the results of the study are compared to approximate solutions. For the systems considered, the study shows that the peak wall pressures in the domed tank are nearly the same as for a vertical-walled tank with excess freeboard. However, for the flat-top tank, the peak roof pressures are significantly higher than predicted using the approximate methods. In all cases, peak wall pressures lower in the tanks are unaffected by local roof or dome interactions.

INTRODUCTON

This study was motivated by the need to update the seismic analysis of record for the Double Shell Underground Waste Tanks (DSTs) at the US Department of Energy Hanford Site north of Richland, Washington. The DSTs have a nominal capacity of one million gallons and consist of a primary steel tank surrounded by an annular space and supported by a circular cylindrical concrete vault with a domed roof. The inner primary tanks have a radius of 37.5 feet. The vertical walls of the primary tank are approximately 35.5 feet high and the dome height of the primary tank is approximately 11.5 feet, giving a total height from the primary tank base to the dome apex of approximately 47 feet. Some tanks contain liquid with an initial free surface

[2] Dytran is a registered trademark of MSC Software Corporation, Santa Ana, California.

high enough to result in significant fluid-structure interaction with the tank dome for the level of seismic excitation considered.

The purpose of the studies described herein was to better understand the effects of this interaction on the tank demands. It was of particular interest to determine if the methodology described in Appendix D of BNL (1995) for predicting maximum wall and roof pressures for curved roofs would provide conservative estimates. Thus, results from time-history computer simulations using the finite element code MSC.Dytran® were compared to results using the methodology from BNL (1995) both for tanks with excess and insufficient freeboard. Similar comparisons were made also to predictions using the simplified estimates described in Malhotra (2005).

The response parameters that were monitored during the computer simulations were the impulsive, convective, and breathing mode frequencies, the horizontal and vertical reaction forces, the maximum unconstrained slosh heights, and the wall and roof pressures.

SYSTEMS CONSIDERED

Before evaluating the flexible-wall tank with a curved roof, two simpler systems were considered. The first of these was a rigid circular cylindrical flat-top tank that was evaluated at four liquid levels. The lowest liquid level represents the situation of a tank with excess freeboard, and was run as a benchmark case. Two intermediate liquid levels included liquid interaction with the roof. The last case was a completely full tank (no head space) that was also run as a benchmark case. The last case is not discussed herein except to note that the results of the computer simulation matched the known solution.

The second simplified system was a rigid tank with a curved roof having the same configuration of the flexible-wall tank of ultimate interest. Finally, the flexible-wall tank with the curved roof was evaluated. All models were three dimensional and incorporated a Lagrangian formulation for shell elements and an Eulerian formulation for fluid elements.

RIGID FLAT-TOP TANK

The flat-top tank considered has a radius of 450 inches and a height of 500 inches. The initial liquid heights considered were 460, 480, 490, and 500 inches. The two intermediate liquid heights resulted in intermittent interaction between the liquid free surface and the tank roof, and are of the most interest. For the seismic input to the system, the 480 inch initial liquid height represents a freeboard height (h_0) to maximum unconstrained slosh height (h_s) of 0.8. The 490 inch initial liquid level represented a freeboard height to maximum unconstrained slosh height of 0.4. Only horizontal seismic excitation was applied to the rigid flat top tank model. The apparent damping in the rigid flat-top system as determined by the logarithmic decrement of the convective response was a few tenths of a percent of critical damping. The system damping consisted exclusively of the artificial bulk viscosities

inherent in Dytran®. A plan view and elevation view of the flat-top tank model showing liquid element sets at which pressures were monitored are shown in Figure 1 and Figure 2.

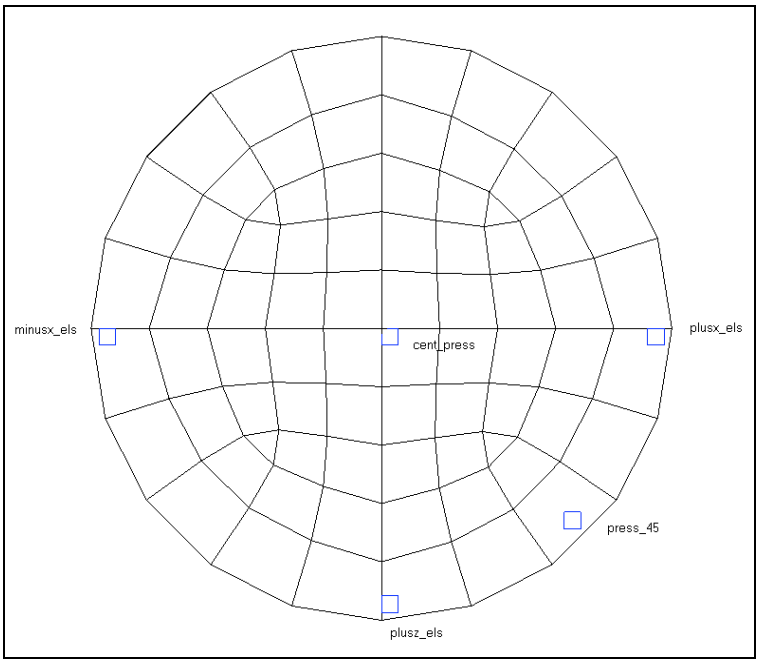

Figure 1. Plan View of Model Showing the Angular Locations of Fluid Elements at Which Pressures Were Monitored.

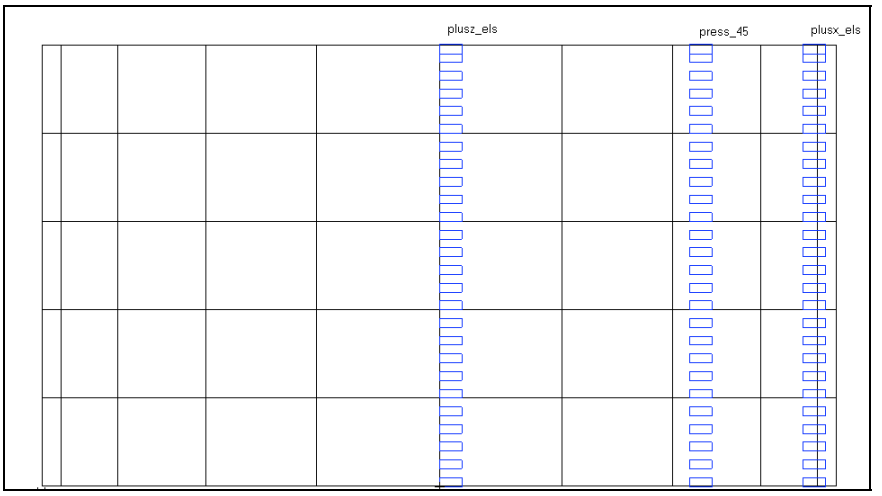

Figure 2. Elevation View of Model Showing the Locations of Selected Fluid Elements Sets at Which Pressures Were Monitored.

At the 460 inch initial liquid level, the peak horizontal reaction force predicted by the Dytran® model was 106% of the value given by the BNL methodology for a tank with excess freeboard if the impulsive and convective contributions are summed using an SRSS combination, and 90% of the value given by the BNL methodology if the two components are summed absolutely. The Dytran® prediction is equal to the

value given by the Malhotra estimate when the two contributions are summed using the SRSS method and is 91% of the Malhotra estimate when the two terms are summed absolutely. Because the tank is rigid, the spectral acceleration for the impulsive mode that is used to calculate the peak reaction force is taken as the peak ground acceleration.

The maximum wall pressures predicted by the Dytran® model for the tank with excess freeboard were almost identical to those predicted using the BNL methodology for a tank with excess freeboard at all heights. The convective frequency given by the Dytran® simulation was the same as predicted by BNL (1995) and Malhotra (2005). The maximum slosh height of 26.9 inches predicted by the Dytran® simulation was 7% greater than predicted by the BNL methodology and 9.5% less than given by ASCE (1998) and Malhotra (2005). The peak horizontal reaction force due to convective effects only was 25% less than predicted using the BNL methodology. In this case the BNL prediction of the convective reaction force was either 15% or 18% of the total reaction force per the BNL estimate depending on whether the impulsive and convective components are summed absolutely or via SRSS, respectively.

At the 480 inch initial liquid level (h_0/h_s=0.8), the peak horizontal reaction force predicted by the Dytran® model was 82% of the value predicted by the BNL methodology for a flat-top tank with insufficient freeboard if the impulsive and convective contributions are summed using an SRSS combination, and 76% of the BNL value of the impulsive and convective components are summed absolutely. The Dytran® prediction is 88% of that given by the Malhotra prediction for a tank with insufficient freeboard using an SRSS combination and 80% using an absolute sum.

The maximum wall pressures predicted by the Dytran® model are essentially the same as for a tank with excess freeboard on the lower 70% of the tank wall, but diverge from this solution in the upper 30% of the tank where the effects of roof interaction become apparent. The total absolute pressures shown in Figure 3 indicate that the BNL estimate is conservative for predicting peak wall pressures in the majority of the wall height, but that it underestimates peak wall forces near the top of the tank. The peak dynamic roof pressure predicted from the Dytran® solution is approximately twice that given by the BNL estimate and more than 20 times greater than given by the Malhotra estimate.

The convective frequency from the Dytan solution is the same as determined for the 460 inch initial liquid level with no roof interaction, and the convective response does not show any additional apparent damping due to interaction with the roof. However, the maximum magnitude of the convective response is approximately half of that determined for the case of no roof interaction. This inhibited convective response evidently is due to the interaction with the roof preventing the development of the unconstrained convective mode shape.

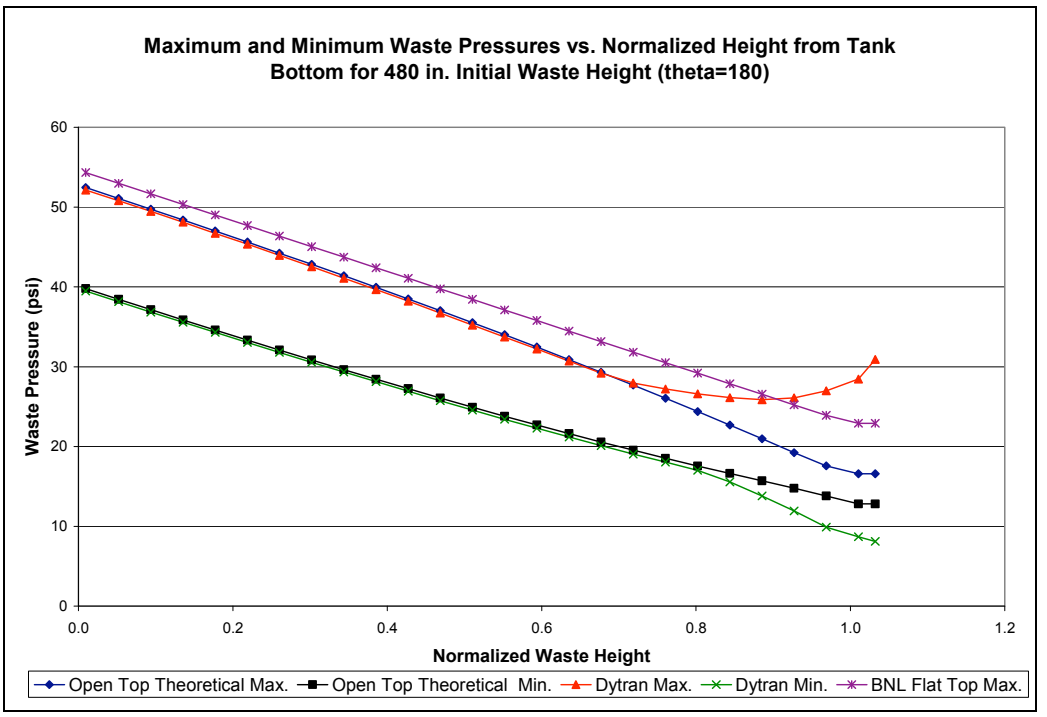

Figure 3. Maximum and Minimum Total Absolute Wall Pressure Comparison for the Roofless Tank, BNL Flat Top Estimate, and Dytran® Solution at the 480 inch. Liquid Level Along the Plane of Excitation.

At the 490 inch initial liquid level (h_0/h_s=0.4), the peak horizontal reaction force predicted by the Dytran® model was 83% of the value predicted by the BNL methodology for a flat-top tank with insufficient freeboard if the impulsive and convective contributions are summed using an SRSS combination, and 78% of the BNL value of the impulsive and convective components are summed absolutely. The Dytran® prediction is 78% of that given by the Malhotra prediction using an SRSS combination and 75% using an absolute sum.

The maximum wall pressures predicted by the Dytran® model are essentially the same as for a tank with excess freeboard on the lower 60% of the tank wall, but diverge from this solution in the upper 40% of the tank where the effects of roof interaction become apparent. The total absolute pressures shown in Figure 4 indicate that the BNL estimate is conservative for predicting peak wall pressures in the majority of the wall height, but that it underestimates peak wall forces near the top of the tank. The peak dynamic roof pressure predicted from the Dytran® solution is approximately 50% greater than given by the BNL estimate and more than eight times greater than given by the Malhotra estimate. The Dytran® solution also predicts that the peak roof pressure at the 480 inch liquid level is 30% higher than for the 490 inch liquid level, which is consistent with a higher impact pressure occurring when the liquid has more headspace available to develop impact energy at the roof.

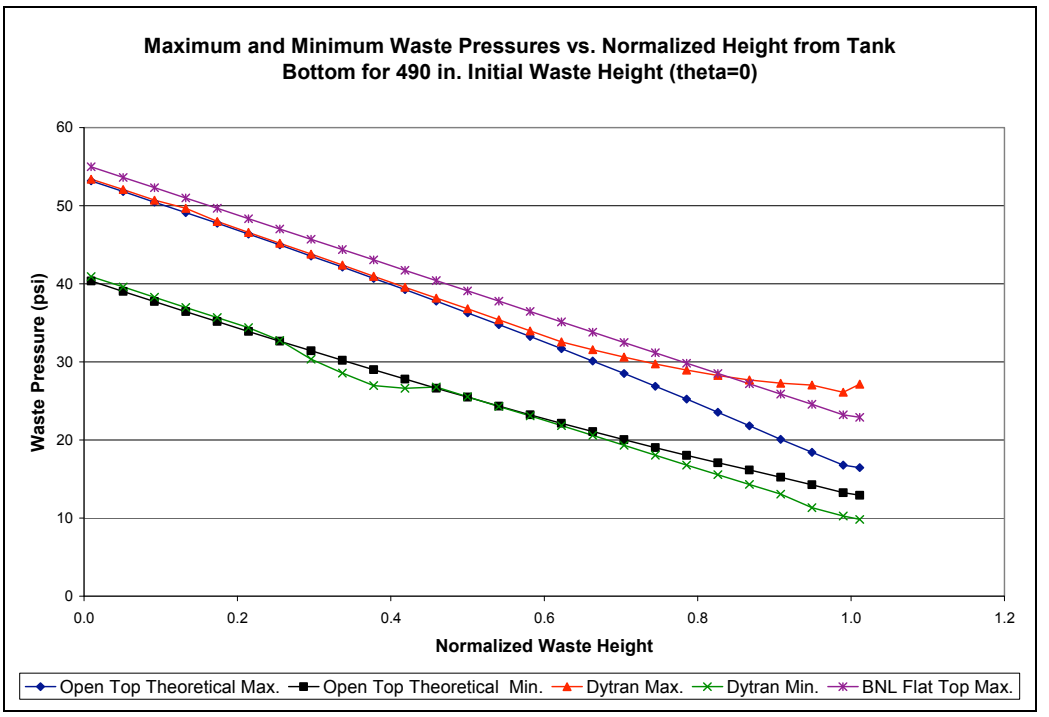

Figure 4. Maximum and Minimum Total Absolute Wall Pressure Comparison for the Roofless Tank, BNL Flat Top Estimate, and Dytran® Solution at the 490 inch. Liquid Level Along the Plane of Excitation.

When the available freeboard is only 40% of the maximum unconstrained slosh height, the convective response following the termination of the seismic excitation shows two interesting characteristics that are illustrated in Figure 5. First, the interaction with the roof has the effect of adding apparent damping to the convective response. Based on the logarithmic decrement of the free convective response, the decay of the convective reaction force is consistent with an effective critical damping ratio of approximately 6%. Second, the interaction with the roof has the effect of significantly increasing the apparent convective frequency relative to the roofless tank response. Rather than the 0.2 Hz convective frequency for the roofless tank, the frequency is increased to an average frequency of approximately 1.67 Hz due to the interaction with the roof. The increased convective frequency is reasonable since the presence of the roof inhibits the longer-period free convective oscillation of the liquid.

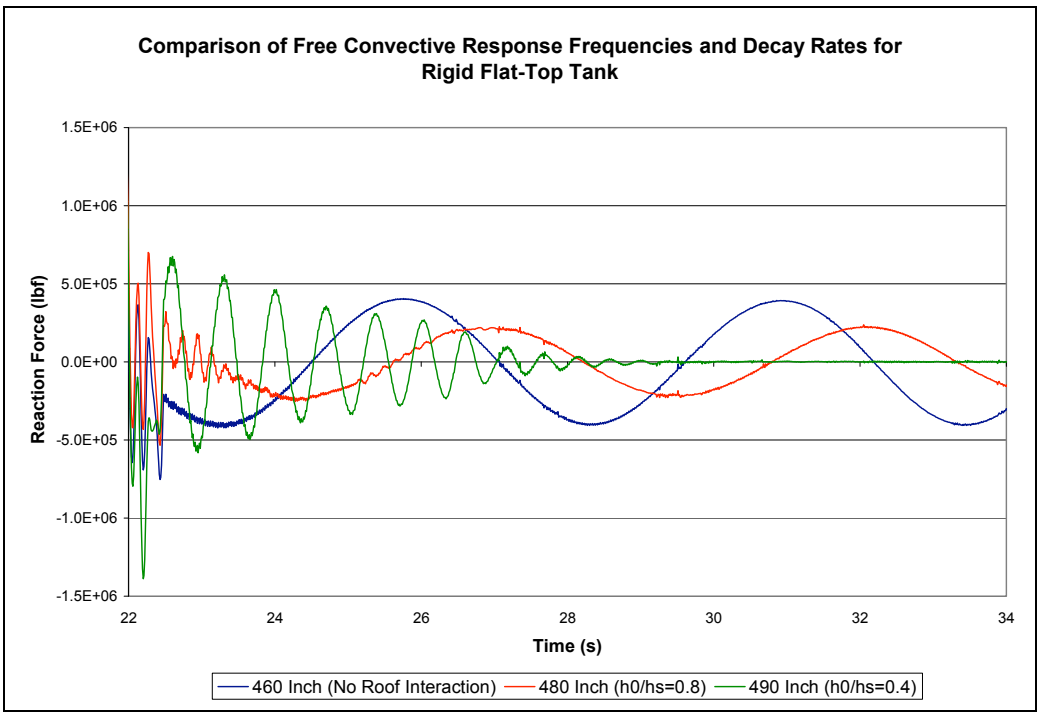

Figure 5. Frequencies and Decay Rates of the Free Convective Response of the Liquid in Rigid Flat-Top Tank at Three Headspace Levels.

RIGID DOMED TANK

Both the rigid and flexible-wall tanks have an initial liquid level of 460 inches and were evaluated using an equivalent flat-top roof height of 484 inches per Kennedy (2003). A plan view of the tank geometry along with selected fluid element sets at which pressures were monitored is shown in Figure 6. As with the rigid flat-top tank, the damping in the rigid dome tank system as determined by the logarithmic decrement of the convective response was a few tenths of a percent of critical damping. The horizontal seismic input for both dome tanks was the same as used for the previously discussed flat-top models.

The peak horizontal reaction force predicted by the Dytran® model was 111% of the value predicted for a tank with excess freeboard when the impulsive and convective contributions are summed using an SRSS combination and is 94% of the value for a tank with excess freeboard when the impulsive and convective contributions are summed absolutely. The percentages are nearly the same using the Malhotra methodology for a tank with excess freeboard.

The peak horizontal reaction force predicted by the Dytran® model was 93% of the value using the BNL equivalent flat top procedure using an SRSS sum and 83% of the BNL estimate based on an absolute sum. Similarly, the Dytran® prediction was 96% of the Malhotra estimate using SRSS, and 86% of the Malhotra estimate using

an absolute sum. That is, the equivalent flat-top predictions for peak horizontal reaction force are conservative relative to the Dytran® prediction.

The maximum liquid pressures were nearly identical to those for a vertical-wall tank with no liquid interaction with the dome over the lower 90% of the tank wall. That is, the pressure deviations from the solution for a vertical-wall tank with excess freeboard were limited to the upper 10% of the liquid, and were minor except at the free surface. The peak dynamic wall pressure predicted by Dytran® at the free surface was 2.7 times higher than for the vertical wall tank with excess freeboard and approximately 62% of the value predicted for the equivalent flat-top tank using the estimate from Appendix D of BNL (1995). Thus, the BNL methodology provided conservative estimates for the maximum liquid pressures in the tank.

The convective frequency of 0.207 Hz predicted by Dytran® represents a slight increase relative to the convective frequency of 0.196 Hz for a vertical-wall tank with ample freeboard as determined using the BNL, Malhotra, or ASCE 4 equations. The slight increase in the apparent convective frequency is consistent with behavior noted for the flat-top tank as shown in Figure 5, though to a lesser degree. The maximum magnitude of the horizontal reaction force caused by the convective response only is 56% of that determined for the case of a vertical wall tank with excess freeboard. For this case, the convective component of the peak reaction force as determined by the BNL estimate is approximately 10% of the total peak reaction force. This reduction in convective response for a tank with insufficient freeboard is consistent with the observation that for a completely full tank, there is no convective response.

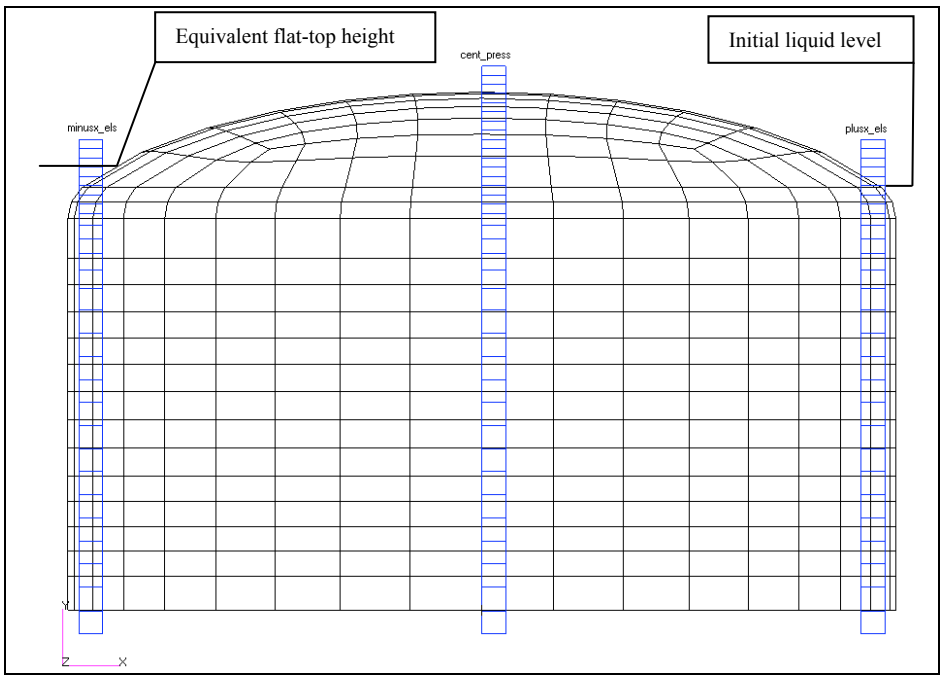

Figure 6. Elevation View of Rigid Domed Tank Model Showing the Locations of Selected Fluid Elements Sets at Which Pressures Were Monitored.

FLEXIBLE-WALL DOMED TANK

In contrast to the rigid tank systems, damping in addition to the inherent bulk viscosities was implemented in the flexible-wall tank. This was via a damping parameter introduced in the central difference integration scheme. The damping was calibrated to provide approximately 3-5.5% critical damping in the impulsive and breathing mode responses in the tank. The range of damping is a result of slightly lower apparent damping based on the decay of the breathing mode response of the system and slightly higher apparent damping based on the decay of the impulsive response of the system. Also, although not shown in Figure 6, the mesh resolution for the fluid elements in the flexible-wall tank system is significantly higher in the vertical direction than it was for the rigid domed tank.

The theoretical calculation of the maximum horizontal reaction force for the flexible-wall domed tank depends on the impulsive frequency of the tank-liquid system as well as the associated spectral acceleration at that frequency. It also depends on the spectral damping corresponding to the impulsive response. The impulsive frequency calculated via the BNL methodology for a tank with excess freeboard is 6.5 Hz. The impulsive frequency calculated for a tank with excess freeboard using the Malhotra estimate is 5.4 Hz. The impulsive frequency for the flexible-wall domed resulting from the Dytran® simulation was 6.25 Hz.

The results of the Dytran® simulation show that the maximum horizontal reaction force is slightly less than predicted for a vertical-wall tank with excess freeboard, and

approximately 30% less than predicted for an equivalent flat-top tank using the BNL or Malhotra estimates with an SRSS combination of impulsive and convective components. The convective frequency and maximum horizontal reaction force due to convective effects only is the same as for the rigid domed tank as expected, but for the flexible-wall tank, the maximum convective reaction force per the BNL estimate is only 5% of the total reaction force owing to amplification of the impulsive response. Further details on the combinations of impulsive frequencies, effective damping, and solution methods used to arrive at the above estimates are provided in Appendix C of Abatt and Rinker (2008b).

One might expect that the reaction force for the domed tank would be greater than that for the corresponding vertical-wall tank with excess freeboard. However, the comparison here is not a direct one because some of the interaction between the tank and contained liquid in this problem occurs in the rigid dome area. The interaction between the liquid and rigid portion of the tank is not amplified by the impulsive frequency, and this may lead to a slightly lower overall reaction force.

A comparison of peak wall pressures showed that in the lower 95% of the tank wall the maximum pressures from the Dytran® solution were essentially the same as those predicted for a vertical-wall tank with excess freeboard. The pressures predicted by Dytran® increased relative to vertical-wall tank solution in the upper 5% of the liquid with the peak dynamic wall pressure nearly three times greater than for the vertical-wall tank, but less than a third of the value predicted for the equivalent flat-top tank using the BNL estimate. In this case, the BNL methodology provided estimates of maximum liquid pressures that are even more conservative than for the rigid domed tank.

DISCUSSION

Dytran® agrees well with the BNL and Malhotra solutions for the vertical-wall tank with excess freeboard. There were two notable observations for this case. First, the BNL solution for the peak horizontal reaction force was slightly unconservative relative to the Dytran solution and the Malhotra estimate when combining impulsive and convective contributions via the SRSS procedure. Second, the peak horizontal reaction force due to convective effects only that was determined using Dytran® was significantly lower than predicted using the BNL or Malhotra estimates.

When the available freeboard was 80% of the maximum unconstrained slosh height (initial liquid level of 480 inches), the peak pressures predicted by Dytran® matched the BNL predictions for a tank with excess freeboard over the lower 70% or more of the tank. Moreover, the BNL solution for a tank with insufficient freeboard is conservative over the lower 90% of the tank. It is only in the upper 10% of the tank that the pressures exceed those predicted by the BNL solution, but near the top, the peak dynamic pressures are approximately twice that given by the BNL estimate and more than 20 times greater than given by the Malhotra estimate. In this case, the interaction with the tank roof is evidently localized enough that it does not affect the

convective frequency, or the apparent convective damping. However, the peak horizontal reaction force due to convective effects only is reduced.

When the available freeboard was 40% of the maximum unconstrained slosh height (initial liquid level of 490 inches), the peak pressures matched the BNL predictions for a tank with excess freeboard over the lower 60% or more of the tank. The BNL solution for a tank with insufficient freeboard is conservative over the lower 85% of the tank. It is only in the upper 15% of the tank that the pressures exceed those predicted by the BNL solution, but the peak dynamic pressures are approximately 50% greater than given by the BNL estimate and more than eight times greater than given by the Malhotra estimate. In comparison to the previous case, although the peak roof pressures are higher in that case, the effects on liquid pressures are also more localized near the top of the liquid column when more freeboard is available.

The additional interaction with the tank roof that occurs when the available freeboard was 40% of the maximum unconstrained slosh height also dramatically increases the apparent convective frequency and apparent convective damping. The results also showed that the BNL and Malhotra estimates for the peak horizontal reaction force are more conservative relative to the Dytran® results for flat-top tanks with insufficient freeboard than for tanks with excess freeboard.

The disparity in the peak roof pressures predicted by the different methods should not be surprising. The Malhotra estimate of roof pressures is based on the contained liquid in the tank subjected to a lateral acceleration equal to the spectral acceleration at the convective frequency of the system. Accordingly, impulsive effects are not reflected in this estimate. In contrast, the BNL estimate of peak roof pressures for a tank with insufficient freeboard is based on the contained liquid in the tank subjected to a lateral acceleration equal to the spectral acceleration at the impulsive frequency of the system (which is the same peak roof pressure predicted for a completely full tank subjected to the impulsive acceleration). The Dytran® simulation naturally captures the convective and impulsive effects plus the dynamic impact effect that is not reflected in either of the other estimates.

The Dytran® simulation at the 480 inch and 490 inch initial liquid levels for the flat-top tank shows non-zero dynamic roof pressures at outside of the central half-angles predicted by BNL or Malhotra. The higher peak roof pressures predicted by Dytran® for the flat-top tank coupled with non-zero dynamic pressures outside the predicted central half-angle *suggests* that the total peak roof force may be higher for flat-top tanks than predicted by the BNL or Malhotra estimates. However, the total peak roof force and variation of the contact area of the liquid with the roof were not parameters that were of primary interest for this study and thus the total roof force was not monitored. Consequently, this investigation does not provide enough information to support a conclusion regarding the peak roof forces predicted by the BNL or Malhotra estimates. This is perhaps the most important practical result that was not provided by this study.

In the two cases of the domed tanks, the estimates of the peak horizontal reaction forces provided by the BNL and Malhotra procedures for are conservative relative to the Dytran® solutions, especially for the flexible-wall tank. The peak liquid pressures for the rigid domed tank are very similar to the solutions for vertical-walled tanks with excess freeboard up to at least 90% of the normalized initial liquid level. This behavior is consistent with results for flat-top tanks, but the agreement between the solutions for the domed tanks and for vertical-wall tanks with excess freeboard extends further up the tank wall than for flat-top tanks. In the flexible-wall domed tank, the peak liquid pressures are indistinguishable from those predicted for a vertical-wall tank with excess freeboard in the lower 95% of the liquid. In both cases, this is consistent with a milder effect of roof interactions for a curved roof relative to a flat roof.

The liquid interaction with the tank dome was captured by the Dytran® simulations as evidenced by the significant increase in peak wall pressures relative to those predicted for vertical-wall tanks with excess freeboard. On the other hand, the peak roof pressures determined using the BNL estimates for equivalent flat-top tanks were conservative, especially for the flexible-wall domed tank. In fact, the peak liquid pressures at all elevations were conservatively estimated by the BNL procedure, and very conservatively estimated for the flexible-wall tank. The peak roof pressures given by the Malhotra estimate are the same as for the rigid domed tank because the estimate depends in the convective acceleration, but not on the impulsive acceleration, which is higher for the flexible-wall tank. In both cases, the maximum roof pressures were dramatically underestimated using the Malhotra procedure.

Part of the conservatism inherent in the BNL solution for predicting peak liquid pressures for equivalent flat-top tanks is due to the assumption that within the central half-angle, the fluid column is trapped between the floor, wall, and roof, and that the dynamic pressure is independent of height on the column. This is in contrast with the prediction from the Dytran® simulations that the peak pressures over the majority of the tank height are not increased by the presence of the roof.

CONCLUSIONS

The following conclusions are supported by the results of this study:

1. The peak horizontal reaction force estimate per BNL for a vertical-wall tank with excess freeboard was conservative relative to the Dytran® solution when the impulsive and convective components were summed absolutely, but slightly unconservative when the two components were summed via the SRSS method.
2. The peak reaction force estimates provided by BNL and Malhotra were conservative for flat-top tanks with insufficient freeboard and for domed tanks regardless of whether the impulsive and convective components were summed via the SRSS method or using an absolute sum.
3. Peak liquid pressures in flat-top tanks with insufficient freeboard or in domed tanks agree with the peak pressures for vertical-wall tanks with excess

freeboard in the lower 60% to 95% of the liquid column, depending on the tank configuration.

4. The effects of the roof or dome interaction on the peak liquid pressures are limited to the upper portions of the tank and the effects are quite localized for the domed geometry considered.
5. In the case of flat-top tanks with insufficient freeboard, the peak roof pressures predicted by the Dytran® simulations were higher than given by the BNL equivalent flat-top tank estimates because the BNL estimate does not include dynamic impact effects.
6. In the case of domed tanks, the BNL equivalent flat-top tank estimates of the peak roof pressures were conservative, especially for the flexible-wall tank.
7. The peak roof pressures predicted using the Malhotra estimate were dramatically lower than either of the other two methods because the estimate does not account for impulsive effects or dynamic impact effects.

ABSTRACT

Nuclear structures are typically reinforced concrete shear wall buildings constructed either embedded in or on the ground surface. Nuclear structures contain equipment, systems, and components that are safety-related and generally require seismic qualification by either full-scale testing or analysis. Evaluation of a safety-related nuclear structure is typically performed by dynamic analysis of a finite element model of the structure considering three orthogonal components of input motion. The paper addresses updates to ASCE 4 in the areas of finite element modeling, damping for multiple levels of response, modal response combination, frequency domain response methods, multi-step analyses, and nonlinear seismic analysis.

MODELING OF STRUCTURES

General Requirements. The arrangements of nuclear plant buildings and major components are structurally complex, and the development of mathematical models for seismic effects requires careful consideration. The amount of detail used to represent a structure in a mathematical model depends on the structural configuration and the use of the model. Specific considerations and requirements pertinent to idealizing complex plant structures are provided in the standard.

The seismic response of a structure shall be determined by preparing a mathematical model of the structure and calculating the response of the model to the prescribed seismic input. Mass and stiffness distribution in the structure shall be appropriately included. The mathematical model shall represent, at a minimum, the structural elements that form the primary load resisting system of the structure. The hydrodynamic effects of any significant water mass interacting with the structure shall be considered in modeling the inertial characteristics. The response parameter(s) of interest shall be identified. Response parameter(s) of interest are defined as the desired results of a specific analysis that will be used in design and/or evaluations. Different structural models are often developed for different purposes and the purpose of each model should be clearly identified.

The frequency range of interest shall be identified and the mathematical model shall adequately represent the frequency range of interest. The frequency range of interest is the intersection of (1) the frequency range of the earthquake input; (2) the frequency range of building response; and (3) the frequency range of the response parameter of interest. Refined finite element meshes and increased analytical rigor are generally required to transmit higher frequencies through the analytical models.

Structural design forces, such as base shear, are functions of relative displacement and are typically not sensitive to high frequency response. Equipment response may, depending on the component, be sensitive to high frequency response. Thus, an analytical model developed solely to determine structural design forces may have a lower frequency range of interest than an analytical model developed to generate in-structure response spectra for high frequency sensitive equipment evaluations. Typical nuclear construction, such as heavy reinforced concrete shear wall confinement/containment structures are generally capable of transmitting high frequency response throughout the structure. The seismic input for a western US site or an eastern deep soil site has much lower frequency content than an eastern US rock site. Where the frequency range of interest extends to high frequencies, it is required that (1) the soil-structure interaction (SSI) and structural models are adequately refined to sufficiently capture the high frequency content of the seismic input in the structural response; (2) the range of high frequency to be transmitted should cover a model refinement frequency of at least equal to 50 Hz; and (3) in-structure response spectra (ISRS) computed using a refined model should contain spectral responses up to 100 Hz.

Models for Horizontal and Vertical Motions. When significant coupling exists between horizontal and vertical structural responses, one combined analytical model (a three-dimensional model) shall be used for the seismic response analysis. Otherwise, separate analytical models for horizontal and vertical excitations may be used. Because of the complexity of structures, equipment locations, and non-uniform mass distribution, eccentricity between the center of mass and the center of rigidity often exists in nuclear plant structures. This creates coupling between the three orthogonal structural responses.

Selection of Finite Element Type. There are two factors to be considered in the selection of finite element types for analysis: (a) type of the structural members to be modeled and, (b) type of the response parameters of interest that are critical to the design of the SSC. The selection of the element type shall also consider the analytical theory on which the element is based, in order to represent major characteristics of the structural system and to capture the response parameter(s) of interest. The selection of the discretization parameters shall consider the size, shape, and aspect ratio of the elements; the internal node points; type of deformation to be modeled (e.g. out-of-plane shear deformation); and the number of nodes required to define the element.

For frame structures, the beam and truss elements should be used; the latter being necessary for members with axial load capability only. When modeling with beam elements, a single element between the support points is sufficient unless determination of dynamic response between the nodes is necessary. Also, it must be recognized that multiple elements with distributed masses between the support points will result in local modes in dynamic analysis that may not be important to behavior of the overall structure but increases the number of modes below the specified cut-off frequency. For shear wall structures, it is preferred to use shell elements that will calculate the variation of stresses within the element as well as out-of-plane shears. Shell elements with transverse shear deformation are required in many nuclear structures with thick slabs and walls and relatively short spans. 3D solid elements may be used to represent massive solid components and are often used to represent soil. Different types of elements can be combined in one model provided that compatibility of forces and displacements at the boundaries are assured.

Selection of Mesh Size. The finite-element model shall produce response parameters of interest critical to design that are not significantly affected by further refinement in the element mesh size and shape. The mesh size must be capable of transmitting the entire frequency range of interest. The selection of element sizes is essentially an exercise of engineering judgment, since the "true solution" to which the results can be compared is often not known. Mesh refinement guidelines include:

- For in-plane shear, piers should have at least three elements vertically.
- For transverse bending in slabs, element size should be smaller of the short side/6 or the long side/8.
- For transverse bending in walls, four elements across vertical spans should be used.
- If transverse bending is important in walls, such as exterior walls resisting soil pressure, mesh the walls as a slab.
- If concentrated loads are important, arrange elements to provide punching shear on critical sections.
- Provide additional refinement around discontinuities, unusual openings and high stress areas.

Damping. Values of damping to be used in dynamic analyses are given in Table 1 as a function of stress level. The stress level is calculated on a member basis and is given as:

- Stress Level 1 structures have low stresses. The member forces calculated for the loading combination are generally less than about 50% the code ultimate strength or stresses are generally less than about 50% yield capacity in the major resisting building elements.

- Stress Level 2 structures correspond to structures with demands less than the nominal ACI, AISC member capacities. The member forces calculated for the loading combination, are generally between about 50% and 100% of the code

ultimate strength or stresses are generally between about 50% and 100% of yield capacity in the major resisting building elements.

- Stress Level 3 structures have responses ranging from "Limited Permanent Distortion" to "Large Permanent Distortion" which corresponds to ASCE 43 Limit States C, B or A. The member forces calculated with F_μ=1, for the loading combination, must exceed the nominal code capacity or stresses must exceed the yield strength in major load resisting building elements.

Table 1 Viscous Damping Expressed as a Fraction of Critical Damping

Structure Type	Stress Level 1	Stress Level 2	Stress Level 3
Welded aluminum structures	0.02	0.04	0.04
Welded and friction-bolted steel structures	0.02	0.04	0.07
Bearing-bolted steel structures	0.04	0.07	0.10
Prestressed concrete structures (without complete loss of prestress)	0.02	0.05	0.07
Reinforced concrete structures	0.04	0.07	0.10
Reinforced masonry shear walls	0.04	0.07	0.10

These values are applicable to all modes of a structure constructed of the same material. Damping values for systems that include two or more substructures, such as a combined concrete and steel structure, or soil-structure systems require special treatment. For generating input motions to subsystems (i.e., equipment or piping attached to a building) or for evaluating structural displacements, the level of damping will depend upon the calculated stress levels. In lieu of iterative analyses to determine the actual Stress Level and associated damping value, Stress Level 1 damping values may be used for generation of in-structure spectra and displacements. Stress Level 1 damping shall be used if the design is governed by an elastic buckling mode.

For the design or analysis of safety-related structures limited to elastic response, Level 2 damping values may be used independent of the state of stress in the structures. Damping values higher than Stress Level 2 values are generally appropriate for structures responding well into their nonlinear range. The analysis may account for such damping, if properly justified, either through the use of a Stress Level 3 viscous damping value, or a combined Stress Level 1 viscous damping value and hysteretic energy dissipation mechanism. For structural design or analysis, the use of the higher damping values (Stress Level 3) is justified because, before the structural elements would reach a displacement limit, they would experience Stress Level 3. The exception is made for elastic buckling where the limiting value may be reached before Stress Level 3 or 2 is reached.

The use of damping values higher than those in Table 1 is permitted if the damping values are properly justified.

Modeling of Stiffness. The mathematical model shall represent, at a minimum, the structural elements that form the primary load resisting system of the structure. The stiffness of secondary elements, which are not part of the primary load path, may be omitted from the mathematical model provided that secondary elements do not unconservatively affect the response parameters of interest by more than 10%. Elements which are rigid compared to the stiffness of other elements in the load path may be considered as rigid bodies in the analysis, provided that the inclusion of rigid elements does not affect the response parameters of interest by more than 10%.

Reinforced concrete elements may be modeled as cracked or uncracked sections, depending on their stress levels due to the most critical seismic load combination. For the generation of input motion to subsystems, consideration shall be given to the uncertainties in the stiffness properties of the concrete elements. The ±15% peak broadening of in-structure response spectra, as required in the standard, is intended to account for the variability in structural properties.

Modeling of Mass. The inertial mass properties of a structure may be modeled by assuming that the structural mass and associated rotational inertia are discretized and lumped at node points of the model. Alternatively, the consistent mass formulation may be used. When appropriate, three translational and three rotational degrees of freedom shall be used at each node point. Mass for some degrees of freedom, such as rotational, may be neglected, provided that their exclusion does not affect the response significantly. The following conditions shall be met:

- Structural mass shall be lumped so that the total mass, as well as the center of gravity, is preserved, both for the total structure and for any of its major components that respond in the direction of motion.

- The number of dynamic degrees of freedom, and hence the number of lumped masses, shall be selected so that all significant vibration modes of the structure can be evaluated.

Mass included in the model used for dynamic analysis shall include all mass expected to be present at the time of the earthquake and shall not include added conservatism. This mass will include the effects of dead load, stationary equipment, piping, and the appropriate part of the live load. The mass shall account for the expected live load, but not less than 25% of the specified design live load for design loads 200 psf and smaller, and not less than 50 psf for design live loads greater than 200 psf.

Modeling of Damping. Damping coefficients listed in Table 1, shall be used for structures composed of the same material or with similar damping characteristics. For structural systems that consist of substructures with different damping properties, composite damping methods, damping matrix sub-structuring, or composite modal damping may be used. The entire frequency range of interest shall be considered when selecting the damping model.

ANALYSIS OF STRUCTURES

General Requirements. The seismic analysis of safety-related structures is typically performed by analysis of linearly elastic mathematical models. Nonlinear analysis may be performed in some cases, especially for beyond design basis calculations. The following methods of seismic analysis are acceptable:

Linear analysis	Nonlinear analysis
Time-history method	Time-history method
Response-spectrum	Response-spectrum
Frequency-domain	Nonlinear static
Equivalent static	
Multistep	

Analyses shall be performed for three orthogonal (two horizontal, one vertical) components of earthquake motion. The axes shall, in general, be aligned with the principal axes of the structure. Nuclear structures are generally stiff, massive and embedded structures for which soil-structure interaction (SSI) effects are likely to be important. Accordingly, regardless of the method chosen for analysis, the mathematical model of the structure shall account for SSI effects as appropriate.

Linear Time-History Analysis. Dynamic analysis of linear (and nonlinear) systems is based on the solution of a set of simultaneous differential equations involving mass, damping and stiffness matrix representations of the structure. Alternate methods, including direct integration and modal superposition, are available to solve the equations. Earthquake effects are imposed in the form of three-component acceleration time histories. A single set of time histories may be used provided that the 5% damped spectra match or envelop the target spectra and the calculated spectra at 2% and 20% damping must exceed 90% of the respective target spectra. Alternately, 3 independent sets of three component time-series can be used from which the peak maximum component response is determined. If 5 or more sets of time-series are used for linear analysis, median maximum component response shall be used.

Linear Response Spectrum Analysis. Methods of response-spectrum analysis are well established in codes, standards and guidelines for seismic analysis and design. A sufficient number of modes shall be included in the analysis to ensure that the inclusion of the remaining modes does not result in more than a 10% increase in the responses of interest. A residual mode may be used to include higher modes in the response calculations, where the residual mode frequency is equal to that of the ZPA.

Combination of Modal Responses. Modal responses shall be combined in a manner that accounts for the relative phasing between modes. Low-frequency modes are out of phase with each other, high-frequency modes are in phase with each other, and modes in between are in transition phasing as shown in Figure 1.

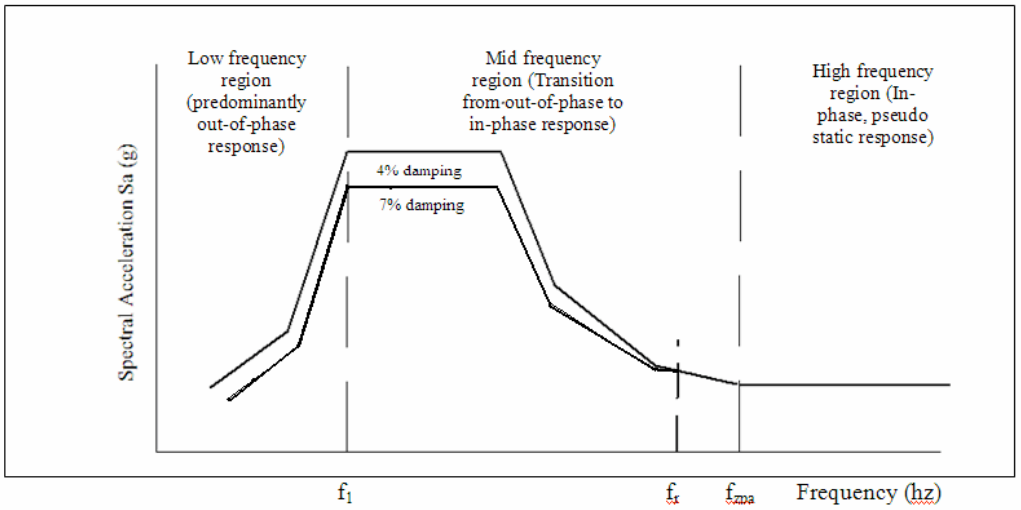

Figure 1. Modal Phasing and the Ground Response Spectrum

Combination of Out-of-Phase (Periodic or Low Frequency) Modal Responses. Combination of the modal responses for the Ith component of motion is calculated using the following double sum equation:

$$R_I = \pm\sqrt{\sum_i \sum_j \varepsilon_{ij} R_{Ii} R_{Ij}} \qquad \text{(Eq. 1)}$$

where: R_I = the response for the I^{th} component of motion

R_{Ii}, R_{Ij} = the signed modal response of interest in the i^{th} (j^{th}) mode, including the residual mode

ε_{ij} = modal correlation coefficients

Eq. 1 is the standard double-sum equation in which the coupling terms, ε_{ij}, account for the correlation between modal responses. If the frequencies of all modes are sufficiently separated, it is acceptable to combine out-of-phase modal responses using the SRSS method. In this approach, ε_{ij} is equal to 1.0 when i is equal to j and equal to 0.0 when i is not equal to j. If there are closely spaced modes, it is permissible to use either of the following two approaches for modal combination. Each of these methods have specific correlation coefficients, ε_{ij}.:

- Modified Rosenblueth's Correlation Coefficient
- Der Kiureghian's Correlation Coefficient (Complete Quadratic Combination or CQC)

Combination of Rigid (In-Phase or High-Frequency) Modal Responses. In the high-frequency region (greater than rigid frequency, f_r, as shown in Figure 1), rigid response is predominant and modal responses are to be combined by algebraic sum:

$$R_{Ir} = \sum_{i=1}^{n} R_{Iri} \qquad \text{(Eq. 2)}$$

where: R_{Ir} = the combined response of the I^{th} component of motion for all modes at frequency greater than rigid frequency f_r.

R_{Iri} = the response of the I^{th} component of motion for mode i for all modes at frequency greater than rigid frequency f_r.

f_r = the rigid frequency that can be identified as the frequency at which response spectra curves for different damping ratios converge.

Combination of Modes with Both Periodic and Rigid Responses. For the general case in which there are both periodic and rigid modal responses, it is permissible to use either of the following two approaches for modal combination:

- Gupta Method (also General Modal Combination or GMC)
- Lindley-Yow Method

These methods address both periodic and rigid modes as well as those modes in the transition region between frequencies f_1 and f_r in Figure 1.

The previous edition of the standard permitted an assumption of abrupt change between periodic and rigid response at a frequency of $1/2\, f_r$. This approximation is no longer permitted in the current standard. Recent work has indicated that periodic response is very strong close to the rigid frequency.

Frequency Domain Analysis. Frequency-domain analysis is generally employed for soil-structure interaction analysis. The frequency-domain analysis method permits the direct use of frequency-dependent parameters such as foundation radiation damping in the equations of motion. In frequency-domain analysis, the input motions shall be generally specified as an acceleration time-series. Each time series is transferred into frequency domain using Fourier transform techniques and once the solution is obtained the response is transformed back into the time domain using the inverse Fourier transform. For frequency-domain analysis, the following requirements shall be met:

- If acceleration time-series are used as input, the time step for the input acceleration time-series shall be chosen so that the maximum frequency of interest is retained. If random vibration theory is used, frequencies should be selected to accurately characterize the response or power spectrum of the input motion for the entire frequency range of interests.

- The frequency interval used to generate transfer functions shall be selected to enable calculation of transfer functions at key structural frequencies and any other frequencies of interest. If interpolation schemes are used to interpolate between these frequencies, the resulting transfer functions shall be checked.

Multistep Analysis. In a multistep analysis, dynamic response analysis is performed as a first step to establish system-level responses, including floor acceleration time series and floor displacement histories. Calculations of demands on components of the structural system are performed in subsequent steps. The mathematical model used for the subsequent analysis is generally more detailed than the model used for the initial dynamic analysis as the latter model is used for the calculation of forces for design and detailing of structural components and systems.

Initial Analysis. The seismic analysis of the structure is performed in the three orthogonal directions. Soil-structure interaction shall be considered. System-level acceleration, velocity and displacement results shall be recorded for subsequent steps in the analysis. In-Structure Response Spectra (ISRS) shall be developed for analysis of the systems, structures and components (SSCs) in or attached to the structure..

Subsequent Static Analysis. For subsequent analysis, the structure is typically modeled with a fixed base. Equivalent static forces shall be calculated as the product of maximum accelerations from the initial analysis and nodal masses and applied to a detailed model of the structure. The analyst should verify that the signs of the values used for the static analysis do not lead to an underestimation of demand on structural components and systems. The use of the static method of analysis to calculate demands on structural components may be very conservative because the maximum values of total acceleration are assumed to occur simultaneously.

Subsequent Dynamic Analysis. Response-spectrum or time (response)-history analysis can be used to determine forces for design of structural components. The use of an envelope response spectrum at the level of the foundation of the structure assumes that the effects of rocking and torsion are small and this assumption shall be verified. If the initial analysis indicates that rocking or torsion effects are significant, the time-history method of analysis is preferred because histories of rocking and torsion can be input at the base of the structure.

Nonlinear Time-History Analysis. Nonlinear time-history analysis shall be used for analysis of seismically isolated nuclear structures for design basis and beyond design basis shaking and may be used for analysis and design of all nuclear structures. Direct integration of the equations of motion and fast nonlinear analysis (FNA), which is best suited to structures with a limited number of nonlinear elements, can be used. A nonlinear representation of force-deformation behavior is typically used for all structural components. A linear elastic component model can be substituted for a nonlinear component model only if elastic response is anticipated and confirmed for the selected intensity of shaking. Nonstructural components that contribute significant lateral strength and/or stiffness to the structure, such as infill masonry walls, shall be modeled using equivalent beam-column or strut elements, or appropriate finite elements. Nonlinear models of components shall be based on test data where available. Nonlinear models of structural components (other than seismic isolators) will generally be enveloped by the basic form of the force-displacement relationships shown in Figure 2.

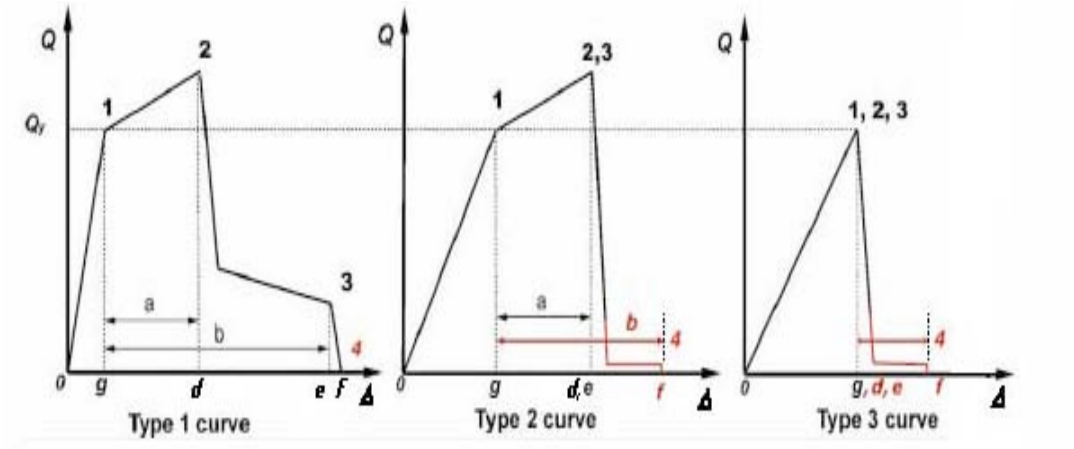

Figure 2 Generalized Force-Displacement Behavior of Structural Components

- The Type 1 curve is representative of ductile behavior characterized by an elastic range (points 0 to 1) and a plastic range (points 1 to 3). The plastic range includes a strain hardening or softening range (points 1 to 2) and a strength-degraded range with residual strength to resist lateral and gravity loads (points 2 to 3). Loss of lateral-force-resisting capacity occurs at point 3, which is followed by loss of vertical-force-resisting capacity at point 4.

- The Type 2 curve is representative of limited ductile behavior where there is an elastic range (points 0 to 1) and a plastic range (points 1 to 3), followed by loss of lateral-force-resisting capacity at point 3 and loss of vertical-force-resisting capacity at point 4.

- The Type 3 curve is representative of brittle or non-ductile behavior where there is an elastic range (points 0 to 1) followed by loss of lateral-force-resisting capacity at point 3 and loss of vertical-force-resisting capacity at point 4.

Three-component sets of earthquake ground motions shall be applied simultaneously to the mathematical model of the structure. A minimum of 3 independent sets of three component time-series shall be used for analysis. If 3 sets of time-series are used for analysis, the peak maximum component response shall be used for design. If more than 6 sets of time-series are used for analysis, the median maximum component response shall be used for design.

Nonlinear Response- Spectrum Method. If the nonlinear response spectrum method is used to estimate demands on components and systems, an acceptable method of nonlinear analysis for nuclear structures is to determine initially the response of the components of a structure using linear methods of analysis with an input excitation consistent with an elastic design response spectrum. The component elastic forces are then reduced by component-specific inelastic energy absorption factors, F_{μ}, to obtain inelastic member forces. Larger values of F_{μ} may be used for

ductile actions but smaller values of F_μ (but 1 or greater) must be used for brittle or less ductile members. For more hazardous facilities, lower values F_μ values are used to add conservatism to the design or evaluation, to reduce the likelihood of unacceptable performance. Recommended values for F_μ consistent with performance levels appropriate for nuclear facilities are presented in ASCE/SEI 43-05.

Nonlinear Static Analysis. The use of nonlinear static analysis shall be limited to low-rise, regular nuclear structures in which second and higher mode effects are not significant. Nonlinear static analysis involves the incremented lateral displacement of a nonlinear model of building frame using user-specified lateral force patterns. The analysis is terminated after the displacement of a control node exceeds the target displacement. The selection of a control node, the lateral load patterns, calculation of the fundamental frequency, analysis procedures, and treatment of soil-structure-interaction shall comply with the requirements of Chapter 3 of ASCE 41.

The target displacement of the building frame shall be calculated by either the coefficient method or the capacity spectrum method. The effect of the earthquake shaking is characterized using a spectral displacement that is transformed into a target displacement for the purpose of component checking. In the coefficient method, the target displacement is calculated as the product of the elastic spectral displacement at the first mode frequency of the structure in the direction under consideration and a series of calibrated factors that transform spectral displacement to roof displacement, elastic displacement to inelastic displacement, and account for the effects of hysteresis loop shape and dynamic second-order effects. In the capacity spectrum method, the target displacement is calculated by plotting the elastic response spectrum in terms of spectral acceleration versus spectral displacement, reducing the ordinates of the elastic spectrum to account for the effects of hysteretic energy dissipation (generating the demand curve), overlaying the results of nonlinear static analysis of the structure in the same coordinate system used for the spectra (generating the capacity curve), and determining the displacement at which the demand and capacity curves intersect.

CONCLUSIONS

Conclusions of this paper are where ASCE 4-98 has been significantly updated in the areas of modeling and analysis.

1. The basic requirement is that nuclear structures are represented by a detailed finite element model for which a three dimensional dynamic analysis is performed. More simplified modeling or analysis may be used, if justified.
2. Eastern United States seismic hazard estimates now indicate significant high frequency amplified seismic input at high frequencies on the order of 25 Hz. As a result, the standard provides modeling guidelines such that high frequency seismic response can be accurately captured. The range of high frequency to be transmitted should cover a model refinement frequency of at least equal to 50 Hz; and in-

structure response spectra (ISRS) computed using a refined model should contain spectral responses up to 100 Hz.

3. Mesh refinement guidelines are provided in the updated standard to capture accurate seismic response.

4. Structural damping levels have been added in this standard update for Stress Level 3. This is for the level of response where limited inelastic behavior is permitted in accordance with Limit States A, B, or C of ASCE/SEI 43-05.

5. Combination of modal responses for response spectrum analyses has been expanded in this standard update. Mode phasing in the low frequency amplified range, the high frequency rigid range, and the transition range in between have been identified and mode combination methods appropriate for each range are discussed.

6. Frequency domain analysis discussion has been updated for this version of the standard. Frequency domain analyses are the standard for consideration of SSI in computed programs such as SASSI and CLASSI to accurately treat frequency-dependent impedance and scattering behavior.

7. Multi-step analyses requirements have been added to this update of the standard in which a less refined SSI model is used to obtain global responses. The global response is then used as input to very refined models to obtain seismic response for purposes of design.

8. Updates include an expansion of the discussion of nonlinear analysis including time history approaches, the response spectrum method that is the basic method in ASCE/SEI 43-05, and static or pushover approaches.

ABSTRACT

Section 7.6 of ASCE 4-Rev 2, *Seismic Analysis of Safety-Related Nuclear Structures: Standard and Commentary*, provides updated guidance for analysis of rocking and sliding of unanchored structures and components subjected to seismic load. This guidance includes provisions both for simplified approximate energy-based approaches, and for detailed probabilistic time history analysis using nonlinear methods. Factors to be applied to the analytical results are also provided to achieve demand estimates at the 80% non-exceedance probability level. The present paper surveys the published literature supporting these provisions. The results of available testing and analyses are compared to results produced by both simplified and probabilistic approaches. In addition, adequacy of the standard's provisions for analysis methods and factors is assessed. A comparison is made between the achieved level of conservatism and the standard's non-exceedance probability target.

BACKGROUND/INTRODUCTION

Section 7.6 of ASCE 4-Rev 2, *Seismic Analysis of Safety-Related Nuclear Structures: Standard and Commentary* (ASCE, 2011), provides guidance for analysis of rocking and sliding of unanchored structures and components subjected to seismic load. Hereafter in this paper, "ASCE 4" shall refer to the draft standard, not to be confused with the existing ASCE 4-98. The guidance in ASCE 4 Section 7.6 is consistent with the current revision of ASCE/SEI 43-05, *Seismi Design Criteria for Structures, Systems and Components in Nuclear Facilities* (ASCE/SEI 43-05), but does provide some evolutionary updates as will be explained throughout this paper.

Seismic design and evaluation of nuclear structures can be divided into to two main tasks, which are each addressed by separate ASCE standards. Analysis of structures to determine seismic demands is governed by ASCE 4, while criteria to be used in the design of these structures are given by ASCE/SEI 43-05. The acceptability of the design is determined by the comparison of demands to capacities, as outlined in ASCE/SEI 43-

05. These standards in combination are intended to satisfy a performance goal, described in ASCE/SEI 43-05 as to reasonably achieve both of the following criteria:

> 1. Less than about a 1% probability of unacceptable performance for the DBE ground motion
>
> 2. Less than about a 10% probability of unacceptable performance for a ground motion equal to 150% of the DBE ground motion.
>
> (ASCE/SEI 43-05 Section 1.3)

Each standard provides a controlled degree of conservatism. ASCE 4-98 stated an intent to produce demands with a non exceedance probability (NEP) of approximately 90%. The new draft of ASCE 4 will change that target to an NEP of approximately 80%. ASCE/SEI 43-05 states an intent to produce capacities with an exceedance probability of approximately 98%. These two margins, one on analysis and one on design, when combined are shown in the ASCE/SEI 43-05 commentary to satisfy the performance goal.

However, ASCE 4-98 did not contain provisions for rocking and sliding of unanchored components. Because the working group felt it would be useful to provide some guidance, ASCE/SEI 43-05 was issued including Section 7.1 containing provisions for evaluation of sliding and rocking of unanchored components. It was necessary under those circumstances to combine the conservatism for analysis and design into the design criteria standard. This conservatism is presented in ASCE/SEI 43-05 as factors of safety to be applied to the best-estimate (median centered) sliding distance or rocking angle to develop design values. These factors of safety were based upon judgment formed by preparation and review of a number of non-published nonlinear time history analysis studies. The ASCE/SEI 43-05 factors are as follows:

Sliding: $\boldsymbol{FS_S} = 3.0$
Rocking: $\boldsymbol{FS_R} = 2.0$

ASCE 4, SECTION 7.6 METHODOLOGIES

As in ASCE/SEI 43-05, the new draft of ASCE 4 provides three general approaches to analyze rocking and sliding of unanchored components:

- Static Evaluation
- Conservatively Biased Reserve Energy
- Time History Analysis

Static Evaluation. The static evaluation is generally consistent with longstanding procedures established in building codes and in the NRC Standard Review Plan. Static evaluation entails an analysis (which generally considers dynamic effects and soil-structure interaction) to develop base shear and overturning moments, which are then multiplied by a safety factor of 1.1. These analyses usually assume the foundation is essentially rigid. Pressures applied to the foundation medium should be verified to be acceptable. If the resulting demand is less than the static resisting capacities, the

component (or structure) will not slide or rock and no further evaluation is necessary. If the factored demands are greater than the static resistance capacities, then nonlinear analysis is required. Two general nonlinear approaches are described.

Reserve Energy Method. The simplified nonlinear approach provided in ASCE 4 is a reserve energy method, with formulations for both rocking and sliding. This method is well described in the appendices of ASCE/SEI 43-05 and elsewhere (Blume 1960, Yim et al. 1980, Aslam et al., 1980), and benchmarked against alternative approaches (Esfendari et al. 2009). It has been shown to be conservative with respect to more rigorous time-series analysis (ASCE 2005). In ASCE/SEI 43-05, the generous conservatism of particularly the sliding analysis is credited by reducing the required general factor of safety from 3, if a true best-estimate is developed, to 2, if the conservatively biased reserve-energy method is used. In ASCE 4 the treatment of safety factors has been changed in general, as will be discussed later, and in particular for the reserve energy sliding analysis, there is no longer any distinction made between this conservative approach and a true best estimate. The reserve energy solutions for both sliding and rocking analyses are treated as best-estimates or mean solutions. These solutions assume rigid rocking or sliding bodies interacting with an undeformable foundation through a coefficient of restitution, and are only appropriate when such conditions approximately apply.

Time History Analysis. Two approaches to nonlinear time history analysis are provided; for each approach a number of sets of time histories matching the design basis earthquake (DBE) spectra and conforming to the requirements of Chapter 2 are required. In the first approach, 5 different time histories (sets) are applied to the same deterministic model. The mean of the 5 solutions is taken as the best estimate. In the second approach, a fully probabilistic solution modeling all significant sources of variability and uncertainty in the particular problem, including time histories, friction coefficients, dynamic stiffness of the support, stiffness of the object, damping, and geometric tolerances is generated. At least 16 independent realizations are required. The 80^{th} percentile non-exceedance probability (NEP) response is taken as the analytical demand. The time history problem may be solved in two or three dimensions, depending upon the relevant geometries.

Adjustment for Analytical Demand Conservatism. The intent of the standard is to produce analytical demands at about the 80% NEP level. The probabilistic time history analysis approach can directly generate this 80% NEP result. The deterministic approaches, reserve energy and the time history mean-of-5, generate results that are taken as mean or best estimates, and which require adjustment up to the 80% NEP level. This is achieved by multiplying the deterministic best estimate by a factor of 1.5. This factor will be shown later in this paper to produce a reasonable estimate of the 80% NEP analytical demand.

Consideration of Uncertainties. Sliding and rocking problems are known to be sensitive to parameters which are usually not well-characterized. These may involve such phenomena as friction, surface irregularity, and phasing of input motions. To control and account for these effects, provisions are made for the consideration of uncertainties. For

deterministic analysis, friction is to be taken at the 95% NEP level for rocking, and at the 5% NEP level for sliding. Alternatively, pure rocking or pure sliding may be assumed. However, displacements due to rocking and displacements due to sliding need not be combined. For probabilistic analysis, friction is to be varied over an appropriate interval. Any combination of rocking and sliding may result and will factor into the reported displacement parameter.

Adjustment for Capacity Conservatism. To ensure the performance goals of ASCE/SEI 43-05 are satisfied, capacity factors precluding potential adverse interactions due to rocking or sliding are provided. Ideally these factors would be provided in ASCE/SEI 43-05 rather than in ASCE 4, because they have to do with capacity margin rather than demand margin. However, as an interim step that will allow future migration of the capacity factors to ASCE/SEI 43-05, ASCE 4 separates the demand factors from the capacity factors. A minimum capacity factor of 2.0 is required for both rocking angle and sliding displacement. The basis for this factor is judgment formed by familiarity with unpublished time history analyses results. Further development of a basis for these factors, particularly computed for the highly nonlinear rocking and sliding responses, may be an appropriate activity in support of the next revision of ASCE/SEI 43-05. However, based upon typical variability in seismic capacities as discussed in ASCE/SEI 43-05 Commentary, a factor of two will result in a capacity with approximately 98% probability of exceedance. In combination with the 80% NEP demand, this is expected to satisfy the ASCE 43-05 performance goal.

The combined demand and capacity factors result in a factor of safety of 3.0 relative to the best estimate. This is consistent with the factor of safety required for sliding in ASCE/SEI 43-05, and slightly higher than that previously required for rocking.

Response Limits. Solutions to rocking problems tend to become unpredictable at rocking angles approaching the stability limit. For example, it has been shown (DeJong 2009) that for ground motions which challenge gross stability, responses to multiple time histories with different phasing matching the same response spectrum can vary from less than 10% of the overturning angle all the way to overturning. Furthermore, this response is also shown to be sensitive to the duration of the shaking, which is not specified by a response spectrum.

To ensure a predictable response, the factored (80% NEP) rotation angle demand is limited to no more than 75% of the stability limit. For time history analysis, configurations which lead to any realization (either deterministic or probabilistic) overturning are prohibited. This prohibition is necessary for deterministic analysis based upon the mean response to 5 time histories because it would not be meaningful to average an overturned response with stable responses. A probabilistic analysis where some of the solutions result in overturning (when overturning is unacceptable) would be considered an “alternative methodology” as permitted in ASCE 4 Section 1.1.3.3. However, where, in general, alternatives to standard methodologies would need to demonstrate at least an 80% NEP, in the case of rocking and sliding ASCE 4 also provides the capacity factors required to achieve the ASCE/SEI 43-05 performance goals.

Therefore, alternative rocking and sliding analyses in which some realizations overturn would need to demonstrate both a 1% or less probability of exceedance given the DBE, and a 10% or less probability of exceedance given 1.5 times the DBE. This would require a large number of solutions, depending in part upon the number of realizations which overturn.

An additional consideration applies to rocking of cylindrical components or of components whose bases have rounded cross sections. The reserve energy method accounts for dissipation of energy as the base impacts the foundation at each transition through the 0° rotation angle. This coefficient of restitution-based energy dissipation is converted into an equivalent viscous damping, which is used to select the appropriately damped input response spectrum. However, it is possible that objects whose bases have circular cross sections may roll around the edge of their base when rocking. This type of response will exhibit much less energy dissipation than a pure rocking response, and the assumptions used to derive equivalent viscous damping are not accurate. To ensure a conservative analytical approach for components with circular bases, the rotation angle demand (80% NEP level) calculated by the simplified method (reserve energy) is limited to less than 10% of the angle at the stability limit. Detailed three dimensional nonlinear analysis can accurately model the rolling behavior of a round-based object, because energy dissipation is not dependent upon a linearization of the impact phenomenon (Sandia 2005). Therefore, when three dimensional time history analysis adequately models the potential rolling behavior of a component, the rocking angle limit remains 75% of the stability limit.

Summary of Methodologies. The nonlinear analysis methodologies and provisions are summarized in flowchart form in Figure 1.

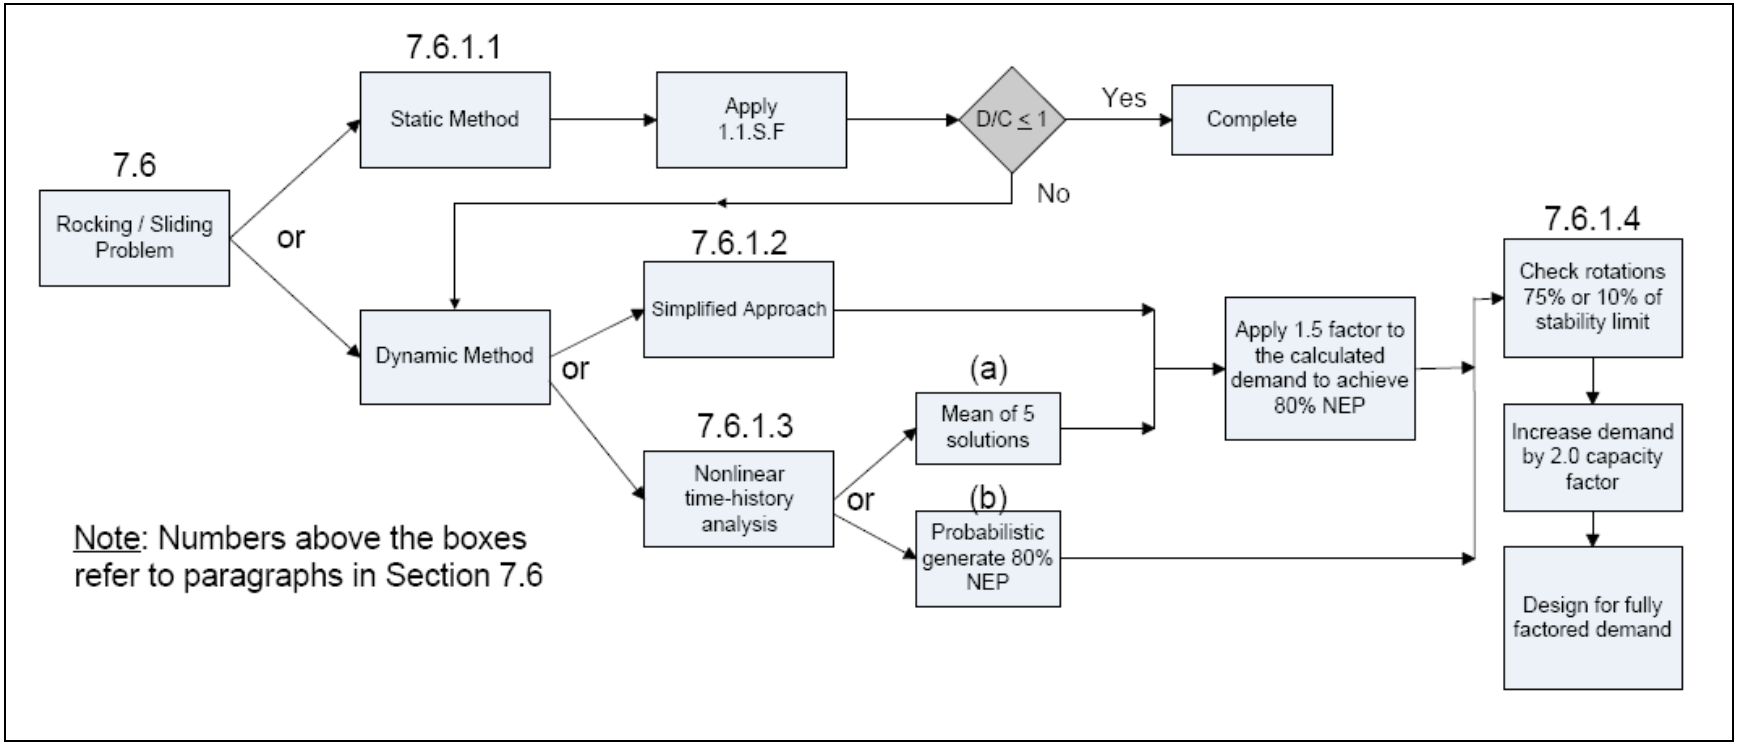

Figure 1: Summary of Rocking and Sliding Analysis Provisions

ADEQUACY OF ANALYTICAL DEMAND CONSERVATISM

Standard Intent. The intent of the standard is to produce analytical demands at approximately the 80% NEP level, given the design basis earthquake (DBE). A key element in this approach is that the mean response, multiplied by the demand factor of 1.5, will produce an approximately 80% NEP response.

Studies (Hutchinson and Chaudhuri 2006, Sandia 2005) have shown that rocking and sliding responses to various time histories matching a given demand response spectrum approximately follow a lognormal probability distribution. To the extent this formulation applies, a demand factor can be calculated from the assumed lognormal standard deviation, β_D,(=($\beta_R^2 + \beta_U^2$)$^{0.5}$ where β_R and β_U are the logarithmic standard deviation for the inherent randomness and uncertainty, respectively, of the seismic response. The 80% NEP demand is given by the following equation,

$$\frac{F_D}{F_C} = e^{0.84\beta_D} \qquad \text{(Eq 1 of 1)}$$

where 0.84 is the standardized normal variable for the 20% (one-sided) exceedance probability level (that is, the 80$^{\%}$ NEP level), F_D is the factored demand and F_C is the calculated median demand, and β_D is the composite lognormal standard deviation of demand. Note that the factor thus calculated applies to the median value, which will be lower for a lognormal distribution than the mean value. Because ASCE 4 applies the demand factor to the calculated mean (or best estimate), Equation 1 is conservative. Values of F_D corresponding to a range of values of β_D are tabulated in Table 1 below.

Table 1. Example Values of F_D/F_C

β_D	F_D/F_C
0.3	1.29
0.35	1.34
0.4	1.40
0.45	1.46
0.5	1.52
0.55	1.59
0.6	1.66

As can be seen from Table 1, a demand factor of 1.5 will produce a reasonable estimate of the 80th percentile demand for problems having lognormal standard deviations of about 0.5 or less, since the required multiplier in Table 1 is less than 1.5.

Seismic response of components typically will have lognormal standard deviations in the range of about 0.2 to 0.4 (ASCE 2005); therefore, the factor of 1.5 provides a reasonable estimate of the demand at the 80% NEP level.

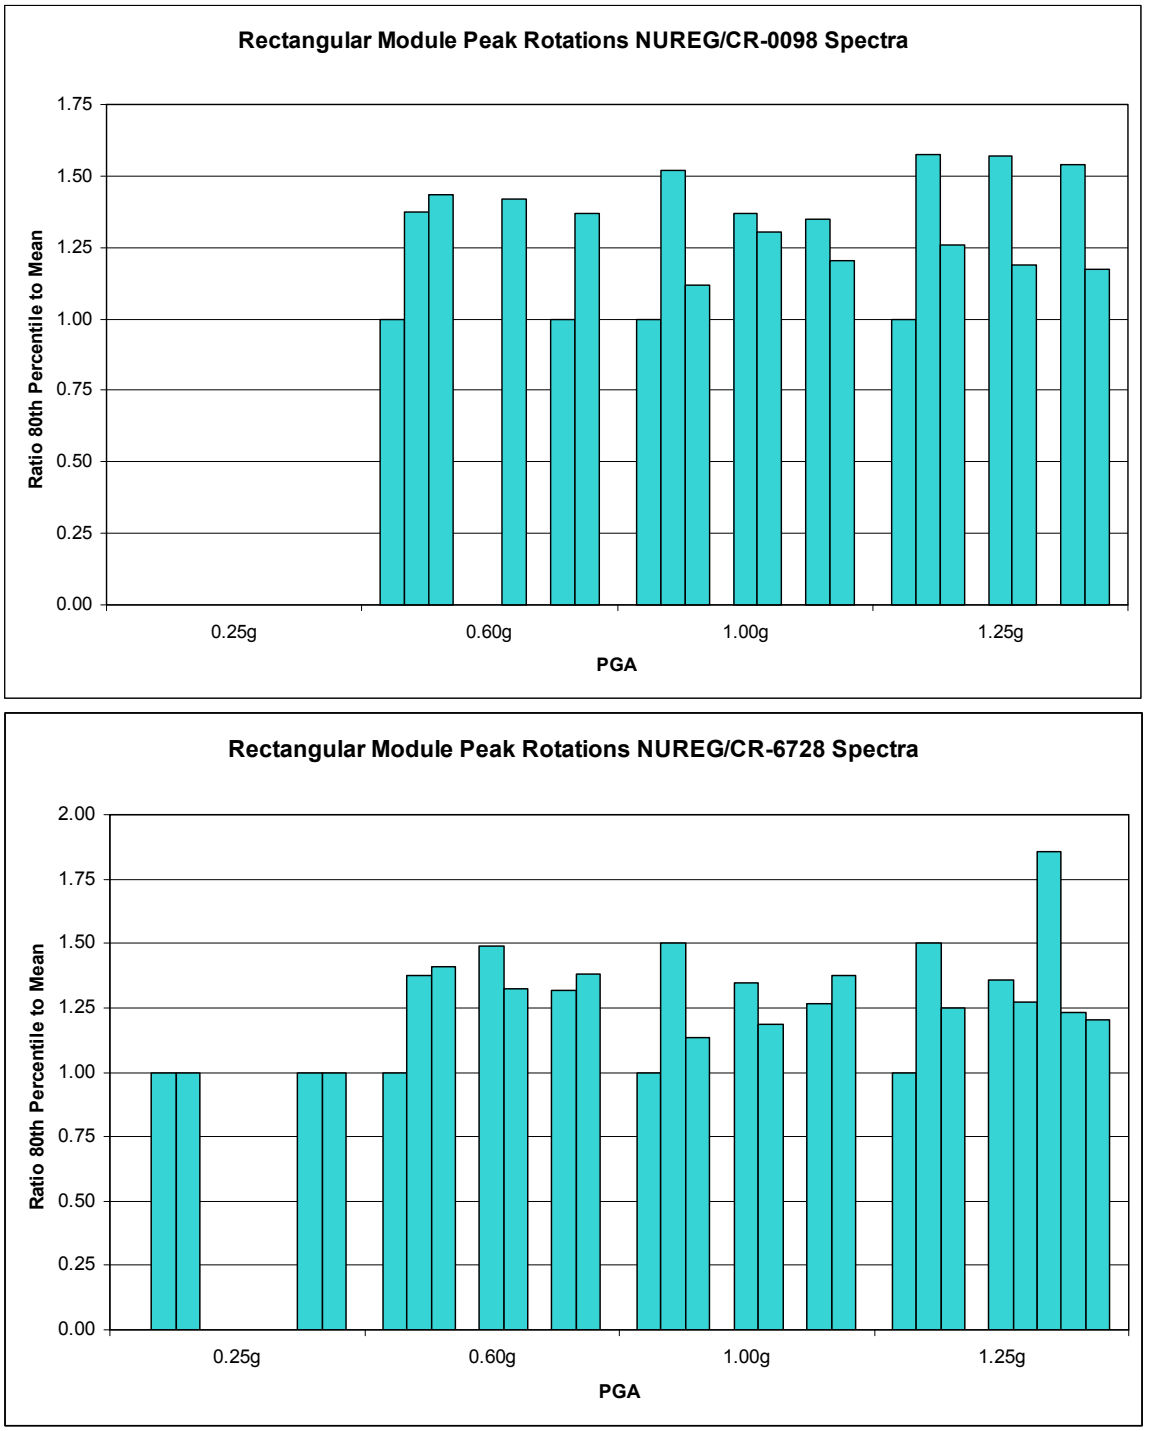
Rocking and Sliding Problems. However, rocking and sliding problems exhibit highly nonlinear and unique behavior. In this section new statistical processing of previously published results of a detailed three-dimensional study of the rocking response of cylindrical casks and rectangular storage modules using nonlinear time history analysis (NUREG/CR-6865, Sandia 2005) is reported. This will serve as an example to illustrate the variability of the responses in this class of problems and to test the adequacy of the ASCE 4 demand factor. NUREG/CR-6865 presents rocking results for casks and modules analyzed to three different standard spectral shapes, with five unique and spectrum-appropriate (magnitude, distance, tectonic environment) time history record sets fitted to each of the three spectra. The spectra are normalized to peak ground accelerations of 1.0g, and the time histories are scaled to various enveloping acceleration levels. For the cylindrical casks there are five acceleration levels, and for the rectangular casks there are four. Other parameters varied include foundation stiffness and coefficient of friction. Various output parameters are reported with analysis; only peak rotations are considered here.

Because of the relatively coarse binning of the model parameters, results from different friction sets and foundation stiffness sets are assumed here to represent distinct statistical populations. Therefore, the statistical analysis is performed on a series of results sets with only five results in each set. While this probably is an adequate sample size to define a mean, it is not considered adequate to define an 80% confidence interval. However, the large number of sample sets, each representing different permutations of friction and foundation stiffness, taken together are considered to provide a meaningful test of the adequacy of the ASCE 4 demand factor as applied to the rocking problem. Significantly, the results reported in NUREG/CR-6865 show demonstrable rolling on the base by the cylindrical casks. In total, there are nine results sets (permutations of three friction coefficients and three foundation stiffnesses) for each spectral shape, each scaled acceleration level, and each component type. In total 243 sets of five results each were processed and are reported here.

Figure 2(a)-(f) below presents the ratios of the estimated 80^{th} percentile peak response to the mean peak response, calculated assuming lognormal distribution of the five results in each result set. There are two reasons why many of the sets are not shown in the figures. First, for low acceleration levels and particularly for the rectangular components, there was numerically zero variability (sometimes due to zero response), which precludes calculation of an 80^{th} percentile response level. Secondly, in cases of higher responses, some of the cylindrical components overturned, which precludes even calculation of the mean.

As can be seen in Figure 2, it is reasonably conservative to estimate the 80^{th} percentile rocking response by multiplying the mean of five time history responses by

a demand factor of 1.5 in accordance with ASCE 4. These figures the result of additional statistical processing of the results published in NUREG/CR-6865).



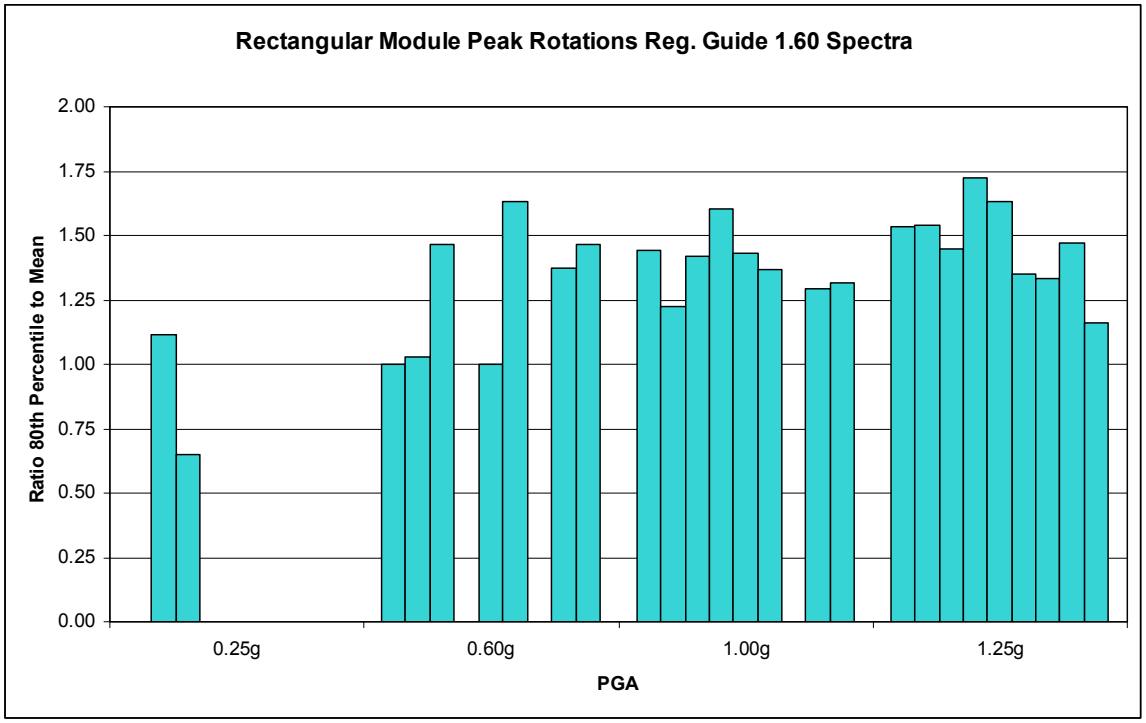


Figure 2(a) and (b): Rocking Response Ratio, $80^{\%}$ NEP to Mean

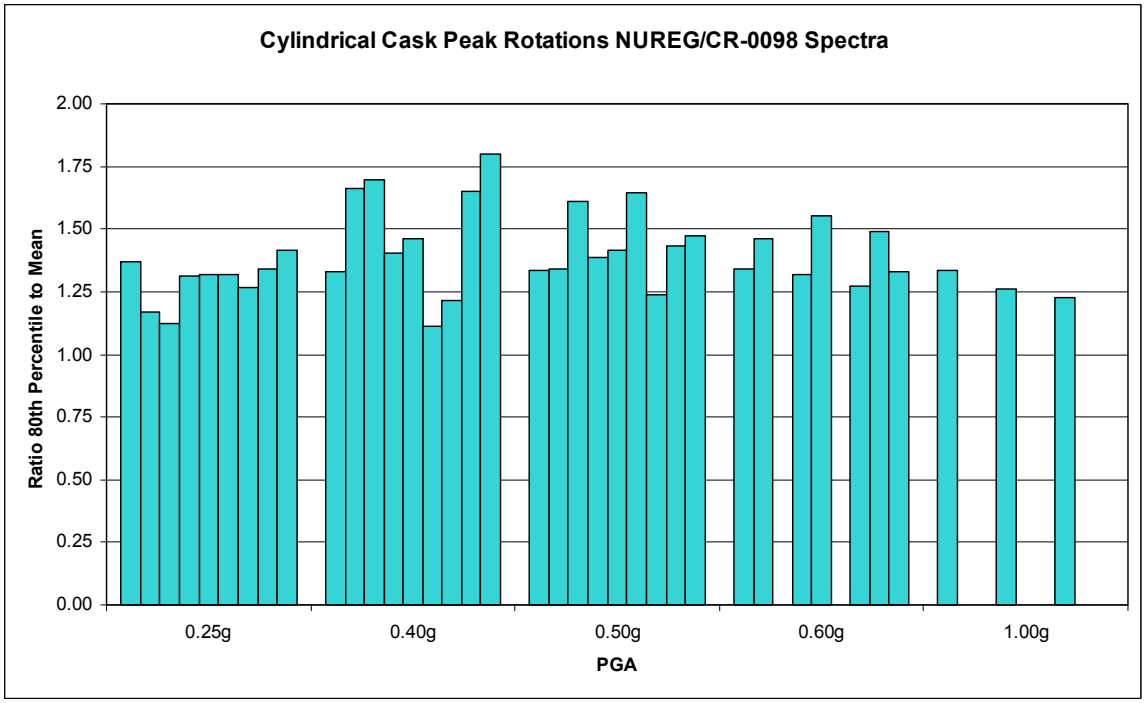

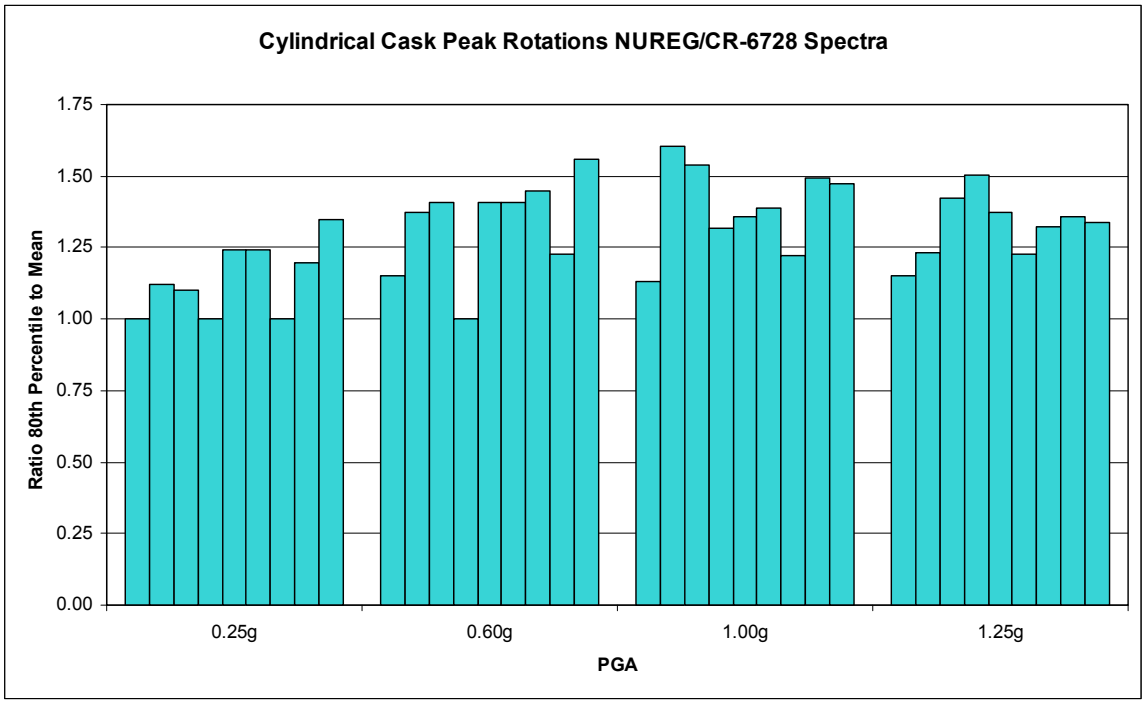

Figure 2(c) and (d): Rocking Response Ratio, 80% NEP to Mean

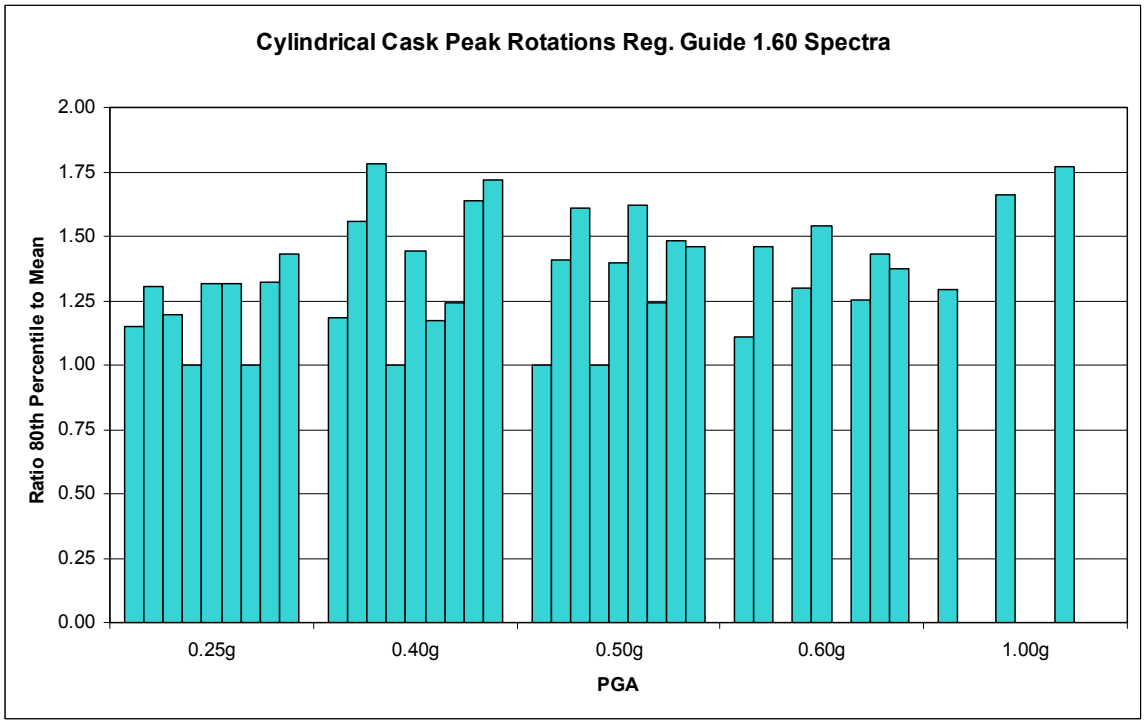

Figure 2(e) and (f): Rocking Response Ratio, $80^{\%}$ NEP to Mean

CONCLUSION

The new addition to ASCE-4 as Section 7.6 provides evolutionary guidance for seismic evaluation of rocking and sliding of unanchored bodies. Following the

provisions of Section 7.6 will produce reasonably conservative estimates of the 80th percentile rocking or sliding demands.

Applicability of Nonlinear MDOF Modeling for Design

Michael Valley[1]

[1]Consulting Structural Engineer; email: michael@mmvalley.net

ABSTRACT

Codes, standards, and guidelines commonly used in the evaluation and rehabilitation of existing buildings recognize and allow various performance-based engineering analysis methods, but much of their focus is on nonlinear static procedures (NSPs). The NSPs codified in those documents are based on single-degree-of-freedom (SDOF) models, which are easy to understand but may not capture adequately the complex behavior of structures with multiple-degree-of-freedom (MDOF) effects. The NEHRP Consultants Joint Venture has completed a project (ATC-76-6, with results published in NIST GCR 10-917-9) to improve the practical application of NSPs and nonlinear response history analysis (NRHA) to structures with MDOF effects.

The NIST GCR 10-917-9 project report summarizes both recent MDOF modeling research and current structural analysis practice as specified in codes, standards, and guidelines and as implemented by leading practitioners. The work of the project includes synthesis of available research and performance of new problem-focused studies. The primary studies compare results from NSP and NRHA for both detailed structural archetypes and simplified models. Issues addressed in ancillary studies include examination of demand parameter sensitivity to ground motion selection and scaling methods, direct determination of NSP target displacement, and practical implementation of the nonlinear analysis methods. Based on available past research and on the new studies, the project report provides guidance on selection of simple nonlinear analysis methods appropriate for design, on implementation of nonlinear analysis methods, and on incorporating uncertainty in nonlinear dynamic and nonlinear static analysis.

Related to the ATC-76-6 project, this paper provides background, a summary of the work performed, and a summary of key findings and recommendations. Related papers provide more detail of the technical work performed.

BACKGROUND

Prevailing practice for Performance-Based Seismic Design (PBSD) is based largely on products that have been developed under the direction of National Earthquake Hazards Reduction Program (NEHRP) agencies and other key contributors. Many of these documents recognize and allow several different performance-based analytical methods, but much of their focus is on nonlinear static analysis procedures.

Using FEMA 440 as a starting point, the purpose of this project was to improve nonlinear MDOF modeling for structural design practice by providing guidance on: (1) the minimum level of MDOF model sophistication necessary to make performance-based engineering decisions; (2) selection of appropriate nonlinear analysis methods; and (3) possible alternative approaches to analytical modeling.

The scope of the investigative effort included two primary activities. The first was to review current research and practice on nonlinear modeling of multiple-degree-of-freedom effects. The second was to conduct focused analytical studies to fill gaps in available research and synthesize available information. A workshop of invited experts was convened to obtain feedback on preliminary findings and to refine the resulting recommendations.

WORK PERFORMED

Review of Current Structural Analysis Practice

Current structural analysis practice often is based on available codes, standards, and guidelines for performance-based seismic design. The project report includes detailed summaries for the following documents relevant to multiple-degree-of-freedom modeling in current engineering practice: ATC 40, FEMA 351, FEMA 352, ASCE/SEI 31-03, FEMA 440, ASCE/SEI 41-06, FEMA P-440A, FEMA 750, ASCE/SEI 7-10, and PEER/ATC-72-1. Those summaries identify the scope, applicability, direction on modeling, analytical requirements, ground motion characterization, and response quantities or demand parameters addressed in each document.

The approaches employed by individual practitioners can differ from prescribed methods for a variety of reasons, including differences in the focus of their practice, the need to resolve engineering issues not fully addressed in available resources, past experience, familiarity with more recent research, or judgment that the documents are deficient in some way. While most practitioners employ linear static and linear dynamic analysis procedures for nearly all design, evaluation, and rehabilitation projects, some advanced practitioners routinely use nonlinear analysis procedures in their work. To establish the context of the ATC-76-6 project, information was obtained from practicing engineers who routinely perform nonlinear structural analysis using various methods. Their observations are summarized in the project report.

Review of Recent MDOF Modeling Research

The scope of the investigative effort included an extensive review of existing research on MDOF modeling. The purpose of this review was to identify and assemble recent available research that could be used to address the challenges associated with nonlinear MDOF modeling in current engineering practice. Review of available research was focused on identifying possible improvements to nonlinear static analysis procedures and possible methods of performing simplified nonlinear response history analyses and was limited to sources published in 2002 and later.

While there was an extensive volume of research investigating nonlinear MDOF effects, much of it proposing variations, complications, and enhancements to nonlinear static analysis procedures, there had not been a single comprehensive study evaluating different analytical methods and their limitations, considering a broad variety of response quantities, across a broad range of structural systems and configurations, using a consistent suite of ground motion records (or response spectra). Review of available research on nonlinear MDOF effects, led to the following

conclusions that affected the problem-focused and ancillary studies conducted as part of the project:

- No single method has been identified in the literature as being uniformly applicable, consistently accurate, and relatively simple in capturing all nonlinear MDOF response quantities of interest.
- Nonlinear static analysis methods generally are incapable of representing the development of multiple inelastic mechanisms, the variety of modal interactions, and timing that produce maxima in nonlinear response history analyses.
- Of primary importance is whether or not simplified nonlinear static analysis methods can produce good estimates of the central tendency (mean or median) of a variety of response quantities needed for design.
- Investigation of various invariant load patterns, adaptive load patterns, single-mode pushover procedures, and multi-mode pushover procedures may help to define the domain over which pushover procedures can be relied upon in design.
- It is possible that a relatively small set of ground motions could be used to establish relevant response statistics in a design context.
- Inelastic spectral displacement, S_{di}, may be useful as an intensity measure for simplified record selection.

Problem-Focused Analytical Studies

The ATC-76-6 project team conducted new analytical studies to fill gaps in available research and synthesize available information into recommendations for improving nonlinear multiple-degree-of-freedom (MDOF) modeling. This section summarizes the different analysis methods, component modeling techniques, software packages, response quantities of interest, ground motion records, and structural system characteristics that were investigated.

The approach taken in conducting problem-focused analytical studies emphasized practical application. Nonlinear response history analysis, which is the most rigorous analysis method available for prediction of structural response to earthquake ground motion, is used as a benchmark against which the accuracy and complexity of less rigorous methods are measured. Rather than seeking to calibrate and further refine the approximate methods that are available at present, studies were used to assess the accuracy and complexity of those methods as they would be employed in practice.

Nonlinear static analysis methods. Three nonlinear static analysis methods were specifically investigated in the focused analytical studies. The Nonlinear Static Procedure (NSP), defined in ASCE/SEI 41-06, is the basic pushover procedure used in practice. It utilizes the application of a single invariant load pattern to determine structural response. As defined in ASCE/SEI 41-06, the load pattern is based on the first mode shape, and the target displacement is determined using the coefficient method. The Modal Pushover Analysis (MPA) procedure, initially proposed by Chopra and Goel (2001), combines results from multiple pushover analyses generated by

assuming load patterns based on the first mode and one or more higher modes. Although various authors have suggested further adaptations of the MPA method, this project used the approach favored by practitioners of determining all response quantities in a single analysis phase. The Consecutive Modal Pushover (CMP), developed by Poursha et al. (2009), considers up to three modes, applied consecutively in stages in a single pushover analysis after the application of gravity loads. Modal forces applied in each stage have an invariant load pattern. First mode forces are applied until a certain displacement is reached. The analysis then continues with incremental forces applied using a second mode distribution, and then a third mode distribution. The maximum values of response quantities in each pushover analysis are retained. Additional ancillary studies were also conducted using an extension of the CMP procedure, by changing the order in which the modal force patterns were applied, varying the signs used in load application, and computing both enveloped and averaged responses.

Software platforms. Analytical models of MDOF systems were developed using the following software platforms commonly used in research and practice: Drain-2DX, *Static and Dynamic Analysis of Inelastic Plane Structures* (Prakash et al., 1993), OpenSees, *Open System for Earthquake Engineering Simulation* (McKenna, 1997), Perform 3D, *Nonlinear Analysis and Performance Assessment for 3D Structures* (Computers and Structures, Incorporated), and SAP2000, *Integrated Software for Structural Analysis and Design* (Computers and Structures, Incorporated).

Response quantities of interest. The response quantities of interest for engineering design (i.e., demand parameters) investigated in the project are listed below. Story-level demand parameters were emphasized, but since design codes and standards generally focus attention on component-level force and deformation demands, focused studies examined the correlation between component-level demand parameters and story-level demand parameters. In each case comparisons are made between peak values, rather than time-varying values, of the parameters. Primary demand parameters addressed in all of the studies include story drift ratios, story shear forces, and floor overturning moments.

Ground motions. Nonlinear response history analyses were performed using the suite of 44 ground motion records of the far-field record set utilized in FEMA P-695 (FEMA, 2009b). Ground motion records are normalized on the basis of peak ground velocity, as discussed in FEMA P-695, and scaled by scale factors equal to 0.5, 1 and 2. These scale factors correspond to ground motions at a Los Angeles, California site with mean recurrence intervals of approximately 100, 400, and 2475 years, respectively.

Codes, standards, and guidelines governing the application of nonlinear response history analysis prescribe, for example, the use of maximum of three or average of seven ground motions, as single components or in pairs. FEMA P-750 (FEMA, 2009d) states that while such ground motion suites might "provide reasonable estimates of mean response for the individual response parameters", they certainly are not "adequate to give an accurate estimate of the variability." Because focused studies aimed to examine the relative accuracy of different analysis methods in

the context of realistic variations in response, the blind application of such codified rules was considered inadequate, and alternatives were studied. Those alternatives include other intensity measures, scaling methods, and subset selection techniques.

System prototypes. Structural system prototypes were used to test the analytical procedures, model types, demand parameters, and ground motions outlined above. Prototypes for regular structural systems and systems with special characteristics were developed. The regular structural system prototypes investigated are steel moment frames, reinforced concrete moment frames, and reinforced concrete shear walls. Individual prototypes were selected based on several criteria: (1) structure types that are commonly encountered in practice; (2) structures for which nonlinear static procedures are expected to produce accurate results and some for which they are not; and (3) structures from previous studies funded by FEMA and NIST to reduce modeling effort. Additional prototypes with special structural characteristics, including systems with explicitly modeled gravity framing, load-pattern-sensitive story mechanisms, weak-story irregularities, concentrically braced frames, and flexible roof diaphragms, were also investigated. Specific design and modeling information for individual structural system prototypes are provided in the project report.

Tables 1 and 2 summarize the problem-focused studies performed.

Table 1 Structural System Prototypes, Nonlinear Static Analysis Methods, and Software Platforms Used in Focused Analytical Studies

System prototype	Nonlinear Static Analysis Methods				Software Platforms			
	NSP	MPA	CMP	Extended CMP	OpenSees	Drain-2DX	SAP 2000	Perform 3D
2-story SMRF	x				1-bay	3-bay

3-story SCBF	x	x	x	x				x

Table 2 Structural System Prototypes, Component Models, and Damping Models Used in Focused Analytical Studies

System prototype	Component models		Damping models
2-story SMRF 4-story SMRF 8-story SMRF	Beam: Column: Panel zone:	lumped plasticity flexure lumped plasticity flexure (no axial load dependence) trilinear shear (nondeteriorating)	Rayleigh (proportional to mass and initial stiffness) 2.5% at T_1 and $0.2T_1$
2-story RCMF 4-story RCMF 8-story RCMF	Beam: Column: Joints:	lumped plasticity flexure lumped plasticity flexure shear distortion and bond slip	Rayleigh (proportional to mass and initial stiffness) 5% at T_1 and T_3
2-story RCSW 4-story RCSW 8-story RCSW	Flexure: Shear: 4-story:	fibers translational spring separate models were used with simplified rotational flexure springs and translational shear springs capped at $1.5V_n$ with pinched hysteresis)	Rayleigh (proportional to mass and initial stiffness) 2.5% at T_1 and $0.2T_1$
6-story SMRF	Beam: Column:	lumped plasticity flexure lumped plasticity flexure (no axial load dependence)	Rayleigh (proportional to mass and initial stiffness) 5% at T_1 and T_2
3-story SCBF	Brace: Beam: Grade beam: Column: Foundation: Roof deck:	asymmetric axial (with compression buckling, tension yielding, and cyclic pinching) lumped plasticity flexure with cyclic degradation lumped plasticity flexure with cyclic degradation lumped plasticity flexure with cyclic degradation (and axial load dependence) (undamped) uplift elements to allow rocking shear with strain hardening and cyclic degradation	5% thus: 2% Rayleigh (proportional to mass and initial stiffness) and 3% modal

Ancillary Studies

Ancillary studies were undertaken to expand the coverage provided by the basic systems and to investigate specific issues. The first ancillary study investigated relationships between demand parameter dispersion, ground motion scaling method, and size of ground motion data set, with the goal of finding more economical approaches for nonlinear response history analysis. The second ancillary study tested the practicality of directly determining target displacement for nonlinear static analysis. The third ancillary study (which is included in summary Tables 1 and 2 above), conducted by practicing structural engineers, applied the methods tested in primary studies (with some extensions) to models of special-case buildings encountered in practice using production software in common use among practitioners. The objective of this third study was to test the accuracy of the methods and to identify practical challenges to their implementation.

KEY FINDINGS AND RECOMMENDATIONS

Problem-Focused Analytical Studies

Table 3 summarizes ratios of response quantity estimates to median results from nonlinear response history analysis (NHRA), for each simplified analysis procedure, each demand parameter, and each regular structural system prototype. It permits head-to-head comparison of the methods employed and systems investigated, but obscures potentially meaningful differences in response over height and at various levels of intensity, which can be observed more readily in figures. Ratios less than 1.0 indicate that the nonlinear static analysis underestimates the median nonlinear response history analysis results; ratios greater than 1.0 indicate overestimation. As shown in Figure 1, the response quantity ratios tell only part of the story. Not only are the ratios for peak story drift of the 8-story steel moment frame worse than those for the 4-story structure (as seen in Table 3); for the 8-story structure, the overall deformation pattern is markedly different and the estimated response can fall outside the range of response predicted for all 44 ground motion records considered.

Table 3 Summary Ratios of Response Quantity Estimates to Median NHRA Results

System Prototype	Response Quantity Ratios[1]			
	Displacement	Story Drift	Story Shear	Floor Overturning Moment
Single-Mode Nonlinear Static Analysis				
2-story SMRF		0.9 to 1.1	0.8 to 1.0	0.8 to 1.0
4-story SMRF		0.6 to 1.3	0.3 to 0.9	0.3 to 1.0
8-story SMRF		0.4 to 1.6	0.3 to 1.0	0.3 to 1.1
2-story RCMF	0.9 to 1.1	0.9 to 1.1	0.8 to 1.0	0.8 to 1.0
4-story RCMF	1.0 to 1.2	0.8 to 1.2	0.6 to 1.0	0.6 to 1.0
8-story RCMF	0.9 to 1.5	0.4 to 1.4	0.4 to 1.0	0.4 to 0.9
2-story RCSW		1.2 to 1.6	0.9 to 1.2	0.9 to 1.3
4-story RCSW		1.1 to 1.8	0.8 to 1.3	0.8 to 1.4
4-story RCSW (δ_t – ESDOF)		0.9 to 1.1	0.8 to 1.0	0.8 to 1.1
8-story RCSW		1.3 to 2.5	0.7 to 1.3	0.7 to 1.4
Multi-Mode Nonlinear Static Analysis (Modal Pushover Analysis)				
4-story SMRF		0.7 to 1.1	0.8 to 1.0	0.8 to 1.0
8-story SMRF		0.7 to 1.9	0.7 to 1.2	0.8 to 1.2
2-story RCMF	0.9 to 1.1	0.9 to 1.1	0.8 to 1.0	0.8 to 1.0
4-story RCMF	1.0 to 1.2	0.8 to 1.2	0.8 to 1.0	0.8 to 1.0
8-story RCMF	1.0 to 1.5	0.7 to 1.5	0.8 to 1.1	0.8 to 1.2
4-story RCSW		1.0 to 1.6	1.0 to 1.3	1.0 to 1.8
8-story RCWS		1.0 to 1.4	0.8 to 1.2	0.9 to 1.2

System Prototype	Response Quantity Ratios[1]			
	Displacement	Story Drift	Story Shear	Floor Overturning Moment
Multi-Mode Nonlinear Static Analysis (Consecutive Modal Pushover)				
2-story RCMF	0.9 to 1.1	0.9 to 1.1	0.8 to 1.2	0.8 to 1.2
4-story RCMF	1.0 to 1.2	1.0 to 1.4	0.7 to 1.4	0.7 to 1.4
8-story RCMF	0.9 to 1.5	0.4 to 1.4	0.4 to 1.0	0.4 to 0.9

[1] Values are the minimum and maximum ratios of estimated response quantity to median value from nonlinear response history analysis.

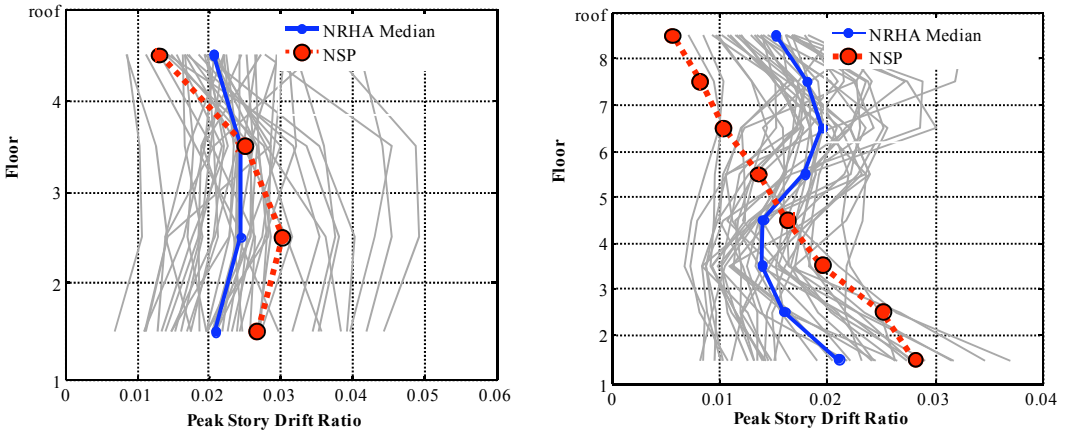

Figure 1 Comparison of nonlinear response history analysis results (median and dispersion) to results from single-mode nonlinear static analysis for 4-story and 8-story steel moment frames (at a scale factor of 2.0)

For the regular structural system prototypes investigated, the following general observations were made:

- For the 2-story systems considered, response quantities from single-mode nonlinear static analysis generally agree well with median results from nonlinear response history analysis. Results for systems with special characteristics, however, show that this observation may not always hold true.
- The accuracy of response quantities from single-mode nonlinear static analysis decreases with increasing height. Response may be underestimated substantially for 4-story steel moment frames and 8-story reinforced concrete moment frames. Underestimation of response occurs mostly in the upper stories and varies significantly between story drift, story shear, and floor overturning moment response parameters.
- In general, estimates of demand parameters for reinforced concrete shear wall structures were better than those for moment frame structures of the same height, provided the target displacement estimate is reasonably accurate.

- Use of multi-mode nonlinear static analysis generally improves the prediction of demand parameters for regular steel and reinforced concrete moment frame systems. In the case of 8-story structures, however, response prediction was still substantially underestimated.
- Use of multi-mode nonlinear static analysis may improve or worsen the prediction of demand parameters for reinforced concrete shear walls, but in most such cases, the response is overestimated.

When judging the adequacy of analytical methods for design decisions, the relevance of the response quantity to design should be considered. For instance, column axial forces due to earthquake loading, which are related to floor overturning moments, may be a more critical design consideration in lower stories than in upper stories. Also, differences in analytically predicted response quantities can indicate changes in performance, but the significance of such differences must be considered in light of the acceptance criteria that define performance. In some cases (e.g., non-ductile components) small changes in a response quantity can lead to large differences in expected performance, but in other cases (e.g., ductile components) performance can be relatively insensitive to changes in a response quantity.

Ancillary Studies

Ground motion subset selection. The approaches studied were successful at producing estimates of median and dispersion values with relatively small subset sizes. Error in the estimates generally decreased as the subset size increased, with relatively good estimates being obtained with 5 records. For estimates of the median using 5 records, mean absolute errors (for story drift, floor acceleration, story shear, and overturning moment) ranged between approximately 3 and 10%, while maximum absolute errors ranged between 20 and 30%. Mean and maximum errors for component-level response quantities (e.g., beam and column plastic rotations) were much larger.

Direct determination of target displacement. In nonlinear static analysis, target displacements have conventionally been determined by equivalent linearization or displacement coefficient approaches, using relationships between the peak displacement response of a yielding SDOF oscillator and that of an elastic counterpart, established on the basis of past computations. An ancillary study investigated the determination of target displacement by two alternative approaches: direct computation by means of nonlinear response history analysis of an equivalent SDOF system, and application of the open source software tool, Static Pushover 2 Incremental Dynamic Analysis, SPO2IDA (Vamvatsikos and Cornell, 2005).

Both approaches were found to produce useful estimates of peak displacement and are recommended as replacements for the displacement coefficient and equivalent linearization approaches. In particular, they are highly recommended in cases where: (1) the target displacement is in the negative tangent stiffness region of the global pushover curve, and (2) the pushover curve is not close to linear before global yielding occurs (e.g., stiffness changes that occur between the pre- and post-cracking regimes of reinforced concrete or masonry structures).

Practical implementation of analysis methods. This ancillary study identified the following challenges to practical implementation of nonlinear response history analysis:

- More information is needed to perform nonlinear response history analysis than is needed for pushover analysis. Appropriate models must be selected and implemented for structural damping and cyclic hysteretic behavior, and proper calibration requires interpretation of experimental test data.
- Ground motion records must be appropriately selected and scaled and applied to the model. At present there is no standard set of procedures for selecting and scaling ground motions.
- A wide variety of structural analysis software is currently in use by practicing engineers, yet only a limited subset of these is capable of nonlinear response history analysis. Software that is capable of advanced analysis is often less capable of more basic structural analysis and/or design tasks, necessitating the development of multiple structural models.
- Since nonlinear response history analysis requires more solution steps than pushover analysis, a nonlinear response history analysis model might need to be smaller and less complex than a pushover analysis model.

Preliminary work to extend the Consecutive Modal Pushover method found that varying the sequence and sign of the modal responses could encompass the various deformation mechanisms found to occur in the corresponding suite of response history analyses. If each CMP analysis is treated as a separate "earthquake," it may be useful to average results for deformations and envelope results for forces, but further investigation is needed to better understand potential limitations in the application of the Extended CMP concept.

Assessment of Nonlinear Analysis Methods

Engineering design decisions are concerned with component forces and deformation demands. Methods for prediction of response, whether local (e.g., component forces and deformations), intermediate (e.g., story drifts and shears), or global (e.g., roof displacement or collapse), depend on the design objective. Good seismic design goes beyond code-based quantitative demand assessment to include good judgment and qualitative evaluation, in which exact numbers are less relevant than understanding of behavior. Simple nonlinear static analysis methods can provide valuable qualitative insight in the evaluation and design process, but care is necessary when they are used alone to establish design quantities.

Nonlinear static procedures. By definition, nonlinear static procedures cannot, except in very simple cases, provide accurate demand predictions for dynamic loading. Many attempts have been reported in the literature to account for these effects, but in most cases the effort needed for implementation defeats the purpose of simplified analysis. Justification for the use of a nonlinear static procedure depends on the procedure employed, the type and configuration of the structural system, the degree of inelastic response expected, and the objectives of the analysis effort.

In general, nonlinear static analysis is always useful and should be part of every evaluation process concerned with inelastic behavior, whether or not the objective is rigorous quantification of demand parameters. Nonlinear static analysis is helpful in many situations, including the following:

- Checking and debugging a nonlinear analysis model, and evaluating the fairness of modeling assumptions
- Augmenting understanding of the yielding mechanisms and deformation demands
- Understanding of behavior and of existence of an adequate load path
- Investigating alternative design parameters and how variations in the component properties can affect inelastic response
- Providing an estimate of the lateral strength of the structure, and estimating structure overstrength in relation to seismic design loads
- Providing information to help establish a force-displacement capacity boundary of a structure in order to estimate global response characteristics such as roof displacement using an equivalent SDOF system
- Providing a global understanding of base shear versus roof displacement response, including estimates of post-yield stiffness and displacement at which the tangent stiffness becomes clearly negative or behavior is close to collapse
- Discovering locations of excessive deformation demands that should become the focus of more detailed study
- Discovering potential problems caused by overloading components with inadequate ductility
- Discovering potential problems caused by story-based strength and stiffness discontinuities, P-Delta effects, and strength deterioration

Nonlinear response history analysis. In practice, appealing features of nonlinear response history analysis include the following:

- More realistic and explicit modeling of response is possible, producing more reliable assessment of seismic performance.
- Possible responses, and their corresponding probabilities, can be determined.
- Generation and application of artificial static load patterns is not required.
- The significance of cyclic loading and associated deterioration can be assessed directly.
- Lateral dynamic instability can be addressed directly.

However, these improvements come at a cost of additional effort and complexity of the procedure. In concept, the major differences associated with modeling for nonlinear response history analysis include the need for a representative set of ground motions, and the need to model more completely the hysteretic behavior of structural components.

It is suggested that demand prediction from nonlinear response history analysis based on the simplest hysteresis diagram is more realistic than demand prediction from a nonlinear static analysis. Modeling of the "backbone curve" (or force-displacement capacity boundary) of individual components is needed one way or another, and the use of a simple component model becomes the core of facilitating the use of nonlinear response history analysis.

Treatment of Variability in Design

Treatment of uncertainty and variability in current code provisions is completely obscured in nonlinear static procedures, and extremely simplistic in nonlinear response history analyses. This neglect of uncertainty may compromise the ability to design for reliable performance.

Even where design decisions are based on central tendencies without explicitly including variability, awareness of the sources of variability (and their corresponding magnitudes) can inform qualitative judgments made in selecting and applying design and analysis methods. For instance, recognizing the likely range of displacement response or the degree to which a small subset of ground motion records reflects the inherent variability of a larger population of representative records may prevent unrealistic confidence in marginal analysis results or may mitigate concern about inaccuracies in simple analysis methods.

Codes, standards, and guidelines that address nonlinear analysis often target median or mean response quantities but require consideration of variability in some manner. Application of probabilistic methods allows direct consideration of such variability. While the characterization of uncertainty is somewhat crude at present, explicit incorporation of rough measures of uncertainty is preferable to ignorance and neglect. The project report recommends an approach to include explicit consideration of variability in nonlinear response history analysis, with possible extensions for nonlinear static analysis.

ABSTRACT

This paper discusses the effectiveness of simplified nonlinear static methods for predicting the seismic response of various steel moment resisting frames (MRFs) and shear wall structures. Different nonlinear static analysis procedures are discussed. Results from focused studies of different archetype structural systems are compared with nonlinear response history analysis (NRHA). The main engineering demand parameters considered are story drift ratios, story shear forces and overturning moments. Suggestions are made for improving accuracy and required effort of alternative nonlinear static procedures used to predict the seismic response of steel MRF and shear wall structural systems.

INTRODUCTION

In civil engineering practice it is common to employ nonlinear static analysis procedures (known as pushover analysis) for design, evaluation and rehabilitation of structural systems. The pushover analysis (PA) is a useful analytical tool in order to assess in an approximate manner the inelastic seismic demands of a structural system, such as story drift ratios, story shear force distributions, overstrength and inelastic element deformations. Further, PA can identify regions in which the deformation demands of a structural system are high, and story mechanisms due to strength discontinuities that may not appear in an elastic analysis(Krawinkler and Seneviratna, 1998). Guidance on utilization of nonlinear static analysis procedures has been provided in various engineering documents, such as ATC-40 (ATC, 1996), ASCE/SEI 31-03 (ASCE, 2003), FEMA 440 (FEMA, 2005) and ASCE/SEI 41-06 (ASCE, 2007) and more recently in FEMA P-440A (FEMA, 2009a).

FEMA 440 concluded that current nonlinear static analysis procedures, which are based on single-degree-of-freedom (SDOF) models, are limited in their ability to capture the complex behavior of structures that experience multiple-degree-of-

freedom (MDOF) response, and that improved nonlinear analysis techniques to more reliably address MDOF effects were needed. This paper summarizes part of a study that was initiated by the National Institute of Standards and Technology (NIST) to address this need. Using FEMA 440 as a starting point, the goal is to improve nonlinear MDOF modeling for structural design practice by providing guidance on: (1) the minimum level of MDOF model sophistication necessary to make performance-based engineering decisions and (2) selection of appropriate nonlinear analysis methods.

ARCHETYPE STRUCTURAL SYSTEMS

In order to evaluate important engineering demand parameters (EDPs) from results obtained from "best estimate" nonlinear response history analysis (NRHA), we use 2-dimensional numerical models of 2-, 4- and 8-story special steel moment frames (SSMF) and reinforced concrete shear wall (RCSW) structures. These structural systems are archetypes that were designed and analyzed as part of the ATC-76-1 project concerned with evaluation of the FEMA P-695 (FEMA, 2009b) Methodology for Quantification of Building Seismic Performance Factors. Both the SSMF and RCSW structures were designed for seismic design category D_{max} (S_{DS} = 1.0g and S_{D1} = 0.60g). The EDP values obtained from such NRHA serve as benchmark values for assessing predictions by means of simplified methods. Details regarding the design of these structural systems are summarized in NIST (2010).

Steel Moment Resisting Frames: The structures comprise 3-bay moment resisting frames that serve as the lateral load resisting system of steel buildings. The final report of this project (NIST, 2010) describes the SSMFs in detail. The subset consists of three structures that have been designed based on response spectrum analysis (RSA). In summary, these buildings are,

- 2-story SSMF (Archetype ID 2-D_{max}-RSA)
- 4-story SSMF (Archetype ID 4-D_{max}-RSA)
- 8-story SSMF (Archetype ID 8-D_{max}-RSA)

Reinforced Concrete Shear Walls: The salient features of the subset of RCSWs utilized in this study are summarized below. The subset consists of three structures, designated here as,

- 2-story ATC-76-1 RCSW (Archetype ID 12)
- 4-story ATC-76-1 RCSW (Archetype ID 13)
- 8-story ATC-76-1 RCSW (Archetype ID 14)

Note that the structures have been designed with a low $0.075A_g f_c'$ axial stress level.

NUMERICAL MODELING OF STRUCTURAL SYSTEMS

Steel Moment Resisting Frames: The bare frame structure is analyzed with the latest version of either the Drain-2DX program (Prakash et al., 1993) or the Open System for Earthquake Engineering Simulation (OpenSees) platform

(http://opensees.berkeley.edu, McKenna, 1997, Version 2.1.1), utilizing recently developed component moment-rotation models (Lignos and Krawinkler, 2009, 2011). The models for flexural behavior of steel components, which are identical in the Drain-2DX and OpenSees versions used in this study, are based on the point hinge concept and utilize a backbone, a bilinear hysteretic model, and cyclic deterioration parameters discussed in detail in Lignos and Krawinkler (2009, 2011). The deterioration parameters are based on regression equations derived from experimental results and provide different values for different steel W-sections as a function of geometric section properties and material properties that control deterioration in strength and stiffness due to local and lateral torsional buckling (Lignos and Krawinkler, 2011). This component model is referred to as the "modified IK model," and analysis performed based on this component model is referred to as Analyt.M1. Results obtained with Analyt.M1 account for cyclic deterioration in NRHA but they do not account for cyclic deterioration in a pushover analysis, which is based on the initial backbone curve. An example of global pushover curves for the 4- and 8-story SSMFs is shown in Figure 1 after utilizing the Analyt.M1 component model.

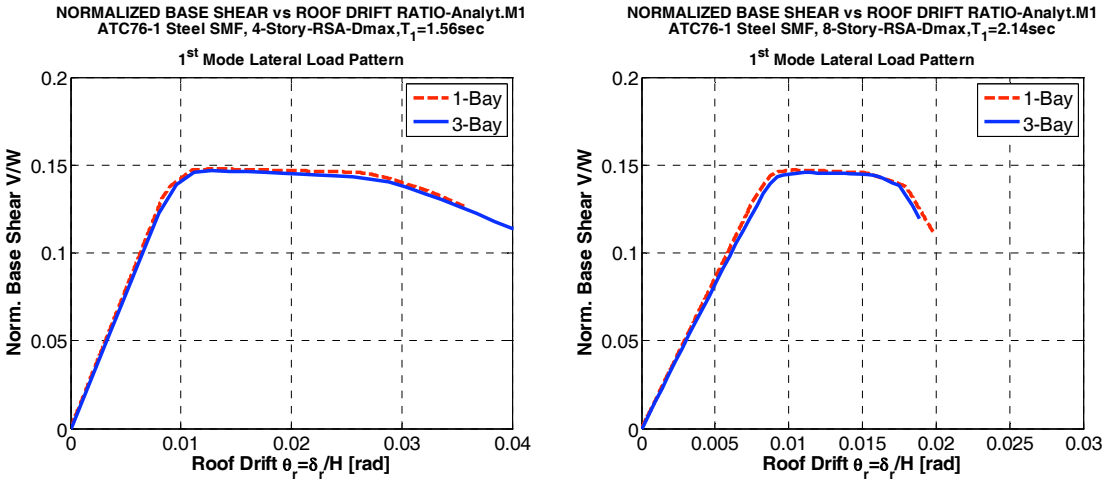

Figure 1. Comparison of global pushover curves ($V_l/W - \theta_r$) of 1- and 3-bay steel SMF analytical models, 4-, and 8-story steel SMFs.

It is often acceptable to represent all moment resisting frames by a single bay frame, resulting in a simplified model. Such a model reduces the computational effort and often facilitates interpretation of global results. But the simplified model may not be adequate to extract local demands such as plastic hinge rotations in individual components and axial and shear forces in columns. Thus, its primary purpose is to assess global and story level EDPs and to detect weaknesses that may become the subject of a more detailed evaluation. The resulting single bay frame is similar to the 'fishbone' model used extensively in Japan (Luco et al., 2003), with the added advantage that overturning moments and column axial deformation effects are represented in the model. Figure 1 shows a comparison of global pushover curves of 1- and 3-bay steel SMF analytical models of the 4-story and 8-story steel SMFs. Details regarding the improved 'fishbone' model are summarized in NIST (2010).

Reinforced Concrete Shear Walls: Displacement-based beam-column elements together with translational shear springs were used to model wall elements for all the shear wall archetypes. The OpenSees C02 model was used for modeling both confined and unconfined concrete. Concrete crushing was taken as the point where the post-peak linear descending branch reaches the residual concrete stress (defined as 20% of the peak confined concrete stress). Confined concrete model parameters were varied over the wall height at locations where transverse reinforcement changed. Concrete tensile strength (f_t), concrete tensile modulus (E_t), and unloading parameter (λ), which defines the unloading slope in terms of the initial concrete modulus (unloading slope = λ_{E_0}), were selected based on the information provided by Orakcal et al. (2006). Reinforcement was modeled as a "hysteretic material" in OpenSees. Expected values of yield and ultimate strength of reinforcement were taken as 68 ksi and 100 ksi, respectively. A tensile strain value of 0.05 was selected to correspond to failure associated with rebar buckling and subsequently rebar fracture. After reaching a strain of 0.05, the stress capacity of the reinforcing bar drops to near zero. Flexural behavior was modeled by 6"x6" fiber elements. Shear behavior was modeled by a translational shear spring. Such a spring was inserted in every story. The properties of the shear spring were based on the NIST (2010) study.

NONLINEAR STATIC PROCEDURES

Given a prescribed lateral load pattern, there are different options for modeling a structure for pushover analysis and for selecting the method for target displacement prediction. In general, the latter is based on predicting the displacement demand for an equivalent single-degree-of-freedom (SDOF) system that represents the first mode characteristics of the multi-degree-of-freedom (MDOF) structure and mapping this demand back to the global pushover curve to find the point at which the structure should be evaluated (sometimes referred to as performance point). In the ASCE/SEI 41-06 coefficient method (ASCE, 2007) this process is greatly simplified and the equivalent SDOF system does not become an explicit part of the target displacement estimation. Figures 2 and 3 show an example of the global pushover analysis of a 2-story SSMF and 4-story RCSW structure, respectively, together with an equivalent single degree of freedom system.

Pushover Analysis Options for SSMFs: The following two options are explored for models of structural components, which then are assembled in the OpenSees analysis platform:

- **ASCE41:** ASCE/SEI 41-06 component models are used, but assuming a post-capping stiffness obtained by linearly connecting peak point C and point E of the generic ASCE/SEI 41-06 model. This modification is made in order to avoid

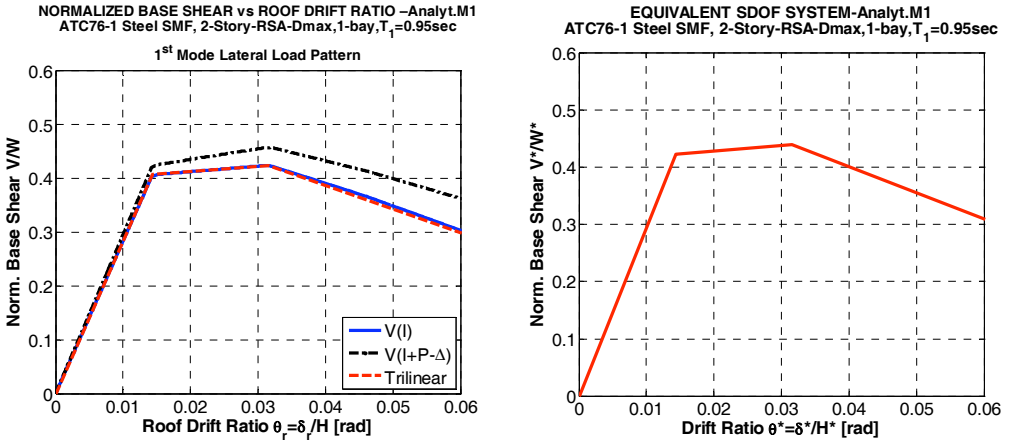
numerical analysis stability problems and to conform better to data and analysis models developed over the last decade.

- **Analyt.M1:** Modified IK component model with monotonic backbone curve is used, i.e., ATC-72-1 analysis option 1 (PEER/ATC, 2010); cyclic deterioration is not reflected in pushover analysis.

Pushover Analysis Options for Reinforced Concrete Shear Walls: In this study the following options are explored for models of structural components, which then are assembled in the OpenSees analysis platform:

- **ASCE41:** ASCE/SEI 41-06 component models are used, but assuming a post-capping stiffness obtained by linearly connecting peak point C and point E of the generic ASCE/SEI 41-06 model.
- **FM:** Fiber model described in NIST (2010) is utilized to represent flexural behavior, and a story shear spring is used to represent shear behavior.

The FM analysis option was executed for all three RCSWs, whereas the ASCE41 option was explored only for the 4-story RCSW.



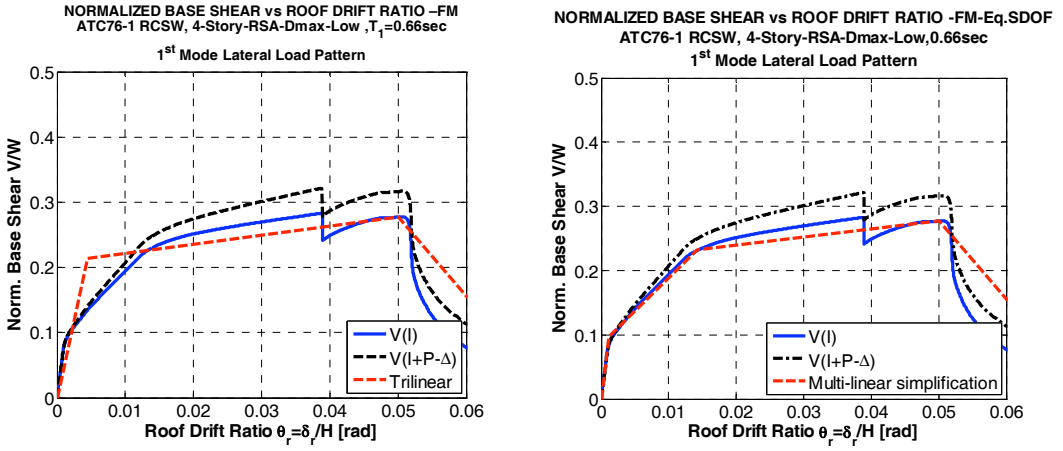


Figure 2. Utilization of global pushover of 2-story SSMF to develop and equivalent SDOF system

Target Displacement Options for Steel Moment Resisting Frames and Reinforced Concrete Shear Walls

- **ASCE41**: Target displacement obtained from ASCE/SEI 41-06 coefficient method. For a shear wall system the target displacement is obtained with an idealized trilinear force-displacement curve recommended in ASCE 41-06 as shown in Figure 3a. This curve utilizes an effective elastic stiffness obtained by placing a line through the displacement at $0.6V_y$.
- **EqSDOF:** Target displacement based on median displacement obtained from a first mode equivalent SDOF system and NRHA using the 44 ground motions of the FEMA P-695 set and the analysis tool IIIDAP (Lignos, 2009). Equivalent SDOF properties are obtained from the base shear V_I – roof displacement pushover curve (not the $V_{I+P-\square}$ – roof displacement pushover curve), which implies that P-delta effects are accounted for approximately in the development of

the equivalent SDOF system (see Figure 2). In the case of shear wall structures in which the global pushover curve shows a clear kink around cracking, the idealized force-displacement curve is better represented by a multi-linear curve that has at least 4 stiffnesses (pre-cracking, post-cracking, post-yielding, and post-capping) as shown in Figure 3.

It should be noted that the primary focus is on target displacements that correspond to three scale factors (SF) of median ground motion intensity (SF=0.5, 1.0 and 2.0)

(a) (b)

Figure 3. Utilization of global pushover of 4-story RCSW to develop an equivalent SDOF system; (a) ASCE 41 procedure; (b) Eq.SDOF system

Findings for Special Steel Moment Frames: Only a summary of results from all the studies is presented herein due to brevity. For illustration, peak story drift ratios, peak story shear forces and peak floor overturning moments for a scale factor of 2 are compared between NSP and NRHA for the 4- and 8-story SSMFs. A summary of findings for the 2-story frame structure is also included. It should be noted that story shear forces are obtained as the summation of the inertia and P-Delta forces noted as $V_{I+P-\Delta}$. Story shear forces are normalized with respect to the seismic weight W of the frame structure. Similarly, floor overturning moments are based on $V_{I+P-\Delta}$ multiplied by the individual story heights and are normalized with respect to the seismic weight W multiplied by the total height H of the frame structure.

2-story Steel Moment Resisting Frame: In the Analyt.M1 component model the post-yield stiffness is caused by a 10% increase in M_y regardless of the amount of pre-capping plastic hinge rotation capacity.

The ASCE/SEI 41-06 criteria for post-capping behavior result in a steep post-capping tangent stiffness leading to rapid deterioration. This does not correspond to statistical data from component tests on which the Analyt.M1 model is based (Lignos and Krawinkler, 2009, 2011). The ASCE/SEI 41-06 coefficient method pays no attention to the aforementioned differences, i.e., it results in the same target displacement prediction for both the ASCE41 and Analyt.M1 pushovers.

All target displacement predictions are within 10% of the median roof drift obtained from NRHA. NSP results compare well with NRHA results, except for the story drift predictions for SF = 2.0 based on the ASCE/SEI 41-06 pushover. The reason is the negative tangent stiffness in the post-yield range of the ASCE41 pushover.

4- and 8-story Steel Moment Resisting Frames: In theses structures the ASCE/SEI 41-06 pushover underestimates post-yield strength and deformation capacities of structures compared to the Analyt.M1 model. The latter model is based on expected values of component properties, whereas more conservative (low) values have been selected intentionally in the ASCE/SEI 41-06 modeling criteria.

The use of the low estimate ASCE/SEI 41-06 pushover model together with an equivalent SDOF model for target displacement prediction (ASCE41-EqSDOF) may provide estimates of performance that are lower than NRHA but might be justifiable. For SF = 2.0 the EqSDOF leads to 33 collapses, which are direct consequences of the relatively short yield plateau obtained in the ASCE/SEI 41-06 pushover. For all options, NSP story drift predictions show a significant deviation from median NRHA values (see Figure 4). In the inelastic range (SF = 2.0) drifts in the lower stories are overestimated and drifts in the upper stories are underestimated. This can be seen in Figure 4 that shows a comparison between peak story drift ratios along the height of the 4- and 8-story SSMFS as obtained from NRHA and alternative NSP methods.

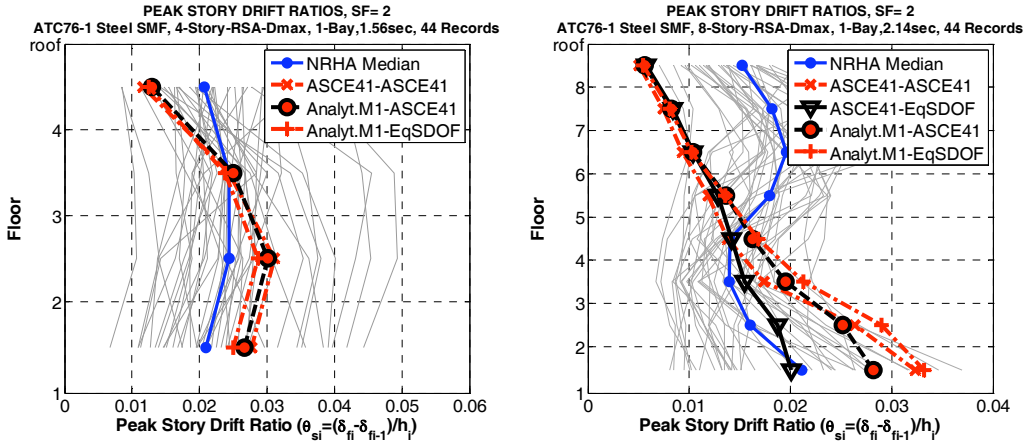

Figure 4. Peak story drift ratios for SF=2 for 4- and 8-story SSMFs

NSP story shear predictions are not good representations of NRHA results in the inelastic range (SF = 2.0). Story shears are consistently underestimated, particularly in the upper stories. But also the maximum NSP base shear, which corresponds to the peak of the $V_{I+P\text{-}delta}$ pushover curves is about 25% below the NRHA median base shear. The reason is dynamic redistribution, which amplifies story shear forces compared to those obtained from a predetermined lateral load pattern. If story shears are an important performance consideration, then the validity of quantitative values obtained from a pushover analysis diminished for the 4- and 8-story steel SMFs (see Figures 5a and 5b). Similar observations apply to floor

overturning moments, which control axial forces in columns of frame structures. In the upper stories the NSP predictions are less than half of those obtained from NRHA. This can be seen from Figures 5c and 5d that show a comparison between the peak floor overturning moments along the height of the 4- and 8-story SSMFs, respectively, as obtained by NRHA and various NSP methods. The situation is better at the base, because maximum shear forces in individual stories occur at different times. The outcome is that even for this relatively low-rise steel SMF structure NSP predictions may provide misleading quantitative information, particularly for force quantities.

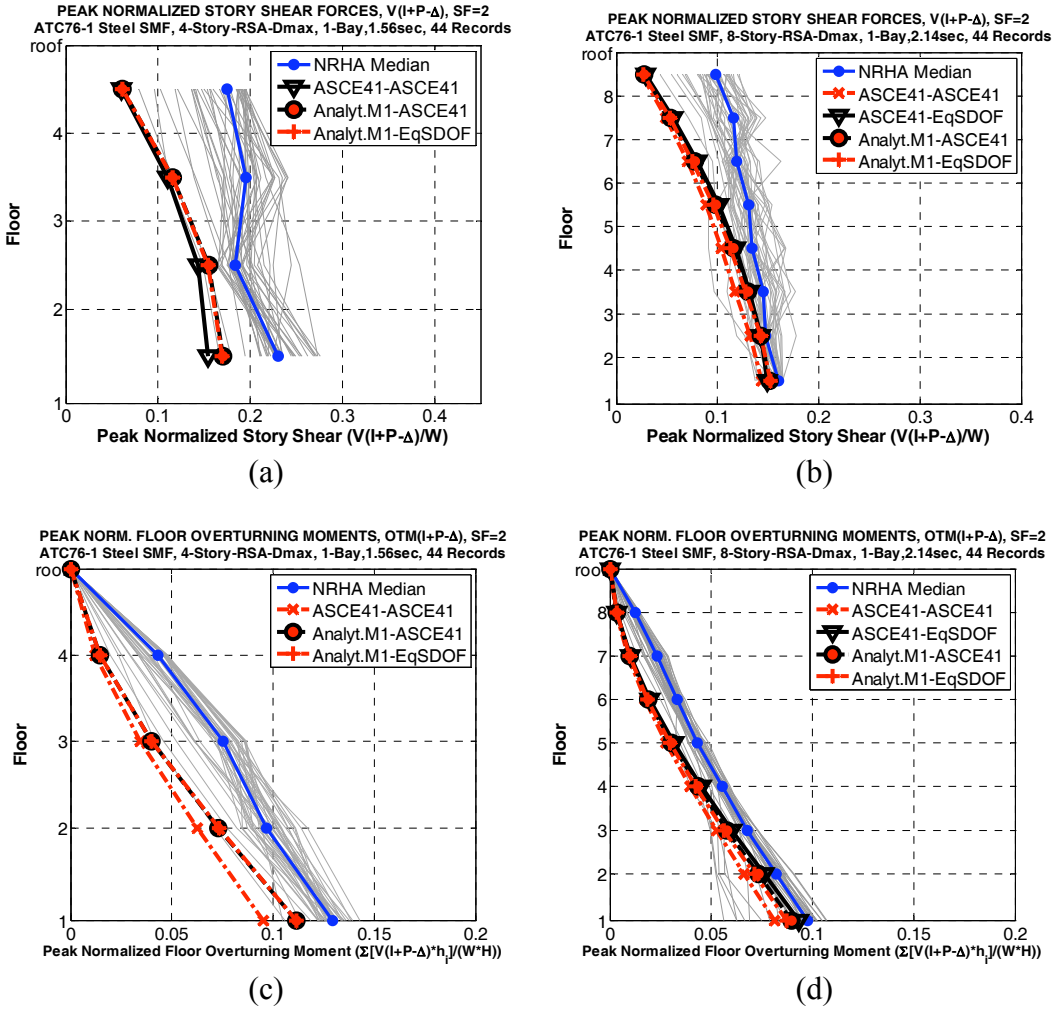

Figure 5. Peak normalized story shear forces and floor overturning moments for the 4- and 8-story SSMFs for SF=2

Findings for Reinforced Concrete Shear Walls: For all RCSW structures (2, 4, and 8 stories) the FM-ASCE41 NSP option (as recommended presently in ASCE/SEI 41-06) leads to rather poor predictions of story drift ratios. An example can be seen from Figure 6 for the 4-story RCSW. Therefore, emphasis was placed on a better representation of the global pushover curve in the equivalent SDOF system in order to obtain a better estimate of the target displacement. For this purpose the global

pushover curve was represented in a multi-linear manner rather than the trilinear manner recommended in ASCE/SEI 41-06. An example of this improved SDOF system can be seen in Figure 3b. The target displacement of the corresponding equivalent SDOF system was predicted with the program IIIDAP (Lignos, 2009), by subjecting the equivalent SDOF system to the set of 44 FEMA P-695 ground motions and computing the median displacement, which was then mapped back to the MDOF domain. This mapped value was used as target displacement to predict the EDPs from the global pushover. The EDP predictions obtained in this manner (denoted as FM-Eq.SDOF) show a large improvement over the predictions obtained from use of the trilinear ASCE/SEI 41-06 equivalent SDOF system for SF=0.5 and 1.0. Figures 6 and 7 summarize the peak story drift ratios, normalized peak story shear forces and peak normalized overturning moments along the height of the 4-story RCSW structure for the two scale factors of interest.

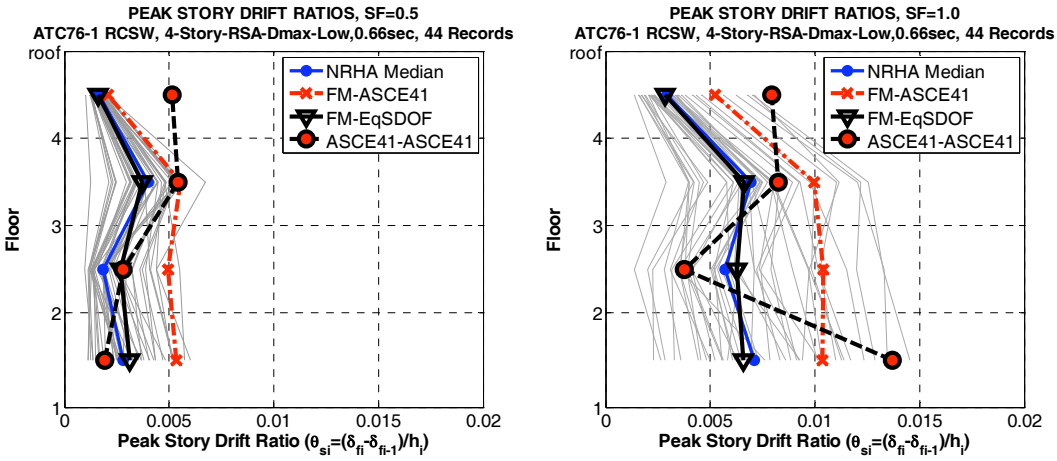

Figure 6. Peak story drift ratios for the 4- story RCSW for SF=0.5 and 1.0

As an alternative, EDP predictions for the 4-story RCSW were also obtained from using ASCE/SEI 41-06 component models to perform the pushover analysis together with the ASCE/SEI 41-06 target displacement procedure (ASCE41-ASCE41 option). The challenge here was to determine moment and shear force strength properties based on ASCE/SEI 41-06 recommendations. The values for bending strength obtained from the FM model and computed from ACI criteria together with ASCE/SEI 41-06 criteria for expected material properties differ by a significant amount. Due to brevity, details about this model can be found in NIST (2010) report.

The estimated strength values (M_c) are significantly larger than would be calculated from basic engineering models and using the reinforcement layout provided in the NIST (2010) report. The FM peak moment value M_c can be obtained only with a much larger axial force that was used in design of this structure. The bending capacity of the wall is very sensitive to the axial force in the wall. A small difference in axial force changes the bending capacity by a large amount, and consequently the failure mode in the wall may change from bending to shear or vice versa. Nonlinear dynamic response in a wall that deforms primarily in shear may be very different from that deforming primarily in bending. This is the reason for the large differences between NSP predictions (ASCE41-ASCE41) compared to those

obtained from FM-ASCE41 and FM-Eq.SDOF in story drift ratios (see Figure 6) and peak story shear forces and overturning moments (see Figure 7). ASCE41-ASCE41 predictions were possible only for SF = 0.5 and 1.0, because for larger ground motion scale factors the predicted roof drift exceeded the deformation capacity indicated by the ASCE/SEI 41-06 pushover.

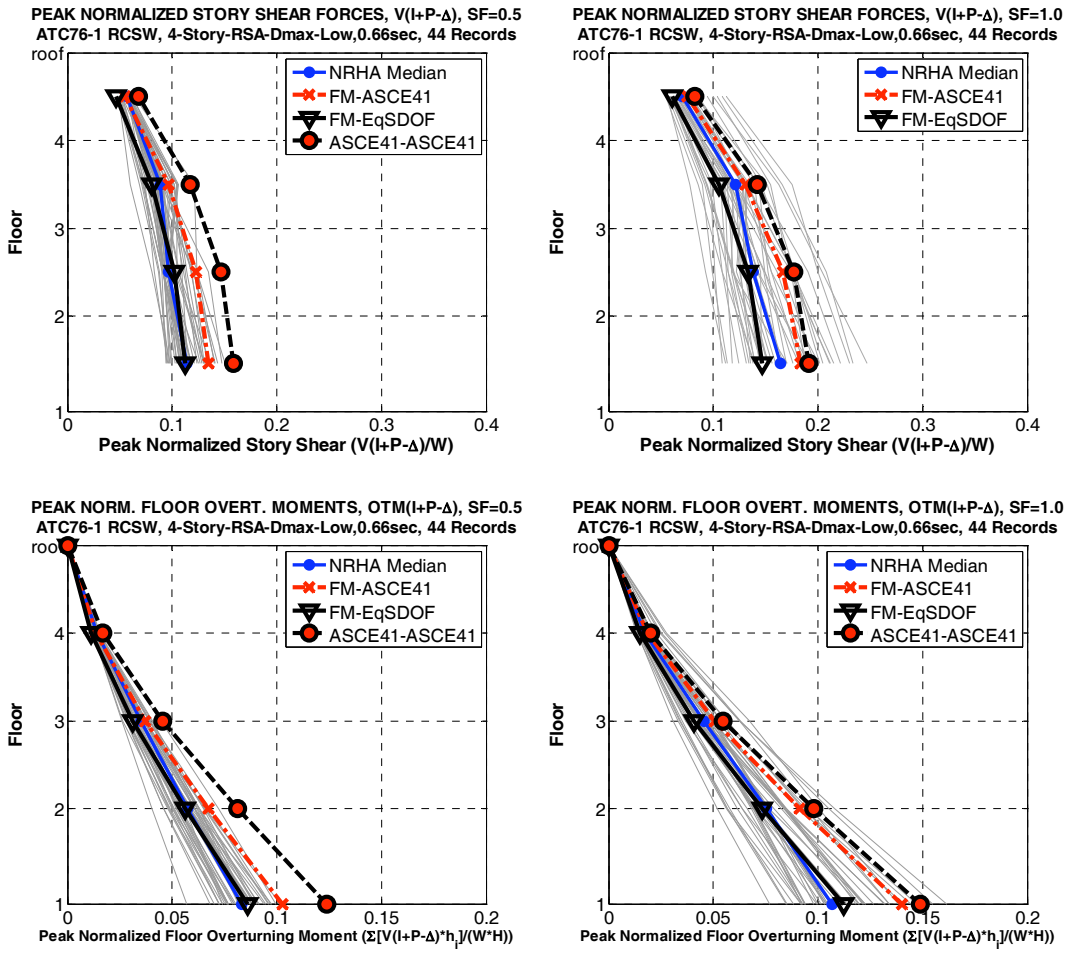

Figure 7. NSP to NRHA comparison, 4-story ATC-76-1 RCSW, three different NSP options, SF = 0.5 and 1.0.

The upshot is that there is a large discrepancy between EDP predictions obtained from a fiber model pushover analysis and an ASCE/SEI 41-06 pushover analysis. This study can only point out this discrepancy but cannot attempt to solve it. The discrepancy is evident in the NSP predictions. The ASCE41 pushover predicts unacceptable performance (represented by intolerable roof drift in the ASCE/SEI 41-06 pushover and by collapses in NRHA with the FM model) at ground motion intensities (represented by the scale factor SF) less than one third of that predicted by the FM model. These observations do not imply that the ASCE/SEI 41-06 component models are incorrect; it merely implies that there are huge differences between a pushover curve obtained from ASCE/SEI 41-06 and a pushover curve obtained from the FM model used in the ATC-76-1 study.

Given that the FM model is an appropriate model to predict EDPs by means of NRHA, it is important to note that the FM-Eq.SDOF NSP approach provides a very good match with NRHA median results for all three story EDPs (drift, shear force, and OTM) – up to a ground motion scale factor of 2.0. The improvement is the multi-linear representation of the pushover curve for formation of the equivalent SDOF system, as compared to the FM-ASCE41 approach in which the pushover curve is represented by a trilinear diagram. The latter does not lead to good EDP predictions in most cases.

SUMMARY

This paper summarizes part of a study that was conducted in order to provide guidance on the selection of nonlinear static procedures (NSPs) for steel special moment frame and reinforced concrete shear wall structures. It also summarizes limitations of use for NSPs to predict engineering demand parameters. Rather than developing new, complex NSP methods, improvements on current NSP methods that are utilized in various guideline documents are suggested.

ABSTRACT

The applicability of nonlinear static procedures for estimating seismic demands in a variety of building types was evaluated within the recently concluded ATC-76-6 project. Results are reported herein for several pushover methods applied to three RC moment frame buildings, relative to baseline data provided by nonlinear response history analysis. Response quantities include peak interstory drifts, floor accelerations, story shears, and floor overturning moments. The single-mode pushover methods that were evaluated include the N2 and ASCE 41 coefficient methods. Multi-modal pushover methods include the modal pushover with elastic higher modes, and the consecutive modal pushover. Target displacements were estimated using typical R-C_1-T relationships.

Results indicate that the good performance of the single-mode methods for low-rise buildings rapidly deteriorates as the number of stories increases. Multi-mode techniques generally can extend the range of applicability of static pushover methods, but at the cost of significant additional computation and with uncertainty about the reliability of the results.

INTRODUCTION

Nonlinear Response History Analysis (NRHA) is recognized as the most rigorous method available for the analysis of structures undergoing inelastic response to earthquake excitation, but its use in practice is limited because of doubts regarding the selection and scaling of ground motions, the interpretation of dispersion in the results, the effort required to develop valid models where cyclic degradation is modeled, and the time required for analysis of complex models. In contrast, Nonlinear Static Procedures (NSPs) have been attractive because of their relative simplicity; their use of smoothed design spectra as input (which dispenses with questions about ground motion selection) and their output of point estimates of response quantities. Nevertheless, questions have been raised about their validity, given their inability or limited ability to consider dynamic interaction of the "modes" of response. Recognition of potential limitations was made in ATC-40 (1996) and demonstrated clearly in FEMA 440 (2005). This resulted in the use of single-mode pushovers being removed from the main body of the *NEHRP Provisions and Commentary* and being restricted for the structural design of new buildings to

buildings less than 40 ft. in height in a non-binding Resource Paper in Part 3 of the *Provisions and Commentary* (BSSC 2009). A more precise quantification of the potential and limitations of pushover methods was sought in the ATC 76-6 project.

This project utilized building designs and models developed in the previous ATC projects. Only relatively simple single-mode and multimode pushover methods were considered, because NRHA generally will be preferred over pushover methods that impose complex analysis requirements on the user and those for which analysis results may have poor or uncertain reliability. Since the applicability of the simple pushover methods to one-story buildings that can be modeled using lumped mass as single-degree-of-freedom (SDOF) systems is not in question, one may view the study as evaluating the point at which additional stories cause the pushover methods to introduce unacceptable error. Evaluation of error in any response parameter may be considered relative to the mean and dispersion obtained in the response parameter obtained in NRHAs of the model for a large number of ground motions considered representative of the hazard level of interest.

BUILDINGS AND MODELS

Although a variety of building types were considered within the ATC 76-6 project, only results obtained for three reinforced concrete (RC) moment-resistant frame (MRF) buildings are reported in this paper. The 2-, 4-, and 8-story RCMRF buildings each have three bays and are regular and symmetric. Each was designed according to the 2003 IBC as described in the FEMA P695 (2009) report. Column sizes were determined to satisfy flexural strength requirements at beam-column joints as well as joint shear requirements.

Models of the building frames reported in FEMA P695 were used in the analyses reported herein. Seismic framing was modeled along with a leaning column to represent P-Δ effects, using planar (2D) models containing one-dimensional line-type elements. Gravity loads were considered using a load combination of 1.05(Dead Load) + 0.25(Live Load) for P-Δ effects as well as for determining the flexural strengths of columns; the effect of potential variation of axial load on column strength was not represented. Nonlinear in-cycle degrading response of beams, columns and joints was simulated, e.g., for beam-column plastic hinges as shown in Figure 1. Typical models have an initial elastic branch, a strain hardening branch, and a descending branch that terminates at an ultimate chord rotation equal to 0.1 rad. An initial uncracked stiffness as well as the potential for shear failures were not modeled. Rayleigh damping amounting to 5% of critical damping was assigned to the 1st and the 3rd mode of vibration, at all beams and all columns, but not at the joints. To compensate for the absence of damping in the joints, the stiffness proportional damping coefficients were increased by 10%. First mode periods based on cracked section stiffness were 0.625, 0.855, and 1.80 sec for the 2-, 4-, and 8-story frames, respectively.

GROUND MOTIONS

NRHAs were performed using the suite of 44 far-field ground motion records identified in FEMA P-695 (2009). The records were normalized as discussed in FEMA P-695. In the present study, the amplitudes of these ground motions were

further scaled by scale factors (SF) equal to 0.5, 1 and 2. These scale factors correspond to ground motion at a Los Angeles, California site with mean recurrence intervals of approximately 100, 400, and 2475 years. Figure 2 shows the mean and the median design spectra for a 400-year mean recurrence interval (SF = 1.0).

NONLINEAR STATIC PROCEDURES (NSPs)

Estimates of response parameter values were determined according to the following five analysis procedures:

- *ASCE/SEI 41-06*: Buildings are "pushed" with a first-mode lateral load pattern according to ASCE 41 until the roof reaches a target displacement defined as:

$$d_t = C_0 C_1 C_2 C_3 S_a(T_e) \frac{T_e^2}{4\pi^2} g \quad (1)$$

where S_a is the elastic spectral acceleration value at effective period T_e, C_0 is the modal participation factor, C_1 is obtained with the improved R-C_1-T relationship developed in FEMA 440 (2005):

$$C_1 = 1 + \frac{R-1}{aT_e^2} \quad (2)$$

C_2 is calculated with the formula suggested in ASCE/SEI 41-06:

$$C_2 = 1 + \frac{1}{800}\left(\frac{R-1}{T_e^2}\right)^2 \quad (3)$$

and C_3 is assumed to be equal to 1. In the preceding, R is the strength reduction factor ($R = S_a C_m W / (V_y g) \geq 1$), and C_m is the modal mass participation ratio (M_n^* / W). Site Class B soils were assumed, and therefore $a = 130$ in Equation (2).

- *Eurocode/N2 method:* The N2 method proposed by Fajfar and Fischinger (1988) has been codified in Eurocode 8 (2004). A pushover analysis is done and the resulting capacity curve is idealized using an elasto-perfectly plastic relationship to determine the period T_e of the equivalent SDOF (ESDOF) system. Different expressions are suggested for short and for medium-to-long period ranges; for the latter case d_t^* is equal to the displacement of the corresponding elastic SDOF system, calculated as:

$$d_{et}^* = S_a(T_e)\left[\frac{T_e}{2\pi}\right]^2 \quad (4)$$

where $S_a(T_e)$ is the elastic acceleration response spectrum at the period T_e.

- *Modal Pushover Analysis (MPA)*: This procedure, initially proposed by Chopra and Goel (2002), determines response parameter values for independent modal pushover analyses in the 1st, 2nd, and possibly 3rd elastic modes of vibration. Although subsequently Goel and Chopra (2005) recommended deformations determined by MPA be imposed on the structure in a second pushover analysis phase to determine member forces, the more common practice of determining all

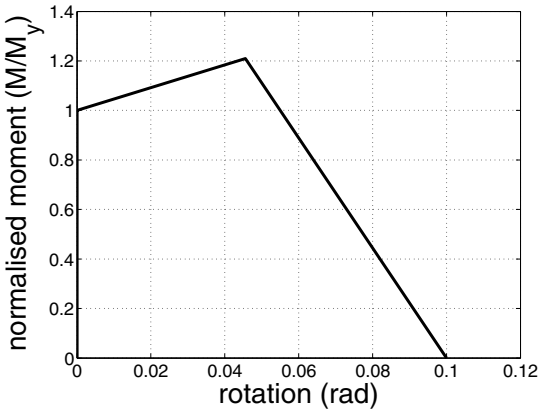

Figure 1. Typical moment-rotation relationship used for the plastic hinge part of component models.

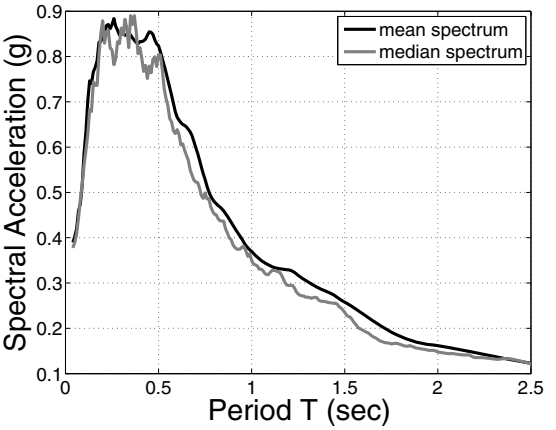

Figure 2. 5%-damped unscaled mean and median response spectra of the 44 ground motion records used in this study.

response quantities by SRSS combination of independent modal analyses (Chopra and Goel (2002)) was followed in this work. Target displacements δ_t for each mode were determined using the ASCE/SEI 41-06 R-C_1-T relationship. Each pushover analysis was done with gravity loads present; the effects of gravity loads, as determined in a separate gravity load analysis without imposed lateral displacements were then subtracted from the modal response quantities, SRSS combinations were taken, and the gravity load effects were then added to the result. Two modes were used for the 2-story RCMRF and three for the 4- and 8-story RCMRFs.

- *Consecutive Modal Pushover (CMP):* This procedure applies lateral loads approximately corresponding to the first, second, and possibly third elastic modes in sequence, all as part of a single pushover analysis. Thus, interaction of multiple modes is considered in a way that may cause different inelastic mechanisms to form. Also, the consecutive application of modal responses may come closer to representing the higher mode responses that take place when the peak displacement response is realized dynamically. Finally, member forces resulting from the analysis are consistent with member capacity limits (e.g. beam shears do not exceed the shears associated with development of a plastic mechanism). As presented by Poursha et al. (2009), the first pushover analysis uses an inverted triangular load pattern for medium-rise buildings and a uniform force distribution for high-rise buildings. A second pushover analysis is done, consisting of a sequence of first and second mode forces. The first mode forces are applied until the roof displacement equals $a_1\delta_t$, where a_1 is the first mode modal mass ratio and δ_t is the target displacement determined for the first mode. Upon reaching $a_1\delta_t$, incremental forces are applied that follow a second mode pattern. Thus, the incremental displacement used for this analysis stage is $(1\text{-}a_1)\delta_t$. A third pushover analysis is required for buildings with periods of 2.2 seconds or higher. The peak value of any demand parameter in each separate pushover analyses is compared to identify the largest (or envelope) value.
- *Modal Response Spectrum Analysis (MRSA):* For buildings responding inelastically whose deformed shapes resemble their elastic mode shapes, perhaps the simplest multimodal approach to estimate deformations is to extrapolate linear

modal response spectrum analysis results into the inelastic regime. In this case, lateral load patterns, matching those used in the MPA procedure, are used in a linear elastic analysis. Target displacements are calculated using the C_1 and C_2 relationships of ASCE/SEI 41-06; the coefficient C_3 was taken equal to 1.0. SRSS combinations of modal demand parameter values are taken to obtain the final response estimate.

RESULTS

Nonlinear Response History Analysis. Figure 3 presents selected results from nonlinear response history analysis. Median results are plotted for different scale factors. Dispersion in response values (e.g. Figure 8) to some degree reflects the method used to scale ground motion records in FEMA P695, which is based on the geomean of peak ground velocities of orthogonal ground motion components. Results for these structures indicate:

- Maximum story drift demand is higher in the lower stories while the minimum values are always at the top story. Story drift tends to concentrate in the lower stories with increasing scale factor. Higher modes appear to have an appreciable effect on story drift and story shears.
- Overturning moments tend to follow the concave pattern associated with first mode or code equivalent lateral force patterns. Dispersion in overturning moments is relatively small, attributable to the contributions of higher mode lateral forces to the overturning moment at any level tending to cancel out. Overturning moments tend to "saturate" as the scale factor increases.
- Story shears in the upper stories are significantly larger than would be expected from first mode or code equivalent lateral force patterns. Base shears developed in the dynamic analyses are larger than the capacities indicated by a first-mode pushover analysis. Story shears tend to "saturate" as the scale factor increases.

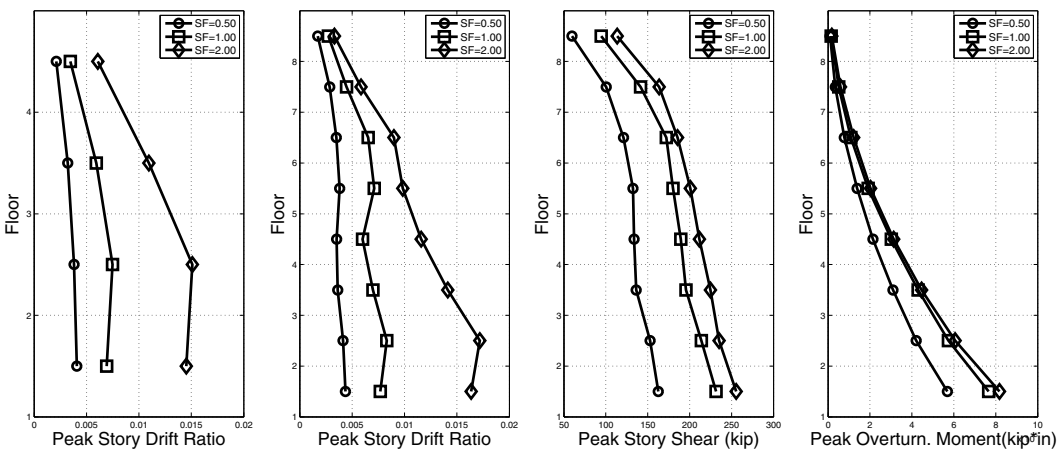

Figure 3. Profiles of median peak response quantities for SF=0.5, 1.0, and 2.0: (a) story drifts for the 4-story RCMRF, and (b) story drifts, (c) story shears, and (d) overturning moments for the 8-story RCMRF.

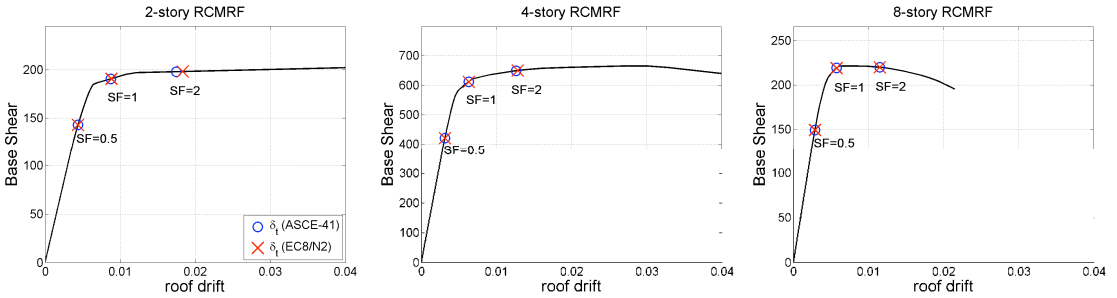
First Mode Nonlinear Static Analysis. Figure 4 shows the capacity curves obtained in first-mode pushover analyses of the three moment frames and the target displacements determined using the formulas of ASCE-41 and Eurocode 8 for the mean spectra scaled by SF=0.5, 1.0, and 2.0. Both methods produce nearly identical target displacement estimates for the three moment frames; for this reason only ASCE-41 target displacements were used for estimating response quantities in first-mode pushover analyses. Roof displacements at yield are about 0.5 - 0.6% of the height. Target displacements for a scale factor of 0.5 are in the elastic regime, those for the records scaled by 1.0 are nearly elastic, and those for a scale factor of 2.0 cause moderate inelastic response, developing system ductilities of 2-3.



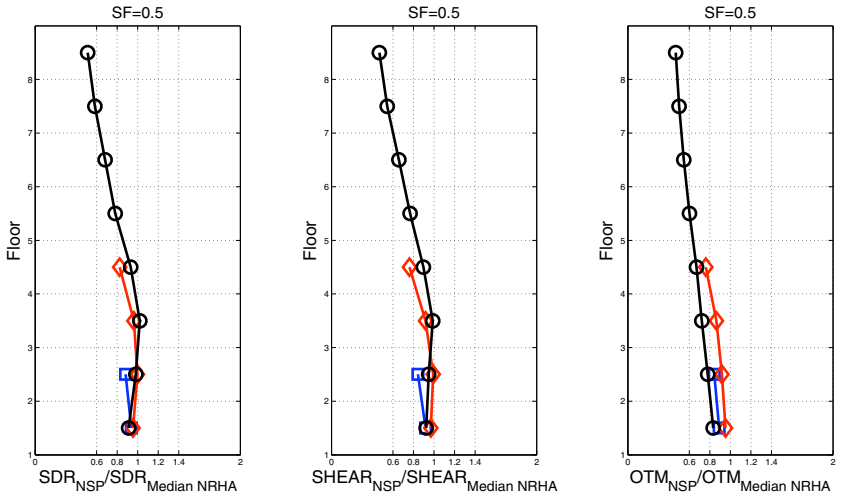


Figure 4. First mode static pushover curves and target displacement estimates for the 2-, 4-, and 8-story reinforced concrete moment frames, for ground motion scale factors of 0.5, 1.0, and 2.0.

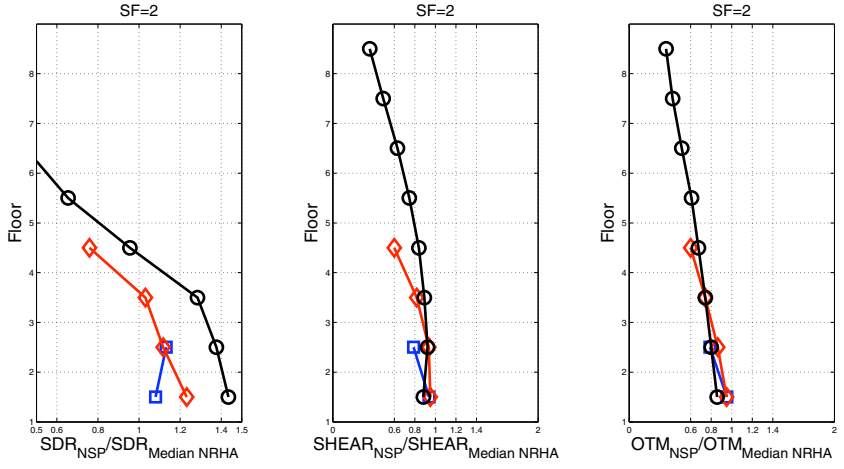

Ratios of demand parameter values determined by first mode pushover analysis and medians of the peak values obtained in NRHA are plotted over the height of each frame in Figure 5 (SF=0.5) and Figure 6 (SF=2.0). Accuracy clearly varies with scale factor (e.g. Figures 5a and 6a), response quantity (Figures 6a and 6b), and number of stories. Accuracy in the estimation of one response quantity does not signify accuracy in the estimation of other response quantities even for the same scale factor and structural model. Reasonable accuracy was obtained for the three demand parameters considered for the 2-story RCMRF, although the error in shear at the upper story slightly exceeded 20%. For the 4-story frame, the accuracy of story drifts, story shears and overturning moments degraded as the scale factor increased from 0.5 to 2.0. Errors in story drift, story shear, and floor overturning moments exceeded 20% at some locations and some scale factors at some locations in the 4-story frame. The degradation in accuracy with increase in scale factor was more pronounced for story drifts. The accuracy of NSP estimates also degraded with increase in scale factor for the 8-story frame, where the error in the top stories of story shears and overturning moments was of the order of 60%. In general, larger errors were encountered in the buildings with more stories.

Modal Pushover Analysis. Figure 7 shows the modal pushover curves for the 2-, 4-, and 8-story reinforced concrete moment frames. Target displacements determined using mean elastic response spectra for scale factors of 0.5, 1.0, and 2.0 are shown. The higher mode pushover curves did not display reversals (e.g. Hernández-Montes et al. 2004). Target displacements were such that elastic response was predicted in the independent 2nd and 3rd mode pushover analyses.

Figure 5. Ratios of first mode NSP and NRHA response estimates for SF=0.5: (a) peak story drifts, (b) peak story shears, and (c) peak overturning moments.

(a) (b) (c)

Figure 6. Ratios of first mode NSP and NRHA response estimates for SF=2.0: (a) peak story drifts, (b) peak story shears, and (c) peak overturning moments.

(a) (b) (c)

Figure 7. Static pushover curves and target displacement estimates for the 2-, 4-, and 8-story reinforced concrete moment frames, for ground motion scale factors of 0.5, 1.0, and 2.0.

For the 2-story frame, second mode contributions to floor displacements (not shown), story drifts (Figure 8a), and overturning moments (not shown) were negligible; reasonably accurate estimates of these quantities were obtained with the first mode estimates. While story shears were estimated with reasonable accuracy for a scale factor of 0.5 even with single mode pushover analysis (Figure 5b), the inclusion of second mode contributions in the modal pushover analysis procedure, while beneficial, did not sufficiently increase the story shear estimates to result in an accurate estimate of story shear at a scale factor of 2.0 (Figure 8b). This suggests a relatively severe constraint on the reliable application of both single mode and simple multimodal pushover methods.

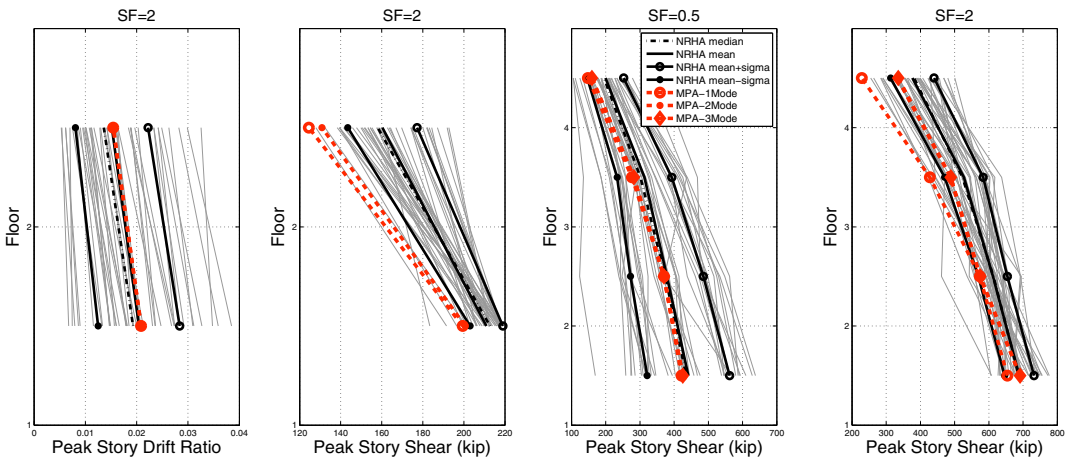

Figure 8. Estimates made with modal pushover analysis and profiles of (a) story drifts and (b) story shears for the 2-story RCMRF at SF=2, and profiles of story shears for the 4-story RCMRF at (c) SF=0.5 and (d) SF=2.

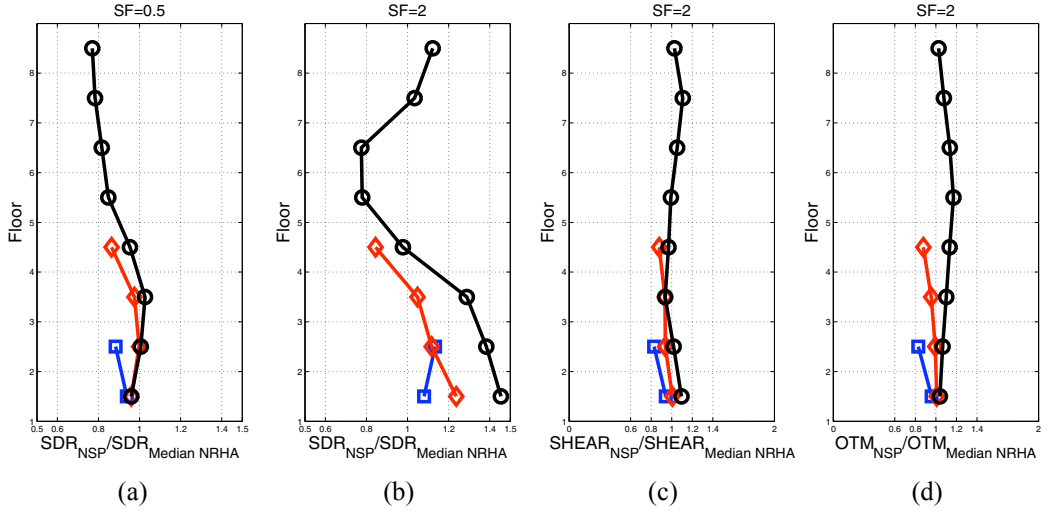

Figure 9. Ratio of modal pushover analysis results and nonlinear response history analysis results for the reinforced concrete moment resisting frames: (a) peak story drift (SF=0.5), (b) peak story drift (SF=2.0), (c) peak story shears (SF=2.0), and (c) peak overturning moments (SF=2.0).

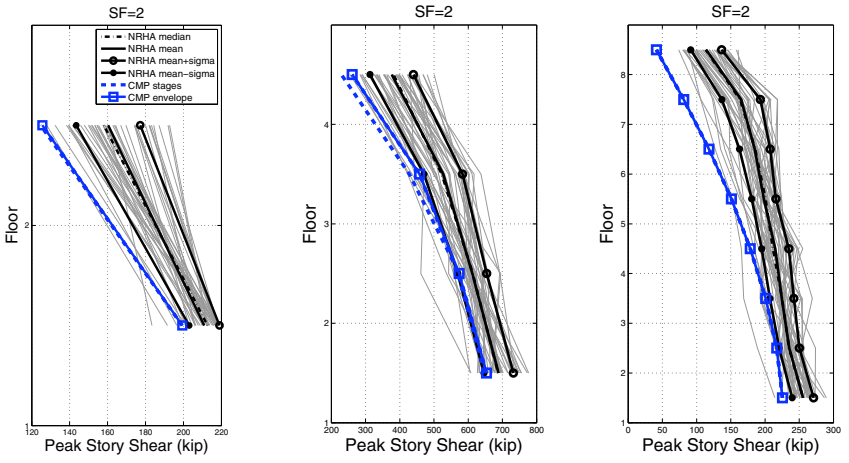
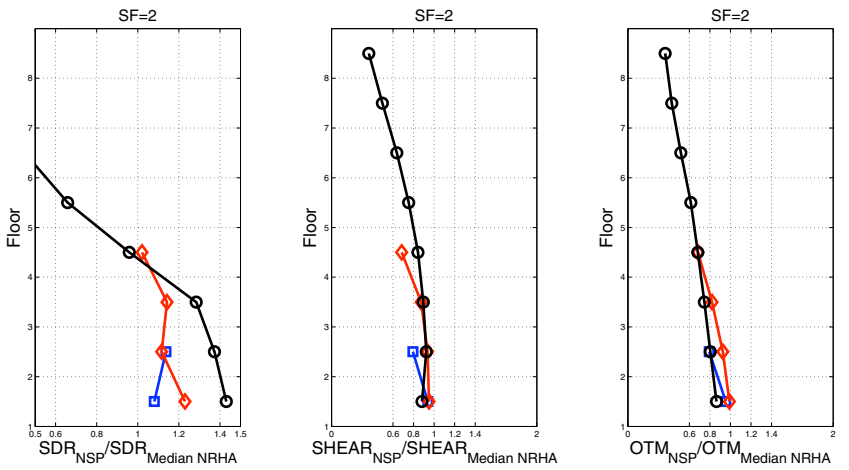
For the 4-story frame, second and third mode contributions to floor displacements (not shown) and story drifts (Figure 9b) were negligible; reasonably accurate estimates of these quantities were obtained with first mode estimates at a scale factor of 0.5 (Figure 5a and Figure 6a). In contrast to the 2-story frame, the accuracy of modal pushover analysis estimates of story shears improved as the scale factor increased from 0.5 to 2.0 (Figure 8c and Figure 8d). While second mode shears had a significant and beneficial effect, third mode story shears, while beneficial, had a relatively small contribution. Relatively accurate estimates of overturning moments were made, and these benefited from inclusion of the second mode contribution (Figure 9d compared with Figure 6c).



For the 8-story frame, second mode contributions to story drift were not negligible and improved the story drift estimates (Figure 9 compared with Figure 5a and Figure 6a), but accuracy varied with location and scale factor. In particular, the accuracy of story drift estimates improved at the upper stories at a scale factor of 2.0. The accuracy of story shear estimates also varied with location and scale factor. Both second and third mode contributions to story shears were appreciable (Figure 9c compared with Figure 6b); inclusion of higher mode story shears improved story shear estimates at the upper stories. Second mode contributions to overturning moments were not negligible and improved the estimates; overturning moments tended to be underestimated at a scale factor of 0.5 (not shown), and were slightly overestimated at a scale factor of 2.0 (Figure 9d).

Consecutive Modal Pushover. Selected results obtained by application of Consecutive Modal Pushover (CMP) analysis to the three RCMRFs are shown in Figure 10 and Figure 11. Figure 10 shows story shear results with dashed lines for the two CMP stages and with solid lines for their envelope, in addition to the single-record and NRHA curves.

For the 2-story frame, story drifts were estimated with reasonable accuracy (not shown). However, story shears were accurately estimated at a scale factor of 1.0, were significantly overestimated at a scale factor of 0.5, and were significantly underestimated at a scale factor of 2.0. Thus, relatively severe limitations on the reliable applicability of the CMP are apparent.



For the 4-story frame, the accuracy of estimates of story drift, story shear, and floor overturning moments varied with location and scale factor. For example, story shears in the upper stories were significantly overestimated at a scale factor of 0.5, and story shears over the height of the building were significantly underestimated at a scale factor of 2.0 (Figure 10b).

For the 8-story frame, peak displacements were overestimated at a scale factor of 2.0, just as occurred with the first mode and multiple mode pushover analyses. As for the 4-story frame, the accuracy of estimates of story drift, story shear, and floor overturning moments varied with location and scale factor.

(a) (b) (c)

Figure 10. Story shear estimates using consecutive modal pushover analysis for the 2-, 4-, and 8-story reinforced concrete moment resisting frame

(a) (b) (c)

Figure 11. Ratio of Consecutive Modal Pushover Analysis results to NRHA results for the reinforced concrete moment resisting frames, for SF=2: (a) peak story drifts, (b) peak story shears, and (c) peak overturning moments.

Elastic Modal Response Spectrum Analysis. Selected results from elastic modal response spectrum analysis are shown in Figure 12 for selected response quantities at scale factors of 0.5 and 2.0. In Figure 12 it is apparent that the accuracy of story drift estimates, while a function of scale factor, is on par with that of the multimodal pushover analysis method (Figure 9a and Figure 9b), while relatively good shear (Figure 12c) and overturning moment (Figure 12d) estimates were obtained under elastic response (SF=0.5) for the 2-, 4-, and 8-story frames. However, even for elastic response (SF=0.5), story shears at the upper stories and overturning moments generally were underestimated for the 4- and 8-story RCMRFs.

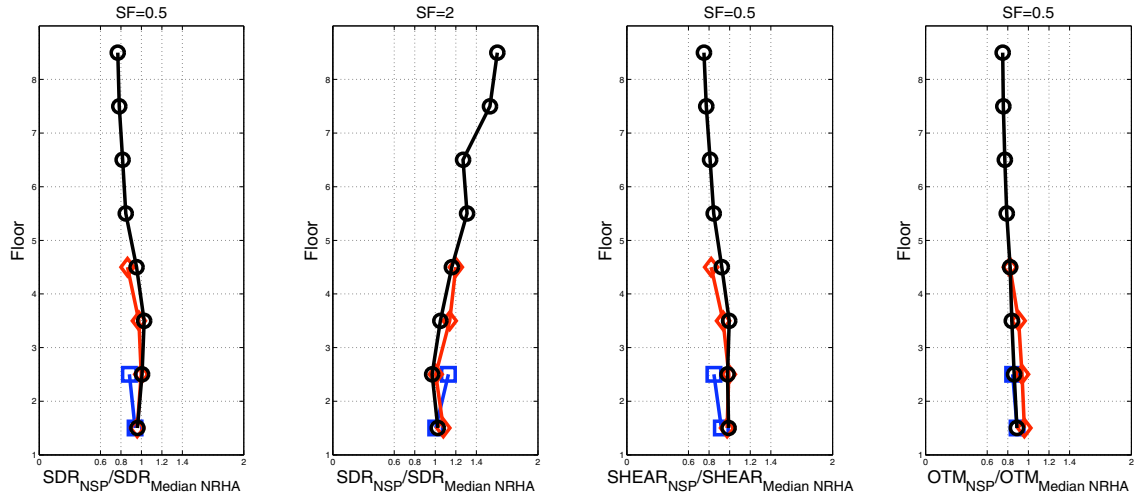


Figure 12. Ratio of elastic Modal Response Spectrum Analysis results to NRHA results for the reinforced concrete moment resisting frames, for SF=0.5: (a) peak story drifts, (b) peak story shears, and (c) peak overturning moments.

CONCLUDING REMARKS

Single-mode pushover analysis is valuable for its ability to characterize inelastic response of a building in the first mode and for illustrating the nature of the inelastic mechanism that develops in first mode response. Pushover methods often will identify, or even exaggerate, the potential for weak story response. However, neglect of higher mode contributions and interaction of "modes" in potentially causing different inelastic mechanisms to develop is a weakness in using NSP methods as a quantitative tool for evaluation of demands in multistory construction.

Accuracy of NSP estimates depends on the response quantity of interest, the intensity of inelastic response (or excitation), as well as the mechanism that develops. Acceptable error relative to median NRHA results depends on the consequences. In non-critical locations a large percentage error may be acceptable while small absolute errors may be critical in other cases. Alternatively, acceptable error might be judged relative to dispersion in NRHA results. In the authors' judgment, without proper consideration of the response dispersion inherent in multi-record NRHA, the limit of reliable applicability of single-mode pushover analysis for local response assessment appears to be about 2 stories for moment-resistant frames, while multimode-pushover analysis appears to be limited to about 4 stories. Although these limits are suggested based on limiting errors relative to median NRHA results, they are not absolute. The development of different mechanisms and issues related to degradation of components and duration of ground motion, not considered in this work, may be important. For the regular frames explored in this study, linear elastic modal response spectrum analysis provided estimates of interstory drift on par with the best multimodal pushover methods. Potential improvements to the consecutive modal pushover analysis method should be explored before fully assessing this method.

With these limitations in mind, appropriate care is advised in all applications of nonlinear static methodologies when used for quantitative, rather than qualitative, estimation of seismic performance.

ABSTRACT

This paper discusses the pros and cons of predicting structural behavior and important engineering demand parameters (EDPs) by means of either nonlinear static pushover (NSP) analysis or nonlinear response history analysis (NRHA) with simple hysteretic models. It will be demonstrated that NRHA comes out as a clear winner if the issue is quantification of EDPs, except for low-rise first mode controlled structures in which torsion is not an important consideration. It also will be demonstrated that NSP analysis has much value in understanding important behavior characteristics that are not being explored in a NRHA in which engineers usually focus on a demand/capacity assessment rather than visualization of response. The conclusion is that both NSP and NRHA have intrinsic value and that it is advisable to employ a combination of both to understand seismic performance and quantify important engineering demand parameters.

INTRODUCTION

Engineering design decisions conventionally are concerned with component forces and story drift. From basic mechanics principles it is clear that component forces depend on component deformations once a structure enters the range of nonlinear behavior. Since component strength decreases when deformations become excessive, recent design provisions for design of new structures and for retrofit of existing structures place limits, either directly or indirectly, on acceptable component deformations. Emerging performance-based design criteria place emphasis also on damage control, which necessitates control of floor accelerations and residual drift, and on explicit consideration of collapse safety, which necessitates the estimation of collapse probability for a given hazard level or for a given life span of a structure.

The upshot is that suitable methods for prediction of demands, whether local (such as component forces and deformations), or intermediate (such as story drifts and shears), or global (such as roof displacement), depend on the design objective. To put the following discussion into perspective, it is emphasized that good seismic design includes more than code based quantitative demand assessment, usually represented by demand/capacity ratios. It includes good judgment and qualitative

evaluation, in which exact numbers are less relevant than understanding of behavior. And here the value of simplified analysis, even if less accurate, increases. This point needs to be considered when judging suitability of various analysis techniques.

The following discussion presents arguments pro and con various analysis techniques, based on the experience acquired in the NIST sponsored ATC 76-6 project (NIST 2010) in which static and dynamic methods for predicting demand parameters are evaluated on 2 to 8 story archetypes of steel and reinforced concrete frame structures and reinforced concrete shear wall structures. The archetypes are described elsewhere in these proceedings (Lignos et al. 2011, Fragiadakis et al. 2011). Most of the archetypes are those designed for evaluation of the FEMA P695 methodology (FEMA 2009) summarized in NIST 2010a.

COMPONENT MODELS AND ANALYSIS PLATFORM

The following component models were utilized in predicting the static and dynamic response of the archetype structures.

ASCE41. This component model is a point hinge model based on the generic ASCE/SEI 41-06 backbone curve (ASCE 2006) but assuming a post-capping stiffness obtained by linearly connecting peak point C and point E. This modification, illustrated in Figure 1, is made in order to avoid numerical instability problems in the analysis, and to better conform to component test data developed over the last decade. This model is used only for pushover analyses.

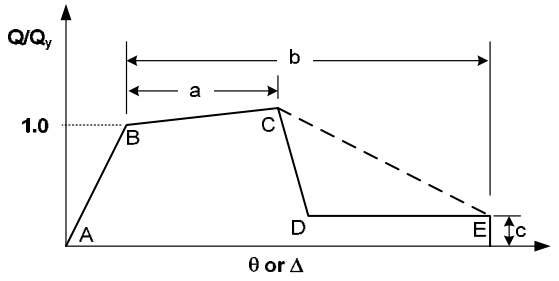

Figure 1. Modified ASCE 41 component model (PEER/ATC 2010).

Monotonic/cyclic deterioration model, Analyt.M1. This component model is a point hinge model that utilizes a modified Ibarra-Krawinkler backbone curve of the type shown in Figure 2 (Ibarra et al. 2005, Lignos and Krawinkler 2009, 2011), a bilinear hysteretic model (for steel frame structures), and cyclic deterioration parameters per analysis option 1 in PEER/ATC-72-1 (PEER/ATC 2010). The deterioration parameters for steel frame structural components are based on regression equations derived from experimental results and provide different values for different steel W-sections as a function of geometric section properties and material properties that control deterioration in strength and stiffness due to local and lateral torsional buckling (Lignos and Krawinkler 2009, 2011). Nonlinear response history analyses (NRHA) utilizing this component model accounts for cyclic deterioration effects explicitly. Nonlinear static analysis utilizing this component model does not account for cyclic deterioration because it is based on the initial

(monotonic) backbone curve. For pushover analysis a modified version of this model (Analyt.M3) was also employed in which the post-yield properties were reduced to account for cyclic deterioration effects in an approximate manner per analysis Option 3 in PEER/ATC-72-1. The pushover results obtained from all three models (ASCE41, Analyt.M1, and Analyt.M3 were very similar until the capping point (point C in Figure 1) was exceeded in several components. Thereafter, the results deviated considerably from each other.

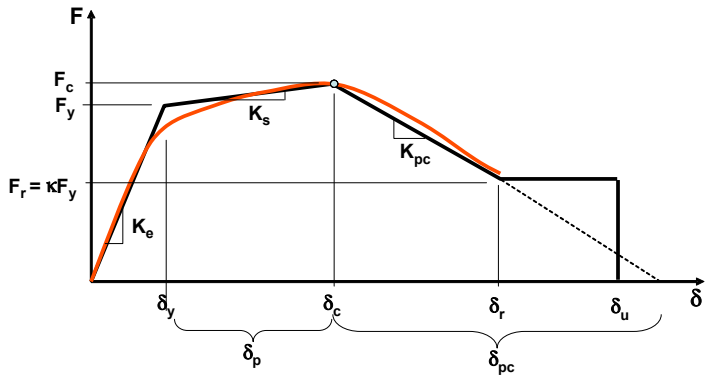

Figure 2. Backbone curve for component model Analyt.M1 (PEER/ATC 2010).

Fiber Model. For shear walls a fiber element model is employed utilized displacement-based formulation together with translational shear springs. Nonlinear degrading properties of concrete and steel materials are explicitly considered. Concrete crushing was taken as the point where the post-peak linear descending branch reaches a residual stress of 20% of the peak confined concrete stress. Confined concrete model parameters were varied over the wall height at locations where transverse reinforcement changed. Reinforcement was modeled as a "hysteretic material" in OpenSees. A tensile strain value of 0.05 was selected to correspond to failure associated with rebar buckling and subsequently rebar fracture. Details of the fiber element are presented in NIST 2010a.

Simplified Spring Model. As alternative to modeling shear wall flexural/axial behavior by means of a fiber model, simplified plastic hinge spring models were used to assist in evaluating results obtained from fiber models. Use of simplified spring models permits explicit modeling of post-yield and post-capping behavior, using modeling parameters similar to those used for the deterioration model shown in Figure 2.

Analysis Platform. Analysis was performed with the latest version of the OpenSees platform (http://opensees.berkeley.edu). The study was concerned only with 2-dimensional modeling of structures. In all analyses Rayleigh damping of 2.5% is assigned at the first mode period T_1 and at $T = 0.2T_1$.

ANALYSIS MODEL SIMPLIFICATIONS

In modeling the steel frame structures, the following simplifications have been explored. A 2-dimensional model of a moment resisting frame structure should represent, at least, the moment-frame(s) as well as all P-Delta effects tributary to the

moment frame(s). If several moment-resisting frames exist, they may be placed in parallel, presuming that the assumption of a rigid diaphragm is reasonable. Thus, a 2-D model consists of moment resisting frames, a P-Delta column, and, if presumed to be important, may incorporate a representation of the gravity system. If the focus is on global and story level engineering demand parameters (EDPs), such as story drifts and shears, it is often acceptable to represent all moment resisting frames by a single bay frame, resulting in the simplified model illustrated in Figure 3. Such a model greatly reduces the computational effort and often facilitates interpretation of global results. But the simplified model may not be adequate to extract local demands such as plastic hinge rotations in individual components and axial and shear forces in columns. Thus, its primary purpose is to assess global and story level EDPs and to detect weaknesses that may become the subject of a more detailed evaluation.

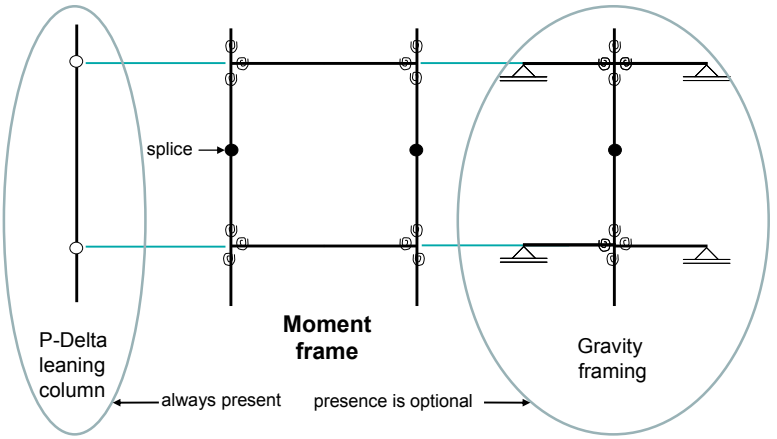

Figure 3. Simplified model of moment-resisting frame structure.

Lumping together multi-bay frames into a single bay frame can be accomplished by setting $\Sigma EI_i/L_i$ and ΣM_p of all beams equal to EI/L and M_p of the single bay beam, respectively, and setting ΣEI_i and ΣM_{pc} of all columns equal to $2EI$ and $2M_{pc}$ of the single bay columns, respectively. For taller frames in which overturning moment and axial deformations in columns are important, these effects can be approximated by setting L of the single bay frame equal to the distance between end columns of the multi-bay frame, and setting the area of the single bay column equal to the area of the end column of the multi-bay frame. This simplification is based on the assumption that overturning effects are resisted mostly by the two end columns. The approximations summarized in this paragraph are reasonable if all bays of the SMF are of about equal width, and become more approximate when spans of the SMF vary considerably.

A fishbone type model can be used to represent the strength and stiffness properties of the gravity framing that is not part of the moment resisting frame, as is shown in the right portion of Figure 3. If the gravity framing is included in the analytical model, then the column of the fishbone can be used also to represent P-Delta effects not directly attributed to the moment resisting frame. Otherwise, the need exists to provide a P-Delta (leaning) column as shown on the left of Figure 3.

The single bay simplification has been tested for the steel SMF structures. Comparisons of results obtained from a 3-bay model and the corresponding single-

bay model (both incorporate a P-Delta column) can be made from Figure 4, which shows peak story drifts obtained from NRHA in which the models are subjected to the FEMA P695 ground motion set scaled by a factor of 2.0 (FEMA 2009).

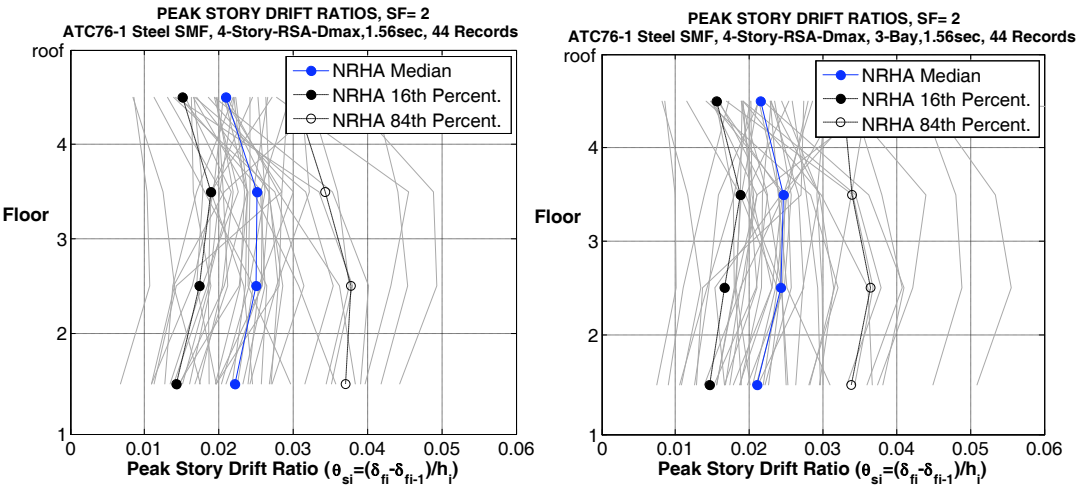

Figure 4. Comparison of peak story drift ratios from NRHA with 44 ground motions, 1- and 3-bay models of 4-story steel SMF

ASSESSMENT OF NONLINEAR STATIC PROCEDURES

By definition, nonlinear static procedures cannot, except in very simple cases, provide accurate demand predictions for dynamic loading. The reasons are higher mode effects and inelastic redistribution that affect modal contributions in every increment of inelastic response. Many attempts have been reported in the literature to account for these effects, but in most cases the effort needed for implementation defeats the purpose of simplified analysis. Justification for the use of a nonlinear static procedure depends on the procedure employed, the type and configuration of the structural system, the degree of inelastic response expected, and the objectives of the analysis effort.

As a preamble, nonlinear static analysis is always useful and should be part of every evaluation process concerned with inelastic behavior, whether or not the objective is rigorous quantification of demand parameters. An incomplete list of arguments for performing nonlinear static analysis is as follows:

- Check and debug a nonlinear analysis model
- Evaluate the fairness of modeling assumptions
- Augment understanding of the yielding mechanisms and deformation demands
- Augment understanding of behavior and of existence of an adequate load path
- Investigate alternative design parameters and how variations in the component properties may affect response
- Augment understanding of behavior close to collapse
- Provide a relatively good estimate of the lateral strength of the structure
- Estimate structure overstrength in relation to seismic design loads

- Provide information that helps to establish a force-capacity boundary of the structure that can be used to estimate global response characteristics (e.g., roof displacement) from an equivalent SDOF system.
- Provide a global picture of the structure's base shear – roof displacement response, including estimates of post-yield stiffness and displacement at which the tangent stiffness becomes clearly negative
- Discover locations of excessive deformation demands that should become the focus of more detailed study
- Discover potential problems caused by overloading components with inadequate ductility
- Discover potential problems caused by story based strength and stiffness discontinuities
- Discover potential problems caused by P-Delta effects and strength deterioration

In practice, the use of nonlinear static analysis methods for quantification of demand parameters (and demand/capacity ratios) is appealing because this type of analysis produces a single, clear result without the need for selection and scaling of ground motion records. However, with those positive features come the following drawbacks:

- The single, clear, static result will deviate from the median result obtained from NRHA with a set of representative ground motions. The amount of deviation depends on the importance of higher mode contributions and inelastic redistribution. Demand parameter values can be significantly under- or over-estimated.
- A single, deterministic answer will not provide information on all mechanisms that potentially may develop when the structure is subjected to a set of ground motions with different frequency characteristics.
- No information is obtained on response uncertainties
- Lateral dynamic instability cannot be addressed directly.

The amount of deviation from median values obtained from nonlinear response history analysis has been the subject of the exploratory studies carried out in the ATC 76-6 project. These studies are not, and cannot be, comprehensive because of the large variability in system configurations and design decisions, which will affect the deviation to various degrees. The following is a compendium of summary observations drawn from these studies. These summary observations are case specific and are intended to aid in the decision process when and to what degree an engineer can rely on quantitative demand parameter predictions obtained from a nonlinear static analysis. The observations are drawn from results of the type shown in Figure 5, which shows comparisons of peak EDPs (engineering demand parameters) obtained from pushover analysis and NRHA. Only one representative example each is shown for steel special moment frames (SMFs) and reinforced concrete shear walls (RCSWs).

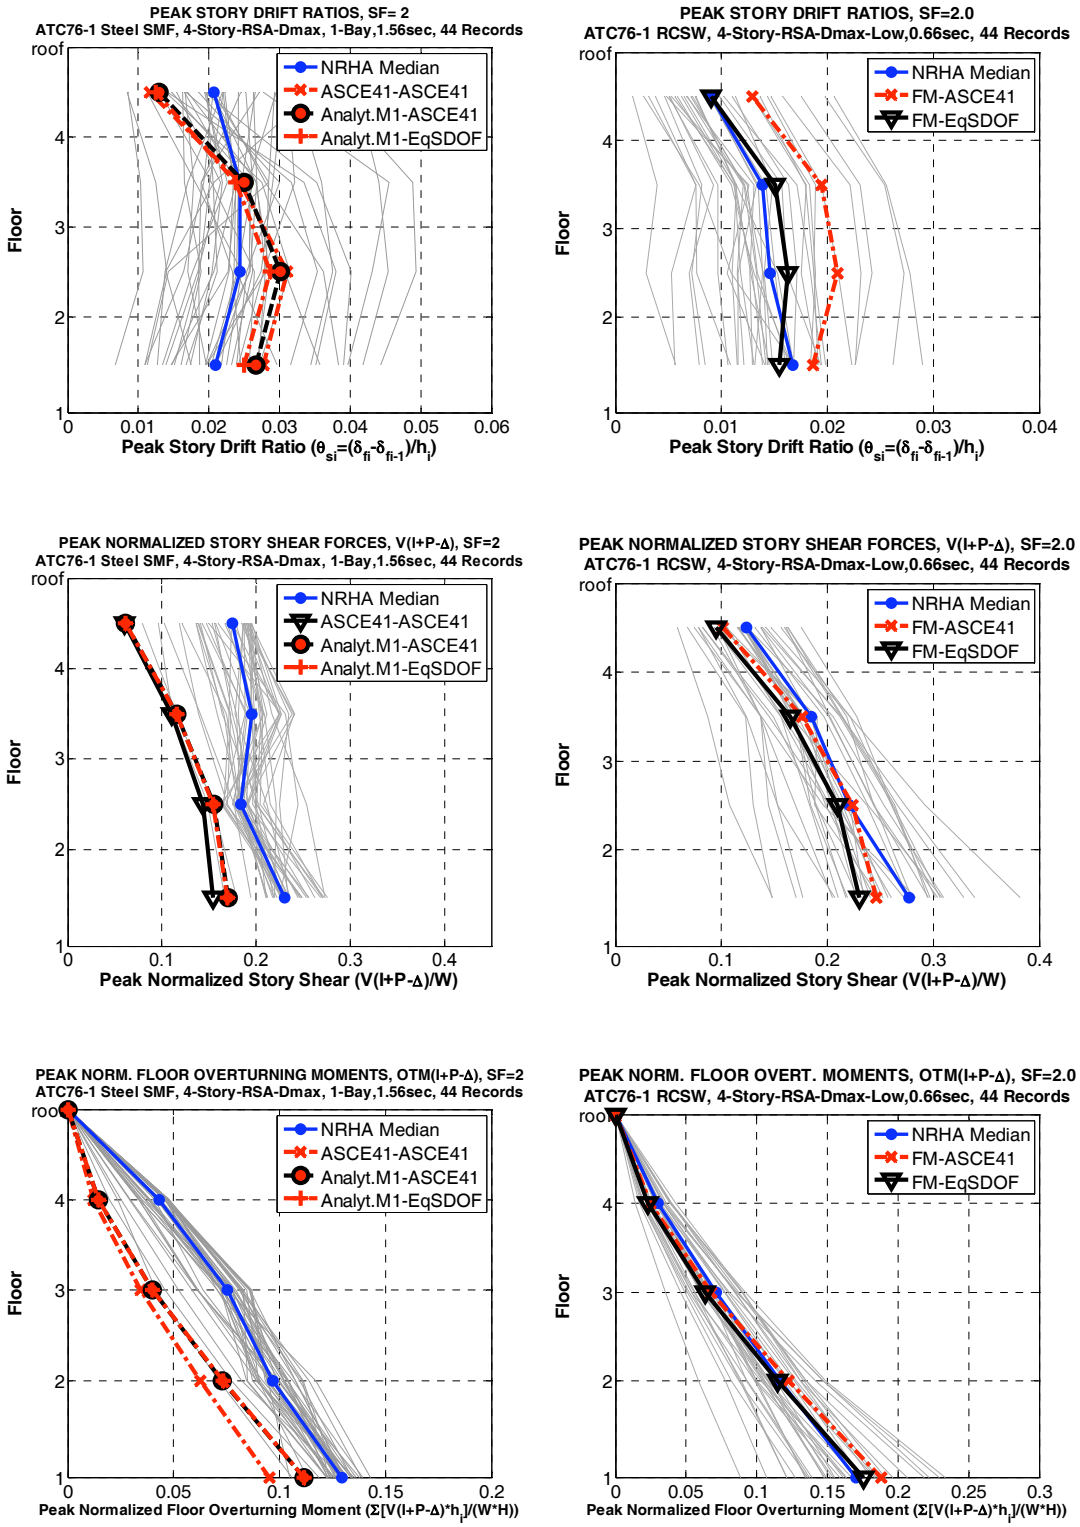

Figure 5. NSP to NRHA comparison of peak story drifts, peak story shears, and peak floor overturning moments; 4-story steel SMF (left) and 4-story RCSW (right); FEMA P695 ground motion set with scale factor of 2.0

First Mode Nonlinear Static Analysis with Invariant Load Pattern

In this procedure a lateral load pattern corresponding to the elastic first mode deflected shape is applied and is incremented to provide a global pushover curve. The target displacement is obtained from the elastic response spectrum under which the response is to be evaluated, using either the ASCE-41 coefficient method or the median displacement obtained from an equivalent SDOF system subjected to a set of ground motions whose spectra represent, in average, the elastic response spectrum. The method should be used with smooth spectra and not with spectra of individual ground motions. The following general observations are made:

- Adequacy of demand predictions from first mode nonlinear static analysis depends on system type and configuration, on the first mode mass participation (related to system type and number of stories), on the extent of inelastic deformations, on the relative spectral accelerations at the modal periods, on the sensitivity of story yield strength to the applied load pattern, on the variation of story strength and stiffness over the height, and on the mechanism controlling inelastic response.
- For the regular 2-story systems considered in this project, response quantities from first mode nonlinear static analysis generally agree well with median results from nonlinear response history analysis.
- The deviation from the median of nonlinear response history analyses increases with increasing height. Response may be underestimated substantially for 4-story steel moment frames and 8-story reinforced concrete moment frames. Underestimation of response occurs mostly in the upper stories and varies significantly between response parameters story drift, story shear, and floor overturning moment. When judging adequacy of first mode nonlinear static analysis, the user needs to consider the relevance of the response parameters for design. For instance, column axial forces due to earthquake loading, which are related to floor overturning moments, may not be a critical design consideration in the upper stories of a moment frame.
- Estimates of demand parameters for the reinforced concrete shear wall structures studied here generally are better than those for moment frame structures of the same height – provided that the estimate of the target displacement is displacement is reasonable. The ASCE-41 coefficient method, which is based on an effective elastic stiffness, often will not result in a good estimate of the target displacement if the pre- and post-cracking stiffnesses of the global pushover curve are clearly different. In such cases it is recommended to compute the target displacement from nonlinear response history analysis of equivalent SDOF systems.
- If the target displacement is in the negative tangent stiffness region of the pushover curve, it is recommended to compute it from nonlinear response history analysis of an equivalent SDOF system. Prediction of target displacements from the ASCE-41 coefficient method is likely to be inadequate in such cases.
- The invariant load pattern might create a perceived weak story if the relative strength of stories is sensitive to the load pattern. If the pushover indicates an irregularity that concentrates drift in a single story, mechanics principles should

be employed to estimate story strength in order to assess whether a weak story indeed exists or whether the perception of a weak story is created by the application of an invariant load pattern.

- If a strength irregularity exists and it is concentrated in a single story, then the first mode nonlinear static procedure is expected to provide good estimates of drift and force demand parameters. If strength irregularities exist in more than one story, then an invariant static load pattern rarely will detect more than the first irregularity, likely producing misleading results. Therefore, if irregularities exist in more than one story, it is recommended to either rectify the irregularities or perform nonlinear response history analysis.
- Pushovers with an invariant load pattern might lead to a misleading perception of the dominant yielding mode. A classical example is the issue of shear versus bending yielding in a shear wall. It has been shown in many nonlinear response history analyses (e.g., Krawinkler and Seneviratna 1998) that for taller structures the maximum shear force in walls, in which a pushover indicates bending yielding at the base, gets amplified by a factor that might be larger than 2.0. Thus, the wall might actually yield in shear rather than bending. For low-rise wall structures this factor will be smaller, but still clearly larger than 1.0. This is an important issue because shear yielding is viewed as much less ductile than bending yielding. Applying an amplification factor to wall shear is one way to mitigate this problem. Another one is to perform nonlinear response history analysis.
- Collapse is an important issue if the target displacement is in the negative tangent stiffness region of the pushover curve (Zareian and Krawinkler 2009). FEMA P-440A (FEMA 2009a) recommends the use of a parameter R_{di} to safeguard against collapse if the target displacement becomes very large. This parameter is useful for the intended purpose, except that the third term in the equation can rarely be quantified with confidence for a structure pushover curve. It is recommended to omit the third term unless all parameters are well defined in the pushover curve.

Multi-Mode Nonlinear Static Analysis Options

The following three multi-mode analysis options were tested in various parts of the ATC 76-6 project: elastic modal response spectrum analysis, multi-mode nonlinear static analysis (commonly referred to as modal pushover analysis, MPA), and consecutive modal pushover (CMP) analysis. General observations on the first two methods are as follows:

- Elastic modal response spectrum analysis is a very useful tool for predicting deformation and force demand parameters, as long as the structure is in the elastic range or close to it. For inelastic systems this method provided estimates of floor displacement and story drift that were as good as or better than those from nonlinear static analysis methods - but only for structures without strength irregularities. The method consistently overestimated story shears and overturning moments for yielding systems, and did so by a large amount for structures responding highly inelastic.

- This analysis method is valuable as a backup method for predicting story drifts for regular structures, but it cannot be considered a generally applicable method for inelastic response prediction because of its inability to account for limited component strength that might control inelastic response.
- Use of multi-mode nonlinear static analysis (MPA) improved the prediction of demand parameters for regular structures, and in many cases by a considerable amount. The results appear to be acceptable for the 8-story structures, which are the tallest structures investigated in this project.
- In many cases this method over-estimated demands in the lower stories of the structure, but did a much better job than the first mode nonlinear static analysis in estimating demands in the upper stories.
- The MPA, which uses invariant modal load patterns, does not protect against misleading drift information that may be caused by load pattern sensitive story mechanisms in more than a single story.
- In most of the regular structures investigated here the second mode contribution was elastic, which simplifies the modal combination and avoids ambiguities that might be caused by displacement reversals sometimes observed in inelastic higher mode pushover analyses.
- When the MPA method is employed, the reader should be aware that the option exists to compute component forces from component deformations, as discussed in Goel and Chopra 2005. This will lead to an improved estimate of component forces but necessitates the execution of a second analysis phase.
- There are many additional options for executing a nonlinear static analysis. Many of these methods have clear advantages in specific applications, but none have been found to be applicable for all conditions. And all these methods involve additional computational efforts. No general recommendations can be made for preference of any of these methods.

ASSESSMENT OF NONLINEAR RESPONSE HISTORY ANALYSIS

The use of nonlinear response history analysis (NRHA) has many hurdles to overcome. Some of them are real (such as increased complexity and the "can't see the forest because of the many leaves on the trees" syndrome) and some are fictional (such as fear of complex modeling). The challenge is to reduce complexity, so that time investment is minimized, and increase the ability to inspect and visualize response so that final design decisions can be based on good engineering judgment rather than numerical results alone. The former requires simplicity in modeling, and the latter requires thoughtful post-processing of analysis data. Thoughtful post-processing of data is under control of the practitioner and the professional program developer who wants to accommodate the practitioner's desire for efficient communication of results. This is only a time-limited stumbling block.

Simplicity in modeling is at the core of facilitating the use of nonlinear response history analysis. In concept, the major difference between modeling for nonlinear static analysis and nonlinear response history analysis lies in the need to model hysteretic behavior of structural components. Modeling of the "backbone curve" of individual components is needed one way or another. It is postulated here

that demand prediction from response history analysis based on the simplest hysteresis diagram is more realistic than demand prediction from a nonlinear static analysis. The latter is based on a simplified global pushover curve and on target displacement prediction that is derived from simplified SDOF models and assumed (usually bilinear) hysteresis diagrams. So, why not use a simple hysteresis diagram for structural components and perform nonlinear response history analysis rather than take a detour of static analysis and a postulated target displacement.

The PEER/ATC-72-1 report (PEER/ATC 2010) provides recommendations for simple component modeling. This could mean a bilinear hysteresis model for steel structural components or a peak-oriented hysteresis model for reinforced concrete components. The associated backbone curve could include a post-capping range of negative tangent stiffness if this range is deemed to be important in response predictions. One could use the modified ASCE-41 force-displacement model (Figure 1) as the backbone curve. Since the tabulated ASCE-41 properties of this model account for cyclic deterioration, there would be no need to incorporate cyclic deterioration in the analysis (PEER/ATC-72-1 analysis option 3). Thus, the modeling effort for NRHA should not be much more complex than the one for nonlinear static analysis. The better alternative is to employ component models that account explicitly for cyclic deterioration (for instance, Analyt.M1).

Appealing features of NRHA include (a) more realistic modeling of response, producing more reliable assessment of seismic performance, (b) exploration of the various possible types of response and their corresponding probabilities, (c) assessment of the significance of cyclic loading and associated deterioration, and (d) lateral dynamic instability can be addressed directly.

These improvements come at a cost, including somewhat more complex modeling and much more complex data interpretation. But most important, execution of nonlinear response history analysis necessitates the availability of a representative set of ground motions associated with the hazard at which demand parameters are to be evaluated. This is the most challenging issue that deserves much attention in order to advance the state of the practice for seismic demand prediction.

CONCLUSIONS

Both NSP and NRHA have intrinsic value, and it is advisable to employ a combination of both to understand seismic performance and quantify important engineering demand parameters.

ABSTRACT

The study describes a procedure to identify bridge fragility parameters utilizing its vibration response recorded during experimental study. For this purpose, bridge damage data observed in a near full-scale shake table experiment is utilized. The bridge was tested under a sequence of earthquake ground motions with increasing intensities. Low and high amplitude tests were performed in series to observe the seismic performance of the bridge starting from yielding to complete failure. In the present study, recorded bridge acceleration during high amplitude tests is utilized and further analyzed to evaluate the degraded performance of the bridge after each high amplitude test. This is done by using extended Kalman filtering (EKF) technique as a tool. The degraded performance of the bridge after each run is measured in terms of degraded stiffness of the bridge at pier ends. In parallel, finite element (FE) model of the same bridge is developed in order to perform time history analysis under a set of earthquake ground motions with various hazard levels. Before applying the ground motions, the FE model is updated with the degraded stiffness of the bridge obtained from EKF after each high amplitude test. This is important to numerically simulate the gradual progression of bridge damage when subjected to earthquake ground motions in sequence. After each time history analysis, bridge response is obtained in terms of the rotation at bridge pier ends. Thus obtained response from time history analyses is used for fragility curve development. The change in fragility parameters represents the progressive damage of the bridge when subjected to ground motions with incremental intensity.

INTRODUCTION

Bridge safety and serviceability are the major concerns to civil engineers. Experience showed that bridges are the most vulnerable components of highway transportation systems. Performance of a highway transportation network under extreme natural disasters greatly depends on the performance of its constituent bridges. During the most recent major earthquake in past, 1994 Northridge

earthquake in California, seven major freeway bridges in the neighborhood of Los Angeles collapsed and a number of bridges suffered from major damage. This resulted in a significant functional degradation of the Los Angeles area highway transportation network. Similar scenario is observed during the Hurricane Katrina in 2005; several bridges were destroyed making the highway transportation system in Louisiana, Mississippi and New Orleans totally disrupted. Hence to minimize such negative consequences of extreme disasters, it is important to evaluate bridge performance under future scenario events and assess the expected risk of highway transportation systems under regional hazards.

Development of bridge fragility curves in one of the most convenient ways to express bridge performance under external loading. Fragility curves represent the failure probabilities of bridges at a damage level under certain loading intensity. These curves can be developed by utilizing bridge damage data obtained from various sources such as numerical and experimental research and real-time seismic events. Numerous studies have been performed over last few decades to numerically simulate bridge performance under seismic excitation and to develop seismic fragility curves. In contrast, availability of bridge fragility curves generated using experimental result is rather scarce. This is because large-scale experiments involving entire bridge models are expensive; component level testing is more common for this purpose. Even if bridge response from large-scale experiments is available, bridge fragility analysis utilizing the recorded response has not been done yet. For example, a near full-scale shake table test is performed on a two span reinforced concrete bridge model and the recorded bridge response is processed to gain desired knowledge on the progressive damage of the bridge under seismic excitations (Johnson *et al*. 2006). However, recorded data has not been analyzed to identify bridge fragility characteristics. Such fragility curves are important indeed not only to characterize the seismic vulnerability of bridges having similar attributes and configurations as of the experimental model, but also to investigate how bridge fragility behavior changes after earthquake events.

The objective of the present study is to identify bridge fragility characteristics by analyzing its experimentally recorded vibration response data. Bridge damage data observed in a near-full scale shake table experiment (Johnson *et al*. 2006) is utilized for this purpose. In this experiment, the bridge was tested under a sequence of seismic ground motions with increasing intensities. In this present research, recorded bridge response is analyzed using Extended Kalman Filter (EKF) in order to quantify the degraded performance of the bridge after each run. The degraded performance of the bridge is measured in terms of degraded stiffness at bridge pier ends.

For fragility analysis, numerical study is performed to simulate the seismic response of the same bridge. Finite element (FE) model of the experimental bridge is developed in SAP2000 Nonlinear (Computer and Structures, Inc. 1995). Time history analyses are performed under a set of ground motions with various hazard levels. Before analyzing the bridge under these ground motions, FE model is updated with the degraded stiffness obtained through EKF. By doing this, FE model of the bridge is calibrated with the experimental model for sequential ground motion run. Obtained bridge response is presented in the form of fragility curves. Change in fragility parameters indicates the degradation of bridge performance due to seismic events.

REVIEW OF EXPERIMENTAL STUDY AND OBSERVED RESULTS

The present study uses the vibration measurement data of a two span reinforced concrete bridge under earthquake ground motions. The data is obtained from large-scale shaking table tests conducted at the University of Nevada, Reno (Johnson *et al*. 2006). Experimental results include bridge response (acceleration time histories and rotational and translational deformations) and the nature of bridge failure from yielding to complete collapse under ground motions with increasing intensity levels. Figure 1 shows the bridge model and experimental plan. Bridge instrumentation plan (i.e., locations of accelerometers) can be found in Soyoz and Feng (2007). Total height of this specimen was 3.28 m from the bottom of the footing block to the top of the superstructure. Bridge spans, each 9.14 m long, were supported on three pier bents with the tallest one at middle. Clear heights of these bents were 1.83 m, 2.44 m and 1.52 m. Each bent consisted of two piers of the same cross-sectional and material properties. The bridge deck was a solid slab post-tensioned in both the longitudinal and transverse directions of the bridge. The axial force was estimated to be 209.2 kN in bent 1 and 3, and 182.2 kN in bent 2. Additional details of the bridge and the experiment are given in Johnson *et al*. (2006).

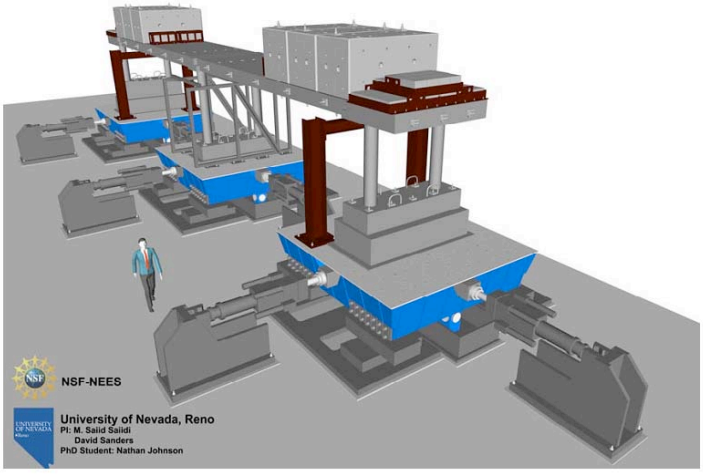

Figure 1. Experimental model of a 2-span reinforced concrete bridge (adopted from Johnson *et al.* 2006)

The experiment was performed by applying the input ground motion acceleration time histories in the transverse direction of the bridge. Low and high amplitude tests were performed in series. No damage was observed during low amplitude tests. Therefore it was assumed that the bridge remained in elastic range during the low amplitude tests. Following these, nine high amplitude tests (Ti, i = 12 ~ 20) were performed. Ground motion intensities during these high amplitude tests were increased gradually to observe the seismic performance of the bridge starting from yielding to complete failure.

Bridge response during high amplitude tests T12, T13, T14, T15, T17 and T18 are used in the current study. Table 1 represents the peak ground accelerations (PGAs) used during these tests and observed damage (in general) in bridge piers.

During Test 19, more than one rebar buckled in Best 3 which was regarded as the failure of the bridge. Following this, an additional test T20 was performed to generate more damage in Bents 1 and 2.

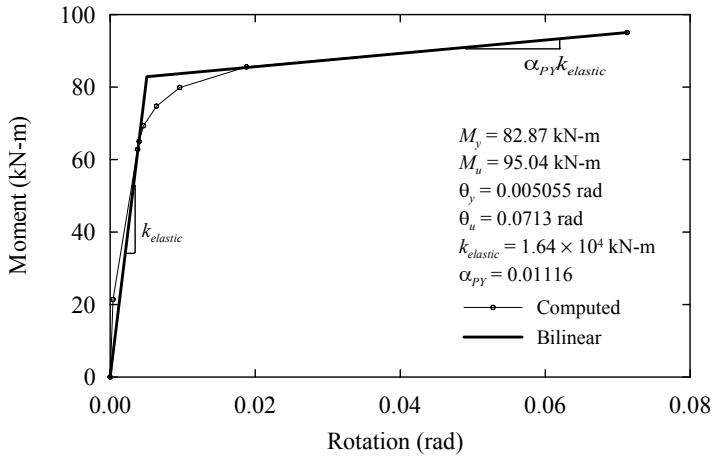

Table 1. Input PGAs and corresponding damage during high amplitude tests

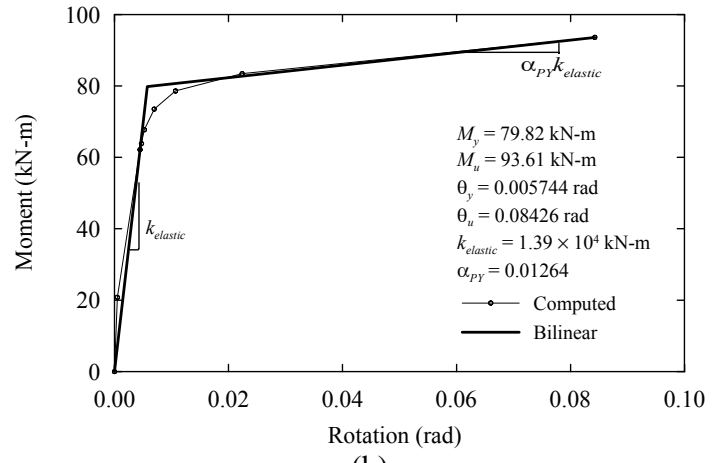
High amplitude test	PGAs (g)	Damage in bridge piers
T12	0.075	No damage
T13	0.15	No damage
T14	0.25	Hairline cracks
T15	0.50	Minor cracking or spalling in cover concrete
T17	1.00	Minor cracking and significant spalling
T18	1.33	Significant spalling



According to the nature of damage observed in bridge piers during high amplitude tests, bridge damage is categorized into four damage levels starting from no damage to major damage (Banerjee and Shinozuka 2008). This categorization is done in accordance with the qualitative damage state descriptions presented in HAZUS (1999). Table 2 lists these damage states and corresponding damage in bridge piers. Moment-rotation relationships of bridge piers in the three bents are also developed in Banerjee and Shinozuka (2008) and shown in Figure 2.

Table 2. Bridge damage states

Damage states	Descriptions of physical damage
No Damage	No damage in bridge piers
Minor Damage	Height of pier flaking/spalling ≤ 80 mm
Moderate Damage	Height of pier spalling > 80 mm or exposure of pier reinforcement
Major Damage and beyond	Significant spalling to buckling of reinforcing bar(s)

(a)

(b)

Figure 2. Moment-rotation relationships of bridge piers in (a) Bent 1 and Bent 3 (b) Bent 2 (adopted from Banerjee and Shinozuka 2008)

QUANTIFICATION OF DEGRADED STIFFNESS OF BRIDGE PIERS THROUGH EXTENDED KALMAN FILTER (EKF)

Quantification of structural damage and the evaluation of post-event structural capacity can be done by calculating the degraded stiffness values of structural elements. This also facilitates the identification of damage locations in the structure. Extended Kalman filtering (EKF) method is an effective tool for this purpose (Mohinder and Angus 2008). This technique has been extensively used over last three decades for structural damage identification (Yun and Shinozuka 1980, Hoshiya and Saito 1984, Loh and Chung 1993, Loh and Tou 1995, Ghanem and Ferro 2006, Soyoz and Feng 2007, Yang *et al*. 2007). Through EKF, the state of a dynamic system can be estimated from its vibration measurement data. The technique is essentially a set of mathematical equations that filters observed measurements (may be associated with noise and inaccuracies) to obtain true state of the structure. In the present study, a

program on EKF is developed using Matlab (Mathworks Inc. 2008). Time histories of bridge acceleration recorded in accelerometers during the high amplitude tests are used as input to the program. Additionally, ground motion time histories at the table level are used as the input ground motions. The program yields the degradation of bridge stiffness at top and bottom of each bridge pier in a dimensionless format (i.e., degraded stiffness/initial elastic stiffness). Table 3 shows these dimensionless stiffness quantities obtained after each high amplitude test. In Test 12, the starting stiffness is taken as the elastic stiffness of the bridge. After this test, obtained degraded stiffness from EKF is presented in Table 3 under T12. This degraded stiffness is considered to be the initial stiffness for T13. After T13, obtained degraded stiffness from EKF is presented in Table 3 under T13 which is again considered as initial value in EKF for T14. The process is continues for all the high amplitude tests. This way the bridge model is updated in EKF program after each high aptitude test before the following test is done to calculate stiffness degradation.

Table 3. Dimensionless stiffness (degraded stiffness/initial elastic stiffness) at bridge pier ends after high amplitude tests

Location of bridge piers		T12	T13	T14	T15	T17	T18
Bent 1	Top	1.00	1.00	0.99	0.91	0.66	0.41
	Bottom	1.00	1.00	0.99	0.94	0.78	0.61

	Bottom	1.00	0.99	0.97	0.86	0.67	0.63

NUMERICAL ANALYSIS FOR FRAGILITY CURVE DEVELOPMENT

Experimental study provides limited data. For fragility analysis, however, a set of bridge damage data is required that represents bridge performance under a variety of earthquake ground motions. For this purpose, a finite element (FE) model of the same experimental bridge is developed and analyzed under 60 earthquake ground motions. Obtained bridge response is used for fragility curve development. The following paragraphs provide the detail of this numerical study.

Bridge Model and Input Ground Motions

The finite element model of the bridge is developed in SAP2000 Nonlinear. Figure 3 shows a 3D view of the bridge model. The bridge is analyzed under 60 ground motion time histories. These motions were originally developed for the area of Los Angeles, CA for the purpose of Federal Emergency Management Agency

(FEMA) SAC steel project[1]. The motions are categorized in 3 sets, each having 20 records of horizontal ground accelerations derived either from historical recordings or from simulations. Each set of 20 records is scaled linearly in order to have return periods of 2500 years, 475 years and 72 years (exceedance probabilities respectively of 2, 10 and 50% in 50 years). These ground motions are applied in the transverse direction of the bridge to be consistent with the experimental research.

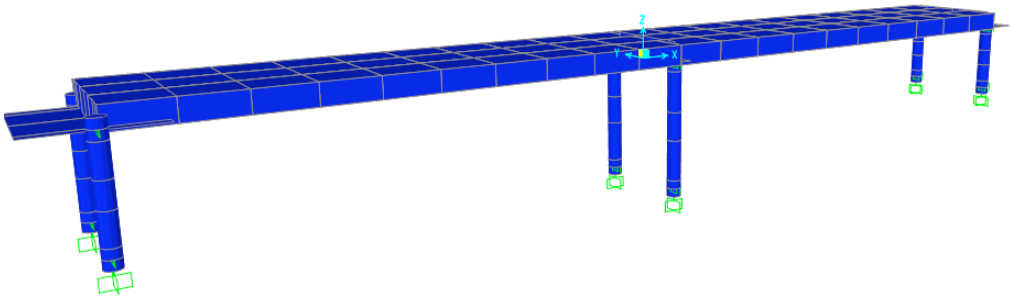

Figure 3. 3D view of FE bridge model

During seismic excitations plastic hinges are likely to generate at top and bottom of bridge piers. This is modeled in SAP2000 by introducing nonlinear links at both ends of each pier. The middle portion of each pier is assumed to be linear. At the beginning, bridge stiffness is taken as the initial (i.e., pre-damaged) stiffness. Thus the moment-rotation values shown in Figure 2 are assigned to the FE model.

Dynamic response of this bridge under 60 LA motions is recorded in terms of rotation at pier ends. This response is assumed to be the representative of bridge seismic performance. In the following step, bridge stiffness is updated with that obtained from EKF after T12 (Table 3) and thereafter analyzed under 60 LA motions. Rotations are recorded at bridge pier ends, which represent bridge seismic performance when the bridge has already experienced an earthquake similar to that used in T12. Following this, the stiffness of FE model is updated again with that obtained from EFK after T13 and a new set of time history analysis under 60 LA motions are preformed. The new recorded response represents bridge seismic performance when the structure was partially degraded due to an earthquake event similar to that used in T13. The process is continued until T18. Each time, bridge stiffness is updated to the appropriate degraded stiffness values so that the numerical model can actually represent the degraded state of the bridge after it experiences a seismic event. A flowchart in Figure 4 shows the process.

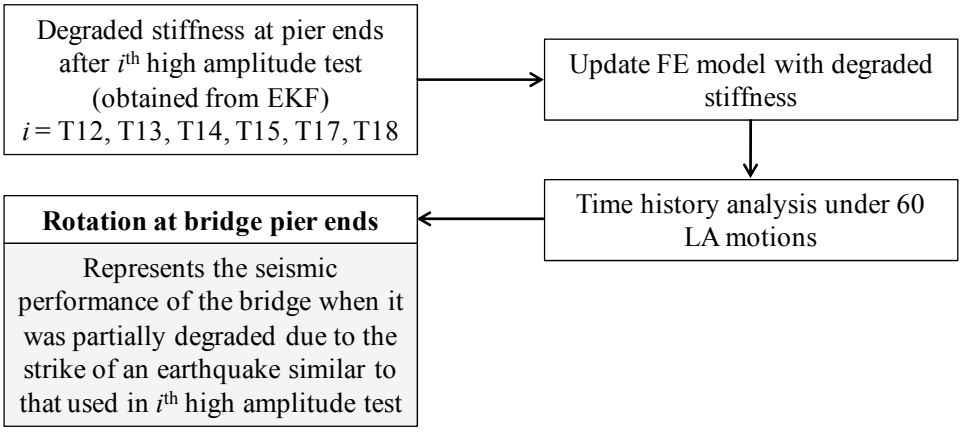

Figure 4. Flowchart showing the steps in numerical study

Seismic Fragility Curves of the Bridge

Prior to the development of fragility curves, bridge response obtained from time history analysis is categorized into different damage states (as discussed in Table 2). This is done by using threshold limits (numeric values) of bridge damage states that correspond to the physical descriptions presented in Table 2. Banerjee and Shinozuka (2008) quantified these limits in terms of rotational ductility by analyzing bridge damage data obtained from the same experimental study. By definition, rotational ductility represents the ratio of observed rotation to the yield rotation. The threshold rotational ductility values are calculated as 3.14 for minor damage, 5.90 for moderate damage and 9.42 for major damage and beyond. That means if obtained rotational ductility from numerical analysis exceeds 3.14, the bridge is no longer in minor damage state; it goes to the moderate damage.

Using rotations at each pier ends from time history analyses, values of rotational ductility are calculated. It should be noted here that piers in Bent 1 and 3 have yield rotation different from that in Bent 2 (Figure 2). Therefore for calculating rotational ductility at pier ends, appropriate values of yield rotation are taken. Damage states are decided by comparing the rotational ductility values with the threshold limits, and used further for the development of fragility curves.

Fragility curves represent probability of bridge failure in a damage state under certain ground motion intensity such as peak ground acceleration or PGA. The current study follows the procedure described in Shinozuka *et al*. (2000) to develop fragility curves at minor, moderate and major damage states of the bridge. A two-parameter lognormal distribution is used to represent the fragility curve. The parameters, median and log-standard deviation, define the shape of the fragility curve. Lower median value indicates weaker curve, as it has high probability of exceeding the damage state at lower intensity level. Thus, it also indicates higher vulnerability (or damageability) of the bridge under seismic excitations.

Table 4 shows the fragility parameter (median value) of the bridge after each high amplitude test. The fragility curves are shown in Figure 5, 6, and 7 respectively for minor, moderate and major damage states of the bridge. For all of these curves,

log-standard deviation is taken as 0.5 so that any two curves cannot cross each other and the curves can be compared in terms of their median values.

Table 4. Fragility parameter (median value in g) of the bridge after high amplitude tests

Damage State	Median value in g					
	T12	T13	T14	T15	T17	T18
≥ minor	0.49	0.48	0.48	0.45	0.36	0.20
≥ moderate	1.10	1.10	1.10	0.91	0.63	0.48
≥ Major	2.43	2.05	2.05	2.05	1.10	0.72

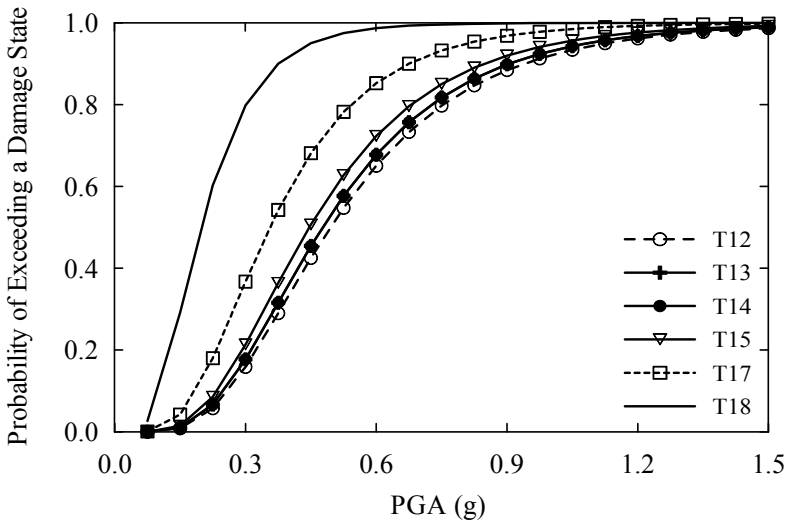

Figure 5. Bridge fragility curves at minor damage state after high amplitude tests

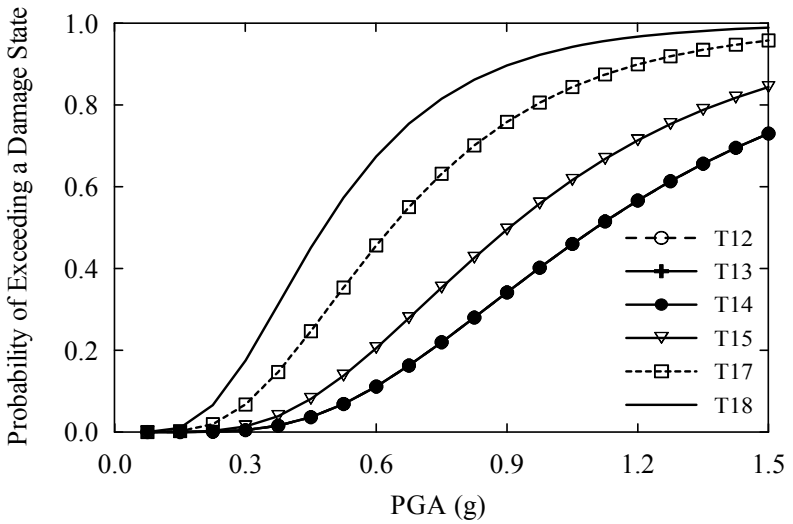

Figure 6. Bridge fragility curves at moderate damage state after high amplitude tests

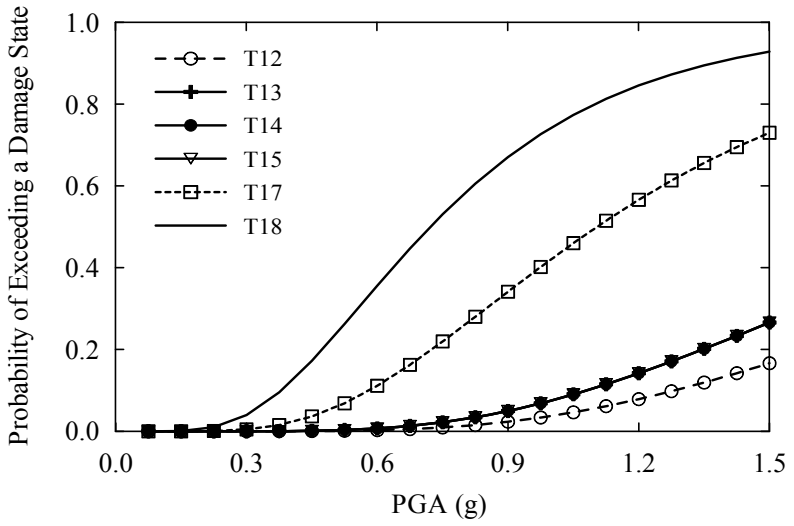

Figure 7. Bridge fragility curves at major damage state after high amplitude tests

PROGRESSIVE DEGRADATION OF BRIDGE FRAGILITY CHARACTERISTICS

The fragility curves in Figures 5, 6, and 7 represent bridge vulnerability under seismic ground motions. As these curves move towards left (i.e., median value decreases), bridge seismic vulnerability increases. It is evident from these figures that bridge vulnerability increases after each high amplitude test. This is quite obvious because bridge stiffness degrades in a progressive manner with the high aptitude tests. Not much degradation was observed in test T12 to T14 during the experiment (Table 1). This reflects properly in bridge fragility characteristics. For all three damage states, median fragility parameters do not have significant change from T12 to T14. Following T15, bridge stiffness degrades to a large extent so as the fragility curves. After T17 and T18, bridge seismic performance in major damage changes rapidly indicating a very high probability of having bridge failure in the higher damage state. The similar phenomenon is observed during the experiment. After T18, more than one rebar buckled in bridge piers, which was regarded as the failure of the bridge.

CONCLUSION

The study establishes a procedure of utilizing structural vibration response recorded from dynamic testing and/or from embedded sensors to determine its fragility characteristics under ambient vibration and natural events. The result shows how bridge seismically vulnerable increases after seismic events. Even if there is not much visible damage in a bridge due to a seismic event, the stiffness may get reduced to some extent which may has significant impact on the bridge seismic behavior. Therefore, consideration of initial (i.e., pre-damaged) condition for the seismic performance evaluation of an existing bridge is misleading; this may overestimate the actual capacity of the bridge. Use of such result in the seismic performance evaluation of highway transportation networks is not desirable.

ABSTRACT

The objective of the presented study is to evaluate the sensitivities of the random variables and Average Daily Truck Traffic (ADTT) on the evaluated reliability of bridges. The reliability analysis is carried out for the Strength I Limit State in the AASHTO LRFD Bridge Design Specification. The Weigh-In-Motion (WIM) data recorded at 24 WIM stations in Missouri are processed and used as an input to simulate realistic live loads due to truck traffic. Gumbel Type I extreme value distribution is used to represent daily maximum positive moments and extreme value theory is used to project the daily maximum values to the maximum values in 75 years of bridge lifespan. Sensitivity analysis is conducted to understand the relative effects of random variables and ADTT on the calculated reliability index. The result shows that the ADTT affects the reliability index as sensitively as other random variables, such as dead load, girder distribution factor, and dynamic impact factor. Hence, explicit consideration of uncertainties in ADTT is suggested for future calibration studies. Alternatively, the reliability index needs to be assessed conditioned on deterministic ADTT.

INTRODUCTION

Bridge design philosophies and specifications have been developed over the years to design bridges with a desired level of reliability. When AASHTO began publishing the standard specification for highway bridges in the 1930s, a factor of safety was used to ensure that the resistance of a bridge is greater than the combination of service loads. The design method is referred to as Allowable Stress Design (ASD). In the 1970s, uncertainties in load prediction were considered by using different load factors depending on the engineer's ability to predict the loads. This design approach is referred to as Load Factor Design (LFD). Recently, the bridge engineering profession has been moving toward the Load and Resistance Factor Design (LRFD). Load factors and resistance factors in the LRFD specification were developed based on the reliability analysis of bridges. FHWA mandated that the AASHTO LRFD Bridge Design Specification should be used for new bridges on which states initiate preliminary engineering from October 2007.

The load factors in the AASHTO LRFD Specification have been calibrated through several NCHRP research projects. The NCHRP Project 12-33 produced

NCHRP Report 368 (Nowak 1999), which is the basis of the current LRFD Specification. For the project, the truck survey results from the Ontario Ministry of Transportation were used to calibrate the live load factor. It was assumed that the surveyed truck data from Ontario in mid 1970s represented two-weeks of heavy traffic on a two lane bridge with Average Daily Truck Traffic (ADTT) of 1,000 in one direction. The development of live load factor was based on reliability analyses of around 200 representative bridges from various geographical regions in the United States. From the evaluated reliability indices, the live load factor of 1.7 was proposed. In NCHRP Report 20-7/186 (Kulicki et al. 2007), the live load factor was increased from 1.7 to 1.75 due to the increase in the design ADTT from 1,000 to 5,000.

Recently, several states in the U.S. calibrated the load factors to consider state-specific traffic environment (traffic volume and truck weights) and bridge configurations. So far, the Michigan DOT has proposed an adjustment factor to increase the live load to account for heavy truck traffic in metropolitan areas (Van de Lindt et al. 2006; Fu et al. 2006). In addition, Oregon, Florida, and New York DOTs calibrated live load factors for Load and Resistance Factor Rating (LRFR) using Weigh-in-Motion (WIM) data collected in each state. Missouri DOT recently completed a research project in which the live load factor is calibrated based on state-specific traffic environment and bridge configurations (Kwon et al. 2010a, 2010b).

In the reliability analysis procedure in the above studies, several random variables are involved in resistance, live loads, and dead loads. While the procedures are thorough and rationale, no attempts has been made yet to understand which random variable contribute the most to the evaluated bridge reliability. In addition, how the local traffic environment (such as ADTT in this study) affects the reliability of bridges has not been quantitatively evaluated yet. Hence, the objective of the presented study is to evaluate the sensitivities of the random variables and ADTT on the evaluated reliability of bridges. The reliability analysis procedure in this study is based on the study by the authors (Kwon et al. 2010a, 2010b).

In the following, overview of the reliability analysis procedures is introduced, which is followed by the introduction on localities of traffic environment in Missouri. The reliability analysis procedure is demonstrated with a typical pre-stressed concrete bridge. Then, the sensitivity analyses of random variables on evaluated reliability are carried out.

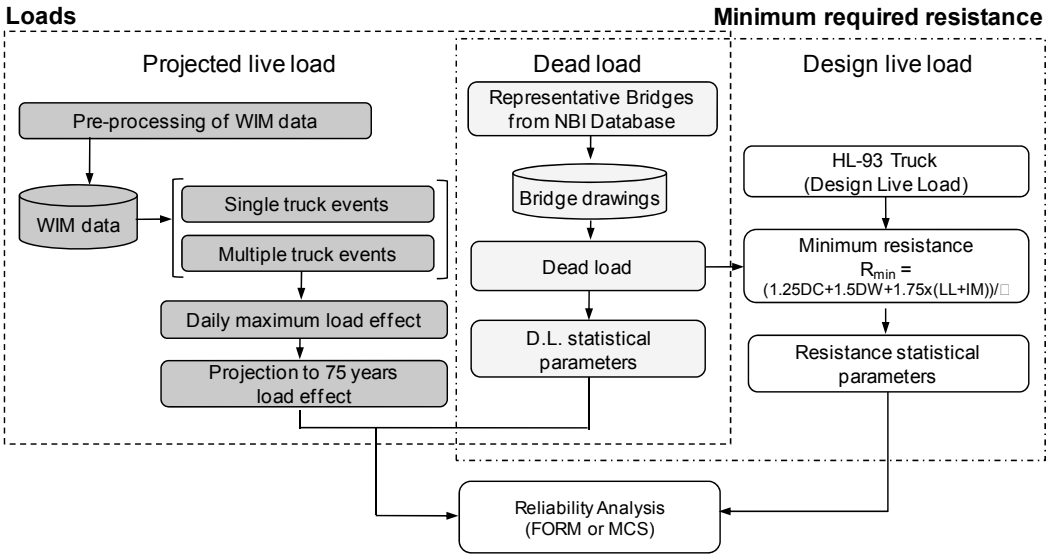
OVERVIEW OF RELIABILITY ASSESSMENT PROCEDURE

The reliability assessment of bridge girders requires identification of uncertain parameters in the expected loads and resistance of bridge girders as depicted in Figure 1. The expected loads need to be assessed considering the uncertainties in dead loads and live loads. Since the assessed reliability will be ultimately used to calibrate the load factor in the design specification, the uncertainties in the live loads should take into account the maximum live load effects throughout the life span of bridges and the expected traffic volume which is generally represented with Averaged Daily Truck Traffic (ADTT). The expected live load needs to be based on a realistic vehicle load model customized for a specific state or recorded vehicle weights from Weigh-In-Motion (WIM) stations. Hence, the evaluation of loads consists of the assessment of short-term live load effects (daily maximum load effects in this study) and the

projection of those to 75 year effects. The procedure for live load assessment is illustrated in the left most column in Figure 1. In addition to the live loads, the uncertainties in dead loads need to be included as shown in the middle column in Figure 1. In terms of bridge resistance, comparison of girder strengths in as-built condition with minimum strengths required by the code shows that the as-built strengths are mostly higher than the minimum required strengths for the Strength I condition (Orton et al. 2010). Since this study is carried out to calibrate the load factors in the bridge design specification, the minimum strength required by the code is used as girder strengths rather than strength in as-built condition.

Even when a bridge girder is optimally designed to have a minimum required strength, previous research showed that structural members tend to have over-strength due to the bias in actual material strength and nominal material strengths. In addition, since the properties of structural materials are not deterministic, the strengths of structural members are inherently random in nature. Hence, the uncertainties in minimum required strengths are evaluated considering the uncertainties in material strengths, fabrication, and professional parameters (Orton et al. 2010).

The reliability assessment of bridge girders requires assessment of the random variables discussed in the above. In addition, the expected ADTTs of the studied bridges need to be carefully determined. In the next section, the localities of traffic environments within a state are discussed which shows the range of ADTTs that bridges are subjected to.



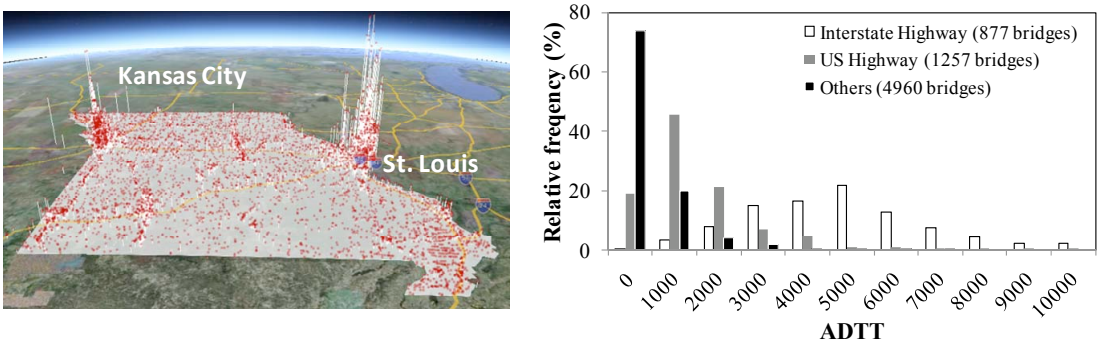


Figure 1. Overview of reliability analysis procedure for bridge girders

LOCALITIES OF TRAFFIC VOLUME AND TRUCK WEIGHT

The traffic volume and truck weights are parameters that significantly affect the assessed reliability of bridge girders. With higher truck weights and volumes, the reliability of bridge girders decreases. While the localities of the traffic environments were discussed in literature (Van de Lindt et al. 2006; Kwon et al. 2010a, 2010b), the load factors in the current design specification, which were developed based on

assumption that ADTT is 5000, are universally applied in most states except a few states which carried out calibration studies based on local traffic data.

To illustrate the level of distributions in traffic volumes, the geographical distribution of ADTTs in Missouri is depicted in Figure 2(a). Each mark in the figure indicates the location of a bridge. The height of the mark shows the relative ADTT. As it can be observed from the figure, a high volume of truck traffic is concentrated in the metropolitan areas of Kansas City and St. Louis. For many bridges in rural areas, the ADTTs are very small. Figure 2(b) compares the distribution of ADTT for bridges in the Interstate Highway system, in the US Highway system, and other rural roads. The average ADTT of Interstate Highway bridges is close to 5,000, which was used for the calibration of the live load factor in current AASHTO LRFD. The distribution of ADTT is close to the normal distribution with fairly large standard deviation. The average ADTT of the US highway bridges is only around 1,100 and bridges on other roads have an average ADTT of only 415. Considering that the majority of bridges in Missouri carry US highway (1257 bridges or 18% of total bridge inventory) or local roads (4960 bridges or 70%), a different live load factor may need to be applied for these bridges in order to have a uniform safety margin. The discussion on the effect of ADTT on the reliability of bridges is provided in more detail later in this paper.

(a) Geographic distribution (b) Histogram of ADTT in different roadways

Figure 2. Regional and roadway dependency of ADTTs in Missouri

Figure 3 compares the distribution of gross vehicle weights (GVW) of three different WIM stations in Missouri. The figures clearly show that even within a state, the distribution of GVWs varies. Even though not investigated in this study, it is speculated that the distribution of GVWs may vary in different states with following reasons; 1) some states in the U.S. have different legal loads and/or different practices in issuing overweight permits, 2) states have different industry which requires transportation of heavy raw materials or final products, and 3) distribution of population and associated traffic demands are not uniform in the U.S. Hence, to achieve the objective of having uniform reliability of bridges through the transition from LFD to LRFD, it is imperative to evaluate traffic environments of each state and calibrate load factors based on the evaluation. In terms of traffic environments, the scope of the study presented in this paper is limited to the effects of ADTT on the assessed reliability index, which will emphasize the importance of defining appropriate ADTT in reliability assessment procedure.

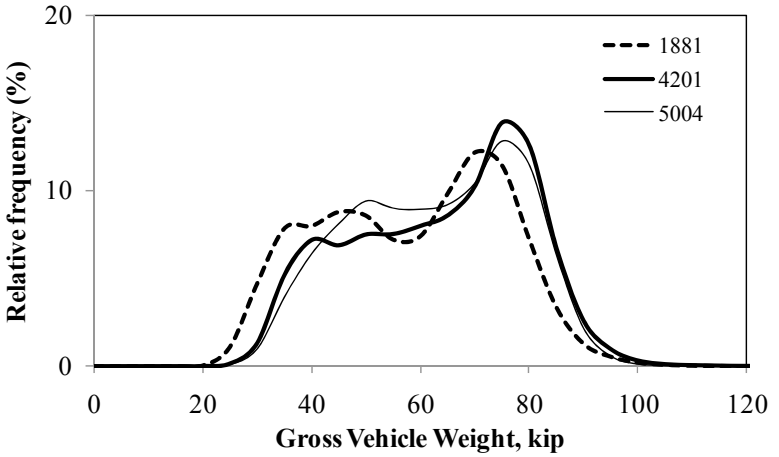

Figure 3. Distribution of GVW of vehicle class 9 (Stations 1881, 4201, 5004)

RELIABILITY ASSESSMENT OF AN EXAMPLE BRIDGE GIRDER

Reliability assessment procedure is discussed in detail with a typical prestressed concrete bridge in Missouri. The bridge consists of a simple span with span length of 90ft and span width of 26ft. Four pre-stressed concrete girders are used to transfer loads to abutments. While the actual bridge carries rural roadway, for traffic simulation it is assumed that the bridge carries Interstate Highway and vehicles run at highway speed.

Minimum Required Resistance

The minimum required resistance consists of live load (HL93 design truck) and dead load. Based on the moving load analysis with the design truck, the maximum positive moment of the bridge span from the live load is found to be 2,313 kip-ft, which includes dynamic impact factor of the design truck load. Maximum moment to an interior girder (1742 kip-ft) is calculated by applying girder distribution factor of 0.753, which is calculated from the geometry of the bridge section and considering the multiple presence factor for the two-lane bridge. The multiple presence factor takes into account the effects of two HL93 design trucks running in parallel on bridge girders. The dead load consists of component dead load (DC, total 1480 kip-ft) and wearing surface dead load (DW, 248 kip-ft). The required minimum resistance is calculated from the load combination of Strength I limit state:

$$M_{req} = (1.25(DC) + 1.5(DW) + 1.75(LL + IM))/\square.$$

From the load combination, the nominal positive moment for an interior girder is found to be 5270 kip-ft. This value is assumed as ‘nominal resistance’ of the bridge girder as a properly designed bridge girder will have a moment strength equal to or greater than 5270 kip-ft.

The deterministic minimum required resistance is converted to a random variable by applying a bias factor and a coefficient of variation (COV). The bias factor and the COV of a prestressed concrete girder section are estimated from the statistical analysis of existing girder sections in which the probabilistic distribution of

materials, fabrication, and professional parameters are considered. The adopted bias factor and the COV are 1.055 and 0.069 (Orton et al. 2010), which are evaluated using the latest material parameters available in literature.

Load Demands throughout the Lifespan of a Bridge

The load demands consist of dead loads and live loads. The dead loads are assumed to be identical with those used for minimum resistance calculation except that the dead loads follow lognormal distribution. Different bias factors and COVs are applied to factory-made members, cast-in-place members, and wearing surface based on the study by Nowak (1999). The live load demands are calculated from Monte-Carlo simulation of moving trucks considering traffic volume (ADTT) and WIM data recorded in Missouri. The WIM data are processed to remove unreliable data points as briefly introduced in the following section.

Filtering of WIM data

The WIM data used in this study were collected for five years between 2004 and 2008 at 22 permanent and 2 temporary WIM stations in Missouri. Approximately 41 million WIM data were collected at the 24 WIM stations and 84% of the data were recorded on Interstate Highways. Since WIM data are recorded while trucks ran at highway speeds, the recorded data are prone to error. Inspection of the recorded data showed that a non-negligible portion of the data has unrealistically large axle weights, gross vehicle weights, or axle spacing. Hence, after reviewing the time series of daily average GVW from all WIM stations, the erroneous data segments, which show unrealistic values are removed from the database. After screening WIM data based on the daily average GVW, the screening criteria in NCHRP Web-Only Document 135 (Sivakumar et al. 2008) is applied to remove outlier data points.

Effects of single heavy truck

The daily maximum moment in a bridge girder may result from a single heavy truck or multiple trucks running in parallel or in series. In the minimum resistance calculation, the multiple presence factor in LRFD Specification takes into account the multiple truck events. For live load demand calculation, the multiple presence effects should be realistically simulated in which the chances of having multiple truck events and distribution of moments to each girder can be appropriately considered.

For single truck events, it is not necessary to run analysis with all ADTT number of trucks to find daily maximum moment as only heavy trucks affect the maximum moment. To understand how the maximum moments are correlated with the GVWs of trucks, the correlation coefficient between GVWs and the maximum moments is calculated. While not presented in this paper for the sake of brevity, the correlation between GVWs and maximum moments is approximately 0.95. A reference is made to Kwon et al. (2010b) for more information. Based on the close correlation, trucks only within top 5% of GVWs are used to find maximum moment due to single truck events.

Simulation of multiple truck events

The chance that multiple trucks exist on a bridge highly depends on the bridge length, number of lanes, average daily traffic, average daily truck traffic, and the traffic flow. In the previous calibration studies (NCHRP 368 and NCHRP 20-7), the following assumptions were used based on limited observation of truck traffic; every 50^{th} truck is followed by another truck with the headway distance less than 100 ft, every 150^{th} truck is followed behind by a partially correlated truck, every 500^{th} truck is followed behind by a fully correlated truck. Similar assumptions were also used for trucks running on bridges with two or more lanes.

In this study, the traffic flow is modeled as a Poisson process. When an event follows a Poisson process, the time between vehicle's arrival to a bridge, is described by an exponential distribution (Cowan 1975). Since vehicles keep certain level of headway distance, the shifted exponential distribution can be used to take into account the headway distance. The vehicle's arrival time to a bridge can be numerically simulated using the distribution, and the distance between vehicles can be compared with the length of a bridge to determine how many multiple presence effects should be considered for moving load analysis. Figure 4 illustrates how the multiple trucks running in series or running in parallel are selected for moving load analysis. For the example bridge, it is found that when ADTT is 5,000, on average 180 multiple truck events per one-day of traffic simulation need to be included in the moving load analysis.

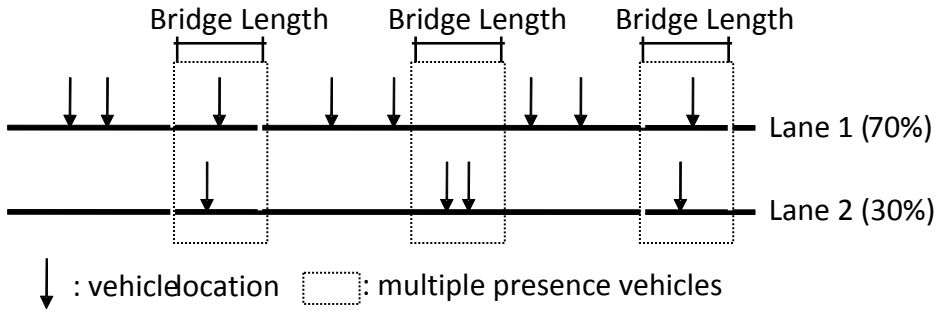

Figure 4. Simulation of multiple truck cases

Based on the 2007 NBI database and field monitoring of traffics at three different locations on IS-44 (near Rolla, Missouri), around 25% of daily traffic (ADT) was found to be truck traffic. In addition, traffic monitoring conducted for this research showed that approximately 70% of vehicles use the travel lane and the remaining use the bypass lane in the IS highway without having traffic congestion. Even though the observation was limited to the specific highway and observed time, this data was used to simulate multiple truck events due to lack of data available in literature.

Distribution of load effects to girders and consideration of dynamic impact

The moving load analysis in the above can result in maximum moment for the entire section of the bridge span. As the reliability analyses are carried out in bridge

girder level not bridge section level, it is necessary to distribute the moment to each girder. For this purpose, the girder distribution factors in AASHTO LRFD specification are adopted. Note that in a real bridge, multiple trucks may not run perfectly in parallel as it was assumed in the multiple presence factor in LRFD Specification. Hence, it is not appropriate to directly apply the multiple presence factor in the LRFD Specification to the moments calculated from truck traffic simulation. Thus, the load distribution factor in the specification is modified to take into account the multiple lane effects from traffic simulation. For more details on girder distribution factors adopted in this study, reference is made to Kwon et al. (2010a).

Due to the roughness of bridge surface and dynamic interaction between bridge superstructure and vehicles, a dynamic amplification factor is applied to the load effects from vehicular live loads. In this study, to be consistent with the procedure adopted for the development of the current AASHTO LRFD Specification, the mean values and the coefficient of variation used by Hwang and Nowak (1991) are adopted to reflect the uncertainties in the dynamic impact. The mean dynamic impact factors of 0.10 and 0.15 are taken for multiple truck events and single truck events, respectively. The coefficient of variation for the dynamic impact factor is taken as 0.8.

Daily maximum values and projection for 75-year load effects

Simulation is carried out for one hundred days of traffic. On each day the simulation considers a number of trucks equal to the ADTT. Both single truck events and multiple truck events are simulated following the procedure discussed in the previous sections. As each daily maximum value is an extreme value of the day, the distribution of the daily maximum values is assumed to follow extreme value distribution. It is assumed in this study that the daily maximum value follows Gumbel Type I distribution:

$$F_{X-1day}(x) = \exp\left(-\exp\left(-\frac{x-u}{\alpha}\right)\right)$$

in which α and u are scale parameters and location parameters, respectively. The distribution of maximum load effect for 75 years, $F_{X-75\,years}$ can be projected using the distribution of daily maximum load effect as follows:

$$F_{X-75\,years}(x) = \left[F_{X-1day}(x)\right]^N = \left[\exp\left(-\exp\left(-\frac{x-u}{\alpha}\right)\right)\right]^N = \exp\left\{-\exp\left(-\frac{x-u_n}{\alpha_n}\right)\right\}$$

where N is the number of days in 75 years. Note that in a previous study (Nowak 1999) the normal probability paper was used to project short-term simulations to estimate long-term (75 years) effects. A comparison of the different projection methods showed that the method adopted in this study is more consistent and conservative than the other method. Detailed comparison of the two projection methods can be found in Kwon et al. (2010b).

Figure 5(a) shows the Cumulative Distribution Function (CDF) of daily maximum positive moments. Note that some of the maximum values result from multiple truck events and others are from single heavy trucks. It can be observed from

the figure that the Gumbel Type I distribution can describe the simulated data points with acceptable accuracy. In Figure 5(a), the mean daily maximum moment for the example bridge is around 875 kip-ft, which is far less than the maximum live load from HL93 design truck (1742 kip-ft including lane load and 1286 kip-ft excluding lane load) despite the fact that the GVW of the heavy trucks in WIM data is generally greater than GVW of HL93 design truck. This difference mainly results from the use of different multiple presence factors in resistance calculation and in load demand calculation. In resistance calculation, the multiple presence factors were developed based on assumption that two design trucks run in parallel, hence, the multiple presence factor is relatively large. In the load demand calculation, on the other hand, multiple presence effects are considered through traffic simulation in which the chance of having two heavy trucks running in parallel is low.

Figure 5(b) presents distribution of the maximum moment in 75 year of lifespan of the bridge. It is important to note that the projected curve mainly relies on the shape of tail portion of the CDF of the short-term simulation (daily maximum value distribution, Figure 5(a)). The maximum moment in 75 year has mean value of 1,637 kip-ft and COV of 0.18.

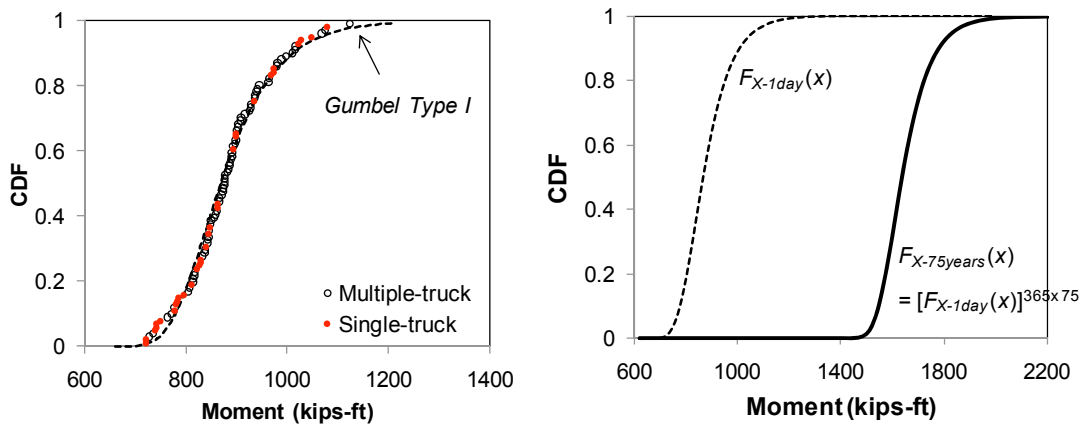

Figure 5. Distribution of 75-year maximum moment

Reliability Assessment

The probabilistic distribution of load demand throughout the lifespan of the bridge and minimum required resistances are estimated following the procedure discussed in the above. The Table 1 summarizes distribution of random variables used in the reliability assessment. Note that some of the uncertainties are propagated into other derived random variables. For instance, the uncertainties in material properties, which are not presented in this paper, are reflected in the uncertainties in resistance. In addition, the uncertainties in impact factor and girder distribution factors are reflected in the load demand. Based on the statistical distribution of resistance and load demand, the reliability index of the example bridge girder is found to be 5.91 using the First Order Reliability Method (FORM). The reliability index of 5.91 is far greater than the target reliability index of 3.5 used for the calibration of load factors in current AASHTO LRFD Specification. The main sources of the difference could be 1) the simulation method for truck traffics, 2) girder distribution

factors to consider multiple presence effects, and 3) projection methods. Each of these is in fact requires further in-depth research as it involves large assumptions which can directly affect the derived reliability index.

Table 1. Statistical parameters for dead load

Random variables	Distribution	Parameters	
		Bias factor	COV
Factory-made members (DC1)	Log-normal (Nowak 1999)	1.03	0.08
Cast-in-place members (DC2)		1.05	0.10
Cast-in-place members (DC3)		1.05	0.10
Wearing surface (DW)		1.00	0.25

Table 2. Statistical parameters for distribution factor (mg) and impact factor (IM)

Random variables	Distribution	Parameters	
		Mean	COV
mg for single lane load	Normal (Hwang and Nowak 1991)	0.536	0.12
mg for multiple lane loads		0.752	0.12
IM for single lane load		0.15	0.80
IM for multiple lane loads		0.10	0.80

Table 3. Statistical parameters for resistance (positive moment, PS girder)

Random variables	Distribution	Parameters	
		Bias factor	COV
PS concrete girder	Normal (Orton et al. 2010)	1.055	0.069

Sensitivity Analysis

Several random variables contribute to the uncertainties in the estimated reliability index. To understand how the reliability index is sensitive to each random variable, sensitivity analysis is carried out with dead load, girder distribution factor, dynamic impact factor, resistance, and ADTT. The mean of the selected random variables is changed between mean minus standard deviation and mean plus standard deviation and reliability index of the bridge girder is revaluated. Note that only mean values are changed for the sensitivity analysis not dispersion parameters. In addition, as ADTT is assumed to be deterministic value in this study, the ADTT is arbitrarily varied from 500 to 50,000, which covers the range of actual ADTTs in Missouri, Figure 2(b). The effect of ADTT is considered only in the projection of daily maximum load effects, not in the traffic simulation.

Figure 6 compares the reliability indices when the mean values of selected random variables are changed. For dead load, the mean value on dead load demand is varied and the dead load for resistance calculation is kept constant. Hence, by increasing mean value from mean-σ to mean+σ, the reliability index decreases. In the same way, as the girder distribution factor and dynamic impact factor in demand calculation increases from mean-σ to mean+σ, the reliability index decreases. As resistance increases, the reliability index increases as expected. It is worth to note that when ADTT varies from 500 to 50,000, the reliability index varies from 6.5 to 5.3. The sensitivity of reliability index to ADTT between ADTT of 500 to 50,000 is close

to that of other random variables such as dead load, distribution factor, or dynamic impact factor. As the multiple presence effect is not fully considered in the sensitivity analysis, the actual effect of ADTT on reliability index could be much higher.

In all previous studies, including the one by the authors (Kwon et al. 2010), the ADTT is assumed deterministic value. As ADTT has as significant effect as other random variables as observed in Figure 6 and as ADTT significantly varies depending on bridges as shown in Figure 2, it is proposed that ADTT needs to be considered as a random variable in the reliability assessment, or the derived reliability index should be conditioned on ADTT as in Kwon et al. 2010.

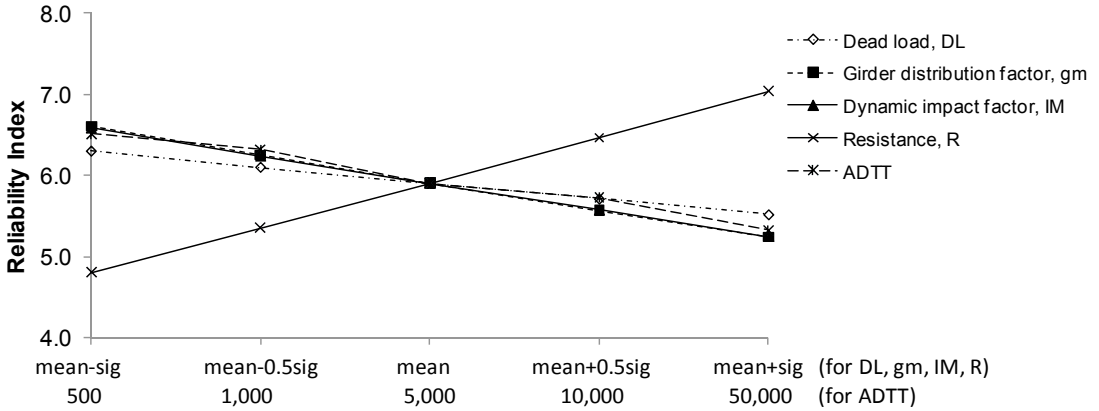

Figure 6. Sensitivity analysis of random variables adopted in the reliability analysis

CONCLUSIONS

The paper presents a procedure for the reliability assessment of a bridge girder using a simply supported prestressed concrete bridge as an example. The main focus of discussion is on localities of traffic environment and sensitivities of reliability index to random variables adopted in the process. Here are summary of findings from this study.

- The NBI Database shows that the traffic volume in terms of ADTT greatly varies depending on the area within a state and roadway system. Thus, it is expected that when calibration study is carried out for the refinement of LRFD specification, either ADTT needs to be considered as a random variable or the reliability index needs to be conditioned on ADTT.
- The collected WIM data shows that statistical distribution of GVW varies depending on WIM stations. It is expected that the distribution of GVW could be different for each state as main industry and legal limits varies depending on states.
- The reliability index has similar sensitivity to dead load, girder distribution factor, and dynamic impact factor.
- When ADTT varies from 500 to 50,000, the reliability index varies approximately from 6.5 to 5.5, which is similar to the range of reliability index when mean values of other random variables (dead load, girder distribution factor, and impact factor) vary from mean minus standard deviation to mean plus standard deviation.

The derived reliability index from this study is higher than the target reliability index used in the previous study as different procedures for traffic simulation, consideration of multiple presence effects, and projection methods are adopted in this study. For more accurate reliability assessment, these procedures require further investigation.

ACKNOWLEDGEMENT

This study was funded by the Missouri Department of Transportation (MoDOT) and Missouri S&T National University Transportation Center (NUTC). All findings and conclusions are those of the authors and do not represent MoDOT or NUTC.

ABSTRACT

Post-hurricane functionality of the transportation system is vital for emergency response and recovery activities. Coastal bridges are among the most critical components of the transportation system susceptible to hurricane induced wave and surge loads that may hamper this functionality. This study explores alternative approaches to develop probabilistic statements of coastal bridge damage potential conditioned upon hazard intensity, known as fragility. Fragility surfaces for a representative bridge structure of the Houston/Galveston area are developed using two different approaches: static analysis and nonlinear dynamic simulation. The static approach is efficient and can provide sufficient fragility models for simply supported bridges with limited connectivity between the super structure and substructure, since their predominant mode of failure is deck unseating or shifting due to connection failure. Nevertheless, for bridges with strong connection between sub and superstructure, the force transfer can cause other components to exceed their limit state. Hence the full dynamic behavior of structure becomes more critical in the fragility modeling of bridges with high strength connections.

INTRODUCTION

High exposure of the transportation system in coastal regions to hurricane events (Chen et al. 2007) along with the continuous development in these areas (Crossett et al. 2004) underscore the importance of studying the vulnerability of the transportation network due to coastal storms. Any damage to the transportation network affects the post event recovery and restoration of a region and also leads to significant economic losses. Since bridges are the key components in the transportation infrastructure which their susceptibility to hurricane induced surge and wave loads was illustrated in past events along the Gulf Coast, this study focuses on the reliability assessment of coastal bridges.

Damages to bridges in recent hurricane events, such as Ivan (2004), Katrina (2005) Ike (2008), drew the attention of the research communities to the performance of bridge structures vulnerable to coastal storms. The study of the bridge performance has started by the reconnaissance lessons (Mosqueda et al. 2007; NIST 2006; Okeil and Cai 2008; Padgett et al. 2008; Robertson et al. 2007). Along with these field observations, coastal researchers have reported on the hydrological aspects of the hurricane induced wave and surge by hind-casting of wave and surge parameters (Chen et al. 2009; Chen et al. 2007; Cheung et al. 2003; Levinson et al. 2010; Panigrahi and Misra 2010; Zhixia et al. 2009). Another critical advance in the field has been developed by the beginning of studies on the evaluation of wave forces on bridge decks (Chen et al. 2009; Douglass et al. 2006; Huang and Xiao 2009; Marin and Sheppard 2009; Meng and Jin 2007; Schumacher et al. 2008); which finally have led to the first specifications for bridges vulnerable to coastal storms (AASHTO 2008). These studies have eased the path toward the probabilistic assessment of the susceptibility of coastal bridges, which is currently lacking in the literature. These models are essential for regional risk and loss estimates, determining the potential damage to major transportation routes and support risk mitigation plans and decision-making about retrofitting.

This paper proposes and evaluates different methodologies for developing of fragility curves for bridges susceptible to hurricane induced loads. Fragility curves provide conditional probability estimates of failure, or of exceeding a particular damage state, given hazard intensity. Analytical fragility curves may be developed by employing dynamic time history analysis of nonlinear finite element models that are capable of capturing evolving structural demand on different bridge components across various modes of failure. However, a static analysis approach has the advantage of computational efficiency that may be sufficient to capture one important failure mode of the bridge structure, deck shifting or unseating. In the static analysis approach, the vertical resistance of superstructure is compared with the maximum demand of the wave forces. Hence this method is appropriate for simply supported bridges, where according to the field observations deck unseating is the most common mode of failure (Chen et al. 2009; Meng and Jin 2007; Padgett et al. 2008).

This paper describes both static and dynamic analysis approaches to develop the fragility curves for coastal bridges and demonstrates the application of these methodologies through a case study representative bridge of Houston/Galveston bridge inventory. Key features include the identification and propagation of uncertainty in the performance assessment for both demand and capacity estimation.

STATIC FRAGILITY MODELING OF DECK UNSEATING UNDER STORM SURGE AND WAVE LOADS

For any given damage state, fragility surfaces provide us with conditional probability of failure (exceeding the given damage state) for given hazard parameter(s), known as intensity measure(s) (IMs). In other words, fragility surfaces introduce the probability of structural demand exceeding structural capacity for the entire reasonable range of intensity measure(s).

For the static analysis of deck unseating, failure is considered when the vertical uplift force is greater than the vertical uplift capacity. Consequently, the bridge span moves freely due to wave transverse and vertical forces. The following subsections describe the probabilistic modeling for estimation of vertical uplift capacity and demand. After attaining the probability distributions of capacity and demand as explained in these sections, the probability of failure of each span can be assessed. Fragility surfaces are obtained by performing 1000 Monte Carlo simulations per unique span of each bridge for each combination of IMs. The spans are considered as series system, thus failure in any of them results in the failure of the entire system. The probability of failure of each span is considered to be independent from others. Hence, the probability of the deck shifting or unseating for the entire bridge, P_F, is the union of probability of failure of each individual span.

Surge and Wave Forces: Demand Modeling

An appropriate wave and surge load model is essential to evaluate the forces on bridge deck. There was a gap in the literature for calculation of wave forces, since these forces were traditionally not considered in bridges design. However, empirical evidence reveals their potential to yield bearings, damage guardrails, shift and unseat spans, among other component damage. Subsequently, a recent body of research has focused on hazard modeling and estimation of surge and wave forces on bridge superstructures (Cuomo et al. 2009; Huang and Xiao 2009; Marin and Sheppard 2009; Meng and Jin 2007; Okada et al. 2006). Douglass et al. (2006) and Aguíñiga et al. (2008) provide reviews of available methods to calculate wave forces on bridge superstructure. The basis of many of the equations for wave loads on bridge decks are from previous works in offshore engineering. Nevertheless, modification is needed to the offshore equations since coastal bridges are located in shallow bodies of water and different geometry. In this paper, the load estimates used to illustrate the bridge response to deck wave forces is derived from the recent AASHTO specifications for bridges vulnerable to coastal storms (AASHTO 2008). The load models were derived from the extensive studies of Sheppard and Marin (2009) and have been selected due to their accuracy with experimental and field data.

The wave imparts two different loads on bridge deck: a slowly time varying force; refer to as quasi-static and a sudden impulse-like force attributed to trapped air. The quasi-static force is composed of a drag, inertial and buoyant force. The calculation of these forces have a theoretical background based on Kaplan's work for offshore platforms and Morrison's equation improved by the added mass computation and discritizing the domain (Marin and Sheppard 2009). Drag and inertial coefficients are found based on experimental tests. The complete equations of the wave peak forces and corresponding coefficients are presented in AASHTO 2008.

Four hazard parameters are used for demand estimation: maximum wave height (H_{MAX}), wave period (T_p), wave length (λ) and relative surge elevation (Z_c). Due to the complexity of wave forces under storm surge and wave passage, it is not possible to condition the probabilistic demands or probability of failure on any one of the wave and surge parameters alone and randomly propagate uncertainties in other parameters while still maintaining accuracy and efficiency in the predictive model. The failure probability is therefore conditioned on at least two hazard parameters as

concluded in recent work (Ataei and Padgett 2010). Implementing the relative surge elevation as one of the hazard intensity measures (IMs) is critical, since as its name suggests, it delineates the elevation of the bridge deck relative to the water surface, and the responses change clearly with its alteration. In addition, the three wave parameters are related to each other, as it is shown for example in proposed equations of (AASHTO 2008), and other ocean engineering literature (Le Roux 2007); hence, it is not rational to employ all of them independently. Thus, a two parameter vector based IM has been implemented, given relative surge elevation along with any of the wave parameters, adopted as wave height herein due to the criteria of "hazard computability".

For probabilistic assessment of structural performance, uncertainties associated with each parameter realization should be taken in to account. Table 1 defines the structural, wave and surge parameters that are considered in the reliability analysis and their corresponding probability distributions. Probability distribution of wave period is briefly introduced here. Wave period corresponds to maximum wave height is calculated using the Longuet-Higgins joint probability of wave height and wave period (Longuet-Higgins 1983). The value of wave spectral density, v, is required for the use of this distribution. In general, the value of v is small during the storm surge. 0.3 is chosen for v according to the Massel's suggestion (Massel 1997).

Table 1. Parameters required for demand and capacity estimation.

Wave and surge parameters					
			Distribution Parameters		
Variable	**Symbol**	**Distribution**	**1**	**2**	**Unit**
Maximum wave height	H_{MAX}	Function of H_s	-	-	m
Wave Period	T_p	Longuett-Higgins	$\nu^1 = 0.3$	-	s
Wave length	λ	Function of T_p	-	-	m
Relative surge elevation	Z_c	Uniform	$l^2 = 90\%$	$u^3 = 110\%$	m
Structural parameters					
Width	W	Deterministic	-	-	m
Girder height	d_g	Deterministic	-	-	m
deck thickness	d_b	Uniform	$l^2 = 95\%$	$u^3 = 105\%$	m
Concrete strength	f'_c	Normal	$\mu^4 = 21$	$\sigma^5 = 4.3$	MPa
Steel strength	f_y	Lognormal	$\lambda^6 = 6.02$	$\zeta^7 = 0.08$	MPa
Concrete density	γ_c	Normal	$\mu^4 = 2400$	$\sigma^5 = 96$	kg/m^3
Steel density	γ_s	Normal	$\mu^4 = 7850$	$\sigma^5 = 78.5$	kg/m^3

[1] Wave spectral density.

[3] Upper bound for uniform distribution, in percentage.
[4] Mean value of normal distribution.
[5] Standard deviation of normal distribution.
[6] Mean value of lognormal distribution.
[7] Standard deviation of lognormal distribution.

In order to take into account uncertainties associated with the surge elevation, a uniform distribution for surge elevation with lower and upper limit of 90% and 110% is considered. Relative surge elevation, which is the difference between deck clearance and surge elevation, is used in the calculation of wave forces. To be consistent with capacity modeling, a uniform distribution for the deck thickness is also considered in demand modeling, where the thickness can be varied from 95% to

105% of the nominal value presented in as built drawings. Other structural geometric parameters that are required for forces estimation are considered deterministic, as the small variation in them cause a negligible effect on the magnitude of wave forces.

Capacity Modeling

The vertical resistance of the span to uplift consists of the dead weight of the deck as well as the connection strength between superstructure and substructure, if any exists. The dead weight of each bridge span is assessed considering uncertainty in the unit weight of construction materials as well as some workmanship or construction errors to reflect uncertainty in as-built plans relative to field condition. A normal distribution for concrete and steel density is selected based upon (JCSS 2001), and the corresponding values are presented in Table 1. To account for workmanship and construction errors, a uniform distribution for deck thickness is considered with lower and upper limit of 95% and 105% of the as-built plan thickness, thereby affecting the span volume and dead weight estimate. Other geometric parameters, such as the girder type and height, are taken as deterministic.

If vertical connectivity is present, its contribution to the capacity model can be characterized by the pullout or yield strength of the dowel bars, depending upon its embedment length. Concrete and steel strengths are also required to estimate the required development length of the dowels and connection strength. The steel and concrete mean strength are based on the properties of the bridge inventory of larger Houston area, and the coefficients of variations are based on (Ellingwood and Hwang 1985) as shown in Table 1. The summation of the deck weight and connection strength per unit length is the total uplift capacity of the deck.

DYNAMIC FRAGILTY MODELING

The use of nonlinear time history analysis is typically preferred over linear static approaches for reliability assessment of the structures since it can capture displacement based demands and account for accumulation of damage over time. For the dynamic simulations, the same structural and wave probability distributions are adopted as those presented in the previous section (Table 1). Since the dynamic analysis requires time history of the loads, the following subsection briefly describes a simplified model to estimate the wave loads time series. The structural demand is measured in the terms of deck displacement for the deck unseating mode of failure. Additionally, column curvature ductility demand and dowels deformation are also recorded during the analysis to allow the fragility modeling of these components presented in a later section.

Surge and Wave Forces: Demand Modeling

The AASHTO equations (AASHTO 2008) adopted for the evaluation of the peak value of wave and surge loads are extrapolated in a simplified deck load time history model. The model is based on previous reports of wave loads with assumptions briefly described herein. Forces are in phase with the wave, hence, the wave forces in this research have been taken as a sinusoid with a period equal to that of the wave and maximum amplitude equal to that of the maximum quasi-static load. The impact

loads are then superimposed on the quasi-static forces. The impact loads were observed to have an effect on the bridge for approximately 5/8 the period of the wave, based on visual observation of results given by (Sheppard and Marin 2009). It is assumed that the wave is moving at a constant velocity. In addition to the vertical and horizontal forces, moment induced by wave should also be considered. When a wave passes over a bridge deck, the forces imparted change dramatically with time, and those forces cause moments on the bridge deck. The moment is calculated about the center of the bridge deck at each time step using the moment arm method. More discussion on the wave load model is provided in (Ataei et al. 2010). Since the bridge deck is allowed to uplift during the simulation if the vertical loads overcome the vertical resistance, the relative surge elevation changes during the analysis. Hence, a procedure is written to update the wave forces during the analysis based on the position of the deck.

Description of Bridge Finite Element Model

The representative bridge of the area of interest that will serve as a case study is a three-span simply supported concrete box beam bridge. The selected bridge is the most common bridge type in the Houston/Galveston bridge inventory. The spans' length is 15.2 m, and the width is 10.9 m. The outmost spans of the bridge are supported on seat type abutments. The substructure consists of two bent caps, each supported with three 0.9m diameter circular concrete columns; all of them with eight #9 longitudinal reinforcement. The bent caps have a rectangular 0.87m width and 0.91m depth cross section. Two different models with different pier-deck connection capacity are analyzed. The first one has a weak connection, where limited resistance to uplift is provided only by the deck weight and resistance of four dowels with the embedment length of 0.2m at each side of the spans. The strong connection model has twelve dowels at each side with 0.7m embedment length. For the dynamic simulation, the bridge deck is considered as unseated if the vertical displacement is more than the embedment length or transverse displacement is larger than 1m, although these limits are easily adaptable.

The numerical model for the bridge is developed in OpenSees, based largely upon past recommendations for typical CSUS concrete bridges (Nielson 2005). Unique consideration, however, is made in the connection modeling to capture the response of the bridge under the coupled vertical and horizontal forces of waves appropriately. Specifically, a contact element has been incorporated to allow the deck to be uplifted from the supports, and settle back on the bent beam when the vertical force reduces during wave passage. This vertical contact element is used in conjunction with a pounding element to reflect the impact loads and energy dissipation upon slamming of the deck back on the supports after uplift. The pounding element is a bilinear spring with properties are calculated based on (DesRoches and Muthukumar 2002) recommendations for impact elements. Contact elements are used in parallel with springs representing the dowel bars. Since the embedment length of the dowels is less than the required development length in tension, their behavior is governed by a pullout model. The properties and probability densities that are used for material strengths and weights are described in Table 1.

Deterministic Response Analysis

A sample deterministic response analysis is conducted to illustrate the dynamic response of the representative bridge with limited connection capacity under hurricane induced surge and wave loading. The mean values for material properties are employed for this deterministic study. The wave and surge parameters are H_{MAX} = 1.9m, Z_c = -0.63m, T_p = 5.8s and λ = 34m. Figure 1 illustrates the deck displacement as well as dowel bars force-deformation behavior. The embedment length of dowel is approximately 200 mm, and as shown in Figure 1, the dowel is completely pulled out after this displacement and does not carry any more force. The deck is fully uplifted and slammed back to its support and large displacements are observed in both the transverse and vertical direction.

Figure 2 depicts the transverse moment-curvature response of the column in the waveward direction of the pier supporting decks 1 and 2, as well as axial force time history. Large axial forces transfer to the column after impact. Also, before failure of the dowels, the column axial load changes from compression to tension due to vertical load. This reveals the important interaction between deck and pier under surge and wave loading, and the potential of strong connections to transfer damage from the super- to substructure—an important consideration in later system fragility analysis considering multiple failure modes.

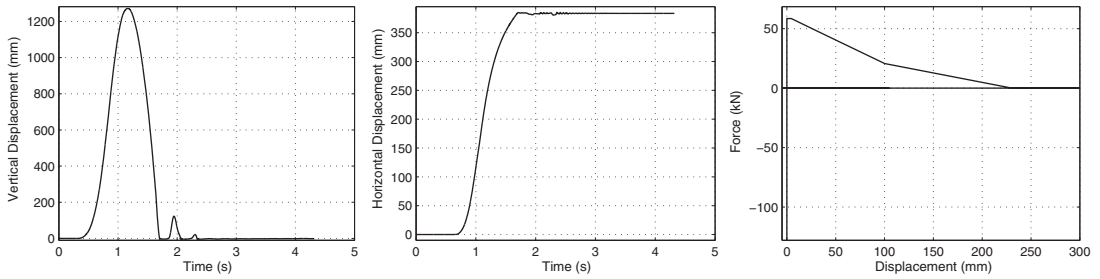

Figure 1. Deck vertical and transverse displacement, and dowel force – pullout model.

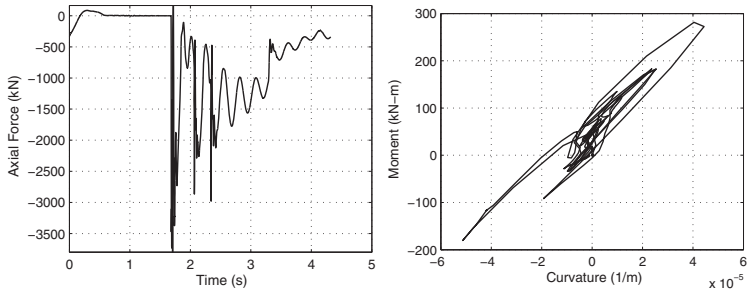

Figure 2. Time history of axial force and moment curvature for one of the columns - pullout model.

COMPARISON OF DECK UNSEATING FRAGILITIES FROM DYNAMIC AND STATIC APPROACHES FOR THE BRIDGE WITH LIMITED CAPACITY CONNECTION

Fragility surfaces for deck unseating have been developed for the representative bridge with pullout connection adopting both dynamic simulation and static analysis strategies. For the bridge with weak connection, all of the components except

connection dowels remain in their elastic range. From the results of the analysis it has been concluded that for the multi span simply supported bridges with limited connectivity, most ranges of realistic hurricane induced hazard parameters lead to extreme cases of deck response (e.g., either well below damage level or resulting in severe deck displacement); hence adopting a higher value for vertical displacement limit leads to almost identical fragility surface. Furthermore, employing the vertical displacement limit state without considering transverse displacement limit state for dynamic analysis leads to the similar reliability estimates. The extreme response of the deck due to wave and surge loads leads to similar probabilistic estimates for static and dynamic analysis, where Figure 3 compares the result of static and dynamic simulation. The findings demonstrate the potential viability of the static approach for assessment of the deck unseating failure mode for bridges with limited capacity connections prevalent in the Gulf coast inventory, and particularly in the Houston/Galveston region.

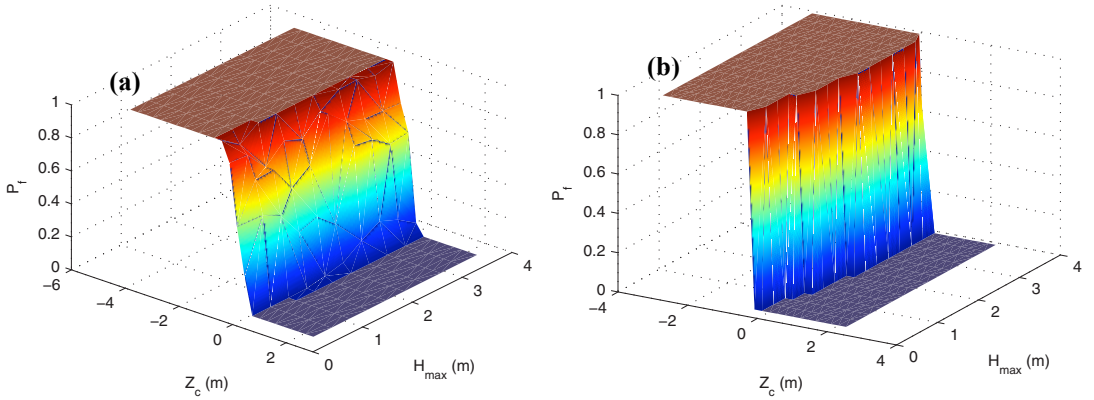

Figure 3. Fragility surfaces for deck unseating: (a) static; and (b) dynamic analysis.

FRAGILITY SURFACES CONSIDERING MULTIPLE COMPONENT FAILURES FOR THE BRIDGE WITH HIGH STRENGTH CONNECTIONS

The fragility under surge and wave load is assessed in this section for the multiple span simply supported concrete box beam bridge with high strength connections. In this model, the connection dowels reach their yield strength prior to pullout. Strengthening the deck-pier connection is also one new design or retrofit detail that has been considered to help avoid unseating of coastal bridges. This strong connection causes significant force transfer to the substructure, thus introduces large demands on columns. Since the column axial force is not constant during wave passage, its yield and ultimate curvature changes during the simulation, which is taken into account by calculating the yield and ultimate curvature at each time step. In this study, two different limit states are considered: yield (major) and complete. For the columns, considering flexural failure by measuring curvature ductility demand as the only demand parameter is not sufficient since another important mode of failure is possible with this strong connection, which is the tensile failure of the columns. For this particular demand (EDP), a column assumed at the major damage state if the axial force is larger than the cracking load of the section, and at the complete state if the tension force exceeds the required force to yield the longitudinal reinforcement.

This discussion reveals that considering both tensile force and curvature ductility demand is required for the columns. Hence, a column reaches the major damage state if the demand curvature passes yield curvature or tensile force exceeds the cracking load. Table 2 illustrates the limit states for the structural components as well as for the entire system. The deck unseating is also considered as one of the complete failure modes by considering the fracture displacement of dowels, as noted in Table 2. However, for the assumed connection type columns exceed the complete limit state before the deck unseating. Nevertheless, the results of this section can be generalized to the cases where the deck unseating occurs before any collapse in substructure by dividing the failure probability into two parts and applying the total probability theorem, as, for example, illustrated in (Baker and Cornell 2005).

Table 2. Limit states.

Limit State	Columns	Connections	System
Yield	$c/c_y>1$ *or* $P_t>F_{crack}$	d_d> yield disp.	Columns or connections in major damage state
Collapse	$c/c_c>1$ *or* $P_t>F_{tmax}$	d_d> fracture disp.	Columns or dowels in complete damage state

Contrasting the deck unseating analysis for the weak connection bridge, it is possible to observe a functional relationship between the EDPs (displacement, curvature ductility demand, or axial force) and the wave and surge parameters. Table 3 shows the relationship and the test of goodness of fit in terms of R^2. It should be noted that the initial clearance of the bridge (Z_{c0} of zero surge) is added to the values of negative of Z_c, since it can take negative values (submergence).

Table 3. Coefficients for functional relationship $\ln EDP = a \ln(-Z_c + Z_{c0}) + b \ln H_{MAX} + c$.

Analysis	*EDP*	Symbol	*a*	*b*	*c*	R^2
Dynamic	Maximum tensile force ratio	P_t/F_{tmax}	3.9121	-0.0679	-7.155	0.781
	Curvature ductility demand	c/c_y	1.9741	-0.0123	-9.568	0.746
	Ultimate curvature ratio	c/c_u	2.8885	0.0948	-14.6789	0.796
	Dowel deformation	d_d	12.162	0.3254	-24.072	0.751
Static	Maximum tensile force ratio	P_t/F_{tmax}	3.7373	-0.0381	-6.237	0.832

For comparison, the maximum forces in columns are also calculated by adopting maximum wave forces in static approach and performing a linear structural analysis. The column curvature and dowel bar deformation are not calculated, since the analysis is linear. The resulting equation for the maximum tensile demand is similar to the dynamic analysis, and the corresponding coefficients are presented in the last row of Table 3.

Fragility surface for each component can be assessed, assuming that distribution of EDPs in logarithmic space is normal, according to the following equation:

$$P(EDP \geq LS \mid \mathbf{im} = [Z_c \;\; H_{MAX}]) = 1 - \Phi\left(\frac{\ln LS - (a \ln(-Z_c + Z_{c0}) + b \ln H_{MAX} + c)}{\sigma}\right)$$

Where Φ is the normal cumulative distribution function and σ is the standard deviation of the regressed functional relationship in the logarithmic space. Figure 4 plots the fragility surfaces for the columns tensile demand and dowel bar deformation

for major damage state. It should be noted that applying either static or dynamic approach yields similar fragility surface for the columns tensile demand. However, this limit state is force-based, and other limit states based on deformation may not be feasible to assess under such simplified analyses methods.

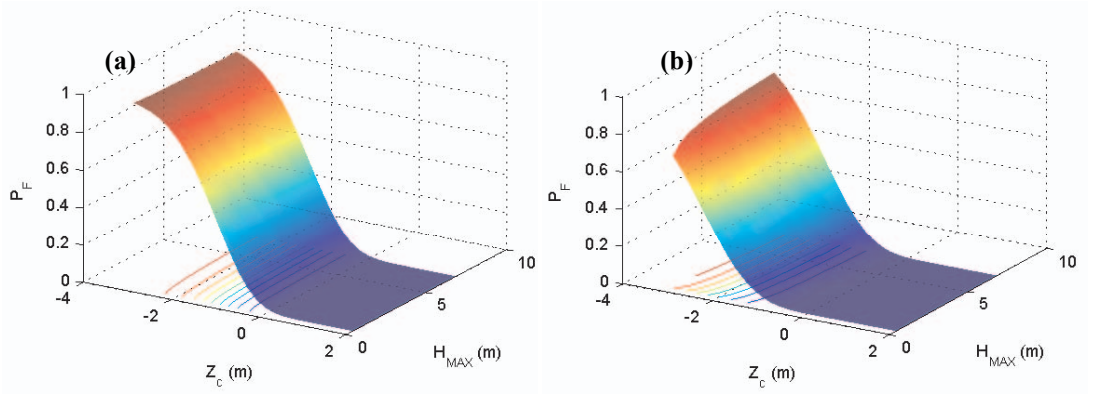

Figure 4. Fragility surface for yield damage state: (a) column tensile demand; and (b) dowel deformation.

The fragility for the entire structure is constructed by the assumption of series system, i.e. the system is in a particular damage state if any of its components is in that damage state. The probability distributions of components are combined into a joint normal probability distribution in the transformed logarithmic space. By this methodology, the system level fragility is shown in Figure 5. For the case study bridge structure, the system fragility is mostly influenced by the columns tensile limit state, in both damage states. Hence, the static fragility for the columns may serve as an efficient and viable lower bound of the system fragility. Future work will investigate alternative system definitions appropriate for capturing the failure modes and consequences of damage for bridges under surge and wave loading.

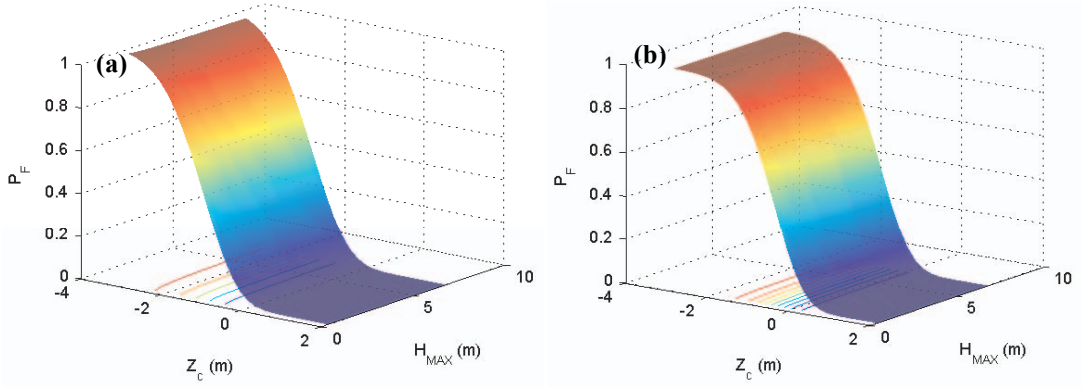

Figure 5. System fragility surface: (a) major; and (b) complete.

CONCLUSIONS

This paper proposes two different analytical methodologies to probabilistically assess the reliability of coastal bridges susceptible to hurricane induced storm surge and wave. A simply supported concrete bridge, as a representative bridge of Houston/Galveston area, is selected for the case study to demonstrate the application of the static and dynamic methodologies for the development of conditional probability estimates given hazard parameters (fragility surfaces). The results of this study reveal that for simply supported bridges, deck unseating is the predominant mode of failure and that a static approach with rigorous uncertainty treatment may approximate the fragility with acceptable accuracy. Conversely, when a strong deck-pier connection exists, the structural demand on substructure should also be taken into account, since large forces are transmitted through the connection from the bridge deck to the substructure. In particular, results show large tensile forces in columns, which is not typical in design of columns and foundations. Currently, the linear static approach is able to account for the columns tensile demand. However, it is not able to correctly account for displacement based demands such as the column curvature. Hence, for a complete system reliability assessment of bridges with strong connections between sub and superstructure, nonlinear dynamic analysis is preferred. Nonlinear static analysis is part of the ongoing research to evaluate its possible applicability for this type of bridge with strong connection, as well as the investigation of system logic for system fragility modeling of bridges under surge and wave loading.

INTRODUCTION

A team of engineers, funded by an NSF RAPID Grant, investigated selected critical electrical equipment, such as switchgear, motor control centers and inverters, at ten sites located in the Port-Au-Prince region that were subjected to strong ground motion during the 12 January 2010 Haiti earthquake. The investigations included a site survey of both damaged and undamaged electrical equipment, and included not only documentation of the physical damage to the equipment, but also consideration of the resulting consequences of the loss of use of the specific equipment and related systems.

While the observed damage modes for the selected equipment when subjected to strong ground motion were not unexpected, it was the consequences of the loss (actual or potential) of the use of the damaged equipment that presented important lessons for the investigating team.

This paper will detail the observed damage for selected non-structural elements subjected to strong ground motion during the 2010 Haiti earthquake. In addition, the paper will discuss the consequences of the loss of critical equipment at selected facilities in the Port-Au-Prince region and possible implications for the seismic design of critical non-structural components required for post-earthquake recovery operations in developing countries.

SURVEY OF SITES SURVEYED IN PORT-AU-PRINCE

Extensive planning prior to the visit to the Port-Au-Prince region allowed the Haiti mechanical and electrical equipment (MEP) survey team to maximize data acquisition activities during their time on site (April 11-15, 2010). The investigation team visited ten sites in and around Port-au-Prince in search of damage to mechanical and electrical equipment. The ten sites are listed in Table 1 and are identified on a map (Figure 1) which shows their general location in relation to the epicenter of the January 12, 2010 earthquake. While the focus was on damage to MEP components, the team observed and made note of damage to nonstructural elements and systems in general, if visible, during the guided tour of each site. Each site was given a unique two character ID (see Table 1) for use in cataloging and cross referencing the hundreds of digital photos and other information obtained by each member of the team.

The specific types of equipment found at selected sites as well as the types and severity of damage to each are discussed in follow on sections of this report. At each location, the team looked for and recorded the following information:

- Facility name, function, and local personnel contact information
- For selected equipment, the equipment name, and model, as well as the specific location and the function of the equipment within the facility
- The latitude and longitude of the equipment location (using hand-held GPS equipment)
- Damage to the equipment as a result of the strong ground motion; if damage occurred, evaluation of possible damage mode(s) (internal vs. external, anchorage, overturning, translation, etc.)
- Impact of the loss of the selected equipment from both a disaster response and disaster recovery perspective
- Contribution of the loss of the selected equipment to significant business interruptions at the facility, and associated level of financial impact of the loss of the equipment
- Detailed digital photographs, engineering sketches and measurements of the equipment layout, the supporting equipment pad, and any existing lateral restraint or anchorage
- Assessment of how long it will take the facility to replace or repair the damaged equipment.

TABLE 1 – SITES VISITED BY PROJECT TEAM TO RECORD MEP DAMAGE

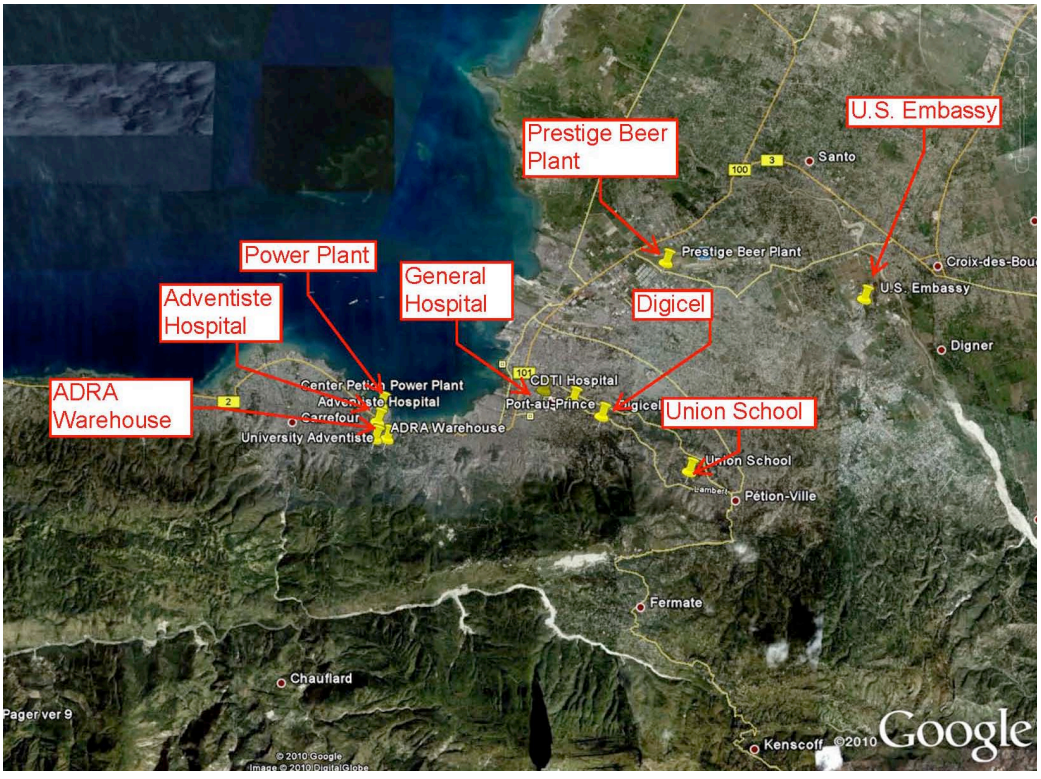

FIGURE 1 – MAPPED LOCATION OF THE TEN SITES VISITED BY THE PROJECT TEAM

TYPES OF ELECTRICAL EQUIPMENT SURVEYED

Facility electrical power distribution and control equipment, as well as system design and installation methods, surveyed at all sites were typical of what would be found in similar facilities in North America. Origin of manufacture was North America for a majority of the power system components (switchgear, transformers, conduit, etc.) at all locations.

Of note was that electrical system design and installation methods in two of the hospitals, Adventiste and Port-au-Prince General, were not as robust as and of less capacity than for similar size facilities in North America. Portions of the installations would not meet basic North American standards, much less the required seismic lateral restraint requirements, due to the absence of conduit or missing cover plates on junction boxes resulting in exposed power conductors and other poor installation practices.

Uniquely different from North American facility electrical systems was the common use of on-site diesel generators as the primary source of power. While all facilities had provisions for service entrance connection to the public utility power grid, very few used the grid as a sole source of power, even before the earthquake, due to reliability and cost. As a result, the North American paradigm of "emergency generator" does not exist in Haiti since on-site generation is frequently the normal source of power. This heavy reliance on user-owned diesel generators has significant implications for post disaster return-to-operational status for critical facilities due to interruptions in fuel availability and delivery. Assessment of the public electrical power utility system was not a focus of this survey but anecdotal evidence suggests that the local overhead electrical power distribution system was heavily damaged by building collapses, thus power was still not available in most of the Port-au-Prince area at the time of this survey. (The team was unable to obtain permission to enter and inspect EDH (Electricity de Haiti), the government owned and operated power plant located adjacent to Center Petion Power Plant.)

It was also common to see inverters used to supply power from deep cycle storage batteries to emergency lighting and similar essential loads during off hours when the generators were shut down. Inverters were also used during power interruptions associated with the transition from normal to alternate sources for facilities without paralleling transfer systems.

OBSERVED DAMAGE AT SELECTED SITES

Damage to electrical components and equipment was observed at all sites to some extent, although a disproportionate amount of damage to electrical equipment and components was observed at several key sites. Displacement of electrical equipment due to the absence of or inadequate anchorage was the most commonly observed damage state. Falling building debris and building displacement induced damage was also an issue. Observed displacement damage states typically had little or no impact

on electrical equipment functionality and any needed repairs had been or could be carried out with local resources. Had the ground motions been larger or lasted longer, the outcome may have been very different. Due to the space limitations of the paper, only damage at selected sites will be discussed below. Readers can find a more in-depth discussion of the damage observed at sites in other publications.

Digicel Building (DB):

Digicel is the main provider of wireless communications in the region. The primary Digicel facility in Port-Au-Prince consists of two major building, one of which sustained considerable structural damage. In addition to the buildings, the site also includes numerous auxiliary non-structural elements that are critical to the functionality of the communications facility.

An unanchored UPS system at Digicel, shown in Figure 2 below, consisted of multiple free standing cabinets located at grade level with top entry and exit electrical conduits. Cabinets were not fastened together, so they could slide independently. The UPS systems provide power to servers that control the cellular network node covering the Port-au-Prince area. As such, the UPS systems were a critical element for the cellular network. Attachment points for the conduit were the ceiling bracket just after the first 90 degree elbow and the top of the UPS enclosure. Stresses on the conduit and the attachment points were at a maximum between these points. UPS cabinets displaced to the right of their initial installation position as can be seen by the offset of their cabinets (left photo, Figure 2). The cabinets may have displaced laterally as much as five inches or more during the earthquake (right photo, Figure 2) in addition to an undetermined floor-to-ceiling interstory drift. Despite displacement demands on the conduit, the connections to the enclosures remained intact.

FIGURE 2 – DISPLACEMENT OF THE UPS CABINETS AT THE DIGICEL FACILITY

There were also multiple microwave antennas located on top of a trussed tower adjacent to the buildings, as shown in the photograph on the left in Figure 3 below. Each antenna either links with major nodes of the carrier's network or serves as an end point link to local cell sites in the Port-au-Prince area. Microwave links at these frequencies are highly directional, requiring highly specialized instruments and technicians to achieve the precision alignment required for reliable data links. The carrier operations manager reported that none of their tower-mounted microwave links required realignment after the earthquake. The only cellular antenna arrays reportedly damaged beyond repair were those at local sites on buildings that collapsed.

While the tower and microwave antennas were undamaged, the cable tray running from the cell tower to the Digicel low-rise building, which contains RF coaxial cables for antennas and microwave links, experienced considerable damage, as seen in the photograph on the right in Figure 3. The cable tray separated from its attachment to the building, probably due to significant differential interstory displacements of the heavily damaged low-rise building. The damage was limited to the cable tray attachment while the cell system itself remained functional. Had the RF coaxial cables been damaged, the ability of the Digicel to quickly restore system wide operation throughout Haiti would have been seriously impaired.

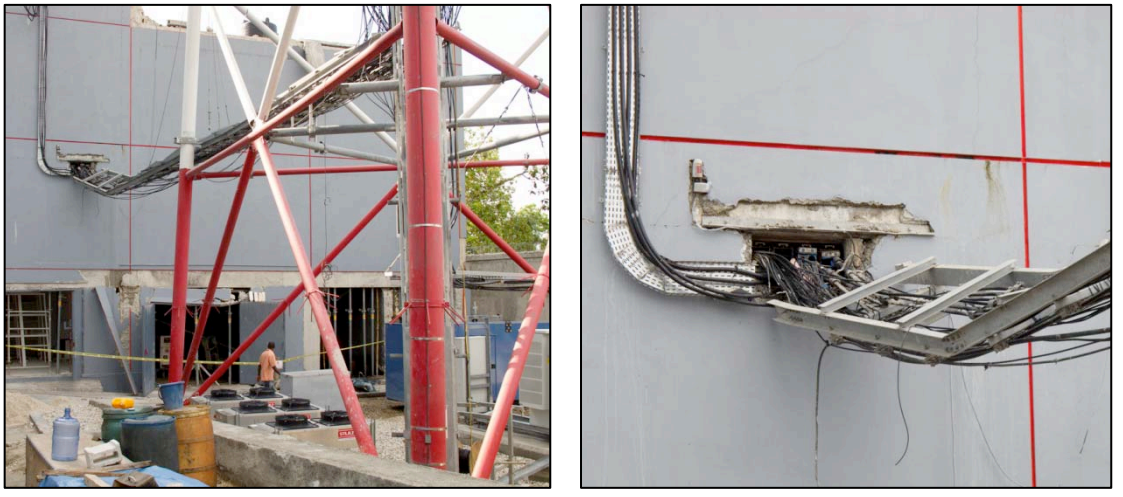

FIGURE 3 – MICROWAVE TOWER AND DAMAGED CABLE TRAY

General Hospital (GH):

Damage to the EDH public utility electrical service entrance area was visible at the Port-au-Prince General Hospital. Major components on site were a station circuit breaker, a diesel generator, an automatic transfer controls cabinet, a liquid filled pad-mounted transformer, and two voltage instrumentation transformers.

The general purpose cabinet with controls installed for automatic transfer of facility power source between the public utility and an on-site generator is shown in the photo on the left in Figure 4 below. The control wiring conduit at grade level pulled out of the cabinet when the cabinet moved off of its concrete pad due to a lack of anchorage, as shown in the photo on the right. Repairs to the cabinet and wiring appeared to be within capabilities of local resources.

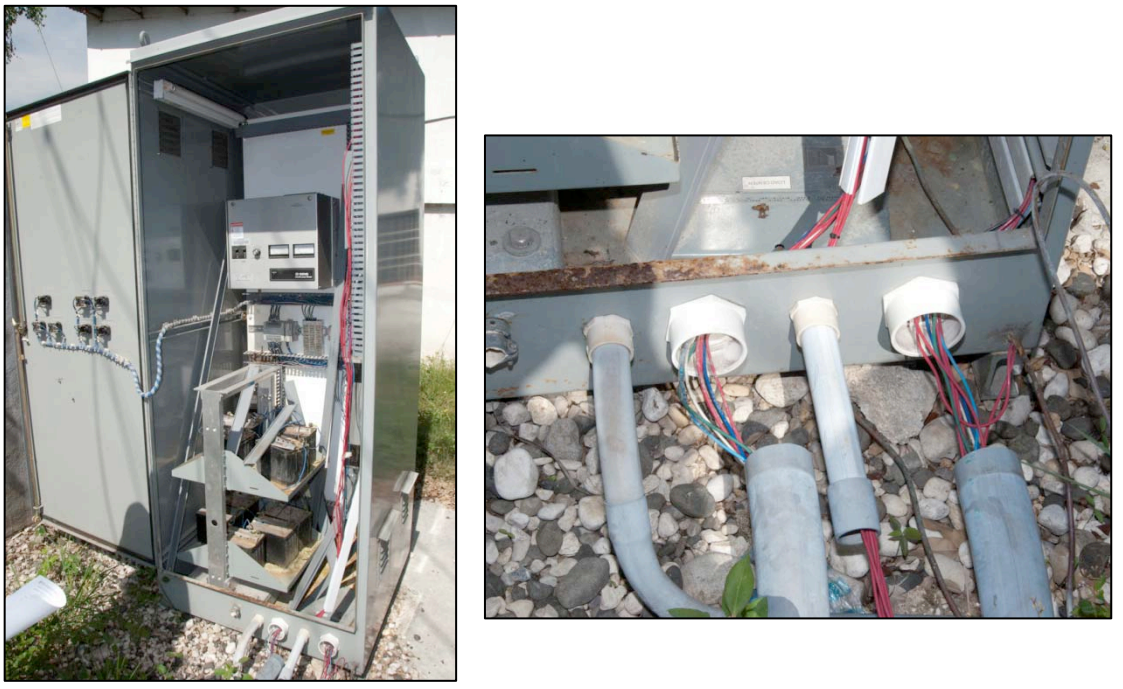

FIGURE 4 – DAMAGE TO AUTOMATIC CONTROL CABINETS

US Embassy (UE):

Overall, the U.S. Embassy buildings performed very well in the earthquake (Sawyer, 2010). There was no visible damage to the building itself, and only very minor damage was noted to selected non-structural elements. This represents validation of U.S. codes and practice for seismic design and construction, especially for structures and non-structural elements that are designed for a higher level of seismic performance.

The only damage visible in the facility's electrical switchgear room was to a general purpose free standing cabinet housing a power quality monitoring system. This cabinet is located on the equipment pad to the right of the draw-out switchgear for the incoming utility power system and was not attached to the draw-out switchgear. The cabinet was poorly anchored; the anchor bolt at the front left corner was observed to have backed out with damage to the flat washer, as shown in the photograph on the left in Figure 5 below. This damage appears to have been caused by impact due to left front corner uplift of the cabinet during rocking motion induced by the

earthquake. The photograph on the right shows damage to the right front corner of the cabinet pad. This corner failure appears to have been caused by a prying moment on the embedded anchor due to cabinet rocking during the earthquake.

FIGURE 5 – DAMAGE TO POWER QUALITY MONITORING CABINET

IMPACT OF LOSS ON DISASTER RESPONSE AND RECOVERY

The impact of the loss of power on the sites that were involved in the response and recovery effort appeared to be substantial. The Adventist and General Hospitals, both of which received a tremendous influx of patients following the earthquake, were limited in their operations due to the lack of city power and the finite capacity of their emergency generators. Staff at both hospital facilities mentioned that the lack of dependable power had an adverse impact on their ability to perform essential medical procedures and to deliver quality medical care.

At the General Hospital, a 440 kw generator that appeared to be in good condition was not being used because it was dedicated for use in the radiology department, which was not in service due to damaged equipment. In discussions with staff, it was unclear why the generator could not be re-tasked for use in another part of the hospital, although there were indications that the skilled labor required to remove and re-install the generator may not have been available following the earthquake.

The ADRA facility, which secures, stores and distributes food and other supplies to those in need, was a key component in the local earthquake response and recovery effort. The ADRA facility was well prepared to sustain post-earthquake operations even with a loss of city power, with relatively large generators in place given the size of the facility. However, it was noted that the anchorage and lateral restraint of the generators and their associated starter batteries appeared marginal at best. If the ground motion at this location had been stronger and/or of longer duration, the chance that the generators and starter batteries would have sustained significant damage would have increased substantially. A loss of emergency power generation capacity

at a facility such as ADRA would have a major negative impact on the response and recovery effort in that region of Port-Au-Prince.

SUMMARY AND CONCLUSIONS

The enormous scale of deadly destruction in Haiti can easily mask important lessons to be learned from the Haiti earthquake that should not be overlooked. Given that the sites surveyed were located approximately 13 to 23 miles from the epicenter of a M 7.0 earthquake with an estimated depth of 8 miles, the Haiti event is typical of an earthquake that could occur during the life of a critical facility located in any moderate to high seismic region of the world. The investigations of the project team at selected facilities in Haiti confirmed that non-structural elements that are well anchored and/or laterally restrained, such as those elements observed at the U.S. Embassy, will perform well during a moderate seismic event. However, the investigation also revealed that many critical institutions in an underdeveloped country such as Haiti do not utilize the state-of-the-art engineering design or construction practices when installing non-structural elements that are key to their post-earthquake operations.

While there is and always will be uncertainty about the exact nature of ground motions from the Haiti event, the damage survey observations were generally consistent with the performance goals of modern building seismic design standards such as ASCE 7-05. Completed in 2008, the new U.S. Embassy in Haiti was a text book example of how effective properly implemented seismic mitigation measures for building equipment and related systems can be in meeting the performance goal of operational after the event.

The focus of this survey team was to evaluate the performance of mechanical and electrical systems in selected critical facilities. The most significant finding was that absent or poorly implemented equipment seismic anchorage hampered the ability to restore essential systems to operation after the event. The survey team also noted that even when there is an awareness of the need to anchor and/or restrain non-structural elements, implementation of the lateral anchorage/restraint in accordance with the procedures detailed in ASCE 7-05 or other similar standards may not be practical due to financial and logistical issues in developing countries like Haiti.

Observations from selected Haiti critical facilities also demonstrate that even for very well designed and constructed critical facilities, a fundamental understanding of how to design, install and inspect electrical equipment seismic restraint is lacking and, as such, poses a significant risk to the post event operability of critical facilities. This long established fundamental knowledge gap suggests that effective methods to advance the state-of-the-art in seismic mitigation for critical facilities must be developed.

Designers of facilities that are being constructed in regions of the world where modern design standards are not typically utilized should be sensitive to the need to provide details for the lateral anchorage and/or restraint of critical non-structural elements that can be installed by the local construction trades. In addition, design professionals should advocate for construction observation to be provided at these critical facilities to ensure proper installation of anchors and lateral restraining elements. Observations of the project team following the Haiti earthquake suggest that there is a need to improve local installation practices for critical non-structural equipment, especially in under-developed regions of the world. Specifically, follow on studies should be targeted at designing and distributing installation details for non-structural elements in facilities that are critical to the post-earthquake response in under-developed countries (e.g., similar to that presented in FEMA 413, 2004 and 74, 2005.)

ABSTRACT

Although the majority of devastation in the January 12 2010 Haiti earthquake was from non-engineered structures, the earthquake also damaged several modern engineered buildings in the capital city of Port-au-Prince. Data gathered on the observed performance of a selection of these structures is being used for the purposes of comparison with, and calibration of, analysis-based predictions used in seismic assessment procedures. Structures were selected for investigation based on their damage state, available design information, and accessibility. These buildings are a small set of important engineered reinforced concrete structures within Port-au-Prince. The available information is being used to construct analytical models using state-of-the-art techniques for nonlinear dynamic analysis. Seismic hazard levels are being estimated by indexing to the level of demand required to bring about the observed damage. Conclusions on the efficacy of these methods are being drawn through comparisons of the predicted response to actual outcomes. The final deliverable is a report documenting the structure and design information; the post-earthquake state; the modeling techniques; analytical results/comparison and evaluation of the methods. As an interim report, this paper presents: (1) general Haiti earthquake information; (2) damage mapping of candidate structures; (3) preliminary analytical modeling.

1. INTRODUCTION

Although the majority of devastation in the January 12 2010 Haiti earthquake was from non-engineered structures, the earthquake also damaged several modern engineered buildings in the capital city of Port-au-Prince. Data gathered on the observed performance of a selection of these structures is being used for the purposes of comparison with, and calibration of, analysis-based predictions used in seismic assessment procedures. The work is being performed as a partnership between academia and industry with university researchers working alongside professionals from the earthquake engineering consultant firm Rutherford & Chekene.

Structures were selected for investigation based on their damage state, available design information, and accessibility. These buildings are a small set of important engineered reinforced concrete (RC) structures within Port-au-Prince: the Teleco high-rise office building, and the cafeteria and classroom buildings at the St. Louis de Gonzague School. The design, site conditions, and observed damage of these structures have been documented by the team, with on-site visual inspection providing failure modes, damage intensity/patterns, and residual state.

The available information is being used to construct analytical models using state-of-the-art techniques for nonlinear dynamic analysis. Seismic hazard levels are being estimated by indexing to the level of demand required to bring about the observed damage. Then, the analytical models are used to predict building response according to accepted seismic assessment techniques in the U.S., and the predicted response is compared to the observed actual performance. In particular, the effectiveness of the structural models to produce similar behavior modes, overall patterns of damage, and appropriate assessment decisions is being evaluated. This paper written during ongoing work presents: (1) general Haiti earthquake information; (2) damage mapping of candidate structures; (3) preliminary analytical modeling.

2. BACKGROUND

The Mw 7.0 earthquake that struck the Republic of Haiti on January 12, 2010, is among the most destructive earthquakes in recorded history. The earthquake occurred at 4:53 PM local time on January 12, 2010 with duration of about 30sec. The USGS reports that the earthquake epicenter was located at 18.457N, 72.533W. Port-au-Prince, with an estimated population of between 2.5 and 3 million people, is located 25 km ENE of the epicenter. Fig.1. shows main shock and aftershock locations (M7 indicated as star; M5-M6 indicated as dark circles and M4-M5 indicated as light circles). Despite recent seismic quiescence, Haiti has suffered similar devastating earthquakes in the historic past (1701, 1751, 1770, and 1860).

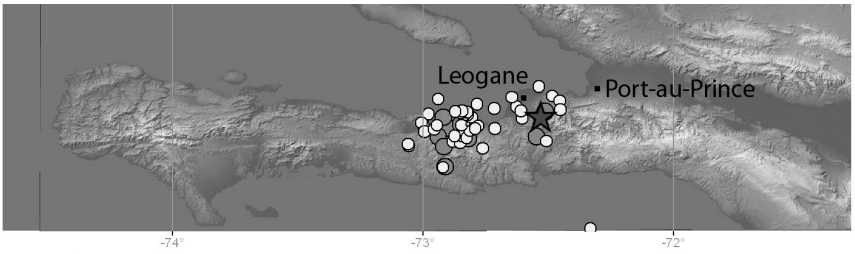

Fig.1. Topographic map of Haiti with the January 12, 2010 (USGS, 2010).

The loss in the earthquake includes: 222,000 deaths, 300k injured and 1,300,000 displaced; 97,000 houses destroyed, 188,000 houses damaged and 20% of structures in Port-au-Prince collapsed. Haiti had no seismograph stations during the main earthquake, so it is difficult to estimate accurately the intensity of ground motions. Nonetheless, the wide range of buildings damaged suggests that the ground motions contained seismic energy over a wide range of frequencies.

Partly because of the recent seismic quiescence since the last devastating earthquake in 1860, most buildings are designed for gravity only and generally no specific provisions for lateral design were considered in the past. This is apparent from the following post-earthquake observations:

(1) Unreinforced masonry is used extensively for partition walls. This is effective for insulation against temperature and noise, but it tends to exhibit little ductility in seismic shaking.

(2) Concrete beams and girders are not always connected with each other in the same plane but instead beams often run across the top of girders.

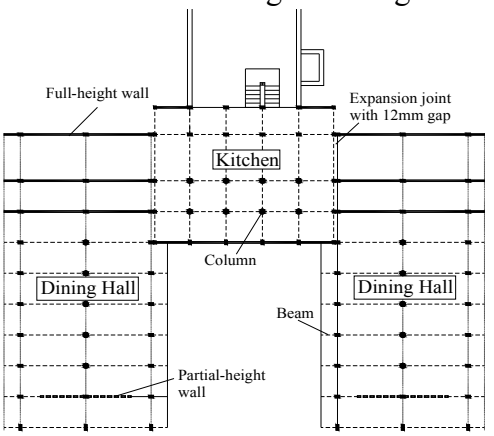
(3) Reinforcing bar ties in concrete columns tend to have large spacing and small diameter (e.g. #2 ties @15-30cm o.c.) which provides limited shear strength and confinement.

(4) Heavy floor systems with small columns are common. Beams tend to be stronger than columns, which resulted in soft story earthquake response in many buildings.

3. DAMAGE MAPPING FOR SELECTED STRUCTURES

In order to gather the required information a field trip was conducted by the team in May 2010. During this trip, many sites were visited and a few structures were selected for investigation based on damage state, availability of the design information, and accessibility. Ideal structures for this study are those that are engineered construction with the potential for design documentation, suffered documentable damage during the January 2010 earthquake, and were safe and accessible for the team to enter to perform reconnaissance work. The selected structures represent a variety of structural configurations, ranging from single story to multistory frame and from regular plan to irregular plan:

(1) Saint Louis De Gonzague School (SLG) Complex
   a. Cafeteria: C-shaped building consisting of 3 single-story RC frame units, one of which has an underground storage floor;
   b. Canopy: single story cantilever column structure;
   c. Classroom building: 2-story 8-bay RC frame structure



(2) Teleco Building: 9-story V shaped RC structure

(3) St. Joseph School (SJC): 4-story RC frame structure

Saint Louis de Gonzague School: Cafeteria Building

The cafeteria is a C-shaped one-story building that consists of three structures separated by expansion joints with a gap of ~12 mm (Fig.2). The kitchen in building rear is disconnected from the two dining hall wings which are located on either side of the kitchen. The vaulted concrete shell roof is supported by gravity beams and columns. None of the full-height masonry infill walls in the building rear (kitchen and dining hall areas) act as bearing walls. Nonstructural, partial-height, unreinforced masonry walls abut the center columns in the front of both dining hall wings.

(a) Photo (b) Plan view

Fig.2. One story cafeteria buildings.

Two main areas of structural damages were observed in the building:

(1) Spalling and shear damage of concrete and buckling of longitudinal bars of the columns in the front of the two dining hall wings, just above the top of the partial-height masonry walls (Fig.3). The shear damage at the top of these concrete columns was most likely caused by a combination of the partial-height masonry walls that reduced the clear-height of the columns and also by the large displacement demands caused by the geometry (torsional response) of the building. The combined center of stiffness of the three structures is in the back of the cafeteria whereas the center of mass of the whole structure is further to the front of the building. Hence the cafeteria building tended to rotate around its center of stiffness imposing large displacement demands on the columns in the front of the two dining hall wings.

Fig.3. Column shear damage in cafeteria building.

(2) Extensive damage to the columns and full-height masonry walls in the area of the two expansion joints between the kitchen and the two dining hall wings (Fig.4). The damage was caused by pounding of the three structures across the 12 mm expansion joints. Observations indicate that pounding occurred in both directions. Longitudinal cracks observed in the vaulted ceiling were most likely preexisting (long-term discoloration of paint due to moisture/water intrusion through cracks). However, they might have been enlarged during the shaking.

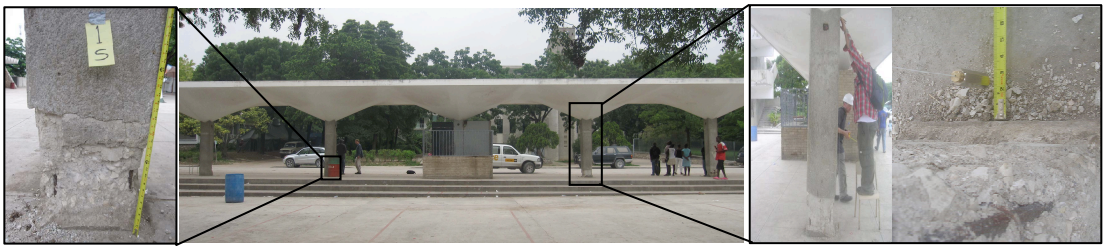


Fig.4. Pounding failure in cafeteria building.

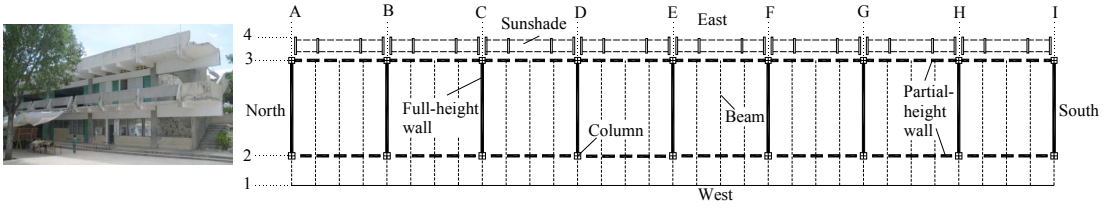
Other columns in the building appear to have performed well, indicating that the typical column shear reinforcement may be sufficient if the column is free over the full story height (no constraining walls). Columns with full-height masonry walls on both sides appear to have performed adequately as well.

Saint Louis de Gonzague School: Canopy Structure

This structure consists of a concrete shell roof supported by six square concrete columns placed in a line (Fig.5b). In the transverse direction the canopy behaves like a cantilever and in the longitudinal direction it behaves like a one-story-five-bay frame. Columns appear to be flexure-governed at the base where they form plastic hinges with noticeable concrete spalling (Fig.5a) and up to 2.9% residual drift in the transverse direction (Fig.5c).



(a) Column damage (b) Canopy structure (c) Residual drift

Fig.5. Photo of canopy structure.

Given the well-defined canopy structure with its localized damage and residual drift it is possible to perform nonlinear incremental time history analyses to find a suitable ground motion and its intensity to replicate the damage. Hence, the canopy structure is serving as a tool to calibrate ground motions, which can then be used to analyze the other structures (classroom and cafeteria) at the Saint-Louis de Gonzague school. Local variations in soil properties throughout the school campus may affect the ground motions experienced by each separate building, which complicates the calibration.

Saint Louis de Gonzague School: Classroom Building

(a) Photo (b) Plan view

Fig.6. 2-story classroom building.

This classroom building is a two-story, eight-bay frame structure with story heights of 3.7 m and bay widths of 8.2 x 8.2 m (Fig.6). The member (beam, column) dimensions in both stories and all eight bays are the same. Most of the participating mass of the classroom building comes from the two suspended levels (2nd and Roof). In addition, a concrete sunshade structure (2 m deep) occurs in the back of the building and contributes some mass but little stiffness to the overall structure. Full-height infill masonry walls exist in all the EW-frames and partial height (mostly 1/3 of column height) infill walls exist in the east NS-frames in the back of the building.

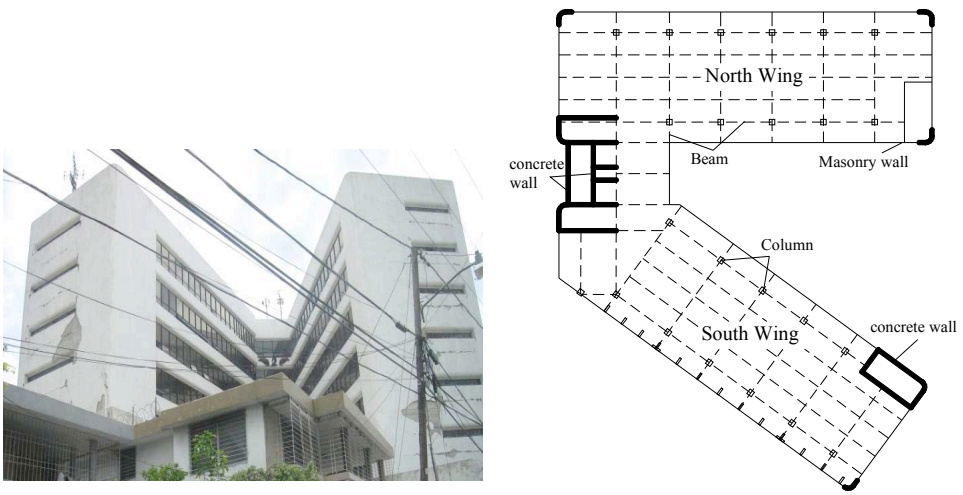
Several major damages were observed in this building:

(1) The front (west side) of the building had partial height infill masonry walls that had mostly been demolished and removed when the team arrived. These infill walls did not directly bear against the columns because of door frames on both sides. Therefore they did not significantly influence the rest of the structure during the earthquake but behaved independently and most likely collapsed due to out-of-plane inertia loads (Fig.7). Due to the larger shear forces in the first story but same member sizes in both stories and the weak-column strong-beam design, the classroom building tended to form a soft story mechanism at the 1st story. This was visible from flexural hinges that formed at the top and bottom of the 1st-story columns along the west NS-frames of the building (Fig7).

Fig.7. Flexural hinge damage in the west NS-frame.

(2) On the NS-frame on the east side of the building, partial-height infill masonry walls abut most columns, shortening the column clear height and leading to shear-governed or flexure-shear behavior. The worst cases are shear failures at the 1st story columns H3 and I3, which are the two locations where masonry partial-height walls are higher than usual because of a restroom (Fig.8). This is aggravated by the fact that column bar splices that occur at the top and bottom of each story, in the regions of the column subject to the greatest moments and shear forces.

Fig.8. Shear-flexural damage in column H3 of the east NS-frame.



(3) In the EW direction, performance is generally acceptable. Full-height masonry infill partitions on every line at both levels provide strength, stiffness, damping, and regularity in this direction. There is spalling around the edges of most of these partitions and crushing at some corners (Fig.9), but little evidence of out-of-plane falling hazards.

Fig.9. Damage in the corners of full-height masonry partitions infilling the EW-frame.

Teleco Building

The Teleco building is a reinforced concrete structure, V-shaped in plan, that has one basement level and eight stories above ground (Fig.10). The North wing of the building is perpendicularly connected to the concrete core of the structure, which contains a stairwell, two elevator shafts and mechanical utility rooms. The South wing of the building is connected to the core at an angle of 55° meaning that the inside angle of the V is equal to 35°. Two additional stairwells exist at the ends of the two wings. The stairwell walls at the end of the North wing are mostly CMU walls except for the outside corner column which is concrete. On the other hand, all four stairwell walls of the stairwell in the South wing are reinforced concrete. Columns change their dimensions and presumably their reinforcement as they go up the building. Most of the girders that span between columns have haunches at their ends (possibly needed for added shear strength) but beams spanning between girders and cantilevering off columns have no haunches. Partial-height unreinforced masonry walls exist in many locations on the building facade where the windows are smaller than the story height (e.g. executive offices and bathrooms adjacent to the core. Interior full height unreinforced masonry walls also exist in the same two areas on both sides of the core.

(a) Photo (b) Plan view

Fig.10. Teleco building.

The Teleco building suffered its greatest damage on the second (ground) level and third level. Many of the columns on these levels showed 2mm to 5mm wide shear cracks (Fig.11a) and some flexural hinging was observed as well. Due to the additional stiffness and strength that was provided by the concrete stairwell at the end of the South wing, displacement demands were smaller on the columns in this wing compared to the ones in the North wing, where the stairwell was unreinforced masonry and suffered significant damage (large shear cracks and destroyed masonry units). Most of the unreinforced masonry walls throughout the building suffered significant damage (shear cracks) from in-plane loading, or they collapsed from out-of-plane inertia loading (Fig. 11b). Because of the end-haunches in most of the girders, columns were generally weaker than the girders, which showed no damage.

(a) Column shear crack (b) Masonry wall crack

Fig.11. Observed damage in the Teleco building.

Openings in the concrete core wall (4 square openings in a row at each story, for ventilation fans near the elevator core, visible from outside at the point of the "V") create a weak plane in the core wall and also tend to be constructed with poorly consolidated concrete. This led to shear failure of the piers in between these openings at Level 3, concentrating seismic drifts in this story (Fig.12). There is also a diagonal crack across the solid portion of the core at this level (visible from the outside), but from limited visual observation from the inside, this crack appears to be only in the mortar façade, not through the concrete structural wall.

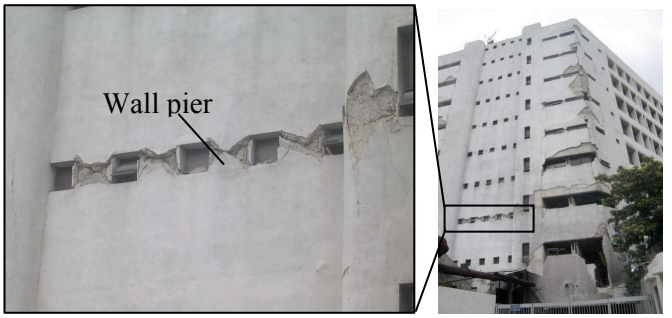


Fig.12. Observed damage in the RC core wall of Teleco building.

4. ANALYTICAL STUDY

Using the information and damage mapping obtained from field work, analytical models are being developed for the investigated structures. The seismic demand and damage predictions are being estimated using nonlinear dynamic

analyses. Several preliminary analytical modeling works are presented in this paper including: (1) selection of ground motions; (2) estimation of material properties; (3) modeling technique; (4) preliminary results and (5) future work.

(1) Selection of Ground Motions

A suite of three earthquake ground motions (group I in table 1) was selected for the dynamic analyses from the PEER Strong Motion Database (PEER 2000) with the following selection parameter matching the 2010 Haiti earthquake: (a) fault mechanism, strike slip; (b) magnitude, 6.9~7.1; (c) distance, 20-30km; (d) PGA, 0.3~0.5g; (e) PGV, 20-80cm/sec. Additional earthquake ground motions were selected by releasing the selection criterion of distance (10-80km, group II). The response spectra of the selected earthquake motions is shown in Fig. 13 with the USGS estimation (USGS 2010) indicated (dash line).

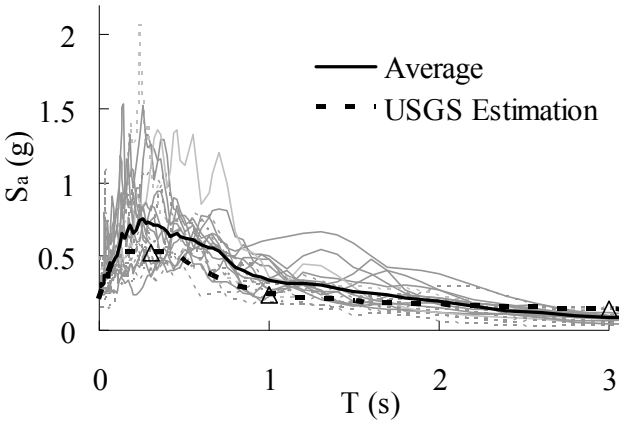

Fig.13. Response spectra of selected earthquake ground motions.

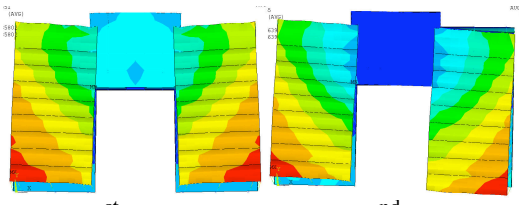
Table.1 Parameters for selected earthquake ground motions

Group	EQ	PGA (g)	PGV (cm/s)	Dist. (km)	Soil class	Direction
I	Imperial Valley	0.309	36.3	23.6	C	85
	Kobe	0.345 0.251	27.6 18.7	26.4	D	90 0
	Landers	0.417 0.283	42.3 25.6	21.2	B	Trans Long
II	Imperial Valley	0.315	31.5	10.4	C	140
	Imperial Valley	0.351 0.238	33 26	43.6	C	352 262
	Imperial Valley	0.313 0.215	29.8 30.2	8.3	C	180 270
	Imperial Valley	0.37 0.221	35.6 42.4	12.9	B	3 273
	Imperial Valley	0.364 0.38	34.5 42.1	12.6	C	140 230
	Kocaeli, Turkey	0.312 0.358	58.8 46.4	12.7	C	180 270

(2) Estimation of Material Properties

The material properties used for creating the analytical model are being estimated from ASCE-41 (2006) and sample material tests conducted by other researchers (Chambers et al. 2010) (KAKO 2010).



(3) Modeling Technique

The analytical models are being constructed using state-of-the-art techniques for nonlinear dynamic analysis. The nonlinear dynamic analyses are being performed using both research software (e.g. ANSYS and OPENSEES) and design office software (SAP2000 and PERFORM 3D). In order to capture the damage observed in the candidate structures during the Haiti earthquake, several structural members must be modeled as nonlinear elements including: columns, beams, shear walls, masonry walls and pounding effects.

The RC beams, columns and shear walls are modeled as elastic elements with plastic hinges at the critical sections determined based on the damage mapping. The plastic hinge is modeled nonlinearly to capture axial/flexural inelastic response using groups of nonlinear coupled springs and to capture shear limit states using nonlinear shear springs (Yavari et al. 2008). For certain cases where the column is under significant combined axial, shear and flexure loading, the fiber model with axial-shear-flexure coupling capability will be used (Ceresa et al. 2009).

Masonry walls, which have a significant impact on the response of the columns as discussed in damage mapping, are being modeled with nonlinear strut-tie models based on in-plane and out-of-plane behavior (Mosalam 2007).

The observed pounding effect is being modeled with high stiffness contact element serials connected with a nonlinear crush spring.

(a) 1st mode (b) 2nd model

Fig.14. Modal analysis of cafeteria building.

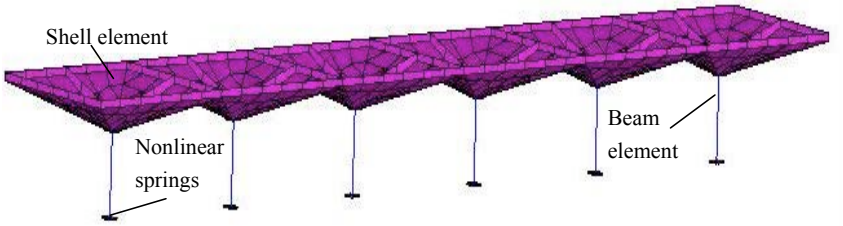
(4) Preliminary Analytical Results

The preliminary analytical results include: modal analysis of the cafeteria building and nonlinear dynamic analysis of the canopy structure. Both analyses are performed using the general-purpose finite element software ANSYS.

An elastic model with cracked section properties is used for the modal analysis of the cafeteria building. Fig.14 shows the first two modes from the analysis.

As seen in Fig. 15, the canopy structure is modeled with elastic elements (shell elements for the canopy and beam elements for the columns). Nonlinear coupled springs are used at ends of each column for modeling the plastic hinge. Fig. 16 shows the dynamic analysis results: (a) roof drift time history in the transverse direction with the measured residual drift indicated by the dashed line; (b) moment-rotation response at the column base in the transverse direction. As shown in Fig. 16(a), after

calibrating the ground motions, the model predicts a damage pattern and residual drift similar to that observed in the field.



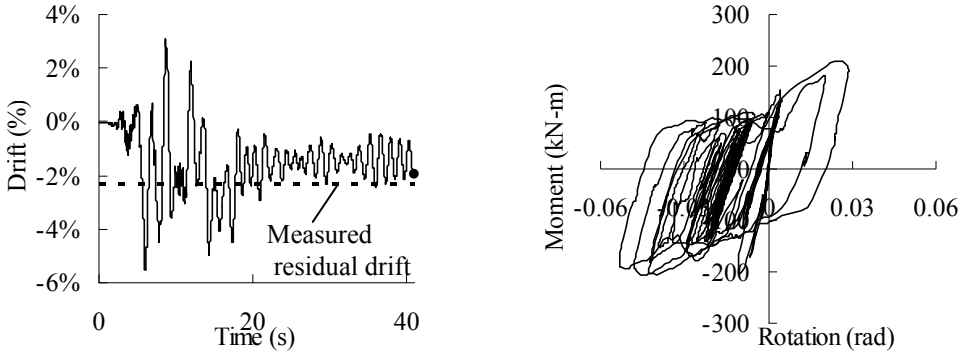


Fig.15. Canopy structure model.

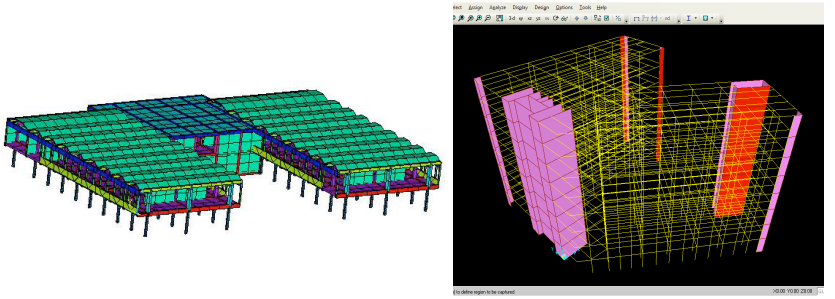

(a) Roof drift time history (b) Moment-rotation response at base

Fig.16. Dynamic analysis results of canopy structure in the transverse direction.

(5) Future work

Nonlinear dynamic analyses on the candidate structures will be performed. 3D nonlinear models of the candidate structures are being developed using the techniques described above, i.e., 3D SLG cafeteria model in ANSYS (Fig.17a) and 3D Teleco building model in SAP2000 (Fig.17b). The efficacy of these analytical models will be evaluated through comparisons of the predicted response to actual observed damage.

(a) SLG cafeteria building model (b) Teleco building model

Fig.17. 3D nonlinear models for the candidate structures.

5. CONCLUSION

Perishable data on the design of several engineered structures and details of their earthquake damage has been documented from field work in Port-au-Prince. That information is being used to construct analytical models using state-of-the-art

techniques for nonlinear dynamic analysis. Seismic hazard levels are being estimated by indexing to the level of demand required to bring about the observed damage. Nonlinear analysis results to date are able to replicate the behavior mode and residual deformation of the canopy structure. This analysis helps to index the amplitude of graound motions in Port-au-Prince. Further conclusions on the efficacy of these methods are being drawn through comparisons of the predicted response to field observations. The final deliverable is a report documenting the structures and design information; the post-earthquake state; modeling techniques; a comparison of analytical results and field observations; and evaluation of the methods with possible recommendations for refinement of current assessment procedures.

6. ACKNOWLEDGEMENTS

This research was supported by the National Science Foundation (NSF) under Grant 1034874. The authors are grateful for this support. Any opinions, findings, and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the National Science Foundation. The authors wish to acknowledge the key assistance of Dr. Patrick Paultre of Univ. of Sherbrooke who coordinated the Haiti trip, and to those in Haiti who generously assisted the authors with the field work: Mr. Roger Laplanche, Mr. Gregory Lewis, Brother Farell Duvert of SLG and Mr. Giovanni Levy of SJC.

Conceptual Transparency: Examples from the Work of Robert Maillart and Jörg Schlaich

E. M. Hines[1]

[1]Professor of Practice, Tufts University; Principal, LeMessurier Consultants, Cambridge, MA 02139; PH (617) 868-1200; email: emhines@lemessurier.com

ABSTRACT

Design processes and design calculations are reviewed for the 1925 Valtschielbach Bridge by Robert Maillart and the 1998 Ingolstadt Bridge by Jörg and Michael Schlaich. This review emphasizes the importance of conceptual transparency in structural design and demonstrates the interconnected nature of theory and practice in actual design processes. It helps to establish engineering thinking as distinct from scientific or mathematical thinking, and allows detailed consideration of how structural design processes may be taught in the university. Examples from the author's own practice and teaching demonstrate the potential for learning environments where university students are introduced to the tools and disciplines essential to creating original work based on fundamental understanding of engineering concepts.

SESSION DEDICATION AND INTRODUCTION: WHAT CAN WE LEARN FROM THE GREAT STRUCTURAL DESIGNERS?

We have assembled this session in order to honor the career of Professor David P. Billington of Princeton University, whose scholarship and voice have influenced countless members of our profession, encouraging us to seek the human stories behind the great works of structural engineering. It is through these stories that Professor Billington has conveyed to us not only the character of the great designers themselves, but also the very ideas and contexts that have made great designs possible. Our collection of perspectives on these ideas amounts to a modest *Festschrift*, recollecting the documents produced by students and colleagues to honor their mentors, documents we have stumbled across over the years working alongside Professor Billington in his Maillart Archive at Princeton.

Session Papers:

- Maria E. Moreyra Garlock: "Felix Candela and the Origins of Inspiration"
- Eric M. Hines: "Conceptual Transparency: Examples from the Work of Robert Maillart and Jörg Schlaich"
- Abbie Liel: "The Influence of Engineering Organization on Design and Construction Processes at Tennessee Valley Authority Dams of the 1930s"

The distinction between theory and practice leads many to assume that engineering design consists of following procedures generated as the results of scientific research. A closer look at the design processes for significant historical structures, however,

reveals intensive engagement between engineering imagination, fundamental principles, technical know-how and human will. Based on this insight, the session showcases some examples of compelling design processes and considers the implications for university engineering education. Attention is given to the distinction between a design process—which implies a personal way of directing creative thinking toward the solution of an actual problem; and a design procedure—which implies rote application of equations and methods. Understanding this distinction opens up possibilities for several important projects including: establishing engineering design as a creative and intellectual discipline equivalent in stature to research, working to reduce code complexity by placing emphasis on principles as opposed to rules, establishing the limits of computer analyses and their relationship to the imaginations of competent designers, and ensuring that engineering students master fundamental concepts in a way that allows them to think creatively.

INTRODUCTION

The calculations and the sketches behind the two structures featured in this paper constituted my introduction to the structural engineering design process under the guidance of Professor Billington. The stories behind both structures have proven to be durable and reliable landmarks on my professional path as a structural engineer. While these calculations and sketches were instrumental in the creation of sophisticated, original structures, they are themselves quite clear and simple. In a world enamored of complexity and computational power, where high-tech is often equated with intellectual merit, they demonstrate a higher level of thinking—one that radically distinguishes the essential characteristics of a system from the trivial—*conceptual transparency*. This power of abstraction serves a vital role in the design of large-scale structures, where failures are catastrophic and experimental prototypes are prohibitively expensive. Overlay these warnings with the imperative of economy and the desire for beauty, and it becomes clear that conceptual transparency addresses equally the need to assume responsibility and the opportunity to work creatively.

ROBERT MAILLART'S VALTSCHIELBACH BRIDGE

The chief concern of engineers is the quality of their assumptions. One of the clearest examples of this point in engineering history, as told by Professor Billington in *The Tower and the Bridge*, relates to Robert Maillart's development of reinforced concrete deck-stiffened arch bridges in the mid 1920's.

> Robert Maillart, the Swiss bridge designer, developed in 1923 a limited theory for one of his arched bridge types which violated in principle the general mathematical theory of structures and thereby infuriated many Swiss academics between the wars. But Maillart's limited theory worked well for that special type of form. Within that category type, Maillart's theory was useful and had the virtue of great simplicity; he developed the theory to suit the form, not the form to suit the theory. In the United States, by contrast, some of our best

> engineers understood the general theory well, but not understanding Maillart's specific ideas, they failed to see how new designs could arise. They were trapped in a view of an engineering analysis which was so complex that it obscured new design possibilities.(Billington 1983, 9-10)

Adherence to a general theory in this case is tantamount to the blind application of equations so often observed in the work of engineering students in fundamental classes. Maillart's much simpler approach, however, with its emphasis on new possibilities for arched bridge forms, represents the heart of creative engineering thinking—creativity not only with respect to the appearance of form, but also with respect to its engineering substance. Even Maillart's calculations were creative. In other words, Maillart recognized that there was more than one way to approximate the structural behavior of his deck-stiffened arch systems and he chose an approximation that exhibited a high degree of conceptual transparency. In the appropriate context, Maillart's calculations were entirely correct. That was precisely what angered Maillart's academic peers, and distinguished Maillart's engineering thinking. Maillart's calculations for the deck-stiffened Valtschielbach bridge, pictured in Figure 1, total 3 ½ pages. The calculations that represented Maillart's conceptual leap filled the last half page, and are shown in Figure 2.

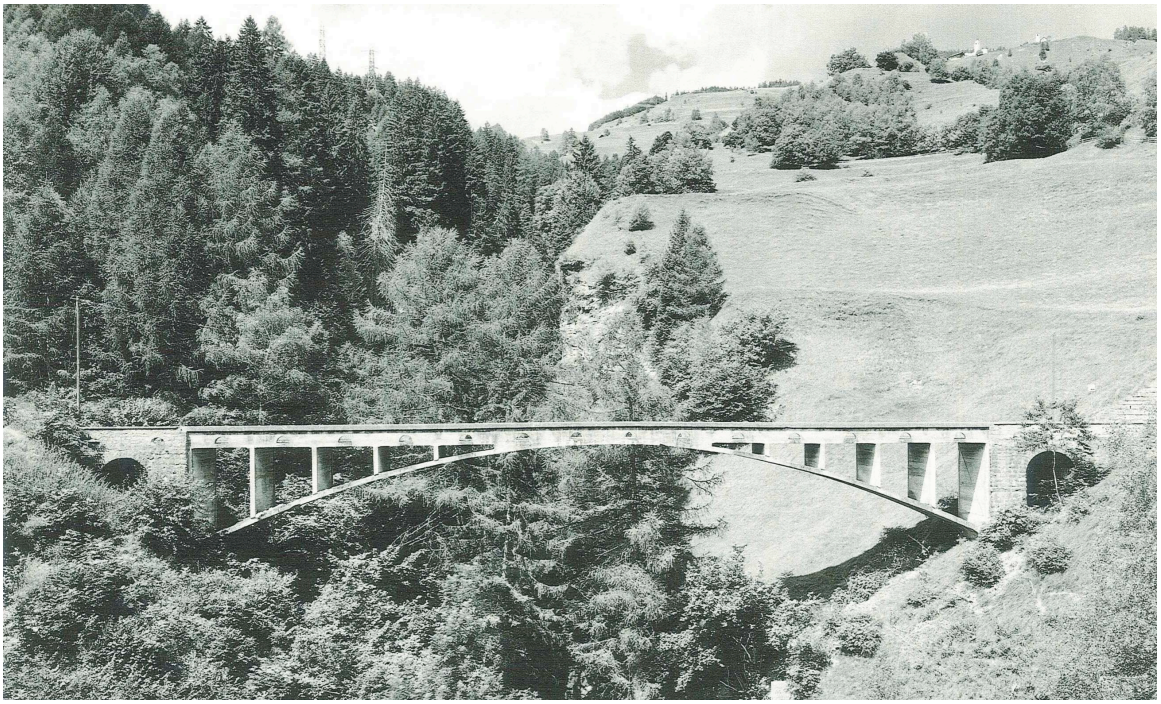

Figure 1. Robert Maillart's 1925 Valtschielbach Bridge in Switzerland (image credit: Billington 2005).

Seldom has the point been made more clearly that the engineering genius of the work rests on the *assumption* supporting this half page, and not on the calculations themselves. Based on the full scale behavior of his previous bridges, Maillart made

the assumption that the deck and the arch deform together, and would thus carry bending moments in proportion to their flexural stiffness. Since the deck was significantly stiffer than the arch, Maillart designed the deck to carry all the bending of the system. Such a conceptual leap reflects at least the same level of intellectual quality as the creation of any general theory, and far surpasses the technical exercise of applying such a theory. From a human point of view, Maillart's conceptual leap exceeded the generalized theory in value, because it led to more economical bridges that have become artistic icons as they have remained both serviceable and durable.

The essence of Maillart's engineering calculation for the Valtschielbach bridge in Figure 2 is represented by the equation

$$M = \frac{pL^2}{2 \cdot 8 \cdot 4} = \frac{0.9 \cdot 40^2}{64} = 22.5tm$$

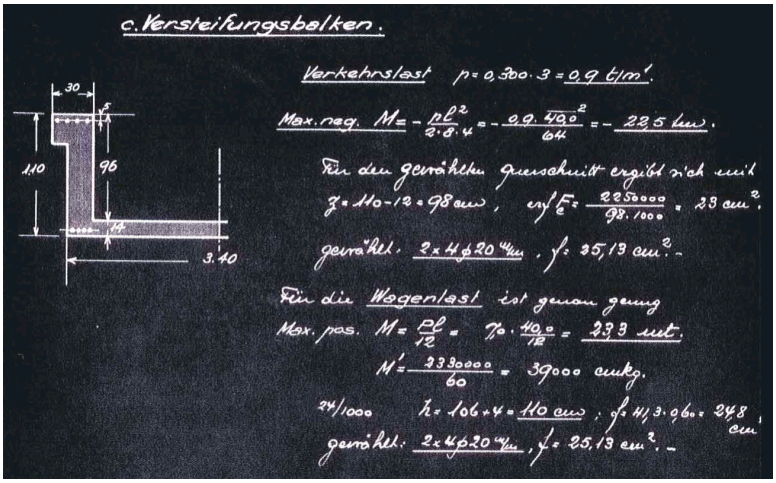

Figure 2. Robert Maillart's deck stiffening calculations for the Valtschielbach Bridge (image credit: Billington 2005).

Using the arch allowed Maillart to reduce his dead load bending moments to zero, while reducing his live load bending moments to approximately 22% of the same moments on a simply-supported beam. Figure 3 shows conceptually the Valtschielbach arch on the left and a simple beam on the right, each with a span of 40 m (131 ft). Assuming the distributed live load of 0.9 t/m (0.603 k/ft) for this example, the live load bending moments shown for the arch and the beam at the bottom of Figure 3 are 162 kft [22.4 tm] and 730 kft. This difference is impressive, but does not emphasize the relative efficiency of Maillart's bridge, which is more efficient than a simple beam by more than a factor of 8.

The top of Figure 3 shows the same spans under uniform load. For this example the same live load has been used for consistency, although it would be more appropriate to use the actual dead load, which is larger than the uniform load shown at the top of Figure 3. The moments under uniform load in the arch are zero, while in the beam they are 8 times higher than in the arch under live load.

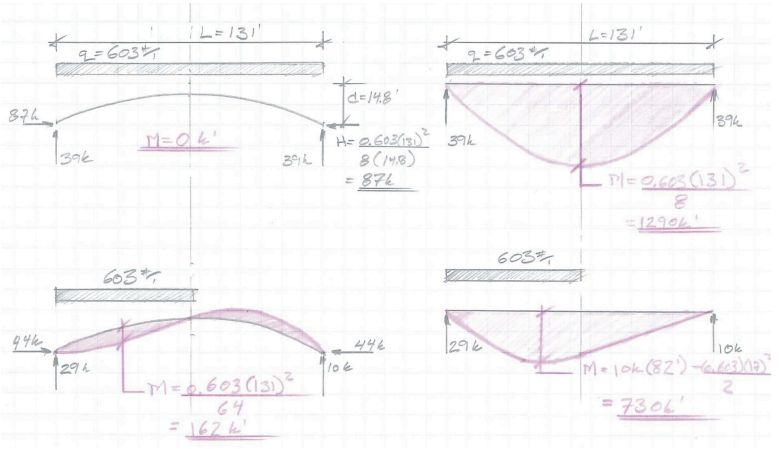

Figure 3. Valtschielbach bending moments explained conceptually.

For this example, it is most appropriate to compare maximum bending overall moments, not just maximum bending moments from a given load case. If the dead loads of the structure are just 25% higher than the live loads, then it can be demonstrated that the deck-stiffened arch reduces bending moments by an order of magnitude compared to the simple beam. See Chapter 9 of *Robert Maillart's Bridges* (Billington 1979) for a complete historical discussion of Maillart's deck stiffened arches and their relevance to the difference between science and engineering.

JÖRG AND MICHAEL SCHLAICH'S INGOLSTADT BRIDGE

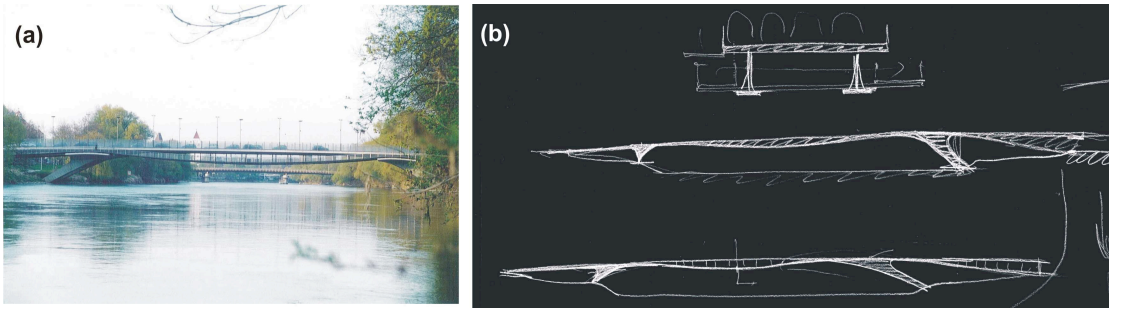

Figure 4. Danube River bridge in Ingolstadt. (a) Elevation. (b) System concept sketches.

Figure 4(a) shows the third bridge over the Danube River in Ingolstadt, Germany, which won a design competition in 1993 and was completed in 1998. Jörg and Michael Schlaich generously allowed us to photocopy many sketches from their collaborative design process for this bridge with Architects Kurt and Peter Ackermann. These sketches and several interviews formed the basis for our story of this design process and the design competition (Hines and Billington 1998). In the discussion of conceptual transparency, these sketches complement the simplicity of Maillart's Valtschielbach calculations by demonstrating the power of drawing as a language of creative expression.

One of the important early system sketches is pictured in Figure 4(b). While simple, this sketch captures the essential ideas of the proposed system: a slender deck, supported as an inverted suspension span, and longitudinally prestressed by the arching action beween two raked piers. The separation between the road and the pedestrian can be seen in the section at midspan. The second elevation below shows a representation of massing with vertical supports between the cables and deck. The sketches are executed quickly in the company of collaborators. They are the standard means of communicating between designers. Yet, it is rare that we consider closely and discuss the sketches that represent the creative process. They are often considered either to stand alone as a flash of genius or to be mundane in their multitude. As representatives of hundreds of sketches developed during a design process, the sketches in Figure 4(b) and in Figure 5 show the kind of communication that is essential to the creative development of an idea in structural engineering.

Often these sketches are accompanied by simple calculations and text. Their value lies in their ability to represent clearly and accurately a dynamic process that is invisible to most students in its human character—composed of sketching, simple calculations, discussion, debate and an iterative approach to the development of an idea. I tell my students that if our imaginations were perfect, we would not need to worry about the discipline of creativity. Our ideas would come fully formed out of our imaginations. Instead, most of us harness the power of our ideas by communicating about them. We communicate with ourselves, with our colleagues, and with our critics. In this communication, we learn more about our ideas and develop them further. While it may not be possible to teach creativity per se, it is certainly possible to teach the discipline required for creative work. And the first step in teaching such a discipline is to demonstrate it by example.

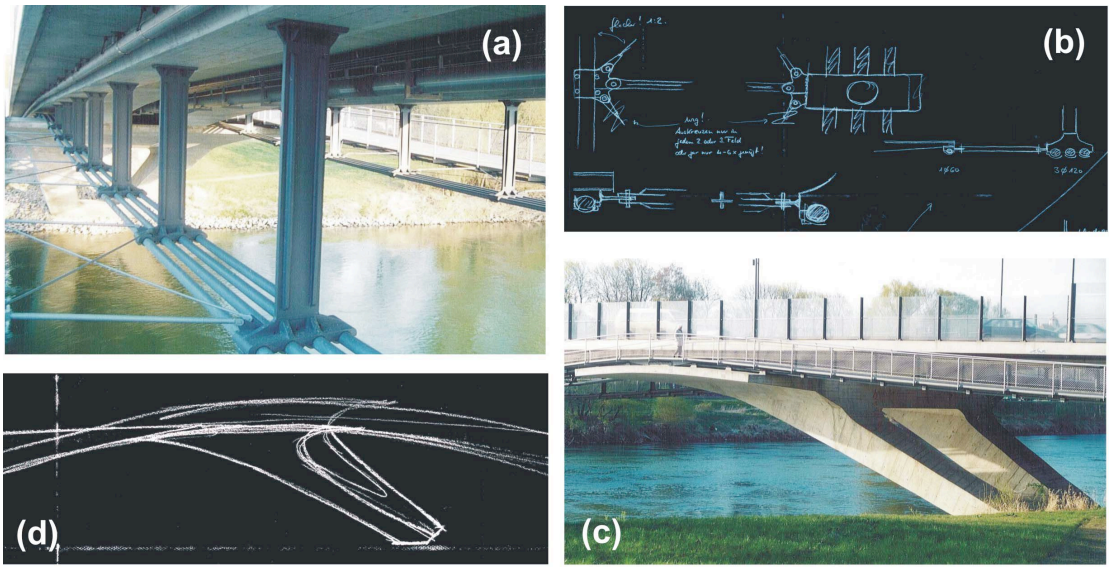

Figure 5. Ingolstadt details and concept sketches. (a) deck support on cables with bracing to pedestrian walkway; (b) concept sketches for connections between deck support cables and pedestrian walkway; (c) skewed pier with deck and pedestrian walkway; (d) pier sketch.

Figure 5 shows this discipline in further details. It is not enough simply to sketch a system. The system relies on its details, and conceptual transparency is largely concerned with the interaction between a system and its details. Figure 5(a) shows the supports between the cables and the deck, along with the horizontal ties between these cables and the pedestrian walkway. Figure 5(b) shows sketches of these details that were developed in close proximity to the sketches in Figure 4(b). Figure 5(c) shows the skewed support, which evolved to retain a high degree of plasticity from a very simple decision to skew the supports by 20 degrees. Figure 5(d) shows the early conceptualization of this support as a plastic element.

The example set in Figures 4(b) and 5 is that the creative work of engineers involves intense communication between the idea of a system and ideas for its details. This communication poses a challenge, because it is easier to fall into a habit of focusing only on the big picture or only on the details. The sketches in a design process need to be effortless because they need to be disposable. The value of any given sketch resides in its relation to all the other sketches and the design process—not in its quality as an independent work of art. The disposable nature of these sketches gives them their value—they record fleeting thoughts and ideas, set down quickly for the purpose of critical evaluation and discussion. To produce them fluently is to speak the language of the engineer. Leonardo Da Vinci's sketch books are compelling precisely because they exhibit his artistic talent not for its own sake but as eloquence in the language of drawing.

DRAWING, THE LANGUAGE OF THE ENGINEER

The concept of drawing as a language was coined by Carl Culmann in the mid 19th century as he developed graphic statics (Billington 2003, Lehmann and Maurer 2006), however for this discussion I would like to consider drawing even more broadly—as a language requiring multiple levels of abstraction, and possessing tremendous intellectual richness.

Expression of thought through language is creative. Creativity involves choice. Intellectual disciplines contribute to creative work when they facilitate judgments required to make choices. Engineering requires the command of three primary languages:

1. The written word and spoken word communicate action—a narrative of what has happened, is happening or will happen.
2. Mathematics communicates quantity.
3. Drawing communicates substance—a real object that is best understood by its appearance is communicated as an ideal through drawing.

University culture clearly recognizes the value of the written/spoken word and mathematics as forms of communication, and the act of acquiring a liberal education involves the extensive use of these languages. Drawing, on the other hand, has often been misunderstood outside of the fine arts, and in engineering has been branded as a

technical discipline. As a form of communication however, drawing is similar to writing, speaking and mathematics: it requires skill, but it also requires intellectual depth. In fact, the two are inextricably linked.

Similar to written and oral communication, the audience matters tremendously. For presentation to an owner, realistic appearance is often helpful. For communication with architects, realistic appearance is also valuable, but can be tempered with abstraction and style in a manner that facilitates a collaborative, creative process. For contractors developing an estimate, depicting quantities and the general level of complexity are helpful. For contract documents more detail is generally more helpful. It requires experience and thoughtfulness, however, even with the most powerful computer modeling systems, to develop contract drawings that are well coordinated. Providing information that is incorrect can be more harmful in the context of a contract than not providing any information.

Figure 6. Lobby Renovation, 100 High Street, Boston, Massachusetts. (a) Before: two levels of retail space at base of 28 story building (photo credit: CBT Architects). (b) After: two-story lobby with structural glass wall hung from cantilevered third floor.

In order to provide contract information in a manner that is consistent and easily understood by an expert, engineers have developed several abstractions such as weld symbols, elevation marks, tolerance numbers and typical details. These abstractions, while often communicated in the form of drawings, are generally not comprehensible to a person who does not speak this language.

In order to provide context for the characteristics of drawing discussed above, I will discuss two recent lobby renovations in Boston and their role in my teaching the 3rd-

Year structural systems design course at Tufts University. Figure 6 shows before and after photos of a lobby renovation completed with CBT Architects at 100 High Street in Boston in the spring of 2009. The former entrance to the building in Figure 6 was located at 150 Federal Street. The lobby renovation consisted of removing three bays of slab framing from the second story in order to create a new 2-story high lobby with a structural glass façade by W&W Glass/Pilkington Planar.

Figure 7 shows the framed area before and after the slab was removed. Since the new glass wall was to be hung from the cantilevered third floor framing, reinforcement of the columns prior to demolition of the slabs required not only considerations of column stability under 28 stories of building dead and live loads, but also of column flexural deflections and their effect on cantilevered slab deflections.

Figure 7. Lobby Renovation, 100 High Street, Boston, Massachusetts. (a) Before: columns and cantilevered girders reinforced prior to removal of three 30 ft x 30 ft bays. (b) After: three bays of slab framing removed, and column reinforcement completed.

Figure 8(a) shows original sketches and calculations developed during concept design of this slab removal. While it may seem natural that sketches, calculations and word occupy the same page of work (as do also graphs and tables often times), it is important to note that many students are not educated to communicate in this kind of language. At the top of Figure 8(a) is a sketch of the plan, which gives context and which will become the primary form of communication in later contract documents. Also listed are the assumed loads. These loads are deliberately simple, and their importance lies in the fact that they allow this communication to stand alone, without reference to other documents. This makes the work easier to check and to discuss with colleagues. For columns supporting a fully-occupied 28-story building, it

became important to be able to check both the relevant assumptions and calculations many times, with many different colleagues. The intellectual merit of the problem lay in distilling the problem down to its essence—to make it so simple that the unconscious could continue to consider the problem at all hours—so simple that one could wake up in the middle of the night and check the work at bedside. The analysis on the lower portion of Figure 8(a) is a simple, single degree of freedom moment distribution, which could be carried out on half a page. A sketch of the physical system, with moment diagrams drawn directly on top of the sketch helped to facilitate this level of conceptual transparency.

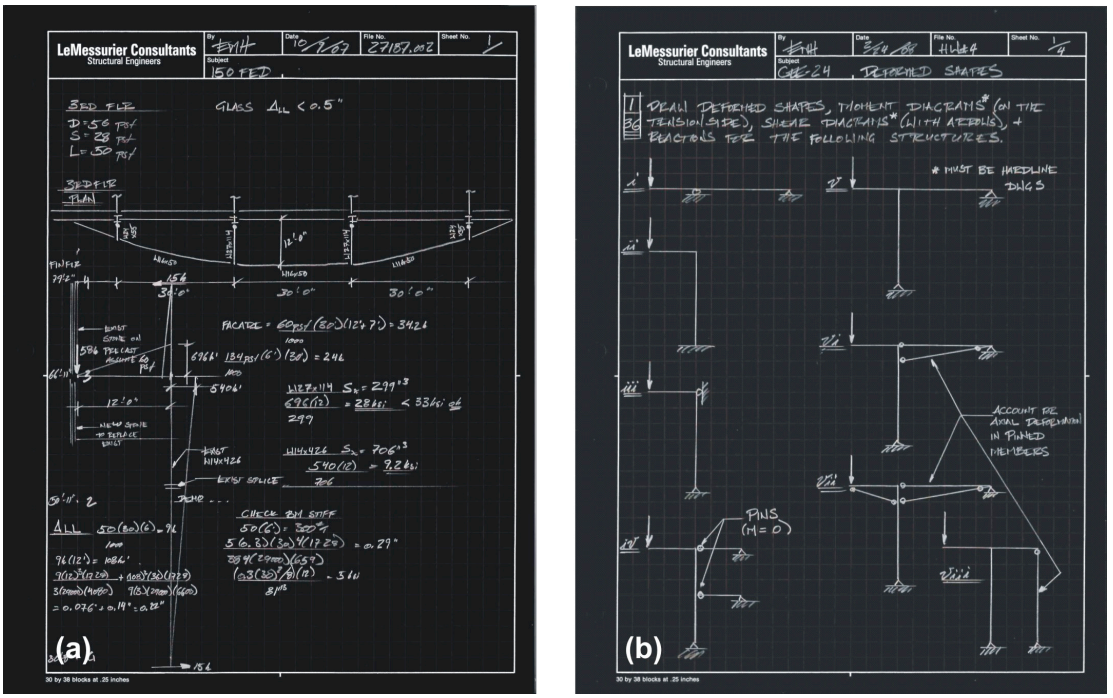

Figure 8. Lobby Renovation, 100 High Street, Boston, Massachusetts. (a) Initial analysis of third floor framing to support hung glass wall. (b) 3rd-Year structural systems homework assignment reflecting the parametric investigation of system behavior completed prior to final design.

Figure 8(b) shows a series of exercises assigned to 3rd-Year structural engineering undergraduate students at Tufts University based on a parametric investigation that followed the calculations in Figure 8(a). The object of the investigation was to determine the stiffening effects due to a range of possible reinforcement schemes for the cantilever and its beam and column back-spans. I learned from assigning this series of problems that there was a significant difference between how I saw these simple sketches versus how my students and teaching assistants saw them. I saw several variations on one theme—a cantilever with a backspan. The variations entailed different types of backspans resulting in different levels of rotational stiffness at the root of the cantilever. My students, however, saw eight different problems, with little or no conceptual thread running through them.

When I solved these problems in Figure 8(b), the moment diagrams and axial force diagrams yielded significant insight into system behavior—even before I calculated any numbers. From the principle of virtual work, more area under these diagrams implied more system flexibility. In other words, the diagrams appear more simple than they actually are—this speaks to the subtlety and effectiveness of their abstraction. Only an expert can see all they have to offer. And to an expert—they facilitate a powerful understanding. A similar observation was treated extensively by the National Research Council in Chapter 2 of their summary of education research entitled *How People Learn*.

> Experts' abilities to reason and solve problems depend on well-organized knowledge that affects what they notice and how they represent problems… The fact that experts are more likely than novices to recognize meaningful patterns of information applies in all domains, whether chess, electronics, mathematics, or classroom teaching… Because of their ability to see patterns of meaningful information, experts begin problem solving at "a higher place." (NRC 2000, 48)

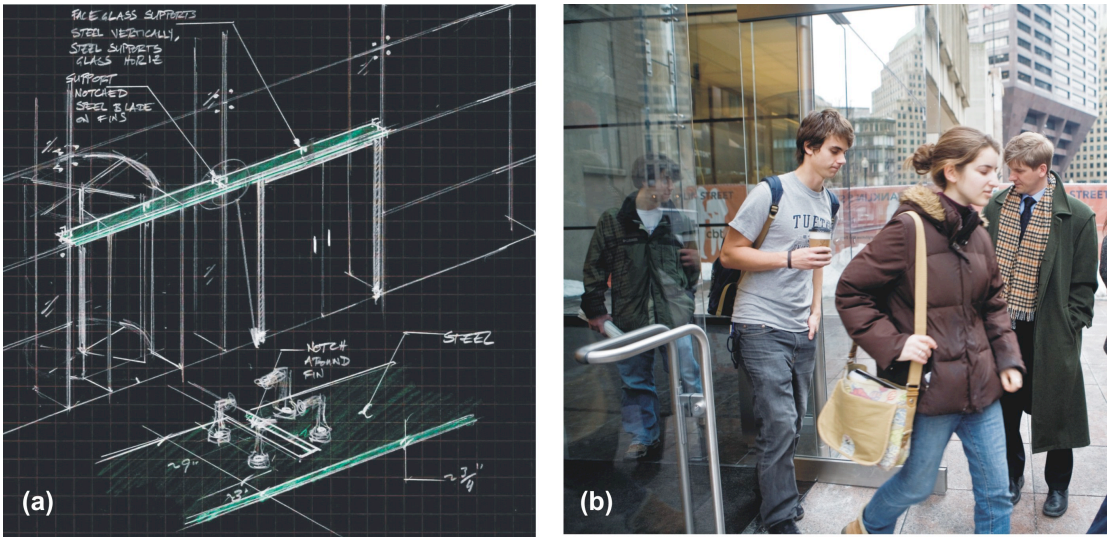

Figure 9. Lobby Renovation, 225 Franklin Street, Boston, Massachusetts. (a) Engineer's sketch of steel reinforcement for glass door header. (b) 3rd-Year Tufts University students walking through the doors depicted in (a) (photo credit: Tufts University).

Figure 9(a) shows a sketch for another structural lobby renovation at 225 Franklin Street in Boston. I developed this sketch during a coordination meeting with the architect, the glass installer and the general contractor. During the meeting, the sketch helped our team to align our interests with regard to developing an extremely light steel header that could be attached to the glass system. Both the system and the details were important to all parties involved, and the actual engineered header system ended up resembling this concept sketch very closely. Figure 9(b) shows my 3rd-Year students walking out of this doorway after having toured the new 225 Franklin Street Lobby.

CONCLUSION: THE ROLE OF DESIGN IN UNIVERSITY ENGINEERING EDUCATION

The role of design in university engineering education is to *motivate and challenge students' fundamental understanding* of the physical world. Design is relevant in the university, not because it prepares students for the working world, but because it is what *motivates and challenges* students' understanding of the fundamentals in the best possible way. Design requires a personal way of directing creative thinking toward the solution of an actual problem, and has little use for rote application of equations that a student may or may not understand. Design requires a philosophical approach rooted strongly in the fundamentals of the discipline, which is the necessary foundation for conceptual transparency. Fundamentals are not just theory, but how theory is applied in a context. To separate theory from practice is to ignore context—and hence to forsake what is most human and most wonderful in engineering.

ABSTRACT

Félix Candela is widely acknowledged to be one of the great structural artists of the twentieth century. Candela was born in Spain, and was exiled in 1939 to Mexico where he created all of his major thin shell concrete constructions. This paper examines Candela's process of design and illustrates through his major works that he acted first as a builder who not only constructs, but also makes the engineering design. He also takes a general form and plays with it to make *structural art*. Structural art implies efficiency, economy, and elegance; but we also illustrate how structural art also implies a sustainable design. Finally, we show that the *inspiration* for the designs of structural artists come from a process that begins with imitation, followed by innovation. Education is crucial for the future of structural art, and in studying it, educators, practitioners, and the general public can recognize the potential for this new art form in the 21st century.

INTRODUCTION

Modern master builders exhibit two characteristics that are fundamental to the best-engineered structures: the ethos of *efficiency* and the ethic of *economy*. Efficiency in this sense means the search for forms that use a minimum of materials consistent with sound performance and assured safety; economy signifies a minimum of construction costs consistent with low expense for maintenance. These two fundamentals imply a plan that pays attention to both design and construction. An engineer who designs efficiently and with a builder's mentality is considered a master builder. But a *structural artist* is an engineer who has all the qualities of a master builder and possesses *aesthetic* motivation in addition. An engineer can be a master builder without being a structural artist, but one cannot be a structural artist without being a master builder.

Many master builders are engineers who work for architects and consider the aesthetic to be the province of the architect; hence, they think of their structures as part of architectural art. While this approach is common practice, it has contributed to one of the greatest myths in our structural engineering profession: that elegance in structural engineering is the province of architects and that while engineers ensure

that it will stand, only architects can make it a work of art. This argument is contradicted by the most talented structural engineers over the last 200 years whose motivation included appearance along with efficiency and economy. One such engineer was Félix Candela.

Figure 1: Félix Candela

Félix Candela (1910-1997) (Fig. 1) was a world-renowned structural artist of thin-shell concrete-roof structures in the mid 20th century. Shortly after completing his degree in architecture in Madrid, the Spanish Civil War broke out and in 1939 Candela was exiled to Mexico. After a few years, he returned to reading the publications on thin shell analysis and design (which he had begun to read on his own incentive in Madrid) and then began to experiment with building thin shell structures. His work was directed toward understanding the performance of thin-shell concrete structures under load, but, in addition, he was gaining insight into the building process for such forms. He was beginning to think like a builder, making forms—not on paper out of drawings but in the field out of concrete. Thus, when he formed his company, it was decidedly neither an architectural nor a consulting-engineering firm but rather a business devoted to building—he became a construction contractor.

Since Candela's formal education was in architecture, and since his shell designs are elegant, most people identify Candela as an "architect". However, based on his career as a builder and designer, and his own words, we can demonstrate that Candela practiced as one of the greatest structural engineers of the twentieth century, and hardly at all as an architect. He remarked at the time that "every day I feel less and less an 'architect'; I am losing interest in making plans and window details and things like that." (Faber 1963) He identified himself more as an engineer and builder: "I must say . . . that although an architect by training, in practice I am a constructor and building contractor," (Candela 1955) and one who makes his own engineering designs. This disassociation from thinking of himself as an architect was reflected even more pointedly in an essay he wrote for a symposium honoring Robert Maillart at Princeton University in 1972. The organizers who invited him to speak suggested "New Architecture" as a title for his paper. Candela began his paper and lecture saying, "The title of my lecture is 'New Architecture'; but I cannot avoid the feeling that I have not too much to do with this subject. I don't think I can speak of my work as of any new architecture or even as architecture at all." (Candela 1973) Later, when Candela republished this paper in Spanish, he renamed it "La Herencia de Mailllart" (Maillart's legacy).

This paper examines Candela's process of design and illustrates, through his major works, that he acted first as a builder who not only constructs, but also makes the design, which then can be expressed through a simplified analysis (Faber 1963, p. 199). He also takes a general form, which sometimes comes from somewhere else,

and plays with it to make structural art. Structural art implies efficiency, economy, and elegance; but we also illustrate how structural art also implies a sustainable design. Finally, we show that the *inspiration* for the designs of structural artists come from a process that begins with imitation, followed by innovation. Education is crucial for the future of structural art, and in studying it, educators, practitioners, and the general public can recognize the potential for this new art form in the 21st century.

CANDELA'S PROCESS OF DESIGN

His Major Works

All of Candela's significant structures were of one geometric form, the hyperbolic paraboloid (hypar), and with that discipline he could build them only 1.5 inches (4 cm) thick. The doubly curved surface of the hypar form (Fig. 2) is developed with two straight line generators; thus, Candela achieved economy of construction by avoiding curved boards for his falsework in construction. While the climate in Mexico is more moderate than that in the United States, other designers successfully have built similar thin shell structures in harsh environmental conditions. For example, Heinz Isler designed many thin shell concrete structures in Switzerland; typically these were 3 inches thick and, like Candela's designs, they serve as models of efficiency, economy, and elegance (Billington 2003)

.

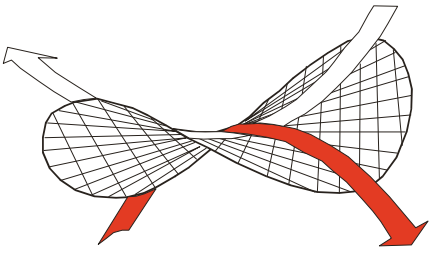

Figure 2: The hyperbolic paraboloid (hypar)

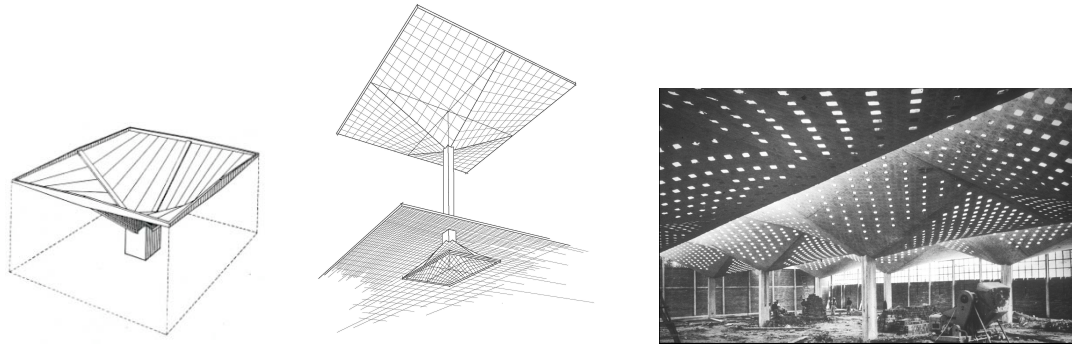

Figure 3: The Cosmic Rays Laboratory (1951) (photo by Bruce White)

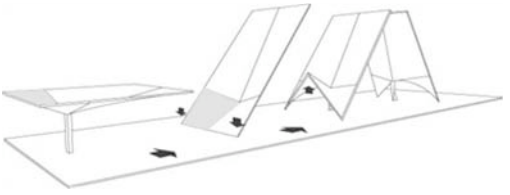
When asked to name his favorite structures, Candela replied: Church of Our Lady of the Miraculous Medal (Milagrosa), the Chapel at Cuernavaca, Restaurant Los Manantiales at Xochimilco, and the Bacardi Rum factory (Basterra and Valero 1998). We will examine these self-proclaimed favorite structures plus his first hyperbolic paraboloid shell (Cosmic Rays Laboratory) and his umbrella shells that comprised the bulk of his work. From all these works, the same pattern emerges. Candela the builder makes the engineering design, and then takes a general form and plays with it to make structural art.

In the Cosmic Rays Laboratory of 1951 (Fig. 3), the architect already had a form—barrel shells—and when Candela took on the construction, he decided to change the



barrels to hyperbolic paraboloids, his first such structure. Although no calculations seem to have survived, Candela certainly became the structural engineer, calling on his earlier study of French and German publications from the 1930s (Garlock and Billington 2008, Kelly et al. 2010).

With the umbrella shells, he recalled his earlier study of a 1936 paper by Aimond (Aimond 1936), who showed a single umbrella with the same basic form that Candela would follow. Since he considered Aimond's umbrella shape (Fig. 4a) visually dull, he refined it by 1952 to achieve a more elegant appearance (Fig. 4b,c). The umbrella he transformed into a church in 1953, Church of Our Lady of the Miraculous Medal (Fig. 5), which resulted from an unusual opportunity that afforded Candela to be the builder, designer, and artist for a structure that is traditionally a work of architecture. Again, however, the project was first a construction and a design second.

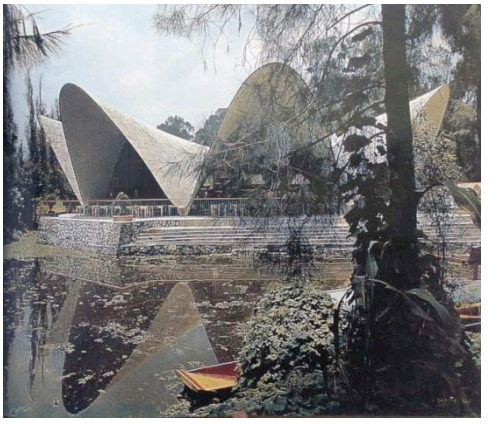

Figure 6. Félix Candela's Restaurant Los Manantiales in Mexico City, Xochimilco, 1958.

Figure 7: Chapel Lomas de Cuernavaca (1958)

For the restaurant Los Manantiales at Xochimilco (Fig. 6), Candela was asked by colleagues to take the project as both designer and builder, but once again the basic shape was not his idea. Colin Faber, working then at Candela's construction company Cubiertas Ala, made a sketch similar to what eventually became the shape of the restaurant. Candela considered the sketch a good beginning and proceeded to refine it carefully (Garay 1994). The restaurant is pure structure and reflects the hand of a structural artist. The same pattern emerged for the Cuernavaca chapel (Fig. 7); the architect approached Candela to be the builder and brought him a sketch of a triangular raised roof. Candela reshaped the form into the thin curved structure that made the chapel unique and dramatic (Draper 2008).

Finally, for a new project he was stimulated by the cylindrical the groin vaults of the St. Louis Airport terminal building designed by the architect Minoru Yamasaki and modified strongly by the engineer Anton Tedesko. For the next project Candela gained, he decided that whatever its function he was determined to create three groined vaults as in St. Louis; it so happened to be a Bacardí Rum bottling plant (Fig. 8). Once again, the client employed Candela as builder first, but that assignment also included, as did most of his other projects, functioning as structural designer. The building is pure structure in a series of hyperbolic parabolid groined vaults. (Segal at al. 2008).

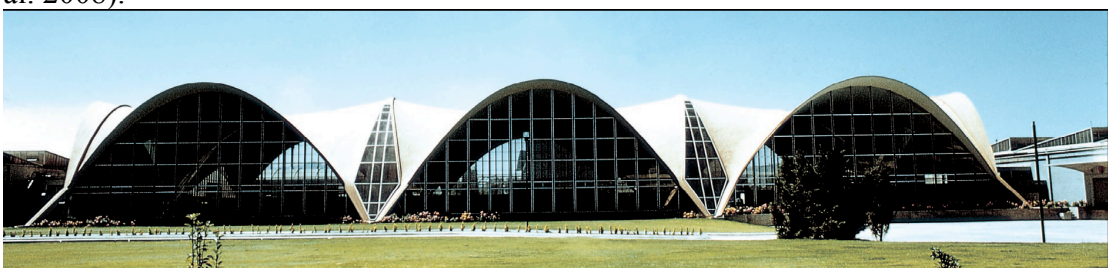

Figure 8: Bacardi Rum Factory, 1960

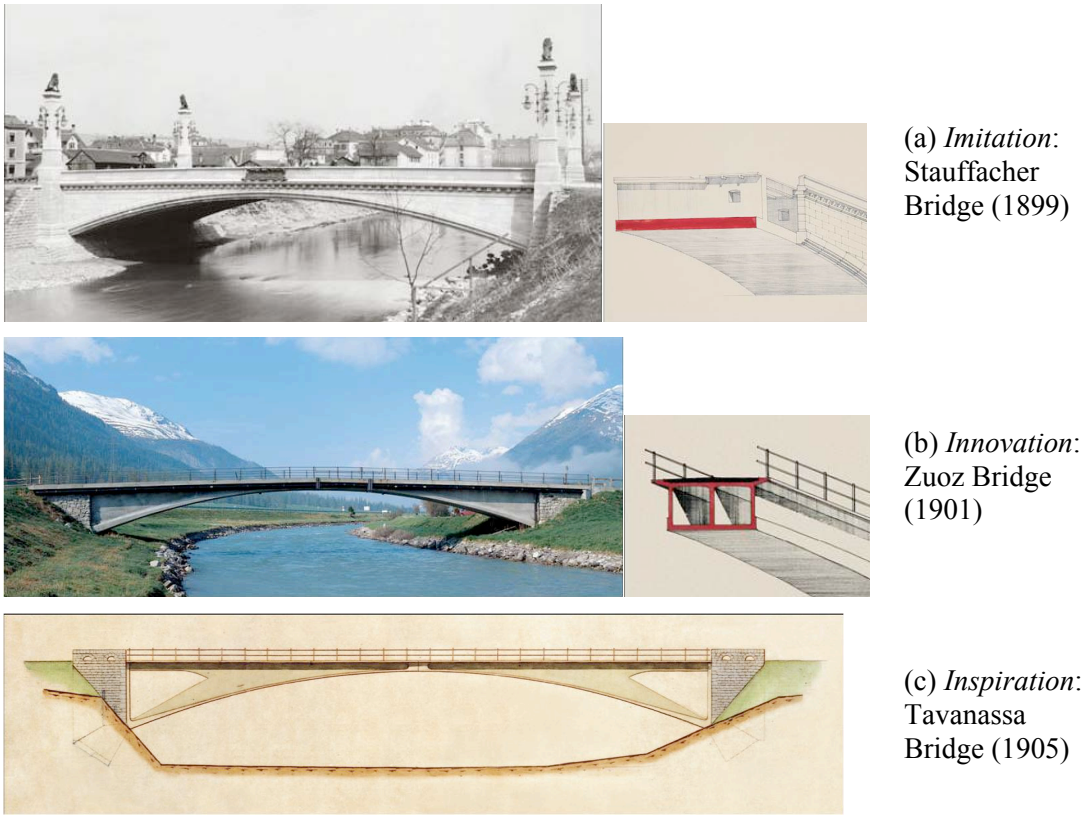
Sustainability

Fashionable new terms like "sustainability" really mean something that has been part of the tradition of structural engineers – especially those who stand out as the greatest ones over the past 200 years – essentially structural artists. Great structural designers understood the need to conserve resources and protect the environment, even before we had the terminology (e.g., "sustainability", "green design") or a metric (e.g. LEED) to define it. Since structural art is defined by efficiency and economy, it implies a sustainable design.

Efficiency, in the context of sustainability and structural design, means not wasting materials and using locally available resources. Candela used local materials which

eliminates the need to transport materials from afar (an environmental and energy advantage). He also designed the structures to be the minimum practical thickness. Since the form of the shell was correct, not a lot of material was needed for strength and stiffness. Furthermore, Candela conserved material during the construction process by reusing the form work.

Economy, in the context of sustainability and structural design, means durability and energy efficiency. Candela's reinforced concrete shells have proven to be durable and easy to maintain. The first author visited several of Candela's structures in Mexico and found all of his shells in good condition (even with more than 50 years of service) despite the thinness of the shell and the frequent earthquakes. Also, many of Candela's structures allow natural light to enter and illuminate the interior, reducing and often eliminating the need for electric lights during the day. For Candela, there was a practical limit in the size of the shells that he was designing based on structural engineering concerns (e.g., problems of deformation), but on energy efficiency as well. Candela has commented that "if one increases the scale, the size increases and the volume gets larger, for example, in the site where one has to place air conditioning. This constitutes a serious limitation." (Garay 1994)



This connection between sustainability and structural artists can be found in designers other than Candela. For example, Heinz Isler has written that the life of a building "should not be just a few years but three generations, about three times twenty, or sixty years without any damage or need for repairs" (Isler 2008, p. 87). Further, when Isler was young, he was against building because he saw how building can destroy nature. Isler was careful not to waste materials, which is good ecologically.

THE ORIGINS OF INSPIRATION

Imitation, Innovation, and Inspiration

Robert Maillart (1872-1940), a Swiss engineer, was one of the greatest structural artists of the twentieth century. Maillart critically studied his built structures and was always striving to improve them. With his Stauffacher Bridge (Fig. 9a) he imitated a bridge built in Geneva that had fake stone walls. This style of design was an inefficient use of concrete since the walls were not structural. With the Zuoz Bridge (Fig. 9b), the walls were part of the structure and the cross section was an efficient hollow box – an innovation of Maillart's. Finally, in the Tavanassa Bridge (Fig. 9b), he eliminated the walls near the abutment that would otherwise crack but not necessary for carrying any loads. This evolution of design (illustrated in Fig. 9) is an example of how structural artists go from imitation to innovation to inspiration.

Candela also began by imitating forms. For example, his umbrella forms were an imitation of something he had seen in an article (Fig. 4a). But the form was re-proportioned to make it more elegant (Fig. 4b,c), and through experimentation, he optimized the rise of the umbrella (Draper et al. 2010). His umbrella-derived inspiration of Milagrosa (Fig. 5) is based on creativity that is rooted in engineering principles of design.

(a) *Imitation*: Stauffacher Bridge (1899)

(b) *Innovation*: Zuoz Bridge (1901)

(c) *Inspiration*: Tavanassa Bridge (1905)

Figure 9: Evolution of Robert Maillart bridges

In addition, Candela's first vaulted shells were of the traditional forms (such as barrels and funicular) – an imitation. His Cosmic Rays Laboratory was an innovation of a hypar shell form – but not an inspiration. Another innovation was the hidden "V-beams" in the groins of "intersecting hypars", i.e. groined vaults. These V-beams were not visible and they stiffened the shell and attracted the forces to the groins, which would carry the load to the foundation. These innovations and his "disciplined play", led him to many creative yet technically correct forms such as Restaurant Los Manantiales (Fig. 6) and Bacardi Rum Factory (Fig. 8) – examples of inspirations.

Influence of Structural Artists

Structural artists are sometimes stimulated by other structural artists. For example, through studying the writings and works of many engineers, Candela was able to educate himself. In particular, structural artist Robert Maillart stands out as his greatest influence: "[Robert Maillart] may have been one of the strongest influences at the critical moment in my career in which I was trying to become a builder of shells." He discovered Maillart's works in two books, Sigfried Giedion's Space, Time, and Architecture and Max Bill's Robert Maillart. Maillart had constructed many slender, elegant arched bridges and pioneered new building forms out of reinforced concrete, striving for new forms that were efficient. Candela devoured his writings, and Maillart's papers opened his eyes to a new way of approaching structures. The Swiss structural artist used simplified calculations rather than rigorous analysis (which he had studied at the ETH in Zurich), a strategy that Candela found

"delightfully sympathetic and encouraging." (Félix Candela, unpublished autobiography)

Robert Maillart influenced Candela, but in turn, Candela influenced other developing structural artists. For example, in the early 1960s, Swiss shell designer Heinz Isler came across a book cover with a photograph of the Restaurant Los Manantiales designed and built by Candela (Fig. 6); its forms were completely new to Isler and appeared almost paper thin, and stimulated Isler to think about how he might express the same kind of thinness (Billington 1985). He was not able to achieve it with his traditional pneumatic forms, but did succeed with his hanging forms, as demonstrated for example by the BP service station built in 1968 (Fig. 10).

Figure 10. Heinz Isler's hanging form of the BP Service Station (1968)

Figure 11. Jack Christiansen's umbrellas.

Jack Christiansen designed many fine thin shell concrete structures in the US. Like Candela, he admired and was also influenced by the works of Maillart and others; but also, he was influenced by Candela. When he learned of Candela's work, he called it "Love at first sight" (Segal 2008). Like Candela, Christiansen designed many shells out of the hypar form such as the umbrellas used at Seattle's World fair (Fig. 11). Other current designers such as Jorg Schlaich (Schlaich 2008, p. 171) and Bill Baker (Baker, 2008) also give credit to Candela for inspiring them with forms

Education and Teachers

Structural art has flourished most impressively in Switzerland, in no small part because of the engineering educational tradition at the Federal Institute of Technology (ETH) in Zurich, and two exemplary teachers in particular: Wilhelm Ritter (1847–1906) and Pierre Lardy (1903–1958). Ritter made a deep personal impression on his students, conveying to them his emphasis on the importance of aesthetics in the education of civil engineers. The strong visual component of his teaching related applied mechanics to structural form and he encouraged his students to visualize the flow of forces within a structure, as well as the ways in which different forms could change that flow. It is not surprising that his teaching produced two of the most outstanding bridge engineers of the 20th century: Robert Maillart (1872–1940) and Othmar Ammann (1879–1965).

The most significant aspect of Lardy's teaching was his continued reference to the aesthetics of structure (especially those of Maillart), not as an isolated topic but as one integral to the engineer's design. Once again, we see the product of his technical teaching combined with an aesthetic emphasis in the works of his students, including Heinz Isler (1926-2009) and Christian Menn (born 1927). Heinz Isler has written that (Isler, 2002)

> "I think that the most important contribution we students got from our teacher Lardy is this:
> He reminded us, the engineering students,
> a) that we have in us a sense for esthetics
> b) that we have the right to use it
> c) that we are allowed to mention our opinion
> d) and that we can find and express it in our projects
> This to my opinion was the invaluable, great, and unique contribution he gave to us. Not the statics, not the theories, not the investigations were his greatest and lasting influence, but encouraging us to find and apply esthetics from within us.
> And for this I am very grateful to him."

Structural engineering education, done properly, can thus inspire students to reach the pinnacle of design: structural art. Teaching structural art is also important because structural engineering since the Industrial Revolution has become a *new art form* parallel to but independent from architecture. It must therefore form an important part of the education of civil engineers. Just like other forms of art – painting, sculpture, music and literature – structural engineering should focus on the exemplary works of structural artists in the education of engineers and in the broader education of *all* students.

This form of teaching is done at Princeton University through the course "Structures and the Urban Environment", which was developed by David Billington and has been taught continually by him since 1974 (with its largest enrollment ever this year of about 240 students). This is a required course for structural engineering majors, who typically constitute less than 10% of the class. About 80% of those enrolled are *non* science or engineering majors. The course centers on fourteen of the greatest structural engineers and discusses what leads us to designate them as artists – structural artists. This argument appears in the basic text for the course *The Tower and the Bridge: The New Art of Structural Engineering* (Billington 1985) but it is more visually expressed and better generalized in the most recent course texts: *Félix Candela: Engineer, Builder, Structural Artist* (Garlock and Billington 2008) and *The Art of Structural Design: A Swiss Legacy* (Billington 2003), the latter of which consists of Swiss structural artists Robert Maillart, Christian Menn, Heinz Isler, and Othmar Ammann along with chapters on their teachers Ritter and Lardy.

CONCLUSIONS

Structural artists are engineers who consider it their mission to create the form—the aesthetic of a structure—as well as to conceive the technical design and the

construction plan. Structural art can only arise when that play is disciplined by efficiency and economy. As Candela explained: "But an efficient and economical structure has not necessarily to be ugly. Beauty has no price tag and there is never one single solution to an engineering problem. Therefore, it is always possible to modify the whole or the parts until the ugliness disappears. This aversion to ugliness is quite the opposite of the task of the professional artist who has to produce beauty as an obligation or of today's star-architect who has to be original at any cost in each new project." (Candela 1973)

A work of structural art satisfies all the above criteria and it is always the product of one person's imagination: an individual who develops the form based on the engineering imagination, makes appropriate calculations, and develops a means of building it. Candela seems never to have created a new form in the sense that some architects do, often without any relationship to efficiency and cost. While Candela worked with architects on some of his projects, the designs were based on his innovative ideas, which in turn were based on the *engineering imagination*.

The *inspiration* for the designs of structural artists come from a process that begins with imitation, followed by innovation. This concept was illustrated through the examples of the designs of Robert Maillart and Félix Candela. Sometimes, the inspiration comes from another structural artist. For example, Candela was stimulated by Maillart, and Isler was stimulated by Candela to express the thinness.

In a design profession it is of the utmost importance to teach the greatest works along with the discipline of calculations. Student engineers need to be exposed to the best that has been done and *all* students need to be educated in structural art so that as citizens they can call for such works in the future and to be able to choose them over the sometimes flashy but excessively costly structures that are wasteful of material and moneys and are difficult to sustain. Education is therefore crucial for the future of structural art and in studying it educators, practitioners, and the general public can recognize the potential for this new art form in the 21st century.

The Influence of Engineering Organization on Design and Construction Processes at Tennessee Valley Authority Dams of the 1930s

A.B. Liel[1]

[1]Assitant Professor, University of Colorado, Boulder, CO 80309; PH (303) 492-1050; email: abbie.liel@colorado.edu

ABSTRACT

This study examines engineering design processes and organization at the Tennessee Valley Authority in its early years from 1933 to 1936. During this time, Norris and Wheeler dams were constructed and plans and designs were begun for several additional dams. The TVA experience provides insights into how design processes evolved and were managed in a large engineering organization. A particularly innovative decision was the choice to build TVA dams by force account, i.e. by hiring their own employees, rather than by selecting contractors through a traditional bidding process. TVA engineers believed this approach would reduce overall design and construction costs, as well as reduce time to completion. Case studies of civil engineering history, like this one, provide an important tool for introducing students to design processes and engineering decision making.

DAM DESIGNERS

Unlike many of the landmark civil engineering works of the 20th century, which can largely be attributed to the engineering know-how and imagination of one individual, such Othmar Amman's George Washington Bridge, the construction of each of the massive federal dams during the 1930s and 1940s largely represents a collaboration of engineering design expertise among many individuals. This collaboration likely resulted from the unique challenges of dam design, which require integration of design of structures, water passage systems, turbines, transmission, and mechanical systems and involve each of the major branches of engineering. As a result, both the expertise and creativity of individual engineers and their interactions to integrate different aspects of the design are critical to the design process.

This study examines one major dam-building agency, the Tennessee Valley Authority (TVA), and their engineering design processes and organization. Much has been written about the TVA: the politics of its early proponents in the 1920s, its origins during the Great Depression, the controversy of creating a multi-state organization to manage a river basin, the conflict between its early board members, and the technical features of its concrete dams. However, little has been written about the development of the engineering organization within this unique and complex political instrument. The story of TVA engineering management during these early years provides an important case study of how an organization grew from nothing in 1933 to build major engineering works, including the planning, design and construction of six major dams by 1940.

THE TENNESSEE VALLEY AUTHORITY CONTEXT

President Franklin Roosevelt signed the act authorizing the Tennessee Valley Authority (TVA) on May 18, 1933, and chose Arthur Morgan as the organization's chairman. Morgan had gained renown as chief engineer of the Miami Conservancy District, for which he devised a flood control plan for the Miami Valley of the Ohio River (1915-1921), and administrative experience from his time as president of Antioch College (1921-1933). He also had experience designing earthen dams, but none with concrete dams or managing a large regional development project. Two others completed the Board of Directors: Harcourt Morgan, president of the University of Tennessee and David Lilienthal, lawyer for the Wisconsin Public Services Commission. In the summer of 1933, the government launched the new Authority with neither employees, technical expertise in the building of concrete dams, nor an organizational structure, but with three board members coming from diverse backgrounds and a desire to quickly begin construction of Norris Dam.

Decisions had to be made on how construction would be carried out, and how the TVA would be organized. Under Morgan's leadership, TVA began by removing the U.S. Army Corps of Engineers from the Tennessee River. The Corps had already begun plans for restructuring the valley, but both Roosevelt and Morgan felt that the duality of their engineering and social goals for the region could be better accomplished by a completely autonomous agency. The Corps of Engineers' legacy was a report that prioritized Norris Dam, on the Clinch River, and Wheeler Dam, on the Tennessee River, ahead of other proposed projects in the region.[1] In other areas, Arthur Morgan's previous experience at the Miami Conservancy clearly influenced early board decisions. Most importantly, the directors chose to build their dams by force account, hiring their own employees, as had been done at the Miami Conservancy. Morgan and other TVA engineers were strong proponents of this system, although little evidence existed as to its superiority and much of the engineering profession remained unconvinced as to its merits. Both the Bureau of Reclamation and the Army Corps of Engineers, for example, usually used the traditional contractor-bid method. Drawing on his connections with the engineering profession and previous employees, Morgan rapidly established a talented engineering staff, but he felt it was essential, too, to enlist the Bureau of Reclamation's assistance in the design of the first two dams.

TVA'S EARLY ENGINEERING ORGANIZATION

Since Morgan was chosen as TVA chairman prior[2,3] to the official authorization of the TVA by Congress, he influenced the writing of the legislation and the initial

[2] Roosevelt announced that Morgan would lead TVA the day he signed the Act in May, 1933. By mid-April, 1933, Morgan and Roosevelt had begun communicating regarding plans for the TVA and Morgan had approval to confidentially begin inquiries about potential personnel.

[3] Talbert, Roy Jr., FDR's Utopian: Arthur Morgan of the TVA, Jackson: University Press of Mississippi, 1987. See also, Letter from Franklin Roosevelt to Arthur Morgan. April 18, 1933. *[Early TVA Correspondence. TVA Library. Knoxville, TN.]*

organization of the Authority. When the congressional committee asked Morgan how many members the Board of Directors should have, Morgan suggested three, a number he and Roosevelt had discussed. In addition, Morgan insisted that the three board members serve as equals and receive equal salaries.[4]

In an interview, Gordon Clapp, who began his time at TVA in July 1933 as assistant director of personnel and later became chairman of the TVA board in 1947, discussed the contradictory understandings of organization each of the original board members brought to the young corporation. Arthur Morgan, Clapp says, focused his efforts on hiring good people; armed with a superb staff, Morgan believed a suitable organization would develop without explicit planning. In the preface to a TVA organizational manual issued in March, 1935, Morgan wrote, "I personally detest regimentation, red tape, and bureaucracy, and am willing to endure a limited amount of confusion in order to give freer play to loyalty, initiative and enthusiasm."[5] Conversely, Harcourt Morgan, the lone member of the board with any experience in public administration, felt that a well-structured organization was essential.

Under the original organizational plan, Arthur Morgan became the general manager of the organization, responsible for coordinating and administrating the various activities of the organization, while the entire board would be responsible for general policies. However, this plan was abandoned only two months later, in August 1933, as Harcourt Morgan and David Lilienthal grew "dissatisfied with what they felt to be a lack of an adequate plan of administration or an effective overall method of control and review of the TVA program."[6] The new organization consisted of a tri-section of the board that continued until the 1936. Under this reorganization, the entire bard maintained responsibility for general policy formulation. Arthur Morgan took responsibility for the engineering and construction programs, with Carl Bock as his assistant engineer. Within the engineering department, separate divisions were created for both of the major projects, Norris and Wheeler, as well as engineering services, maintenance and construction, and reservoir clearance.[7] Harcourt Morgan took charge of agriculture and fertilizer considerations, and David Lilienthal assumed jurisdiction over electric power issues.

DESIGN OF NORRIS DAM

Having obtained the Army Corps of Engineers' designs, the Board of Directors asked the Bureau of Reclamation, the federal dam-building agency with the greatest experience in large concrete dams, to do the design work for both Norris and Wheeler dams, their first projects.[8] The Bureau of Reclamation engineers, led by J.L. Savage, redesigned the dams and furnished TVA with complete designs and specifications. The decision to discard the Corps' designs seems to have been largely based in politics rather than engineering and, particularly, Morgan's well-documented dislike

of the Corps of Engineers. Sherman Woodward, the TVA water resources engineer charged with reviewing the Corps of Engineers' designs, deemed them "naïve and in need of improvement."[9] However, careful evaluation of the two designs shows this negative assessment to be unjustified; the final Norris dam design had a lower reservoir elevation and removed the Corps' planned navigational lock, but the general shape of the dam remained similar to the Corps' original design and, certainly, the Bureau of Reclamation engineers had the Army Corps' design at their disposal. As well, there is some indication that the Bureau engineers utilized designs from recently completed Madden Dam on the upper Chagres River, in Panama, for the Norris design.[10] The Army Corps' preparation work, as well as the engineering expertise provided by the Bureau of Reclamation and mapping assistance from the United States Geological Survey, allowed TVA to begin construction of Norris and Wheeler Dams almost immediately. This quick start was imperative, in light of the politics of the Great Depression. TVA hired construction forces at the same time as the Bureau prepared the plans.

FORCE ACCOUNT CONSTRUCTION

TVA design plans and specifications were not put out to bid for contractors, but rather, were built by the organization's own construction employees, the so-called "force account" construction method. Arthur Morgan's experience at the Miami Conservancy District greatly influenced the decision to use the force account method for engineering and construction. Morgan originally had planned to use the traditional contract method for the Miami Conservancy dams. However, World War I led to fluctuations in materials and wages, and contracts included contingencies. Unwilling to accept these uncertainties, Morgan chose to hire his own workforce at the Miami Conservancy District. [11] Comparisons between his earlier years in private engineering practice and his years at the Miami Conservancy led Morgan to criticize the customary contract forms and specifications for their "ambiguity, repetition, [and] stereotyped phraseology."[12] Morgan viewed his plan for the Tennessee Valley as a scaling-up of the work he had done at the Miami Conservancy, and wanted to incorporate the same non-traditional construction methods. In his later writings, Morgan claimed that "the idea to take this course [the force account method] was mine."[13] Though the Bureau of Reclamation's construction work has always been done through the traditional bid-contracting system, Savage, the Bureau's chief design engineer, supported the choice of the force account method. The minutes of the July 29, 1933 board meeting read, "Mr. Savage believes the best and most economical results will come from the direct responsibility of the construction superintendent to the Authority, without the intervention of a contractor."[14]

[14] "Minutes July 29, 1933 Meeting, Board of Directors" *[TVA Library. Knoxville, TN.]*

TVA leaders were convinced that the force account method shortened time to completion of the projects. At a July 29, 1933 board meeting, the directors acknowledged that plans for Norris Dam could not be finished for six months and that "it would be difficult to take bids until the plans are finished, but it is possible to begin work very soon by force account."[15] The extra time required to use the traditional contracting method was certainly unpopular in the midst of the Great Depression. Praising the original board's decision in retrospect, Gordon Clapp described the shortened construction time-line as the major advantage of TVA's force-account method: "Building a dam by contract, in fact, is to build a dam at least twice, once on the drawing boards before you move a cubic yard of dirt and building it again on the site."[16] There is, however, little empirical evidence that TVA's use of the force account method significantly reduced project completion time.

In addition, the TVA board believed that the interaction between construction and design teams facilitated the realization of improvements that could be made and added to the as yet unfinished plans, a concept Morgan referred to as "dynamic design". In describing the advantages of the force account method, Morgan wrote, "I had found [at Miami Conservancy] that in large outdoor constructions there would almost certainly be actual conditions that could not be anticipated at the start."[17] Ross White, construction superintendent at Norris Dam, advocated the force account construction method saying, "It may be necessary to change substantially the foundation plans when the excavation for the foundation has exposed the nature of the underlying rock."[18] Morgan later claimed that several changes at Norris Dam made late in the design process, including the decision to increase concrete density, thereby increasing the safe reservoir level by 10%, would have been impossible to make in a traditional contractor-bid system.[19]

The Board of Directors further justified doing their own construction because it would allow the Authority to provide good working conditions, a characteristic Morgan wanted to be a hallmark of the TVA organization. In particular, TVA employees worked a total of six 5.5 hour days per week, with three days spent on the construction site, the others in training programs. The board felt that the feasibility of this type of work schedule under the typical contractor-bid systems would have been very difficult, if not impossible: "the whole training program depends on the direct handling of the work by the authority."[20]

The implementation of the force account method meant that the final design of Norris dam was only a few weeks ahead of construction. However, the board members' criticism of the traditional contracting methods and promotion for the force account were unusual. Excepting those in the Tennessee Valley, all major federal American dams were built in the traditional method. TVA eventually utilized this force account method of construction for each of its major dams.

TVA ENGINEERS

TVA engineers were chosen based on their previous engineering work and a particular ideology, including previous "progressive" work and a belief in "the feasibility of this [TVA] approach [for multi-purpose dams]."[21] During the summer of 1933, Arthur Morgan, and Bock, his assistant hired a team of respected engineers, drawing on Morgan's personal connections to quickly recruit technical staff.[22] Barton Jones, who eventually became TVA's chief design engineer, had worked with Morgan at Morgan's own firm, Morgan Engineering Company, the Miami Conservancy, and Antioch College. Morgan had also previously employed other high-level TVA engineers, including Bock, Woodward, Ross Riegel and Ned Sayford, James Bowman, and Emerson Chandler. In addition, Morgan recruited Dudley Dawson, head of training, from among the faculty at Antioch College. Morgan himself acknowledged the important legacy of Miami and his employees there, writing, "The general plan of the river control of the TVA and the dam building and administrative organization there was largely the work of men trained on the Miami Conservancy Project."[23]

The TVA also recruited a number of employees with previous dam-building experience with the U.S. Army Corps of Engineers or the Bureau of Reclamation. Theodore Parker, chief construction engineer, and Nicholls Bowden, hydraulic engineer, had both worked on large hydraulic projects with the Army Corps of Engineers. Byrum Steele and Robert Moore were former Bureau of Reclamation employees, Steele having worked on Hoover Dam.[24] Moore, who joined TVA in 1937 as assistant director of water control planning, had previously worked as the Senior Engineer in Charge of Structural and Hydraulic Design for the Bureau of Reclamation and played a major role in that organization's designs for Norris and Wheeler Dams.

ORGANIZATIONAL CHALLENGES

TVA Organization. The tri-section of the Board of Directors created the most fundamental organizational problem during TVA's first three years as it required the directors to split their time between leadership and general administration and oversight of the daily operation of the Authority. The TVA's organization at this time was unlike most private corporations, which tend to have a larger board of directors and a separate group of managers who direct the day-to-day operations of the organization.

Facing dual responsibilities, each director did not have adequate amount of time to address both the administrative and the operational issues. Although splitting their responsibilities was beneficial when initially conceived because it allowed each member of the board to focus especially on a particular aspect of the organization, the personal projects and personality clashes soon damaged the overall organization. John

[21] Clapp, "Men and Management Rebuild a River", pg. 9
[22] Personnel decisions had to also be approved by President Roosevelt. *[Early TVA Correspondence.]*
[23] Morgan, The Miami Conservancy.
[24] Personal communication with Donald Jackson, Professor of History, Lafayette College.

Blandford, secretary to Arthur Morgan, and, later, TVA general manager, described the characteristics of the board between 1933 and 1936: "In reality, there was no board then in existence. Officials had to catch each director severally by his coat tails and get the necessary documents signed."[25] Separation between the three directors allowed each to hire based on personal relationships or convenient political appointments. This intense interest in specific projects and people, as well as personality clashes amongst the board members significantly decreased the effectiveness of the tri-section of the organization. F.X. Reynolds, an employee in the personnel department, reflected in an interview, "disagreement was not taken kindly, and irritations caused reprisals and hindrances, and, they tended to deny to each other the things to which each was entitled. It was this spirit rather than the mere organization that caused the trisection to operate worse than could be deduced merely from structure."[26] On an undated organizational chart, Carl Bock wrote, "Mature consideration indicates the desirability of having the Directors retire from the administration of those phases of the TVA program which they collectively delegated themselves as individual directors back in the fall of 1933."[27] However, no provision was made, and organizational remedies were not made until 1936.

Although much of the personal squabbling was limited to the Board of Directors, bureaucracy and "red tape" led to a loss of morale that permeated all levels of the organization. Those employees who reported directly to the Board of Directors complained of inadequacies in the service departments and of time wasted on bureaucratic and administrative decisions. The accounting department was described as both "unsatisfactory" and "inefficient" and the personnel department found to be unresponsive to engineering needs.[28] Carl Bock wrote, "These problems require more than half my own time and energy to combat... They are likewise sapping the energy of heads of our engineering departments, and this situation, coupled with failure to authorize some much needed assistance, creates a serious situation." The bureaucratic problems, Bock believed, were not a result of the people hired, but rather the organizational system that had developed.[29]

The morale problem extended beyond the existing organization as managers reported a difficulty in hiring as the public gained knowledge of the conflicts among the Board of Directors: "Recent contacts with high grade prospects for key position invariably elicit questions as to the probable effect of this split on the candidate's situation."[30] Concerns about morale at all levels also inhibited the adoption of suggestions for reorganization, as the administration believed they would further worsen the situation.[31]

Engineering and Construction Organization. On an undated organizational chart from the mid-1930s, Carl Bock noted that "the authority is slowly changing from a planning and construction agency to a construction and operating agency."[32] He also acknowledged, "It was fundamentally impossible to design a suitable organization at the beginning because there had been no precedent for an enterprise such as the TVA. With the benefit of actual experience it should now be possible to introduce desirable forms of reorganization and this ought to be accomplished to the fullest extent possible."[33] In particular, the organization could learn from the design and construction experience at Norris and Wheeler dams. These changes in function of the authority required an alteration in the organization of the design and construction departments between 1933 and 1936.

Archival letters, interviews and other papers indicate a number of specific complaints regarding the engineering and construction organization. In particular, engineers frequently lamented the separation between electrical engineers, who were in the commercial electricity department, from the rest of the engineering division. This separation hampered communication between engineers and transmission power planners; while the engineers determined power capacity at dams, the electrical engineers designed the transmission lines, often without consulting each other, leading to repeated work once conflicts were discovered.[34] According to Reynolds, organizational difficulties increased costs: "in engineering, program money was lost because decisions were not agreed upon between the electrical engineers and the dam-building engineers."[35] The separation between the design department and the operating division also led to inefficiencies in TVA operation. Parker, Jones and Woodward, the three highest-ranking engineers, reported in October, 1936, that while they designed Norris to be operated by twelve people, twenty-eight men were on site, and, as a result, more facilities were needed.[36]

TVA engineers also found basic workplace amenities to be lacking.[37] The engineering design team reported that they had been moved from office to office often, and were not given enough space to work. The rapid increase in workforce from TVA's inception in May, 1933 to nearly 10,000 employees by July, 1934 exacerbated problems with workplace facilities. As TVA people and projects increased, difficulties emerged in employee training programs as well. The large number of isolated construction camps made it a necessity to provide a branch of training at each construction and operating center, requiring duplication of some training programs.[38]

Archival papers show that the organizational structure created animosity between the engineering department and other divisions, particularly the staff in the

personnel office. Steele discussed the barriers he found in hiring talented engineers: "past experience has shown that there were many difficulties in building up the design force to adequate strength to handle the work under consideration. These difficulties, however, have increased rather than decreased, due to the bureaucratic procedure established by the Personnel Department."[39] An unsolicited memo on suggestions for improvement written by members of the engineering staff described the personnel department as one of their most significant problems. Signatures on this memo included the head construction plant engineer (Ackerman), the chief engineer (Parker), the chief design engineer (Steele), the acting chief design engineer (Jones), the general construction superintendent (White), and several project and construction engineers.[40] Salary policy, developed by the personnel department, was another point of contention. Exit interviews conducted when engineers left the organization indicated that engineers felt that the aim of the new salary policy was to "throttle their opportunities with TVA."[41] The combination of the bureaucratic hiring process and unpopular salary policy made it difficult for the engineering organization to maintain and hire the staff necessary for their operations. A 1937 report in *Engineering News Record* that private engineering hires had increased further increased concern among TVA engineers about their ability to hire the best engineers.[42]

These organizational difficulties challenged the original fluid organizational strategy, proposed by Arthur Morgan. Personal animosities and the tri-section of the board hampered the productivity of the leadership of the organization; excess red tape and loss of morale decreased the effectiveness of the engineers and laborers. Though TVA successfully hired what Morgan considered to be "good people", organizational difficulties did not solve themselves, and, by 1936, a major restructuring of the organization, of the type originally advocated by Harcourt Morgan, was necessary. One of the critical changes was the institution of the office of general manager. The position was given to Blandford, who had joined the organization as Morgan's personal assistant in September, 1933.

ENGINEERING ECONOMY: TVA DESIGN COSTS

Despite the expectation that the force-account construction method would reduce the overall cost of TVA projects, A.J. Ackerman, the head construction plant engineer, acknowledged in 1937 that "design costs are way out of line," and that there were "possibilities here for introducing economies."[43] Though Ackerman's memo emphasized that he does not have enough data to make comparisons to other engineering organizations, the high design costs of the first TVA dams beg

comparison with dams built either by private sector or the other federal dam building organizations.

Total design costs at TVA dams, as a percentage of total structural cost, range from 2.2% at Wheeler to 6.8% at Hiwassee, as shown in Table 1. The two dams designed entirely by TVA forces (Pickwick Landing and Guntersville) had higher design costs than Norris and Wheeler, designed by the Bureau of Reclamation. Although Wheeler Dam probably had low design costs because the strong foundation material allowed the Bureau of Reclamation to use a particularly repetitive design, the total design cost for Pickwick Landing was twice that of Wheeler. Moreover, Hiwassee, the first tributary dam constructed after Norris, also had markedly higher design costs than either Norris Dam or Tygart Dam, constructed by the Army Corps of Engineers on the Monongahela River. However, overall structural costs among all the structures are similar.

Table 1. TVA dam design costs, in relation to total structural cost.

Dam	Year completed	Design cost	Total cost	Design costs as % of total structural cost
Norris[44]	1936	$561,248	$15,733,562	3.7%
Wheeler	1936	$507,927	$20,806,321	2.5%
Pickwick Landing	1938	$1,076,229	$21,902,776	5.1%
Guntersville	1939	$746,670	$17,837,168	4.5%
Hiwassee[45]	1940	$734,549	$10,764,624	6.8%
Tygart[46]	1938	$675,000	$18,400,000	3.8%

TVA engineers and administration attributed the large design costs in part to the TVA's young organization and lack of engineering experience. While other dam building organizations were able to reuse previous designs, TVA had no design experience to build on. By the 1930s, the Bureau had a standardized routine that lowered their design costs. Perhaps even more importantly, the force account method uniquely employed by TVA may have increased the design costs, while reducing the overall cost of construction, reflecting the mantra that, "With force account work, it is generally possible to apply the principle of spending another dollar to save two dollars."[47] While other dam building agencies were unable to make significant modifications in design after contractor bidding, the TVA design team worked with the field engineers and construction team to make modifications as the project progressed. Justifying the large design costs to the Board of Directors, Bock said, "it is our considered policy to scrap designs and make them over when by so doing a better construction will result or when substantial sums can be saved on construction

[44] Design costs for Norris, Wheeler, Pickwick Landing and Guntersville dams are given in the TVA memos: "Comparison of Design Costs of TVA Projects," dated May 12, 1937. *[Carl Bock Papers]*.

[45] The best estimate available for the design costs at Hiwassee is in TVA's technical report, The Hiwassee Project (Washington: Government Printing Office, 1946).

[46] The estimate of Tygart design costs is based on a letter from the Secretary of War, Harry Woodring, to West Virginia Senator Rush Holt on July 19, 1937. *[RG 77/111 Box 1682, Folder 5221. National Archives. College Park, MD.]*

[47] "Letter to Board of Directors." Feb. 15, 1937. *[Carl Bock Papers.]*

operation."[48] Cost engineer H.A. Sargent also acknowledged that some of the redesign was the result of having started the design before structural characteristics or equipment to be used were determined.[49]

To demonstrate these overall savings, the engineering department completed a detailed study of design changes and resulting economies for Norris Dam. As construction work progressed and more knowledge about the Norris site became available, TVA, together with the original Bureau design team, altered the diversion scheme to use spillway blocks rather than diversion tubes, eliminated the need for needle valve outlet conduits to regulate outflow, redesigned and moved the powerhouse, and removed a cutoff trench at the heel of the dam. Each of these changes increased the design costs, but resulted in estimated total savings of $980,335, a remarkable result considering the $561,248 total design price tag.[50] Similar TVA studies showed significant savings from redesign and the force account method at Pickwick Landing, Guntersville and Chickamauga Dams as well.[51]

CONCLUSIONS: THE IMPORTANCE OF STORIES IN ENGINEERING EDUCATION

In the words of the *American Society of Civil Engineers,* in civil engineering education we aim to prepare and inspire our students to,

> *serve competently, collaboratively, and ethically as master: planners, designers, constructors, and operators of society's economic and social engine, the built environment; stewards of the natural environment and its resources; innovators and integrators of ideas and technology across the public, private, and academic sectors; managers of risk and uncertainty caused by natural events, accidents, and other threats; and leaders in discussions and decisions shaping public environmental and infrastructure policy.*[52]

While ensuring that students gain the necessary technical expertise is essential to meeting these goals, it is insufficient. Case studies and stories of past civil engineering successes and failures provide a powerful tool for teaching students about the economic, societal and political impacts and considerations that affect any major engineering effort. In the early Tennessee Valley Authority described here, a group of political and engineering leaders set out to restructure the Tennessee River and the region's economy. Their story illustrates how one organization designed major civil engineering structures. Of particular importance are the insights into how the TVA went about building the human capital and technical expertise to design and construct the early dams. The early TVA engineering efforts also demonstrate the important role of engineering management and organization in facilitating or hindering design processes. In the mid-1930s, the engineering organizational structure seems to have

complicated efforts to collaborate across different branches of the organization and to integrate the different components of dam design (civil, mechanical, electrical and chemical). Even so, the TVA introduced a major innovation in design and construction, choosing to design and build the dams in-house. This design-build approach, which has recently gained increased popularity, probably facilitated the introduction of certain design changes and unique engineering features late in the dam design process and, in the process, provided design engineers with the flexibility to cope with some of the organizational and communication challenges they were faced with. These lessons – and others like them – can help our students better understand and navigate engineering design processes, including technical considerations of economy and efficiency and human considerations.

ACKNOWLEDGEMENTS

I first undertook the study that provides the basis for this paper as an undergraduate research project at Princeton University. It would not have been possible without the guidance, wisdom, and mentorship of Professor David P. Billington of Princeton University who introduced me to a love of scholarship and engineering stories. Sinead MacNamara and Angela Ovecka gathered some of the archival research materials.

A Comprehensive Assessment of Building Damage after the January 12, 2010 Haiti Earthquake

ABSTRACT

This damage assessment relied heavily on the use of remote sensing technology. Never before has the availability of high-resolution satellite and aerial imagery been so open and accessible. Data from different missions (World Bank-ImageCat-RIT Remote Sensing Mission (15cm optical and 2 pt/m2 LiDAR), Google (15cm optical), NOAA (25cm optical), Pictometry, as well as satellite imagery from GeoEye and Digitalglobe) has allowed damage from the Haiti earthquake to be viewed through multiple sensors and at different times. These multi-dimensional perspectives have been invaluable in understanding the magnitude and scope of damage caused by this earthquake.

BACKGROUND

This paper provides a brief account of how technology, inspiration and collaboration were used to quickly assess the amount of damage caused by the January 12, 2010 Haiti earthquake. In less than a minute, this event leveled approximately 20 percent of the buildings in greater Port-au-Prince; killed close to a quarter of a million people; injured as many; and left over a million individuals homeless. While not considered a *great* earthquake (from seismological standards), this event will rank as one of the deadliest earthquakes of the 21st century.

This event will also be known as one of the first events where technology (especially high-resolution imagery) was embraced at such a large scale in a real operational sense. Almost from the very onset of the disaster, high-resolution satellite imagery was available to provide the first glimpse of the devastation caused by this earthquake. Days later, very-high resolution aerial imagery was available to provide even more detail on the damage caused in this event. Together, these valuable datasets allowed a small army of remote sensing experts to provide one of the most accurate assessments of building damage in the last decade. Furthermore, this information was shared with Haitian government officials in relatively short time – within two months of the earthquake – in the

form of a *Building Damage Assessment Report* in support of the Post-Disaster Needs Assessment (PDNA) and Recovery Framework.

This paper discusses how three key international organizations – the World Bank (WB), the United Nation Institute for Training and Research (UNITAR) Operational Satellite Applications Programme (UNOSAT) and the European Commission's Joint Research Centre (JRC) – worked together, in the framework of the joint declaration signed in 2008 between the World Bank, European Commission and the United Nations Development Group on post-crisis Assessments and Recovery Planning, to produce this rapid assessment of building damage and how these organizations are continuing this collaboration to improve response protocols for future disasters. It is clear from the Haiti experience that the future of post-disaster damage assessments has changed dramatically and that the "bar has been raised" for the next event. The main purpose of this chapter is to document key lessons from the Haiti experience and to recommend improvements that can be implemented by future responders.

DAMAGE ASSESSMENT

The main outcome from the joint collaboration was the *damage assessment*. Damage was measured by the number of buildings in different damage states. For ease of use, the joint team agreed to use a damage scale that was developed several years ago in Europe – the European Macroseismic Scale – 1998 version. Fundamentally, this was one of the most important decisions made by the WB-UNOSAT-JRC team because it ensured a common basis for measuring the effects of the earthquake. By agreeing to use this scale, the damage assessment results from each organization could be combined without significant re-adjustment.

Table 1 shows the damage totals for the ten communes that were significantly affected by the earthquake. In total, over 90,000 buildings were either destroyed or experienced heavy damage. This represents slightly less than one third of the building inventory in the affected areas. Most of the damage occurred in Port-au-Prince; however, significant numbers of buildings were also destroyed in Carrefour, Delmas, Leogane and Petion-Ville. Based on median floor area estimates for different occupancy uses, this damage translates roughly to over 26 million square meters in building area affected with about one third of this total associated with buildings that will have to be either replaced or significantly repaired. The total repair cost to buildings is estimated to be over $6 billion (US).

SIGNIFICANT BREAKTHROUGHS

Years from now, many of the details of the joint WB-UNOSAT-JRC Haiti response will be forgotten; however, there are a number of outcomes that will remain a legacy of this monumental effort. What was accomplished during the Haiti campaign changed the landscape of global disaster response forever. The sheer magnitude of the event and its impact on the country of Haiti and its people required a new paradigm of data collection and damage assessment. Some of the notable accomplishments include:

- PDNA damage assessment based primarily on the use of remote sensing technologies,
- Crowd-sourcing technology as a means of mobilizing the expertise and passion of hundreds of volunteers around the world to rapidly assess the level of building destruction in greater Port-au-Prince, and
- A myriad of geo-spatial products that helped to chronicle the relief efforts of tens of volunteer organizations over time.

Note: 1-EMS-98: European Macro-seismic Scale (1998)

PDNA Damage Assessment – Past post-disaster damage assessments in support of a PDNA have been based on a variety of methods and data sources. Most common were field reports that attempted to capture the magnitude and scope of the disaster by focusing on heavily-affected areas and "extrapolating" these observations to the rest of region. In the past decade, remote sensing technology has had a role in these damage assessments but primarily as a verification source or as a means to visually portray to decision-makers and the public the amount of damage that had been sustained in the disaster. The notion of using remote-sensing technology as the primary basis of establishing the "damage estimate" is new and the fact that the Post-Disaster Needs Assessment framework adopted by the Haitian government is based on a direct result of this assessment is noteworthy. What was fundamentally a slow and tedious process was greatly enhanced by free and widely-available high-resolution satellite and airborne imagery. Rather than taking months to complete a preliminary count of damaged buildings, the application of remotely-sensed data allowed this damage assessment process to be shortened by a factor of two or three.

[1] EMS-98 scale includes five damage grades: 1 – no visible damage; 2 – minor damage; 3 – moderate damage; 4 – very heavy damage; and 5 – Destroyed.

Currently, there is a Ministry of Public Works effort designed with support from the World Bank and co-financed by the World Bank, GFDRR[2] and USAID[3] OFDA[4] that is focused on conducting a "house-to-house" assessment of building damage levels in order to ensure the safety of each building and to estimate the rebuilding or repair costs of all affected structures. This level of investigation is considered the most reliable and most accurate indicator of damage and thus represents the benchmark to which the remote-sensing assessment must be based. Since this process is still ongoing, a final comparison is not possible at this stage; however, early indications are that the remote-sensing based results are highly reliable with respect to counts of heavily-damaged or destroyed buildings. The World Bank/GFDRR financed portion of the structural building assessment is being implemented by UNOPS and the USAID OFDA portion is implemented by PADF[5].

Despite the obvious power of remote sensing technology, it is not without limitations. As we observed from ground surveys, much of the damage that resulted in the Haiti earthquake could not be detected from traditional aerial imagery (i.e., nadir views). With damage phenomena known as "soft-story" failures"[6] so prevalent in this earthquake, ground surveys played an important role in "filling in" the complete picture of damage. One of the key recommendations of this effort is the need for detailed protocols that systematically identify where these ground surveys are to be completed and to what extent. Some research is already being performed to help answer these questions (Saito et al, 2010).

Future post-disaster damage assessments – whether for earthquakes or for other hazards – will surely include a major remote-sensing component. As the technology improves in both resolution and delivery, the use of remote sensing will be commonplace not only for the most spectacular events but for smaller and moderate-sized events. And the Haiti earthquake will serve as the benchmark for what can and should be accomplished in these disastrous events.

Crowd-sourcing – Crowd-sourcing or human computation is a relatively new development and certainly a new concept in the area of disaster response. The notion of using a large community of experts to help perform damage assessments in disasters has been introduced by a number of individuals and organizations. With the Internet becoming the foundation of "social networking," it is not unexpected that virtual damage surveys using high-resolution imagery displayed on "Google Earth" type platforms emerged as a major source of damage information for the Haiti PDNA. After the Haiti earthquake, hundreds of individuals from around the globe passionately sought ways of contributing their expertise, time and knowledge to help support the people of Haiti.

[6] These types of structural failures occur when the stiffness of the lower stories of a building are much "softer" that than upper portions of a building. Soft floors usually result when large open spaces at the first level. The effect when significant ground shaking occurs is for the upper floors to collapse onto the lower story. Many of these failures were observed in Haiti.

ImageCat working with a network of partners including the Earthquake Engineering Research Institute[7] reached out to the engineering and scientific community to help in quantifying the extent of damage caused by the Haiti earthquake. In direct response to this event, ImageCat and EERI formed the GEO-CAN (Global Earth Observation – Catastrophe Assessment Network) community to help the World Bank in its effort to quantify building damage. Using very high-resolution aerial imagery, this community was able to identify the number of heavily-damaged and destroyed buildings in greater Port-au-Prince. A major product from this effort was the delineation of the pre-earthquake footprints of these buildings that would later be used by the joint WB-UNOSAT-JRC effort to quantify the amount of building area that needed to be replaced or repaired. In addition, the footprints offered an efficient way of combining the damage assessment results from the World Bank effort (GEO-CAN), and the UNOSAT and JRC teams. Using crowd-sourcing as the main information technology tool for post-disaster damage assessment, the GEO-CAN community was able to deliver its first count of damaged buildings in less than a week.

The GEO-CAN community consisted of over 600 experts from 23 different countries with over 60 major universities represented, about 20 government agencies and non-profit organizations, and over 50 private companies[8]. Current efforts by the World Bank, EERI and ImageCat are ongoing to institutionalize the GEO-CAN community as a permanent tool in the World Bank damage assessment toolbox.

Geo-Spatial Products – Led primarily by the UNITAR/UNOSAT group, a myriad of geo-spatial products emerged throughout the post-Haiti earthquake campaign. Early products were used for tracking emergency response activities, such as the locations Internally Displaced Persons (IDP). Later products included atlases that showed the locations of severely-damaged and collapsed buildings – see Figure 1. These damage atlas sheets were critical in deploying emergency teams to assess the safety and integrity of all buildings in the greater Port-au-Prince area.

Some other novel applications include 3-D models of Port-au-Prince that were constructed using LiDAR data collected during the World Bank-ImageCat-Rochester Institute of Technology Remote Sensing Mission (see Figure 2). A final report prepared by the World Bank and ImageCat contains a more comprehensive discussion of the various data products that were prepared by numerous organizations using high-resolution satellite, aerial (both nadir and oblique) optical imagery and LiDAR data (World Bank and ImageCat).

One of the important lessons learned from the Haiti earthquake was that free access to high-quality imagery was an important factor in motivating researchers and response organizations from around the world in producing rapid and transparent damage assessments. Corroboration of damage results was possible because of the number of

[7] The Earthquake Engineering Research Institute is a professional organization of engineers and scientists that are dedicated to reducing the effects of earthquake on people and structures. Founded in the late 1960's, its membership exceeds several thousand individuals. For more information on the organizations and its accomplishments over the last several decades, please see http://www.eeri.org.

[8] See http://www.virtualdisasterviewer.com for a complete list of organizations that participated in the GEO-CAN Haiti Initiative.

independent studies that were performed in this event. Although manual interpretations of damage were most common, many studies focused on automated or semi-automated approaches. Over the next year, we will be able to evaluate what methods were most effective at quantifying the scope of damage in this disaster. Already several major journals have committed to publishing special issues on the Haiti earthquake with special attention to remote sensing technologies. Through these reviews and exchanges in information knowledge, the response community will be able to build on the lessons learned in the Haiti earthquake so that the process of damage assessment will be even more robust and efficient in the future.

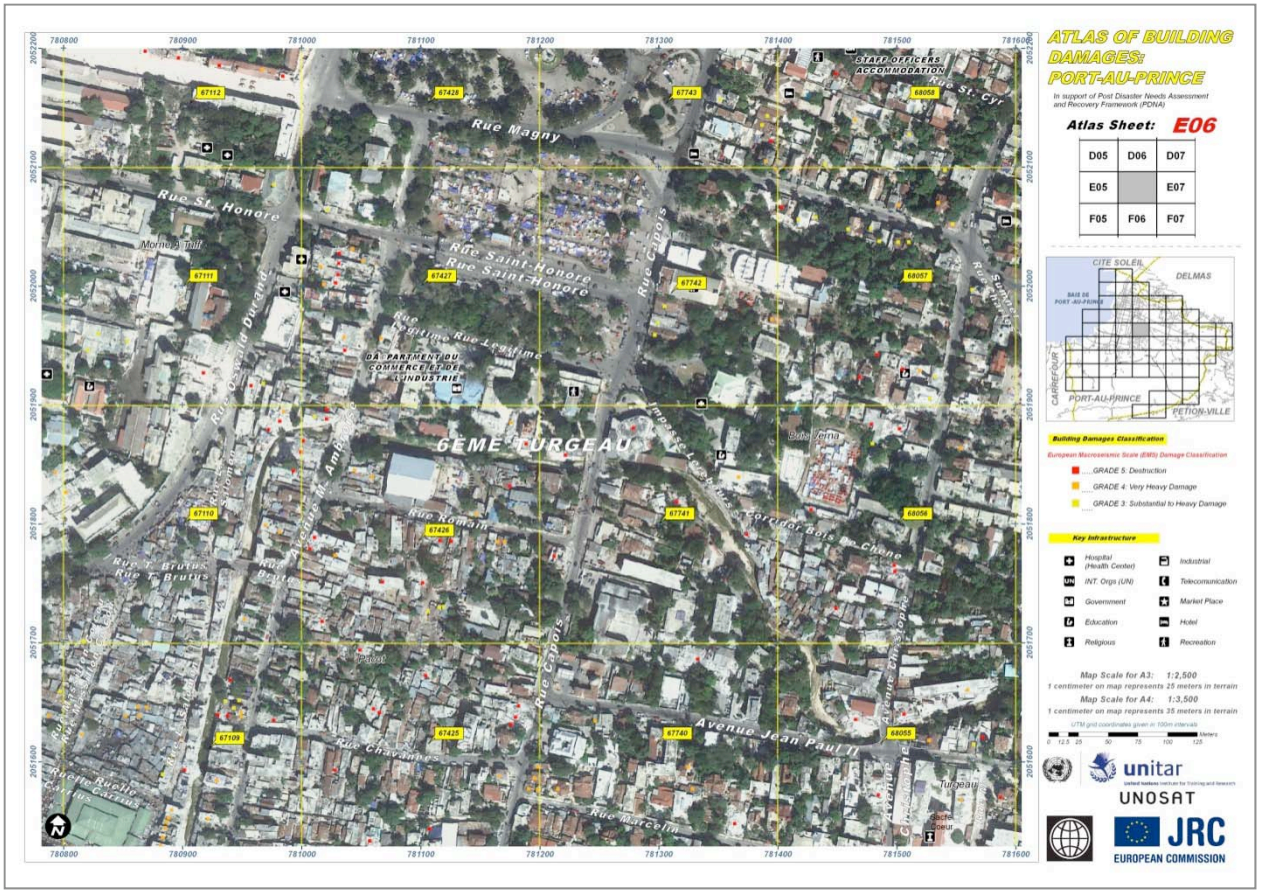

Figure 1 - Damage Atlas Sheet – Haiti Earthquake

Figure 2 - Purdue University's 3-D building Models as viewed in Google Earth

CONCLUSIONS

While the area of remotely-sensed damage assessment took a quantum step forward in the Haiti campaign, there is still significant room for improvement. Some of the areas that deserve further investigation or review are:

1. The establishment of standard operating procedures to ensure that damage assessments performed by multiple groups are consistent, transparent and combinable. An important element of any protocol will be standard definitions of damage and a damage scale based primarily on remotely-sensed imagery. Current efforts by the joint WB-UNOSAT-JRC team are focusing on a preliminary set of guidelines in this area (JRC et al., 2010).
2. The availability of high-quality imagery in near real-time. A key factor in the success of the Haiti response was having access to very high-resolution imagery within a matter of days. Rapid access to these data allowed a number of operations to proceed with greater confidence, i.e., deployment of emergency personnel to assess the safety of damaged structures. The fear of "overcommitting" resources before the priorities were known was somewhat mitigated by having these early "snapshots" of the devastation caused by the earthquake.

3. More work in training field personnel in how to use the "derived" products of satellite and aerial imagery. What was evident from post-earthquake interviews with field personnel was that existing workflow processes did not include the use of high-resolution imagery or derived damage products in the early emergency phase. For that reason, the use of the damage atlas sheets and general damage statistics was limited at that stage. Perhaps, an important purpose of the standard operation procedures discussed above could include clear guidance on how these damage products could be used for building safety assessments, siting of evacuation camps, siting of relief centers, etc. Additionally, there is an opportunity to integrate remotely-sensed products into the recovery process. For example, tracking and monitoring the progress of rebuilding or reconstruction can be a product of remote sensing technologies.
4. Refining the application of crowd-sourcing techniques in both damage assessment and in exposure mapping. In Haiti, one of the most severe impediments to the rapid mapping process was not having quantitative information on what was there before the earthquake. In most developed countries, property information (parcel locations, building sizes, some structural data) is typically available through cadastral and tax records or other government databases. This information is important in identifying what the reconstruction needs are because it provides data on what existed before the disaster. Because this information was largely absent in Haiti, a significant amount of time was spent trying to construct this information post-event by "digitizing" remote sensing images. Because there are a number of countries that would be in the same situation as Haiti, refining crowd-sourcing techniques to quickly develop key datasets, including locations of damaged structures and as spectacularly demonstrated by the Open Street Map initiative[9], is highly recommended.
5. Exploiting the lessons learned from the Haiti Earthquake. The response to the Haiti earthquake with respect to technology exploitation was phenomenal. In many respects, the event served as a testbed for assessing the efficacy of a wide range of technologies, including remote sensing. The lessons learned from this event must be leveraged so that when the next mega disaster occurs, we are not "re-learning" how to respond or how to implement these new and emerging technologies. What is needed is a "tsunami" of publications, reports, briefs, book chapters that document our successes and failures, in a way that also guides the way forward for future applications. It is the hope of the current authors that this book chapter contributes to this mission and that in a small way, we have defined part of that direction.

ABSTRACT

This research applied the nondestructive testing (NDT) technique of acoustic emission (AE) to monitor fatigue cracking in steel structures and utilized artificial neural networks (ANNs) for fatigue life prediction. The neural network classification network known as a Kohonen self organizing map (SOM) was first used to classify the AE data into the different source mechanisms occurring during fatigue cracking. This research developed methodologies for placing sensors, collecting acoustic emission data and eliminating noise from the raw data. The ultimate goal of this research was to monitor for steel fatigue cracking and accurately predict remaining fatigue lives using AE flaw growth data and back propagation neural networks (BPNNs). The procedures for doing so are presented herein.

INTRODUCTION

Acoustic emission is a powerful NDT technique when evaluating the health of structures. Artificial neural networks can be used to classify the AE data into different source mechanisms using a Kohonen SOM neural network and to predict the fatigue or residual life of the structure using the AE flaw growth data as input to a BPNN. Laboratory testing has been performed on notched A572-G57 steel bars for prediction using BPNNs (Barsoum et al. 2009). The AE sources were classified into plastic deformation plus plane strain and plane stress fracture mechanisms. Fatigue lives were predicted with a maximum error of under ± 20%. Notched steel I-beams were also tested in the laboratory, and the maximum prediction error was 5.3 % based on the third quarter of data (50-75%) of the average fatigue life (Korcak 2010 [1]). Field testing has been conducted on a Florida girder bridge which was examined to be structurally deficient (Korcak et al. 2010 [2]). The acoustic emission data were classified using a SOM into three different mechanisms, which included possible concrete cracking. A similar test was conducted on two Florida mast arm poles susceptible to fatigue cracking in order to identify and locate the fatigue crack (Korcak et al. 2010 [3]). This paper proposes a procedure for structural health monitoring of steel structures using acoustic emission and neural networks. Sensor placing methodology and effective

noise filtering techniques are addressed. Valid neural network setup for source classification using a SOM and fatigue and residual life predictions using BPNNs are demonstrated.

LABORATORY TESTING

A572-G50 Steel Bar Testing

Twenty A572-G50 steel bars with a 3.81mm (0.15 in) deep V-notch were fatigued at six discrete stress levels for prediction purposes using AE and BPNNs (Barsoum et al. 2009). To ascertain the noise behavior coming from the testing machine and environment, before the actual testing, several noise tests were performed as the MTS machine was switched on, but both the mean cyclic load and the span setting were set at zero. Readings from the two-channel PocketAE[1] system (with AEwin[2] software imbedded) were recorded for half an hour, and three graphs were plotted to illustrate the noise behavior. The sources of noise present were (1) the hydraulic pump, hydraulic valves, and actuator piston; (2) the hydraulic grips that contributed rubbing noises; and (3) electromagnetic interference from the PocketAE charger interface, which is a long duration signal. The average frequency (counts/duration) histogram of the noise spectrum is shown in Figure 1, with the bulk of it falling between the ranges of 1 kHz to 30 kHz.

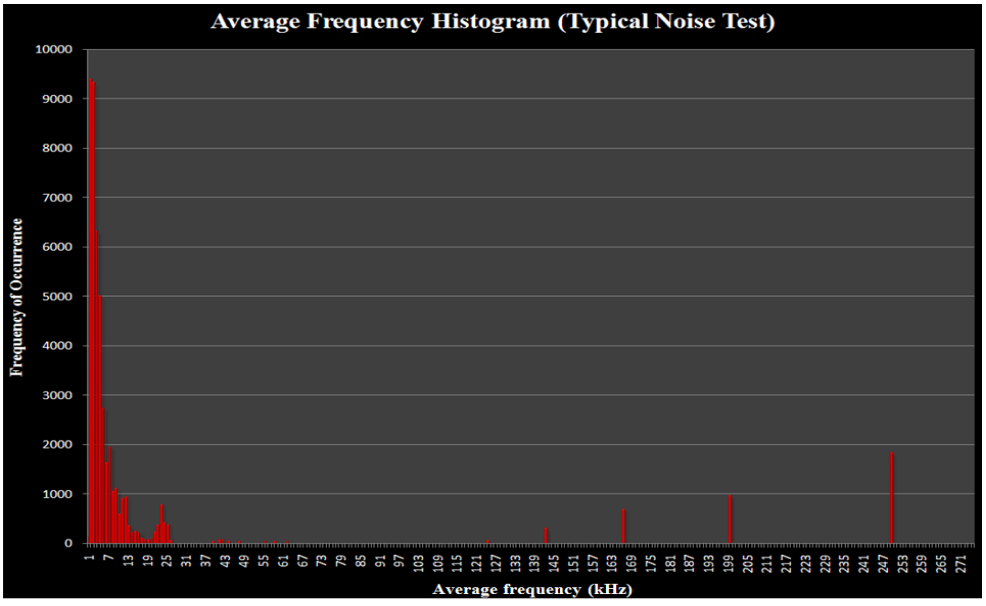

Figure 1: Average frequency histogram for a noise test (Barsoum et al. 2009)

The duration vs. counts plot is shown in Figure 2, and the average frequency (counts/duration) limits can be established as labeled in the plot, which agrees with the findings in Figure 1.

[1,2] Physical Acoustics Corporation

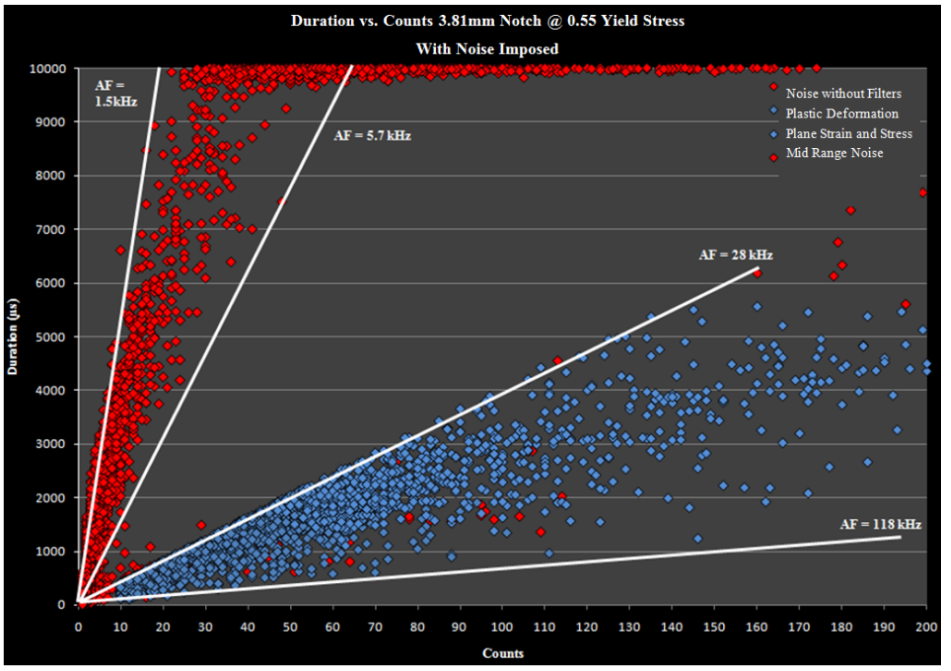

Figure 2: Duration vs. counts point plot with noise overlap (Barsoum et al. 2009)

A plot of the amplitude histogram of the noise signal indicates an amplitude range between 30 to 34 dB. As two filters can be applied to each of the transducers based on the findings, one filter was set to remove the AE hits of average frequency less than 25 KHz, and the other removed hits of counts less than 10. The constant noise signals of particularly long duration were later removed manually from individual files.

The actual AE data from the fatigue testing was later classified by SOM[3] into three mechanisms: plastic deformation plus plane strain and plane stress cracking. A BPNN[4] was then trained on eight bar specimens, and fatigue life was predicted using the data from the first quarter (0-25%) and the third quarter (50-75%) of the experimental fatigue life. The prediction results were within ±20% for first quarter data and ±12% for third quarter. These results indicated that, as might be expected, constant crack growth rate AE data yielded better predictions than crack initiation AE data (Korcak 2010 [1]).

Steel I-Beam Testing

In attempt to predict the fatigue life of bridge girders, ten simply supported S4x7.7 steel I-beams with span of 2.84 m (112 in) were tested (Korcak 2010 [1]). A 10 kip MTS actuator was used to apply a cyclic loading of 300 to 3,800 lb_f sinusoidal at 1 Hz. Each I-beam had a 0.254 cm (0.10 in) deep notch cut into the bottom

[3,4] NeuralWorks Professional II/Plus software

flange. Two transducers were mounted with hot melt glue on both sides of the notch. The noise tests indicated a noise amplitude threshold at 40 dB. One filter of the PocketAE system removed hits of average frequency less than 14 KHz, while the other removed hits with counts of less than 5. The ten beams tested had fatigue lives ranging from 11,811 to 19,653 cycles. The BPNN was trained on five specimens and used to predict fatigue lives on the other five with a maximum prediction error of ±18.4% for the 1st quarter data, -16.8% for the 2nd quarter data, and 5.3% for the 3rd quarter data. The prediction yielded less error when the data from the third quarter of the fatigue life was used, which is preferable in the actual bridge testing as fatigue monitoring becomes more crucial.

FIELD TESTING

Florida Girder Bridge

AE testing was done on a Florida steel girder bridge (Korcak et al. 2010 [2]) in order to monitor for any fatigue cracking and then predict remaining fatigue life using the recorded AE data and a BPNN. The 55.5 m (182 ft) long bridge had four spans and steel girders supporting a reinforced concrete deck. It was built in 1951 and had recently been classified as structurally deficient. The Florida Department of Transportation (FDoT) loaded the bridge on its two lanes with two trucks carrying concrete blocks, simulating a loading of 80,000 lb_f. A four-channel acoustic emission system was used to obtain the acoustic information from the different bridge members during the load testing as well as from live traffic. A robust four-channel AE PCI/DSP-4[5] system was used, connected to a laptop with AEWin software, which collected and recorded the data as shown in Figure 3. Four integrally pre-amplified 150 kHz piezoelectric transducers were hot melt glued onto the top side of the bottom flange of the beam, since the coating of the bridge made it difficult to bond anything to it. The bottom I-beam flange had a flat plate welded to it, where the rubbing of the surfaces or even cracking of the welds could generate acoustic activity. Figure 3 shows the welded plate and one of the AE transducers.

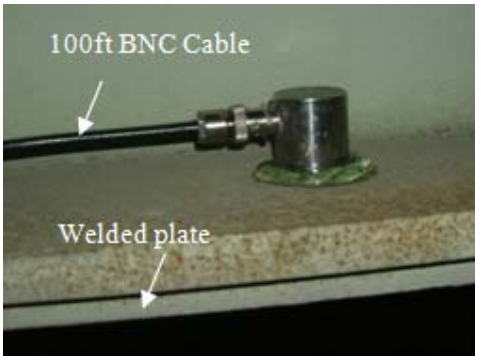

Figure 3: Transducer placement (Korcak et al. 2010 [2])

[5] Physical Acoustics Corporation

AE hits of zero duration or rise time were removed from the raw data as they were clearly noise. The data were then classified into three different mechanisms using a SOM, as shown in Figure 4 in an amplitude histogram. It should be noted that both the amplitude distributions for AE sources above the threshold amplitude resembled normal distributions. From Figure 4, Mechanism 1 had a wide range of amplitudes consistent with concrete cracking at the top of the I-beam; Mechanism 2 was thought to be rubbing of the welder reinforcing plate; and Mechanism 3 appeared to be rubbing from the side supports (Korcak et al. 2010 [2]). However, with these sources of AE data, no fatigue life prediction could be made.

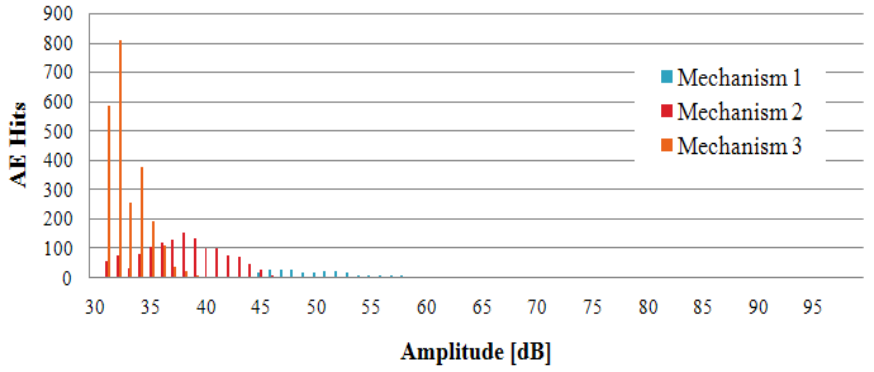

Figure 4. Source classification (Korcak et al. 2010 [2])

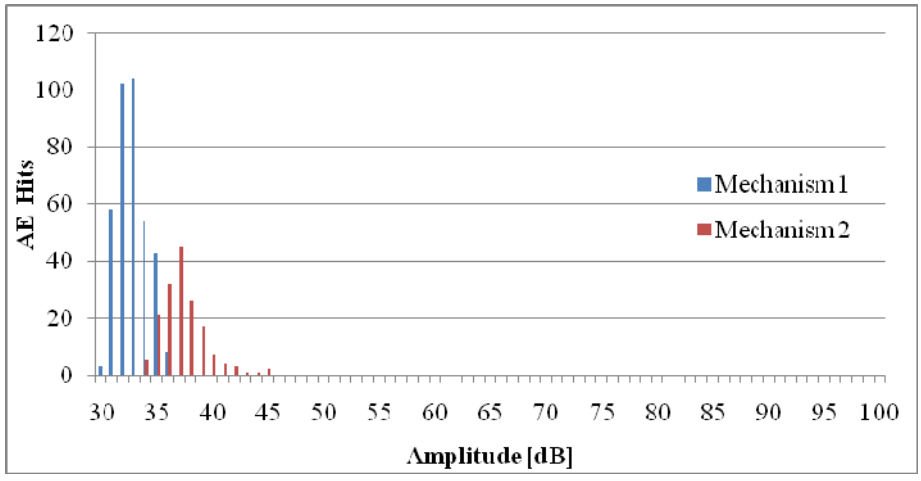
Florida Mast Arm Poles

Two Florida mast arms identified by FDoT to be highly susceptible to fatigue and large vibrations were tested to demonstrate the capability of real time monitoring for fatigue cracking as well as residual life prediction (Korcak et al. 2010 [3]). Monitoring was done on one pole without a known crack and another with a known crack. The PocketAE system was used in both tests. For the pole without a known crack, the two 150 kHz transducers were placed on opposite sides of the pole, close to the bottom where the maximum stress was expected, as shown in Figure 5 (a). Figure 5 (b) shows welds around the pole bottom. A defect in the weld can initiate a crack; moreover, the area of interest included bolt attachments which introduced rubbing noises.

(a) PocketAE and transducer placement (b) Welds

Figure 5. Two-channel PocketAE setup (Korcak et al. 2010 [3])

A preliminary classification of the AE data is shown in Figure 6. Two AE parameters (amplitude and average frequency) were fed into the SOM neural network which subsequently classified the AE data into two mechanisms.



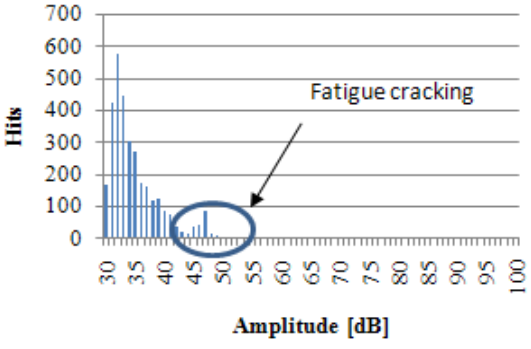


Figure 6: Source classification (Korcak et al. 2010 [3])

Two transducers were placed on either side of the crack on the second pole to verify the source in order to identify whether the emissions are coming from the crack or the rubbing of the bolt nearby. The test setup and AE data are shown in Figure 7. From Figure 7 (b), the separate high amplitude hump without overlap is most likely fatigue cracking. With the small data set for fatigue cracking no attempt was made here to predict fatigue life.

Procedure for Fatigue Monitoring

The actual field and experimental testing shown above are examples of steel structure fatigue monitoring, failure mechanism classification and fatigue life prediction. The general procedure for real time structural steel fatigue crack monitoring is summarized below.

1. Transducer placement
   a. Transducers are mounted on the surface of the steel structure using hot melt glue. The surface where the transducers are attached should be free of rust or dirt.
   b. If the fatigue crack location is known, two transducers can be placed on either side of the crack (Figure 7) to verify the location of the source (can be observed from the events vs. x-position plot from AEWin software). This should be used to ensure that the data utilized are from the known crack location.
   c. If the crack location is unknown, the transducers should be placed near the component that has the highest tensile stress.
   d. The nearby bolts or welded reinforcing plates can contribute rubbing noises which will also be recorded by the transducers. This requires special attention during post test analysis.
2. AEWin Software Setup

   AEWin software was utilized in this research when both the four-channel system and the two-channel PocketAE system were used. The amplitude threshold setup of 30 dB is recommended for isotropic materials. The maximum duration should be set high enough to allow all data of interest to be captured. The AE waveform parameters -- peak definition time (PDT), hit definition time (HDT), and hit lock-out time (HLT) -- as illustrated in Figure 8, are set to separate noise from fatigue cracking data. Typical values for PDT, HDT, and HLT for common materials are listed in Table 1.

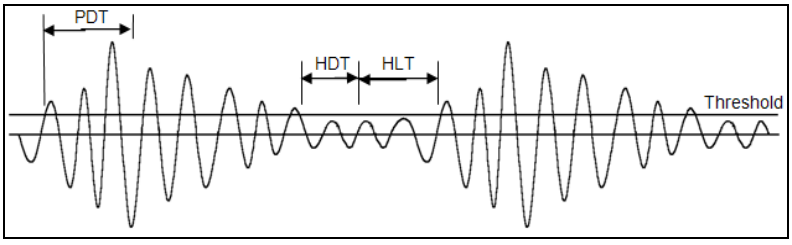

Figure 8: AEWin Waveform Parameters (Dorfman 2004)

Table 1. Waveform parameter values for common materials (Dorfman 2004)

Material PDT (µs) HDT (µs) HLT (µs)			
Composites, Non-Metals 20 - 50 100 - 200 300			
Small Metal Specimens 300 600 1000			
Metal Structures (High Damping) 300 600 1000			
Metal Structures (Low Damping) 1000 2000 20000			

3. Noise filtering
    a. In laboratory testing, noise can be monitored before the actual testing by simply turning on the testing machine with the specimen in the grips, but with the load set to zero. The AE data from the noise test can be plotted in three graphs: average frequency histogram (Figure 1), duration vs. counts (Figure 2), and an amplitude histogram. These graphs indicate the average frequency and count characteristics of the noise signal, which will be applied to the filters. However, AE hits with zero duration or rise time, or extra long duration are also noise and should be removed manually from the individual data files. Efforts should also be made to reduce any friction between the contacts (in steel-steel connection, noise emissions will be transferred), for example, a plastic block can be placed between the actuator and testing specimen.
    b. In field testing for infrastructure, it is preferable that the same noise monitoring procedure discussed above should be performed before the actual test whenever feasible. In addition, rubbing of surfaces in contact or bolt connections (Figure 3 and 5) will always contribute to noise that will be captured by the transducers, and will be later identified during source classification as displayed in Figure 4. As the AE data is acquired, AE hits of small counts and zero duration or rise time should be deleted manually in every data file.
    c. For prediction purposes, after the failure mechanisms are classified, the indicated noise data can be further removed to make better prediction training files.
4. AE Data Acquisition and Processing
    a. AE data acquired by the AEWin software are saved as an ASCII file for further processing. The data file should include time, channel, rise time, duration, amplitude, average frequency, etc. One can perform multiple tests and append all the data files into one file.
    b. Using a spread sheet such as Microsoft Excel, the data file is edited further to remove noise as explained above in step 3.
5. Source Classification using a SOM
    a. To prepare the input file, all AE hits of different parameters are compiled into an ASCII file without time information, labels and titles (only numbers).
    b. Open NeuralWorks Professional II/Plus software and choose **Self Organizing Map** in the **InstaNet** menu; the window display is as shown in Figure 9. The **Input** value should be the number of AE parameters provided in the input file. The product of **Rows** and **Columns** yields the

number of failure mechanisms. Note that a valid classified mechanism plot should resemble a normal distribution. In **I/O Files**, the **Learn** and **Recall** file should be the same input file. The rest of the setup follows the default values shown in Figure 9.

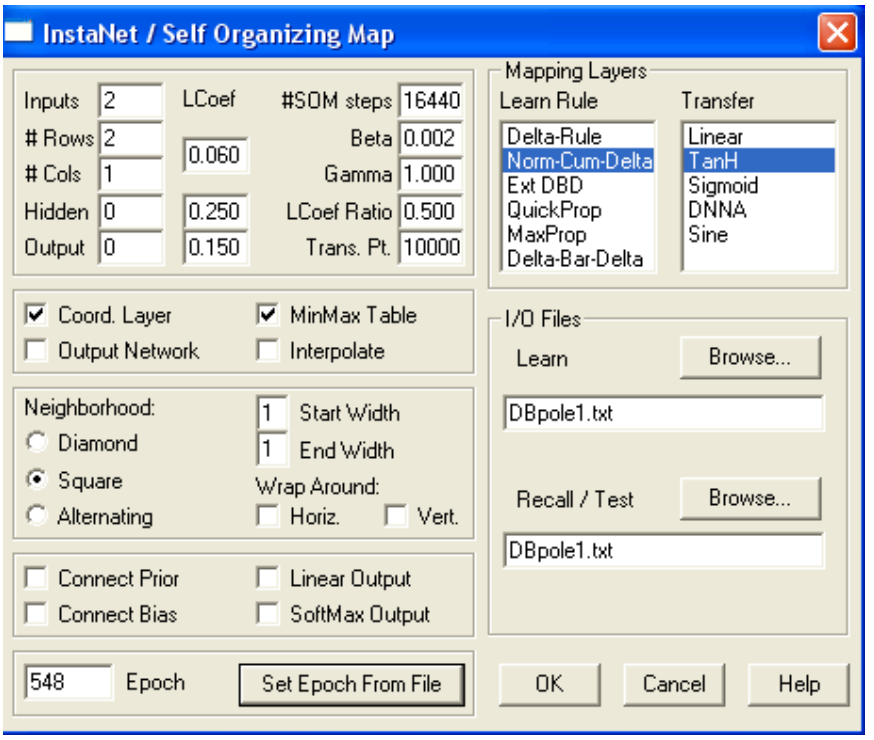

Figure 9. SOM setup window

c. The rest of the steps follow that of the SOM tutorial (Hearn et al. 2004). The output file includes two mechanisms (0 and 1), as the product of **Rows** and **Columns** in the above step is set to 2. Append the output file to the AE hits data, and sort one column of the mechanism from smallest to largest (zeros to ones) to get data sorted into two mechanisms. Graphs of interest such as amplitude histogram, average frequency versus amplitude and energy versus amplitude are then plotted.

6. Fatigue Life Prediction using a BPNN

a. To predict the fatigue life (or residual life) of the steel structure, for this research, the amplitude distributions were used as input data. Take the 1st quarter data (0-25% of fatigue life) of the steel bar testing as the training file input to the BPNN (Barsoum et al. 2009); the software is then trained on eight specimens, and predicts on the remaining three. The training and testing files are given in Tables 2 and 3, where the number in bold is the actual experimentally determined fatigue life which is used to train the

network. For small data sets, the training file should include a good sample of the data (low fatigue life, high fatigue life, and some in between), and a rule of thumb is that that 60% of the AE data should be used to generate the training file, and the remaining 40% for the testing file (Barsoum et al. 2009).

b. Open the NeuralWorks Professional II/Plus software and choose **Back Propagation** in the **InstaNet** menu; the window display is as shown in Figure 10. The **Input** indicates the number of the input values in the training file (not including the fatigue life), which in this case is the 71 amplitude frequencies of occurrence (30-100 dB), as shown in Table 2. The hidden layer 1 (**Hid 1**) value follows the 2n + 1 rule, where n is the number of failure mechanisms classified by SOM. The other training

parameters have to be determined through trial and error iterations to obtain the optimized setup, by comparing the output error after each parameter change in the initial settings.

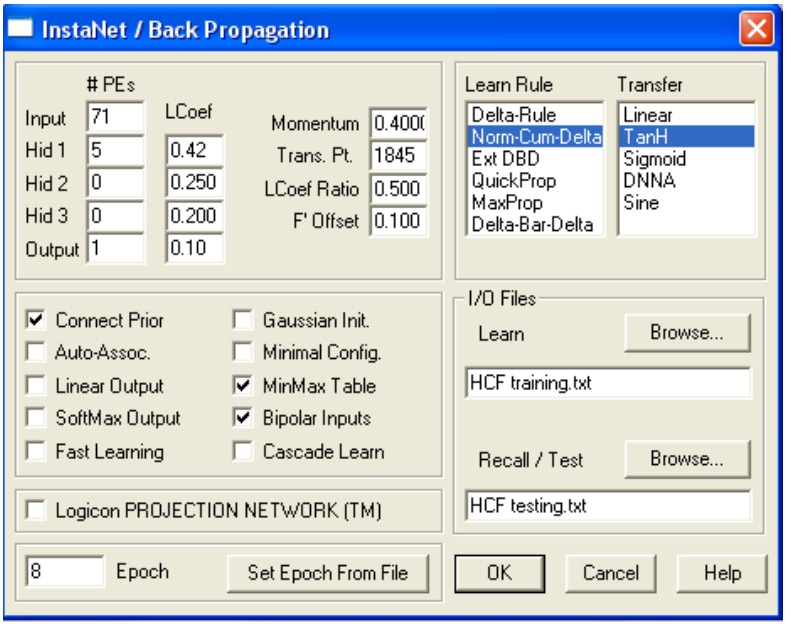

Figure 10. BPNN setup window

c. The rest of the steps follow that of the BPNN tutorial (Horvath et al. 2007). The **Convergence Criterion** should be adjusted to specify a stopping criterion based on the **RMS** error for the eight files in the training set.
d. The output file includes the predicted fatigue life, and the errors between the predicted value and actual value can be compared as shown in Table 4.

Table 4: 25% steel bar fatigue prediction results (Barsoum et al. 2009)

Conclusions

This paper provided a procedure for structural steel fatigue crack monitoring using the acoustic emission technique. This included failure mechanism classification using a self organizing map (SOM) neural network and fatigue life prediction using a back propagation neural network (BPNN). Methodologies for transducer

placement, noise filtering and neural network software setup were presented with details. The fatigue life prediction of steel specimen based on the AE data from the first 25% of experimental life (crack initiation data) herein yielded errors of less than ±20%; however, worst case errors in the ±5% range have been obtained from the third quarter (50-75% constant crack growth rate) AE fatigue data (Korcak 2010 [1]). From this it can be concluded that acoustic emission and neural networks are effective techniques for fatigue crack growth monitoring and predicting the fatigue and residual life of steel structures.

ABSTRACT

Two large-scale experiments are currently in progress in the structural laboratory at Hunan University, China to assess the progressive collapse behavior of reinforced concrete (RC) building systems: the first system comprises a flat-plate structure while the second is a beam-column moment frame. Results from the first test are reported in this paper while construction of the second system is in progress with collapse testing scheduled during the summer of 2011. The collapse experiment of the flat-plate structure consisted of a push-down test to simulate the loss of an interior column. The next proposed test will assess the system response of a half-scale three story RC frame building to sudden column removal. The tests will enable a clearer understanding of force redistribution, slab contribution and catenary effects during progressive structural collapse.

INTRODUCTION

A comprehensive computational and experimental investigation of the progressive collapse resistance of reinforced concrete (RC) structures is presently underway as part of a collaborative effort between the National Institute of Standards and Technology (NIST), the University of California, Davis and Hunan University, China. Full-scale component tests have been conducted by NIST, large-scale frame tests are ongoing at Hunan University and computational studies in support of these experiments are in progress at UC Davis.

This paper summarizes preliminary findings from the recently concluded collapse testing of a flat plate frame model. Also outlined is the proposed progressive collapse test on a half-scale 3-story moment frame building due to sudden column removal scenarios.

FLAT PLATE FRAME MODEL TEST

The flat plate frame structure was designed to resist a total dead load of 5.25 kN/m^2 and a live load of 5.0 kN/m^2 in accordance with the building code requirements in China. The 1:2.34 model frame constructed for progressive collapse testing was composed of a 2x2 bay single story structure as shown in Figure 1. The column height was 1.4m with cross-section dimensions of 216x216 mm and the thickness of the flat plate was 90 mm. Reinforcement in the middle strip comprised 6.5mm bars at 150 mm in 2 layers at the top and bottom whereas the column strip was composed of 2 layers of 6.5mm bars spaced at 90mm at the top and 150 mm at the bottom. The concrete used in the construction had a cube (150mm) strength of 39.5 MPa and the yield strength of the reinforcement was 425 MPa.

Figure 1. Model structure (left) and imposed distributed load on slab (right).

Collapse Loading. The model frame was fixed on the strong floor of the lab with the help of a foundation beam. In order to approximately simulate the impact effect of the original loads on the flat plate due to sudden column loss, the total applied uniform load was 2 times the design load. The load was applied in 9 stages: sand bags were used in the first six stages and steel blocks were used in the final three stages of loading. The model structure with all of the imposed loading is shown in Figure 1.

The removed column was replaced by a hydraulic jack attached to a load cell as shown in Figure 2. After the 4th stage of loading the imposed load was 10.25 kN/m^2 (corresponding to the design dead and live load), and the force in the jack was released to attain a zero force state. Loading of the cantilever portion of the floor was ceased at this stage. The next 3 loading phases consisted of applied uniform loads of 2.4 kN/m^2 each and the hydraulic jack was released at the end of each stage to measure the corresponding slab deformations and bar strains. The final 2 stages composed of applied uniform loads of 1.98 kN/m^2 and 1.15 kN/m^2, respectively. Test measurements include: the horizontal and vertical displacement of the flat plate, the inclination of the plate surface, the concrete strain at the top and bottom surface of the plate, the strains in the longitudinal reinforcement at the top and bottom, and the vertical displacement and residual axial force in the interior “removed” column.

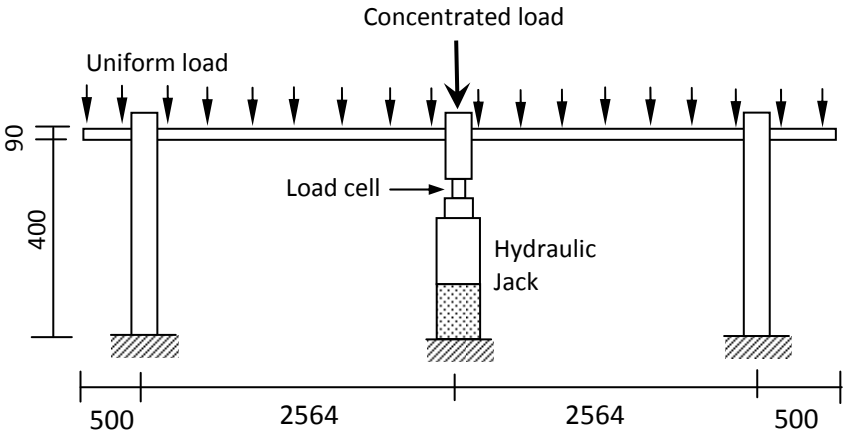

Figure 2. Schematic view of imposed slab loading

Preliminary Results. Following the applied load of 10.25 kN/m^2, the measured vertical displacement beneath the removed column was 90 mm. At this stage, a concentrated push-down load was applied through an actuator attached to the top of the interior column (see loading frame above the floor in Figure 1 and also the schematic view of the applied loads in Figure 2). Push-down vertical loading continued till the displacement reached approximately 285 mm at which stage a punching shear failure of the slab occurred. The final damaged state of a typical exterior column is shown in Figure 3. Also shown is the complete overview of the cracking pattern in the top surface of the slab where the yield lines are clearly visible. It is of importance to note that the longitudinal reinforcement in the slab was continuous through the column section.

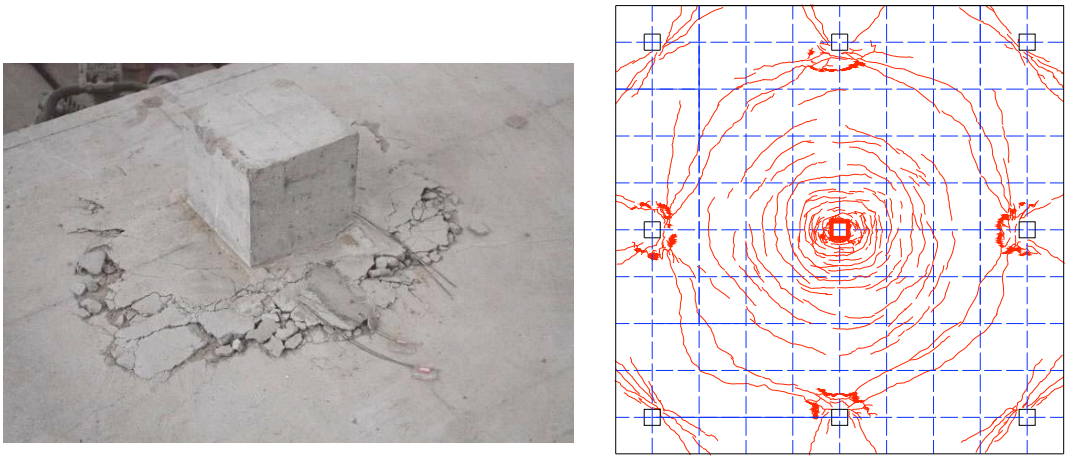

Figure 3. Punching shear failure of exterior slab-column section (left) and overview of observed cracking and yield lines on slab at failure (right).

PROPOSED HALF-SCALE MOMENT FRAME TEST

The second phase of the large-scale experimental collapse test will feature a half-scale model of a moment frame building. The three-story model represents the lower floors of a ten-story moment frame structure designed to meet the requirements of Seismic Design Category "C" as per ASCE 7-2005 and detailed to ACI 318-08 specifications. The imposed gravity loads include 30 psf superimposed dead load (SDL) and 100 psf live load (LL). The half-scale test structure was designed for 200 psf (1.2SDL + 1.6LL) of uniformly distributed superimposed load. The plan and elevation of the model building are displayed in Figure 4.

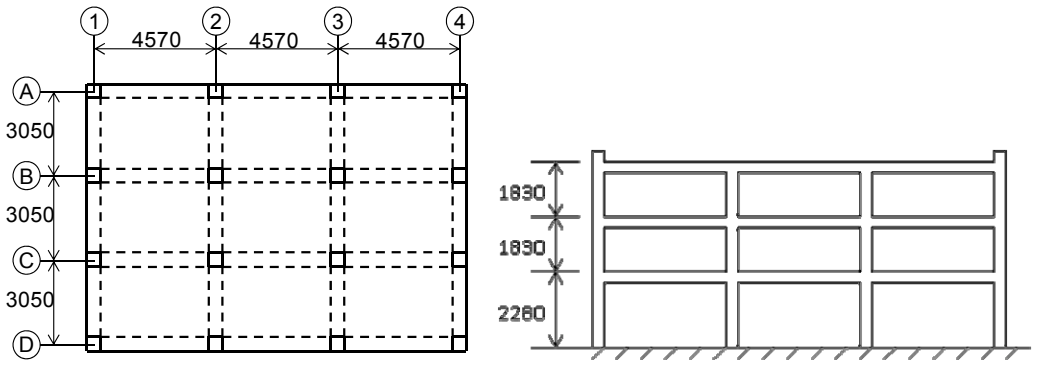

Figure 4. Model frame configuration

The proposed test plan includes sudden column removal by controlled explosion or other means followed by push-down loading of the removed column. The initial sequence of column removals was as follows: Removal of corner column D1 followed by removal of columns C4 and B2. To gain an understanding of the system response to these loading scenarios, numerical simulations were carried out using a macromodeling approach (Bao et al., 2008). The macromodeling simulations were also complemented by more refined analyses using LS-DYNA (Hallquist 2005) to incorporate slab effects. Results of the simulation are presented in Figure 5.

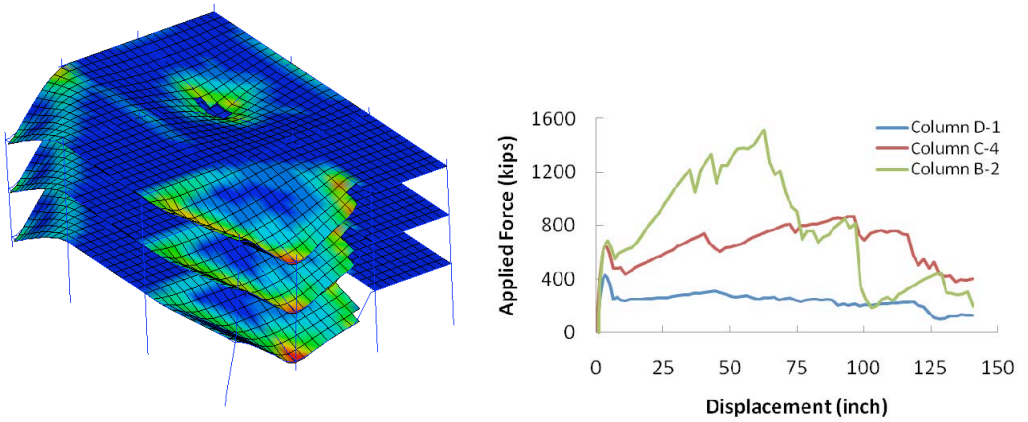

Figure 5. Numerically simulated push-down simulations for different column removal scenarios

Additional studies are underway to consider alternative column removal scenarios including the removal of multiple columns. Final testing details will be established following a comprehensive computational study which is expected to conclude by the end of January 2011.

CONCLUDING REMARKS

The proposed tests will enable a clearer understanding of force redistribution, slab contribution and catenary effects during progressive structural collapse. As indicated earlier, the test program is part of a larger effort to develop modeling guidelines for progressive collapse analysis of RC structures as well as establish measures of structural robustness to progressive collapse following the loss of one or more primary load-carrying elements in a building.

ABSTRACT

A number of analytic tools have been applied to or developed for progressive collapse modeling. However, the lack of relevant experimental test data makes it difficult to validate these tools or identify which aspects of the modeling approaches or software formulations may need additional refinement. The cost of full scale testing to validate these analytical tools is extraordinarily expensive due to the physical size of the structures that need to be tested and the range of phenomenology that needs to be investigated. This paper investigates the use of small scale building models, which can be tested in a centrifuge to provide properly scaled gravitational loads, for studying progressive collapse of damaged buildings. For this effort, a reinforced concrete building (3-bay x 4-bay, 4-story) was designed, constructed at 1/18th scale and tested in a centrifuge while several ground floor support columns were dynamically removed. The test data, including overall collapse response, were compared with the results of pretest analyses performed using a high fidelity, explicit finite element code. This testing effort was designed to contribute to improved validation of simulation tools for progressive collapse modeling.

INTRODUCTION

'Progressive' collapse of a building damaged by an explosion means that damage to the structure is not limited to the area directly affected by the weapon(s) blast loading, i.e. the region of collapse may continue to expand beyond the region of direct blast damage. Potentially, this progressive failure of the building can result in the complete collapse of the entire structure. A well known example of partial progressive collapse occurred in the Oklahoma City bombing which occurred in 1995. An explosion destroyed several support columns on one side of the building but the damage zone progressed to include approximately ½ of the structure before finally being arrested by the stability of the remaining structure. The threat of terrorist attacks against civil structures has increased the need to design buildings resistant to progressive collapse. This requires improved simulation tools for assessing the likelihood of progressive failure for a structure should the load carrying capacity of one or more structural members be seriously compromised.

Although various analytic tools for progressive collapse assessment have been developed to date, the lack of experimental test data makes it difficult to validate them or identify which aspects of these tools may need additional refinement.

This paper considers 'small scale' testing technology that is applicable to testing progressive collapse of structures in the laboratory. The successful use of small scale testing in combination with good correspondence between test response and high fidelity modeling of collapse response provides a clear demonstration of how this testing approach can be applied to advance the state-of-the-art in understanding progressive collapse behavior of buildings. The results of this work contribute to validating models for progressive collapse simulations. Increased accuracy of and confidence in progressive collapse assessment tools will result in advances in effective progressive collapse resistant design methods and criteria.

PROGRESSIVE COLLAPSE TESTING

In order to assess the validity of progressive collapse simulation methods, applicable and accurate testing methods and procedures are needed. For any testing procedure to produce accurate and reliable results, it must reproduce basic features of progressive collapse events. Weidlinger (2003) and Ettouney (2006) have shown that progressive collapse is both a local and global event. The collapse will progress from one structural component to the next: which will require accurate modeling of those components (columns, beams, joints, etc.). In addition, it was shown that the process of complete structural collapse can be considered as a global loss of structural stability: which requires accurate modeling of the global structure. This local/global behavior is a major challenge for developing valid full scale tests for progressive collapse. As a result, very little test data is available to validate either simplified or complex three dimensional models used for blast initiated progressive collapse predictions.

The cost of full scale testing for a sufficiently complex structure can be extraordinarily expensive due to the physical size of the structures required to be tested and the range of phenomenology that needs to be investigated. Real world events that have resulted in progressive collapse of full scale structures are generally not instrumented. To date, laboratory or field testing of full scale test articles generally involve small assemblies of structural components. These tests are useful and produce data that aid in validating some aspects of progressive collapse behavior. However, they do not provide a rich enough testing set to fully assess analytic models that might be applied to collapse simulations.

Performing progressive collapse tests on sub scale structures, such as 1/2 or 1/3 scale, are less expensive than full scale tests due to the reduced cost of construction but face the fundamental challenge that the gravitational loads that drive progressive collapse are not properly scaled. That is, full scale gravitational loads are applied to sub scale test articles. To achieve a 'properly scaled' test for a sub scale structural model, the gravitational loads must be increased. For example, consistent gravitational loads for

a 1/2 scale structure would be 2 Gs, for a 1/3 scale structure, 3 Gs, etc. Clearly, it is impractical to properly scale gravity for structural test articles of substantial size.

Small scale testing is another approach that can be considered for progressive collapse investigations. Using 'replica scaling', the small-scale model is built by reducing all the lengths in the full-scale design by the scale factor. For example, a 1/18-scale reinforced concrete beam is 1/18 the length, width, and height of the full-scale beam. The experimental effort described herein applies replica scaling methods to the problem of progressive collapse testing of a reinforced concrete moment frame building. The use of replica scaling at small-scale to solve reinforced concrete design problems is well established with many universities and laboratories around the world having contributed to the development of fabrication techniques, see (Harris 1966, White 1970, Carpenter 1972, Mirza 1972, Harris 1980, Gran 1982 and Harris 1999).

As mentioned above, Earth gravity does not 'scale' appropriately when using replica scaling. For example, gravity in a 1/18-scale experiment should be increased to 18 g. This is of particular interest for progressive collapse testing because all of the loads in the problem are gravitationally induced loads. Small scale models that can physically be placed in a centrifuge can benefit from having properly scaled gravitational forces. This is the basic idea behind performing small-scale progressive collapse experiments in the centrifuge.

There are other parameters that do not scale naturally to the required value when using replica scaling. Specifically, viscosity and fracture toughness, both of which are material properties. In some cases, the small scale material can be adjusted to match the required properties. For example, in the case of steel, a different alloy or heat treatment can be selected to attain the desired properties. With concrete, it is not practical to independently control the strain-rate dependence and fracture toughness while maintaining a match to the compressive strength. For progressive collapse problems, the effects of strain rate are expected to be minor, even for small-scale models. The fracture toughness of the model concrete, which mostly affects cracking but not ultimate failure, is generally secondary to compressive strength.

DESIGN OF TEST STRUCTURE

This testing effort involved designing a code compliant full scale structure, then fabricating it at $1/18^{th}$ scale and finally testing it in the centrifuge under 18 g gravity. The structural configuration was chosen to be 4 bays x 3 bays x 4 stories tall as shown in Figure 1. The full scale bay size was chosen to be 20 feet in both directions. Each story height was 12 ft. The overall size of the structure was chosen so that a $1/18^{th}$ scale test article would fit within the size constraints of the centrifuge test platform.

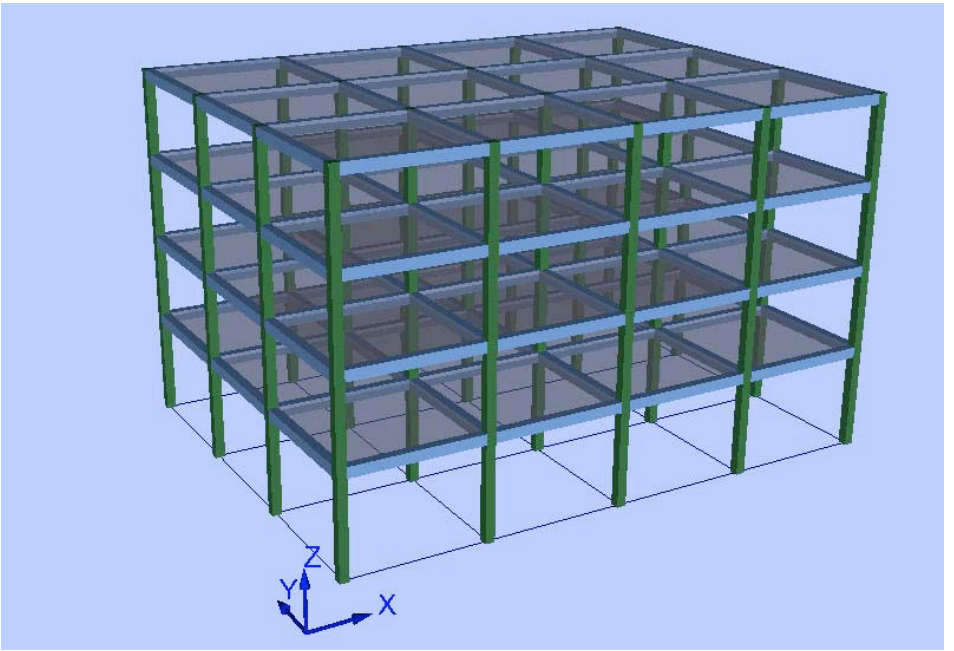

Figure 1 Multi-Story Test Structure

The building was designed according to the 2003 IBC design code for low seismic regions and typical wind conditions of 90 MPH. The availability of 1/18th scale equivalents for #9 and #11 reinforcing bars guided the designer to utilize these size bars as the primary reinforcing in the design. All full scale dimensions were scaled down by 1/18th to define the appropriate dimensions for the small scale test article.

FABRICATION OF TEST STRUCTURE

Maintaining reasonable consistency between small scale and full scale material behavior is one of the primary challenges of performing small scale testing. In this effort, a 1/18 scale reinforced concrete structure was constructed. To represent the concrete material, a close approximation to the Fine Aggregate Cementitious Material (FACM) developed by the U. S. Army Corps of Engineers ERDC (Gran 1996) was used. This material was selected because it has an aggregate size distribution appropriate for the 1/18-scale structure and it has mechanical properties that are a good match to full-scale concrete.

To represent 1/18 scale steel reinforcing, all physical dimensions of the reinforcing needed to be scaled accordingly. The main steel reinforcing bars in the beams and columns of the test structure were modeled with steel threaded rods. Previous investigations have shown that the threads provide a reasonably good match to the bond between full-scale rebar and concrete. The nearest matches of standard thread sizes to the desired rod diameters are 1-64 threads for 1/18-scale #9 bars and 2-56 threads for 1/18-scale #11 bars. The pitch diameter of the 1-64 thread is about 0.058 in. and the pitch diameter of the 2-56 thread is about 0.067 in. For comparison, 1/18-scaled diameters of #9 and #11 bars are 0.062 in. and 0.076 in., respectively.

Because the threading process induces strain hardening in the steel, the annealing schedule during the cold-drawing of the bare wire was adjusted in order to approximately match the desired strength of the finished threaded rods. No heat-treatment of the rods was done after threading.

Testing was performed to characterize the small scale concrete and steel material behavior. This allowed appropriate constitutive model fits that account for differences between full scale and small scale materials to be developed and used in a high-fidelity computational model of the small scale structure's response.

The 1/18th scale test article was fabricated by SRI International (Gran 2010) using precision construction procedures. Metal forms were created to facilitate placement of the small scale reinforcing steel and pouring the fine aggregate concrete. All longitudinal and stirrup reinforcing steel in columns, beams and slabs was fabricated with fine tolerance and placed for one complete floor level of the structure at a time as shown in Figure 2. Then the concrete was prepared and poured for that floor level. Model concrete was mixed and placed in three batches for each story, one for the columns, one for the beams, and one for the floor slabs. By far, the most difficult placement was in the columns because of the need to push the concrete through the closely spaced beam reinforcing steel. To assist with placement, electric engraving pencils were fitted with extended probes to use as internal vibrators to remove air voids in the columns. The concrete was left to harden for about a week before the forms were removed, cleaned, and reassembled for the next story, Figure 3. Two vertical laser beams mounted above the assembly area were used to accurately locate each floor in the horizontal plane. By aligning each story with the lasers, leaning and twist of the structure was prohibited. The completed test article is shown in Figure 4.

HIGH FIDELITY SIMULATION MODEL

The NLFlex finite element code, (Vaughan 1983), was used to perform high fidelity simulations of the 1/18th scale structure to plan the specific details of the centrifuge testing series. NLFlex has been extensively validated for blast effects modeling of reinforced concrete and steel structures under a wide range of Department of Defense field test programs. It uses advanced constitutive models (Mould 1993, Mould 1994) for representing the full range of nonlinear material behavior that occurs for steel and concrete materials during a collapse event. The NLFlex constitutive models for steel and concrete were fit to available lab data for the small scale steel reinforcing and small scale concrete actually used to construct the test article.

Pretest simulations were performed to investigate the response of the small test article under various floor load levels and a variety of potential damage states. Structural damage scenarios considered involved the dynamic removal of one or more ground floor support columns.

The high fidelity models of the test structure used continuum elements to represent the concrete material in the building and beam and bar structural elements to explicitly represent all of the reinforcing steel in the structure. Figure 5 presents a close up view of the model illustrating the refined finite element discretization used in the model. Note that the display tones were chosen to aid visual identification of the individual structural components associated with different floor levels in the building.

CENTRIFUGE TESTS

The testing approach used for this investigation was to subject the 1/18th scale test structure to the properly scaled gravitational loading (i.e. 18 g) and then dynamically remove one or more ground level support columns. The gravitational loading on the structure would either be successfully redistributed to neighboring components or the structure would experience either a local or more global collapse.

A key factor contributing to the collapse of structures is the amount of mass loading the structure is supporting at the time one or more of its support columns are damaged. In addition to the 'self weight' of the reinforced concrete structural members (i.e. columns, beams and slabs), an actual building will also contain a large amount of non structural 'dead load' such as electrical and air conditioning systems, plumbing, non structural building façade, etc. Also, there is a significant amount of non structural 'live load' including office furniture, interior movable partitions, etc.

The self weight of the multi-story test article is fairly minimal and distributed mass loading representing additional dead and live load contributions were added to the structure for the tests. Bags of steel shot were adhered to each concrete slab in the test article to provide additional dead and live loading of approximately 250 lb/ft^2.

The 1/18th scale test article was installed in the centrifuge at the U.S Army Corp of Engineers centrifuge located at Vicksburg, MS, see Figure 6. It was subjected to two different tests in which ground floor column supports were dynamically removed while the structure was subjected to 18 g gravity. The first test removed one column adjacent to the corner column of the building. Pretest simulations had predicted no collapse for this damage scenario and the test results corresponded to the simulation results. The second test, performed at a later date, removed two additional columns (see Figure 7).

Figure 6 Multi-story Building Test Article Installed on Centrifuge Platform

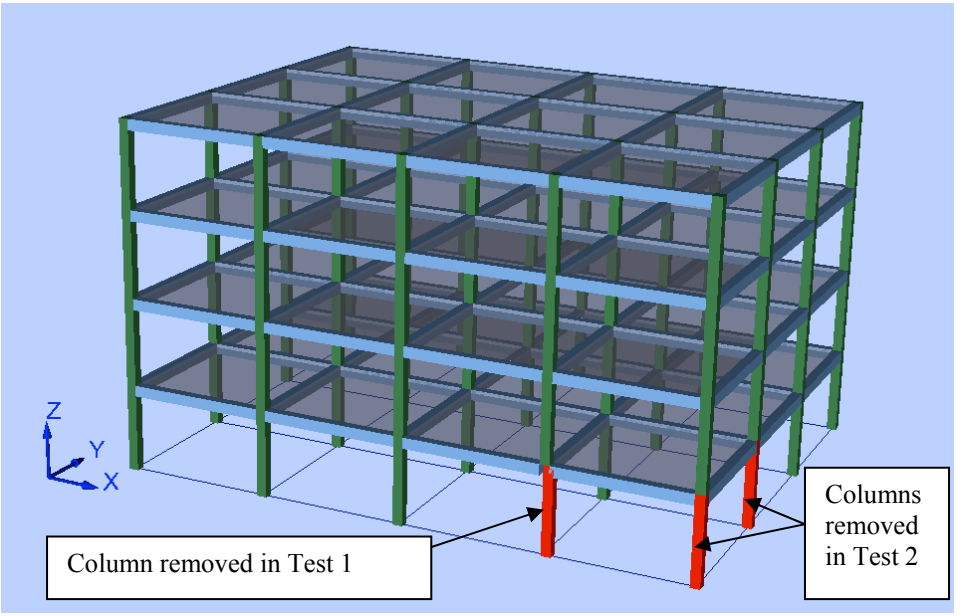

Figure 7 Multi-story Building Showing Columns Removed During Centrifuge Tests

Pretest simulations had predicted a partial collapse of the structure. The predicted collapse zone was consistent with the results of the actual test as shown in Figure 8. Figure 9 presents snapshots from the NLFlex pretest simulation using a roughly similar view position as was used for the high speed camera recording the building's response during the test. The images show the complex deformations and interactions that are occurring in both the test and the simulation. It's interesting to note the overall level of qualitative agreement between the simulation and the test article's response although specific details vary.

Direct comparison of laser displacement gage measurements and pretest simulation results are presented in Figure 10. These records represent the displacements for vertical measurements made on the collapsing portion of the structure. Note that several of the collapsing gauges quit providing data once deflections reached the point that the laser gauge was compromised. It is clear that the first order response characteristics are well represented between the pretest simulation and measurement.

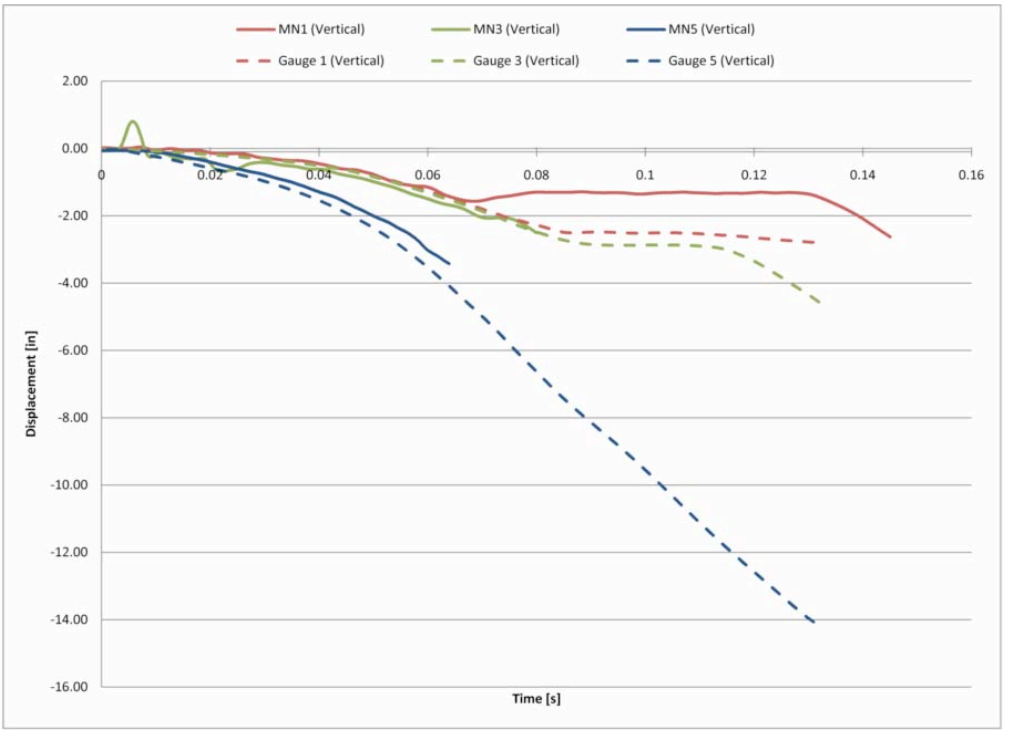

Figure 10 Test 3 Comparison of Pretest Calculated and Measured Vertical Displacements for Collapsing Section of Structure

Conclusions

A full scale multi-story building structure was designed according to standard building codes and fabricated with high precision at 1/18th scale using replica scaling. Pretest planning simulations using the NLFlex finite element software were used to map out a sequence of tests which provided a representative range of structural response to several different levels of damage. Pretest predictions were in good agreement with all major aspects of collapse behavior for the structure. The test results provided a significant validation demonstration of the NLFlex software for progressive collapse applications.

This effort pioneered the use of small scale testing under properly scaled gravity loads for progressive collapse applications. Small scale testing was found to be practical and useful for studying progressive collapse phenomena.

Although there are differences between full scale and small scale structures due to scale effects and the practical challenges of manufacturing a small scale structure, simulation tools can effectively account for these scaling effects within the computational model.

ABSTRACT

Due to highly fragmented nature of the of Architecture Engineering Construction (AEC) industry and time constraints, little attention has been devoted to the conceptual design process. Multidisciplinary teams start with a limited set of requirements, mostly imposed by the Architect, to work on only a restricted number of design alternatives. Therefore, final designs often lack satisfactory performance throughout its life. This paper uses a decision support tool, the IVCG, which combines the searching power of evolutionary computation with the exploration power of an interactive visualisation tools to assist designers at the conceptual design stage. This approach facilitates members of the different disciplines involved to interact with the system independently to identify those regions of the search space which best satisfy the requirements of their individual disciplines. It then allows them to agree on a 'mutually inclusive' region that partially satisfies the needs of all parties involved in the design. The system also uses the Pareto optimisation algorithm to focus on a limited number of solutions, inside the Pareto front, for the multi-disciplinary team to interactively explore solutions within this region. This enables selection of a workable number of 'compromised solutions' that are acceptable to all parties involved.

Keywords: Evolutionary computation, Visualisation, Exploration, Conceptual design, Decision support, Compromised solution.

INTRODUCTION

The impacts of global warming have significantly alarmed nations towards acting more responsibly. Additionally, there is an increasing awareness about the negative impact of buildings on the environment. According to USGBC 2007, in the U.S. over 70% of electricity, 40% of raw materials and 12% of water consumption is attributed to buildings alone. This is an alarming situation. Furthermore, Turner and Frankel (2008) argue that the lifecycle performance of many new buildings is below that of older buildings and often below code requirements. According to Miller (1993), the overall design cost is less that 10% of the building cost while the construction costs are around 80%. Research has shown that decisions made that the conceptual stage are responsible for committing about 70 to 80% of the building costs. In current conditions, time is a major limiting factor in the conceptual stage of the design. Therefore, decisions made at this stage are usually rushed, mostly fragmented and are predominantly based on heuristics and from the experiences of previous projects. Fig. 1 shows the impact of decision-making and the cost of redesign at various stages of the design.

From Fig. 1 it is clear that decisions made at the conceptual stages of the design process have much greater impact on the final design; and the cost of redesign at this stage

is negligible when compared with other design stages. These issues necessitate an urgent need for closer collaboration at the conceptual stage of the design.

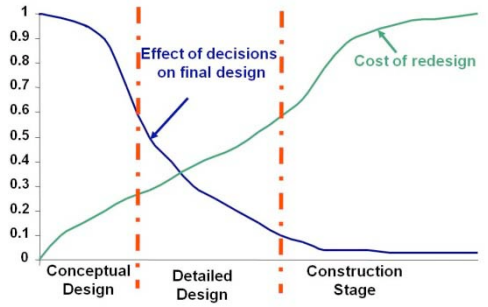

Fig. 1: Effects of decision making and the cost of redesign at different stages

Successful application of evolutionary computation (EC), particularly genetic algorithms (GAs), to solve multi-dimensional problems has shown to be promising. Applications of EC in building design goes back to the early 1990s: Grierson & Pack (1993) addressed topological and geometrical optimisation problems. Rajan (1995) also conducted a similar investigation using trusses instead of frames. Parmee and Bullock (1993) described how the GA has been successfully applied to the design of a hydropower scheme.

From 1997 to the present day, there has been a noticeable growth in interest in the application of GAs specifically to conceptual building design. One reason for this is that building design problems are highly multi-dimensional, multi-criteria and multi disciplinary problems with lots of inherently conflicting criteria. Grierson and his co-researchers in Waterloo (Grierson and Khajehpour, 1999; Grierson and Park, 1997), Rafiq et al. in Plymouth (Mathews et al., 1996; Rafiq et al., 2003) and Miles et al. in Cardiff (Miles et al., 1995; Miles et al., 2001; Sisk et al., 2003) are perhaps among the first researchers who have made particularly significant contributions to this area.

Recently, there has been recognition of the value of human-computer interaction at various stages of the design process. As the main focus of this paper is on the conceptual design process, only relevant literature in this area will be reviewed.

A comprehensive review by Takagi (2001) lists a number of approaches towards application of interactive evolutionary computation. One of the first preliminary design systems devised by Pham & Yang (1993), allowed the GA to produce configurations for the user to view and evaluate in order to formulate decisions about further redesigns. Jo (1998) discovered that adding human interaction to his evolutionary design system meant domain knowledge could be incorporated online and solutions could be independently visualized in a space layout problem which allowed the user to modify individual elements of the design. User interaction has also been further considered in a multi-objective environment: Fonesca and Fleming (1993) proposed a decision-maker (DM) that controls which objectives have more importance within a non-dominated set of solutions. Horn (1997) points out that there are three different approaches to decision making in multi-criteria problems: make a multi-criteria decision before search, make a decision after search or integrate the search and decision making. The latter approach would appear to be the most powerful, incorporating iterative search and decision making.

Mathews & Rafiq (2000 & 2003) developed a Conceptual Building Design (CBD) system using the Structured GA. This system used the objective oriented functionalities of visual C++ that allows the user to manipulate the system more interactively. A powerful

GUI was used which included a number of interactive dialogue boxes for effective user interaction. To enable better interaction at run time, the design hierarchy was made available to the designer. A tree control provides basic functionality for manipulating the nodes (different frame systems) and branches (different design options) within a hierarchy. Using this facility allows the designer to include or exclude particular design options from the GA search at the runtime. The system also enables the designer to trace the design evolution process throughout a whole run of a GA operation. This was an important facility which added transparency to the otherwise 'black box' GA operation.

Grierson and Khajehpour (2002) used Pareto optimisation techniques for the multi-criteria conceptual design with the use of colour-filtered graphics. In this investigation, a large set of Pareto non-dominated solutions were captured. Subsequently, they used colour filtering of the Pareto-optimal design set and created a large body of informative graphics that identify trade-off relationships between competing objective criteria, as well as design subsets having particular designer-specified attributes. This research demonstrated that effective use of visualisation tools enables discovery of interrelationships between design parameters.

Research in Plymouth Engineering Design Centre by Parmee and Bonham (1998) resulted in development of an Interactive Evolutionary Design System (IEDS) based on a system of iterative redefinition of variables and objective space by a designer. These ideas evolved from many years of research in using evolutionary computing to aid engineering design, starting from general ideas to locate and analyse robust regions of the search space. Development of cluster-oriented genetic algorithms (COGAs) allowed inclusion of user preferences between objectives. COGA extracts regions of good solutions from a GA run by selective filtering of high performance solutions through the search process.

INTERACTIVE VISUALISATION CLUSTRING GENETIC ALGORITHM

The Interactive Visualisation and Clustering Genetic Algorithm System (IVCGA) developed by Packham et al. (Packham 2003, Packhan & Denham 2003) was designed to focus on user interaction from the outset. This work is centred on a user interface that allows exploration of specific regions of the solution space by 'zooming in' to interactively selected regions, in order to evaluate the merit of solutions within these regions against the project requirements. It allows the designer to increase the number of solutions inside or outside these regions by creating new design alternatives using further GA runs.

The IVCGA was designed to offer the following features:

- The fast generation of diverse data by running a simple GA for a low number of generations whilst maintaining the diversity of solutions generated.
- An easy to use interface that allows direct manipulation of both the data and views. Various high dimensional visualization techniques are added that enhances human-led exploration of the solution spaces.
- An automatic clustering procedure is incorporated into the system which identifies clusters of design solutions relevant to the problem in hand. Colour is used to highlight important clusters (better design alternatives), enhancing perceptual understanding of the data.
- Extensive interaction is supported thus enabling further data generation with the GA, both inside or outside regions identified by the user.

- Permits investigation of inter-relationships between design parameters and objectives.

METHOD

Building design is a multi-disciplinary activity, involving a number of individuals from a variety of disciplines, each with a differing emphasis on the design requirements. Thus, the objective of this study is to illustrate how the IVCGA can face the challenges of multi-disciplinary design and how it is efficiently used in a multi-disciplinary design environment. This research has been conducted in close collaboration with an Architect, a Structural Engineer and a Building physicist. Differential requirements of each can be summarised as follows:

- The Architect: Space; functionality; appearance; user comfort.
- The Structural Engineer: Building stability; structural performance; strength; safety.
- The Building Physicist: Mechanical; electrical; heating cooling and ventilation systems (HVAC) and user comfort.

Some details of how the IVCGA deals with the above issues are discussed below.

Architectural requirements

A major architectural objective is to have column free spaces to maximise the utility of the building in terms of its flexibility and future use.

From literature and discussions with the architect, it was discovered that architects plan building footprints based on specific architectural grids, which are functionality dependent. The following architectural grids are commonly used by the architects: 1.0m, 1.2m, 1.5m & 1.8m. The following structural grid (bay sizes) combinations can be generated from these architectural grid sizes:

4m, 4.5m, 4.8m, 5m, 5.4m, 6m, 7m, 7.2m, 7.5m, 8m, 8.4m, 9m. These grid dimensions were used to determine the size of the building footprint.

Types of cladding, window types and window sizes determine external building appearance. Some of these aspects also overlap with the structural engineers and building physicist requirements.

For the case study presented in this paper, 4 cladding types and 4 window types are used and window ratios are varied from 25% to 100% of the bay area.

Structural Engineering requirements:

A pivotal requirement of the structural engineer is the use of optimum structural element sizes that are capable of carrying loads safely to the ground. Generally, an optimum bay size reduces the load carried by each element and hence the overall cost of the building. In this study, bay sizes have been considered to be an important structural requirement and structural steel was used as the main construction material. Column, beam and floor types were based on the UK Steel Construction Institute standard member sizes and types.

In order to minimise the calculation time, prior to the optimisation process a comprehensive parametric study was conducted and look up tables were created to enable the optimisation program to select optimum member types and sizes for each bay size. The size of the bays used are those as shown in the ‘Architectural requirements’ section. The number of storeys used in this was from 1 to 8, with inclusion of 7 different floor systems.

Building Physicist requirements:

Calculation of a building energy usage is a complex issue, which is outside the scope of this paper. However for optimisation purposes, it is necessary to include building energy usage to enable a long term cost comparison for different design concepts even if it is a relative cost of energy consumption.

Most building physicists use complex simulation programs and Energy Plus programs (http://apps1.eere.energy.gov/buildings/energyplus/) to assess building energy consumption and thermal comfort for buildings. Using these tools may be feasible for a single building, while optimisation algorithms deal with a population of designs that consist of thousands of alternatives. For this reason, in this study 'LT Method 2.0' of Baker and Steemers (1994), is used for rapid calculation of energy consumption. Of course, at the later design stages, when a few selected design alternatives are singled out by the design team, more complex simulation tools would be feasible to use for more reliable calculation of energy consumption and thermal comfort.

For the purpose of this study, 'LT Method 2.0' divides the building into active and passive regions. Active regions are those parts of the building that are not lit, heated or ventilated naturally. A 6m perimeter zone (along the outer perimeter of the building, adjacent to windows) is restricted for the passive zones; any area outside this zone is an active zone which requires mechanical lighting, heating and ventilation.

For this study the climate data for 12 months of the year for Cambridge, UK has been used. South facing buildings with large window ratios and a maximum building width of around 12m would be the optimum design solution for energy consumption.

THE PROPOSED APPROACH

Conceptual building design is a highly multi-dimensional and multi-disciplinary process. This paper introduces a novel method of resolving these multi-disciplinary issues. To tackle this problem, at first, each member of the design team interacts with the IVCGA independently to address their discipline specific needs. In this case, a multi-objective problem is simplified into three separate, single objective problems for which the main (dominant) objective is determined by each discipline running the IVCGA. During this independent interaction with the IVCGA, the system also computes values of the objectives related to the other two disciplines. This alerts the members of the individual disciplines about the consequences of choices made by one discipline on the other two members and on the overall design. Hence, the following stages are considered:

1. **Search and optimisation stage**: in this stage the solution space is widely searched to discover a population of optimum solutions that satisfy the requirements of a given discipline. Each member of the design team defines their own objectives. Some details of objectives related to each member of the team will be discussed later. The dominant objective of the search process is that determined by the discipline running the IVCGA. This objective is interactively selected using drop down menus provided by the system. It is worthwhile noting that unlike other previous optimisation processors that were trying to find a single solution "the so-called global optimum solution", the IVCGA searches the design space to locate a set of feasible solutions that best fit the problem requirements. In this optimisation process no constraints, except the upper and lower bounds of the design independent variables, are imposed. Other constraints are defined interactively by the user at run time. At the end of this stage the IVCGA identifies clusters of feasible solutions based on the single dominant

objective. Different colours are used to present clusters of solutions having similar characteristics.

2. **The exploration stage:** at this stage, members of the design team independently interact with the IVCGA to explore the suitability of the solutions generated during the search stage. They explore regions by highlighting part of the solution, using the cursor to draw boxes around regions of interest. Using their domain expertise they explore the suitability of each region and finally select a region which the domain expert thinks is a best fit for the purposes of their discipline requirements.

To simplify the output, only the building footprint is presented as the graphic outcome of the design, with a brief description of the major design components.

Once individual members of the design team have conducted independent exploration of the solution space and selected their discipline specific regions, the system superimposes these regions to find an area that overlaps the requirements for all parties. This region is called "the mutually inclusive region"; a region that contains design alternatives that partially satisfies the requirements of all parties involved in the design.

Essential discipline-related design requirements are defined as objectives specific to these disciplines, and are summarised in the following sections.

Architectural requirement

The principle objective function of the architectural requirements used in this paper is to minimise the number of fire escapes and columns used in the building (maximise column free space). To achieve this, the term "areaLoss" was introduced. AreaLoss is calculated as the sum of the area occupied by the columns and the fire escapes. Non-useable area around a column is considered to be $1m^2$ and an area of $18m^2$ per floor was used for each fire escape. In order to satisfy the architectural requirement, the areaLoss was minimised. Number and location of fire escapes are determined by fire regulations.

Structural engineering requirements:

The structural engineer requires the use of optimum structural element sizes that are capable of carrying loads safely to the ground. For this case study structural steel is used as the sole construction material. A spreadsheet was created listing optimum member sizes and recommended floor types for each bay size. This spreadsheet is used to obtain optimum floor system and optimum structural sizes. The cost of the structure is calculated as the cost of: total superstructure, substructure, foundation, ground slab, prelims & external works, finishes & walls and cladding and windows. In order to make this data more useful and comparable, all costs are converted to cost/m^2 of the floor area and stored in looking up tables to be used by the optimisation algorithm.

Building physicist requirements

Calculation of energy usage for a building is a complex issue, which is out of the scope of this paper. However it is necessary to include building energy usage in the optimisation process to give a long term cost comparison for different design concepts, even if it is a relative cost of energy consumption (termed as 'eCost' in this study). As stated previously, the 'LT Method 2.0' was used to calculate 'eCost'.

Design Variables and Objectives

From the above three disciplines, a total of seven independent variables are selected, these being:

1. Number of storeys: single to 8 storeys
2. Bay size (i.e. sizes 4m to 9m): 12 options (8 options selected for this study)
3. Number of bays along the length of building (single bay to 16 bays): 16 options
4. Concrete floor type: 8 options
5. Wall cladding type: 4 options
6. Window type: 4 options
7. Window ratio, ranging from 0.25 to 1.00: 16 options

Clearly, within a more realistic problem, many more design variables would be used. However, even with this small number of design variables and the simplicity of the assumptions made, there are approximately 3 million possible solutions. Traditionally it would be exceptionally difficult to transverse a search space of this size to find compromise solutions. Normally, designers may only consider a small fraction (i.e. numbers in the range of 4 to 5) of this search space, thus possibly missing superior alternative solutions.

The IVCGA optimisation tools use 3 core objectives (Arealoss for the architectural requirements that maximises the lettable floor space; StructCost for structural requirements that minimises the structural costs; and eCost that minimises building energy consumption.)

The IVCGA is a novel and powerful tool, with the core component of user-led exploration. A key outcome of this exploration is to enable users to explore and discover boundaries of the solutions that contain alternative designs which may best satisfy the requirement of a particular discipline. For details of the IVCGA exploration process refer to Packham and Denham (2003).

PRACTICAL EXAMPLE

Problem definition

In this paper, multidisciplinary issues regarding the design of a commercial building with a total lettable area of 8000 m^2 is investigated. Structural steel has been selected as the main construction material. As mentioned, the design team consists of three disciplines: the architect, the structural engineer, and the building physicist.

The architect view

Running the IVCGA, the architect selects the “areaLoss” as the objective of the optimisation process. Initially, a 100 population size and 21 generations are used to generate 2100 solutions. No restrictions or filtering of information, to discourage the generation of impracticable solutions, have been implemented at this stage.

Fig. 2 left hand (LH) frame shows the entire solution space satisfying the architectural objective of minimising areaLoss. Each dot on Fig. 2 represents one solution; and the darker the colour, the fitter (i.e. better) the solution is. The exploration process is interactive and the user has full control. For example to explore a preferred region for the architectural solution space, the architect draws a box around the specific region of the solution space which they signify to be useful for further exploration (e.g. total building footprint area between 7500m^2 to 8500m^2 and up to a maximum of 350m^2 areaLoss has been selected inside the box in Fig. 2 LH frame). The IVCGA automatically discards all

solutions that are outside the comfort zone of the architect and zooms into the selected area. The new solution space is shown in Fig. 2 RH frame.

The additional use of colour enables the user to emphasise the clusters that are important to the user whilst keeping other interesting data also available. For example, in Fig. 2, concepts presented by yellow and pink represent two distinct clusters of high fitness solutions.

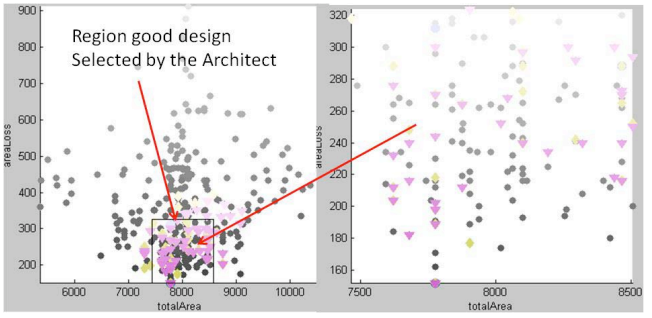

Fig. 2: LH-whole design space; RH-Zoomed in on the selected region

The system has a graphic user interface where a right mouse click on a particular solution (e.g. those shown by pink triangle or yellow diamond) presents to the user a 2D floor plan of the selected solution. It also gives some other important textural details about the selected design option, such as footprint dimensions, floor type, bay size etc. A cut-down screenshot of this process is given in Fig. 3. While this information is useful, it is a simplified graphic user interface which could easily be replaced with an interface with 3D Studio Max or even with virtual reality or building information modelling (BIM) programs such as Revit & TEKLA, which give more practical information about the building. Work in this area in progress.

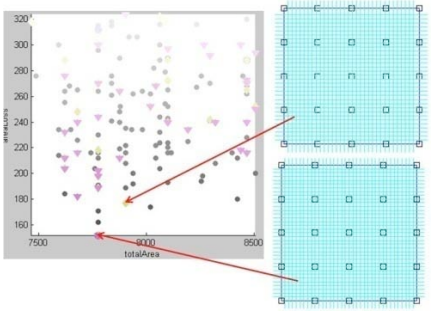

Fig. 3 samples of designs selected by the architect

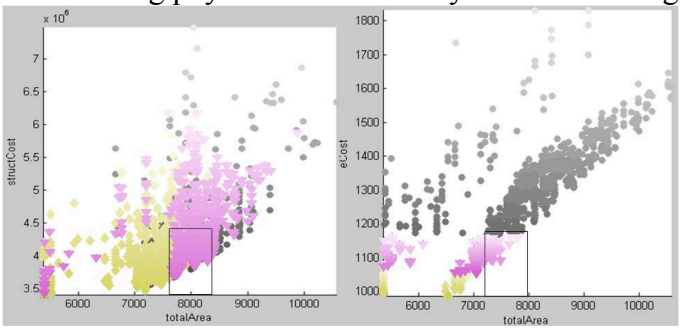
It is worthwhile to note that the cyan lines in Fig. 3 represent architectural grids.



The IVCGA also allows the designer to generate more designs solutions inside the boundaries of the selected region by performing another set number of generations inside the selected area (i.e. the area within the rectangle selected interactively by the Architect.)

Using other graphic facilities of the IVCGA, the designer can conduct further explorations to enhance their understanding of the interrelationships between design parameters. This is achieved by defining which variables are plotted against each other. As an example, plot of the areaLoss against the number of storeys could provide the architect with significant information.

The structural engineer and the building physicist views

The structural engineer selects the 'structCost' and the building physicist selects the eCost as the objective of the optimisation. They minimise the overall cost of the structure and energy requirements of the building, respectively.

Like the architect, the structural engineer and the building physicist can conduct similar explorations to identify the boundaries of the solution spaces that best suit their individual disciplinary requirements. In this example, the preferred areas selected by the structural engineer and building physicist are shown by the boxes in Fig. 4.

(Structural Engineering) (Building Physicist)

Fig. 4: Solution spaces generated using structCos and eCost as objectives

Mutually inclusive region of the multi-disciplinary solution space

Once independent exploration of the solution space is completed by all members of the design team, and each has identified their regions of best solutions, these areas previously identified independently as their discipline 'comfort zones' can be superimposed on each other. This enables identification of a mutually inclusive region that partially satisfies the requirements of all disciplines involved in the design.

Fig. 5 exemplifies a superimposed solution space that contains the preferred solutions selected by all three disciplines interactively (in this case study the combined-solution spaces contains 3x2100 = 6300 alternative designs). In Fig. 5, solutions coloured purple and pink represent a mutually inclusive region of the solution space that partially satisfies the requirements of all three parties. This mutually inclusive region is identified by overlapping three clusters: cyan - the architectural preferred area; green - the structural engineer preferred area; and red - the building physicist preferred region.

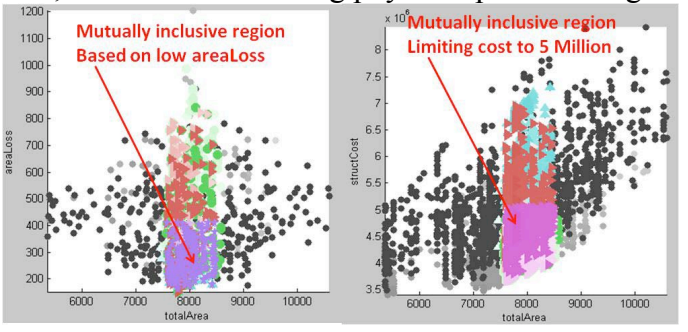


Fig. 4: Mutually inclusive regions

Pareto optimal front

Mutually inclusive region defines a framework for the future of multi-disciplinary exploration in which members of the design team can focus only on the solutions within

the boundaries of this region. For this case study, the region contains 1448 individual solutions which is by itself a large solution space to contend with. In order to narrow down the exploration space, a Pareto algorithm was implemented in a novel way to rank solutions within this region and identify a Pareto set based on the non-dominated rule defined by Pareto. Using this method, 147 designs alternatives were found to be non-dominated solutions. Fig. 5 give details of this Pareto set.

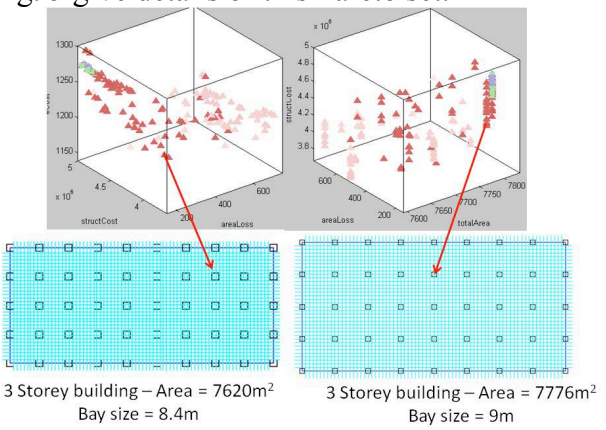

Fig. 5 Pareto non-dominated set – LH-frame: three objectives and RH- frame total area against areaLoss and structCost

In Fig. 5 - LH frame, solutions adjacent to the vertical axis are those designs which have lower values for all three objectives. Unfortunately, the total area for most of these buildings is approximately 7600m^2, considerably less than the required 8000m^2. Conversely, by plotting the 2 objectives against the totalArea it is discovered that the cluster of solutions at the RH end of the design space contain superior solutions with a floor plan area close to 8000m^2 and lower structCost. This phenomenon also demonstrates the knowledge discovery aspect of the IVCGA as a useful decision support tool.

CONCLUSIONS

- Previous research discovered that changes identified and implemented at the conceptual stage of the design process have maximal impact of final design and building costs.
- This paper demonstrates that the IVCGA, a powerful decision support tool, facilitates user interaction, enabling members of the multi-disciplinary design team to conduct fast and efficient exploration of the solution space at the conceptual design stage. This enables selection of the most suitable solution to satisfy the requirements of all 3 core disciplines involved in the multi-disciplinary team.
- User interaction through the IVCGA enhanced the multi-disciplinary design team members' understanding of the overall design issues, allowing them to appreciate the effects that their decisions have on other parties and on the overall design.
- A novel use of the Pareto optimal front was an ideal way of solely focusing on non-dominated solutions which is in the region of 10% of the overall design. This assists design team members in their decision making.
- In conclusion, the use of the IVCGA at the conceptual stage of the design process, not only enables independent user interaction, so designers can focus specifically on their discipline-specific objectives, but also upon completion of the run

combines this data to provide solutions that are acceptable to all members of the design team. This enables production of a structure that is not only structurally sound, but also cost effective with limited adverse environmental effects in a building with maximal utility of the space available.

- Further research could cover the addition of more design parameters such as: other construction materials; construction cost and time and life cycle costs. In terms of visualisation, interface with virtual reality and building information modelling tools such as Revit and TEKLA will provide a more realistic view of the building design process and life costing.

Open Sourcing the Design of Civil Infrastructure (OSD-CI): A Paradigm Shift

T. Kijewski-Correa, M. ASCE[1]

[1]DYNAMO Laboratory, Department of Civil Engineering and Geological Sciences, University of Notre Dame, 156 Fitzpatrick Hall, Notre Dame, IN 46556; PH (574) 631-2980; email: tkijewsk@nd.edu

ABSTRACT

Few will argue the importance of civil infrastructure to society, yet its condition has been allowed to deteriorate to a staggering level. Meanwhile the research and design practice dedicated to it has relied only upon limited, fractured resources scattered physically across the community with little formal collaboration. As the information used in the design, analysis and even management of civil infrastructure is trapped inside proprietary systems, these essential public works projects often do not benefit from the full expertise and latest advances available in the wider engineering community. To address this problem, a new virtual organization has been launched: **Open Sourcing the Design of Civil Infrastructure (OSD-CI),** welcoming *Citizen Engineers to* engage in four dimensions of collaboration (sharing hardware, software, knowledge and manpower). This paper presents the ongoing development of this concept, specifically focusing on two recent prototypes allowing this crowd to contribute and assess engineering data.

INTRODUCTION

A few years ago, no one would have believed that a global team of volunteers could write a major operating system kernel or a comprehensive encyclopedia. But today, Linux and Wikipedia and many similar open source projects serve as evidence that loosely organized teams can create and maintain the complex technical and intellectual infrastructure upon which society increasingly depends (Raymond 2001). These projects have succeeded not by accepting participants indiscriminately, but by creating a meritocracy that rewards expertise regardless of its source. Yet interestingly, what is viewed as the best cognitive model (the crowd) has been applied to relatively non-technical societal problems (Surowiecki 2005). Why not then tap it to address once of society's grand challenges: its aging civil infrastructure?

Interestingly, civil engineering is naturally suited towards open source concepts: complex systems like buildings, bridges and other lifelines have many different stakeholders, require many kinds of technical expertise, and have a lifetime far beyond any one contributor. As the information used in the design, analysis and even management of civil infrastructure is trapped inside proprietary systems, these essential projects often do not benefit from the full expertise and latest advances available in the wider engineering community. To address this problem, a team of civil engineers, computer scientists and social scientists at the University of Notre

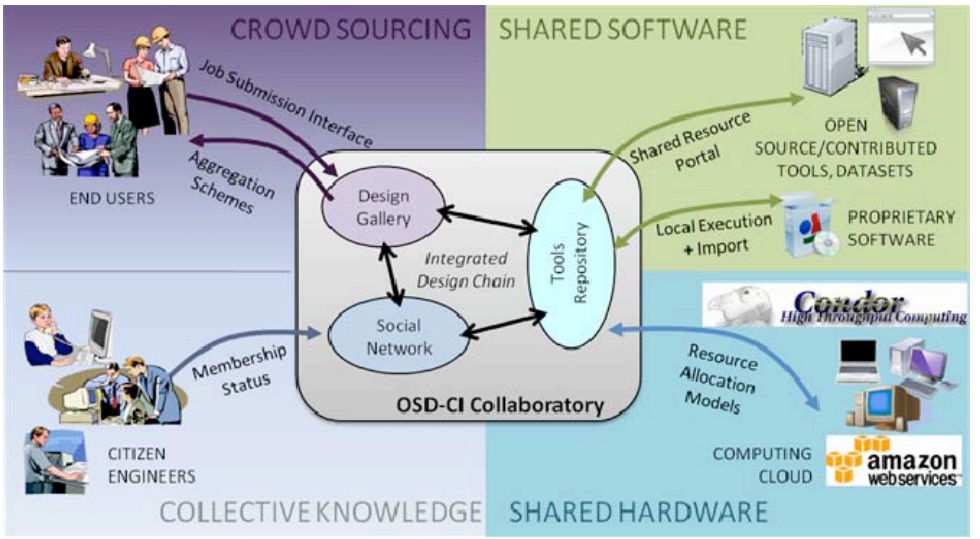

Figure 1. Four dimensions of sharing and mechanisms interfacing them in OSD-CI.

Dame are engaged in the formation of a new type of virtual organization for **Open Sourcing the Design of Civil Infrastructure (OSD-CI)**. OSD-CI will allow stakeholders – engineers, public officials, researchers, students, and even the public at-large – to review, propose, modify, evaluate, and contribute to designs, analyses, databases and other fundamental research that supports civil infrastructure and will provide these *Citizen Engineers* with unparalleled access to tools that will empower their individual inquiry.

The OSD-CI Concept

While it may seem bold to suggest that engineers would agree to crowdsource their problems, it is important to note that the profession presently operates within a limited crowd construct. Both scholarly research and state-of-the-art design depend on the efforts of predecessors and contemporaries, and the crowd, via peer review, citations, and standardization, decides whose work is best (Surowiecki 2005). This project now boldly extends that crowd to the public at large, with appropriate policies, governance structure, incentives, and control mechanisms to assure trustworthiness in technical tasks (Johnson 2006, O'Mahony and Ferraro 2007). As shown in Figure 1, this collaboratory would accept job submissions from end users (firms, researchers, fellow *Citizen Engineers*), who would specify relevant details (scope, constraints, models, etc.), deadlines, submission formats, and requisite credentials. *Citizen Engineers* with the proper credentials and membership status (a concept discussed in a later section) can volunteer to contribute to these job submissions, either individually or as part of teams, using the various computational resources and tools housed in the portal. The products produced by *Citizen Engineers* are archived in the collaboratory's design gallery and can be retrieved and commented on by any member of the public to form a truly transparent archival system for Civil Infrastructure projects. These products are ultimately delivered back to the end user through various aggregation schemes.

One may ask: what are the incentives for end users to bring their jobs to the OSD-CI portal? Eventually, every firm is faced with projects requiring expertise outside the restricted range of their staff's abilities and experiences. The crowd provides a flexible and informal mechanism to obtain needed expertise for specific projects at little to no cost. The OSD-CI therefore provides a mechanism through which firms of varying sizes can "crowdsource" specific projects, allowing the firms to both focus on their core competencies and obtain the expertise to solve problems requiring a more diverse group. Conversely, *Citizen Engineers*, whose demographics may be broad, have similarly diverse reasons to join the crowd. For members of the general public, status and ratings within a community of users and the chance to be part of a larger initiative that serves the public good has been shown to sustain involvement. However, to attract *Citizen Engineers* with higher level qualifications, other incentives are required. Networking, potentials for career advancement, and exposure to potential employers may be sufficiently attractive, especially for the legions of unemployed engineers. For licensed engineers, OSD-CI activities can be used to earn professional development hours (PDHs). Of course, direct monetary compensation will be warranted for those working on the most complex and challenging problems. Thus, one of the major research endeavors of this project is to determine which types of incentives work best for wide ranging tasks within OSD-CI.

Cyberinfrastructure Requirements

There are many successful examples of open sharing of computational resources (SETI@Home), source code (Linux), knowledge (Wikipedia), and even manpower (Amazon's Mechanical Turk); however, the unique feature of OSD-CI is that it will enable collaboration in all four of these dimensions as part of an integrated design chain shown in Figure 1. While this in and of itself is challenging, it is further compounded by the fact that these social computing principles have never been applied in high risk application domains where failure has serious implications. However before the issue of how to assure trustworthy work can be tackled, a robust cyber-platform must be developed to support these four dimensions of collaboration and their three distinct repositories of interacting data: (1) a design gallery consisting of all the active job submissions, (2) the social network representing the properties, qualifications, and actions of all the *Citizen Engineers* participating in the system, and (3) the tool repository -- a collection of open source and contributed tools from members of the collaboratory. Figure 2 provides examples of these tools such as data archives, real-time data, tele-experiments, simulation/analysis tools, and e-design aids (Kareem et al. 2008, Kwon et al. 2008). A key feature of the tool repository is the provision for both open source tools to be embedded in the system *and* the capacity to upload/download information and results to/from proprietary software whose analyses have been executed locally by a *Citizen Engineer* outside the portal. As such, *Citizen Engineers* will retain ongoing access to the analyses they trust and have access to new collective resources that all can be seamlessly integrated in the design chain. Further, since computational demands of various actions in the portal will vary widely, at times surpassing the local computational resources of the *Citizen Engineer*, there is the capability to farm computations out, e.g., to Condor or Amazon's Elastic Computing Cloud.

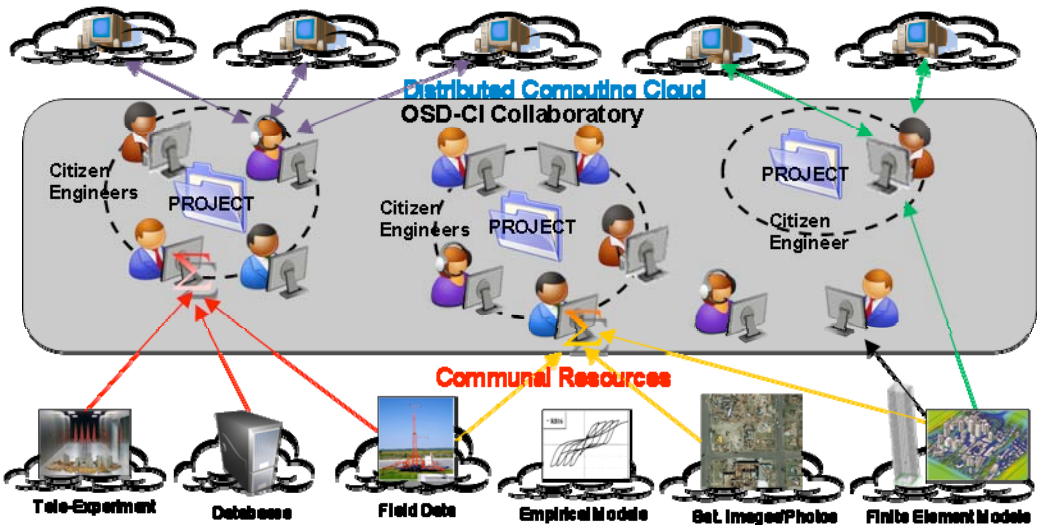

Figure 2. Schematic of *Citizen Engineer* interactions and use of distributed resources.

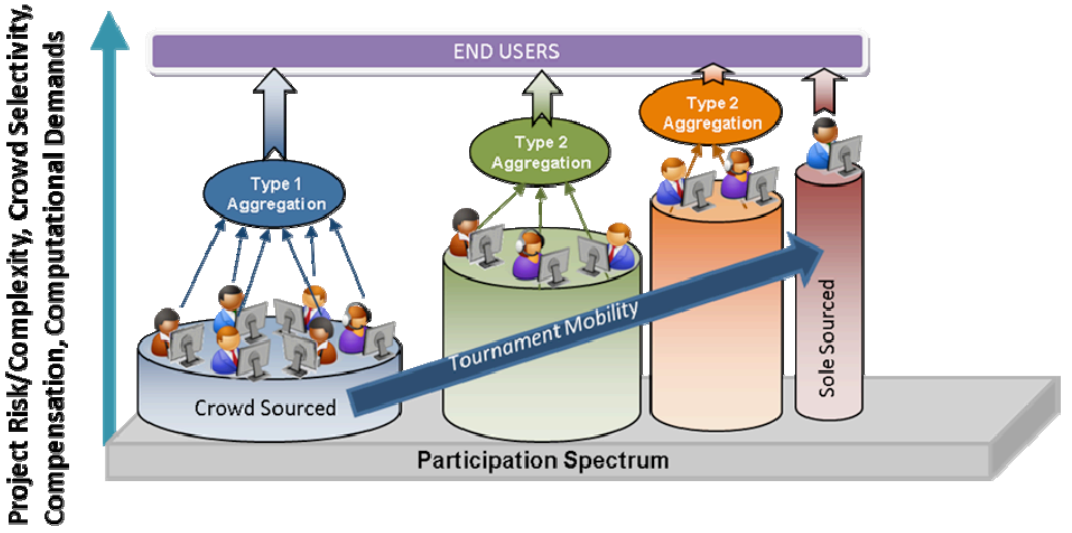

Figure 3. Tiered organizational structure of OSD-CI.

Balancing Trustworthiness and Openness

Many open source systems began with no controls in order to foster maximum openness, e.g., Wikipedia. Interestingly, its founders later regretted that structure and the lack of *a priori* roles for experts (Lih 2009). Considering the high levels of risk involved in the proposed effort, the competing requirements of trustworthiness and openness are be best optimized through a tiered collaboratory. This concept, shown in Figure 3, acknowledges that there is a wide spectrum of tasks with diverse requirements that not all members of the crowd would be qualified to address. At the highest tiers, projects would be increasingly complex, may require sophisticated analysis tools and substantial computational resources, and in turn offer higher levels

of compensation, but as a result, greater selectivity within the crowd. This produces a spectrum of participation from crowdsourced to sole sourced.

One of the major advantages of the tiered system is that it provides a mechanism for building trust through transparent credentials and rating systems for all its *Citizen Engineers*, based on the accumulated reviews received from past contributions (similar to ratings on e-Bay and Amazon). These ratings will not only create incentives, but they will also provide end users with information that they can use to pre-qualify *Citizen Engineers* for their projects and a mechanism to evaluate and even aggregate their submissions. The result would be a form of tournament mobility as shown in Figure 3, where *Citizen Engineers* would start off "competing" at lower tiers and as their efforts are positively evaluated they would become qualified to "compete" at higher levels.

EXAMPLE CROWDSOURCED PORTALS FOR CIVIL INFRASTRUCTURE

Having summarized the basic concept behind **Open-Sourcing the Design of Civil Infrastructure**, two case studies will be presented to demonstrate the cyberinfrastructure that can support various activities executed by *Citizen Engineers*.

Case Study 1: Applying a Participatory Sensing Paradigm to National Infrastructure Monitoring

There has been considerable attention paid to the concept of ubiquitous sensing for evaluation of aging infrastructure. As visual inspections are generally executed every 1-2 years, potentially significant damage can be present for sometime before the next inspection cycle. Therefore the first prototype developed in OSD-CI portal seeks to leverage the multi-sensor array with the highest on board computational and decision making power: humans. The prototype, launched late in the summer of 2010, asked *Citizen Engineers*, in this case Notre Dame engineering students and any family and friends they referred to the portal, to collect visual evidence of degrading infrastructure. By mobilizing citizens to collect images of troubled infrastructure in their communities, the capability for identifying potential troubled structures in the period between their regular inspections is greatly enhanced. Further, by these simple engagements of the general public, overall attitudes and awareness surrounding civil infrastructure can be heightened, creating more stewards of our national infrastructure and allies in reversing our infrastructure crisis.

To facilitate this crowdsourced project, the development of a robust and reliable portal was first necessary. The portal includes a welcome page (Fig. 4) with relatively standard features that permit users to create a secure account and manage their profile. The more significant objective was to create a seamless approach to receive geotagged photos acquired in the field. It was important to remove technological barriers from this process to maximize participation by citizens as they are going about their daily routines. As a result, users, after establishing an account tied to a specific email address, were provided with a detailed tutorial that demonstrated how to enable geotagging on their smart phones and a means to directly submit the images from their phones or upload them directly through the web portal (Fig. 5). In the event the participant did not have geotagging capabilities, i.e., phone does not permit geotagging or participant was using a standalone digital camera, users

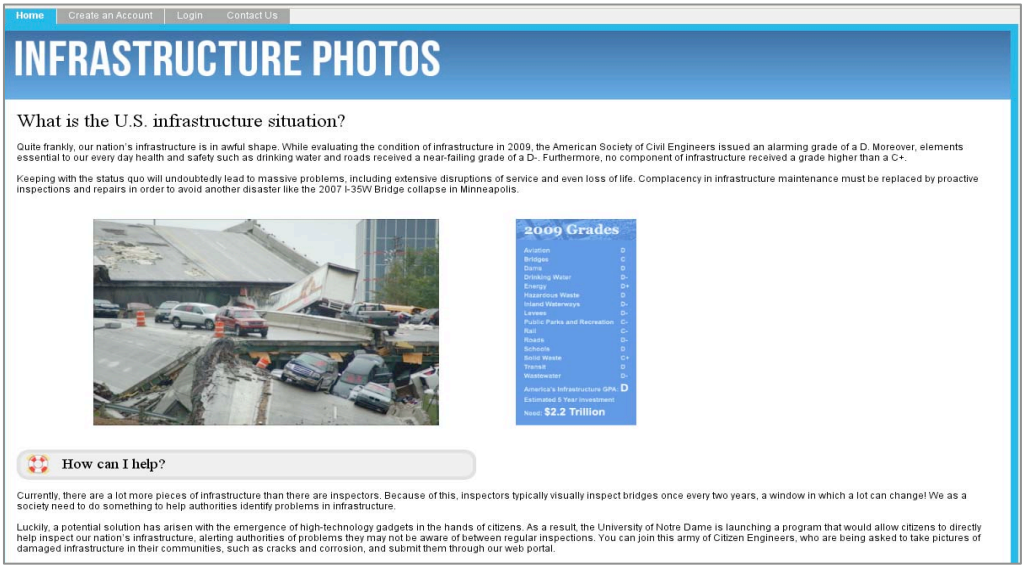

Figure 4. Front page of infrastructure photo portal.

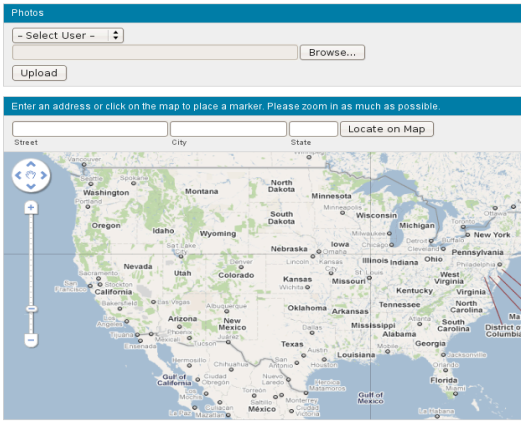

Figure 5. Manual uploading options in infrastructure photo portal.

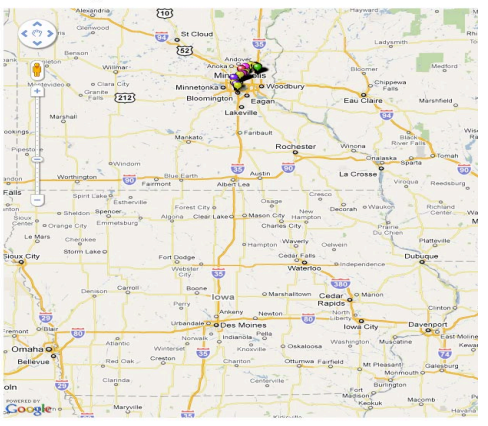

Figure 6. Google maps interface for representation and visualization of submissions.

can either input the street address or use a movable marker to pinpoint the site locations in Google Maps during the image upload process (see Fig. 5). However, the experiment found that the overwhelming majority (99%) of photos submitted were geotagged, proving that this is a seamless way to collect data on distributed infrastructure systems.

At the server side, submissions are tied to a database for indexing. This database allows all submissions to be visually represented using colored balloons/pins as shown in Figure 6, so that the details of any submission of the crowd can be easily viewed by administrators by clicking on any of these balloons/pins. Further, the use of Google Maps creates an easy to navigate interface familiar to most users.

It should be noted that the portal was opened one week before the start of classes in the Fall 2010, leaving a limited time for participation by most students.

Even so, the portal received documentation of a wide range of infrastructure degradation from cracks and holes in pavements to significantly deteriorated bridges and piers. However, only about a third (32%) of *Citizen Engineers* creating accounts actually uploaded one or more images – a common issue in virtual organizations – however the active users submitted on average 21 photos each.

Case Study 2: Applying a Crowdsourcing to Infrastructure Assessment

While the previous case study provides a demonstration of how *Citizen Engineers* can be harnessed to collect data, this data needs to be effectively analyzed to make meaningful decisions. This begs the question of what would be the most effective motivator for *Citizen Engineers* to conduct such analyses, providing their time, knowledge and effort with little or no promise of pay or recognition? The issue of motivation is central to the entire spectrum of crowdsourced activities, but specific to engineering, where the tasks are highly technical and thought intensive, the question is even more relevant. To answer this question, an experiment was developed in the Fall 2010 to evaluate the types of extrinsic motivators that are most effective in enhancing not only the quantity but also the quality of *Citizen Engineer's* contributions. In order to simulate a meaningful and authentic crowdsourced civil engineering task likely to resonate with citizens' volunteer spirit, the case study utilized a database of 400 photos of damaged reinforced concrete and masonry buildings collected by the author during field reconnaissance in Léogâne, Haiti in March 2010, two months after the catastrophic earthquake. The objective of the crowdsourced task was to ask *Citizen Engineers* to identify the type and severity of damage in each photo. Considering the large repositories of photos from reconnaissance following disasters, often not completely categorized or databased by their curators, if the crowd could be leveraged to accurately execute such a task, then an automated repository could be created and easily mobilized for future disasters.

The primary challenge was first to develop a schema that can break the classification of a damaged structure into a series of simple, progressive steps that could easily be replicated by citizens without an engineering background and could be implemented readily in the portal. The final classification schema used in the experiment is shown in Figure 7, customized for the construction style in Haiti. The schema asks which elements are visible, if they are damaged, and if so the type of damage and its severity The first three classifications are largely objective, while the fourth is quite subjective. A detailed web tutorial was created to familiarize the *Citizen Engineers* with the schema. Figure 8a shows a screen shot of part of this tutorial focused on element identification. Later stages of the tutorial introduce various damage patterns and, as shown in Figures 8b-c, allow *Citizen Engineers* to take self-quizzes to gauge their understanding of each step of the schema.

After *Citizen Engineers* create an account, complete a brief entrance questionnaire collecting various demographic and attitudinal data, and conclude the tutorial, they are unknowingly and randomly assigned to one of four groupings depicted in Table 1. An equal distribution of participants (~50) is assigned to each of these groupings, assuming a total of 200 participants. The groupings explore the effect of monetary vs. moral incentives, as well as the impact of information fed back to the participants. Specific to the latter point, all participants receive information on the number of photos they have classified or "tagged" in the database, however, 50%

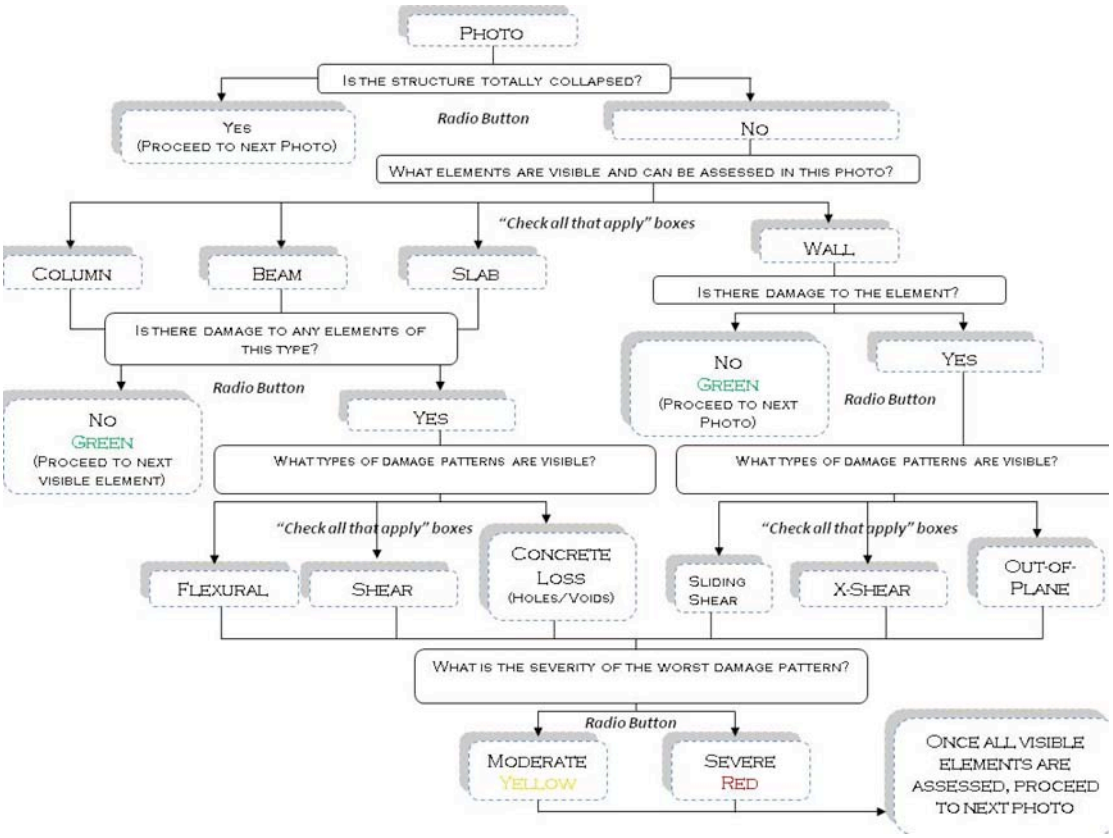

Figure 7. Schema for classifying earthquake damage to reinforced concrete and masonry structures in Haiti.

of the participants will also receive feedback on their ranking (in terms of number of photos classified) relative to others in the portal. This is expressed as a second status bar, shown at the top of each screen shot in Figure 9.

Table 1. Four possible groupings for participants in the Haiti photo classification experiment.

		Incentives	
		Utilitarian	**Moral**
Information	**Individual**	Incentive: cash prize based on performance Information: sees only personal progress	Incentive: watches short movie about earthquake in Haiti and need for help in assessing damage. Information: sees only personal progress
	Collective	Incentive: cash prize based on performance Information: sees progress relative to all other participants.	Incentive: watches short movie about earthquake in Haiti and need for help in assessing damage. Information: sees progress relative to all other participants

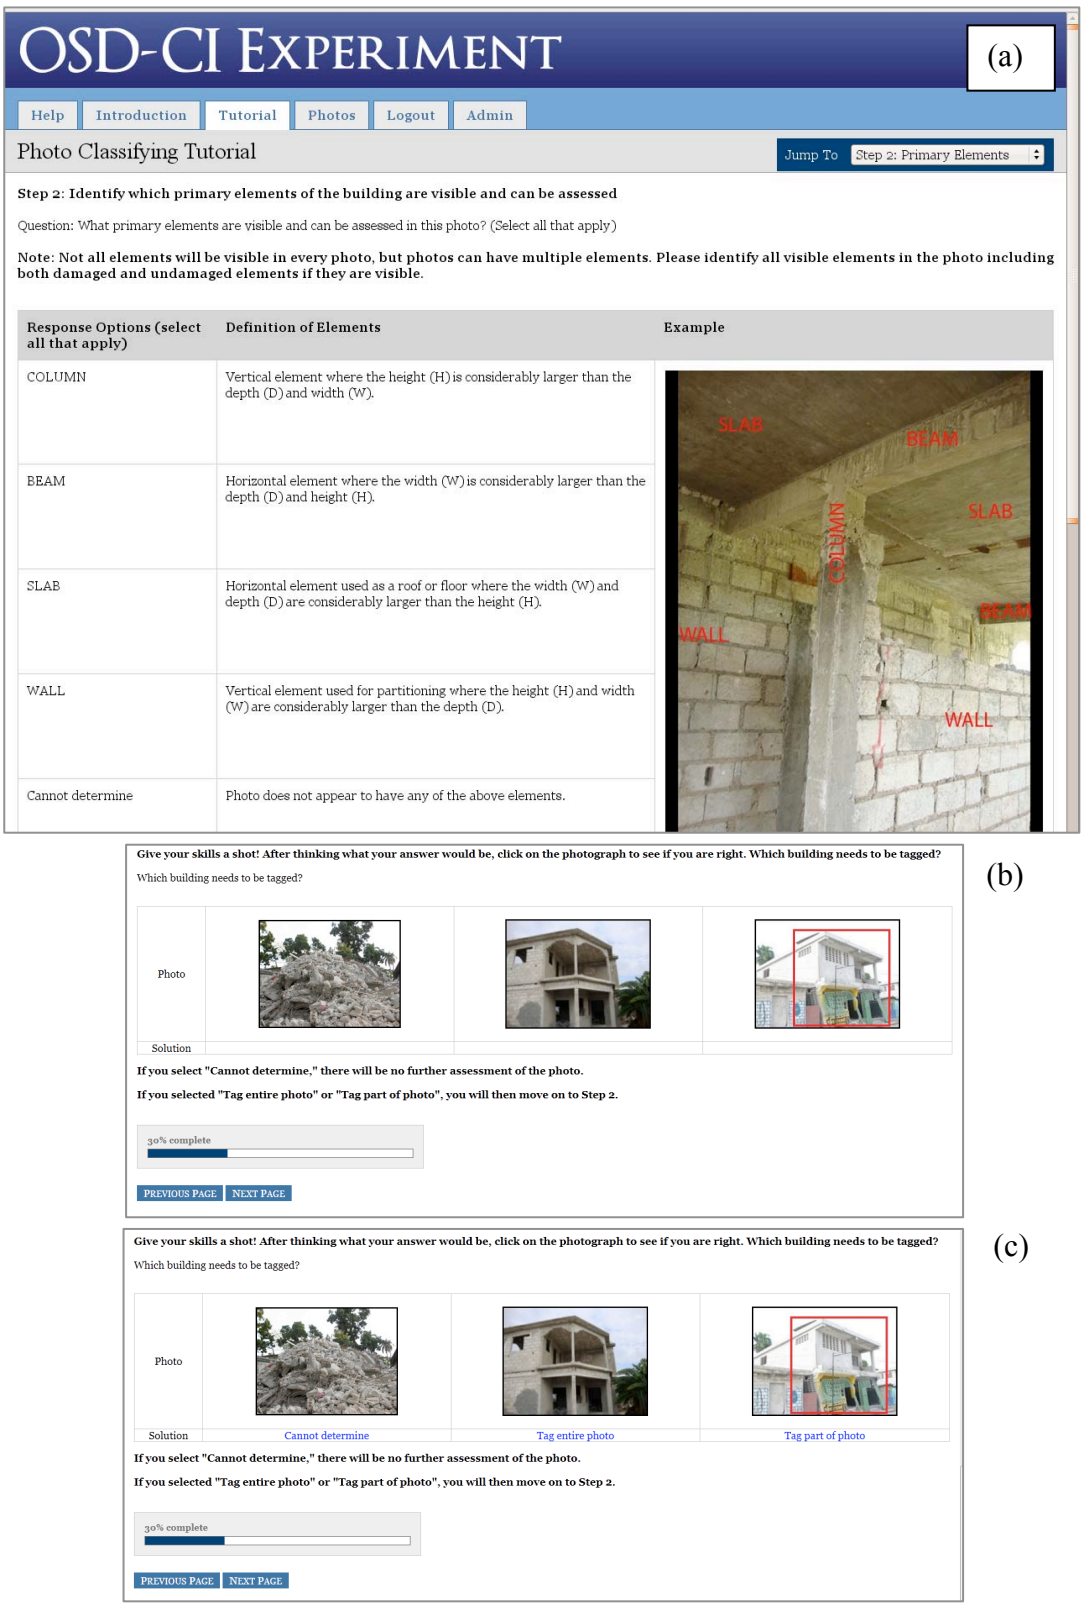

Figure 8. Screenshots of Haiti photo classification tutorial: (a) definition of structural elements, (b) self quiz, (c) self quiz with solution.

Figure 9. Screenshots of Haiti photo classification process: (a) identification of structural elements, (b) determination of damage, (c) classification of damage type. Status bars shown at top of each screen shot indicative of what a *Citizen Engineer* in the collective information grouping would see. Individual information assignees would see the same interface but with only the first status bar.

The classification process uses a set of web pages that adapt to the previous responses at each step of the schema. An example of this sequence of pages is shown in Figure 9. Each participant is asked to classify a minimum of 25 randomly assigned photos of buildings in Haiti; however it is hoped, by virtue of the incentives and information they receive, that they will classify more and possibly all 400 photos within seven days of joining the study. At the close of the seven day period, all participants complete an exit questionnaire to gauge their attitudes and identify any functional issues with the portal or classification schema.

As both quantity and quality of classification is of interest in this application, three expert taggers (structural engineers) have independently classified all 400 photos in the database to create a "key" against which each *Citizen Engineer* can be graded. The analysis of the data collected from the study that evaluates performance of the crowd as a function of their assigned groupings, wide ranging variables associated with their survey responses, as well as their monitored actions within the portal (time spent on each photo, etc.) is beyond the scope of this paper; however, space does permit a brief discussion on the participation within the portal.

The portal was opened in November 2010 to Notre Dame students. In total 242 students created accounts, hailing from the Colleges of Science, Engineering, Business, Architecture, and Arts & Letters. These users executed 9445 photo classifications over a two week period or approximately 30 classifications per user. In fact, a handful of users classified all 400 photos in the database. More importantly, this resulted in an average of 23.6 classifications for each photo in the database. This would allow the "wisdom of the crowd" to be effectively gauged for each photo with sufficient statistical significance. Again not only will this allow various incentives and motivational constructs to be evaluated, but also will determine if the crowd is capable of achieving consensus or if refinements to crowdsourced engineering tasks are required. This could, for example, include grouping *Citizen Engineer*s based on their expertise or past performance within the portal and assigning their work units accordingly.

CONCLUSIONS

This paper introduces the formation of a new virtual organization to enable **Open Sourcing the Design of Civil Infrastructure (OSD-CI)**, allowing all stakeholders – engineers, public officials, researchers, students, and even the public at-large – to engage as *Citizen Engineers* in four dimensions of collaboration: harnessing human effort, tapping collective knowledge, pooling communal software and leveraging distributed computational hardware, to rehabilitate our nation's deteriorating civil infrastructure. It should be noted that this project is particularly challenging as most social computing applications have only been attempted on projects with relatively modest technical demands, while structural design faces significant policy and technical challenges. However, this project demonstrates how the collaboration between civil engineers, computer scientists and social scientists can develop cyberinfrastructure and the appropriate policies and governance to extend one of the most powerful cognitive models – the crowd – to one of the most pressing societal problems – the design and maintenance of civil infrastructure – by leveraging an army of *Citizen Engineers*.

The two case studies presented in this paper demonstrate how cyberinfrastructure can be developed to facilitate a participatory sensing paradigm to monitor civil infrastructure using geotagged photo submissions and how extensions of these portals can be used to harness the wisdom of the crowd to assess and ultimately curate archives of reconnaissance photos of damaged infrastructure. This latter portal, using actual field data from the 2010 Haiti earthquake, has provided the opportunity to further study the incentives (moral vs. monetary) and motivators (feedback regarding *Citizen Engineer*'s status relative to others in the portal) required to maximize both the quantity and quality of voluntary work units within crowdsourced civil engineering projects. The outcomes of this research and the data collected through this latter case study will be critical to determine how best to incorporate distributed *Citizen Engineers* into a faithful design process that ensures extreme trustworthiness in technical tasks, while promoting participation as a first step in realizing the grander vision that is OSD-CI.

Assessment & Reduction of Transportation Structure Vulnerability Past, Present & Future

Sena Kumarasena[1], PhD, PE and Raymond Daddazio[2], PhD, PE

Abstract: Following the events of 9/11/2001, FHWA together with AASHTO commissioned a Blue Ribbon Panel (BRP) on Bridge & Tunnel Security. It was charged with the task of examining the issues and developing the initial road map for improving the bridge and tunnel security in the United States in the face of this new reality; organized terrorism on American soil. The recommendations of the panel was published in September of 2003, and has been a key reference and a source document for assessing vulnerability and planning of structural hardening of many key bridge and tunnel facilities in the US. Even though a considerable knowledge existed in related areas, especially within the military type organizations, at the time the BRP, bridge and tunnel security was in its infancy. Over the decade since 9/11, much progress has been made in both infusing the considerable knowledge that existed in other areas. These include counter terrorism intelligence, monitoring and enforcement as well as structural hardening and blast resistant design applied to military buildings and other facilities of sensitive nature. In addition to this cross-over of operational and design methodologies, considerable new knowledge and experience in vulnerability assessment and mitigation has been generated specific to bridges and tunnels. One key aspect of this evolution is the crystallization of the idea that any holistic vulnerability assessment and risk mitigation of the transportation infrastructure must consider multi-hazards and just not terrorism.

However, many challenges and considerable difficulties still remain in improving safety and security of many existing bridges and tunnels to a meaningful level. The paper examines the evolution of bridge and tunnel security, the progress to date and also the challenges and opportunities as we as look to the future in developing promising new approaches and initiatives. It can be shown that viable approaches are available to bring bridge and tunnel security to the next level in a cost effective manner in a relatively short time; same way how the earthquake security initiative of the 70's improved the seismic worthiness of bridges and tunnels in America and beyond.

1. Introduction

The transportation system and its assets are a vital component of the economic and social infrastructure of a nation and probably represent the largest component of its public investment. A catastrophic disruption to it would have immense consequences in terms of direct and indirect economic loss, breach of public safety and mobility of people, goods and services within the affected region. Due to regional and global interdependencies, the effects can reach well as beyond the area of direct impact. Also, they often generate lasting impacts on socio-psychological wellbeing of the public due to feelings of insecurity and vulnerability in the aftermath.

Historically, large scale loss of life from disruptions to the built-environment has been due to natural disasters[3] such as large magnitude seismic events, massive floods, wide-spread fires and severe wind events. Considerable gains have been made in improving the performance of structures against such conventional threats or hazards. A structure properly designed using current design codes and properly constructed do in fact perform satisfactorily against the events that they have been designed against. Nowhere have these gains been more rapid, visible, and fruitful than in the area of seismic risk mitigation as clearly evident by the satisfactory seismic performance of newer facilities properly designed and constructed in the recent past and the damage and loss of life suffered in regions where such enforcement is lacking.

The drive towards prevention of seismic damage as a critical regional issue in California was propelled forward by the San Fernando Valley Earthquake in 1971. Prior to this massive undertaking by CalTrans, seismic risk was deemed more or less something that one has to live with, its mitigation considered too expensive or impractical for wide-spread implementation, and was left largely to the intuition of the individuals designing a particular facility. Within the relatively short span of about four decades, it has matured considerably beyond its initial scope of preventing structural collapse and resulting loss of life and also beyond the initial region of focus in California to become an issue of global awareness. The bar in state-of-the-art seismic risk mitigation is no longer set at just preventing loss of life due to structural collapse of an individual facility; but at life-line engineering on one hand where the goal is to ensure availability of critical routes for emergency operations and ensuring public access to critical facilities, services, and an uninterrupted supply of food & fuel; and at performance based design on the other hand where the goal is to ensure continued “normal” operation of a given facility

[3] Except acts of war

following a major seismic event by ensuring any damage following a seismic event is minimal.

As the state of the art continues to advance in seismic hazard mitigation, the global community is facing yet another threat; equally unnerving if not more in terms of its lack of warning and potential devastation; that of organized terrorism. Terrorism brings considerable engineering challenges in hazard mitigation due to the shear magnitude of the potential blast loads that structures could become subjected to, and the evolving nature of the hazard.

Similar to the case with seismic risk mitigation, the public agencies at the federal, state and local levels and the engineering community is looking to mitigating the thereat of this latest challenge on two fronts – operational improvements designed to deny the opportunity to inflict damage and engineering improvements designed to harden the existing transportation infrastructure initially designed and built with no such considerations. Another key outcome of this recent evolution of ideas is the notion that any holistic risk mitigation of transportation infrastructure must consider multi-hazards, and not just terrorism.

2. Evolution of Blast Resistant Design

The initiating event in the design of non-military structures to explosive loading was the destruction of the United States Embassy in Lebanon in 1983, Figure 1. Prior to this, the design approaches, the data that supported these approaches and the structures were all military in nature. These approaches were codified in publications such as: TM 5-855-1[4] "Design and Analysis of Hardened Structures to Conventional Weapon Effects" and TM 5-1300[5] "Structures to Resist the Effects of Accidental Explosions." Following the 1983 terrorist attack in Lebanon, the US government developed new rules for the blast resistant design of embassies known as the Inman standards[6] calling for changes in design and siting. For new construction, these standards mandated a security setback

of 100 feet from streets, sites of 15 acres or more, locations far from downtown and reduced use of glass. The implementation of these design standards resulted in the construction of imposing walled compounds such as the embassy in Santiago shown in Figure 2.

Another defining event was the destruction of the Alfred P. Murrah Federal Building in Oklahoma City, Oklahoma in 1995, Figure 3. About 5000 pounds of ammonium nitrate fertilizer, nitro-methane and diesel fuel was detonated in front of the building killing 168 people. This incident remains the deadliest act of domestic terrorism in American history. At this point, the U.S. General Services Administration embarked on a building security technology program to develop the policy and requirements for building security used in the design and construction of GSA buildings. This still evolving effort has conducted explosive tests and developed design tools to assist design professionals.

Much of this information can be found in the Whole Building Design Guide[7] which is a program of the National Institute of Building Sciences that has been supported by federal agencies, private sector companies, non-profit organizations and educational institutions.

The attack on the World Trade Center in September 2001, Figure 4, refocused our society on the Importance of making buildings safe for the public that inhabits them. It also drew attention to our critical transportation infrastructure and with this attention a whole new set of challenges arose. The primary differences between the protection of buildings and protection of transportation infrastructure such as bridges and tunnels are related to the age of bridges and tunnels coupled with their essential function of moving people and goods. The engineer must work with century old structures where the threat, for example, a vehicle borne bomb, cannot easily be kept away from the structure as its essential function is to transport vehicles. The potential threat of large explosives coupled with small standoff distances, renders much of the military based design guidance inapplicable.

Figure 4: World Trade Center Site

Acknowledgements: Figure 4 is a public domain photograph from http://rst.gsfc.nana.gov/Sect4/Sect4_2.html

A key component to the work that has been done is full scale field testing. These tests go beyond the regimes that are encompassed in the military design manuals as the threats, structures and the fundamental behavior of these structures and components are not the same. Extensive testing has been done on steel and reinforced concrete columns, beams and connections as well as on windows and curtain wall systems. Testing has been done to develop structural designs and detailing that prevent disproportionate collapse as well as retrofit concepts for existing structures. Testing has been done to better understand air blast propagation in an urban environment and when the scaled range of the explosive is small. One lesson is clear, rational design cannot be accomplished through naïve application of the military design standards.

[7] The Whole Building Design Guide, http://www.wbdg.org/

The evolution of the work over the last quarter of a century has resulted in a better understanding of the response of structures and material to extreme loadings. This understanding is based on full scale testing and the enhancement and calibration of computational structural dynamics and computational fluid dynamics software. An experienced structural engineer can use the results of this software to accurately simulate the response of structures and together with the design team and owner communicate choices that effect rational and cost effective design that incorporate resiliency while advancing design excellence, Figure 5, where safety and security can be achieved without compromising the aesthetics and the airily appearance.

3. Bridge & Tunnel Security Against Terrorism Following 9/11

The events of 9/11 brought the threat of organized terrorism to the infrastructure as an issue of utmost importance to national security. While terrorism has been a growing issue around the world for several decades, 9/11 dispelled the general perception that it

was largely an issue contained to known troubled spots distributed around the world. It was the watershed moment, much like the San Fernando Valley Earthquake in 1971 that crystallized the nation's determination to do everything possible to protect the public safety, economic wellbeing and the critical infrastructure against the threat of terrorism.

While a considerable prior knowledge existed with respect to blast resistant design applications involving military buildings and other critical facilities as embassies, there are some challenges in applying these directly to the transportation infrastructure, especially to large bridges and tunnels that would constitute the primary targets of terrorist organizations. These differences include:

1. Access: Buildings can be provided with barricades, large stand-off distances and other access restrictions. However, general traffic has to be provided with free access to bridge and tunnel facilities. Further they contain chambers, doorways, platforms designed specifically to make access to the critical structural elements relatively easy.
2. Vintage: Existing transportation infrastructure consists of many large scale facilities designed and built at a time when man-made sabotage was not a major considerations. These facilities contain elements critical to their overall structural integrity within close proximity of the travelled roadway.
3. Criticality: Many of these facilities represent major links in and out of large cities and are critical elements of the transportation system and the economy. Many of the urban transportation networks do not contain either the capacity or the redundancy to handle an event that would put these links out of service.
4. Practicality: Strengthening existing structures against potential threats contain serious practical limitations. The practically implementable hardening on an existing facility is often effective only against the lower end of the spectrum of the possible threats, and many structures contain areas that are very difficult to be hardened.
5. Lead Time: There is a considerable time lag from when a critical facility is considered for risk mitigation to the actual implementation of the hardening measures. There is significant time associated with assessments, prioritization, identification and development of the hardening methodology, and the needed testing and verifications before their implementation.
6. Regeneration Cycle: Building facilities are renewed and/or replaced at a considerably faster rate than bridges and tunnels. Thus the integration of newer design standards within the building industry is easier and has a much shorter implementation cycle than possible with bridges or tunnels.

7. Resource Limitations: The large number of existing bridge and tunnel facilities of critical importance and the limitations of available funding require some prioritization based on a number of parameters, and only some of the facilities identifies as needing the hardening will receive the necessary resources within a given cycle funding.
8. Evolving Nature: Terrorism is an evolving hazard where the future conditions are uncertain and cannot be predict or quantified even on a probabilistic basis. The deterministic design of hardening measures assumes parameters that may not be representative of future threats conditions.

On the other hand, the operational approaches to terrorism risk mitigation are readily transferable to the context of transportation structures. These countermeasures consist of the so called 4D's championed by USACE; Deter-Deny-Detect-Defend by removing the means of inflicting damage by focusing on the human element essential to terrorism. This will be a central strategy to safeguarding the transportation infrastructure as long as terrorism remains a threat; and will be an inseparable part no matter how advanced the state-of-the-art in structural aspects of bridge and tunnel safety and security would become. These two compliments one another where advances in engineering in making facilities more robust would lead to more effective operational approaches by allowing a sharper focus on a narrower band of potential threats.

Responding to the new challenge, FHWA together with AASHTO appointed a Blue Ribbon Panel (BRP) on Bridge and Tunnel Security. It was commissioned to identify issues in Bridge & Tunnel Security and to formulate a roadmap for moving forward, The final BRP report was published in 2003 and this is one of the most significant formal documentation of the issues with recommendations on both short term and long term courses of action. The report includes a standardized methodology for prioritization and risk assessment of the existing facilities, provides some commonsense design measures based on available knowledge. The report also provides a listing of common vulnerabilities within the existing assets, some quantification of threat levels and recommendations for future research and development.

The risk assessment procedure outlined in the BRP (2003) is applicable to a transportation network as a whole (to identify and prioritize at the facility level) or to a given facility (to identify and prioritize at the element level). Since its original publication, this basic procedure has been adopted and refined by various owner organizations to suit the particular conditions. BRP condenses down some of the essential elements to a few tables and criteria (Tables 1, 2 and 3 reproduced below):

Table 1. Bridge and Tunnel Security Issues

Key Topics in Infrastructure Security	Specific Issues
1. Foundations for Policy	• Criteria Establishing Investment Priorities • Institutional Continuity
2. Planning, Design, and Engineering	• Design Review for Secure Structures • Research and Development (R&D) Needed to Support "Design for Security" • Design Criteria • Design Specifications
3. Management and Operational Practices	• Best Practices • Practice Review • Institutional Relationships • Preparedness • Personnel and Vehicle Security • Communication/Outreach
4. Information Security	• Procurement Practices • Information Security
5. Mobilization ("Notice") and Response ("Trans-event")	• Threat Warning • Early Response • Initial Response
6. Recovery (Post-event)	• Damage Assessment • Functional Continuity

Table 2. Critical Bridge Components

Suspension and Cable-Stayed Bridges	Truss Bridges	Arch Bridges
• Suspender ropes, stay cables • Tower leg • Main cable • Orthotropic steel deck • Reinforced and prestressed bridge decks • Cable saddle • Approach structures • Connections • Anchorage • Piers	• Suspended span hangers • Continuous and cantilever hold-down anchorages • Compression chords or diagonals • Connections • Decks • Piers	• Tension-tie • Connections • Decks • Piers **Multi-girder/Freeway Overpass Bridges** • Decks • Connections • Piers

The vulnerability mitigation is divided in to two basic parts:

A. Mitigating Threats:

- Establishing a secure perimeter using physical barriers – Deny (Access)
- Surveillance, CCTV, monitoring and enforcement – Detect (Presence)
- Visible presence of security and surveillance – Deter (Perpetrators)
- Minimize time on target – Defend (Removal of threat)

B. Mitigating Consequences:

- Provide stand-off distances from critical elements –
- Increase design redundancy –
- Structural hardening / strengthening of vulnerable key elements –
- Develop a rapid response and recovery plan –

Table 3. Magnitude of Threats

Threat Type	Largest Possible	Highest Probability
Conventional explosives	Truck*: 20,000 lbs Barge: 40,000 lbs	Car bomb*: 500 lbs
Collision to structure (i.e., the size of a vehicle that could collide with a structure)	Truck: 100,000 lbs GVW Water Vessel: depends on waterway	Truck: H-15 Water Vessel: (see AASHTO spec. LRFD on vessel impact)
Fire	Largest existing fuel or propane tank Largest fuel vessel or tanker	Gasoline truck (3S-2) Fuel barge
Chemical/biological HAZMAT	These threats exist; however, the panel is not qualified to quantify them. Therefore, other experts should assess these threats in this way.	

* Largest possible conventional explosive – for a truck, based on largest truck bomb ever detonated internationally by a terrorist act. For a barge, based on the assumption that it is the largest explosive that could pass by unnoticed by current security at place at major waterways.

** The size of an explosive charge that can be concealed within the trunk of an automobile without being visually detected when inspecting the automobile.

As noted before these two complement one another and form essential components of implementing an effective security plan against terrorism. Under the leadership at the federal, state and other local agencies, considerable gains have been and are being made in implementing the identified strategies; using the protocols and the general approach outlined in BRP. Many structures have been hardened by implementation of a range of measures that protect the most vulnerable elements.

Further, some early steps have been taken in making improvements to new structures starting from the planning process. This is very critical due to following reasons; The logistical complexity, practicality and the cost involved in Mitigating Threats (Part A above) would be somewhat similar whether the facility is existing or new. So addition of these as an afterthought, while not preferable, is possible. However, there are considerable differences in the logistical complexity, practicality and the cost of Mitigating Consequences (Part B above) depending on whether the facility is an existing one or one being planned. This is due to the following:

- Many existing facilities designed and built without security as a consideration contain critical structural elements placed immediately adjacent to the roadway. Providing stand-off distances after the fact would mean restricting the travelled roadway, which often is not often possible.
- Increasing design redundancy with respect to many of the key vulnerabilities listed in BRP Table 2 on an existing bridge is typically neither practical nor economically viable[8].
- The structural hardening, especially in the light of the above, is very expensive and even then can typically be accomplished for relatively low magnitude threats noted as Highest Probability Threats in Table 3 of BRP.

Thus, examining options for enhancing safety and security must be started right from the planning and the conceptual stages as changes aimed at mitigating consequences are difficult to be implemented as a later addition.

4. Capturing The Full Potential in Bridge & Tunnel Security

Many of the recommendations of the BRP are being implemented to mitigate the risk of terrorism to select facilities from the nations' most vulnerable transportation structures. However, more work remains to be done if the maximum long-term benefits were to be gained in the most cost effective manner. As noted before, in combination with other measures, structural hardening of existing facilities (within the constraints of practical viability) remains the best option available in safeguarding public safety and public investment. However, some difficulties remain:

- Structural hardening to mitigate system vulnerabilities (Table 2) in existing structures against even the probable threat levels sometimes prove difficult
- Structural hardening for largest possible threat levels (Table 3) for many existing facilities remains elusive and a practical impossibility.
- Structural improvements may be more practical during major rehabilitations of existing structures but this require planning on a case-by-case basis, there is potential for developing a formal approach to make this happen.

[8] While there are some parallels in seismic hazard mitigation (of the past) and the process of improving bridge and tunnel safety and security, there are also some key differences. The modifications to existing bridges and tunnels needed for seismic upgrading are typically localized to bearings, and key members in the vicinity of supports. The scope of structural changes are much broader in improving safety & security

- As seen by such recent examples as I-35 collapse and the I-90 tunnel ceiling collapse, effective bridge and tunnel safety and security must go beyond terrorism and consider resiliency to a multitude of hazards in the formation of structural solutions (multi-hazard resiliency)

As we move forward, innovation towards creating economical, elegant transportation structures with considerably higher safety and security standards must remain our goal. This however requires and making some fundamental improvements to the design process to enable the newly constructed structures meet not only the challenges of today, but also some allowance for the unknowns tomorrow could bring.

While many aspects of the BRP report has come to fruition with the leadership of public agencies at all levels, one area with significant potential not yet fully explored remain the development of more resilient structures through innovations in design approaches, analysis capabilities and materials application. This area remains one of considerable potential. In general, the current state-of-the-art in bridge and tunnel security is perhaps comparable to early to mid stages of the seismic risk mitigation initiative. It has been demonstrated that there is considerable room for further innovation quite within reach to provide considerably safer, yet economical and elegant structures designed with multi-hazard resiliency as a central functional requirement (Kumarasena, 2008).

ABSTRACT

It has been roughly three decades of utility-scale wind farm development in the US without much clear guidance for the design and permitting of these structures. However, since late 2009 an effort has been underway to develop a US Recommended Practice for the design and permitting of wind energy structures. This task has been undertaken by a joint committee of the American Wind Energy Association (AWEA) and the American Society of Civil Engineers (ASCE).

While the stated goal of a practical design guideline for Code compliance is straightforward, technical challenges and unresolved issues have been encountered during the Recommended Practice's development process. This paper describes several of those technical issues including the following:

- Reconciling the regulatory requirements of American Code versus those of International and European wind industry commercial certification.
- Reconciling the fatigue provisions of Eurocode and AISC.
- Reconciling extreme wind speed profiles of ASCE and International Wind Turbine Standards
- Establishing Code-compliant seismic design parameters and procedures for the combination of earthquake plus turbine operational loads.
- Handling specialized design procedures used in the wind industry that are based on foreign reference documents that have not been translated into the English language.

This paper discusses possible solutions and the ongoing efforts to resolve these technical issues. The paper also makes suggestions for needed research and calls for dedicated U.S. national leadership focused in shaping an industry that is known for producing safe and reliable structures that produce alternative and cost-effective energy.

INTRODUCTION

Codes and standards. In the US, there are currently no dedicated design standards or guidelines for wind farm towers, even after more than thirty years of utility-scale development of domestic wind farms. Development of recommended practices for wind turbine support structures is currently under way by committees supported by industry groups such as the American Wind Energy Association (AWEA) and the American Society of Civil Engineers (ASCE). The draft document is titled *Recommended Practices for Compliance of Large Wind Turbine Support Structures* (AWEA/ASCE, 2010). The document is being developed by the Structures Project Team under AWEA's Large Wind Turbine Compliance Guideline Committee in conjunction with the Wind Energy Structures (WES) subcommittee under ASCE's Structural Wind Engineering Committee (SWEC). This paper discusses some of the technical challenges specifically related to tower design and permitting faced by the Tower Subgroup (hereunder "the committee") within the Structures Project Team.

A recognized document of design recommendations would result in some obvious benefits to the structural engineering design and permitting process by establishing the following (Agbayani, 2010):

- A minimum baseline for tower designs and a more uniform level of design safety and quality.
- A consistent and "level playing field" for engineers engaged in tower design by helping to define the extent of required work.
- A consistent criteria for tower design plan review among US building department jurisdictions, resulting in more uniform and streamlined structural permitting.
- A common frame for engineers to communicate terminology and conventions.

Wind Tower Structural Systems. A typical wind turbine generator system (WTGS) configuration consists of a three-blade horizontal-axis wind turbine mounted on top of a steel tower. Figure 1 shows typical lattice and tubular tower structures. The lattice towers were used predominantly in the early days (early 1980's) of the US wind industry. However, in the last decade, the utility-scale wind industry has transitioned to almost exclusive use of tubular towers that routinely reach heights of 80 m (Agbayani, 2009). The tubular tower is a thin-shell steel structure. It is a fabricated tube consisting of slightly tapered truncated cone segments called "cans." Can segments are welded together to form the longer tubular sections of the tower mast. Cans are formed from sheets of flat steel plate. Since the fabricated tube tower is the current staple of the utility-scale wind industry, the initial draft of the tower design recommendations addresses only tubular towers and no other structure type.

European Certification. The commercial wind turbine industry evolved in Europe, and European wind turbine manufacturers continue to dominate the global market. Even the newer generation of Asian turbine manufacturers complies with existing European standards. For this reason, European wind industry standards, such as the

IEC and Eurocode (or EN) standards, are the basis for most wind tower designs. Wind turbines and towers are certified (i.e., validated and plan checked) by a handful of certification agencies, such as Germanischer Lloyd (GL), Det Norsk Veritas (DNV) and the American Bureau of Shipping (ABS). Certification is achieved by demonstrating design compliance with International Electrotechnical Commission (IEC) standards such as IEC 61400-1 (IEC, 2003), agency-specific standards, e.g., *GL Rules* (GL, 2003), or a combination of both. Certification agency rules in turn reference Eurocode design standards such as EN 1993-1-6 (EC3-6, 2007) for thin shell steel strength design and EN 1993-1-9 for fatigue design. Achieving certification is the industry standard for establishing the commercial legitimacy of a turbine-tower system in a way that is analogous to a UL listing for an electronic device or to an ICC Evaluation Service test report for a structural product. The absence of such documentation would make a product appear suspect and less marketable compared to its certified competitors. Moreover, certification is often a condition of financing for utility-scale wind farm projects (Agbayani, 2008).

Figure 1. Typical lattice towers (left) and tubular towers (right). (Photographs courtesy of MSKA.) (Agbayani, 2009)

TECHNICAL CHALLENGES AND UNRESOLVED ISSUES

Several technical issues have been encountered during the development of the tower structural design best practices recommendations. While some issues have been resolved, others remain unresolved, and further research may be necessary in some cases. These issues are discussed in the following sections.

Reconciling Regulatory Code Requirements and Commercial Certification. The design basis for most utility-scale wind farm towers are the design criteria (typically based on the Eurocodes and IEC standards) provided in certification agency rules. However, regulatory requirements for structural permitting center around building code compliance, specifically with the International Building Code (IBC, 2006) and ASCE 7 (ASCE, 2005) in most of the US.

Key to reconciling the commercial and regulatory requirements is the recognition that the certification agency rules and IEC standards are very specialized for the design of wind farm towers. The building code, on the other hand, is not specialized for wind farm towers. That said, the committee at this point in time is recommending the following best practices:

1. **Design basis.** For the purpose of complete structural design, certification agency rules may serve as the most thorough design basis for the design of wind farm towers at the present time. The building code by itself is a "blunt instrument" that, although well-developed for conventional building structure design, lacks the precision and detail to be a wind turbine tower design basis.
2. **Design capacity (resistance).** For the purpose of plan review for code compliance, the most straightforward strategy may be to use the capacity equations found in US steel stack standards such as ASME STS-1 *Steel Stacks* (ASME, 2006) and the Troitsky textbook on steel stack design (Troitsky, 1990), recognizing that the thin-shell steel stack is the closest structural "cousin" to the fabricated-tube tower. This standard and reference have been used successfully for wind tower design for many years. Also, direct comparison to European tower design calculations indicates reasonable agreement in calculated design capacity. For these reasons, the current draft of the committee's design recommendations contains design strength equations derived from these sources. An excerpt of the local buckling strength equations is shown in Figure 2. Use of the American Institute of Steel Construction (AISC) specifications (AISC, 2005) would have provided a familiar design reference for the comfort of most plan reviewers, but unfortunately, the AISC provisions limit the applicability of its equations only to manufactured tubing (e.g., HSS and pipe sections), and no guidance is given in the high slenderness range encountered in thin shells.

$F_n = F_{cr}$
$\phi_c = 0.90$
Slenderness parameters:

$\lambda = D/t$ where D is the outside diameter of the tower shell and t is the shell thickness.
$\lambda_1 = 0.11E/F_y$
$\lambda_2 = 0.357E/F_y$
λ_{MAX} = No maximum value is specified, but it is rare in most practical tube towers to find slenderness values in excess of 330.
For $\lambda \leq \lambda_1$
F_{cr} should be the smaller of the following:
$F_{cr} = F_y$
F_{cr} due to flexural buckling calculated in accordance with "stepped column" procedures.
For $\lambda_1 < \lambda_p \leq \lambda_2$
$F_{cr} = QF_y$
where $Q = 0.038E/[F_y (D/t)] + 2/3$
For $\lambda_2 > \lambda <= \lambda_{MAX}$
$F_{cr} = 8000/(D/t)$

Figure 2. Excerpt from (AWEA/ASCE, 2010) showing local buckling strength equations.

3. **Design loading.** For the purpose of plan review for code compliance, the most straightforward strategies may be the following:
    a. Fatigue. See the section below titled "Reconciling the Fatigue Provisions of Eurocode and AISC."
    b. Extreme wind. See the section below titled "Reconciling the Wind Provisions of Code versus Wind Industry Standards."
    c. Earthquake. See the discussion below titled "Seismic Design Criteria."

Reconciling the Fatigue Provisions of Eurocode and AISC. Fatigue calculations may govern structural design, so they should be part of the plan review submittal. Typical wind industry design practice for fatigue is to use EN 1993-1-9 modified with safety factors from IEC 61400-1. The most direct reference standard for fatigue design would be the AISC (or AWS) fatigue provisions. Direct comparison of the most commonly used fatigue detail categories and fatigue S-N curves indicates that the European approach to fatigue design is more conservative than that of the AISC fatigue provisions. A comparison of S-N curves from Eurocode and AISC is shown in Figure 3 for normal stress in a typical girth weld of a tubular tower. Effort is ongoing to determine the reason for the differences.

In the meantime, the committee's current recommendation is simply that the tower fatigue design should be compatible with the turbine's commercial certification. Since the AISC provisions have the authority of a code reference standard, baseline Code compliance of the more conservative EN provisions would be easy to show. However, for use as a design basis, the committee cautions against using less conservative fatigue design provisions to effectively undercut the design safety of the commercial certification.

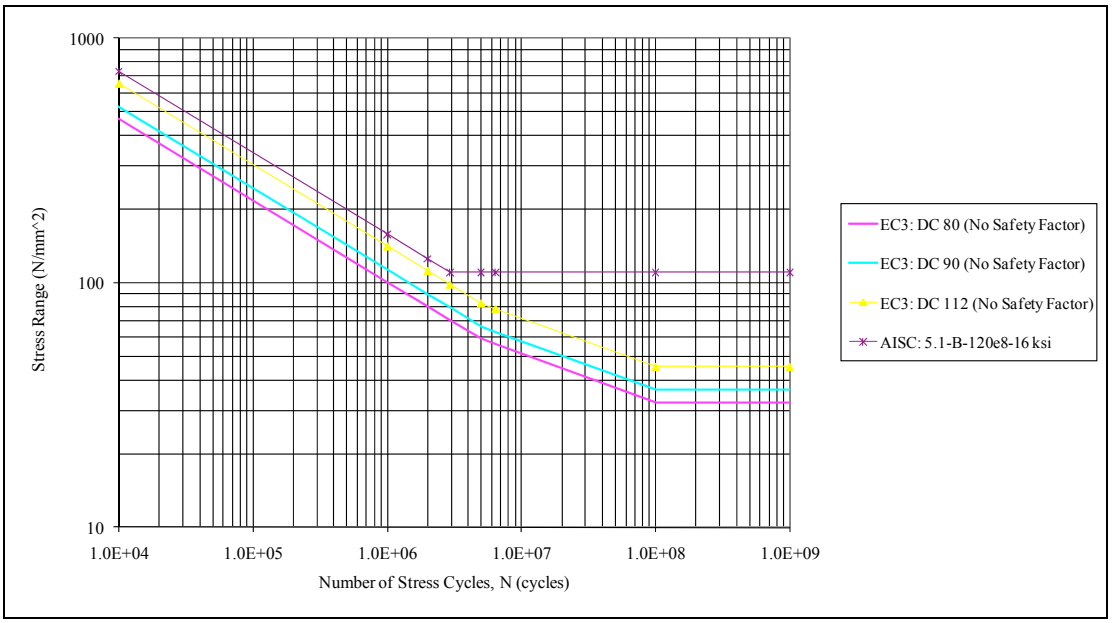

Figure 3. Comparison of Eurocode and AISC S-N curves for CJP girth welds.

Reconciling the Wind Provisions of Code versus Wind Industry Standards. In order to show code compliance for plan review purposes, the task would be to show that the IEC Site Class rating meets the Code wind requirements. However, some key differences should be observed. The tower wind design loads are based on IEC 61400-1 (IEC, 2003), and the IEC loads are obtained from a complex time series software simulation with a turbulent wind model by the turbine manufacturer's load department. It is reasonable to assume that most building departments do not have this software/analytical capability. Also, much of the turbine modeling information is proprietary and therefore not amenable to plan review scrutiny. The more straightforward and feasible strategy is to show that the IEC wind loads envelope the Code wind loading requirements.

The ASCE 7-05 design wind closely matches the definition of IEC design load case (DLC) 6.1:

- The IEC wind load factor of 1.35 is approximately similar to the ASCE wind load factor of 1.6 multiplied by a K_d (directionality factor) value of 0.95.
- Standard air density values of 1.225 kg/m^3 are equal.
- Both specify a reference wind speed defined as a 3-second, 50-year wind. Reference heights are different (10 m and hub height for ASCE 7 and IEC, respectively) but can be reconciled. The IEC velocity profile power law exponent is 0.11. At Exposure C, the exponent based on the square root of K_z is 0.105, which is approximately equal to 0.11.
- IEC application of load is within 15 degrees of the front of rotor, which is consistent with ASCE 7's projected area (0 degrees) application.

For these reasons, the committee has recommended that the IEC DLC 6.1 can be offered to the plan reviewer as the "Code compliance" wind load case on the basis of the matching wind definition. Moreover, it should be observed that other DLCs can sometimes provide larger magnitude design loads than DLC 6.1. Such cases illustrate the shortcoming of the Code wind provisions to completely assess the governing load case for wind tower design.

Seismic Design Criteria. Numerous utility-scale wind farms in the US are sited in seismically active regions. Wind farm sites by their very nature are located in regions of sustained moderate to high wind speeds and therefore the likelihood of an earthquake occurring simultaneously with typically expected wind conditions needs to be considered in design. However, ASCE 7 (ASCE, 2005) design load combinations do not consider a case with simultaneous wind and earthquake loading. For buildings the probability of a design level wind and seismic event occurring simultaneously is sufficiently low that the committee responsible for ASCE 7 felt a combined wind and earthquake load case is not required. The same cannot be said for wind energy structures and the committee has proposed best practices combined wind and seismic load combinations.

Seismic Ground Motion Values. Seismic ground motion values for tower and foundation design should be determined using the ASCE 7 procedure, except that spectral response acceleration parameters should be adjusted to 1% damped values per IEC 61400-1 Annex C instead of 5% damping as typically assumed in building design. A multiplicative adjustment factor equal to 1.4 should be used to adjust spectral response acceleration, S_a, from 5% to 1% damped values. Future research and instrumentation of WES may justify use of larger damping values.

Performance Objective. Wind farms are not capable of providing continuous electrical power due to the varying nature of wind and therefore the committee felt that they do not qualify as an Occupancy Category III structure per ASCE 7. An importance factor equal to 1.0 (Occupancy Category II) is typically used for tower and foundation design unless a higher importance factor is required due to the occupancy category of an adjacent structure.

Building code seismic design requirements do not ensure that structures will remain operational after a design level earthquake. Similarly, a wind turbine support structure designed using *Recommended Practices for Compliance of Large Wind Turbine Support Structures* may be damaged during an earthquake beyond a level that is economically repairable or the turbine components may be damaged by the earthquake induced shaking. However, wind energy is becoming an increasingly important contributor to total electricity production. Therefore, the operability of a wind farm after a seismic event may be important to recovery of the affected region.

Enhanced performance objectives, such as operational performance after a design level earthquake, may be established to meet specific owner requirements. However, a clear distinction should be made between the required minimum performance objective of the *local building code* (life-safety) versus that of any supplementary, project-specific contractual agreements. A performance factor (similar to an importance factor of 1.5 for essential facilities) may be established to improve expected earthquake response. A major consideration in establishing this performance factor is coordinating with the wind turbine manufacture to establish acceleration thresholds for turbine components that will ensure operational performance (e.g. operational performance if nacelle acceleration during an earthquake is limited to 2.0g). Using advanced analysis techniques and the established nacelle acceleration limits the Engineers can evaluate support structure options that will achieve these improved performance goals.

Seismic Load Combinations. By the very nature of their function wind turbines have a reasonable likelihood of being in an operational state during an earthquake and may also be subjected to simultaneous earthquake and emergency stop loads if a shutdown is triggered by the earthquake. ASCE 7 seismic load combinations do not include consideration of concurrent earthquake and turbine operational loads. It is of critical importance to recognize that seismic plus operational loads may in some cases govern tower and foundation design. Therefore, the committee recommends the evaluation of seismic plus operational load combinations, regardless of the absence of a codified

requirement. Figure 4 shows recommended best practices load combinations including seismic plus operational loads that should be considered in addition to ASCE 7 prescribed load combinations. Note that for these recommended load combinations the minimum specified value of the seismic response coefficient, C_s, per ASCE 7 Equations. 15.4-1 and 15.4-2 should not apply. These load combinations are based on recommendations of IEC 61400-1 Annex C and Eurocode 8 standards that do not contain a similar minimum value for the seismic response coefficient. Operational and earthquake loads should be combined as an absolute sum. Alternatively, other methods may be used to combine operational and earthquake loads provided that they are justified by rational engineering analysis.

Seismic Load Combination:

$$U = (1.2 + 0.2S_{DS})D + \rho Q_E + 1.0M$$

$$U = (0.9 - 0.2S_{DS})D + \rho Q_E + 1.0M$$

where,

M = operational loading equal to the greater of: 1) loads during normal power production at the rated wind speed; or 2) characteristic loads calculated for an emergency stop at rated wind speed.

ρ = 1.0, redundancy factor (for nonbuilding structures not similar to buildings ρ = 1.0 per ASCE 7 Chapter 12.3.4.1).

All other variables are as defined in ASCE 7 Sections 2, 11, 12, and 15.

Figure 4. Excerpt from (AWEA/ASCE, 2010) showing seismic load combination equations.

Analysis Procedures. Any analysis procedure (equivalent lateral force, modal response spectrum analysis, or response history analysis) permitted by the local building code is acceptable for use with the *Recommended Practice*.

If the equivalent lateral force procedure is used, the vertical distribution of seismic forces should be calculated based on the procedure given in ASCE 7 Chapter 12.8.3 with the following recommended modification. The effective seismic weight of the nacelle and rotor should be assumed to be located at the turbine's center of gravity, and the effective seismic weight of the tower structure (including ladders, platforms, railings, etc.) should be distributed to nodes located at tower can joints. Seismic forces should also be assumed to act at these locations.

ASCE 7 Table 15.4-2 presents response modification factors, R, for various nonbuilding structures not similar to buildings, but does not explicitly include wind turbine support structures. For evaluation of structures sensitive to buckling failure (typically one of the primary failure modes for tube towers) ASCE 7 Chapter

15.7.10.5 implies a value of R equal to 1.0. The committee recommended use of R equal to 1.0 unless a larger value is justified by rational engineering analysis that is reviewed and accepted by the Engineer of Record.

In practice, often only the peak seismic loads and peak operational loads are available. As a result, the combination of operational and seismic loads with an absolute sum procedure may be an overly conservative approach, especially considering that the respective peak loads do not occur at the same instant of time and in the same loading direction. Seismic response history analysis considering time varying earthquake ground acceleration and operational or emergency stop loads can be used to more accurately predict response and reduce potential design conservatism. Seismic response history analysis procedures should conform with the requirements of ASCE 7 Chapter 16. The committee recommends that any such analysis be conducted with analysis software capable of simulating both structural response and global turbine dynamics, including aerodynamic interaction. Future research is recommended to establish probability-based load factors for the wind plus seismic load combination, using techniques similar to those used in development of the ASCE 7 load combinations.

Specialized Design Procedures. There are several design procedures for the tower and tower components that are routinely implemented in design according to certification agency rules. Unfortunately, these design procedures have no available parallel in US reference standards. Examples of specialized design procedures include the following:

1. Special finite element analysis (FEA)
    a. Top flange eccentricity analysis. The top flange of the tower may be eccentrically loaded by the yaw bearing of the wind turbine. Involvement of the yaw bearing requires a complex nonlinear FEA of a mechanical engineering nature, not often encountered in civil engineering analysis: non-standard or exotic materials; ball bearing; nonlinear gap and contact elements; and pretensioned bolted connection. The committee approached this issue by describing this analysis and providing references to several European papers on the topic. Owing to complexity, there was no attempt to provide a design basis at this time.
    b. Hotspot analysis at shell penetrations. No US reference standards found in the Code give any guidance on this topic. For this reason, the committee felt it most effective at this time to provide reference to the International Institute of Welding (IIW) standards (IIW, 2003) that provide a thorough description of the hotspot analysis method using FEA techniques.
    c. Nonlinear buckling and pushover analysis. No US reference standards found in the Code give any guidance on this topic specifically applied to wind farm towers. For this reason and the complexity of the FEA, the committee felt it most effective at this time to provide a reference to the GMNIA analysis method (i.e., geometric and material nonlinear analysis with imperfections) as found in EN 1993-1-6 (EC3-6, 2007).

2. Bolted splice flange design. No US reference standards found in the Code give any guidance on this topic. FEA is an acceptable method for flange analysis, but unnecessarily difficult in light of simpler manual design methods available in European references. For this reason, the committee felt it most effective at this time to provide references to European papers on this topic. Since some of the reference papers are not in English language, future efforts by the committee may be a comprehensive English-language technical review of the various flange design methods.

CONCLUSION

There are no dedicated design standards or guidelines for wind farm towers in the US. This paper presented technical challenges encountered by the committee in developing best practices recommendations for wind tower structural design. Solutions to code compliance issues and also recommendations for further research and study have been discussed.

ABSTRACT

It is not unusual in petrochemical plants for two adjacent nonbuilding structures to be connected together by large diameter pipe. Common examples of these nonbuilding structures include pipe racks, equipment modules, and heat exchanger structures. Typically, these structures are modeled separately from each other without considering the effects due to large diameter pipe connected to adjacent structures. The pipe is typically modeled and analyzed independent of the nonbuilding structures by considering the equipment as anchor points and the supporting structures as supports, guides or anchor points. This method of modeling nonbuilding structures connected by large diameter pipe is acceptable for static loads; however, the results can become very misleading when applied to earthquake loads. It is even more difficult to rationally apply the effects seismic displacements to these independent models. In this paper three methods of seismic analysis and corresponding results are presented using a simplified 2-D example of two nonbuilding structures connected by a large diameter pipe. The first method uses the traditional method of analyzing the two structures independently and accounting for loads due to seismic displacements from an independent pipe model. The second method utilizes a combined model which includes two nonbuilding structures connected by a large diameter pipe. The seismic load is applied statically to the structures. The third method utilizes the same combined model as the second method with analysis done using Response Spectra Analysis. The results of each method are graphically compared. The paper also includes the results and conclusions drawn from the methods which were investigated.

INTRODUCTION

Petrochemical nonbuilding structures, such as pipe racks, equipment structures, and equipment modules, are typically analyzed and designed using an independent model for each nonbuilding structure and piping system. These models do not consider the size and quantity of pipe interconnecting the adjacent nonbuilding structures. There are many advantages to using these independent models to analyze a nonbuilding structure. The independent model allows the engineer to focus on the

loads that are tributary to that structure alone. The analysis and design is broken down into simple discrete models that can be worked on independently. This work process is sufficient for configurations where there is no potential for lateral load transfer. An example of this would be two adjacent nonbuilding structures connected with small diameter pipe with flexible configurations. Lateral load transfer is likely to occur in cases where two or more nonbuilding structures are connected by large diameter pipe (typically larger than 12 inch diameter) in relatively inflexible configurations. An example of a case where lateral load transfer can occur is shown in Figure 1. This paper provides proposed guidelines for analyzing nonbuilding connected by large diameter pipe.

The design of nonbuilding structures with potential to transfer lateral loads should be approached differently than nonbuilding structures with no mechanism to transfer lateral loads between the structures. In order to transfer lateral loads a mechanism is required that acts like a collector element or drag strut such as a pipe rack strut or a connected large diameter pipe.

The following sections examine methods for analyzing seismic loads on nonbuilding structures connected by large diameter pipe. Example problems of each method are presented and the results are graphed and compared.

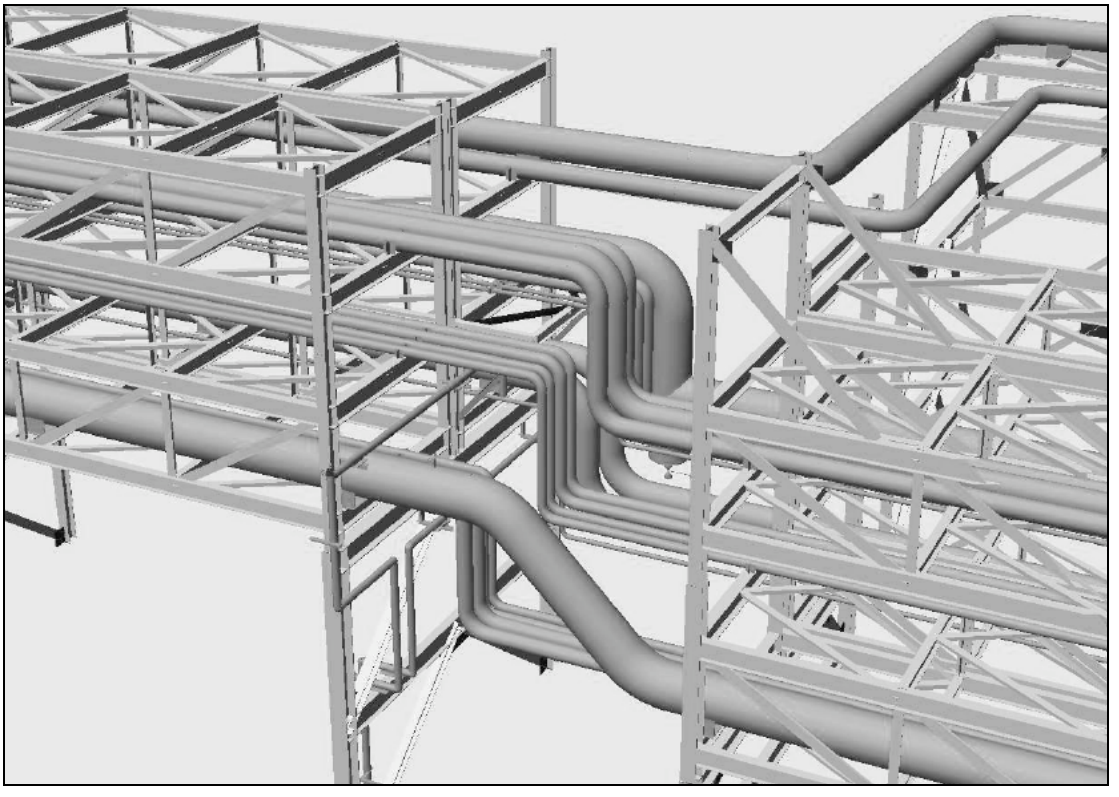

FIGURE 1: Nonbuilding Structures Connected by Large Diameter Pipe

Challenges of Seismic Analysis Nonbuilding Structures connected by Large Diameter Pipe

It is clear that there is advantage to modeling nonbuilding structures independently for cases where there is no significant lateral load transfer to adjacent structures. When substantial lateral load transfer is involved the amount of lateral load retained by an independent model is difficult to predict without also considering the stiffness and natural periods of adjacent connected structures. Considerations of seismic displacements also become problematic for an independent model of a structure that is connected by large diameter/stiff pipe to adjacent structures.

Earthquake load distribution is significantly impacted by the stiffness of the connected elements and the natural frequency of the adjacent connected structures. Industry practice is to model individual structures independently. The method of analysis is typically either Equivalent Lateral Force Procedure (ELFP) or Response Spectra Analysis (RSA). ELFP is more commonly used for simple, regular structures. Direct application of the ASCE 7 [ASCE 2005], ELFP to predict seismic shear transfer between nonbuilding structures presents several challenges, such as shear transfer and seismic displacements.

The concept of amplified seismic displacements cannot directly be applied to a independently modeled structures due to the amount of interconnecting pipe that adds stiffness to the overall system and transfers shear from one structure to another. When planning the model of connected nonbuilding structures consideration should be given to the mechanism connecting the structures. For example, if there are struts connecting the structures then they should be designed as collector elements and modeled to capture the seismic shear transfer. If there is pipe between the two structures then the flexibility of the pipe and its connection to the structures should be considered. If the pipe is not anchored or guided and allowed to slide on one structure then the friction force should be the largest force considered for effects of the seismic displacements between the structures.

Directionality of load presents another challenge. When nonbuilding structures are resisting lateral loads due to earthquake there are many possibilities for the direction of loading relative to on another due to the differences in natural periods. At one moment the structures can be moving towards each other and the next moment they will be moving away from each other. When the structures are connected by a rigid/stiff element such as a large diameter pipe their responses to seismic loads are interconnected and complicated. Sometimes the worst case response is when the structures are moving in synchronicity.

Prior to the evolution of sophisticated structural analysis programs, structural analysis models were necessarily simplified to save computing effort. Thought was put into creating these models in order to take advantage of symmetry and model only members that were necessary for the distribution of loads. This has become a lost art since computing power and memory is no longer an issue. It is now relatively easy to create and run a large structural analysis model. Unfortunately, the methods of managing and summarizing the behavior of large complicated structural analysis models have not kept up with the computer advancements.

Methods are required that account for the complexity of interconnected structures and yet capture the overall behavior when subjected to seismic loads in a way that is

clear and concise. An independent model reflects the characteristics of one structure but does not capture the distribution of forces between adjacent structures. A combined model is capable of capturing the distribution of forces but may be too complicated to provide practical information about the behavior of the connected structures. In some cases the independent model may be more appropriate. Under other circumstances the combined model may be better suited. In order to apply these methods successfully guidelines should be developed to help the engineer choose the appropriate method of analysis. Oversimplified methods may lead to overly conservative results or incorrect results. Combining all interconnected structures into one large model can become an onerous and tedious method that would bog down the practicing engineer and introduce more chances of errors.

METHODS OF ANALYSIS AND EXAMPLE PROBLEM

Three methods were examined for modeling nonbuilding structures connected by large diameter pipes. In order to effectively and concisely compare these methods example problems consisting of simplified, two-dimensional plane frame models were used. Appendix 1 presents the basic example problem common to all methods and some of the parameters used in the analysis study. The example problem includes a large diameter pipe with an expansion loop. The pipe is assumed to be anchored to each structure. The seismic weight and stiffness remains constant for the strong frame for each method in all the load cases. The stiffness of the weak frame was varied in each of the load cases; however, the seismic weight remained the same as that of the strong frame. Thus the natural period ratio was varied by only varying the stiffness of the Weak Frame. Graphed comparisons of the three methods are shown in Appendix 2. There are graphs of seismic shear distribution between the frames for different natural period ratios of the strong frame to weak frame. Results of Methods A, B and C are presented in Appendix 3. The following sections outline each method that was evaluated.

METHOD A: INDEPENDENT MODELS THAT ACCOUNT FOR AMPLIFIED SEISMIC DISPLACEMENTS

This Method considers each nonbuilding structure as an independent model. The seismic displacements are calculated for each nonbuilding structures. The seismic displacements are amplified by the seismic displacement amplification factor, C_d, and applied to the corresponding piping systems in the independent piping models. The reaction forces in the piping models at anchors and guides are applied to the corresponding locations in the independent nonbuilding structure models.

Unlike a combined model, the independent models require analysis in steps. The following steps (shown graphically in Figure 3) are typically used for seismic evaluation of independently modeled nonbuilding structures connected by large diameter pipes:

STEP 1: Independent nonbuilding structure models are analyzed for seismic loads caused by tributary seismic weight (V_{SS} and V_{SW}). Deflections due to seismic loads are calculated.

STEP 2: Independent models of the interconnecting pipe are analyzed for the amplified seismic displacements. Reaction forces (V_{DS} and V_{DW}) due to the induced amplified seismic displacements are calculated.

STEP 3: Independent nonbuilding structure models are analyzed for the combined seismic shear, V_T, due to tributary seismic weight and due to reactions of the interconnecting pipe caused by seismic displacements.
($V_{TS} = V_{DS} + V_{SS}$ and $V_{TW} = V_{DW} + V_{SW}$)

The resulting sum total base shear for the nonbuilding structures is higher than the base shear calculated for the total seismic weight. In this method the force due to the deflection of the large diameter pipe adds seismic shear to both nonbuilding structures. In reality seismic shear should be transferred from one structure to another and no additional seismic shear should be created.

METHOD B: COMBINED MODEL WITH ELFP APPLIED SEISMIC FORCES

Method B uses a combined nonbuilding structure model and the ASCE 7, ELFP for evaluating seismic loads. Several load cases are used in this method to capture the behavior of the structures. Seismic loads are applied in different directions in order to determine the worst combination of seismic shear for each of the connected nonbuilding structures.

The Strong Frame and the Weak Frame are modeled together with loading and boundary conditions such that only two dimensional behavior is observed. The models of the two frames are connected by a pipe loop which is pinned to each structure to model a combined pipe anchor and pipe guide.

Figure 4 graphically shows the load cases evaluated for the example problem using this method. The example problem has been simplified to include only two connected nonbuilding structures and two possible directions of seismic loading for each structure. The number load cases become significantly larger for cases where there are more than two connected structures and cases of orthogonal seismic loading. The limitations of this method are the same as those of the ELFP as described in FEMA 450, Section 5.2.3. In the ELF procedure, the distribution is based on simplified formulas that are appropriate for regular structures as specified in FEMA 450 [FEMA 2003] and ASCE 7 [ASCE 2005]. The ELFP is adequate for most regular structures; however, the ELFP may be inadequate in the following cases:

1. Structures with irregular vertical distribution of strength in the different levels of the structure. This may lead to possible concentration of ductility demand in a few levels of the structure.

2. Structures with irregular stiffness and mass and properties in which case the simple equations for vertical distribution of lateral forces may lead to incorrect results.

3. Structures in which the torsional motion and the lateral motions in two orthogonal directions are strongly coupled.

When these conditions occur a more thorough procedure that considers the dynamic behavior of the structure should be used.

METHOD C: COMBINED MODEL WITH SEISMIC LOADS EVALUATED USING RESPONSE SPECTRA ANALYSIS

Response Spectra Analysis is a common method of modal analysis used to analyze seismic loads on a structure. In this method the natural periods and associated mode shapes are evaluated for a specified seismic dead weight and structural stiffness. Mass participations factors are evaluated for each mode shape based upon the mass and stiffness distribution of the structure. The weighted response of each mode is calculated using the mass participation factors. These responses are added together using a process called modal superposition to determine the overall response of the structure. More background information regarding RSA can be found in dynamic analysis textbooks [Paz 1991] and [Craig 1981].

In the Response Spectra Analysis procedure, the distribution of seismic forces over the height of the structure is based on properties of the natural vibration modes, which are determined from the mass and stiffness distribution.

The results for Response Spectra Analysis were obtained using a commercially available structural analysis software called RISA-3D [RISA (2010)]. Figure 5 shows the dominant mode shapes for the example problem.

The Strong Frame and the Weak Frame are modeled together with loading and boundary conditions such that only two dimensional behavior is observed. The models of the two frames are connected by a pipe loop which is pinned to each structure to model a combined pipe anchor and pipe guide.

COMPARISON OF METHODS

Appendix 3 provides graphs of shear distribution using the three methods presented herein. Figures 6, 7, and 8, show the base shear distribution verse natural period ratio of the weak frame to the strong frame (T_{weak} / T_{strong}) for Methods A, B and C, respectively. Figure 9 shows a comparison of total seismic base shear for each method as it varies with natural period ratio.

In industry practice, a version of Method A “Independent Model Method” is most commonly used for analysis of nonbuilding structures with large diameter pipes. Method A; however, does not accurately model the distribution of seismic shear throughout the system as the natural period ratio increases. Although Method A is simpler than the combined models, the results become increasingly conservative as the seismic displacements and the natural period ratios increase. The reason why Method A yields higher base shear at larger natural period ratios is because the seismic displacements are larger at the Weak Frame. The larger seismic displacement causes a larger reaction for the pipe because the pipe is reacting against a forced displacement. The weaker the frame the more unrealistic this displacement becomes. Figure 10 shows a graph of seismic displacement ratio verses base shear. The trend in this graph is that as the seismic displacements increase the base shear increases.

The Method B: "ELFP Combined Model" is more complicated than the Method A: "Independent Model Method" and yields results that are very close or slightly more conservative than the Method C: "RSA Method" in ranges of the parameters examined in this paper.

Figure 9 shows a graph of the total base shear for all three methods with increasing natural period ratio. The downward trend in base shear in this graph is due to the natural period of the Weak Frame being in the constant spectral velocity range. This range yields a smaller base shear for the same amount of seismic weight.

In Figure 9, the graph results of Methods B and C are very similar; however, the results of Method A are more conservative for high natural period ratios and large seismic displacements. Figure 9 shows when the natural period ratio is close to unity ($T_{weak} / T_{strong} \approx 1$) and the seismic displacements are low then the independent model base shear distributions are similar to those of the combined models using ELFP and Response Spectra Analysis.

SUMMARY OF FINDINGS

The following is a summary of the findings based on the analysis and parameters studied in this paper:

1.) When using an independent model for each structure, it is difficult to accurately account for the interconnecting effects of nonbuilding structures connected by large diameter pipes. Independent models become less accurate as seismic displacements increase and natural period ratios between the connected structures become larger.

2.) Combined models of multiple nonbuilding structures can be very complicated and their use for defining the behavior of the structures can become limited. It is recommended that combined models be as simplified as possible in order to capture the load distribution and capture the essence of the structural behavior.

3.) When considering the necessity of a combined model, compare the relative stiffness of the connected structures and their relative natural periods. Structures that are very flexible and have long natural periods may transfer their seismic shear to stiffer structures with short natural periods.

4.) When designing for the shear transfer from one structure to another, account for the additional shear transfer to the structure attracting additional seismic shear load, however, design the nonbuilding structure that is shedding seismic shear for its full tributary shear. This should be done in case something is modified to the structure attracting additional seismic shear loads or the connecting mechanisms.

5.) Consider structural strut beams between structures that are connected by larger diameter pipes. This will force the structural behavior in a more controlled manner because the struts and their connections can be analyzed and designed for the load they transfer.

6.) The geometry of the interconnecting pipes may cause torsional loads on the structure or equipment nozzles which may not be captured in the independent models.

7.) Foundation mounted equipment or equipment supported on other nonbuilding structures may receive the interconnecting piping loads. It is important that the allowable nozzle loads on the equipment are not exceeded by loads from interconnecting pipes and the effects of seismic displacements. If this is the case then other mechanisms for seismic shear distribution should be investigated.

ACKNOWLEGEMENT
The authors would like to acknowledge the valued input from Josh Plummer, SE with RISA Technologies and his review.

Abstract

This paper discusses the nonlinear analysis of a structural steel frame subjected to low level far field blast loads. Such blast loads are considered typical for buildings designed for petrochemical plants. The analysis involves the use of a beam and hinge model similar to what can be used for a nonlinear seismic design. An example frame, based on Chapter 12 of ASCE 2010, "Design of Blast-Resistant Buildings in Petrochemical Facilities", is analyzed. The resulting dynamic response is compared to a simpler SDOF equivalent analysis and a to more comprehensive nonlinear finite element analysis. For simple steel frames in typical petrochemical plant applications, the use of a nonlinear hinge model provides a reasonable level of accuracy.

Introduction

The need for, and use of, blast analysis in the petrochemical industry is common. To support this activity, owner and engineering companies have produced a number of internal specifications and practices for the design of blast resistant structures. The industry standards group Process Industry Practices has published two publicly available standards (PIP STC01018 and PIP ARS08390). The American Society of Civil Engineers has published guidelines suitable for petrochemical industry buildings (ASCE 2010). In these publications, and in common practice, the predominant blast design method is a member-by-member analysis using a single degree of freedom (SDOF) equivalent approach.

SDOF equivalent methods and member-by-member approaches are adequate for many structural elements; however the need arises for a "fit for purpose" method applicable to structural members and assemblies for which the response cannot be mathematically described in terms of a SDOF system, or where coupling effects between members will have a significant effect on the response. Moment resisting frames represent such an example because of the coupling of lateral and vertical modes and because a blast wave traveling along a roof beam will excite a number of higher beam modes. ASCE 2010 and UFC 3-340-02 describe SDOF equivalent methods as acceptable for preliminary frame analysis, but prescribe the use of multi degree of freedom (MDOF) methods for a final analysis. Additionally, ASCE 2010

recommends the use of a coupled analysis if the natural periods of connected members differ by less than a ratio (greater/lesser) of 2.

The term “fit for purpose”, perhaps itself a debatable subject, refers to an appropriate level of analysis for the overall parameters and requirements of the calculation. For petrochemical type buildings subjected to blast loading, the basis for using a simple, approximate approach is based on:

- The objective is to design a safe structure with reasonable conservative accuracy given time, budget, resource, and schedule constraints.

- The most common source of an explosion is from a vapor cloud, which involves an accidental release of fuel, mixture with air, and ignition. Estimates must be made of the volume of fuel released, the volume of fuel within the explosive fuel-air mix range, the ignition location, and the degree of congestion, and the direction to an occupied building. Vapor cloud explosions are typically evaluated using release scenarios, a dispersion analysis, and risk criteria (API RP 752, API RP 753).

- Empirical formulas are used to calculate the magnitude of blast loads on the surfaces of a building. The negative blast phase is almost always considered to be insignificant and conservative to neglect. The use of more comprehensive computational fluid dynamics methods are not considered warranted unless blast wave reflections from nearby obstructions is considered to be significant.

- Computed blast loads are almost always low level and far range. The blast wave is considered to envelope the entire building and the free field overpressure is considered to be constant over the dimensions of the building.

- The response limit criteria used, consisting of ductility ratios and support rotations, is simple to implement, however the limiting values are considered conservative.

An Engineering Level Frame Analysis (ELFA) is a descriptive label for this "fit for purpose" category. There are multiple ways to implement such an analysis. The use of computer programs with a nonlinear dynamic analysis capability will be needed. ASCE 2010 mentions the use of either a frame analysis (nonlinear hinges) or a finite element analysis (nonlinear material). ASCE 2010 also recommends use of the same limiting values of ductility ratio, support rotation, and drift as used for SDOF methods.

This paper focuses on the steel frame analysis example provided in Chapter 12 of ASCE 2010 (refer to Figure 1). To avoid showcasing one particular method or computer program over another, details of the computer program implementation are not provided in ASCE 2010, so this paper also serves to provide additional detail. The Chapter 12 example analysis was performed for the original 1997 edition of the ASCE report using STABLE, an implicit nonlinear frame analysis program written by the

US Army Corps of Engineers. This computer program is no longer in use. An ASCE Structures Congress presentation in 2001 (Barker 2001) re-created the Chapter 12 analysis using ADINA, an explicit nonlinear finite element program.

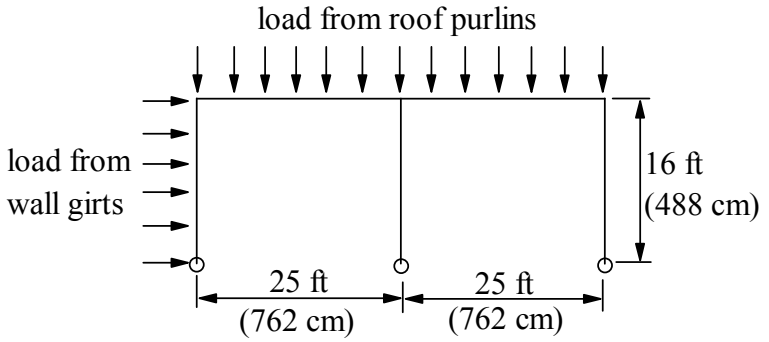

Figure 1: Steel Frame Example (ASCE 2010, Chapter 12)

This paper will examine a method of carrying out an ELFA paralleling the ASCE 2010 Chapter 12 example using a frame (nonlinear hinge) analysis. Comparisons will be made with a SDOF equivalent solution, and a more comprehensive finite element (nonlinear material) analysis.

MDOF (Nonlinear Hinge) Analysis

A MDOF analysis using beam elements is normally not thought of as a finite element analysis even though the computer program used is often the same. Programs for a beam and nonlinear hinge analysis must have the appropriate beam analysis capability using standard steel shapes, and nonlinear hinges. Programs commonly used for structural design may have included this capability for the purpose of a seismic analysis (ASCE 7, Chapter 16, or ASCE 41). The program used for this example is SAP2000 Advanced, version 14.2.0.

SAP2000 Advanced has a nonlinear direct integration capability. Nonlinear behavior is introduced by manually locating hinges on beam elements. There is no limit on the number of hinges or locations. The hinges can include the effects of interaction with axial forces and user-specified post-yield behavior. Significant advantages to this type of analysis are that the same 3D model can be used for static analysis and code checks; changes can quickly be made to member sizes, frame dimensions, and mesh criteria; and frame videos can be made with color coded hinge behavior.

MDOF (Nonlinear Hinge) Implementation

Blast loading for the ASCE 2010 Chapter 12 example was based on a provided free field blast wave (peak overpressure = 1.2 psi, positive phase duration = 50 ms). Using formulas provided in ASCE 2010 Chapter 3, frame loads were recalculated as shown in Figure 2. Rear wall rise time is calculated from ASCE 2010, Figure 3.10b.

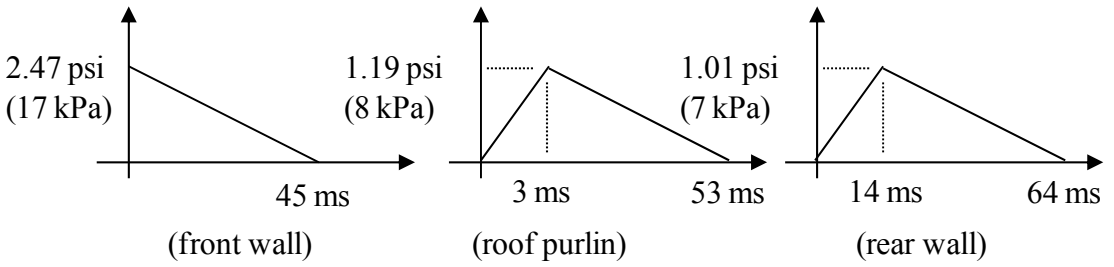

Figure 2, Frame Loading

The building has a width, perpendicular to the traveling blast wave, of 100 ft (30.5 m), length, parallel to blast wave travel, of 50 ft (15.2 m), and height of 16 ft (4.9 m). The moment resisting steel frames are oriented in the short, 50 ft (15.2 m) direction.

The externally applied blast pressures are applied to the frame at the location of each girt and purlin based on a tributary area approach. Each roof purlin supports a tributary width of 20 ft (6.1 m) and tributary length of 4 ft (1.2 m). Each wall girt supports a tributary width of 20 ft (6.1 m) and tributary height of 3 ft (0.9 m). Peak blast loads based on tributary area are 21.341 k (94.9 kN) for each front wall girt, 13.709 k (61.0 kN) for each roof purlin, and 8.726 k (38.8 kN) for each rear wall girt. Peak blast loads for more closely spaced end span girts and purlins were reduced accordingly.

The blast wave arrival time at each roof purlin was calculated using the blast wave speed of 1,169 ft/s (356 m/s) and applicable distance from the front building wall. The rear wall blast arrival time of 43 ms was calculated from the blast wave speed and 50 ft (15.2 m) building length.

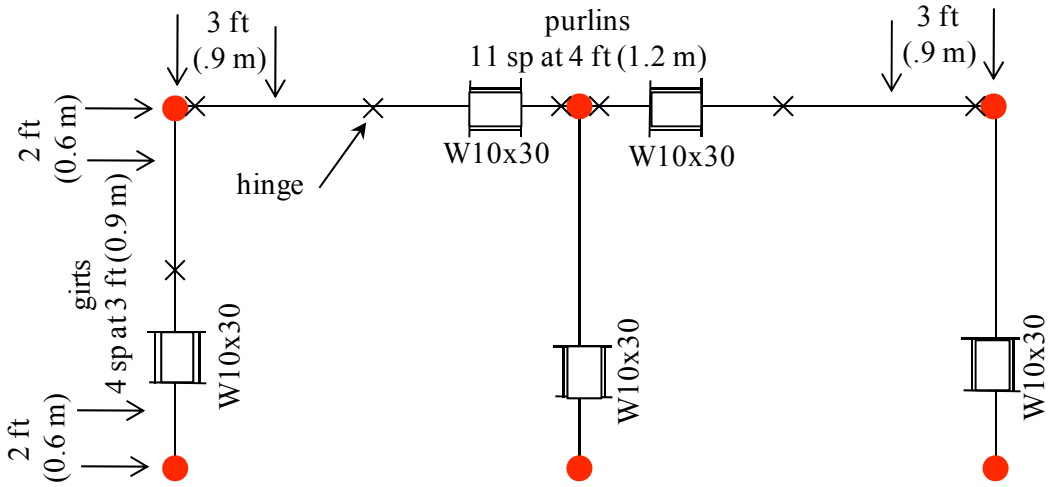

Figure 3: SAP2000 Analysis Frame

The nonlinear hinges were determined by inspection of the frame and located at the midpoint and ends of the two roof beams, and midpoint and top end of the front

face column (refer to Figure 3). SAP2000 does not limit the number of hinges, thus additional hinges could be included if desired. The analysis results can be used to confirm that yield moments are not exceeded elsewhere. The value of the hinge yield moment was manually set to $(F_{DY})(Z_X)$ or 1,866 k-ft (2,109 kN-m) as indicated in the ASCE 2010 Chapter 12 calculation. This hinge value implements the strain rate increased yield stress, F_{DY}, and plastic section modulus, Z_X. Alternatively the hinge yield moment can be calculated by SAP2000 based on the input member size, yield stress, and hinge modification factor.

Mass, manually calculated from the tributary weight of roof panels, wall panels, purlins, girts, and frame members was input as linear values for each beam and column. The program allocates mass to the nearest node, thus a suitable level of meshing must be specified. The initial static dead load was not considered in this example, but must be considered in a real design. The SAP2000 program provides for this capability.

Finally, user-specified nodes must be defined where each time-history response measurement is to be obtained.

Entering the data for this analysis proceeded quickly, and a solution was thus obtained. Though this example represents one of the simplest forms of a MDOF analysis, additional time was necessary to verify the results. Verification steps included:

- Beginning with a static linear analysis (with separate vertical and horizontal load cases) and checking that the deflected shape was as expected.
- Performing a linear dynamic analysis (without the hinges) and checking that the deflection response was as expected.
- Performing the nonlinear dynamic analysis (with the hinges) and checking that each hinge time-moment behavior was as expected.
- Varying the direct integration time step and checking for the level of variance in the results.
- Varying the mesh size and checking for the level of variance in the results.
- Reviewing a video of the overall response for anticipated global response.
- Reviewing time plots of sidesway deflection, beam deflection, column deflection, and base reactions for anticipated results.

The results of the analysis indicate a peak sidesway response at the top of the left column of 3.292 in (84 mm) at time 0.139 s. The peak vertical response at midspan of the left beam is -2.603 in (-66 mm) at time 0.155 s. The peak horizontal response at

midheight of the left column is 4.084 in (104 mm) at time 0.114 s. Displacement-time plots are provided in Figures 5, 6, and 7.

SDOF Equivalent Analysis

For comparison purposes, a SDOF equivalent analysis was performed. The method uses empirical factors to approximate the effects of distributed load and mass. The advantages of the method are that it is fast and relatively easy to understand given a basic knowledge of dynamics. Simple extensions such as for a two DOF overturning/sliding analysis can be derived if required. Limitations are that the method applies accurately only to predefined circumstances (i.e. bending, first mode), bending is the predefined mode of response unless specifically derived otherwise. More complex extensions (i.e. MDOF frames) would involve far too much effort for the benefit provided. Solutions are available in the form of closed-form equations, charts, and spreadsheets. The most versatile solution is a spreadsheet solution, thus the spreadsheet described in ASCE 2010 Chapter 6 was used for this example.

Applicability of a SDOF analysis for frame components is typically limited to trial calculations; usage for this example provides a simple approximate verification.

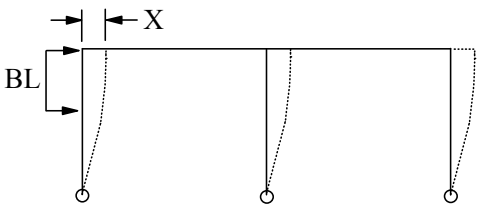

Figure 4, SDOF Equivalent Sidesway Analysis

The SDOF sidesway analysis uses load and mass calculated from a tributary area equal to the roof plus the top half of the walls (refer to Figure 4). Unlike the ASCE 2010 Chapter 12 example, the stiffness is determined by applying a lateral load to the static model used for code checks (a static model needs to be created anyway for an actual analysis). The sidesway analysis results in a peak response at the top of the left column of 3.379 in (86 mm) at time 0.0921 s.

The SDOF beam equivalent analysis uses fixed end conditions. The peak response at the midpoint of the left beam is 1.86 in (47 mm) at time 0.038 s.

The SDOF column equivalent analysis uses a fixed top and pinned base boundary condition. The peak response at the midpoint of the left column is 2.635 in (67 mm) at time 0.024 s.

Displacement-time plots are provided in Figures 5, 6, and 7.

MDOF (Nonlinear Material) Analysis

For comparison purposes, a more comprehensive analysis is desired. Because detailed input data from the previously presented results using STABLE and ADINA are not available, the analysis for this comparison was re-performed using the ANSYS finite element analysis program. The program includes the ability to use nonlinear material properties, thus the formation and location of plastic hinges are determined by the analysis.

Advantages for this form of analysis are that, given proper modeling, the analysis can consider a global response or local effects from close-in explosions, incorporate a higher level of detail (fidelity), and include modeling of connections so that the behavior can be examined.

Issues related to this form of analysis are the additional time required to program and validate the model, the additional time and computer resources required to execute the analysis, an increased complexity in making changes to the model, and the need to prepare a separate model for conventional-load static code checks.

The ANSYS model used similar configuration and loading parameters as for the SAP2000 analysis, with only a few differences. A nonlinear steel material was implemented instead of defined hinges. As for the two other analysis methods, the material was assumed to be elastic-perfectly plastic and incorporated a strain-rate adjusted yield strength.

The results of the analysis indicate a peak sidesway response at the top of the left column of 3.257 in (82 mm) at time 0.160 s. The peak vertical response at midspan of the left beam is -2.777 in (-71 mm) at time 0.159 s. The peak horizontal response at midheight of the left column is 4.119 in (105 mm) at time 0.118 s. Displacement-time plots are provided in Figures 5, 6, and 7.

Comparison of Results

A comparison of sidesway response methods is presented in Figure 5. The result indicates a very similar peak response value from the three analysis methods. The accuracy of the SDOF equivalent method in this comparison is due to the use of a lateral stiffness calculated from a static frame analysis. The MDOF methods compare favorably with each other and have a higher continuing response due to additional plastic hinges in the frame.

A comparison of roof beam response methods is presented in Figure 6. The SDOF equivalent method underestimates the peak response, mainly due to plastic hinges at the beam ends which reduce the stiffness. The beam end hinges also shift the phasing of the response. Again, the two MDOF methods compare favorably with each other.

A comparison of column response methods is presented in Figure 7. The SDOF equivalent method provides a similar first peak value, but underestimates the remainder of the response. This is mainly due to sidesway deflections at the top of the

column. Note that the peak deflection used to calculate ductility and support rotations should consider the effect of sidesway deflection at the top of the column. Thus Figure 8 is provided to illustrate adjusted response values for the two MDOF methods, where half the sidesway response is subtracted from the column midpoint deflections. Figure 8 indicates a somewhat better comparison, however the SDOF equivalent method slightly overestimates the positive peak response and underestimates the rebound response.

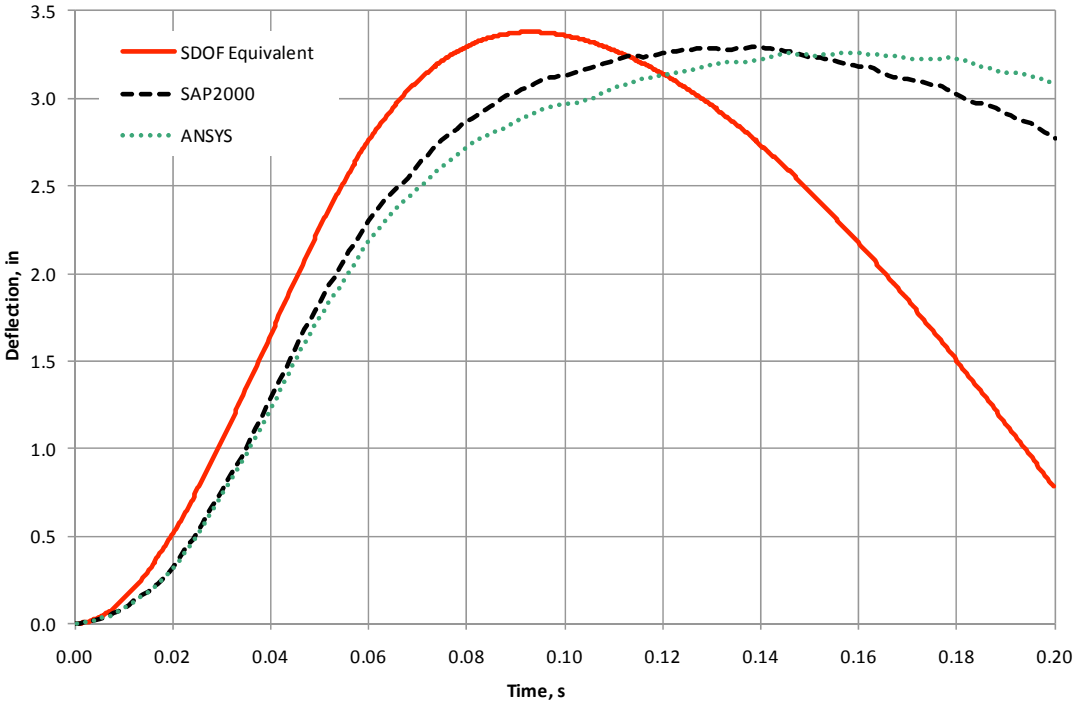

Figure 5, Sidesway Response at Top of Left Column

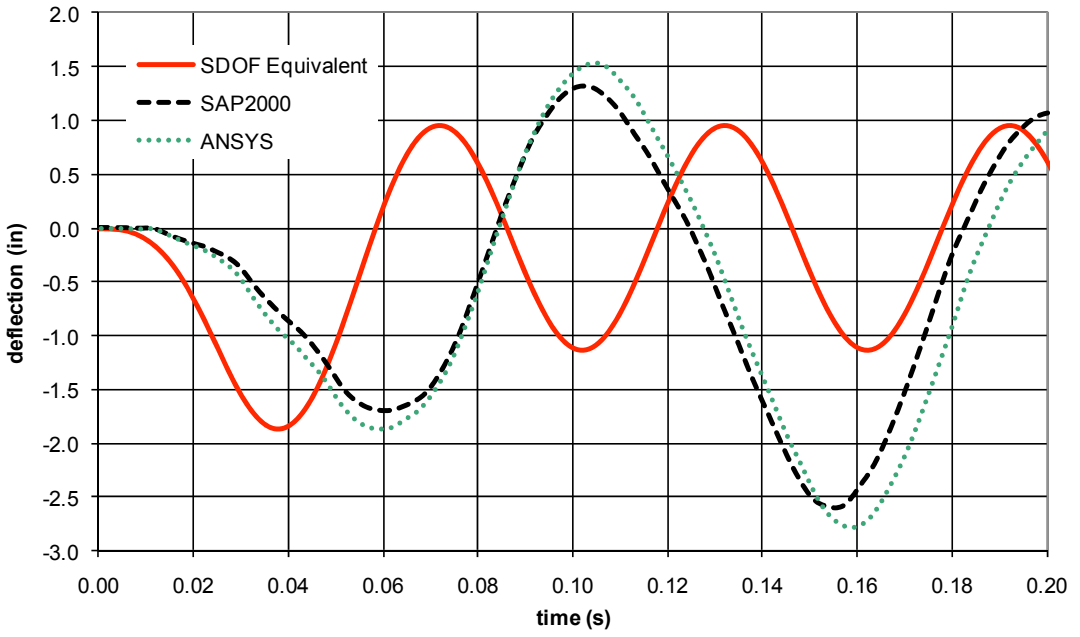

Figure 6, Beam Midspan Vertical Response

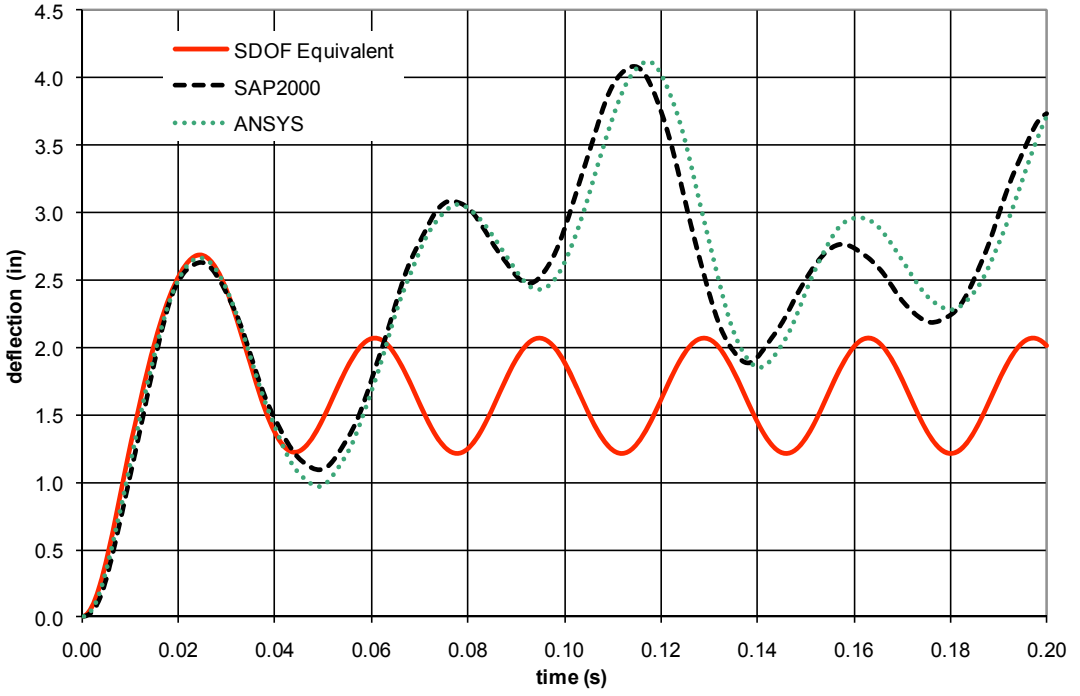

Figure 7, Column Midheight Horizontal Response

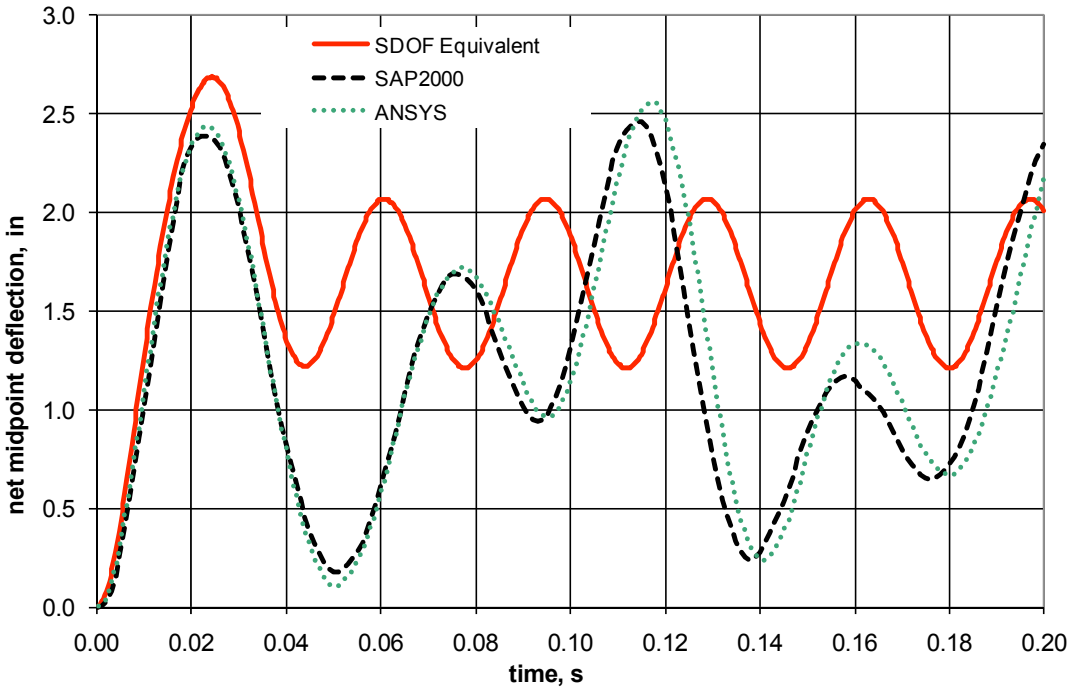

Figure 8, Sidesway-Adjusted Column Midheight Horizontal Response

Conclusions

The accuracy of results using the SAP2000 nonlinear hinge analysis compares favorably with the more comprehensive ANSYS nonlinear material analysis. Aspects of the SDOF equivalent analysis results are similar; however different frame configurations and loading could lead to greater differences. The use of SDOF equivalent method for trial calculations appears to be justified.

The SAP2000 data input for this analysis can be entered quickly and changes are simple to make. Conventional load code checks can be performed using the same model. The model verification that is vital to any computer nonlinear analysis can be more time consuming than that for data input.

The frame model in this example is intended for relatively simple steel frames subjected to low level, far field, blast loads.

The ability of framing members to reach and sustain plastic deformations must be manually verified using applicable code or specification criteria. P-delta effects can and should be included within the MDOF analysis.

ABSTRACT

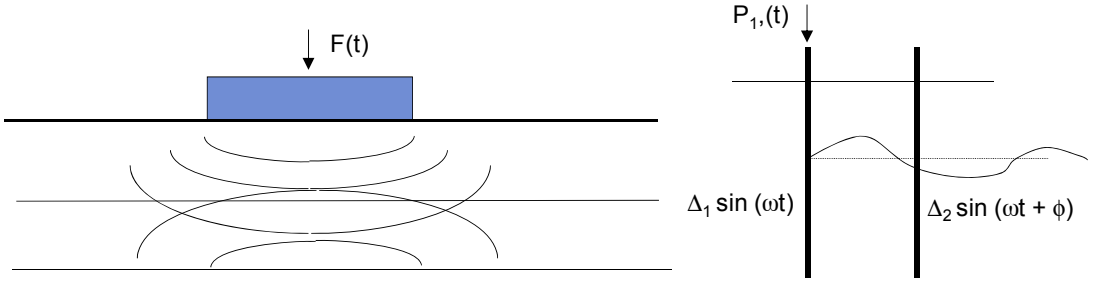
The design of foundations for vibrating machinery involves solving the equations of motion. To do this, the basic values of load, mass, and impedance need to be determined. Soil / pile impedance is easily the most complex of these values. Current means of evaluating soil impedance is through the use of computer software. Because of the complexity of the calculations, such software is often seen as a "black box" that takes user input data and reports a result. Familiarity with the assumptions and formulas behind computer calculations is important, as is a visual grasp of how results will be affected by changes to input data. Also of significance is having the ability to confirm the reasonableness of computer results. This paper addresses these subjects.

BACKGROUND

Understanding and interpreting computer based results is not always easily accomplished. The calculation of stiffness and damping is relatively straightforward when dealing with soil supported mats on homogeneous soil. Values can be easily determined manually, or by using a spreadsheet. Stiffness and damping calculations for layered soil or for pile groups may appear reasonably simple in theory, but become complicated and tedious in implementation.

For soil supported foundations, several situation-specific methods are available for design which include a homogeneous halfspace, layer over a halfspace, layer over a rigid stratum, shear modulus increasing with depth, and shear modulus increasing hyperbolically to a specific depth. General purpose methods include an equivalent pile (soil column), and a cone (Wolf 2004).

Pile supported foundations involve single piles as well as the arrangement of piles in a group. Situation-specific charts and figures are available. The most commonly used general method for individual piles is the Novak plain strain approach which allows for floating piles, end bearing piles, and layering within the length of the pile. Methods for determining the impedance of pile groups are either direct (all at once), or use superpositioning (combinations of two piles).



The most comprehensive method for soil / pile supported foundations is a detailed finite element analysis which usually involves a prohibitive amount of effort to implement. Even some of the "simplified" methods are considered to be time-demanding. Simplified calculations are further complicated by the use of complex numbers, which of course are not a part of normal structural calculations. For the solution of the equation of motion, complex numbers are easier to deal with symbolically and computationally. Complex numbers enter into the calculation through the implementation of material and geometric damping.

Software available on the market typically provides input and output values, but the inner workings are not accessible to the user. Thus only a "black box" calculation is available which can create design challenges for the verification of computer results. This paper provides some guidance for understanding impedance and discusses the validation of computer results.

Software authors assume that users are fully versed in the documentation and theory before attempting a design. In reality, software users may actually have only a general knowledge of the method basis. This provides a problem for verification because careful input checking alone may not be sufficient. Some potential issues when using one of the more common programs, Dyna 5, are discussed.

VISUALIZATION

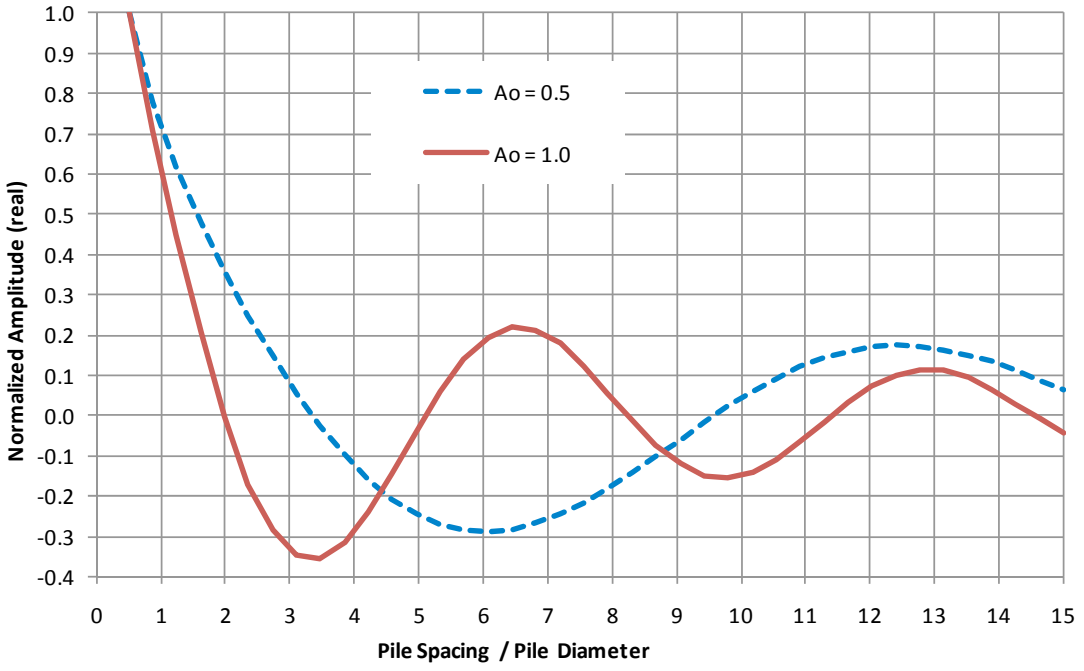
The transmission of stress waves through the soil is how foundation impedance occurs. It is also a convenient way to visualize how impedance is affected by calculation parameters. Basically, stress waves that travel away from the foundation, never to return, result in a large amount of energy loss through geometric damping. Stress waves that impact a different soil layer, reflect back to the foundation and will change the impedance depending on the amount of reflection, attenuation, and phasing of the reflected wave (Figure 1a). Stress waves that impact an adjoining pile, change the total pile group impedance depending on the attenuation and phasing of the stress wave where the impact occurs (Figure 1b, Figure 2).

(a) Through Soil Layers **(b) Between Piles**

Figure 1, Transmission of Stress Waves

For soil layers, the cone analysis method (Wolf 2004) calculates the reflection and refraction of waves at each soil layer boundary with attenuation calculated from soil

layer reflection coefficients and from a spread in the shape of a cone. For pile groups, methods such as described by Gazetas (Gazetas 1991) calculate the attenuation and phasing of stress waves as they spread laterally from a source pile to a receiver pile. A close understanding of these methods provides a good understanding of the principles involved in determining impedance.



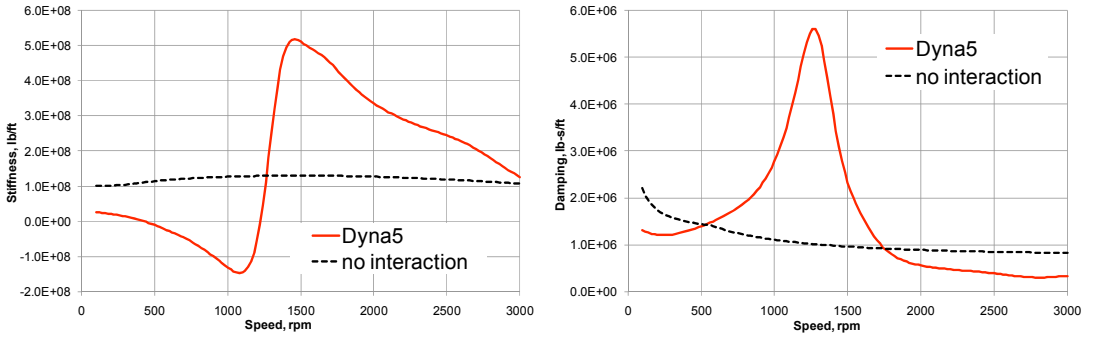


Figure 2, Attenuation & Phasing of a Shear Wave Ao = Diameter-Based Frequency Factor

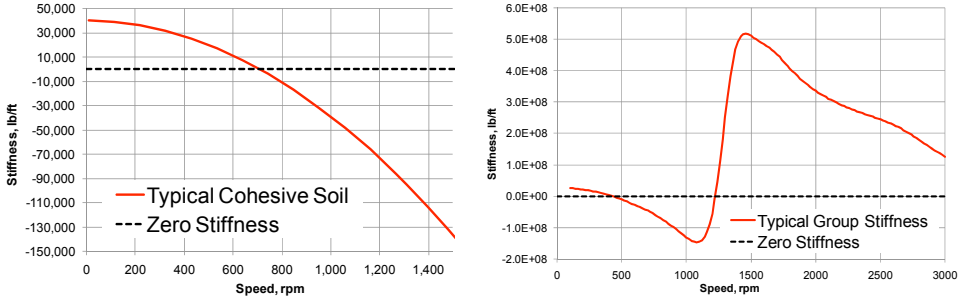
The following paragraphs describe several instances of seemingly counter-intuitive results. The appropriate evaluation of results is aided by considering how the transmittal of stress waves occurs and through the use of visual aids to help put specific results in context.

EFFECT OF PILE GROUP INTERACTION

Often a software user may desire to verify the program generated group pile stiffness values by simply using the single dynamic pile stiffness multiplied by the number of piles. This rough approximation is inaccurate as the group pile interaction effects are much greater than the single pile dynamic response. Figure 3 illustrates the comparison of a range of dynamic stiffness and damping values as function of frequency. Thus single pile results will not provide insight to validate group pile program results. By observation of Figure 3, stiffness and damping values near zero rpm indicates that the use of static interaction factors would be equally unsatisfactory (i.e. a constant stiffness value over the frequency range).



a) stiffness comparison b) damping comparison

Figure 3, Effect of Pile Group Interaction

An appendix is provided in this paper to illustrate the vertical impedance calculation for a single pile as well as for a four pile group. The calculation is based on Novak's plain strain method. The procedure is similar to that used by the Dyna5 program and the results may be used for an approximate verification of the results. The response for horizontal and rocking is more complicated due to coupling between horizontal and rocking modes, and due to soil stiffness based on a combination of shear and compression waves.

NEGATIVE STIFFNESS

One phenomenon that appears to be counter intuitive is the occurrence of negative stiffness values in the solution. The user may initially presume that there was a program malfunction. However, this can be a valid result and there are several causes. First, foundations supported on a highly cohesive soil with a high Poisson's ratio value (i.e. clay) can produce a negative stiffness at higher frequencies (Figure 4a). The effect is the result of part of the soil vibrating in phase with the foundation. Because in-phase soil mass is not included in the mass of machine-foundation models, the resulting stiffness can become negative. Secondly, a negative stiffness can result from a pile group vibrating within a specific frequency range (Figure 4b). This is a geometric effect from the shear wave velocity and the spacing between piles.

a) cohesive soil b) pile group

Figure 4, Negative Stiffness Situations

Though a negative stiffness would make a fundamental difference in a static situation, there is no practical or numeric defect when solving the equations of motion.

For most software programs dealing with block-type foundations, it is not necessary to provide any further action other than to note that the stiffness is negative and continue with the design. If a flexible structure is to be analyzed and the stiffness is to be transferred to a finite element program, a negative stiffness may not be a valid input value. Therefore, it will be necessary to convert the negative stiffness, K_N, to an equivalent positive value stiffness (usually the static stiffness, K_S, is chosen) and additional mass, M_A. The equation below, with ω as the circular frequency, can be used to accomplish this conversion.

$$M_A = (K_S - K_N) / \omega^2$$

STRONGER SOIL, LOWER STIFFNESS

Another counter intuitive phenomenon is where an increase in shear wave velocity (i.e. stronger soil) results in a decrease in pile group stiffness. When the shear wave velocity is varied, the shear waves impacting adjacent piles are shifted in phase (refer to Figure 2). The result is a decrease in stiffness, plus a shift in frequency. Figure 5 provides an illustrative sample comparison where the stiffness decreases at frequencies near 1,500 rpm.

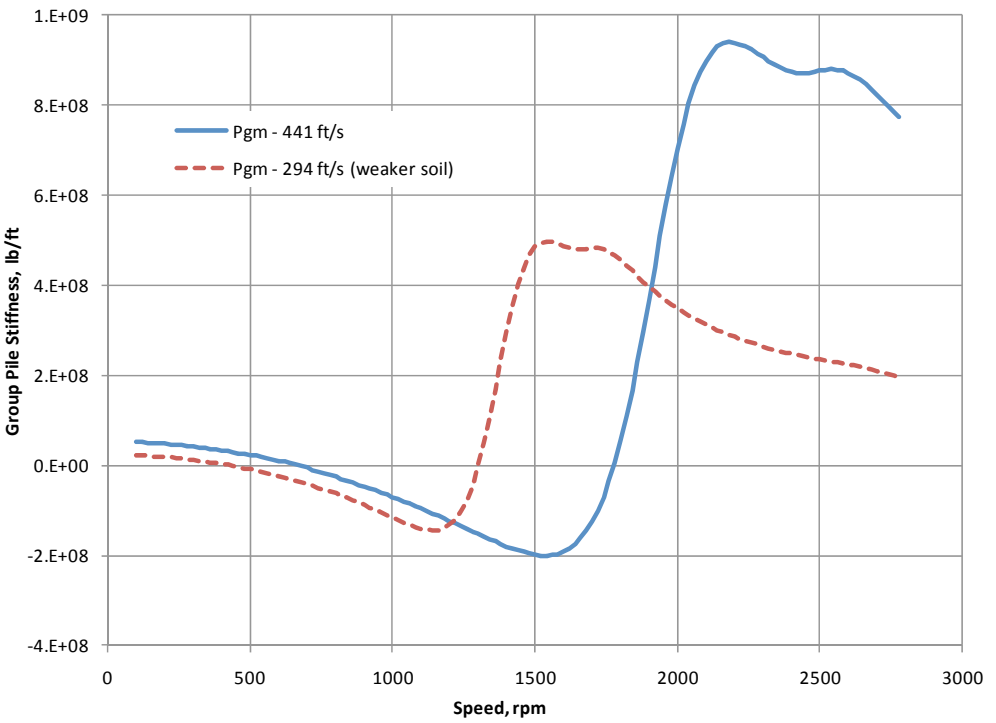


Figure 5, Effect of Group Piles Stiffness from Variation of Shear Wave Velocity

DAMPING LIMITS BASED ON CRITICAL DAMPING

The implementation of project specification criteria that specifies damping limits based on a percentage of critical damping can be problematic. Limitations on damping are used to account for variability in measured soil values. The use of critical damping based limits appears to have originated from frequency independent impedance methods for uniform soil conditions. Because geometric damping is computed as a coefficient, the damping ratio is calculated as follows:

Damping Ratio = (damping coefficient) / (critical damping coefficient)

Critical Damping Coefficient = $\sqrt{\text{stiffness} \times \text{mass}}$

The calculation of critical damping and usage of a percentage of this value can be an issue due to the following factors,

- Negative Stiffness: As discussed previously, this can occur for specific circumstances such as cohesive soils and or for pile groups (Figure 4). One logical resolution is to use a critical damping value based on the static stiffness, however the resulting static-based damping value can be unrealistic at certain frequencies.

- Change of Mass: Mass can affect the damping limit. A change in foundation mass, without any change in the soil interface, would result in a different damping limit.

- Large range of damping values in pile groups: Pile group geometric damping at certain machine speeds can be very large and the application of critical damping based limits would result in a dramatic drop in damping. At other machine speeds, damping could be below the limit and the application of critical damping based limits would result in no reduction whatsoever (Figure 6).

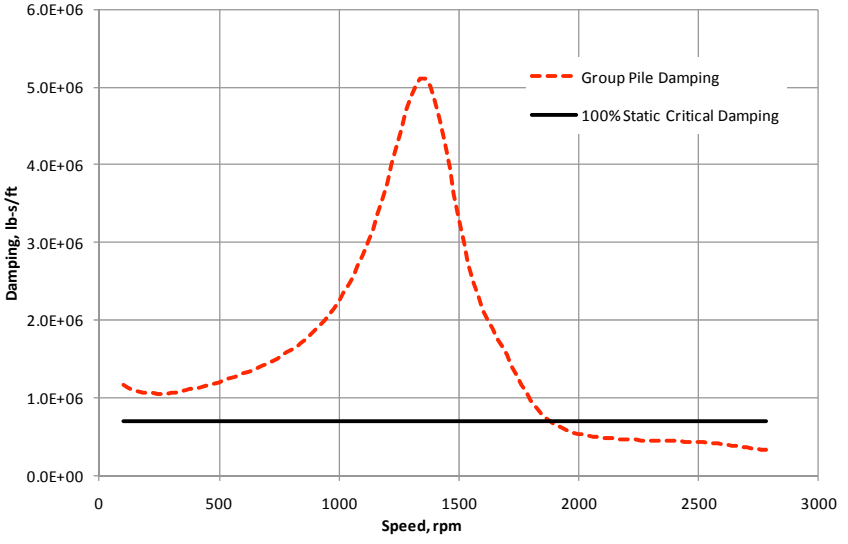

Figure 6, Group Pile Damping Versus Static Critical Damping

- Software Limitations: Some commonly used programs do not include the capability to specify a damping ratio limit, or to specify different limits for each mode of vibration.

A consistently conservative alternative is to implement a uniform reduction from the calculated theoretical damping value. Dyna 5 for example, implements a uniform reduction as a damping safety factor (For Example, DSF = 2 represents a 50% reduction).

RESONANT RANGE ISSUES

Another project specification issue is the avoidance of the resonant range. Resonance occurs when the exciting frequency is very close to the natural foundation frequency; the associated high vibration response will be detrimental to the machine. A natural frequency for an uncoupled mode occurs where the foundation stiffness, $K = M \omega^2$ (refer to Figure 7). Typically a specification will state that the frequency ratio (machine exciting frequency divided by natural foundation frequency) shall be outside a resonant range (usually given as 0.7 to 14, or 0.8 to 1.2). Alternative criteria are rarely included. Meeting resonant range criteria in project specifications can become difficult due to the following factors:

- The dynamic analysis is normally performed using the measured shear wave velocity, plus values that represent higher and lower variations resulting in additional resonant ranges.
- A flexible tabletop-type support may have hundreds of natural frequencies.
- A reciprocating machine will have primary and secondary exciting frequencies.
- A pile group may have several natural frequencies. Refer to Figure 7 which shows the resonant ranges (based on 0.8 to 1.2) to be avoided. As shown, the shaded regions indicating the resonant ranges can greatly limit the design.

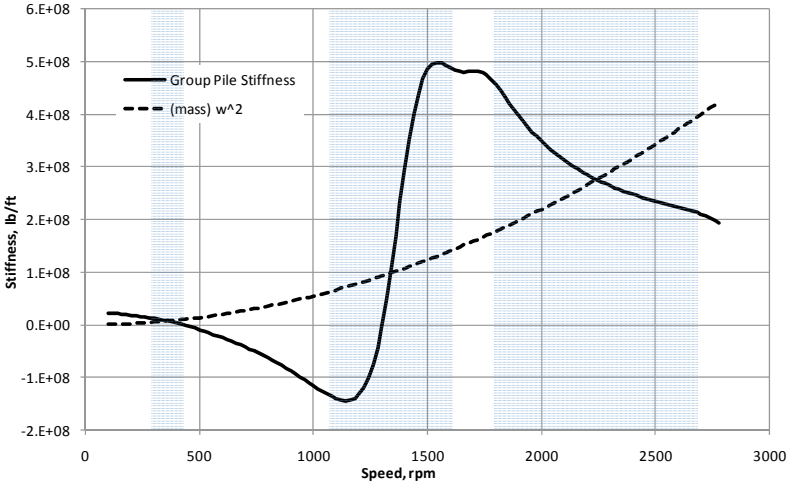

Figure 7, Indication of Three Vertical Natural Frequencies and Resonant Ranges for a Pile Group

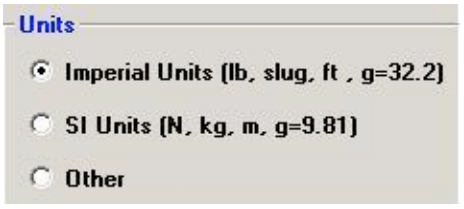
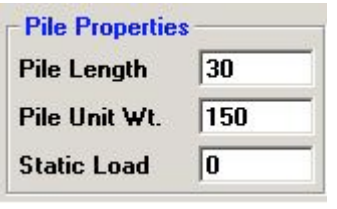


The resonant range, being a function of frequency, covers a wider range of values with higher natural frequencies. In situations where avoidance of the resonant range is not practical, an alternative would be to increase the damping reduction from theoretical values. Where 50% of the theoretical value would normally be used, 25% of the theoretical value would be used (for the Dyna5 program, this equates to a DSF = 4).

SOFTWARE ISSUES



Because of the complexity of calculations, engineers must typically rely on computer software for designing vibrating equipment foundations. Design using software may not simplify the engineering process due to a lack of software usage guidance resources. Pitfalls related to the user interface can greatly affect the results. It is important to thoroughly understand the program input values as well as to verify the results in the output data. A common perception is that program input data verification will detect modeling mistakes. However, if the user is unfamiliar with the program assumptions and defaults, the user may not realize that input values are incorrect.

This paper discusses some input quirks found in Dyna 5. Dyna 5 is a commonly used program that, when used properly, produces reliable results. If other programs are used, it is recommended to look for similar issues presented in the following bullet list.

- Units: Units are defined in Dyna 5 under the setting summary (Figure 8a). The units chosen are not repeated on the data input screens (Figure 8b). In the Dyna 5 settings, it is strongly recommended to select "Echo Input Data" under the Output Flags section (Figure 8c). This option directs the program to include input values, with units of measure, in the output text file (Figure 8d).

a) units designation

b) data input

c) echo designation

```
GRAVITATIONAL CONSTANT SET TO  32.20 ft/s**2
*****************************

FREQUENCY UNITS :  RPM
***************

LENGTH UNITS : ft
*************
```

d) results with units

Figure 8, Dyna 5 Screen: Units of Measure

- Density: Density is not described as weight or mass density on the data input screen. Note that the program's imperial unit for mass is slugs. Where "Density" is shown (Figure 9), a mass density is expected by the program.

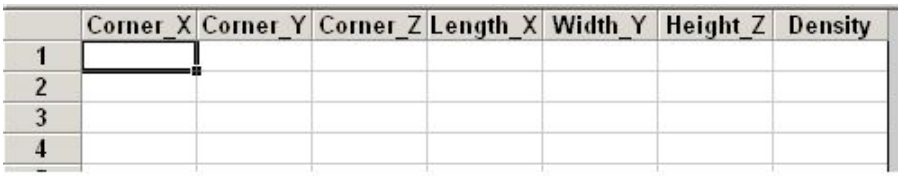


Figure 9, Dyna 5 Screen: Density Input

- Damping Values: The material damping entered in Dyna 5 (Figure 10) is defined as the tangent of the loss angle, which is equal to twice the damping ratio.

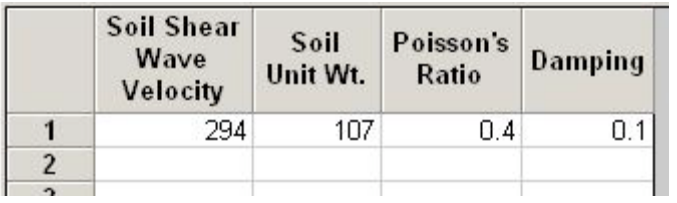

Figure 10, Dyna 5 Screen: Damping Input

- Pile Tip Condition: Dyna 5 includes an option for the pile tip condition to be "Floating" or "End-Bearing" (Figure 11). This is actually a low frequency damping modification. Geometrical damping vanishes at low frequencies, leaving only material damping. The pile tip condition determines how this is to be implemented. "Floating" is the default condition which specifies a straight line transition. "End-Bearing" is the alternate condition where Dyna 5 will calculate the deposit's first natural frequency, below which the radiation damping will be abruptly eliminated.

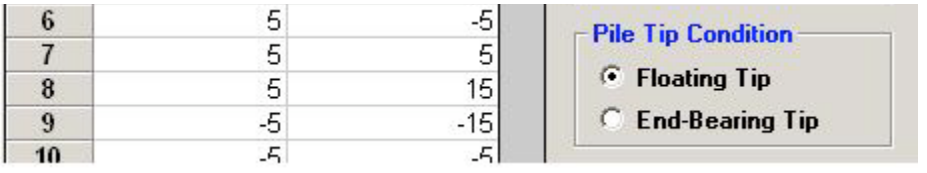

Figure 11, Dyna 5 Screen: Pile Tip Condition Input

Once input parameters have been verified, manual and visual verification of the software results must be achieved. Manual verification is performed by examination of the printed results. Visual verification is performed by using the Dyna 5 plotting capability (Figure 12). If desired, plot data can be extracted for use in other software. Note that data files must reside in the Dyna 5 program directory in order for the plotting routine to function.

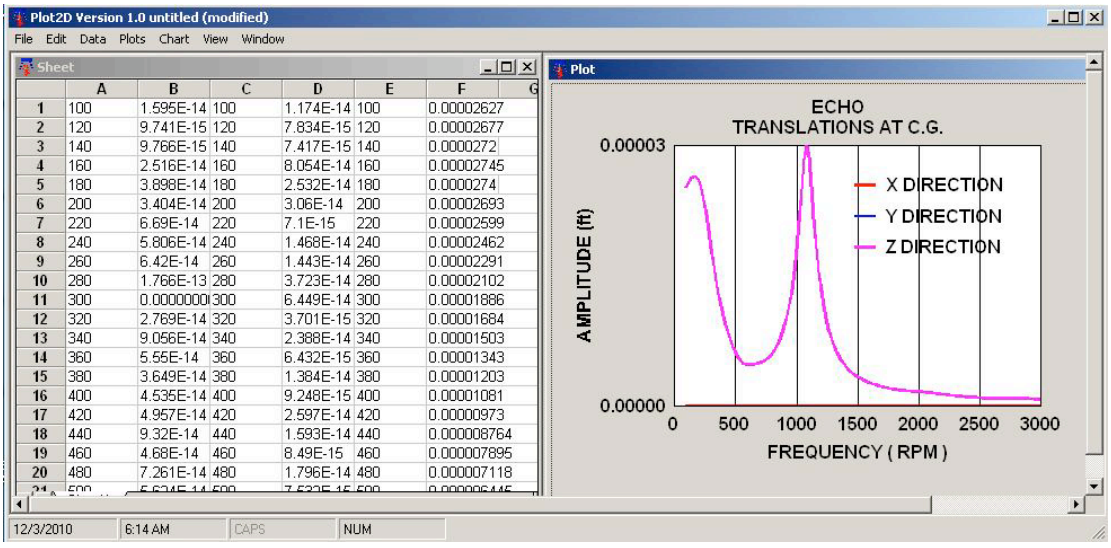

Figure 12, Dyna 5 Screen: Graphing Options

An independent manual verification of results may be necessary to validate program results. For pile impedance, the sample calculation provided in the Appendix provides a vertical impedance calculation for a four pile group. The results should be close enough to help identify if the program solution is reasonable. Manual verifications can also be based on any of a number of graphs and tables available for a variety of soil and pile situations. Note that chart data from various resources may define the frequency factor, A_O, based on either the radius, R, or the diameter, D.

$$A_O = R\,\omega / V_S \quad \text{or} \quad A_O = D\,\omega / V_S$$

In addition, pile interaction factors may be based on either a dynamic-based definition (i.e. Mylonakis & Gazetas 1998) or a static-based definition (i.e. Kaynia & Kausel 1982). If implemented properly, the result will be the same.

$$\alpha = \frac{(\text{pile 2 dynamic deflection})}{(\text{pile 1 dynamic deflection})} \quad \text{or} \quad \alpha = \frac{(\text{pile 2 dynamic deflection})}{(\text{pile 1 static deflection})}$$

SUMMARY

Designing foundations for vibrating machinery requires knowledge of both the theory and the software used. Soil / pile impedance is clearly the most complicated issue requiring software interface. It is recommended that the design engineer utilize the applicable design software with caution. While software results are highly dependant on accurate input data, the program input assumptions may not always be readily apparent to the user. In order to validate the program results, a grasp of the basic theory is required to facilitate visual and manual results verification. This paper provides a fundamental description of vibratory equipment foundation analysis methods, discussions on counterintuitive design results, and recommendations on software verification.

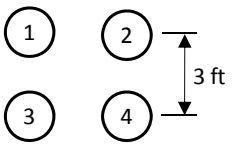
Appendix

Part 1: Single Pile Vertical Impedance:



Given:

uniform soil
machine speed, MS = 750 rpm
soil shear wave velocity, V_S = 300 ft/s
soil unit weight, Y_S = 110 lb/ft^3
pile unit weight, Y_P = 150 lb/ft^3
pile radius, R_P = 0.5 ft
pile pattern = 2 piles by 2 piles

floating pile tip
soil poisson's ratio, v_S = 0.35
pile modulus, E_P = 804,230,000 lb/ft^2
soil damping ratio, β_S = 5%
pile damping ratio, β_P = 10%
pile embedment, L_P = 30 ft
pile spacing, Sp = 3 ft

1. Calculate circular frequency, ω:

$\omega = (MS)\,(\pi) / 30 = (750 \text{ rpm})(\pi) / 30 = 78.54$ rad/s

2. Calculate non-dimensional frequency, A_O:

$A_O = (\omega)(R_P) / (V_S) = (78.54 \text{ rad/s})(0.5 \text{ ft}) / (300 \text{ ft/s}) = 0.13$

3. Determine soil reaction against side of pile, S_V: (Novak 1978)

refer to Figure A1 using $A_O = 0.13$: S_V (real) = 1.9, S_V (imaginary) = 0.16

$S_V = 1.9 + i\ 0.16$

4. Calculate pile area, A_P:

$A_P = \pi (R_P)^2 = (\pi)(0.5 \text{ ft})^2 = 0.785 \text{ ft}^2$

5. Calculate pile mass per unit length, μ:

$\mu = (Y_P)(A_P) / (\text{gravity}) = (150 \text{ lb/ft}^3)(0.785 \text{ ft}) / (32.2 \text{ ft/s}^2) = 3.66 \text{ lb-s}^2/\text{ft}^2$

6. Calculate soil shear modulus, G_S and G_S':

$G_S = (Y_S)(V_S)^2 / (\text{gravity}) = (110 \text{ lb/ft}^3)(300 \text{ ft/s})^2 / (32.2 \text{ ft/s}^2) = 307{,}453 \text{ lb/ft}^2$

$G_S' = G_S [1 + i\ 2\beta_S] = (307{,}452 \text{ lb/ft}^2) [1 + i(2)(0.05)] = 307{,}452 + i\ 30{,}745 \text{ lb/ft}^2$

7. Calculate complex pile elastic modulus, E_P':

$E_P' = E_P [1 + i\ 2\beta_P] = 804{,}230{,}000 \text{ lb/ft}^2 [1 + i(2)(0.1)]$
$= 804{,}230{,}000 + i\ 160{,}846{,}000 \text{ lb/ft}^2$

8. Calculate frequency coefficient, Λ:

$$\Lambda = L_P \{[\mu \omega^2 - G_S (S_V)] / (E_P')(A_P)\}^{0.5}$$
$$= (30 \text{ ft}) \{[(3.66 \text{ lb-s2/ft}^2)(78.54 \text{ rad/s})^2 - (307{,}453 \text{ lb/ft}^2)(1.9 + i\ 0.16)] / (804{,}230{,}000 + i\ 160{,}846{,}000 \text{ lb/ft}^2)(0.785 \text{ ft}^2)\}^{0.5}$$
$$= 0.26 + i\ 0.99$$

9. Calculate pile tip resistance, R_V: (Veletsos 1974)

if $v_S < 0.4$
then $b_1 = 0.35$, $b_2 = 0.8$, $b_3 = 0$, $b_4 = 0.75$
otherwise $b_1 = 0$, $b_2 = 0$, $b_3 = 0.17$, $b_4 = 0.85$

$$R_R = 1 - (b_3)(A_O)^2 - (b_1)(b_2 * Ao)^2 / [1 + (b_2 * A_O)^2]$$
$$= 1 - (0.0)(0.13)^2 - (0.35)(0.8 * 0.13)^2 / [1 + (0.8 * 0.13)^2] = 1.0$$

$$R_I = b_4 + (b_1)(b_2)(b_2 * A_O)^2 / [1 + (b_2 * A_O)^2]$$
$$= 0.75 + (0.35)(0.8)(0.8 * 0.13)^2 / [1 + (0.8 * 0.13)^2] = 0.75$$

K_{ST} = 4 (G_S')(R_P) / (1 - v_S) = 4(307,452 + i 30,745 lb/ft^2)(0.5 ft) / (1 - 0.35)
= 946,010 + i 94,601 lb/ft

$R_V = K_{ST} (R_R + i R_I)$ = (946,010 + i 94,601 lb/ft)(1.0 + i 0.75)
= 933,094 + i 187,492 lb/ft

10. Calculate impedance coefficients, A, B, C:

sin (Λ) = 0.40 - i 1.11
cos (Λ) = 1.47 + i 0.30

A = (E_P')(A_P)(Λ)(cos Λ) / (sin Λ)(L_P)
= (804,230,000 + 160,846,000 lb/ft^2)(0.785 ft^2)(0.26 + i 0.99)(1.47 + i 0.30)) / (0.40 - i 1.11)(30 ft) = 26,495,827 + i 8,685,694 lb/ft

B = (E_P')(A_P)(Λ) / -(sin Λ) / L_P
= (804,230,000 + 160,846,000 lb/ft^2)(0.785 ft^2)(0.26 - i 0.99) / -(0.40 - i 1.11)(30 ft) = -18,400,243 - i 2,135,954 lb/ft

C = A + R_V = (26,495,827 + i 8,685,694 lb/ft) + (933,094 + i 187,492 lb/ft)
= 27,428,921 + i 8,873,187 lb/ft

11. Calculate single pile impedance:

K_V = [(A)(C) - (B)^2] / C
= [(26,495,827 + i 8,685,694 lb/ft)(27,428,921 + i 8,873,187 lb/ft) - (-18,400,243 - i 2,135,954 lb/ft)^2)] / (27,428,921 + i 8,873,187 lb/ft)
= 14,633,044 + i 9,657,535 lb/ft

12. Calculate stiffness and damping:

stiffness = K_V (real) = <u>14,633,044 lb/ft</u> (Dyna5 = 14,550,000)

damping = K_V (imaginary) / ω = (9,657,187 lb/ft) / (78.54 rad/s) = <u>122,964 lb-s/ft</u>
(Dyna5 = 122,300)

Part 2: Group Vertical Pile Impedance

1. Determine interaction factors, α:

(option 1, approximate equation) (Gazetas & Makris 1991)

$$\alpha = \text{sqrt}\,[R_P / S_P] * \exp\,[-(\beta_S + i)(S_P / R_P - 1)(A_O)]$$

(option 2, interpolate from available chart, such as attached Figure A2)
(Mylonakis & Gazetas 1998)

Note: For the following equations, the chart needs to be based on,
α = (pile 2 dynamic deflection) / (pile 1 dynamic deflection)

using option 1,

between the same pile (1-1, 2-2, 3-3, 4-4), $S_P/2R_P = 0.5 \rightarrow \alpha = 1 + 0i$
between adjacent piles (1-2, 1-3, 2-4, 3-4), $S_P/2R_P = 3 \rightarrow \alpha = 0.31 - i\ 0.24$
between diagonal piles (1-4, 2-3), $S_P/2R_P = 4.2 \rightarrow \alpha = 0.18 - i\ 0.27$

2. Assemble interaction matrix for the pile group, [α]:

$$[\alpha] = \begin{bmatrix} \alpha_{1,1} & \alpha_{1,2} & \alpha_{1,3} & \alpha_{1,4} \\ \alpha_{2,1} & \alpha_{2,2} & \alpha_{2,3} & \alpha_{2,4} \\ \alpha_{3,1} & \alpha_{3,2} & \alpha_{3,3} & \alpha_{3,4} \\ \alpha_{4,1} & \alpha_{4,2} & \alpha_{4,3} & \alpha_{4,4} \end{bmatrix} = \begin{bmatrix} (1.0 + i\,0.0) & (0.31 - i0.24) & (0.31 - i0.24) & (0.18 - i0.27) \\ (0.31 - i0.24) & (1.0 + i\,0.0) & (0.18 - i0.27) & (0.31 - i0.24) \\ (0.31 - i0.24) & (0.18 - i0.27) & (1.0 + i\,0.0) & (0.31 - i0.24) \\ (0.18 - i0.27) & (0.31 - i0.24) & (0.31 - i0.24) & (1.0 + i\,0.0) \end{bmatrix}$$

3. Calculate the inverse of the interaction matrix, [ε]. Inversion can be performed using built-in routines available in Excel or MathCad. In Excel, the Minverse routine can be used by first converting the matrix of complex numbers into an equivalent matrix of real numbers as follows:

$$\begin{bmatrix} (a_1 + ib_1) & (a_2 + ib_2) \\ (a_2 + ib_2) & (a_3 + ib_3) \end{bmatrix}^{-1} = \begin{bmatrix} a_1 & a_2 & -b_1 & -b_2 \\ a_2 & a_3 & -b_2 & -b_3 \\ b_1 & b_2 & a_1 & a_2 \\ b_2 & b_3 & a_2 & a_3 \end{bmatrix}^{-1} = \begin{bmatrix} \varepsilon_1 & \varepsilon_2 & -\varepsilon_4 & -\varepsilon_5 \\ \varepsilon_2 & \varepsilon_3 & -\varepsilon_5 & -\varepsilon_6 \\ \varepsilon_4 & \varepsilon_5 & \varepsilon_1 & \varepsilon_2 \\ \varepsilon_5 & \varepsilon_6 & \varepsilon_2 & \varepsilon_3 \end{bmatrix} = \begin{bmatrix} (\varepsilon_1 + i\varepsilon_4) & (\varepsilon_2 + i\varepsilon_5) \\ (\varepsilon_2 + i\varepsilon_5) & (\varepsilon_3 + i\varepsilon_6) \end{bmatrix}$$

Applying either inverse procedure results in,

$$[\varepsilon] = [\alpha]^{-1} = \begin{bmatrix} (1.06 - i0.28) & (-0.28 + i0.2) & (-0.28 + i0.2) & (-0.04 + i0.08) \\ (-0.28 + i0.2) & (1.06 - i0.28) & (-0.04 + i0.08) & (-0.28 + i0.2) \\ (-0.28 + i0.2) & (-0.04 + i0.08) & (1.06 - i0.28) & (-0.28 + i0.2) \\ (-0.04 + i0.08) & (-0.28 + i0.2) & (-0.28 + i0.2) & (1.06 - i0.28) \end{bmatrix}$$

4. Sum the 16 individual real and imaginary values from the inverted matrix:

$\Sigma\varepsilon = 1.88 + i\ 0.78$

5. Calculate the group impedance:

$K_{GV} = (K_V)(\Sigma\varepsilon) = (14{,}633{,}044 + i\ 9{,}657{,}535\ lb/ft)(1.88 + i\ 0.78i)$
$= 20{,}010{,}634 + i\ 29{,}677{,}526\ lb/ft$

6. Calculate stiffness and damping:

stiffness = K_{GV} (real) = <u>20,010,634 lb/ft</u> (Dyna5 = 15,480,000)

damping = K_{GV} (imaginary) / ω = (29,677,526 lb/ft) / (78.54 rad/s)
= <u>377,866 lb-s/ft</u> (Dyna5 = 397,500)

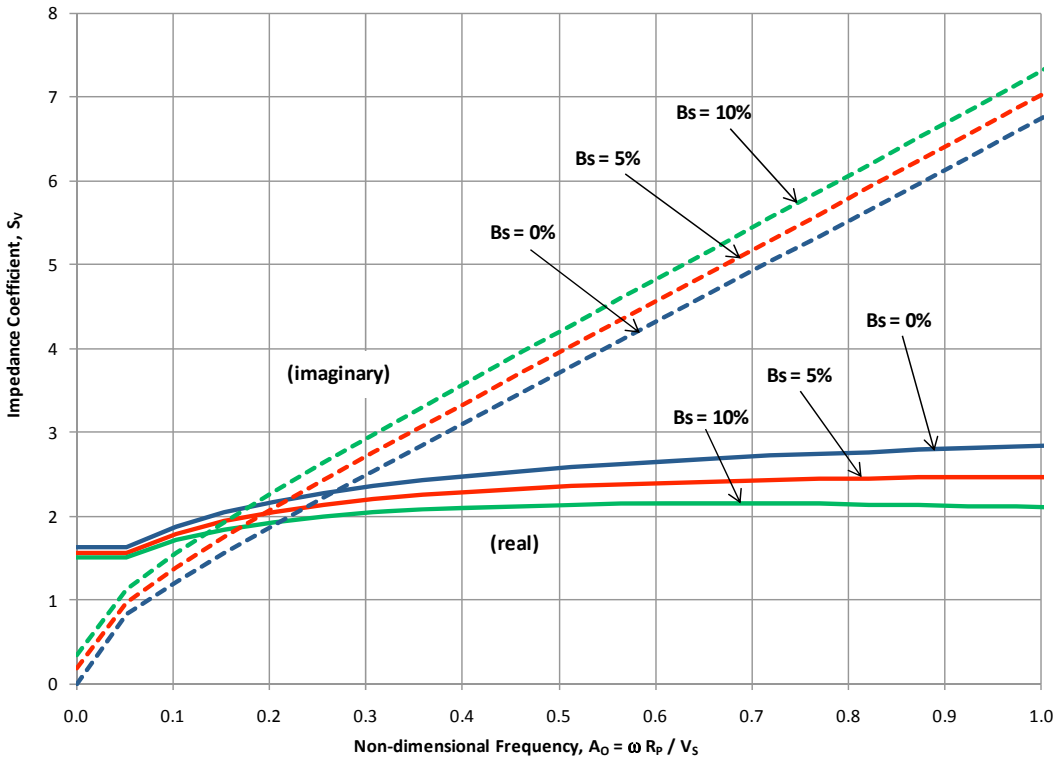


Figure A1 (S_V for low-frequency pile tip = floating)

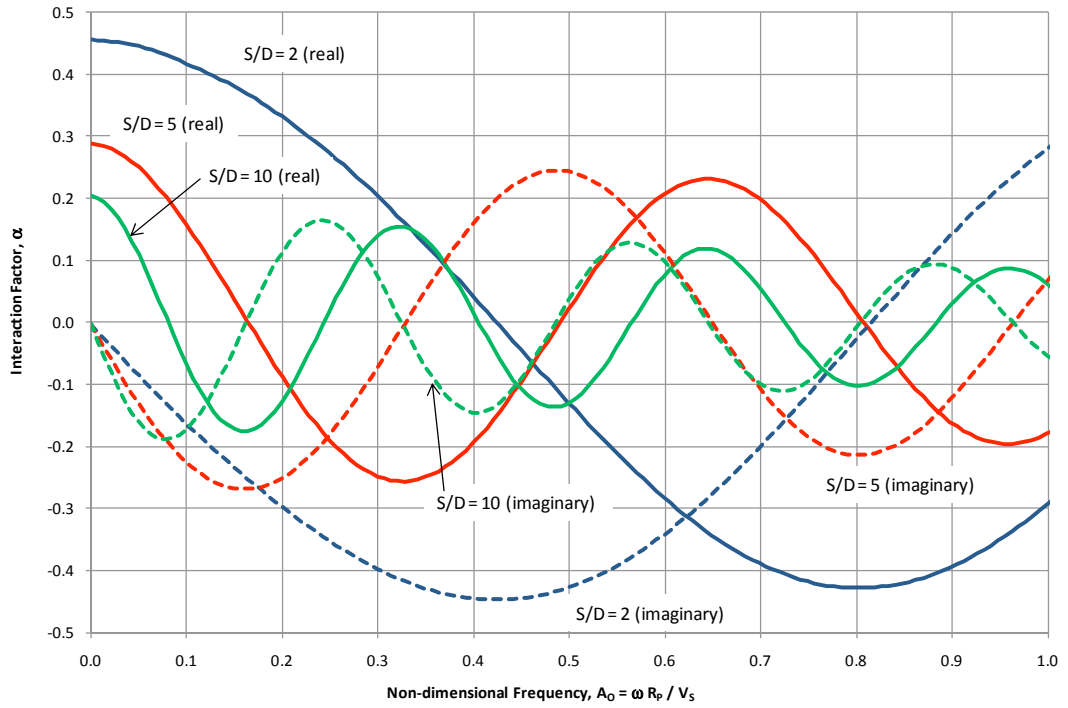

Figure A2 (values of α_V)

$L/d = 20$, $E_P/E_S = 1000$, $\upsilon_S = 0.40$, $\rho_P/\rho_S = 1.25$, $\beta_S = 5\%$

Weight Management Considerations for Onshore Modularized Petrochemical Facilities

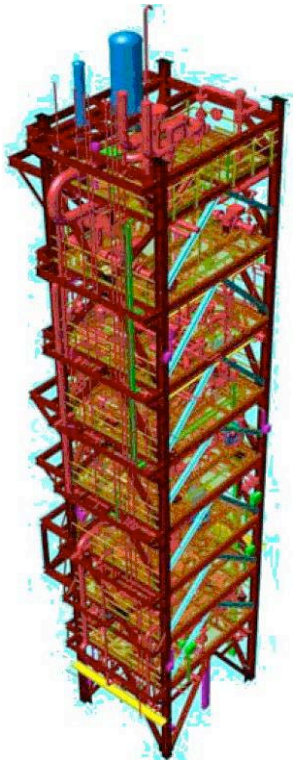
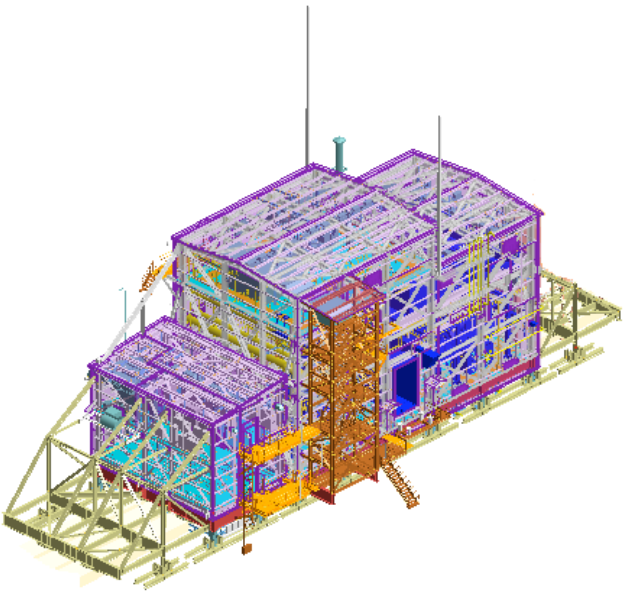
ABSTRACT

Modular construction is a well-proven technique for the North Slope of Alaska and the offshore petrochemical industry and is often preferred because of site conditions. Modularization is not a technique generally associated with conventional land-based petrochemical facilities, but certain project conditions, such as limited manpower availability and severe weather conditions, can make it the best construction execution method to achieve cost savings. Structural engineering for modular structures is more complex than for conventional structures due to requirements associated with transport, handling, and final placement of complete modules or major sub-assemblies. A primary source of the additional complexity is the need for structural engineers to participate in the Weight Management process.



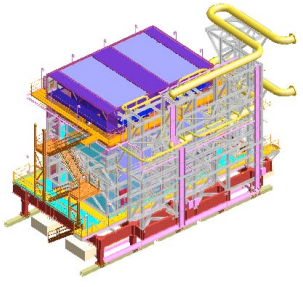
Determination of module weight and Center-of-Gravity (COG) location is a key component of the Weight Management process. This paper provides an overview of the Weight Management process and presents a structural engineer's roles in this process. An implementation example is provided to show how the weight control data is generated by the weight reporting scheme to be used to assist project planning and management, specifically in material procurement and transportation logistics planning.

INTRODUCTION

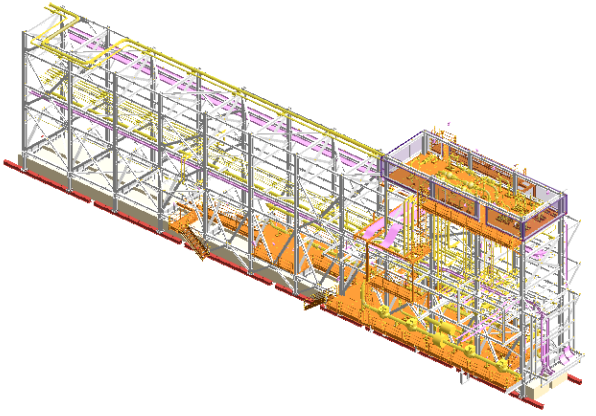


Modular construction[1], or modularization, refers to the assembly of components into packaging facilities that can be transported from the established offsite fabrication shops and yards to the project construction site for installation and pre-commissioning activities. Figure 1 illustrates 3-D isometric views of modules for onshore petrochemical facilities. Modular units generally cost 10%-15% higher than field erected units. However, the higher cost of modularization is often offset by performing the work at the fabrication site instead of in the field. Modularization

[1] Module - A transportable pre-assembly of process plant components designed to minimize site installation and commissioning labor costs.
Stick Built - The concept of erecting items at the job site from basic fabricated pieces without the use of pre-assembly or modularization.



reduces the overall project cost due to lower field construction costs and a shorter field construction schedule. Onshore modular construction is found to be attractive due to the following potential benefits: better productivity, increased quality, reduced construction support requirements, minimized site congestion and interferences, lower direct labor rates, reduced safety risks associated with elevated work activities, and better supplier access.



(a) Tower Module

(b) Gas Compression Module

(c) Air Cooler Module

(d) Piperack Module

Figure 1. Isometric Views of Modules for Onshore Petrochemical Facilities.

Currently developed onshore modularization techniques require careful attention with regard to internal access, methods of module transport, methods of placement, and problems associated with the greater compactness of a modular plant, including the limitations on the design of foundations, underground services, and cable routing.

These considerations must be incorporated into the onshore modularization Weight Management process throughout the project life cycle.

Among all engineering disciplines, Structural is the most involved discipline because modular structural steel must be designed to support all module components, withstand dynamic forces during transportation, and allow for installation by crane or transporter at the construction site. During a project feasibility study, structural engineers are often requested to provide technical evaluations and recommendations with respect to module identification, size limit, weight restriction, etc. It is not uncommon for a structural engineer selected to be the weight control engineer. Thus, a thorough understanding of the structural engineer's roles throughout the Weight Management process facilitates successful modularization project execution.

The following sections provide an overview of a recommended onshore module Weight Management process illustrated with flowcharts and the structural engineer's roles throughout the process. An implementation example is presented in the Appendix to demonstrate a typical periodic weight and COG data reporting process.

OVERVIEW OF THE ONSHORE MODULE WEIGHT MANAGEMENT PROCESS

Figures 2 (a) and (b) illustrate a typical Weight Management process associated with various project execution stages and facilitate the following:

- Evaluation of the current project condition with respect to the design development status.
- Evaluation of the defined constraints of Weight Management.
- Determination of whether the design should proceed.
- Determination of whether a design cycle should be repeated.

The extent, level, and frequency of weight reporting as part of a Weight Management process vary depending on the sensitivity of the specific module designs, the associated technical requirements, and whether weight considerations and COG are of a high priority in the project.

Decisions to be made during the process are heavily dependent on historical information by keeping good records of previous experience and continuous evaluations of weight and COG predictions across various project stages. A weight control reporting system is required to support the Weight Management process whereby at any time, accumulated weights can be checked against previously predicted weights. If discrepancies are found, the weight control reporting database can be managed and analyzed, so that the final weight can be achieved within the specified target weight.

If early weight estimates are based on relevant experience and reliable records, the process often demands no more than monitoring the weight of the structure as the project proceeds. Conversely, if early weight estimates are poor and low, the weight

control effort for the remainder of the project will become exceptionally arduous and require substantial management involvement in addition to monitoring weights and COGs. This will lead to additional design work by all disciplines during and after detailed design, causing schedule delays and increased cost.

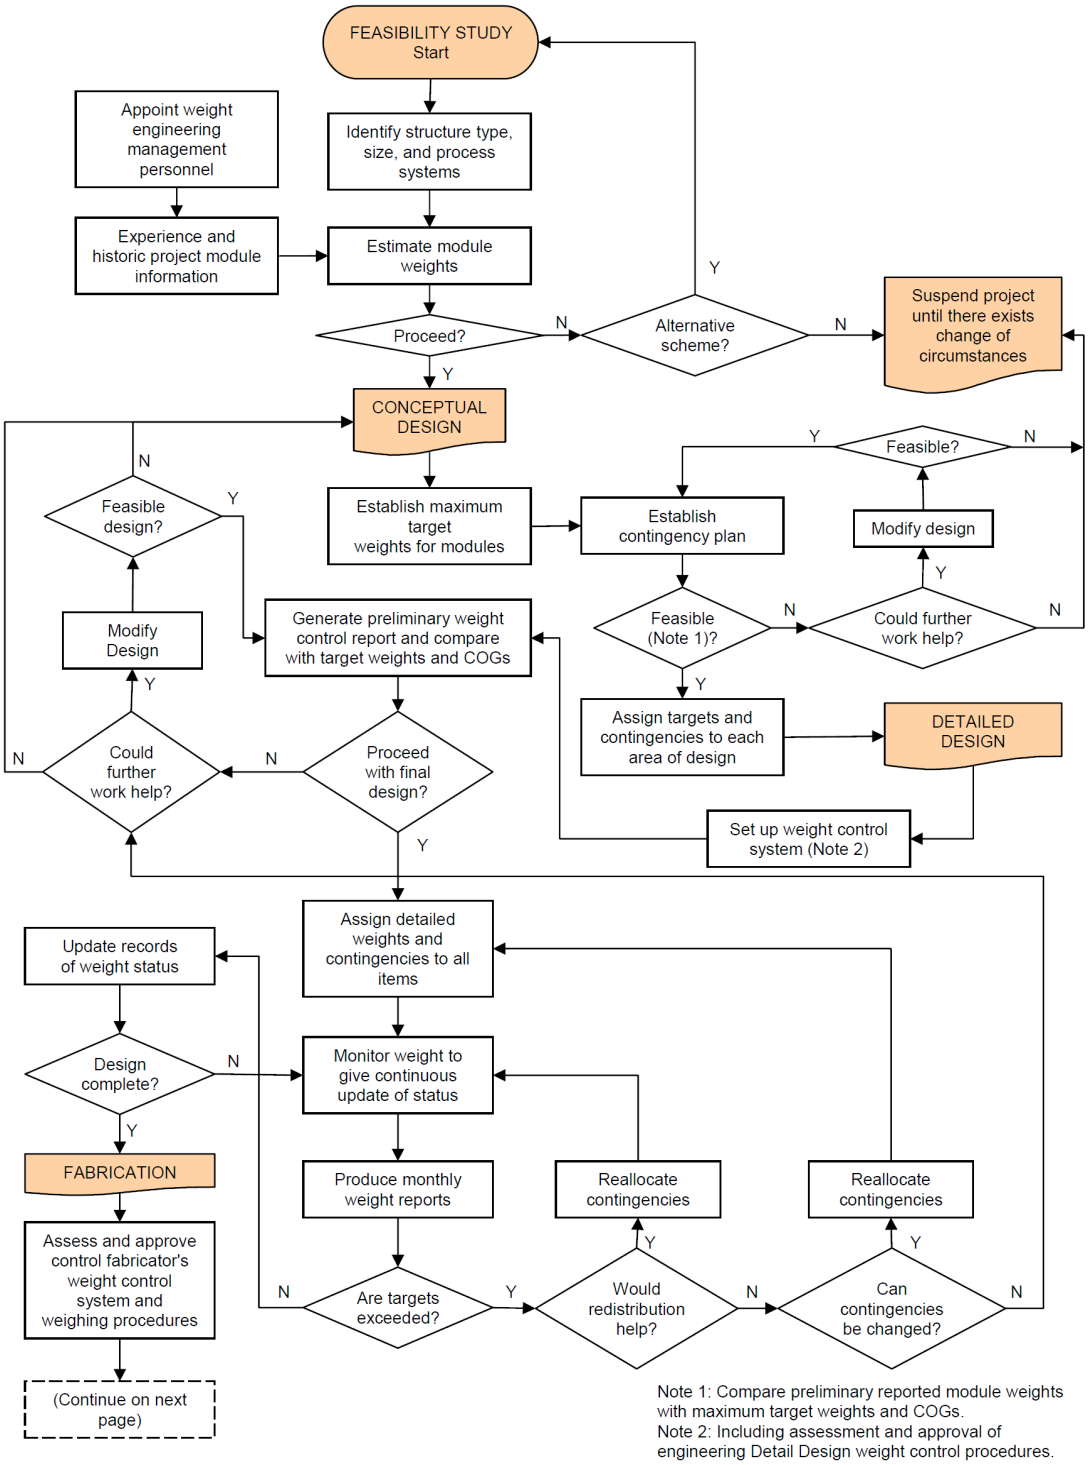


Figure 2(a). Recommended Onshore Modularization Weight Management Process.

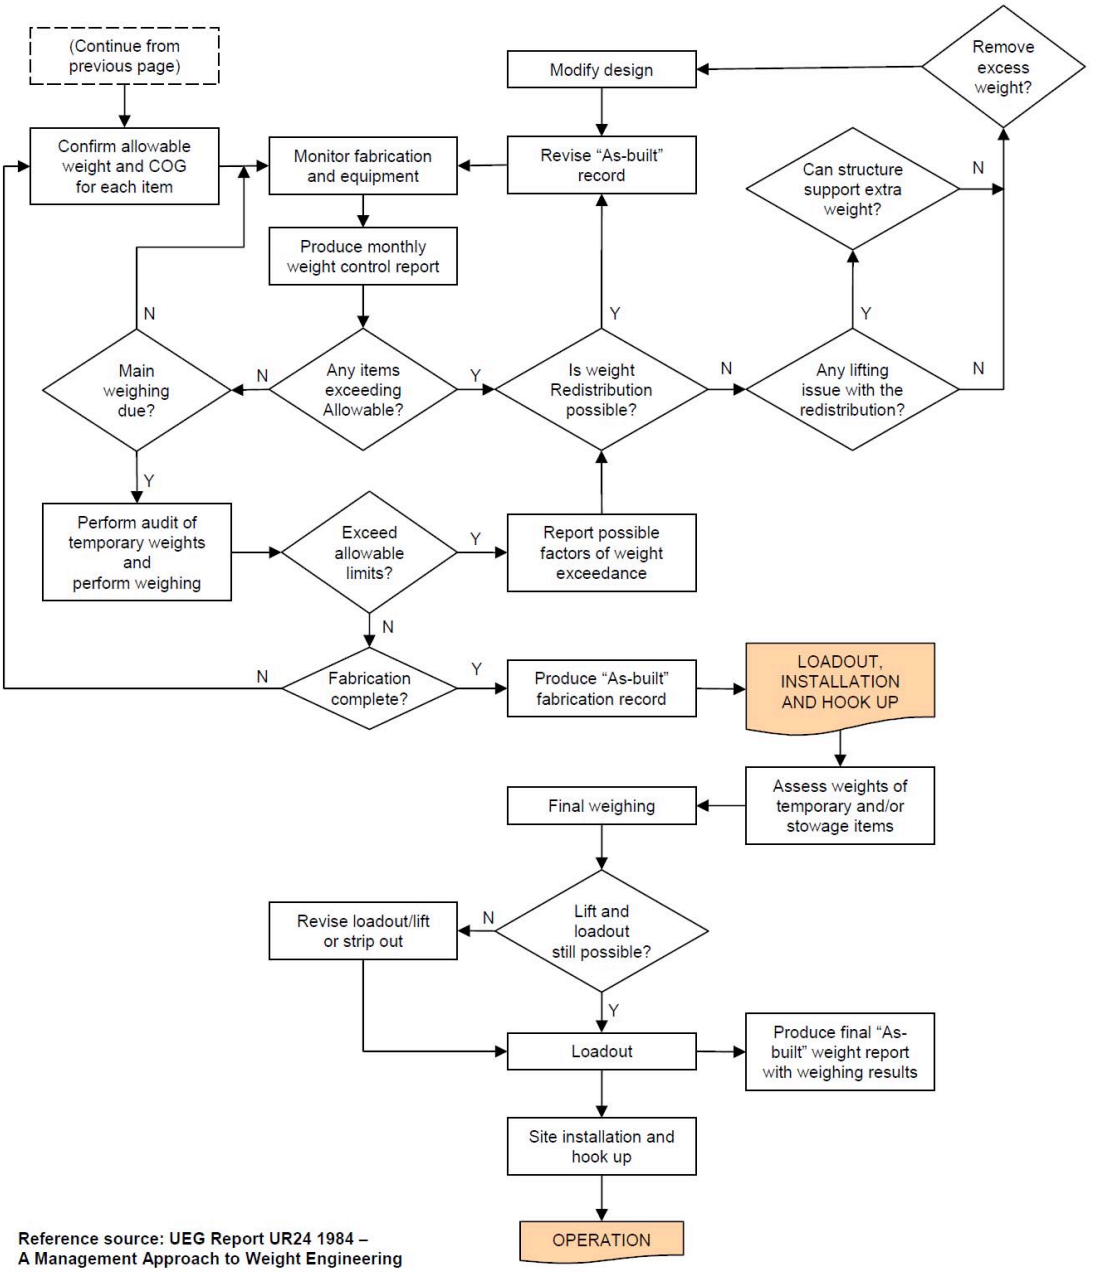

Figure 2(b). Recommended Onshore Modularization Weight Management Process (Continued).

STRUCTURAL ENGINEER'S ROLES THROUGHOUT THE WEIGHT MANAGEMENT PROCESS

The following discussion assumes that modules are fabricated and then transported by barge and over land, to a site where they are lifted and set on foundations.

For onshore modularization projects, the structural steel weight may reach as high as 70% of the total module weight, therefore, the Structural discipline is viewed to be primarily responsible for module design, its evaluation and acceptance, and

construction support. Structural engineers should engage in well-facilitated discussions about the project Weight Management plan starting from the feasibility study stage.

Stage 1 – Feasibility Study
Since data often is not readily available from previous projects, most of the weight estimates are expected to be based on the personal experience and expertise of the study leader. Structural engineers, who should have the best sense of weight accuracy and understanding among all the engineering disciplines, should participate in preliminary feasibility studies with project management and client representatives to assist in the development of schedule, risk analysis, and modularization strategy from a Weight Management perspective.

Stage 2 – Conceptual Design
The naval architect and the lifting contractor should be brought in at this stage to ensure that all the requirements of construction, transport and final installation can be met. However, this is not always possible due to client's project funding and resource allocations. The structural engineer should perform preliminary analysis to set up barge and lifting requirements, such as maximum weight and required barge deck stiffness. For land transportation, heavy haul routes should be identified considering transporter requirements, preliminary module configuration and weight limitations, as well as fabrication yard and project site constraints.

Stage 3 – Detailed Design
The use of a computerized weight control scheme becomes essential at this stage. In a large scale project, the number of module items may reach as many as 15,000 or more. Each of these items requires regular revision when information becomes more accurate. The weight status levels would typically be:

1. Current Estimated Weight
2. Weight with Well-Supported Information (such as developed drawings, supplier certified data, etc)
3. Weight without Well-supported Information
4. Final Weight

Current Estimated Weight (item 1) is equal to Weight with Well-Supported Information (item 2) plus Weight without Well-supported Information (item 3), which includes a suitable contingency. As the detail design progresses, item (2) improves, item (3) decreases, and items (1) and (4) should ideally converge.

Data of total weights and COGs for each installation phase (such as upon fabrication completion, during barge loadout, at project site installation and hook-up, etc) should be stored in the weight control database, in which the user is allowed to edit each data item separately, so that up-dates can be carried out quickly and effectively. A highly refined editing system should be developed to provide a concise summary with focuses on the major trends in weight build up and a breakdown of total weights by

each discipline. The structural engineer should participate in the development of this database and ensure correct generation of COG data.

Considerations in Determination of Module Weight and COG Location

An acceptable COG envelope should be developed based on combined weight and COG acting under various load conditions, including lift, transport, in-place, etc. The module structural engineer can conduct a sensitivity assessment to ascertain the effect of load distribution on the COG.

The following are various parameters that may require to be considered:

- Lift capacity
- Jacking capacity during weighing (Figure 3)
- Pile capacity
- Sea and land transport stability (Figure 4)
- In-place stability

Figure 3. Module Weighing by Hydraulic Jacking Load Cells.

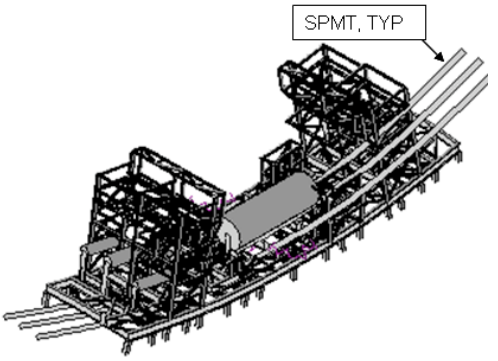

Figure 4. Module Deflected Shape Without Outrigger During Transportation.

The structural engineer should discuss with the client any design risk associated with the weight and COG characteristics, including special weight control problems and the areas to receive the weight control emphasis. During design development, it is not unusual that the projected COG approaches or exceeds the acceptable COG envelopes; the module structural engineer should re-evaluate these situations and determine if immediate actions are needed.

If the weight reports indicate that target weights are being exceeded, or module COGs are becoming unacceptably offset from the envelopes, a corrective action is required either by modifying the structure to accommodate the change or by distributing or repositioning the excessive weight.

Structural Design and Analysis Considerations

The following presents the considerations of structural design and analysis during detailed design phase:

- Detailed module structural analysis should validate a land transportation scheme, such as Self Propelled Modular Transporter (SPMT). Analysis should incorporate

a hydraulic load balancing system between each module and the SPMT. In order to minimize strengthening steelwork, the module's self weight should be evenly distributed over the SPMT support points.

- Module structural analysis models should be created for different transport scenarios, such as loadout, transport, installation, etc. To ensure that overall module stability considerations are properly addressed, the target weight and COG envelopes should be applied to these models, with added safety factors applied in accordance with project specifications. The benefit of using this approach is: When final weights and COGs are obtained during fabrication stage, the previously conducted analyses will still be valid and re-work will be avoided.
- Module lifting and feasibility studies are recommended to be performed by module design structural engineers.
- When structural engineers review vendor drawings for structural load calculations, they should ensure that weights shown on these drawings are accurately reflected on the weight reports from other disciplines.
- Weight factors to account for mill tolerances, welding, and paint should be added to the analysis process.
- Structural engineers should be involved in establishing the method and degree of weight control that will be required for subcontractors and vendors.
- Structural item contingencies should be updated on a regular basis with an understanding of how other disciplines provide their current item contingencies.
- Generating module transportation logistic data drawings for land transportation contractor would reduce the risks associated with problematic weight, stability, and clearance issues.

Weight Reporting Quality Assurance Considerations

Quality assurance can be delivered for reported weight data by developing a verification scheme and the following list:

- Establish common terminology for weight items.
- Develop procedures to maintain consistency in reporting methodology.
- Develop database specific to each module.
- Ensure consistent breakdown of discipline data.
- Employ discipline checklists to ensure that there are no missed items or double dipping.
- Verify equipment weight and COG data against the latest Master Equipment List.

Module Design Documentation Considerations for Weighing

The following module design records and any criteria specific to weighing should be clearly identified and provided to the fabricator:

- Completed sets of weight data collection sheets and related information, such as assumptions, sources of weight and COG data, references, etc.
- Records of the information used to develop estimates and reports.
- Design history and changes.
- Preliminary weight control plan.
- The constraints associated with the weight and COG limits.

Stage 4 – Procurement, Fabrication and Construction
This stage includes module fabrication, all installation, and hook-up work before operations.

During the fabrication stage, fabricators should report and monitor weight growth, but not manage weight growth. The engineering team should be aware that module weighing can be done using different methods, some of which are more accurate than others while some are less expensive. The selected weighing process and operations, including weighing method and in-situ weight monitoring, must be included in the weighing procedure. Prior to the management approval of the fabricator's weighing procedure, the structural engineer should provide technical recommendations and comments considering the module structures and project conditions.

Weight Management strategies at this stage should include supervision during fabrication to ensure that detailed weight reporting is occurring. Additionally, the weighing plan needs to be developed, because the selected weighing technique may affect the erection and/or transportation process. For example, load cell locations established by the fabricator should be submitted for structural engineer's approval, so that the structural members can be confirmed to resist jacking reactions properly. Also, the proposed load cell locations can be verified not to hinder any transporter arrangements.

The weight control manager may assign the module structural engineer to review predicted module weighing reports and final module weighing result reports before module loadout from fabrication yard. Module fabricator may add temporary items before loadout. Structural engineer's review on these weighing reports would prevent overstress of structural members, as the added temporary items may exceed the stowage weight considered in structural design.

THE WEIGHT CONTROL REPORTING SCHEME

Weight control reporting is the most significant activity throughout the Weight Management process. An example is presented in the Appendix as a guideline for the determination of module weight and COG data, as well as proposals on corrective actions when the target weight is exceeded and/or an unacceptable module COG offset is indicated. The main results of module weights and COGs, considering various transport load case conditions, are illustrated and discussed.

Challenges of Implementing an Effective Weight Control Reporting System
The significance of weight control reporting system is often overlooked due to a lack of disciplined "weight thinking" within the industry. Weight control is often regarded as an unnecessary and unfulfilling task, thus insufficient effort has been taken to make the systems work effectively. Weight control personnel often have insufficient authority within the design team to carry out their true function, as a result, the methods are ineffectively applied. Workflows among disciplines are often not created with the explicit goal of engaging fabricators and contractors early in design to ensure

that constructability considerations in the weight control reporting system are properly addressed. An undisciplined weight control approach is particularly apparent in projects which involve innovative concepts (i.e., lack of previous experience).

Another common misconception in weight control reporting is that the weight control manager may provide recommendations on the periodic weight reports without acquiring further verification and evaluation from structural engineers. However, some of the recommendations, such as weight shedding opportunities and addition of temporary items, may alter the structural design criteria and assumptions. The outcome may be detrimental if a module's structure is indeed required to be modified to accommodate the proposed changes.

CONCLUSION

Successful Weight Management for onshore modularized petrochemical facilities depends on a disciplined approach to record and update weight data related to each module component. Such a system is best developed at the outset of the Weight Management process, so that all engineering discipline weight control personnel acknowledge and appreciate the importance of their roles and responsibilities in the overall Weight Management effort.

Figure 5. A Piperack Module Sail Out with a Successful Weight Management Approach.

The challenge for the weight control team is to incorporate "weight thinking" into current discipline responsibilities and create an integrated weight reporting system across all disciplines.

This paper strives to introduce the onshore modularization Weight Management considerations to the structural engineering community. The general aspects of the Weight Management process, as well as structural engineer's roles throughout the process, are presented and discussed. Specifically, the importance of weight control reporting, as part of the Weight Management process, is emphasized and demonstrated with an example.

APPENDIX: WEIGHT CONTROL REPORTING EXAMPLE

The periodic weight and COG reporting of bargeable piperack Module PR-01 is covered in this example, given that:

Figure A1. Bargeable Piperack Module PR-01.

- Units: weight units are in Metric Tonnes (MT). All dimensions or coordinates are in meters (m).
- Client Established Target Weight: 730 MT
- Contingency: The project is at the end of conceptual design phase, the weight Contingency is set at 15% except Piping and Structural, since their calculated weights were based on data extraction from the 3D schematic modeling.
- Non-module weights (including piling, fencing, etc.) are excluded.
- Wet or operating module weights are not considered.

1. Provide discipline classification.
The weight is classified into the following engineering disciplines when applicable:

- Architectural
- Electrical
- HVAC
- Instrumentation, Automation and Telecommunication
- Loss Control (Fire & Safety)
- Mechanical
- Piping
- Structural

2. Define load cases.
During this reporting period, four (4) load cases are monitored for each module as shown in Table A1:

Table A1. Module Reported Weight Descriptions at Each Load Condition.

Condition Description	Reported Weight Description	Remarks
Loadout	= Subtotal + Temporary + Ship-Loose	Inclusive of any ship-loose items on the module, internal sea fastening, and temporary equipment items or installation components that may be on board at the time of loadout.
Transport	= Subtotal + Temporary + Tiedowns (+ Ship-Loose)	Inclusive of any ship-loose items transported on the module, internal and external sea fastening and tiedowns, and temporary equipment items or installation components that may be on board. Note: Ship-loose items are currently not

		planned to be transported directly on the module, .i.e., they are not considered as part of the barge transport weight.
Installation	= Subtotal + Temporary + Ship-Loose	Inclusive of any ship-loose items transported on the module, internal sea fastening, and temporary equipment items or installation components that may be transported on road.
In-Place (Dry)	= Subtotal + Ship-Loose + Site-Installed	Inclusive of module structure, equipment, piping bulks, electrical bulks and, if any, accommodation (but without items of consumable or variable loads, stores, crews and their effects). In-place dry weight also excludes external loads.

3. Check module dimensions are within maximum allowable values.

In this reporting period, module dimensions are within client approved module maximum allowable and dimensions as established in Table A2 based on historic data:

Table A2. Module Dimensions Summary.

	Module PR-01	Allowable	Exceed Allowable?
Length (m)	60	70	No
Width (m)	8	9	No
Height (m)	15	20	No

4. Define COG coordinates and constraints.

In this reporting period, module COG constraints are established in Table A3 based on historic data and preliminary input from the transportation contractor.

Table A3. Module COG Constraints.

Module Type	Longitudinal COG (X)	Transverse COG (Y)	Vertical COG (Z)
Piperack	Within L/3	Within W/3	Within H/2 + Height of trailers (1.5 m)

Note: Effect of trailer/SPMT arrangement is not included in the COG constraints.

A local coordinate system as shown in Figure A2 is used for the calculation of module COGs. The Z origin is based on the bottom of column base plate elevation. The X and Y origins are at southwest outer corner of the module outline (Note that module local coordinate system should not be changed once it is established for the project, but this information should be provided in each weight report).

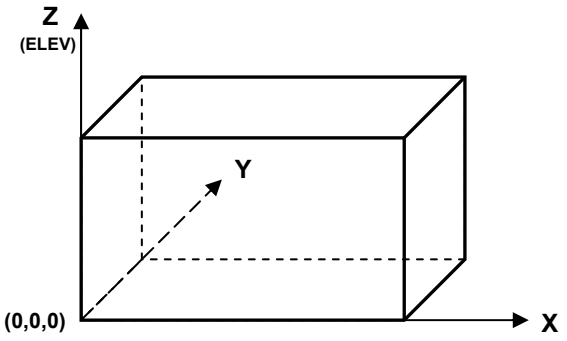

Figure A2. Module Local Coordinate System.

5. Generate up-to-date predicted module weight and COG information from discipline input.

Table A4. Discipline Reported Weights and COGs.

Discipline Description	Source	Status	Total Dry Weights (MT)			C.O.G. Coordinates (m)

6. Process information to present facility weight status for the modules at the load cases stated in Step 2 and provide a summary of results, including areas of concern and recommended actions.

Table A5. Summary of Module Reported Weights and COGs.

Condition Description	Reported Weight (MT)	COG Coordinates (m)			COG Constraints [Min - Max] (m)		
		X	Y	Z	X	Y	Z
Loadout	710.5	**42.23***	3.21	8.28	20 – 40	2.7 – 5.3	0 – 9
Transport	**738.2 (NG)**	**41.77***	3.12	8.21	20 – 40	2.7 – 5.3	0 – 9
Installation	710.5	**42.23***	3.21	8.28	20 – 40	2.7 – 5.3	0 – 9
In-Place (Dry)	707.2	**42.14***	3.24	8.27	20 – 40	2.7 – 5.3	0 – 9

Note: *Exceeds the allowable COG offset envelope.

Module PR-01 currently falls outside the transportation constraints in the longitudinal (X) direction as indicated in Table A5. The following are the factors of the above preliminary COG results:

- The COGs were calculated using data in the computer model which is in development and only 20% complete. COGs for piping and equipment (including data for inline instruments and electrical weights) were calculated manually.
- The Pressure Safety Valve (PSV) platform design by vendor has been changed and the revised equipment and platform layout drawings will be developed.

- Any material or equipment that is currently defined as a ship-loose item is subjected to change.

It is recommended to consider the first floor East-West access walkway as a ship-loose item. The predicted weight after weight shed during transport condition will become 714 MT (refer to Tables A6 and A7 below). The proposal will ensure that the module weight is within transportation envelopes (i.e., 730 MT) and thus to minimize future rework in the detail design phase. This action requires further structural analysis and client agreement.

ABSTRACT

Built 100' deep into dolomite bedrock, the influent pump station at Valley Creek Wastewater Treatment Plant in Alabama is approximately 360' long and 230' wide. Several elements of this underground structure failed in April 2005 only a few weeks after its commissioning, partially flooding the pump station and rendering it inoperable. After the causes of the failure were determined, the engineer presented several repair options. The accepted repairs included wall and floor thickening using 25,000 epoxy grouted steel dowels, uplift stabilization of the entire underground structure using 700 high-capacity rock anchors, installation of concrete and steel transverse bracing for previously laterally unsupported basement walls, modifications to various structural elements for reconfigured load paths by new transverse bracing, hydrophilic urethane crack injection in the mat slab to reduce groundwater infiltration, and epoxy injection of numerous cracked structural concrete elements. Despite the magnitude and the challenges of the repairs, the pump station was restored within three years of the failure and is fully operational.

INTRODUCTION

Valley Creek Wastewater Treatment Plant is an 85 Million Gallons per Day (MGD) sewage treatment facility (Photo 1). With the pump station in operation, it has 600 MGD of peak flow treatment capacity.

The pump station is built in a 100' deep excavation into dolomite bedrock. The footprint of this underground concrete structure is approximately 360' long and 230' wide and extends out 35' from each side of the substructure's long span. The underground concrete structure has three major functional areas: the wet well, the dry well, and the flume (Figure 1 and Figure 2). The wet well, which is continuous through the total depth of the pump station, is the receiving point of influent. The dry area located in the middle part of the pump station along the long span houses about 20 large pumps and discharge lines. The 35' wide and 35' high flume, which runs along the long span of the pump station on the opposite side of the wet well is supported by 53'tall concrete space frame of columns and beams. In addition, two stair wells, an elevator shaft, and an air shaft are located in the flume area.

The superstructure, which houses the control room, restrooms, loading dock, and storage rooms, is a 55'-tall steel and concrete frame structure with concrete masonry units (CMU) infill walls. Movement of heavy equipment in and out of the pump station is performed by an overhead gantry crane system running along the long axis of the pump station.

Several elements of the underground structure, including the mat slab, failed on April 2, 2005. Damage was visible in numerous concrete structural elements in the form of cracks and spalls. After the failure of the mat slab, groundwater flowed into and partially flooded the pump station, with the water level in the dry well of the station reaching 14' above the base mat. Heavy rains fell in the area days prior to the failure. The groundwater level outside of the pump station two days after the failure was approximately 68.5' above the base of the mat slab.

This paper presents the details of repair and retrofit procedures that were followed after determination of the cause of failure.

INVESTIGATION

The forensics engineering team conducted field observations performed a detailed structural analysis and design review, and conducted geotechnical testing and analysis. Details of this investigation was published in the proceedings of ASCE Structures Congress -2010 (Samarajiva and Gosain, 2010).

Distress observed in the field investigation can be summarized as follows:

1. A crack in the mat slab 2" wide and 100' long in the dry well adjacent to the wall that separates wet and dry wells;
2. Numerous cracks in the mat slab, flume structure, columns, beams, and walls;
3. Heaving of the mat slab.

In order to conduct a failure analysis, a finite element analytical model of the entire underground structure was implemented. The detailed failure analysis concluded the following:

1. The structural failure of the mat slab was caused by groundwater uplift pressure on the mat slab;
2. The underground perimeter walls of the structure were not designed to withstand the groundwater pressure present at the time of failure;
3. The structure as a whole did not have sufficient capacity to resist uplift forces under hydrostatic pressure if the groundwater elevation was close to the surface;
4. The strength of the structure was inadequate to resist the lateral earth pressures even without the presence of groundwater.

REPAIR OPTIONS AND CRITERIA

All repair options had to address four structural issues:

1. Repairing the damaged beams and columns under the flume;
2. Grouting or injecting the cracks in the mat slab to reduce infiltration of ground water if no dewatering system is installed;

3. Strengthening the perimeter walls to resist lateral loads due to earth pressure and groundwater;
4. Anchoring the mat slab to reduce buoyancy of the structure or installing a permanent dewatering system.

Based on the owner's input, five conceptual repair schemes depicted in Figure 3 were developed with approximate construction costs. After evaluating the associated risk, construction issues, cost and life expectancy of the pump station, the owner chose a combination of Options C and D. This included strengthening the structure to resist the hydrostatic lateral pressure due to groundwater and yet put in place a dewatering system to maintain the groundwater levels below a chosen threshold.

ENGINEERING CHALLENGES

Given the challenging nature of the project, the engineer consulted the facility's original general contractor and a subcontractor to develop a better understanding of challenges associated with the proposed repair options. The presence of the structural frames inside and large shot rock fill in the basin outside led the subcontractor to recognize that installation of rock anchors of the perimeter walls would be highly cost prohibitive. Therefore, Options A and B were abandoned. The geotechnical engineer found that complete grouting of the shot rock fill would be virtually impossible, and therefore Option C was also dismissed. The partially excavated backfill Option E would limit accessibility to the pump station. In addition, the buried lines in the proposed excavation area would hamper sewage transfer operations. Also, the owner wanted to limit the repair work only within the pump station.

As a result, repairs were limited to Option D or a variation of this option. Even though the impact of wall strengthening on the sewage retention capacity in Option D appeared to be insignificant, the introduction of an internal bracing system would severely hamper the pump station maintenance operations. For example, it would be virtually impossible to remove and replace the pumps if transverse braces were installed at every current frame location. Furthermore, installing transverse braces at the lowest level of beams would limit maneuvering space for internal operations of the pump station.

Based on those restrictions and the owner's operational requirements, the transverse bracing locations were limited to every other frame and these were installed only above the first beam level. As a result, the walls needed to be strengthened together with the installation of the transverse braces.

After considering all the associated issues and the owner's desire to have the pump station operational even during a failure of the ground water pumping system, the repairs items 1 to 11 pictured in Figure 4 were designed. These are described below.

During construction, some additional structural deficiencies were discovered. The majority of these deficiencies can be attributed to the discovery of the substitution of precast hollow core slab panels for a cast-in-place reinforced concrete slab at the

ground level to function as a diaphragm. It was determined that these hollow core slab panels were not designed to act like a diaphragm. As a result, creating new access hatches for the wet well repairs became impossible without strengthening the diaphragm slab. In addition, the concrete corbels for the bridge crane and the transfer beams under the crane columns were found to be structurally deficient. In order to address the later identified deficiencies, the repairs items 12 to 16 pictured in Figure 4 were also designed which are described below.

REPAIR DESCRIPTIONS

1. Anchoring the Mat Slab Using Rock Anchors

Nearly 680 rock anchors were installed on 9'x9' grid in the dry well and 9'x12' grid in the wet well (Photo 2). Finite element analysis was used to ensure effectiveness of the anchors when they were repositioned beyond the allowable 2' tolerance. Each anchor was design to sustain a tensile force of 580 kips. About 55 of these anchors were randomly subjected to Proof Tests and about 5 of these anchors were subjected to Extended Creep Tests.

2. Mat Slab Major Crack Injection

The major crack in the mat slab was injected to its full depth using hydrophilic polyurethane grout (Photo 3). Injection could be stabilized only after several attempts to bridge the gap.

3. Housekeeping Topping Slab Overlay for the Base Mat

Presence of many fractures in the area made it difficult to seal all the cracks. An 18" housekeeping topping slab was placed over the existing mat slab by sandwiching a drainage mat in between (Photo 4). The purpose of the drainage mat was to ensure free dissipation of ground water seeping through numerous cracks in the base mat.

4. Transverse Bracing

New 36"x36" transverse bracing struts were designed to match the existing beams. Concrete was chosen for the wet well section to and galvanized hollow structural steel square sections were chosen in the dry areas (Photo 5). Galvanized steel braces were chosen mainly to expedite the repair process. Use of galvanized steel was not a suitable option in the wet well due to the possibility of corrosion, The complexity of precise positioning of the bracing struts was met by the contractor.

5. Waler Beam in Wet Well

A new 96"x60" high strength concrete waler beam was attached to the concrete wall with epoxy grouted galvanized dowels (Photo 6). The purpose of this beam was to transfer lateral earth forces more uniformly than the existing wall. For accessibility reasons, the locations of construction joints, stirrups assembly, and lap splicing were

customized so the contractor could conduct other repair tasks simultaneously in the level below.

6. Wall Strengthening

Existing perimeter walls were thickened to increase the shear capacity (Photo 7). These 72"thick perimeter walls were thickened over a 35' height above the mat slab with thickness varying from 72" at the bottom to 24" at the top of the thickened section using high strength concrete. Epoxy grouted galvanized steel dowels were used to ensure composite action between the existing wall and the new wall.

7. Epoxy Inject Cracked Beams, Columns, and Walls

All minimally cracked structural concrete elements were epoxy injected. The purpose of epoxy injection was to reestablish aggregate interlock lost during the failure.

8. Recasting Heavily Damaged Concrete Beams

Some concrete beams were distressed beyond repair due to yielding of steel. Such heavily damaged concrete beams were demolished and recast to their original sizes. However, reinforcement was redesigned in the beams to function as struts.

9. Externally Bonded Ties for Columns and Struts

Structural columns were originally designed without column ties and introduction of the cross bracing frame caused some beams to function as struts. As a result, new externally bonded steel plates were designed for the columns and beams to function as ties. Epoxy anchors were used to attach steel plates to the columns and beams (Photo 8).

10. Repair Concrete Spall

Concrete spalls throughout the structure were repaired using standard repair methods using polymer cementitious mortar. The purpose of spall repairs was to ensure adequate concrete cover over the reinforcement.

11. Permanent Dewatering System

Based on a ground water study, a new programmable 4-pump dewatering system was installed. This system is capable of autonomously maintaining groundwater levels between user set limits.

12. Wet Well Diaphragm Strengthening

A new high strength concrete overlay slab was installed over the wet well topping slab to improve the diaphragm capacity (Photo 9). Epoxy anchors were used to ensure adequate shear transfer between the topping slab and the overlay.

13. Concrete Beams Inside the Flume

Certain parts of the superstructure were directly supported on hollow core concrete planks. These hollow core concrete planks were found to be inadequate to take the superstructure design loads. Therefore, 36”x36” concrete beams were installed inside the flume under the superstructure. In order to establish contact between the hollow core plans and the new beams, self-consolidating concrete was poured into the formwork through ports in the existing hollow core planks.

14. Steel Trusses to Support Crane Beams

The crane support beams were found to be under designed for the rated capacity of the pump station crane. This beam was at a location where it is difficult to install a fully assembled truss (Photo 10). Therefore, a series of galvanized steel trusses were designed to facilitate field assembly so workers could install them in pieces without the use of a heavy crane.

15. Corbel Strengthening

The crane supporting concrete corbels did not meet the minimum reinforcement requirement in design codes (ACI-318). As a result, additional reinforcing bars were epoxy grouted into the crane support corbels to meet the necessary strength requirements.

16. Closure of the Stair Well Openings

Existing stairwell openings were found to have reduced the diaphragm capacity below acceptable limits. As a result, the stair well openings in the middle of the top diaphragm were closed to ensure continuity in diaphragm action. New stair well segments were designed to provide access to the stair wells from the exterior (Photo 11).

CONCLUSIONS

After six months of investigation and analysis and five months of repair design, a plan was accepted by the owner to repair the pump station. These repairs included 700 rock anchors, nearly 25,000 epoxy-grouted dowels, 650 tons of steel and 8,000 cubic yards of concrete. The total cost of repairs amounted to $ 33 million and the original construction cost was about $52 million. Photo 12 shows the interior view of the structure after the repairs were completed.

Despite the magnitude and challenges of the repairs, the pump station was restored and fully operational to the owners’ satisfaction in less than three years from the time of failure. The success of these unusual repairs should be credited to the exceptional team work and creative structural solutions by all parties engaged and the owner’s unwavering commitment to restore the pump station to serve the community.

ABSTRACT: To expedite the design of foundations for the SCR support structure (40 m wide x 170 m long x 85 m high) at a Southeastern U.S. coal fired power plant, a number of STAAD Pro v8i (Bentley Systems, Inc., 2008) models were developed and Excel (Microsoft 2003) spreadsheets utilized. The forces were summarized in Excel to assist in the reinforcing design. There were a large number of primary load cases which resulted in thousands of service and strength load cases that needed to be analyzed. The large amount of data generated required post processing using Excel to consolidate and summarize the information. Typically, information is copied from STAAD Pro v8i and pasted into the appropriate location in the spreadsheet, however, one spreadsheet was utilized which uses Open STAAD (A library of exposed functions) to extract the pertinent information and combine the plate forces (Mx, My & Mxy). This spreadsheet was enhanced by graphics of the foundation plates that were then color coded to represent the extent of the required reinforcing. This provided a convenient visual representation of the extents of the required reinforcing.

Due to poor soil capacity and large loads, micro piles to rock were required to support the pile caps. The micro piles were modeled in STAAD Pro v8i and the forces extracted to an Excel spreadsheet which compared the values to allowable capacities. Foundation thickness was confined due to existing obstructions (feed water pipes, electrical duct banks, etc) which limited the foundation shear capacity. In a number of locations micro piles were located within *d* of the columns requiring a deep beam shear check of the foundation. Another spreadsheet was developed to provide this check by extracting the plate moments and shear for each load case and applying it with the appropriate deep beam shear formula. A comparison between the allowable deep beam shear and the actual was then made.

INTRODUCTION

Plant Robert W. Scherer, located near Macon, Georgia, is an electric generating facility consisting of four coal-fired units having a total capacity of approximately 3,500 megawatts. A large environmental controls initiative at the facility includes the construction of bag houses, selective catalytic reduction (SCR) facilities, and flue gas desulfurization (FGD) facilities. The Selective Catalytic Reduction (SCR) structures support numerous pieces of equipment used in the reduction of nitrogen oxides from the flue gas. The SCR reactors and dampers, as well as inlet and outlet ducts, are supported at various locations throughout the structure. Each SCR structure is approximately 40m wide by 170m long. The Units 1 and 2 structure is approximately 105 m high, while the Units 3 and 4 structure is 85m high. Each structure spans over two existing precipitators and is located between the boiler house and stack (See Figure 1). (Adeyefa, A. 2011, et al)

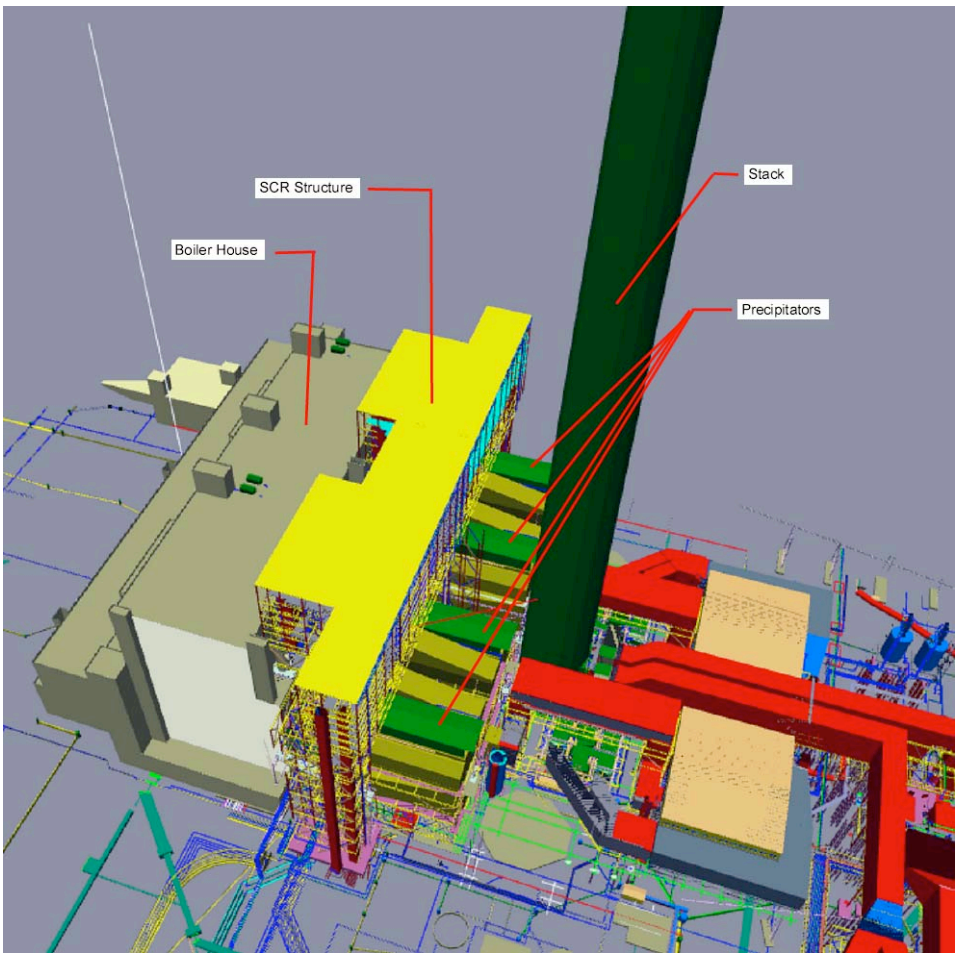

Figure 1 – SCR Structure – Units 1 & 2

The SCR structure has 70 columns to grade which are supported on numerous concrete foundations embedded on micro piles which extend to rock. This was necessary due to the limited soil capacity and the magnitude of the loading from the SCR structure. In addition the thickness of the pile caps was restricted due to existing underground obstructions such as piping and electrical duct banks.

Due to the number of loads and load combinations, as well as the number of foundations required to support the SCR structure, STAADPRO v8i was used to analyze both the structure and the foundations. Excel was used to extract data from STAAD v8i and to assist in the design of the foundation reinforcing. This paper describes the techniques used to determine the pile cap forces, pile forces and the design of the reinforcing for the pile caps for the units 1 & 2 SCR structure.

MASTER FOUNDATION MODEL

The SCR Structure was modeled in STAAD Pro v8i and consists of 10,292 beams, 4249 nodes, 74 primary load cases and 480 service load cases. It supports numerous pieces of equipment as well as dampers and large duct runs. The SCR structure is supported on 70 columns which in turn are supported on 21 pile caps with a total of 845 micro piles

drilled to rock. A master foundation model was created which contained all of the pile caps, piles and the primary loads from the steel model of the SCR structure. From this master model the individual pile caps were extracted and designed. The pile caps were modeled as four node or three node plate elements and the micro piles were modeled as prismatic members. Rigid links were utilized to simulate the foundation thickness to the support node of the SCR columns. An average pile length of 3 m was used with the properties of the section adjusted to address the average expected length of the micro piles. The plates were given the properties of concrete with f'c =34.47 MPa, E= 26 GPa and a density of 23.5 kN/m^3.

The ASCE/ACI service and strength load combinations as per the ASCE 7-05 and ACI 318-05 were then developed and input into the master foundation file. This resulted in 115 (LC #1 to 116) primary load cases, 615 service load cases (LC#120 to 734) and 774 strength load cases (LC#1000 to 1774). The individual foundation models were run and the results were extracted from STAAD v8i to spreadsheets to design the reinforcing and check the micro pile capacity.

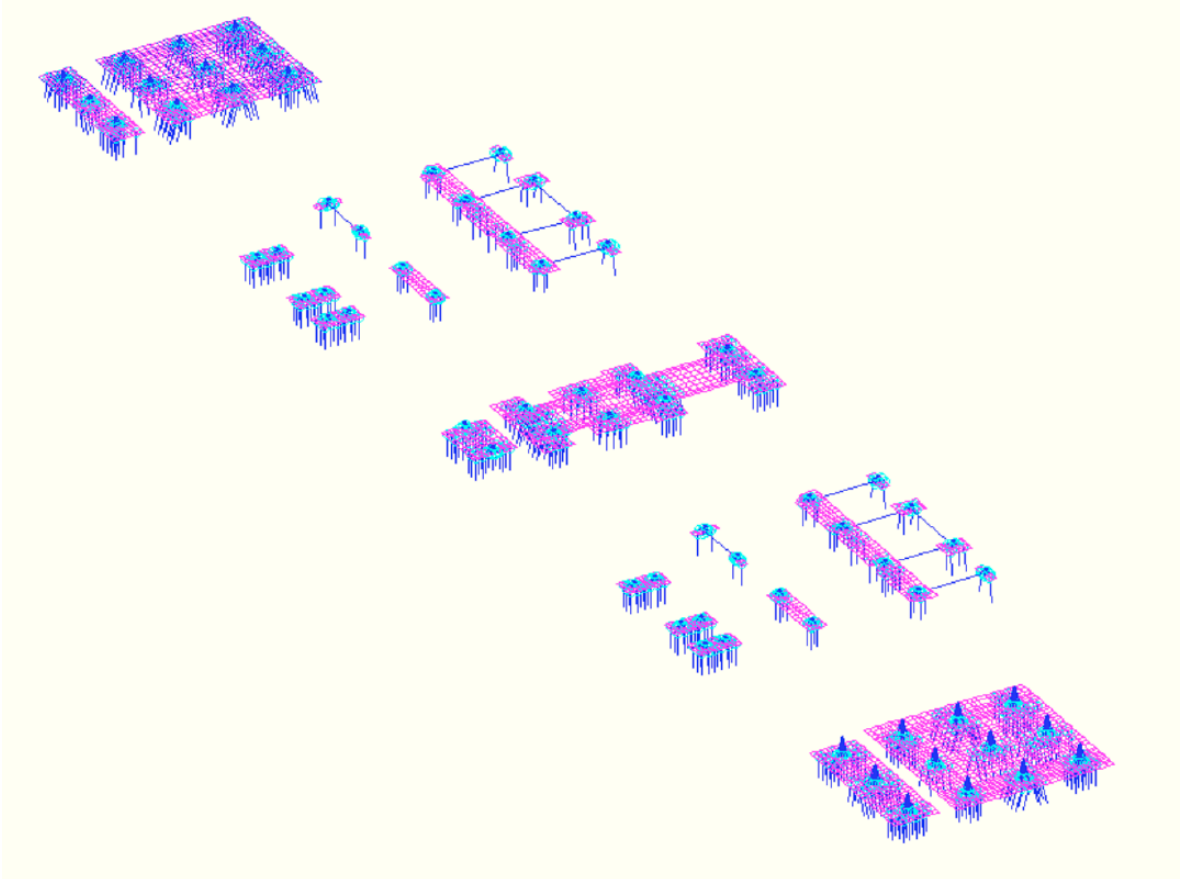

Figure 2 - Master Foundation STAAD Model

PILE CAPACITY CHECK AND PILE CAP REINFORCING DESIGN

To check the pile capacity, the service load reactions for the micro-piles were enveloped in STAAD Pro V8i and copied to the pile support reaction spreadsheet which summarized them in a handy table (See Figure 5). This table was then conditionally formatted using the allowable loads for the micro-piles, which were provided by the project geotechnical engineers. The conditional formatting colored the cells yellow if they were within the allowable loads and red if they exceeded the allowable loads. In this manner the micro-pile layout and number were checked to determine if the micro-pile configuration and number were acceptable.

To assist in the design of the pile cap another spreadsheet utilizing OpenSTAAD (Bentley Systems, 2008) was developed by WorleyParsons to extract the plate information, combine the moments and summarize them in a table. Worksheets were added to this spreadsheet to extract the top and bottom moments, Mx & My, and display them for each plate. Reinforcing capacities were input into the spreadsheets and the cells colored to represent the extent of the required reinforcing. Similar worksheets were made for the shear values, Vx & Vy.

To complete the process a calculation package was developed for the foundations with an appendix containing the design for each individual foundation. The main body of the calculation summarized the results for each foundation. In this manner all 18 foundations that support the SCR structure were designed and documented.

EXAMPLE FOUNDATION

The first foundation that was designed using this methodology was the south tower west foundation (STWF), which will be used as an example. The foundation is 6 m x 19.5 m x 2 m thick and is supported on 64 – 0.244 m diameter micro piles. The foundation supports three columns of the SCR structure. The micro piles surrounding the center column are battered at 14 degrees to the north and south respectively (12 north & 12 south). The 20 micro piles under the south end were symmetrically placed about the column. The 20 micro piles under the north end could not be placed symmetrically due to underground obstructions. The STAAD v8i model is shown in Figure 3.

Figure 5 - STWF Pile forces Summary

The value for compression, tension and shear were then compared to the allowable loads that were provided by the geotechnical engineers of 2002 kN compression, 1001 kN kips tension and 89 kN of shear. Since the pile forces were all less than the allowable pile forces, no modifications were required to be made to the pile layout. If any of the values would have exceeded the allowable values, the pile layout would have been revised to add vertical or battered piles or move piles. The model would be re-analyzed and the results copied to the pile forces spreadsheet for review. This process would be repeated until the all the pile forces were below the allowable pile forces.

Pile Cap Design

The design of the pile cap utilized a spreadsheet that was developed at WorleyParsons. This spreadsheet contains VBA macros which opens the STAAD file selected by the user, extracts the Mux, Muy, Muxy, Vx & Vy values, combines the Mux, Muy & Muxy values as per Wood (Wood, R.H., 1968) and Armer (Armer, R.G.T., 1968), separates the top and bottom Mux & Muy values and the maximum and minimum Vx & Vy values and writes them to a data file. It then summarizes the information in a convenient table and gives the user the option of writing the data to a pivot table adjacent to the analysis summary. All this is accomplished via the “Calculate” command button; see Figure 6 and Figure 7.

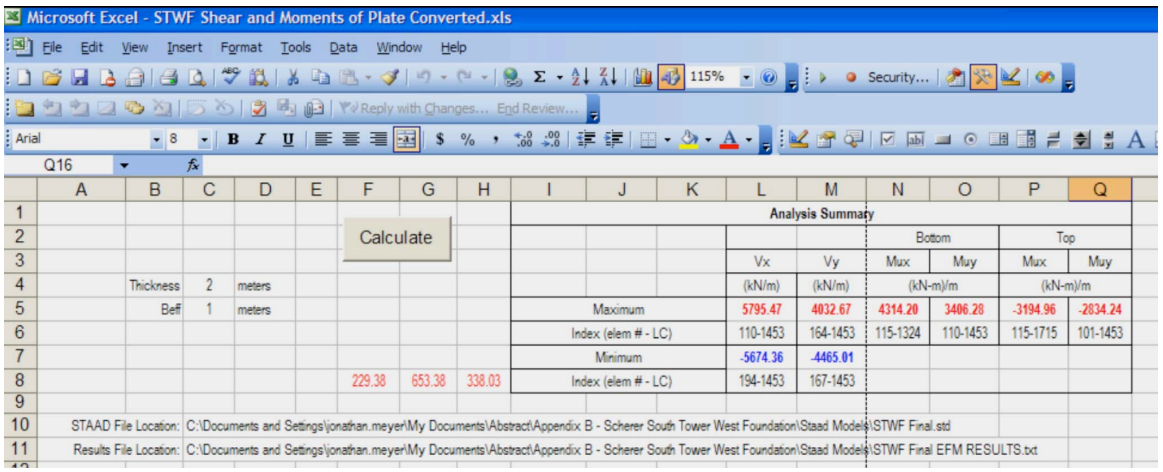

Figure 6 - Shear and Moments of Plate Summary

S	T	U	V	W	X	Y	Z	AA
Elem #	MAX of Mux	MAX of Muy	MIN of Mux	MIN of Muy	MAX of Vx	MIN of Vx	MAX of Vy	MIN of Vy

Figure 7 - Shear and Moment of Plate Pivot Table

To facilitate the pile cap design, additional worksheets were added to show the moments in each plate and color code them to selected reinforcing. The following lists the worksheets that were added and a short description of what it does:

"Mat" – Contains a map of the foundation plates with the plate numbers that correspond to the model.

"Mux Bottom" – Reads the plate number from the "Mat" worksheet and extracts the plate's maximum value of Mux from the pivot table which is the bottom moment in the plate in the x direction. See Figure 8.

"Muy Bottom" - Reads the plate number from the "Mat" worksheet and extracts the plate's maximum value of Muy from the pivot table which is the bottom moment in the plate in the y direction.

"Mux Top" – Reads the plate number from the "Mat" worksheet and extracts the plate's minimum value of Muy from the pivot table which is the top moment in the plate in the x direction.

"Muy Top" - Reads the plate number map from the "Mat" worksheet and extracts the minimum value Muy from the pivot table which is the top moments in the plate in the y direction.

"Vx" – Reads the plate number map from the "Mat" worksheet and extracts the largest absolute value Vx from the pivot table which is the maximum shear in the x direction.

"Vy" - Reads the plate number map from the "Mat" worksheet and extracts the largest absolute value Vy from the pivot table which is the maximum shear in the y direction.

Figure 8 shows the Mux Bottom worksheet for the STWF. The dots represent the pile locations, and the numbers in the cells are the values of the moments along the x direction for that plate. The outlined borders approximately represent either a distance d from the pier or the outline of the edge of the pier (column base plate). The cells have patterns which correspond to the reinforcing required in that area.

To determine the reinforcing required, the moment & shear capacities of various configurations of bars was calculated. Since the maximum value for each worksheet is shown, the user can select reinforcing that meets the demand of the foundation, input the FMn value in the appropriate cells and see where the reinforcing is required by the patterns in the cells. Along the top and left side is a distance from the start of the foundation to enable easy recognition of the extent to which reinforcing is required. This methodology was followed for each of the moment and shear worksheets (deep beam shear was also checked when applicable utilizing another spreadsheet).

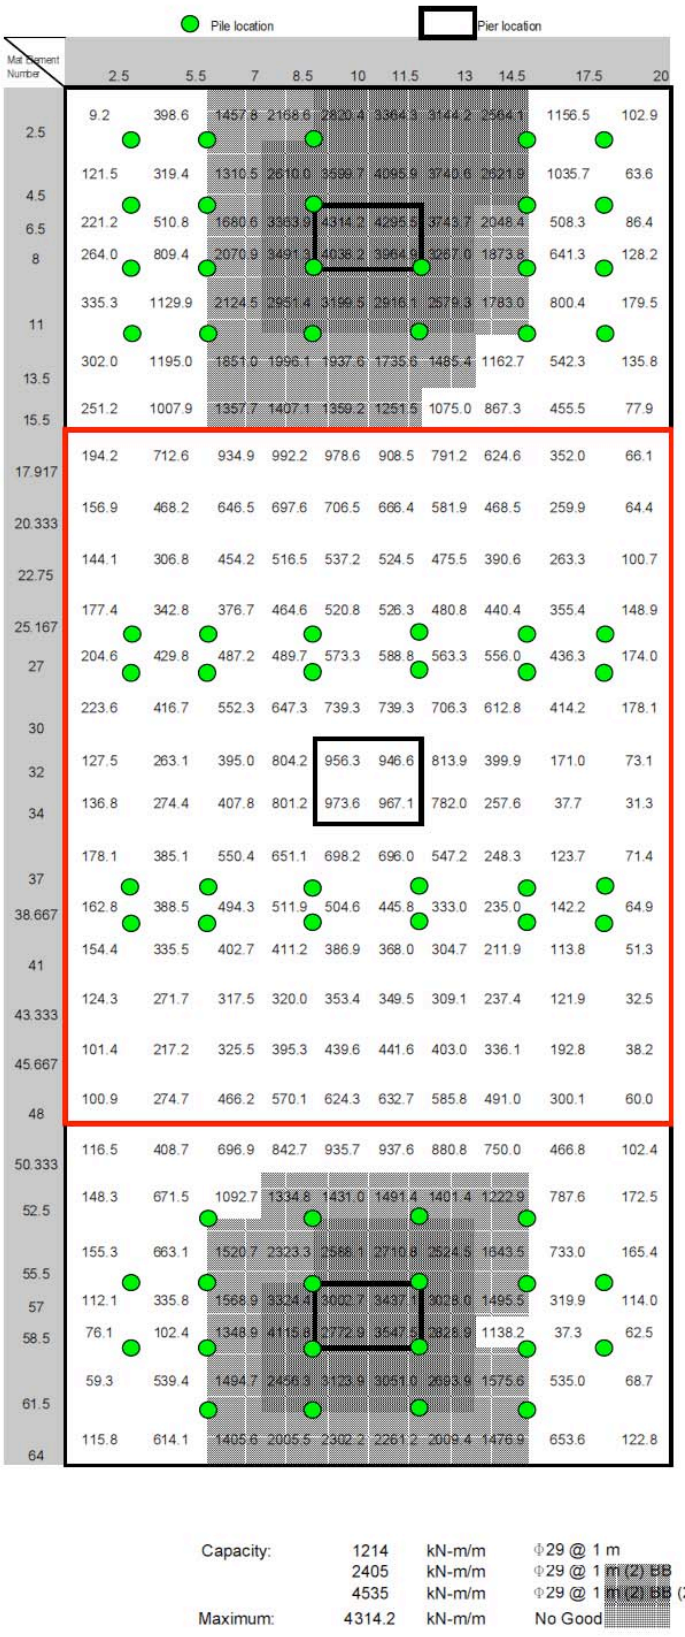

Figure 8 - Mux Bottom Worksheet

CONCLUSIONS

The design of the unit 1 & 2 SCR structure's foundations was able to be systematically approached via outlined procedure using STAAD v8i to analyze the foundation and Excel spreadsheets to post process the data. Once familiar with the spreadsheets the design of the foundations proceeded quickly. If additional manpower was available, it would have also been possible to have more than one engineer participate in the design. In addition, when presented with field changes, (i.e. existing adjacent caissons being larger than shown on the design drawings, or rock being deeper than expected) the models were quickly modified, the results exported to the spreadsheets and the effect on the foundations evaluated. In some cases this resulted in additional reinforcing being added, existing caissons being trimmed back to allow for clearances or piles being skewed to avoid interferences. Using these design procedures proved to be very effective and efficient in both the original design process and when confronted design modifications due to field changes.

ACKNOWLEGMENTS

I would like to thank the management and staff of The Southern Company and WorleyParsons for the opportunity to participate in the design of the unit 1 & 2 SCR foundations.

INTRODUCTION

Concrete pedestals of elevated water storage tanks support a steel vessel, schematically shown in Figure 1, or a concrete vessel, schematically shown in Figure 2.

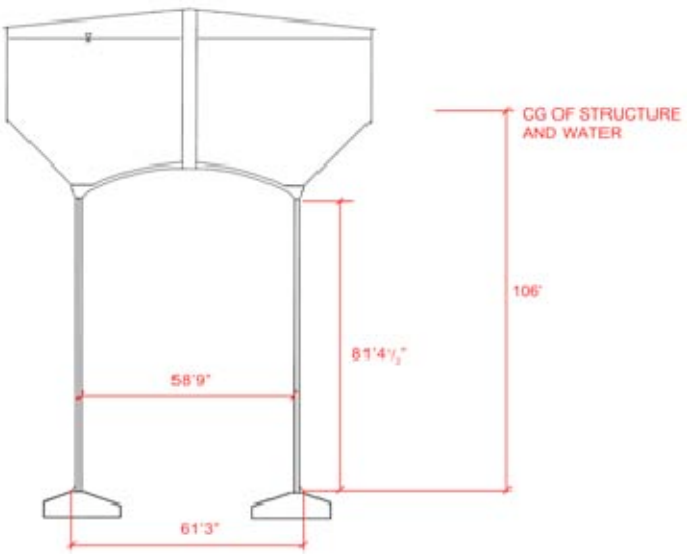

Figure 1. 2.0 MG composite elevated water storage tank.

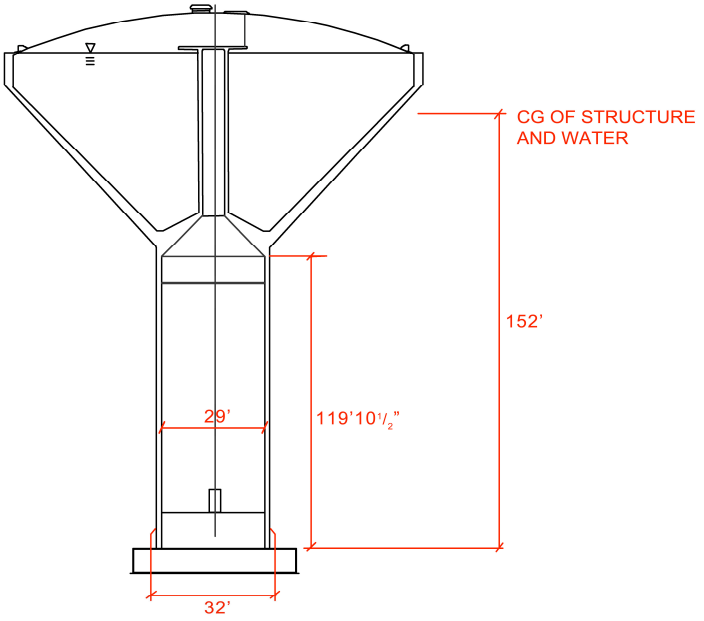

Figure 2. 2.0 MG concrete elevated water storage tank.

ACI Report 371R-08 [1] recommends that elevated tank pedestals be designed in accordance with ACI 318 (Code) [2]. The Code permits the shear strength of members to be calculated as the sum of the strength provided by concrete alone and the strength provided by shear reinforcement. For the concrete contribution to shear strength, Chapter 11 of the Code allows the designer of tank pedestals the choice of considering the pedestal as a compression member or as a shear wall. The Code provisions for compression members are based on tests of beams and beam columns of rectangular and solid circular cross sections. The Code provisions for shear walls are based on tests of walls of rectangular sections. The pedestals of tanks exemplified by the pedestals shown in Figures 1 and 2 are of thin-walled circular hollow sections. In addition, Chapter 21 of the Code provides requirements for structural walls subjected to seismic forces.

This paper discusses the concrete shear strengths of elevated tank pedestals obtained from ACI 318, proposes alternate concrete shear strengths based on theory and test results on plain concrete, and presents concrete shear strength and limit state obtained from a pushover analysis of the pedestal shown in Figure 2.

SHEAR STRENGTH OF PEDESTALS FROM ACI 318

ACI 318 allows the shear strength of the pedestal to be the sum of the shear strength contributed by concrete and shear strength contributed by shear reinforcement. Considered in this paper is the contribution of concrete without shear reinforcement to the total shear strength of the pedestal.

To apply ACI 318, the concrete pedestal can be considered to act as a member subjected to shear, flexure, and compression or, alternatively, to act as a wall.

For compression members with circular sections, the Code states that the area of the section to be used in computing the shear load can be taken as the product of

the diameter, D, and d = 0.8D, where d is the location of flexure steel relative to extreme compression fiber. This approximates closely the gross area of the concrete section A_g. We consider that A_g and d so defined also apply to hollow circular sections such as those found in pedestals.

With the section of the member so defined, for normal-weight concrete subjected to shear and flexure without compression, the Code allows the shear strength

$$V_c = 2\sqrt{f_c'}A_g \quad (1)$$

This corresponds to a shear stress $v_c = 2\sqrt{f_c'}$ uniformly distributed over the area of the section.

For members with compression, the Code shear strength is

$$v_c = 2\sqrt{f_c'}[1 + f_{cu}/2000] \quad (2)$$

where
$f_{cu} = N_u/A_g$ and
N_u = factored vertical compression load comprising a full vessel of water and the dead weight of the structure above the section investigated.

At the base of the pedestal of the composite tank, shown in Figure 1, f_{cu} = 960 psi and (2) leads to $v_c = 3.0\sqrt{f_c'}$. At the base of the pedestal of the all-concrete tank, shown in Figure 2, f_{cu} = 1,690 psi and (2) leads to $v_c = 3.7\sqrt{f_c'}$.

The Code also permits an alternate computation of shear strength of a compression member that includes the effect of flexure steel as well as bending, shear and compression. This alternate is not considered here because recent tests [3] show that it may lead to low factors of safety.

The Code provisions for shear strength of walls include a pair of expressions of which the lesser strength of the two governs.

$$v_c = 3.3\sqrt{f_c'} + 0.25\, f_{cu} \quad (3)$$

where
$f_{cu} = N_u/A$ and
$A = hd$

The second of the pair, taking $l_w = D$, $N_u/l_w h = f_{cu}$, and $M_u/V_u l_w$ approximately equal to H/l_w where H is the approximate location of the center of gravity of the structure plus a full vessel of water, is

$$v_c = 0.6\sqrt{f_c'} + (1.25\sqrt{f_c'} + 0.2\, f_{cu})/(H/l_w - 0.5) \quad (4)$$

Pedestals of elevated tanks are commonly constructed of 4,500 psi concrete. For the composite tank, $H/l_w = 1.7$, (4) governs, and $v_c = 3.9\sqrt{f_c'}$. For the all-concrete tank, $H/l_w = 4.7$, (4) also governs, and $v_c = 2.1\sqrt{f_c'}$.

The seismic provisions of the Code for structural walls limits the strength contributed by concrete to

$$v_c = V_c/A_{cv} = \alpha\sqrt{f_c'} \quad (5)$$

where $\alpha = 3.0$ for $h_w/l_w \leq 1.5$, $\alpha = 2.0$ for $h_w/l_w \geq 2.0$ and varies linearly between 3.0 and 2.0 for h_w/l_w between 1.5 and 2.0. With h_w equal to the height of the pedestal, (5) leads to $v_c = 3.0\sqrt{f_c'}$ for the composite elevated tank and $v_c = 2.0\sqrt{f_c'}$ for the all-concrete tank.

In summary, ACI 318, as applied here, limits concrete shear strength in pedestals of elevated tanks shown in Figures 1 and 2 as follows:

Loading Condition	Concrete Strength, $v_c/\sqrt{f_c'}$	
	Composite Tank	All-Concrete Tank
Seismic	3.0	2.0
Nonseismic	3.6	2.1

PROPOSED ALTERNATE SHEAR STRENGTH OF CONCRETE FOR PEDESTALS

We base our proposal for concrete shear strength of elevated water storage tank pedestals on the three invariant cap model of Schwer and Murray [4]. The model uses the first invariant of the stresses,

$$I_1 = \sigma_1 + \sigma_2 + \sigma_3 = 3P, \quad (6)$$

the second invariant of the deviatoric stresses,

$$J_2 = [(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)]/6, \quad (7)$$

and the third invariant of the deviatoric stresses,

$$J_3 = s_1 s_2 s_3 \quad (8)$$

where
σ_1, σ_2, σ_3 = principal stresses,
s_1, s_2, s_3 = principal deviatoric stresses,
P = hydrostatic pressure,
and positive stresses are considered compressive.

The failure function is based on these three invariants and the cap hardening parameter, κ, as follows:

$$F(I_1, J_2, J_3, \kappa) = J_2 - R^2 F_f^2 F_c = 0 \quad (9)$$

where
F_c = hardening cap function [4],
R = Rubin function [4],
$F_f = \alpha - \lambda \exp(-\beta I_1) + \theta I_1$, (10)

and α, λ, β, and θ are parameters determined from calibrations of triaxial compression tests on plain concrete test specimens.

The failure surface, F, can be visualized as a surface in Haigh-Westergaard principal stress space with the hydrostatic axis at equal angles from the principal stress axes, the deviatoric plane perpendicular to the axis at a distance from the origin that is proportional to the hydrostatic pressure, a radius in the deviatoric plane that is a function of $\sqrt{J_2}$, and its polar location at an angle that is a function of J_2 and J_3. The intersection of the failure surface by a plane that contains the hydrostatic axis and deviatoric radius at polar angle of zero is F_f, and is known as the compression meridian. Points on the compression meridian are obtained from triaxial tests, frequently on cylindrical test specimens, but cubes as well, in which the confining pressure on the cylindrical surface is held constant and the axial stress is increased to failure. Figure 3, based on calibrations found in Reference [5], shows the compression meridian corresponding to $f_c' = 4{,}500$ psi a commonly used concrete strength in the construction of elevated tank concrete pedestals. In Figure 3, σ_1 is the axial stress and σ_3 is the confining stress in a test of a cylindrical specimen and $\sigma_1 - \sigma_3 = \sqrt{(3J_2)} = \sqrt{3}F_f$.

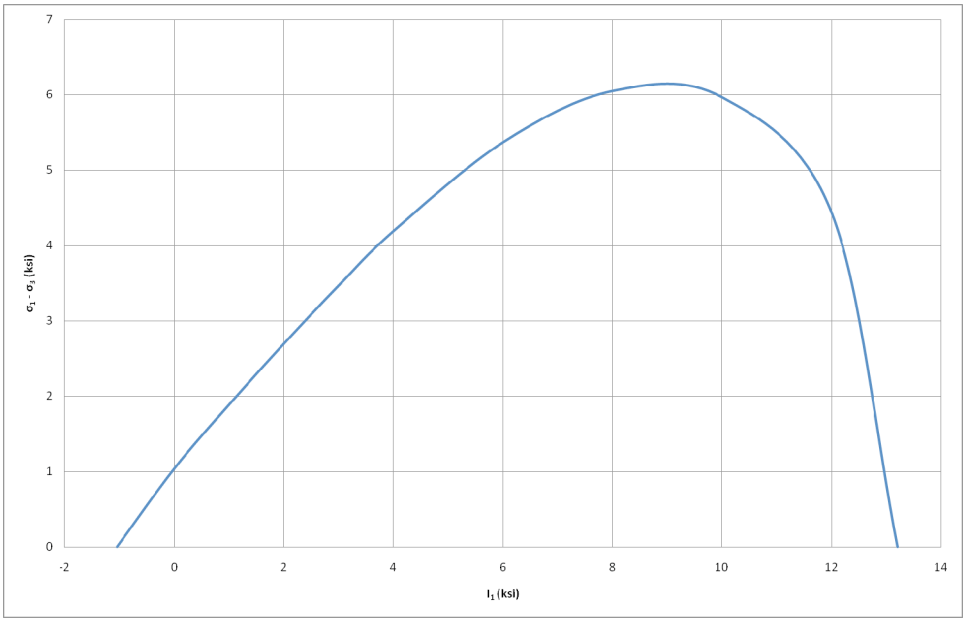

Figure 3. Compression meridian.

Two other meridians of the failure surface include the extension meridian and the shear, or torsion meridian. Points on the extension meridian are obtained from triaxial tests where the axial stress is held constant and the confining stress is increased to failure. Points on the shear meridian are obtained from triaxial tests where the axial stress is increased and the confining stress decreased, or the axial stress is decreased and the confining stress increased, so that I_1 remains constant.

The Rubin function, R, scales the extension, shear, and other meridians to the compression meridian, therefore, R = 1 for the compression meridian [4]. The shear meridian value at $I_1 = 0$ is pure shear and is equal to $(\sigma_1 - \sigma_3)/3$.

Figure 3 shows that at $I_1 = 0$ the variation of $(\sigma_1 - \sigma_3)$ is nearly linear. A similar observation holds for the shear meridian. This suggests that the shear strength of confined concrete may be taken as

$$v_c = C_1 + C_2 I_1 \tag{11}$$

where C_1 and C_2 are functions of f_c'.

Since the shear strength of concrete is commonly taken proportional to the square root of f_c', we take $C_1 = k_1\sqrt{f_c'}$, and inspection of available test results suggests that C_2 could be taken proportional to the cube root of f_c': $C_2 = k_2(f_c')^{1/3}$, where k_1 and k_2 are constants to be determined from available test results. Then,

$$v_c = k_1\sqrt{f_c'} + k_2(f_c')^{1/3}I_1 \tag{12}$$

and

$$I_1 = \sigma_1 + \sigma_2 + \sigma_3 = \sigma_v + \sigma_h + \sigma_r \tag{13}$$

where
σ_v = vertical stress in the pedestal,
σ_h = hoop stress in the pedestal,
σ_r = radial stress in the pedestal.

The radial stress σ_r, is zero, considering the pedestal as a cylindrical shell. The hoop stress σ_h, is a secondary stress resulting from discontinuity of deformation at the base of the pedestal which can be neglected. Then,

$$v_c = k_1\sqrt{f_c'} + k_2(f_c')^{1/3}\,\sigma_v. \tag{14}$$

To determine k_1 and k_2, we use the laboratory tests conducted by Kupfer, Hilsdorf, and Rusch [6]; Mills and Zimmerman [7]; Launay and Gachon [8]; Khaloo and Ahmad [9]; Cardenas, Hanson, Corley, and Hognestad [10]; and strength results included in Reference [5]. The data in the above references were plotted to obtain part of a compression meridian near $I_1 = 0$, similar to that shown in Figure 3 and the Rubin function, that has been calibrated in Reference [5] for the concrete strengths in Reference [5], was applied to obtain the shear meridian. Table 1 summarizes the k_1

and k_2 values so obtained. Reference [11] includes an extensive list of test results conducted by others. These are not used here because the required extrapolations lead to k_1 values that are twice and three times as large as those in Table 1 and the extrapolated values were considered inaccurate.

For $f_c' = 4{,}500$ psi, a frequently used concrete strength in the construction of elevated water storage tank pedestals, the average values of k_1 and k_2 in Table 1 lead (14) to

$$v_c = 340 + 0.30\,\sigma_v \tag{15}$$

where σ_v is positive when compressive.

The pedestal of the composite steel-concrete water storage tank, shown in Figure 1, works at a compression stress of approximately 650 psi due to self-weight and the weight of a full vessel of stored water. For this condition and for this tank, (15) leads to $v_c = 535$ psi $= 8\sqrt{f_c'}$. The pedestal of the all concrete water storage tank, shown in Figure 2, works at a compression stress of approximately 1,200 psi. For this tank, (15) leads to $v_c = 700$ psi $= 10\sqrt{f_c'}$. These shear strengths of $8\sqrt{f_c'}$ and $10\sqrt{f_c'}$ would result if the cross section of the pedestals were uniformly compressed. However, under lateral loading of the pedestals, maximum compression will result only at one point on the section and diametrically opposite to it tension and cracking may result. To compare the shear strength of (15) to the shear demand of the uncracked and cracked sections, we performed a pushover analysis of the pedestal of the tank shown in Figure 2.

PUSHOVER ANALYSIS OF THE PEDESTAL OF THE ALL-CONCRETE TANK

The pushover analysis was performed with a finite element model of the all-concrete tank shown in Figure 2. The model included one-half of the tank defined by a vertical plane that included the vertical center line of the axisymmetric structure of the tank. Symmetry conditions on the vertical edges of the model included the structural action of the excluded half of the tank. Solid elements, 1 element through the thickness, 50 elements around the circumference, and 120 elements over the height of the pedestal wall modeled the concrete of the pedestal. Rod elements connected to the nodes at the corners of the solid elements modeled the vertical reinforcing. The circumferential reinforcing was excluded from the model, as it was considered to be shear reinforcing. A lumped mass, approximately at the center of gravity, represented the mass of the vessel and the contained water. The lumped mass was rigidly connected to the top edge of the pedestal. The three components of displacement were restrained at all nodes at the base to model a fixed base.

The response of the model was computed with LS-DYNA using Material 159. Material 159 is based on the three invariant concrete model defined in [4]. Material 159 has been calibrated with published results of triaxial tests, laboratory impact tests on beams, and test results of selected structures. The push was effected by applying a low lateral velocity to the lumped mass.

RESULTS OF THE PUSHOVER ANALYSIS

The results of the pushover analysis are presented in Figures 4 through 10. Figure 4 shows the pushover lateral force as a function of the lateral displacement at the lumped mass.

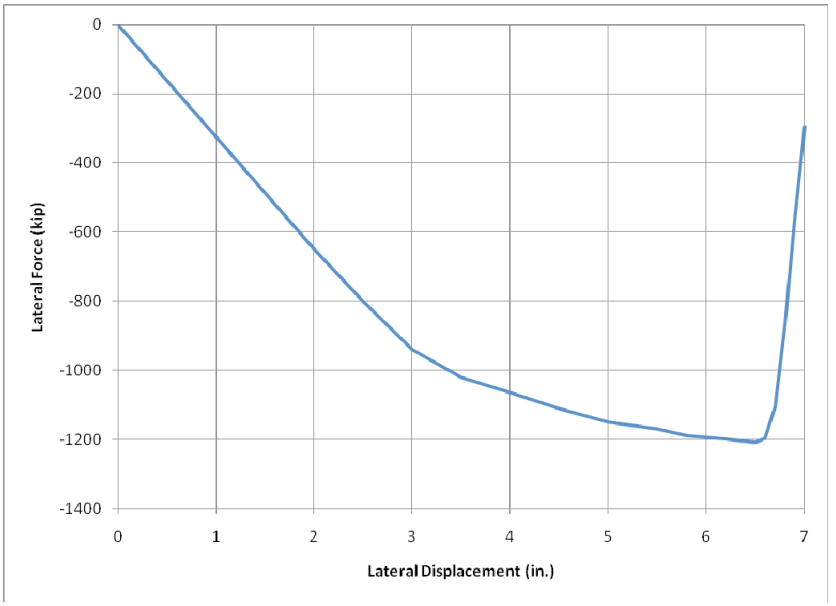

Figure 4. Variation of pushover lateral force (kip) with lateral displacement (in.).

The first flexural crack starts at the base at a lateral displacement of 2.5 in. Immediately before the development of the crack, Figure 5 shows that the shear strength given by (15) exceeds the shear stress demand at all points on the circumference of the base. For the stress conditions at the crack, a lengthy calculation, not shown here, results in the Rubin function value of 0.47 consistent with the polar angle value of 52° close to the extension meridian of the failure surface. This stress condition relative to the compression meridian is shown in Figure 6. Following the initial flexural crack, flexural cracking proceeds circumferentially and inclined cracks are indicated by the accumulated damage above the base shown in Figure 7.

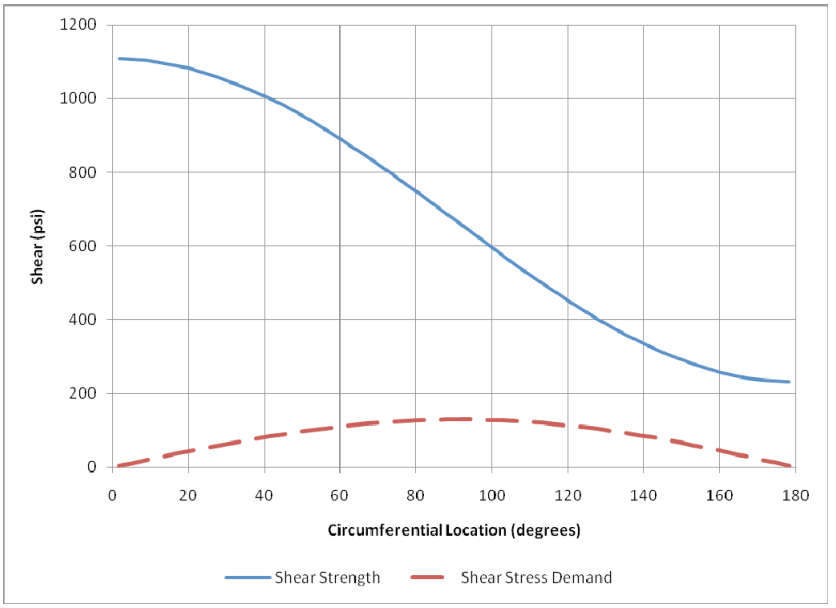

Figure 5. Circumferential variation of shear strength (psi) and shear stress demand (psi) at the base for a lateral displacement of 2.5 in.

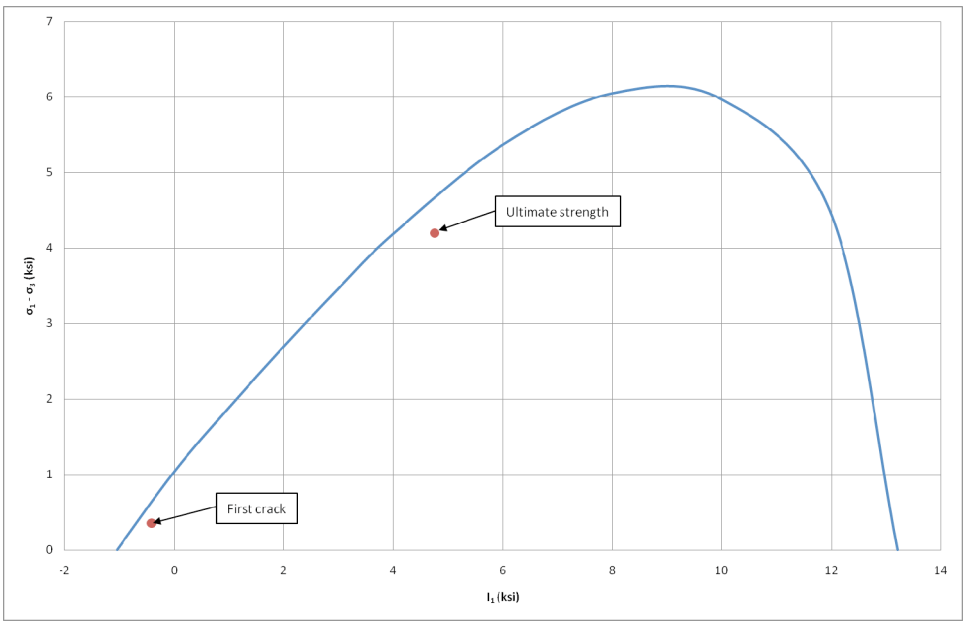

Figure 6. Points on failure surface at first crack and at ultimate strength.

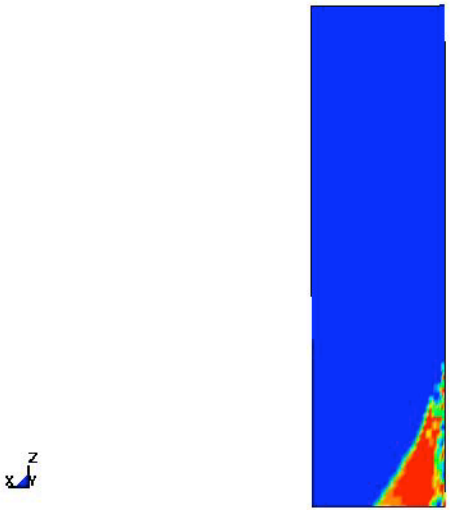

Figure 7. Accumulated damage indicating cracking above the base for a lateral displacement of 5 in.

At a lateral displacement of approximately 6.6 in, the lateral force reaches its maximum of approximately 1,200 kips on one half of the pedestal or 2,400 kips on the complete pedestal. At this force level, Figure 8 shows that the shear strength given by (15) exceeds the shear stress demand at all points on the circumference of the base. Also at the maximum lateral force, the average shear stress over an uncracked section is 116 psi = $1.7\sqrt{f_c'}$. Figure 9 shows the circumferential variation of the first stress invariant and the principal stress difference. At the most highly compressed point on the circumference, the Rubin function is equal to 0.92 consistent with the polar angle of 8° close to the compression meridian of the failure surface.

This stress condition, shown in Figure 6, indicates compression failure of the concrete. The circumferential distribution of stress in the vertical reinforcement, shown in Figure 10, indicates that steel stress is low relative to yield stress. A statics calculation indicates that the eccentricity produced by the lateral load is 96% of the mean radius of the pedestal wall and, therefore, close to the tipping point.

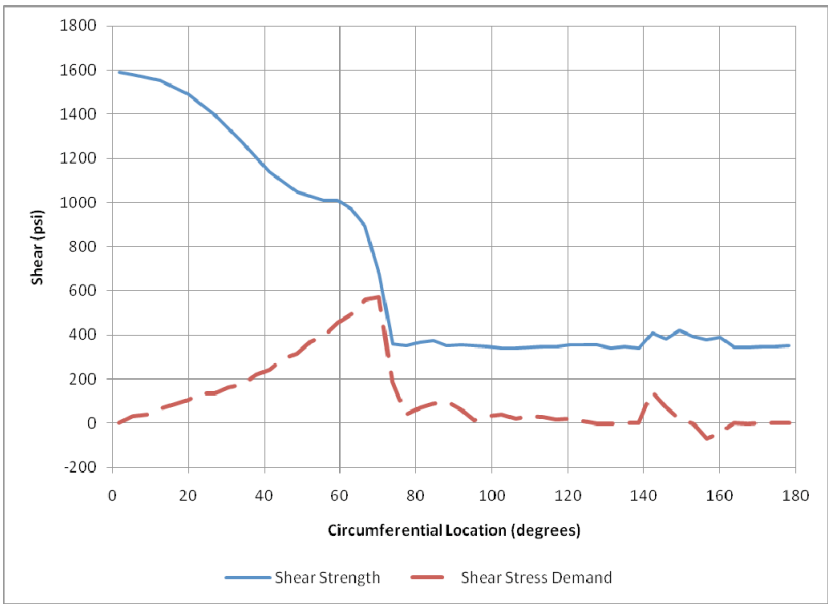

Figure 8. Circumferential variation of shear strength (psi) and shear stress demand (psi) at the base for a lateral displacement of 6.6 in.

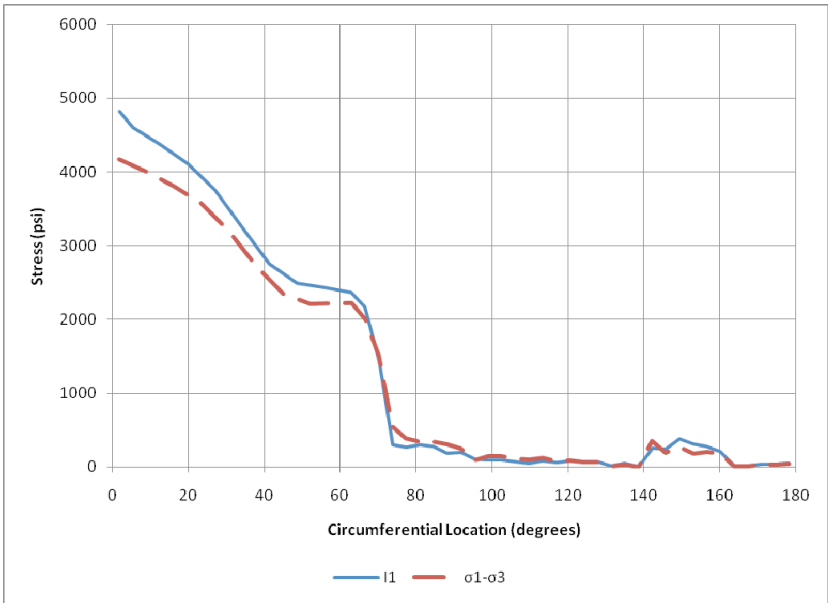

Figure 9. Circumferential variation of first stress invariant (psi) and principal stress difference (psi) at the base.

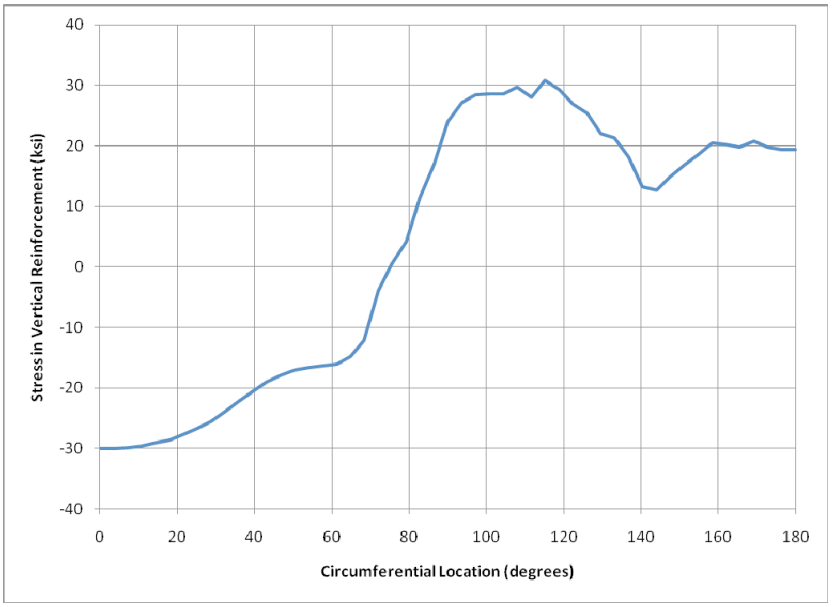

Figure 10. Circumferential distribution of stress (ksi) in the vertical reinforcement

DISCUSSION

The proposed concrete shear strength that includes the beneficial effect of compression is based on limited test data. The reason for this is that the bulk of triaxial test data available in the literature do not include loadings that result in tensile first invariant of stresses, I_1, or loadings that result in near zero value of I_1. More triaxial tests on plain concrete are required for better definition of concrete shear strength in presence of compression.

The pushover analysis of the all-concrete elevated tank pedestal shown in Figure 2 indicates that concrete compression rather than concrete shear strength and flexural steel strength are limiting the ultimate lateral strength of the pedestal. The ductility requires a study that should include the contribution of the vessel and the base slab.

The pedestal of the composite elevated tank shown in Figure 1 has a lower height-todiameter ratio. Its geometry will resist a larger overturning moment and, therefore, concrete compression may not be the limiting strength. A pushover analysis needs to be conducted to determine if concrete shear strength or steel stress limits its ultimate lateral strength.

During the calculation of the pushover several questions arose that require further investigation. The lateral load was generated by applying a low velocity at the center of gravity of the mass representing the structure and the stored water. The intent was to achieve quasi-static loading. This follows the suggestion of the developer of the Material 159 in the LS-DYNA software. The calculated response indicates that a small amount of dynamic variation of the force resulted. This suggests that variation of the applied velocity should be explored to arrive at an optimal velocity that reduces the dynamic effect to an acceptable level while

controlling the amount of output that is generated. Also, the effect on the calculated response of initialization of the applied velocity and the time step used should be explored.

ABSTRACT

Wiss, Janney, Elstner Associates, Inc. (WJE) was asked to investigate cracking and spalling of the concrete foundations of a number of liquid storage tanks at an ethanol manufacturing plant located in western Oregon. The plant was new at the time and the cracking and spalling of the foundations occurred immediately after the tanks were put into service. An initial attempt by the plant to repair the foundations failed immediately. WJE was asked to investigate the cause of the cracking and make recommendations for repairs.

There were twenty metal liquid storage tanks at the plant ranging in size from 62 feet in diameter and 52 feet in height to 14 feet in diameter and 5-1/2 feet in height. All twenty tanks were constructed on foundations with a 1 in 12 slope. The only attachments of the tanks to the foundations were hold down bolts spaced evenly around the perimeter of the tanks, which were intended to prevent overturning.

Although analysis indicated that friction between the base plates and the compacted fill was sufficient to resist sliding of the tanks due to gravity, wind and earthquake forces, it was evident that the tanks were sliding down slope. A study of the thermal expansion and contraction characteristics of the tanks by WJE found that thermal cycling would cause the tanks to migrate down slope.

Ultimately, WJE was tasked with determining which of the twenty tanks were at risk of additional damage and determining if (and how) the process could be arrested. This paper discusses the problems with constructing metal storage tanks on sloped base foundations and proposes an innovative method to prevent downward sliding of these types of tanks.

INTRODUCTION

In mid-2008, WJE was asked to investigate cracking and spalling of the concrete foundations of a number of liquid storage tanks at an ethanol manufacturing plant located in western Oregon. The plant was new at the time and the cracking and spalling of the foundations occurred immediately after the tanks were put into service.

An initial attempt by the plant to repair the foundations failed immediately. The cracking, which although initially was only observed in the foundations of a limited number of tanks, caused concerns regarding the integrity of the remaining sloped base tanks. Consequently, WJE was asked to: 1) determine if the other sloped base tanks were also experiencing damage; 2) determine the risk of future damage for the other sloped base tanks; and 3) develop schematic repairs to prevent future damage to the sloped base tanks that were determined to be at risk. This paper describes our work.

BACKGROUND

Twenty of the liquid storage tanks at the plant were constructed on sloped base foundations. Typically, liquid storage tanks of this type have bases that slope to center. In tanks with bases that slope to center, the outflow pipes attach to the center of the tank beneath the tank. Presumably, the designer of the tanks at this ethanol plant hoped to avoid the construction and maintenance difficulties of having underground outflow pipes by constructing the tanks on sloped foundations located above grade (Figure 1). By constructing the tanks in this manner, the outflow pipes could attach at the side of the tanks at the low end.

The tanks were of varying diameters and heights but otherwise of similar construction. The tanks ranged in size from 62 feet in diameter and 52 feet in height, to 14 feet in diameter and 5-1/2 feet in height. The tanks were generally constructed with 1/4 inch and 3/16 inch thick stainless steel plate walls. All of the tanks had 3/16 inch thick base plates. The tanks were supported by perimeter reinforced concrete foundation walls with continuous spread footings. The foundations were backfilled with compacted fill. The tanks and foundations were all constructed on a 1 in 12 slope.

The foundation wall thickness varied but was generally 14 or 16 inches thick. The walls were generally reinforced with two mats of reinforcing steel with both vertical and horizontal reinforcing. The tanks were anchored to the foundation walls with hold down anchor bolts, generally 1-1/4 to 2 inch diameter bolts, spaced evenly around the perimeters of the tanks. The anchor bolts were attached to the tanks with welded steel anchor chairs generally located 1-1/2 to 2 feet above the base of the tanks. The design drawings indicated a gap between the edge of the tank base plates and the anchor bolts of approximately 1/8 inch to 1/4 inch.

At the low end of the tanks, there was a notch in the foundation walls for the attachment of the outflow pipes. The outflow pipes were generally welded to the base of the tanks at the low end and the notches were in-filled with unreinforced concrete.

Nine of the tanks were fully clad with light gauge metal siding panels. Eleven of the tanks did not have cladding. The anchor bolts were hidden at the tanks that had cladding and were exposed at the tanks that did not have cladding. Most of the tanks operated at high temperatures (170 to 180 degrees Fahrenheit) and some tanks also had internal agitators that caused the tanks to vibrate.

FOUNDATIONS IN DISTRESS

We were first contacted because concrete was spalling off the foundation walls around the low end anchor bolts and around the outflow pipe of the Process Condensate Tank. The Process Condensate Tank is a 44-1/2 foot diameter by 40 foot tall tank with 24 anchor bolts located around its perimeter. At eight of the low end anchor bolts and at the outflow pipe, the concrete at the outer edge of the foundation had broken out (Figures 2 and 3). It was reported that the concrete at these locations spalled and cracked shortly after the tank was put into service. Initial repair attempts by the plant included cutting and chipping the affected concrete and patching with a cementitious repair mortar. The patches subsequently failed and were chipped away again prior to our inspection.

Eleven of the tanks did not have exterior cladding and we were able to measure the positioning of the tanks relative to the anchor bolts. At ten of the eleven tanks, it was observed that the tank base plate was in contact with and engaging the low end anchor bolts. Observations at the mid-slope anchor bolts at many of the tanks also demonstrated down slope movement of the tanks (Figure 4).

At the ten tanks where the base plate was in contact with the low end anchor bolts, distress in the concrete foundations included cracked and delaminated infill concrete around the outflow pipes, cracked and de-bonded grout between the tank base plate and foundation wall, and vertical cracking of the foundation walls at the low end anchor bolts.

Measurements of tank movement were difficult to obtain at the tanks with exterior cladding because the cladding concealed the anchor bolts. At these tanks, observations were limited to the condition of the concrete foundation walls.

At six of the tanks with cladding the distress in the concrete foundations was limited to cracking and delamination of the concrete infill around the outflow pipes. At two tanks, the loose, cracked concrete around the outflow pipes was removed and replaced prior to our visit. By the time of our inspection, new cracking and delaminations were already observed in the repair patches indicating that the tanks were continuing to move (Figures 5 and 6).

WHY ARE THE TANKS SLIDING?

A review of the original design calculations indicated that friction between the underside of the tanks and the compacted fill was relied on to resist wind and earthquake sliding shear forces. WJE's analysis, and observations, demonstrated that friction was adequate to resist the effects of the down slope component of gravity and dead load acting on the tanks. However, our observations indicated that the tanks were clearly moving down slope. The question was why?

The tanks, which were primarily constructed of stainless steel plates, expand when heated and contract when cooled. The frictional forces acting on the bottom

plate always act opposite of the direction of movement. A tank that heats and cools on a level foundation will expand and contract about the center of the tank since that is the only point about which the sum of the frictional forces resisting the tank movement will be in equilibrium in all directions. For a tank on a sloped base, there is a force due to gravity and the dead load of the tank that always acts in the direction down slope. As a result, when the tank expands or contracts, for the sum of the forces acting up and down slope to be in equilibrium, the frictional forces acting on the underside of tank cannot be equal in both directions. The result is that the center of gravity of the tank moves slightly down slope with each heating and cooling cycle.

To simplify the description of the analysis, the circular tank base can be idealized as a flat steel bar resting on a sloped base. In Figure 7, the forces due to thermal expansion are shown on the idealized steel bar with a component of the tank weight acting down slope due to gravity. As the bar expands due to heating, more of the bar must expand down slope in order for the up slope and down slope frictional force components and the down slope component of dead weight to be in equilibrium. Conversely, as shown in Figure 8, when the bar contracts due to cooling, a longer portion of the bar must contract on the high side of the bar in order for the frictional forces and the down slope component of dead weight acting on the bar to remain in equilibrium.

As a result, the low end of the bar does not contract upward as far during the cooling cycle as it expanded downward during the heating cycle resulting in a net movement downward. Similarly, the high end of the bar expands upward a small amount during expansion and contracts downward a larger amount during cooling resulting in a net movement downward.

We decided for a number of reasons that determining the actual magnitude and number of thermal cycles would be a nearly impossible task. One problem was the tanks were enclosed and were subjected to both daily and seasonal temperature cycles both before and after being placed into service. Although any temperature change can theoretically cause a tank to expand or contract, a study to develop a correlation between daily temperature fluctuations and changes in the average temperature of the steel base plates for twenty different tanks was beyond the scope of the project. A study to determine the level at which small temperature cycles could offset the elastic response of the soil and develop frictional forces was also beyond the scope of the project. Luckily, this level of analysis was unnecessary. Our analysis had identified that a mechanism for movement of the tanks existed and the observed movement of the tanks was consistent with the mechanism.

CAUSE OF DAMAGE

What happens when the tanks try to expand after they have already come into contact with the low end anchor bolts? After the tanks come into contact with the low end anchor bolts all future tank expansion is forced to occur up slope. When this occurs the anchor bolts must resist the forces developed due to friction acting across the entire tank bottom as well as the down slope component of the dead load. Our

analysis found that when the tanks were full of liquid, these forces could be huge. Figure 9 demonstrates this load condition.

Frictional resistance is applied in the direction opposite of movement. The magnitude of the frictional force is equal to the product of the normal force acting on the friction plane and the coefficient of friction between the two materials (in this case the stainless steel base plate and the compacted fill). The tank weight is calculated from the weight of the tank components. The fluid weight is calculated from the volume and density of the fluids used in the tank. In our analysis, we assumed a coefficient of friction of 0.3 between the base plate and the compacted fill.

Our analysis indicated that if the Process Condensate Tank, which was 44-1/2 feet in diameter and 40 feet in height, was in contact with the anchor bolts and full of liquid during a heating expansion cycle, it could generate 1,432,000 pounds of horizontal force on the down slope anchor bolts. The capacity of the anchor bolts was found to be controlled by concrete breakout strength and was approximately 7,700 pounds per bolt. Since only ten anchors were determined to be effective in resisting downward movement of the tank, the demand-to-capacity ratio (DCR) was approximately 18.7.

The Process Condensate Tank has an operating temperature of approximately 175 degrees Fahrenheit when filled with liquid and in operation. Based on the fact that the concrete broke away from the low end anchor bolts as soon as this tank was placed into service, it was apparent that the tank had migrated down slope due to ambient temperature variations while it was still empty. As soon as the tank was filled and heated, the tank simply expanded and pushed the low end anchor bolts outward failing the concrete around the bolts. It was also not a surprise to find that the first attempt to patch these locations also failed.

FUTURE RISK ASSESSMENT

Once the mechanism for movement and damage was identified, the question became one of future risk of the remaining tanks at the plant. During our inspections, we found that most of the tanks were already bearing on the low end anchor bolts. At many of the tanks, there was already cracking and incipient spalling of the foundation walls at the low end anchor bolts.

A demand-to-capacity based risk analysis was performed for all of the twenty sloped base tanks. In the analysis, the sliding resistance of the existing hold down anchors was calculated and compared to the maximum possible down-slope force demands that could be generated by the tanks accounting for frictional and gravity forces.

The anchor bolts were originally designed only to provide uplift resistance to prevent tank overturning and were not intended to resist horizontal sliding of the tanks. However, for the risk assessment, horizontal force capacities were assigned to

each of the anchor bolts. The capacity of the individual bolts was determined to be the lesser of the following:

1. Bearing capacity of the tank bottom plate against the anchor bolt
2. Shear strength of the anchor bolt
3. Concrete breakout strength of the side of the foundation walls

Bearing capacity of the tank bottom plate against the anchor bolts was determined in accordance with AISC 360-05 *Specifications for Structural Steel Buildings* design provisions using properties for stainless steel from the Specialty Steel Industry of North America (SSINA).

The anchor bolts are ASTM F-1554 Grade 55 galvanized steel bolts. The shear capacity of the bolts was determined in accordance with AISC 360-05 design provisions.

Concrete breakout strength was determined in accordance with ACI 318-05 *Building Code Requirements for Structural Concrete*, Appendix D. In all cases, concrete breakout strength was determined to be the controlling failure mode for the horizontal force capacities of the anchor bolts. Observations at the Process Condensate tank and at one other tank confirmed that concrete breakout was the controlling failure mode.

The total capacity that the foundations have to resist the horizontal forces generated by tank expansion and gravity effects is equal to the number of anchor bolts providing resistance multiplied by the horizontal force capacities of the individual bolts. In the risk analysis, we typically utilized half the total number of anchor bolts (those on the down slope side of the foundation). In some instances, the number of anchors effective was half the anchors minus one, depending on the bolt layout for each tank. Bolts that aligned at the exact mid-point of the tank were determined not to be effective in resisting sliding.

Our assumption that all of the bolts in the lower half of the circumference provide equally effective resistance to sliding is generous. More likely, the anchors located in just the bottom third of the circumference would provide the majority of resistance to tank sliding.

Our analysis indicated that nineteen of the twenty sloped base tanks were at risk of sliding and causing damage to the foundations at the down slope end. The DCRs for the nineteen tanks at risk varied from a low of 2.6 to a high of 18.7. Only the smallest tank, which had a diameter of 14 feet and a height of 5-1/2 feet, was not at risk. Confirming our analysis was the fact that that the tank with the highest calculated DCR, the Process Condensate Tank, was the first to experience advanced stages of distress. Generally, our observations of tank performance and level of foundation distress coincided with the calculated DCRs. A number of tanks with calculated DCRs in the 11 to 12 range appeared to be at the beginning stages of concrete breakout.

It was interesting to note that larger diameter tanks were generally found to be at higher risk of foundation breakout failure. This was because there were relatively more anchor bolts for the smaller diameter tanks since these tanks are generally more susceptible to overturning than the larger diameter tanks.

THE REPAIR

If allowed to progress unabated, further sliding would likely lead to damaged piping and mechanical equipment as well as possible heavy damage to the tanks and foundations. A number of different repair concepts were considered; however, the challenges were numerous.

One repair concept was to simply add anchor bolts around the perimeter of the tanks. Although this approach would arrest the sliding of the tanks, it would generate large forces at the new anchor bolts when the tanks attempt to expand and contract with future temperature changes. We determined that bolting the tanks to the foundation walls would likely cause damage to occur.

Another approach considered was to buttress the tanks at the low end of the foundations. This repair approach was problematic for a number of reasons. First, the magnitude of forces that could be generated by the tanks at the low end was enormous. So any attempt to buttress the tanks would have involved large soil excavations and addition of considerable volumes of additional concrete at each tank. Second, the tanks were simply not constructed to be loaded in this manner. There was a likelihood of tank wall buckling if the tanks were buttressed at the low end. As a result, any attempt to buttress the tanks from the low end of the foundation would also have had to include significant strengthening and bracing of the tank walls or base plates, or both.

Ultimately, WJE developed a conceptual retrofit design that included adding a series of springs (tie rods) on the high end of the foundations. The concept was to pre-tension the springs to exactly offset the down slope component of dead load acting on the tanks. The springs would all be oriented so that they only generated forces parallel to the slope of the foundation. By installing retrofit anchors of this type, the tanks would still be allowed to expand and contract due to thermal cycling in all directions; however, there would no longer be a driving force acting down slope to cause the tanks to migrate in that direction with each heating and cooling cycle. The conceptual retrofit anchor design is schematically shown in Figures 10 and 11.

There are a number of additional benefits to the proposed solution. One is that the horizontal forces imparted on the springs are directed back to the existing foundation on the high end. There is no need to add significant additional size or weight to the existing foundations in order to offset the forces in the new anchors. Another benefit is that the forces are transmitted to the tanks in tension directly to the base plate at the high end of the foundations. As a result, there were no concerns with

buckling of the tank walls or plates and there was no need to modify or strengthen the existing tank construction.

The pre-loaded springs solution would also accommodate a number of different load conditions. In the event that the tanks were emptied, the springs would pull the tanks slightly up slope, but in so doing, would relieve the forces in the springs. In the event that the tanks were re-filled and again began experiencing thermal cycles, the tanks would migrate down slope until the forces in the springs became equal to the down slope component of dead load. At that point, the tanks would be back in equilibrium and additional thermal cycles would not cause the tanks to move upward or downward.

After the proposed new tie-rod attachments were to be installed, the damaged concrete around the low end anchor bolts and outflow pipes could be repaired with normal concrete patching procedures.

Although schematic repairs were developed to address the sliding of the tanks, a final design was not developed and the repairs were never instituted because the plant was shut down for economic reasons not related to the condition of the tanks.

Considerations for Retrofitting Existing Pipe Bridges

Xiapin Hua, Fluor Corporation, Sugar Land, TX, xiapin.hua@fluor.com

ABSTRACT

Pipe bridges are widely used to cross over roads, highways, railroads and obstructions. Retrofitting of existing pipe bridges are required for many reasons such as additional levels, outriggers, and past modifications which were not considered in the original design. There are many items to consider when evaluating, analyzing and reinforcing existing pipe bridges such as operating loads, test loads, seismic loads, wind loads, analysis methods, and reinforcement plans.

Pipe bridges are classified as pipe rack structures, which belong to non-building structures. The nature of pipe bridge structures are not similar to regular building structures, which have less redundancy to resist seismic or wind loads. Wind load determination can be a challenging topic due to the lack of research and design guidelines. In this paper, there is a comparative study of wind load determination, which is based on ASCE 7, ASCE Wind Loads on Petrochemical Facilities, a reference calculation performed in the 60s, current design practices and AASHTO wind pressures. The consideration of operating loads, test loads, seismic loads and load combinations for pipe bridges are also discussed in this paper.

Usually, existing pipe bridge evaluations and retrofit plans will rely on a structural analysis of the existing bridge. In order to eliminate or minimize the extent of upgrades and satisfy client expectations, several design approaches and options need to be tried and compared. These efforts are also important to meet the project schedule and budget requirements. In some cases, obstructions will add to the difficulties of the retrofit project that requires additional efforts for passing code check, connection verifications and foundation reinforcement. Spring boundary conditions and analysis modeling options are discussed in this paper. It is found that the force redistribution among the structural members and foundations is important for retrofit projects, especially for pipe bridges located in congested areas. The enhancement for pipe bridge members, connections and foundations are also discussed and presented in this paper.

WIND LOAD CONSIDERATIONS

Unlike regular open structures with beams and columns, trussed pipe bridges consist of many lattice members that may produce a larger area projected on a plane normal to the wind. The maximum force depends on the wind angle of attack.

ASCE-7-05 [1] equation 6-28 specifies the general procedure for wind load on open structures. The shape factor of 1.6 to 2.0 is recommended for flat sided members per Fig. 6-22, and 0.7 to 1.2 for pipes $(D_1(q_z)^{1/2} \leq 2.5)$ per Fig. 6-21. The shape factor depends on the ratio of solid area to gross area, round member size and velocity pressure calculated at height z above ground.

Per ASCE Wind load for petrochemical facilities [2], a minimum of shape factor 0.7 for pipes is suggested. The total loads on pipes are determined per the diameter of the largest pipe plus 10% of the width of the pipe rack (A_s=(D+0.1W)L). In chapter 4.2, the force coefficient C_f is calculated as the functionality of frame solidarity ratio and number of frames. The optional calculation method for the force coefficient C_f is also provided in Appendix 4A. This method provides a greater range of solid ratios and frame spacing variations.

It is found that some of the existing pipe bridges built in the 1960's that still stand today were designed for a wind load of 30 psf on one truss, in which the wind load is assumed acting at 45°. In the original calculations, the shape factor of 0.6 for pipes, 1.3 for columns and 1.0 for the truss members are utilized and the wind load is assumed to apply on one truss only plus wind on the front surface of pipes.

Rutz [3] listed the wind pressure recommendations from late 19th century and early 20th century, in which a table contains 5 references to address the recommendation of 30 to 40 psf wind load to be used**.** Smith [3] addresses wind pressure on both trusses and the surface of a railroad train on the bridge. In table three, it states that some trussed bridges designed for 30 to 50 psf on one truss with or without the wind on train in the design of the 1880's bridges.

The equation 3-1 of AASHTO signs [4] provides similar design methods as ASCE -7. Table 3-6 provides a wind drag coefficient (Cd) for trusses and states "the drag coefficient for a truss with a very small solidity ratio is merely the sum of the drags on the individual members". According to note 3 of table 3-6, the magnitude of drag coefficient depends on member solidity ratio and the spacing of the elements in line with the wind. The drag coefficient of 2.0 is selected for the truss bridges in AASHTO Pedestrian Bridge specifications [5].

Table 3.8.1.2.1-1 of AASHTO LRFD bridge design specification specifies that windward of 50 psf and leeward of 25 psf for the trusses and columns are to be used, which is based on 100 mph wind speed. Table 3.8.1.2.2-1 further provides the base wind pressure for various angles of attack, in which the wind pressure varies from 75 to 17 psf laterally versus 50 to 0 psf longitudinally, based on 0-60 degree skew wind angle variations.

Table 1 provides the comparative study of wind loads on the boxed trusses using five different methods, in which the projected vertical area of truss members (see Fig. 1) is calculated as follows: Chords: 150*2*0.50=150 ft^2, Verticals: 8*8*0.25=16 ft^2, Diagonals: 11*20*0.25= 55 ft^2, and Columns 3x1.22*8=29.3 ft^2, Total area per truss A_s= 250 ft^2. For simplicity, the dimension of center to center instead of out to out is used in this study.

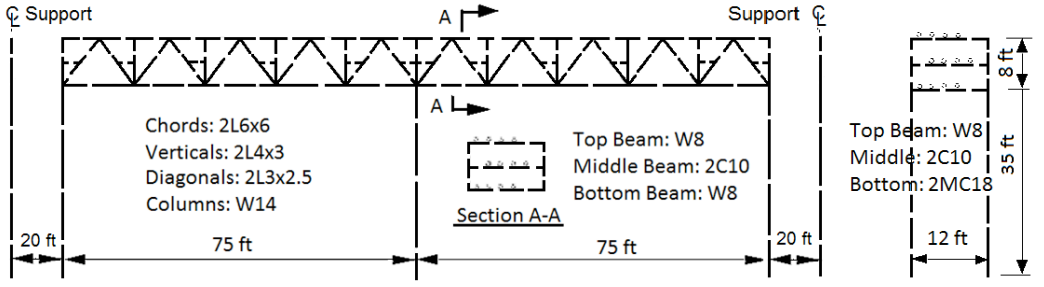

Figure 1. Pipe Bridge Elevation View and Section View

Table 1 Wind Load Calculations [3]

Method 1is based on ASCE 7 [1] and Wind Load on Petrochemical facilities [2]:
Assuming wind speed 90 mph and exposure category B, the velocity pressure at height z is q_z = 0.00256(Kd)(Kz)(Kzt)(V^2) I = 13.75 psf (Equation 6-28 of ASCE 7-05), where Kz is the exposure factor = 0.78 (Table 6-3 for a height of 43 ft), I = 1.0 (Table 6-1), K_d = 0.85 (Table 6-4), K_{zt} = 1.0, C_f = 1.8 (Fig. 6-22) and G = 1.14 for comparison purpose. Wind loads [1] on the truss members can be calculated as $F_{member}=q_z$ G C_f A=(15.7) 1.8 (2 trusses*250) = ***14.2 kips***. The wind load on the pipes [2] is $F_{pipe} = A_s$ (0.7) (13.75 psf) = A_s (0.7) (13) = 8.3kips, where A_s= (D+0.1W)L = 3x (6/12 + 0.1x12) 170=870 ft^2**.** Total wind load in the transverse direction is F_{tl}= 22.5 kips.
Method 2 is based on the reference calculations in the 60's:
The wind loads on the truss members is calculated as F_{member}= 30 psf (150+16+55+1.3x29.3) = 7.8 kips. F_{member}= 0.707 (7.8) =***5.5 kips*** based on 45^o wind skewed angle. The wind load on the pipes is $F_{pipe} = A_s$ (0.6) (30psf) = 4.6 kips, where A_s=6/12*3*(75x2+20)= 255 ft^2**.** Assuming 12.4 kips (7.8+4.6=12.4 kips) acting at 45^o to the truss, total wind load in the transverse direction is F_{tl}= 0.707(12.4) = 8.77 kips. Same wind force is assumed in the longitudinal direction.
Method 3 is based on Ch. 4 and appendix 4A of ASCE Petrochemical wind [2]:
In the transverse direction: A_{gross}= 150*8 =1200 ft^2, Solid Ratio ε = 250/1200 = 0.21, N=2, S_f = 12', B = 151' (per Fig. 4.1, assuming verticals as the columns), S_f / B = 0.08, α_{max}=(10+52 ε)^o =21^o. Per Fig. 4A.3, the force coefficient is C_f =2.7. Wind loads on the truss memers can be calculated as F_{member}=(15.7) 2.7 (250) = ***10.7 kips*** (for two trusses). In the longitudinal direction: A_{gross} = 8'*12'=96 ft^2, A_{net}= 8x0.33x2+ (8+10+18) 12/12 =41.3 ft^2, Solid Ratio ε = 41.3/96 = 0.43, N=11, S_f = 15', B = 13.22', S_f / B = 1.03, α_{max}=(16+52 ε) ^{o} =38 ^{o}. Per Fig. 4A.3, the force coefficient is C_f =10.8 (approximate). Wind loads on the truss members can be calculated as $F_{member2}$=(15.7) 10.8 (41.3) = ***7.2 kips***.
Method 4 is based on AASHTO signs [4]
Assuming wind speed 90 mph and wind exposure B, the velocity pressure at height z is p_z=0.00256 (Kz) G (V^2) I_r (C_d)= 37.5 psf per Eq. C3-1, where K_z is the height and exposure factor = 0.78 (per ASCE-7 for a height of 43 ft, AASHTO only provides K_z=1.05 for wind exposure C), G = gust effect factor= 1.14 (minimum), Ir = 1.0 (per Table 3-2), C_d = wind drag coefficient = 2.0 per table 3-6. The wind load in the transverse direction is F_{member}= (250*2 trusses* 0.0375) = ***18.75 kips***.
Method 5 is based on AASHTO LRFD Bridge Design Specifications [5]
Assuming wind load acting at 21 ^{o} normal to the truss. As the values used in AASHTO Table 3.8.1.2.2-1 are based on 100 mph wind speed and exposure C, the reduction factors of 0.81 and 0.75 are used here for the wind speed of 90 mph and exposure B. In transverse direction, F_{member}= (250*2 trusses) *0.068 (0.81*0.75) =***20.4 kips***, in the longitudinal direction, F_{member} =(42x11) 0.020 (0.81*0.75) = ***5.61 kips***.
(1) ASCE 7 section 6.5.12.3 requires that MWFRS (Main Wind Force Resisting Systems) shall be designed for the wind load cases in any directions. For method one, wind load analysis in the longitudinal direction is not included.
(2) Wind load on pipes is based on reference [2].
(3) Wind load on the columns below boxed truss is not considered.

This comparison study shows that 1) Methods 4 and 5 yield the highest wind loads compared to the other three methods, in which no shielding is considered; 2) Method 2 yields the least wind design force in the transverse direction, in which 45^o skew wind angle is considered; 3) Method 3 reduces the wind loads in the transverse direction by 25% compared to method 1 (see Fig. 2 for details).

Conclusions and Suggestions: 1) Both method 1 and 3 are reasonable for estimating wind loads on the truss members and method 3 may be utilized to estimate the wind load in the longitudinal direction. 2) Further research and study will be needed, which should include the wind tunnel testing of truss members and pipes.

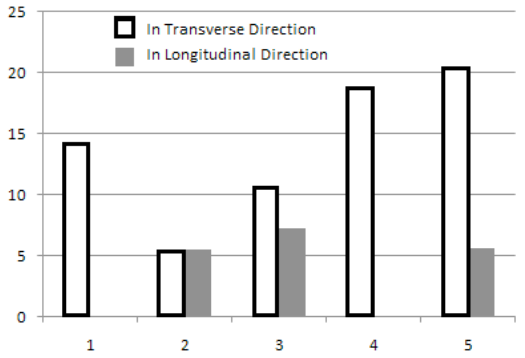

Figure 2. Wind Loads on the trusses (kips)

SEISMIC LOAD CONSIDERATIONS

Pipe bridges have less redundancy than buildings and lack the non structural components which increase damping and energy absorption during a seismic event. The dead load participation of piping systems in the existing structure may not be easily estimated. The intent of a seismic retrofit depends on the regulatory requirements and the wishes of the owners. Due to constraints of project schedule and budget, assumptions need to be made because of limitations and uncertainty in the absence of significant investigations and detailed analysis.

Old pipe bridges were usually not designed for seismic loads nor seismic detailing, so upgrading the existing pipe bridge for today's code is difficult and may be impossible. ASCE 7 Table 15.4-1 [1] provides seismic coefficients for non-building structures similar to buildings, in which the detailing of AISC 341 [7] is not required if the response modification R = 1.0, Ω_0=1 and C_d=1 for steel ordinary moment frames is utilized. This option usually yields a huge seismic design force that requires significant upgrades to the existing structures. This may not be suitable for a retrofitting project. To eliminate the AISC 341 detailing requirement, the seismic design category may need to be changed to category C or lower. If R =3, Ω_0=3 and C_d=3 are selected for non-building type structures, AISC seismic detailing will not be required. Besides, this option provides lower seismic design forces in that the redundancy factor ρ is reduced from 1.3 to 1.0. To reduce the seismic design category, verifications of existing soil conditions may be needed. In some cases, soil improvement may be required to achieve required the site class. Site specific ground analysis will be helpful for the possible reduction of peak ground accelerations.

The seismic force determination is affected by many factors. The goal is to reduce the seismic design forces as much as possible and avoid a significant upgrade to the existing structures. In this study, the period determination for static analysis (Table 2) is per model response spectrum results (Table 3). Factors considered include two design cases (Fig. 3) along with two different boundary conditions, the directions of the

forces applied, the design parameters of structure period (T_2), model base shear (V_t), and force scaling factors which are summarized in Table 3.

seismic design category C, group II, I_e =1.0 (Table 11.5-1) R = Ω_0 = C_d = 3 Per Item H in Table 12.2-1. $W_{DL+Operating}$ =330 kips	T_0= 0.2, S_{ds} =0.39, S_{dl} =0.18. S_{dl} /S_{ds}=0.09, T_s =0.46, T_L=12 (Fig. 22-12)  FIGURE 11.4-1 DESIGN RESPONSE SPECTRUM
C_s = S_{ds}/(R/I_e) = 0.13 (12.8-2) $C_{s(min)}$ = 0.044 $S_{ds}I_e$=0.017 (15.4-1) $C_{s(min)}$ = 0.03 (Control) (15.4-1) T_2 = 0.9 ~ 3.5 from Table 3 (Note: section 12.8.2 is not used for determining the period of the bridge) $C_{s(max)}$ = S_{d1}/T/(R/I) =0.03~0.07 (12.8-3) V_1 = C_s W= 9.99~22 kips (see table 3) (12.8-1)	
Method 2 ASCE-7 Response Spectrum analysis	
Model Response Parameter I/R=0.33 (ASCE Sec. 12.9.2) For case II pinned condition, the spectrum load in the transverse direction =32.4 kips Model base shear V_t =0.33 (32.4) = 10.6 kips Scaling of Forces: Scale factor $SF_{(force)}$ = 0.85 V_1/V_t = 0.88<1, use 1 (Per ASCE 12.9.4.1, the Dynamic Analysis base shear cannot be less than 85 percent of the Static Analysis)	

For the model response spectrum analysis (method two), there are 20 modes participation with seismic category S_{ds} =0.39 and S_{dl} =0.18. The design response spectrum is plotted by using Risa 3D version 8, which matches ASCE 7 Fig. 11.4.1 shown in Table 2. The analysis results indicate 97% of the mass participation in both horizontal directions. The period of the structure varies from 0.9 to 3.5 which depend on structure types and the boundary conditions listed in Table 3.

This study shows that 1) The spectrum loads for the pinned base analyses decreased by 50% from the fixed base values due to a longer period; 2) The super structure rigidity affects the seismic design forces, in which the spectrum loads of the braced frame in the transverse direction is 20% to 40% higher than these of the un-braced frames. 3) The base shear of case II fixed condition is the highest due to a shorter period.

OPERATING LOAD CONSIDERATIONS

A retrofit project usually starts with a walkthrough for evaluating the existing conditions to determine the weakness and obstructions which may not appear in the existing drawings or calculations.

For the case of demolishing existing pipe to make room for new pipe and cable trays or adding pipe using empty space, the structural retrofit will usually not be required if the new loads are equal to or less than the original design operating loads. If additional steel levels or significant outriggers are added to the existing pipe bridges, the structure system may have to be reinforced to pass the code check. In some cases, even if the new loads are not significant, the evaluation for the existing structure may still be important in that the existing structure may have been previously upgraded several times and may not have been verified in the past design.

The operating loads for old pipe bridges could be very light and may only be 50% of the pipe operating loads used today. A review of the existing structure drawings can help with understanding the original design and past modifications. Original piping drawings are also a good source for evaluating the products in the existing pipe. Coordination with the owner and field trips will be an important step for verifying the actual operating loads.

TEST AND THERMAL LOAD CONSIDERATIONS

Test loads (such as hydro test) for the newly added pipes could cause the failure of the existing structures, especially the existing structure loaded with pipes in larger sizes. In order to secure the existing structures during the test, temporary supports or crane lifting may be necessary. An air test is also an option.

The verification of existing friction and thermal loads could be a complicated task that requires coordinating with piping and the owner. If friction load controls the

design, wind load shall not be considered simultaneously. For a bridge supporting large and rigid pipes, modeling the pipes using a link (such as a compression only link) between pipes and the structure members can be helpful to pass the structural code check. Reduction of the lateral pipe stresses can also be achieved by coordination with the piping group. For example, providing the lateral stiffness of the structure at the guide locations may be an option.

LOAD COMBINATIONS

ASCE 7 chapter 2.3 and 2.4 provide the general requirements of load combinations based on factored loads for strength design and nominal loads for allowable design. Other considerations may be needed when applying the load combinations. For example, the consideration of certain percentage of contents left in the equipment [8] for the combination of dead load and wind load could be important for verifying the existing structures**.** This can help on reducing the calculated overturning moment in an extreme wind load condition.

EVALUATION AND ANALYSIS

In a conventional design, the design sequence is to calculate the loads first, design the super structures, and then design the foundations. For a retrofit project, evaluating the existing structure becomes the first priority of making the retrofit plan. The design sequences may have to be set backwards to check the column base connections or the foundation capacities first and then verify the super structures. This is due to the limited anchor connection capacities. The retrofit constraint for modifying existing foundations could also be a major concern. The redistribution of design forces may have to be considered when underground obstructions are present and/or modification to the existing structure is impossible. An example of this consideration is to add knee braces to the bent framing in the transverse direction. This will help to reduce the column base moment reactions and eliminate the modifications to the foundations.

To study and compare the different design options, corresponding member stresses, deflections and design forces are calculated as shown in Fig. 3 and table 4. Design case I and II consist of three different boundary conditions. Design case III only includes a spring boundary condition. The load combination of 0.9D+1.6W and 1.2D+1.6W in transverse direction is used for studying these three cases.

The fixed boundary condition assumes that existing foundations are strong enough to take the additional loads. The advantage of this option is to keep the flexible structure unmodified. The pinned boundary condition assume**s** a weak base connection or weak foundation capacities. In this case, the super structure framing may need to be strengthened for the load redistribution. The spring boundary condition is to utilize the foundation flexibility to reduce member stresses, connection design forces and lateral deflections of the super structures. This option may yield none or fewer modifications to the existing structures. Case III is to consider obstructions in the middle bent, in which the knee brace geometry is modified to fit the existing condition (Fig. 3).

In reality, there are no absolute fixed or pinned base conditions. The behavior of the connection rigidities depends on the overall soil-structure interactions. When modeling the spring boundary conditions, factors of existing anchorage capacity and foundation flexibility may need to be considered. In this study, 4000 k-ft/rad is used for spring boundary conditions. To calculate the rotation constant, both steel and spread footings are modeled in one analysis file and the subgrade spring constant of 50 kips per cubic inch is utilized. The rotation constant is determined by dividing the column base moment by the rotations read at the column base joint. It is also found that the magnitude of rotation constants is affected by the footing sizes and the super structure rigidity. In table 4, numbers in the shaded area represent the failure of structure members, column base anchorage, steel connections or framing drift criteria.

This study shows that original structure is overstressed either in the base connection, moment connections or steel members (see Table 4 and Fig. 3). The added knee braces will help redu**ce** the design moments at the connections and column bases.

P-compression force , T-tension, V-shear, M-moment
M_1-moment (kip-ft) for bent 1, M_2-moment (kip-ft) for bent 2, N_1-axial force (kips) for bent 1, N_2-axial force (kips) for bent 2

In summary, the column base moment is the highest for fixed boundary conditions, which significantly exceed the existing column base connection capacities; the pinned boundary condition causes high drift along with big moments at the bottom beam to columns of the transverse bents that need review; it is found that spring boundary conditions offer the best solution that meet all design criteria. (See Table 4 and Fig. 3).

FOUNDATIONS

A walk down of the area is an important step for checking out obstructions and constructability limitations that may prohibit foundation modifications. Other considerations are to verify the capacity of column anchorage to the concrete pedestal at the early planning stage. These connections may have very limited capacities. Many old anchor bolts are hooked L bolts that have less capacity than headed bolts.

ACI 318 appendix D Section D3.3.4 requires that anchors shall be governed by the steel strength of a ductile steel element. For anchors loaded with a combination of tension and shear, the strength in all loading directions must be controlled by the steel strength of the ductile steel anchorage element. The pull out strength in the tension of single hooked bolts is described in Table 5.

Table 5 Pull Out Strength of Hooked Bolts

for ductile steel failure mode governs: $0.75\ \phi N_{pn}\Psi \geq N_{ua}$ and $\phi N_{pn} > \phi N_{sa}$, (Section D3.3.3) N_{sa} is nominal strength governed by the steel, $N_{sa} = nA_{se,N}f_{uta}$ (D-3) Where $\phi = 0.70$ (Section D 4.4(c) (ii))	$N_{pn}=\Psi_{c,p}N_p$, (ACI 318 D-14) $\Psi_{c,p}= 1.0$ (Section D 5.3.6) $N_p = 0.9f_c' e_h d_a$, (ACI 318 D-16) where $3\ d_a <= e_h <= 4.5\ d_a$ (Section D 5.3.5)
If e_h= 5.5", d_a= 1.25" and f_c' =3 ksi are assumed, N_p= 18.6 kips, ϕN_{pn} = 0.7(18.6) = 13 kips, for moderate or high seismic region, pull out strength = 0.75(13) = 9.7 kips per bolt.	

For the pier design, ACI [10] requires a minimum of 2 #4 ties or 3 #3 ties distributed within 5" of the top pedestal. A similar requirement can be found in the other references [2] [11]. For old existing piers, this requirement is rarely met because existing piers usually consist of very few ties compared to the current standards (see Fig. 4). It is also very expensive to upgrade existing piers to meet today's code. Figure 5 shows a pier strengthening detail, in which additional reinforcement including dowels with 90 degree hooks and new ties around the existing pier can provide additional strength.

Post installed reinforcement either is determined on the basis of bond/plain concrete cone failure or designed as a lap splice per provider's technical data. For a project located in a seismic zone, a conservative design approach may be required in that the cyclic loading may result in reductions in bond strength.

In order to balance the foundation stability, thickening the existing footings or combining individual footings together may be required. This will increase the moment capacities of the spread footings. In some cases, the footings sizes may need to be enlarged to not overload the soil strength. Typical details for thickening and enlarging existing footings are shown in Figure 5. Special constructability should be considered to make sure that the reinforcement can be placed in the field. Through dowels are much stronger than regular dowels in that they do not rely on bonding to deliver the forces. This option is usually limited by the available working space. Verifying the overall structural stability during foundation construction is also important. Reduced wind loads [9] can be used for the verification.

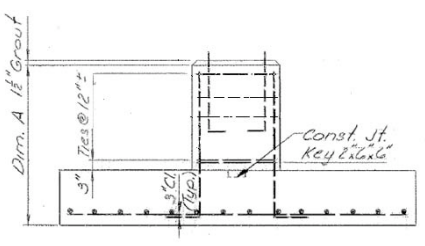

Figure 4. Existing Spread Footing

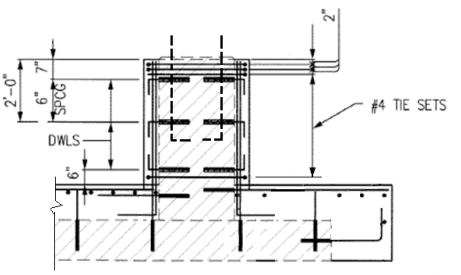

Figure 5. Foundation Reinforcement

SUPER STRUCTURE ENHANCEMENT CONSIDERATIONS

Steel member and connection reinforcement could be difficult due to limited material strength. Verifications could be more difficult if the existing drawings are not available. AISC design guide 15 includes the historic summary of ASTM structural steel and bolt information, which can provide the design information for the existing structural elements [12].

When retrofitting, constructability is a key consideration. A field survey for the existing structures may be required because the existing column orientation, size of anchor bolts and structure members may be different from these shown on the existing drawings. Field drilling and bolting is always preferred over field welding to avoid hot permitting process and lead released during construction. Old bolts may not be marked as today's bolts. To avoid overestimating the existing bolt capacity, replacing the bolts can be a quick and conservative way for a retrofit project. When replacing bolts, structural accessibility and potential interferences are key elements to be considered. Chapter 14 of AISC guide 15 provides guidance and details for the enhancement options of existing connections.

Many existing trussed bridges were designed as warren trusses with a moment framing system in both directions. Adding new structure members to release the design forces in the existing connections can be an easy way in the retrofit plan.

Fig. 6 and 7 show the connection detail 1 and detail 2 used for the newly added braces. In detail 2, a connector that consists of an end plate and cover plates is designed so that the axial force will be transferred to the channel webs. Fig. 8 shows the brace connection detail if knee braces are required in the longitudinal direction. In this detail, the knee brace is connected to the existing column web using an end plate connection. To transfer the horizontal force component to the column flange, a T plate and a set of angles are bolted on the other side the column. Bolted connections are selected due to hot permit limitations.

In some cases, the horizontal braces of a boxed truss bridge may not be strong enough to resist the new loads. If strengthening a horizontal diaphragm is required for distributing the lateral forces, the horizontal framing connections for the bridge will need to be verified and reinforced. If the replacement of the structure braces and connections are required, construction sequences will have to be considered to avoid the failure of the structural system during the construction period.

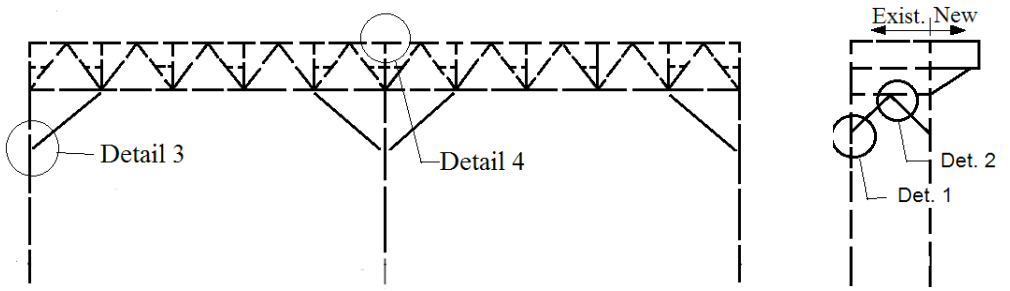

Figure 6. Connection Locations

To maintain the structure integrity during construction, minimum lateral resistance has to be maintained to resist the lateral, operating and construction loads. In this case, the replacement of the braces may need to be specified such as replacing one connection at a time. The design loads during construction can be found in ASCE 37 Design Loads on Structures during Construction [9].

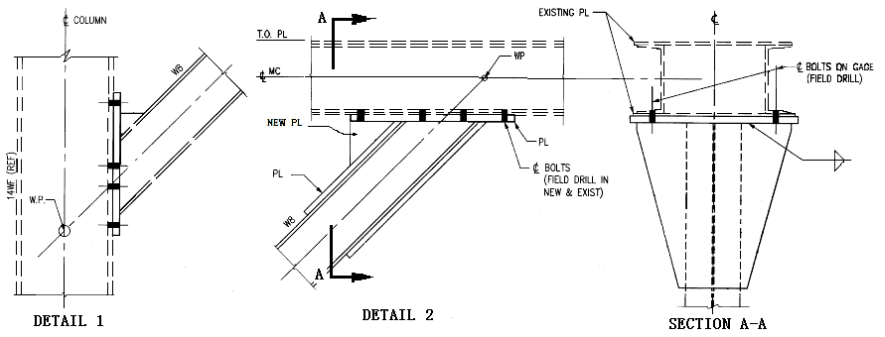

Figure 7. Detail 1 and 2 - Brace connections in Transverse Direction

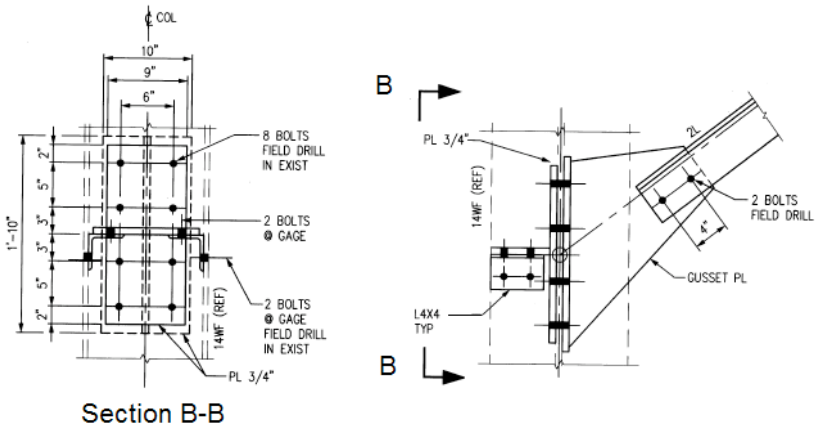

Figure 8. Detail 3 - Brace Connection in Longitudinal Direction

For continuous span trusses, top chord connections to the bent structures usually present high tension forces. Connection reinforcement may be required. Detail 4 in Fig. 9 uses a cover plate to transfer the unbalanced axial forces.

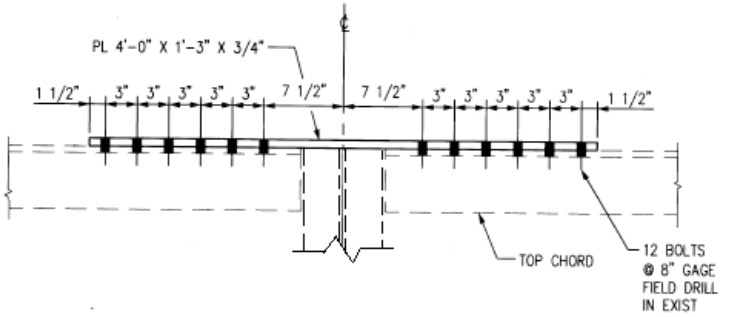

Figure 9. Detail 4 – Top Chord Connection in Longitudinal Direction

SUMMARY

Loading determinations for a retrofit project is a complex task that requires code interpretation, literature research, site verification and the considerations of construction, permitting and the owner's requirement. The structural analysis for an existing pipe bridge with new additions is different from the method used for designing a new structure, which requires efforts of trial and error and by comparing several different options to achieve the best solution. Constructability is the key element for determining the final details of the structure reinforcement.

ABSTRACT

Built in the early 1970s, Aloha Stadium is a welded plate girder and steel frame structure located in Honolulu, Hawaii that was not designed for contemporary hurricane wind loads, much less the large earthquake design forces that current code now prescribes. The owner of the stadium elected to voluntarily upgrade the structure to resist current-code-level wind and seismic events. This paper presents the results of a multi-year detailed structural analysis and a multi-year structural strengthening project for Aloha Stadium.

INTRODUCTION

Built in the early 1970s, Aloha Stadium is a welded plate girder and steel frame structure located in Honolulu, Hawaii that was not designed for contemporary hurricane wind loads, much less the large earthquake design forces that current code now prescribes. The owner of the stadium elected to voluntarily upgrade the structure to resist current-code-level wind and seismic events.

Structural System

The stadium is comprised of six primary structural "modules" that can be thought of as distinct or separate structures: two end-zone seating stands and four sideline seating stands. Large welded plate girder raker frames form the primary structure supporting the main roof and seating areas. In the end-zone stands, the raker frames are supported by a concrete substructure that also includes the lower areas of seating at the field level. In the sideline stands, the steel raker frames are supported by steel space frames that also support the field level seating areas at the sidelines. The slideline stands typically cantilever beyond their foundation supports. Figures 1 through 4 show overall views of the stadium structure.

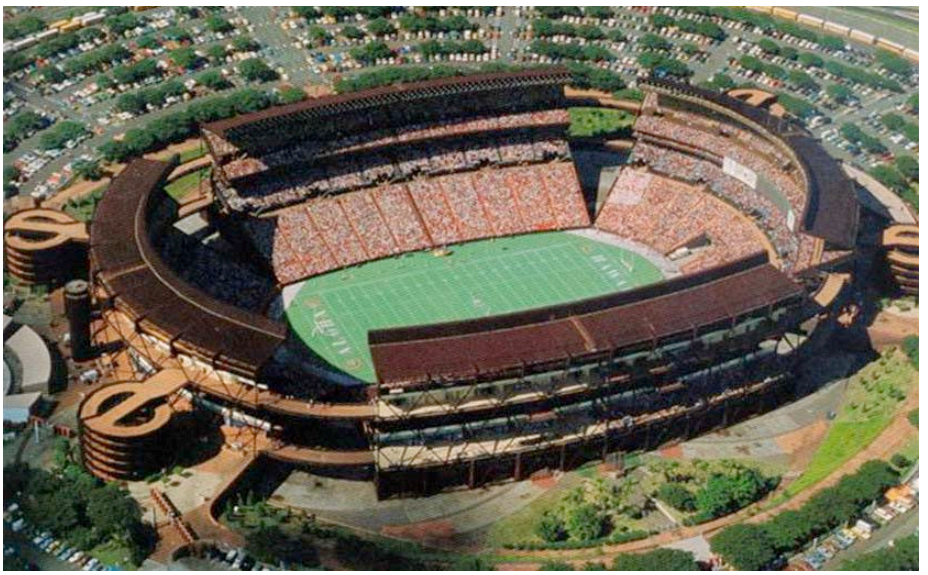

Figure 1: Overall view of Aloha Stadium in football configuration.

Figure 2: View of the typical raker frame at the end of the sideline stands.

Figure 3: View of the sideline stands from the exterior of the stadium.

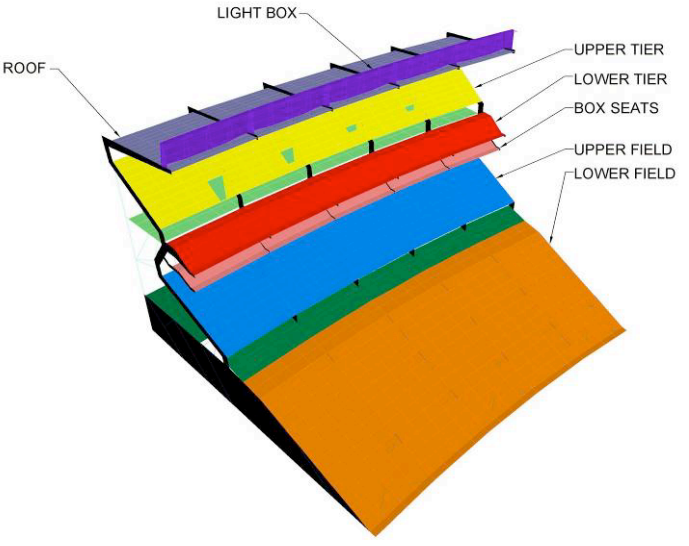

Figure 4: Bird's eye schematic view of sideline seating stands, defining stadium features.

The facility contains approximately 50,000 seats primarily for the viewing of athletic events. The stadium previously had the ability to move four of the six sections of seating stands to allow the stadium to be changed between either football or baseball configurations. During 2006, a policy decision was made by the owner to permanently maintain the stadium in the football configuration.

LIVE AND DEAD LOADS

Design dead loads are not significantly changed from the original design criteria and although design live loads for fixed stadium seating have actually decreased compared to the original design criteria, our analysis predicted significant overstresses in the as-designed connections of one of the large space frame trusses that support the sideline stands, and overstress conditions and vibration-related complaints were also identified in the pedestrian bridges due to live loads.

Space Truss Connections

Large trusses span parallel to the field and cantilever beyond the last foundation support, resulting in very large tension forces in the top chord of the truss. The connections of concern consist of two bolted, bent steel plates that behave as combined tension and shear connections (Figure 5), typical at 16 locations. Close observation of these connections revealed that the connections were indeed experiencing distress: paint had locally flaked away from some of the connections, indicating that yielding had occurred in the connecting angles, and a number of connections had clearly moved or slipped since the structure had last been painted about 20 years ago (Figure 5), suggesting possible deformation at the bolt holes in the web of the chord member.

Figure 5: View of the problematic connection (left), and close-up (right) showing localized flaking of paint, which is evidence of yielding, and a gap in the paint along the toe of the connecting bent plate, which is evidence of movement (arrow).

The combination of the sufficiently large calculated overstresses due to dead and live load only and the evidence of yielding and movement resulted in the recommendation

that strengthening of these connections be expedited and completed prior to the next use of the stadium. In the interim, movement gages were installed to assess whether additional movement under dead loads and nominal live loads was occurring.

Strengthening measures were completed a few months after identification of the problem and prior to any scheduled events at the stadium; strengthening included addition of top and bottom connection plates to deliver the tension load in the truss top chord to the other members that frame into the connection (Figure 6).

Figure 6: Connection plates were added to the truss chord top flange (flange cover plate, arrow in figure on the left) and bottom flange (triangular gusset-style plate, arrow in figure on the right).

Pedestrian Bridges

Eight previously removable curved pedestrian bridges exist connecting concourses between the seating stands. An overstress condition was identified in the curved steel girders, along with longstanding pedestrian-induced vibration and deflection issues. A system of tension rod stays was installed, which shifted the natural period away from the dynamic pedestrian loading and improved the structural performance of the bridges.

WIND LOADS

The original structural drawings for the stadium, which were prepared in the early 1970s, specify a uniform projected wind design pressure of only 20 pounds per square foot (psf). Given that hurricanes can strike the Hawaiian Islands, the original design pressure is significantly underconservative compared to the plausible if not likely wind pressures that might result from a hurricane strike. Therefore, due to the unique building facade conditions and shape of the Aloha Stadium structure, wind tunnel modeling of the

Aloha Stadium was performed during 2007 and 2008. Cermak Peterka Petersen (CPP), of Fort Collins, Colorado, performed the wind tunnel studies. The wind tunnel testing, data extraction, and final data interpretation were all performed in general conformance with *Minimum Design Loads for Buildings and Other Structures* (*ASCE 7-05)*.

Through a series of iterations between CPP, who analyzed the pressure tap data, and WJE, who reviewed the structural effect of the pressure data utilizing the structural analytical models, design wind pressures were developed for 12 main wind force resisting system (MWFRS) global load cases.

Due to hurricane wind directionality effects, global and local MWFRS wind load cases were developed separately for each of the north and south end-zone seating stands. In addition, using the wind tunnel results from all four sideline structures, envelope-type load cases were developed for a single sideline stand that were representative of wind loading on all four sideline seating stands.

Structural analyses were undertaken, using the design wind pressure results of the wind tunnel modeling, to better understand the weaknesses of the existing structural design, and to develop structural strengthening for this complicated, multi-structure stadium.

SEISMIC EFFECTS

The stadium was designed at a time when Honolulu was only seismic Zone 1 (described as "only minor damage anticipated") in the 1970 *Uniform Building Code* (UBC), and when modern seismic design philosophies, including ductile design detailing, were still being developed. In the *International Building Code* (IBC), the stadium is assigned to Seismic Design Category D, which is indicative of significant seismic hazard. Although voluntary seismic improvements are not required to conform to any standard, the owner desired that any seismic-related strengthening work conform to the seismic requirements of the 2003 IBC, with the added goal of conforming to the 2006 IBC where possible. Comparison of the seismic design provisions between the 2003 and 2006 editions of the IBC finds that the specified seismic design forces for "cantilever columns", such as those that support the main roof at Aloha Stadium, double when going from the 2003 IBC to the 2006 IBC due to corresponding changes between ASCE 7-02 and ASCE 7-05. It should be noted that since both of these versions of ASCE 7 require that connections be designed for the basic seismic design forces multiplied by an overstrength factor, which means that connections are required to stay essentially elastic. Thus, the net effect of this change on connection design forces is not as drastic as it might initially appear; however, the relative change from the requirements of the 1970 UBC to current code is quite large, as shown in Figure 7, and significant strengthening was required to meet the requirements of current code. Further, since the connections were designed to remain essentially elastic, the ductility demands on the connections, which consist of circa 1970s welded connections with potentially non-ductile details and bolted connections, are extremely low.

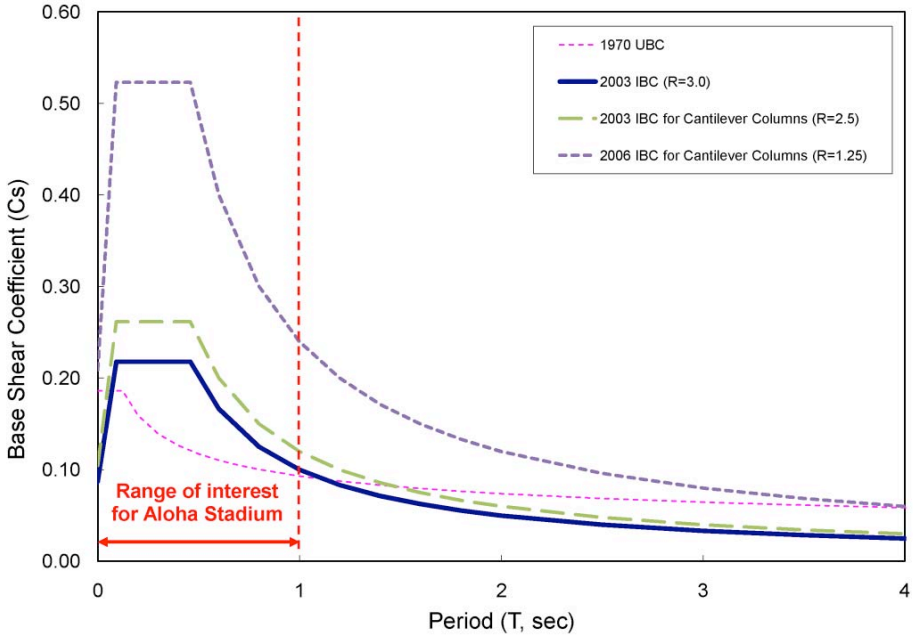

Figure 7: Spectra of seismic base shear design coefficients for Aloha Stadium.

In our analyses, the horizontal response spectra were based on the requirements of the 2006 IBC, using a response modification factor, R, of 1.25 and an Importance Factor, I, of 1.25, to address the conceivable, though not particularly likely, possibility that the stadium could be occupied during a design-level earthquake. The vertical response spectrum was defined as two-thirds of the spectrum used for lateral response, which is commonly accepted practice for seismic structural design.

When combining two orthogonal directions, ASCE 7-05 requires 100 percent of the force in a single direction to be combined with 30 percent of the force in the perpendicular direction. This requirement is based on the assumption that the building being analyzed is generally simple and regular, with a single, clearly apparent reference coordinate system; however, the Aloha Stadium seating stand structures are complex, irregular, curving structures that do not necessarily have a single easily defined reference coordinate system. Due to this complexity, the square root of the sum of the squares (SRSS) approach was taken to combine the three different directions of seismic response. The appropriateness of using the SRSS method for combining directional seismic load effects with complex structures is described by Wilson *et al*. (1995).

Because seismic design forces were based on modal response spectrum analyses, scale factors were applied to the two horizontal base shear components as specified by ASCE 7-05. For the sideline stand model, the adjustment factor was 1.60 for the longitudinal direction and 1.05 for the transverse direction. For both endzone stand models, the adjustment factor was approximately 1.55 in both directions. The general use of the response spectrum scaling factors from ASCE 7-05 for analyzing Aloha Stadium is conservative in our opinion. This is because the scaling factors were

developed for normal, structurally regular, generally rectangular buildings with distinct horizontal diaphragms and concentrated masses at discrete floor levels, and are thus conservative when applied to an irregular structure with inclined diaphragms and well distributed mass, and for which separate orthogonal design base shear forces may not have much meaning. When these scaling factors are combined with the response modification factor R of 1.25 and importance factor I of 1.25, the resulting seismic design forces are well within the elastic seismic response range; that is, the final effective R factor is likely less than 1.0. Note that according to strict interpretation of ASCE 7-05, a new stadium relying on an ordinary steel moment frame would not be permitted in Seismic Design Category D due to the arbitrary height limits found in ASCE 7-05; however, since this is an existing structure that is in essence being checked for fully elastic or even "greater-than-elastic" forces, we believe that the existing structure will meet or even exceed the intent of the 2006 IBC after implementation of structural improvements.

STRENGTHENING FOR WIND AND SEISMIC LOADS

With respect to wind and seismic loads, the major nonconformities identified by the structural analyses involved the vertically cantilevered raker frame columns that support the main roof and some members of the braced frame system. Raker columns were strengthened; beams and bracing members were strengthened and stiffened; and critical connections were strengthened or replaced, as described below.

Raker Frames

The welded plate girder raker frames were overstressed in both strong- and weak-axis bending as well as web shear in the elbow joints. To address these overstresses, cover plates were added to the top flanges of selected raker roof beams and rear flanges of selected raker columns, and haunch plates were added to the undersides of the roof raker beams and to the interior faces of the raker columns just below the roof level. Steel plate shear walls parallel to the exterior of the stands were also added to resist lateral forces that would otherwise cause weak axis response in the raker columns. Finally, diagonal web stiffener plates were added to the raker elbow joints to increase both the shear strength of the web and create tension/compression struts to transfer bending stresses around the corners of the elbow. Figure 8 shows installation of new column haunch plates and steel plate shear walls; Figure 9 shows installation of a new raker beam cover plate; and Figure 10 shows new diagonal web stiffener plates at raker elbows.

Figure 8: View from the upper seating level, looking outward. The arrows indicate the new steel shear walls and the new haunch plates.

Figure 9: Typical new steel plate added to the top of a raker roof beam.

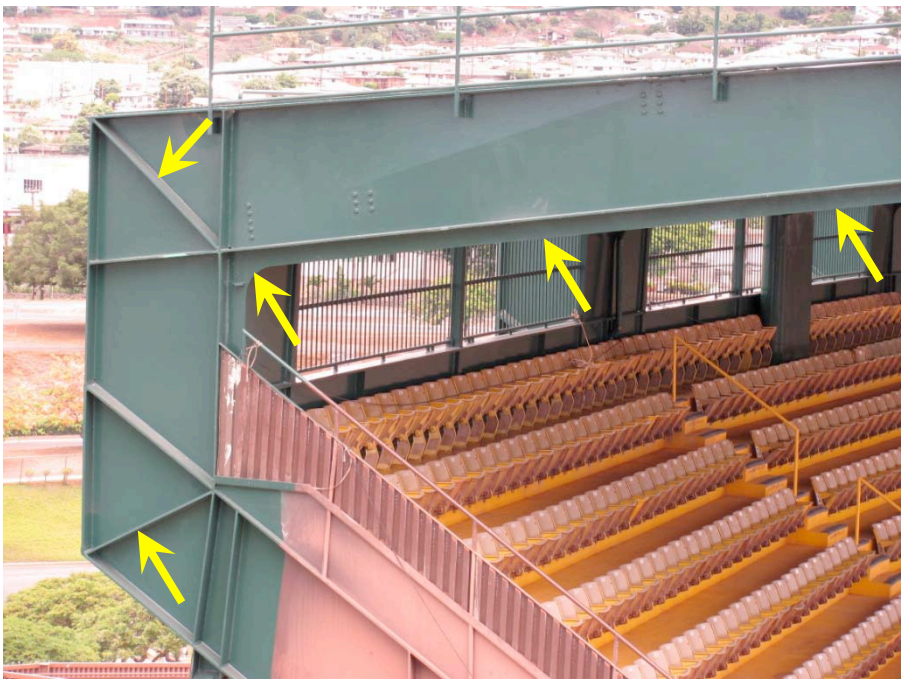

Figure 10: New diagonal web stiffener plates at raker elbows and new haunch plate, as indicated by arrows.

Connections of Raker Frames to Diagonal Bracing

Web compression stiffeners in raker beams were also substantially overstressed due to lateral bending just above the termination of the perimeter diagonal braces, so diagonal HSS braces were added to strengthen and laterally stabilize this region of the raker frame. The new braces also serve to transfer loads from the new steel plate shear walls to the work point at the top of the existing diagonal bracing system (Figure 11).

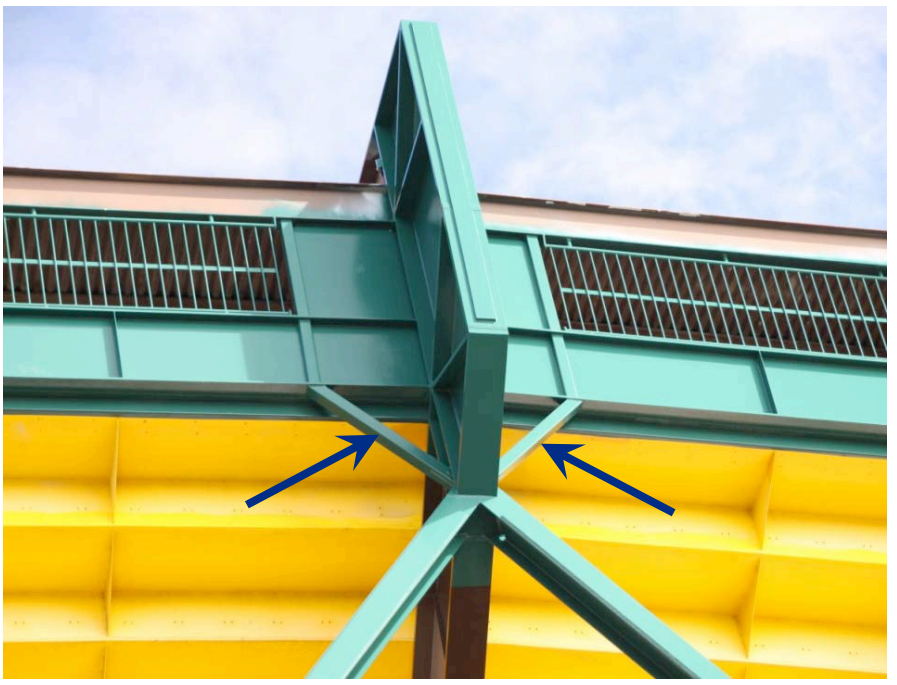

Figure 11: New HSS braces were added to connect the tops of the perimeter diagonal bracing to the new steel plate shear walls.

Strengthening of Exterior Diagonal Bracing

The last major strengthening to be implemented was improvement of the compression buckling strength of the exterior diagonal bracing on the sideline stands. A large number of braces were calculated to be exceedingly slender, so much so that interaction of compressive axial load from seismic loads and the relatively minor bending caused by member self-weight or seismic vibration perpendicular to the longitudinal axis of the brace member tended to cause unusually large calculated design interaction ratios. Addition of flange cover plates that terminated short of each brace end connection (Figure 12) improved the compression buckling strength of the braces without increasing the tension capacity, thereby averting a need for strengthening of the tension capacity of the brace end connections.

Figure 12: Steel plates were added to diagonal bracing on the sideline stands.

Identification of Other Elements for Future Strengthening

Due to the phased construction approach that was necessary to keep this structure in service during construction work, all wind and seismic strengthening was not performed in a single construction project. As part of our assignment, we identified elements to be included in future strengthening phases, including:

- Strengthening of selected lower portions of the raker frames, similar to the strengthening described herein for the upper portions;
- Strengthening of selected connections elsewhere in the structure that are overstressed due to seismic loads;
- Modification of connections of pedestrian ramps and bridges to the stadium stands to allow greater differential movement between the various structures; and
- Anchoring the now-disused transporter frame assemblies that support the sideline seating stands to the foundations to resist sliding of the sideline stands.

CONCLUSIONS

Aloha Stadium was designed and constructed during the 1970s, before the advent of modern seismic building codes and long before the potential for a direct hurricane strike on the island of Oahu was recognized by the building code. The authors were retained to design strengthening measures for the stadium that would bring the structure into general conformance with the modern building code. A number of existing structural members were strengthened and stiffened. Further seismic strengthening measures will be implemented in future phases of the project. In

addition to the need for seismic- and wind-related strengthening, which is not unusual for a building of this age, a significant and unexpected deficiency relating to dead and live load was discovered in a series of connections; the overstresses in these connections were so large that the connections in question had yielded under service loads. These deficient connections were strengthened as well.

Seismic Design Retrofit & Detailing for Special Structures

Crystal Roe Starr, P.E., LEED AP, Engineer, MWH Americas Inc., Walnut Creek, CA 94596; email: crystal.starr@us.mwhglobal.com

ABSTRACT

With increasing knowledge of structural performance during seismic events, new building design has evolved to include redundancy, building regularity, ductile detailing, and continuity among many changes that set precedence for the retrofit of existing buildings. Many existing buildings require a seismic retrofit not only to perform to the level of similar new buildings during an earthquake but to even perform at all. However, it is impractical to seismically retrofit all existing buildings. This is why priority is given to retrofitting various essential facilities and in many instances, enforced through regulations. Many municipalities are required to seismically retrofit many of their essential facilities because of the economical and life safety impacts of not doing so. This paper will outline the seismic retrofit of an essential water storage facility for the City of San Francisco in accordance with ASCE 41-06. In addition, this paper will discuss in brief the temperature analysis performed on the reservoir.

INTRODUCTION

The University Mound Reservoir North Basin (UMRNB) was originally constructed in 1885 as an open-cut, in ground 55-MG reservoir with an earthen embankment dam and concrete floor slab (Figure 1). In 1962, UMRNB was upgraded with a thin pan-joist concrete roof system with girders in one direction, supported primarily on cast-in-place columns and footings which are integral with the concrete lining. The thin roof slab with overall dimensions of approximately 750’ x 650’ is divided into 15 segments separated by seismic joints. There were 12 segments along its perimeter and 3 at the interior (Figure 2).

The goal of the UMRNB seismic retrofit performed in 2007 by MWH Americas Inc. was to provide assurance that the reservoir would be capable of supplying fire fighting and drinking water after the maximum credible earthquake. The maximum credible earthquake is based on the 8.2 km proximity of the site to the nearest fault, the San Andreas Fault. The earthquake magnitude considered was the repeat of the 1906 type earthquake with a moment magnitude (Mw) of 7.9. The deterministic site-specific response spectra at the median plus one standard deviation (or the 84th percentile) level was used. This is also the required maximum credible earthquake

required for design by the Division of Safety of Dams (DSOD), a regulatory agency who oversees the protection of the lives and property due to dam failure. The potential loss of surrounding property due to failure of the embankments on the north and east sides of the UMRNB dictates the jurisdiction of DSOD.

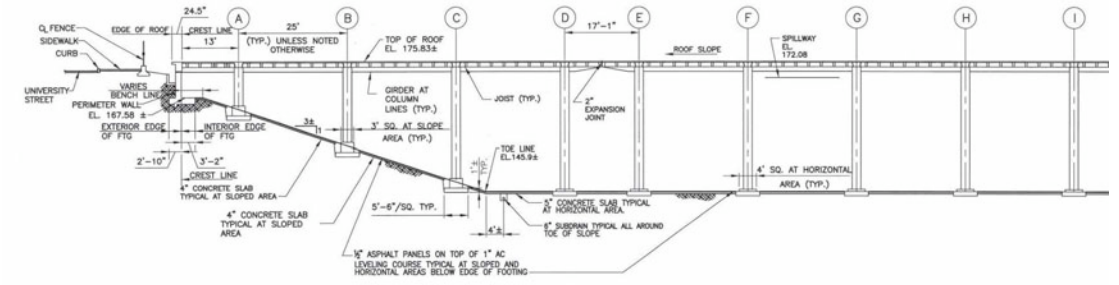

Figure 1. Existing Typical Section

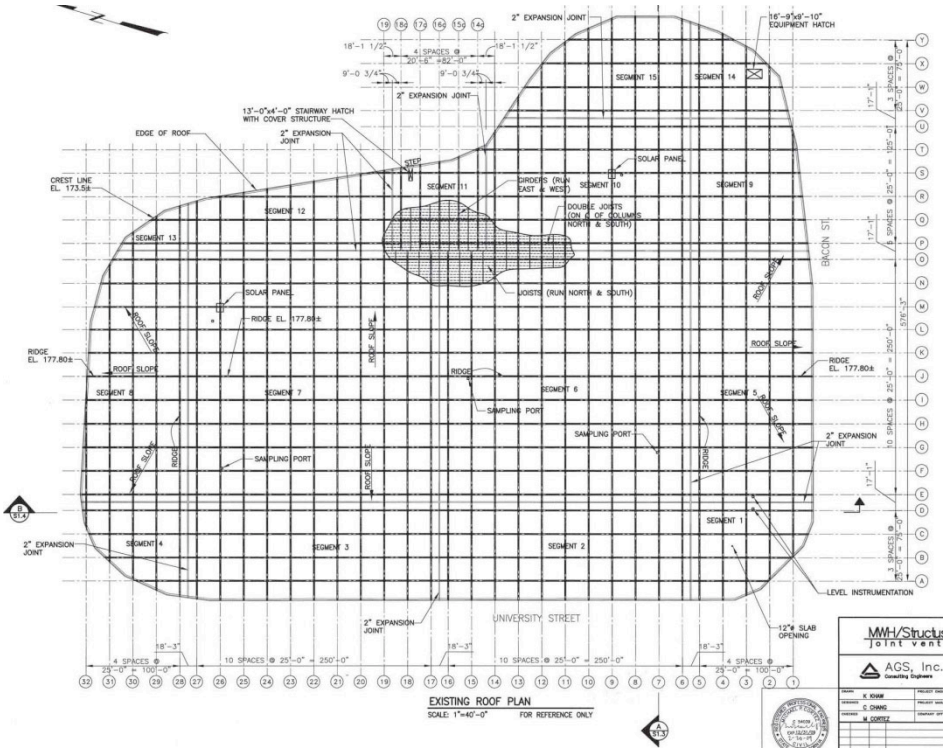

Figure 2. Existing Roof Plan

SEISMIC CRITERIA

Seismic design and evaluation for retrofit of the reservoir was based on the standard for *Seismic Rehabilitation of Existing Buildings*, ASCE 41-06 requirements in conjunction with the City building standards. The provisions of ASCE 41 are based on FEMA 356 Prestandard and FEMA 274. ASCE 41 supersedes FEMA 356, however FEMA 274 is still an active standard.

Seismic rehabilitation in accordance with ASCE 41 is a performance-based design, which differs from procedural new building design. Performance-based design is ideal for seismic retrofit design because with increasing knowledge of building behavior and advanced structural modeling tools, building performance can be predicted. For this reason, new building design procedures include redundancy, emphasis on building regularity, ductile detailing, and element continuity. With most existing buildings designed using dated building codes that do not achieve this level of performance (hence the premise of ASCE 41), it is difficult to predict the performance of the buildings. Therefore, a procedural based design for retrofit of existing building is unrealistic and a performance based analysis must be utilized.

The performance-based design of ASCE 41, prescribes performance levels based on findings from a seismic evaluation that must be conducted. The performance level is defined as the extent of damage that a building and its occupants can afford during and after a seismic event. The performance level can be categorized as one of the following, in order of severity from least to most severe; Operational, Immediate Occupancy, Life Safety, or Collapse Prevention. Table 1 shows the performance level classifications used on the project.

Table 1. Structural Performance Objectives

Component	Earthquake Level	Structural Performance Level	Non-Structural Performance Level
Reservoir Roof	BSE – 1	Immediate Occupancy	Operational (1-A)
	BSE – 2	Immediate Occupancy	Immediate Occupancy (1-B)

During the seismic evaluation, certain considerations must be analyzed which include the structural characteristics, site seismic hazards, occupancy, societal impacts, and economic considerations. Once the performance level is determined the Rehabilitation Objective can be selected. There are three Rehabilitation Objectives, Basic Safety Objective (BSO), Enhanced Objective and Limited Objective. The UMRNB rehabilitation program fell into the Enhanced Rehabilitation Objectives

category in accordance to Table C1-1. *Rehabilitation Objectives* of ASCE 41. Following the guidelines of the Enhanced Rehabilitation Objectives, UMRNB retrofit design was to be analyzed at a Basic Safety Earthquake-1 (BSE-1) and Basic Safety Earthquake-2 (BSE-2) hazard level.

The BSE-1 is a "Design Earthquake" defined as an earthquake with a 10% probability of exceedance in 50 years, and a mean return period of approximately 475 years. However, since the BSE-2 is required for design and more critical, the BSE-1 analysis is moot for seismic retrofit design.

The BSE-2 is a "Maximum Earthquake" defined as an earthquake with a 2% probability of exceedence in 50 years, and a return period of approximately 2475 years. However this earthquake shall not exceed the maximum earthquake ground shaking based on a deterministic approach (84% MCE- 84 percentile of the Maximum Credible Earthquake).

SEISMIC ANALYSIS

In accordance with ASCE 41, linear or nonlinear analysis procedures may be selected for an existing building evaluation. The building must meet the requirements of the standard. It is evident that all existing buildings have some nonlinear response or ductility, but not all buildings need to be designed with nonlinear procedures. A linear analysis can be selected for a building with spatial regularity where nonlinear response can be distributed uniformly throughout the structure at the response level to which the building is to be evaluated based on the performance objectives. The nonlinear analysis procedures provide results that are close approximations of the expected response of the structure for the given performance level.

A Linear Analysis was selected for the UMRNB Project as the structure met the requirements for linear design. Linear Analysis in accordance with ASCE 41 is similar to traditional new building design but includes adjustments for some nonlinear behavior of the structure.

All component actions must be identified as either deformation-controlled or force-controlled. Deformation-controlled action is the yielding behavior of a component. Type 1 and Type 2 curves in the stress-strain diagrams of Figure 3 represent the ductile yielding of a component with an initial elastic range followed by a plastic range. In the plastic range the component has a residual strength gain followed by a loss of strength with increasing plastic deformation during the strain-hardening phase. Alternatively, force-controlled action is the nonductile and brittle behavior of a

component. Type 3 curve of Figure 3 represents a force-controlled stress-strain diagram where an element experiences elastic behavior followed by a loss of strength. Table 2 shows possible deformation-controlled and force-controlled actions identifications for various components as were used for the UMRNB design elements.

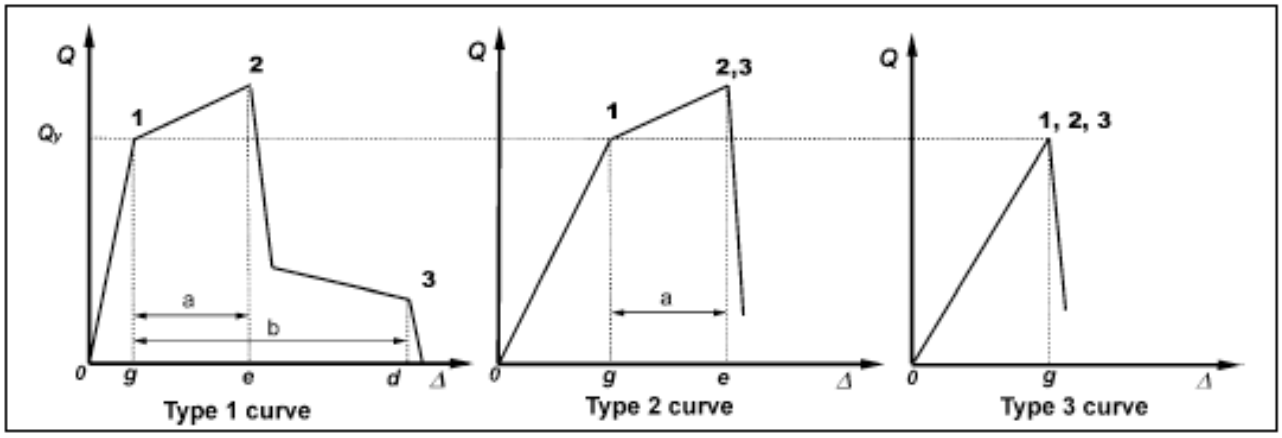

Figure 3. Component Force vs. Deformation Curves

Table C2-1 Examples of Possible Deformation-Controlled and Force-Controlled Actions

Component	Deformation-Controlled Action	Force-Controlled Action
Moment Frames		
• Beams	Moment (M)	Shear (V)
• Columns	M	Axial load (P), V
• Joints	--	V[1]
Shear Walls	M, V	P
Braced Frames		
• Braces	P	--
• Beams	--	P
• Columns	--	P
• Shear Link	V	P, M
Connections	P, V, M[3]	P, V, M
Diaphragms	M, V[2]	P, V, M

1. Shear may be a deformation controlled action in steel moment frame construction.
2. If the diaphragm carries lateral loads from vertical seismic resisting elements above the diaphragm level, then M and V shall be considered force-controlled actions.
3. Axial, shear, and moment may be deformation-controlled actions for certain steel and wood connections.

Table 2. Component Identification

MODELING

Three-dimensional finite element models of UMRNB were developed using SAP 2000, Version 11, a finite element software (Figure 3). Both the existing structure and the proposed seismic upgrade elements were included in the models. The models were used for static, non-linear pushover and thermal analysis.

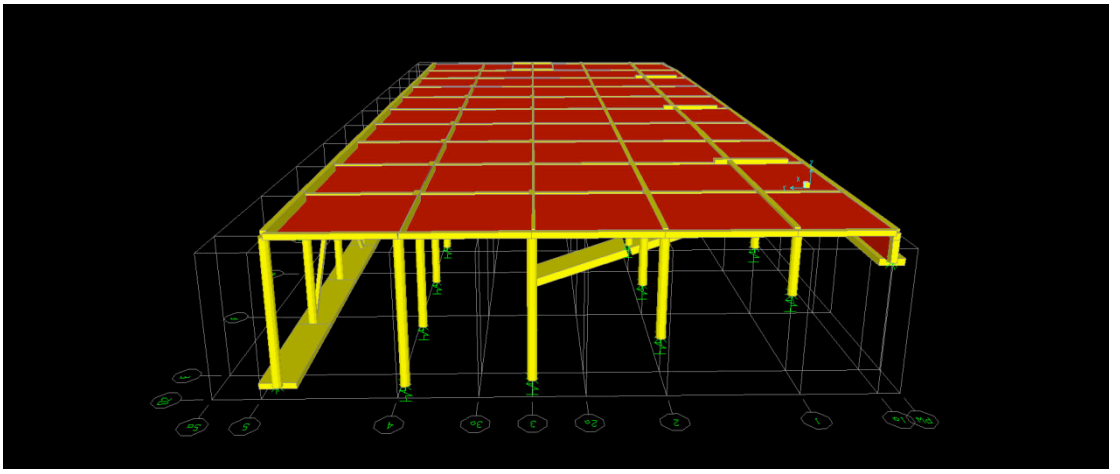

Figure 3. SAP model of a single roof segment

The foundation elements of the structure were modeled with springs based on geotechnical recommendations and calculated values to represent the soil structure interaction. The elastic spring constants were a function of the stiffness, length and embedment of the foundation with respect to the stiffness of the soil in accordance with FEMA 356 Chapter 4. All the supports were restrained in the lateral direction and moment resistance was released in all directions. The existing column footings were modeled as pinned supports with elastic springs. The perimeter wall footings were modeled with linear springs below the footing. New foundation elements, grade beams and shear walls were modeled with similar linear springs. However, rotational springs were added to the base of the shear walls to allow out-of-plane bending.

Cracked section properties were used for dynamic analysis. Effective moment of inertia was assumed to be 50% of gross moment of inertia for the beams, columns and cracked walls.

RETROFIT ELEMENTS

The UMRNB retrofit elements were selected based on stiffness requirements and space constraints. Shear walls, brace frames, moment frames and collectors served as the new lateral force resisting elements (Figure 4).

The perimeter walls provided vertical support of the perimeter roof segments without lateral resistance. The new lateral resisting elements in the long span were new shear walls directly in front of the perimeter wall and braced frames at the opposite side of the segment. Adjoining the roof and perimeter wall was considered by this forced too much load into the perimeter wall and put torsion of the roof segment. Braced frames were chosen for the bays toward the center of the structure because they would allow more water circulation than would shear walls. In the short span of the segments, shear walls were provided along the embankment slope. Forces were transferred through the diaphragm through collectors in the roof that were attached to existing girders and double joists. At the floor, grade beams transferred forces through the floor slab.

Shear walls were designed integral with the existing columns. The instability of the shear walls due to overturning, was restisted by a micropile foundation. Micropiles were selected in lieu of large diameter piles because we wanted to minimize any disturbance to the embankment.

The new lateral system at the interior segments were new concrete moment frames. The concrete moment frames would allow the roof segments to move.

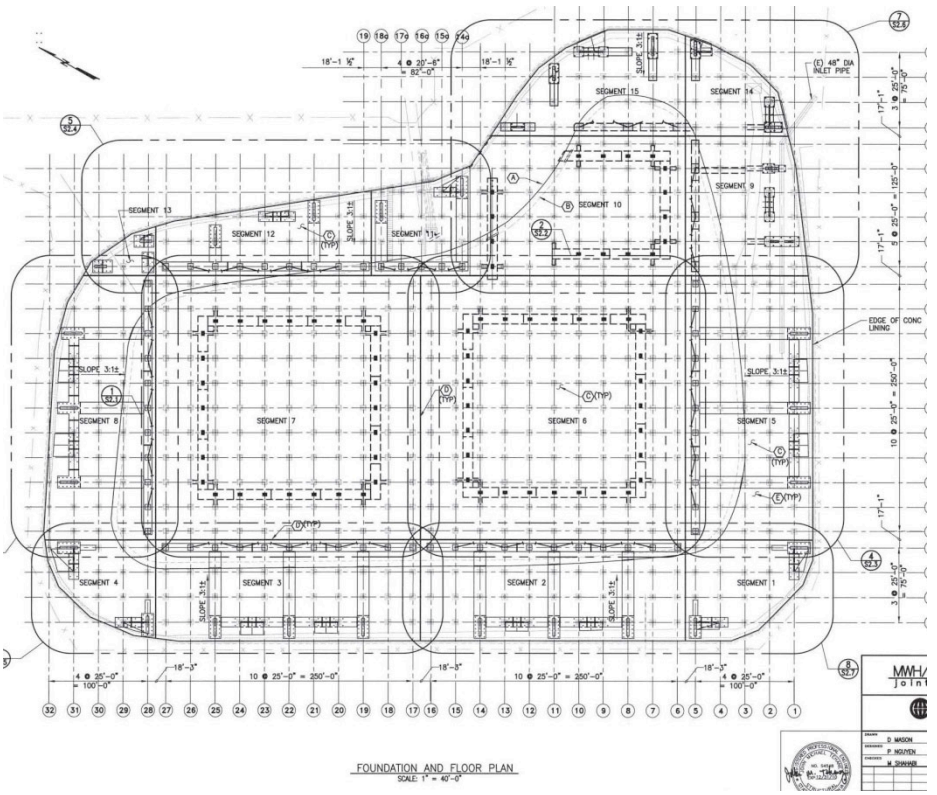

Figure 4. New foundation and floor plan

THERMAL ANALYSIS

A thermal analysis was a design consideration that became a governing load condition for the UMRNB design. The original scope of work for the project included a basic thermal analysis check. However, thermal movement was observed at a similar reservoir retrofit which warranted a detailed thermal investigation of the University Mound Reservoir based on measured expected temperatures.

The reservoir was undergoing a retrofit of a similar nature, with major moment frames, braced frames and shear wall components. This reservoir retrofit was the basis of our design for UMRNB. We were fortunate that this reservoir was in construction during the design phase of UMRNB. Of many lessons learned and taken from this reservoir, temperature considerations was the most prevailing. During visits to the site, some cracking of the roof and noises within the reservoir were observed after the braced frames and shear walls were locked to the roof slab.

We performed a detailed SAP thermal analysis of the roof slab for the UMRNB (Figure 5). To no prevailing surprise, thermal expansion and contraction is prevented in the roof slab once the braced frames and shear walls are locked to the roof. This type of restraint imparts significant tension and compression stresses in the roof. Compression on hot days as the roof slab wants to expand and tension on cold days

when the roof wants to contract. To mitigate overstressing our 3-inch thick roof slab reinforced with welded wire fabric, we identified the areas of high stress concentration using our SAP analysis models. The areas of large stress as predicted were located where the roof is restrained, at the braced frames and shear walls.

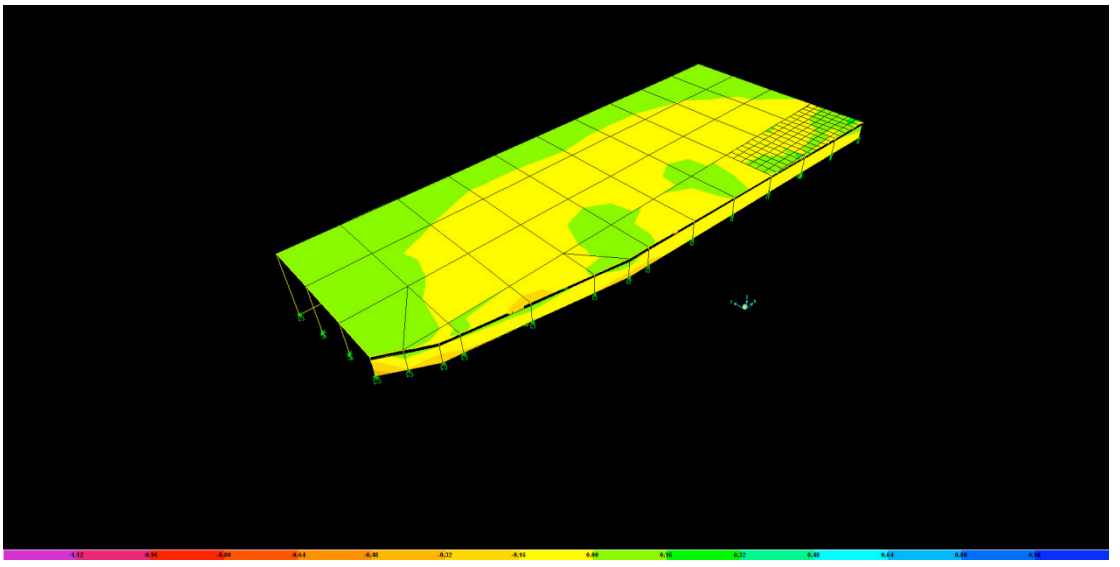

Figure 5. Thermal SAP analysis model of a single roof segment

For our thermal analysis, we used measured field and historical temperatures. The exterior roof surface temperature was observed to be within the range of 20°F higher than ambient temperature. Our estimated modeling temperatures at the exterior roof surface were 130°F on a hot day and 22°F on a cold day. These temperatures were the maximum and minimum expected roof surface temperatures. However, we discovered a reflective white coating that can be applied to the roof surface that would radiate direct sunlight that could be used to restrict the heat absorbed by the roof slab at its surface. The manufacturer of the reflective coating guaranteed the roof temperature would remain at ambient temperature with the use of this product. Our new modeling roof surface temperatures became 108°F at maximum and 22°F at minimum. The estimated temperatures within the reservoir were 60°F in the summer and 50°F in the winter. When the roof was analyzed under the thermal gradient 108°F to 60°F and 22°F to 50°F, the roof was significantly overstressed. We knew we could increase the tensile strength of the roof by adding FRP, however the compression capacity of the roof is limited to the existing capacity of the roof slab.

We devised a plan to specify an installation temperature for the roof to brace frames and roof to shear wall (or locking temperature) that is based on the temperature range in which we know the roof can be stressed under without exceeding its capacity. This locking temperature was determined to between 80°F and 60°F. This would set summer installation temperatures between 108°F and 60°F. Likewise, the winter

installation temperatures were set between 22°F and 80°F. Notice the lower bound temperature is used for summer installation temperatures and higher bound temperature is used for the winter installation temperature which produces the largest thermal gradient.

Not only was the roof capacity checked, but the member capacities were checked for thermal loading. For seismic design in accordance with ASCE 41, a phi factor of 1.0 is allowed. However, for thermal analysis which isn't included in ASCE 41, typical code level reductions are used for member designs. Therefore, it could not be assumed that seismic conditions governed member design.

CONCLUSIONS

Construction sequencing must be clearly defined in the Specifications and scope of work. Poor construction sequencing was evidenced by the difficulty of achieving the locking temperature in the field. The Contractor was able to lock in most of the braced frames and shear walls to the roof slab in the summer months when the locking temperatures were achievable. However, remaining braced frames were difficult to lock into place when it became cold in the winter months because the reflective coating was placed above the roof. The reflective coating would prevent the roof from absorbing any natural sunlight, which poses difficulty in the winter months. In hindsight, proper sequencing and scheduling would have negated this problem. The reflective coating should have been placed after the braced frames and shearwalls were locked to the roof at the locking temperature.

Floating Stair using High Performance Structural Materials

Mark C. Waggoner

Principal, Walter P. Moore and Associates, Inc., 221 West 6th Street, Suite 800, Austin, Texas 78701; PH 512.330.1270; email: mwaggoner@walterpmoore.com

Abstract

In 2007 Walter P Moore relocated its corporate headquarters in Houston, TX, in 2007 to three floors in a tall building in downtown Houston designed by the firm. Working with the architecture firm Gensler, initial planning efforts identified the need to connect the workflow of the office via a new, common central stair atrium cut into the existing floor plates. The final design for the stair was chosen from an internal design competition that sought to identify a lightweight, progressive structural solution that highlighted the creative abilities of the firm.

The design implemented for the stair consists of a cantilevered, stringerless arrangement that takes advantage of the intrinsic elements that exist functionally in a stair by rewriting the structural behavior of the stair through manipulation of the boundary support conditions. Using this design framework, individual elements of the stair were minimized through the use of high performance materials, including ultra-high performance fiber reinforced concrete (UHPFRC) and high strength steel cables.

In addition to the optimization process that enabled the ultra-thin sections, a unique approach to vibration design was taken. The stair was intentionally designed to be somewhat flexible, allowing a platform for discussion of vibration perception topics with the clients who visit the office. The stairs are outfitted with a small tuned mass damper (TMD) and instrumented with accelerometers whose output is displayed on a large screen at the bottom of the stair.

Stair Concept

What are the essential elements of a stair? Functionally, a stair must have treads, guard rails, handrails, and stringers for structural support. Or does it? The design concept of the stair emerged from a fundamental examination of the basic components of a stair and how they might be exploited as structure. The inspiration was to eliminate any elements that acted only as structure, and simply use the basic essential functional elements of a stair to provide support.

Looking at the fundamental elements of the stair, the walking surface typically consists of thin but wide slabs of concrete – quite suitable to take compressive loads. Likewise, the handrails and guardrails are thin, linear elements which are well proportioned for tensile loads but unsuitable for compression. However, the manner by which stairs are typically supported at either end produces bending forces that place compression in the upper elements and tension in

the lower elements – exactly the opposite of the available structural opportunities in the stair elements.

By flipping the stair on its end and cantilevering it from the top, the forces induced in the stair elements – tension on top, compression on bottom – match the suitable structural functions of the respective stair tread and railing elements. Thus the stair is not supported at its lower end, allowing the dramatic floating appearance but in fact only as a by-product of the manipulation of structural forces. Resolution of the horizontal forces at the top end of the stair is provided by a vertical W16 beam, which easily spans to the existing building floor levels to distribute forces to the floor diaphragms.

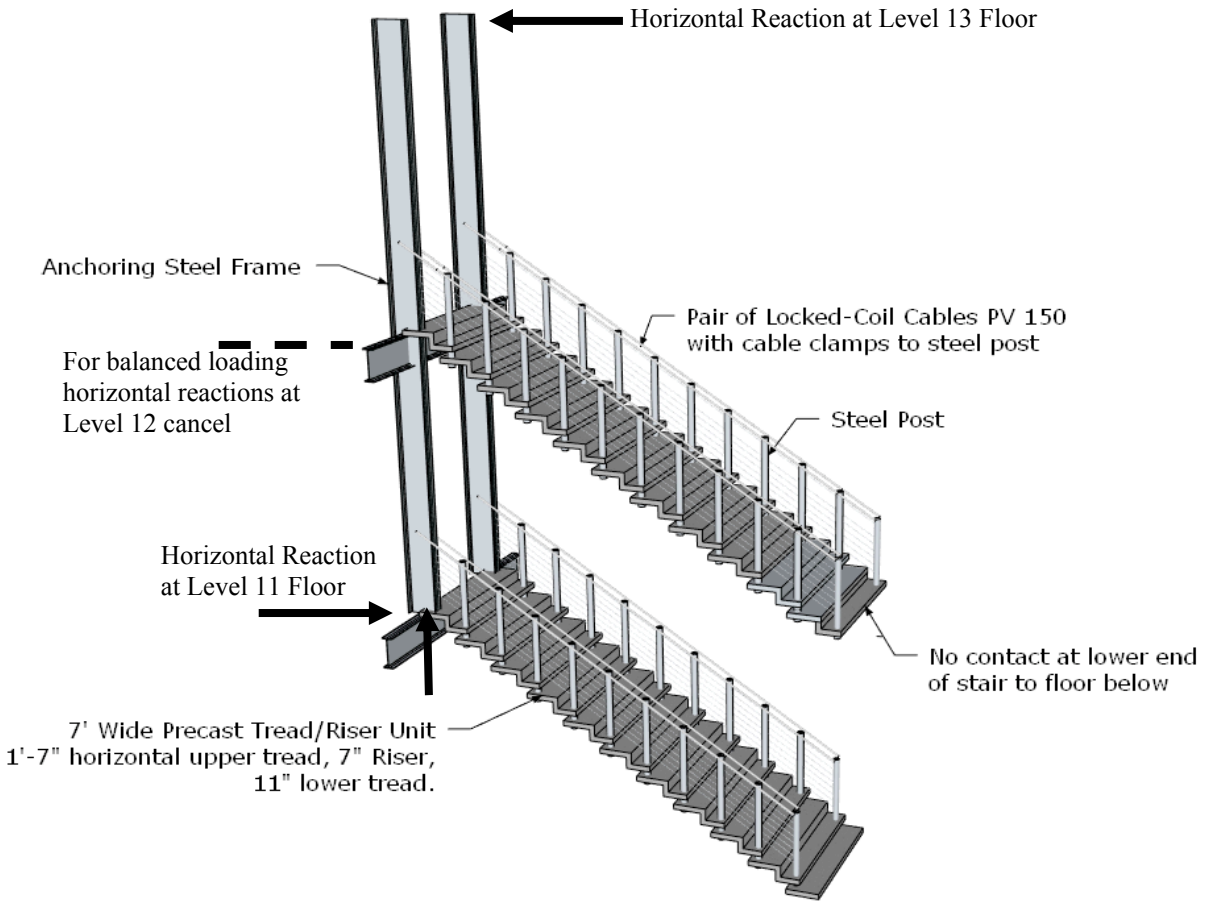

Figure 1: Stair Design Concept

Stair Elements

The "cantilevered beam" consists of a trussing of the upper tension elements with the lower compressive elements. Using the 42" height required of the guardrail provided a robust depth for the span – the equivalent of span/15 in structural terms. Rather than introduce diagonals to

create the truss, a clean appearance was maintained by utilizing flexural stiff vertical posts rigidly connected to the treads and risers to create a vierendeel system.

Using this basic form, the various stair elements were realized in state-of-the-art high strength structural materials to allow the lightest elements possible, and also to create a demonstration of use of advanced materials. Ultra-high performance fiber reinforced concrete (specifically, Ductal by LaFarge) was used for the precast tread and riser units. Using UHPFRC enabled the units to be only 1" thick typically, with a stiffening rib at the connection to the steel post. Combined with a compressive strength around 18,000 psi, the UHPFRC utilized high performance organic fibers that enabled elimination of most rebar in the tread/riser units. Design of the UHPFRC was accomplished using a code framework developed by the Japanese Society of Civil Engineers (JSCE, 2006). In this stair application the UHPFRC is enhanced by the inherent compressive forces flowing through the bottom chord of the truss, effectively prestressing the concrete material.

Figure 2: UHPFRC Precast Tread/Riser Units

The guardrail of the stair, working as the top tension chord of the truss, is made of two 1½" diameter locked coil cables. Not needed for strength, sizing of the cable is based on a combination of stiffness requirements and prescriptive code requirements for guardrail dimensions. Each pair of cables is clamped to the tops of the solid 3½" stair posts through a machined cable clamp, which is bolted to the top of the steel post through a tapped, threaded hole. The top ends of the cables are anchored with an open spelter socket.

The steel posts are solid 3½" A36 steel rods, selected from common bar stock. At the lower connection to the precast units, the post is threaded externally and passes through a blocked out hole in the unit above. Nuts clamp the concrete rib and transfer the moment from vierendeel

truss action through bearing and bending in the steel post. A high strength A490 bolt is threaded up through a hole in the lower precast into a hole in the end of the pipe to secure the lower precast element.

Figure 3: Cable Clamps

Figure 4: Post Connection to Precast Units

Vibration Design

A unique approach was taken to design of the stair for vibration. Rather than seek to eliminate vibration, a common request of our clients, we chose to feature the movement of the stair. At a base frequency of 3.5 Hz without taking any enhancement to the design for vibration, the stair was in a range where perceptible accelerations could be expected.

Our design practice frequently tackles complex problems of vibration design and the associated human perception issues. We frequently attempt to explain to clients what different levels of vibration might feel like so that they may make important and often very costly decisions on tradeoffs of cost in implementing various levels of acceleration control. Such explanation is often futile without physical demonstration to the layman. In order to help better educate our clients on vibration issues and what it means to "feel" a structure move, we chose to target our stair design flexibility in a range to facilitate these discussions.

To better understand what actual performance might be expected, extensive time history analysis was conducted of an analytical model of the stair. Simulations of one, two, four, and six people traveling on the stair simultaneously was conducted using various pacing rates. Predicted accelerations were in the 2 to 3 percent gravity range, a level that is readily perceptible.

As a measure to allow the flexibility to tune and limit the acceleration levels, the cantilever stair concept offered an excellent opportunity to incorporate a tuned mass damper (TMD) at the tip of the cantilever. A pivoting TMD was bolted to the underside of the stair at the lower two post locations. The pivot arm contains an offset mass aligned with an air damper, and reacts on a steel spring bearing on the underside of the lower tread unit. The mass is provided by steel plates which can be adjusted in both number and position to tune the properties of the TMD. The damper is an off the shelf air damper.

To provide real time feedback on the stair response, the lower end of the stair near the TMD was equipped with an accelerometer which is linked to a display read out at the bottom of the stair. The TMD is also equipped with a lock-down mechanism such that it can be turned "off", so that the user can experience the effectiveness of the TMD in reducing the response of the stair. Measurements indicate that the stair damping was enhanced from 0.5% critical for the bare stair to around 6% critical with the TMD engaged.

Erection

The stair was erected from the top down by progressively hanging each post and precast unit onto the top lock coil cables. Due to the sequential nature of the deflections, Walter P Moore provided the erector with setting dimensions based on simulation of the stair erection using a staged construction analysis. Interestingly, one flight of stairs was erected properly to specified setting dimensions and came to the correct elevation at the lowest tread, an important consideration to meet the code tolerances on variation in tread height. The second flight was set without consideration for the preset dimensions, and came out of tolerance but was easily adjusted through jacking and shimming at the top of the cantilever.

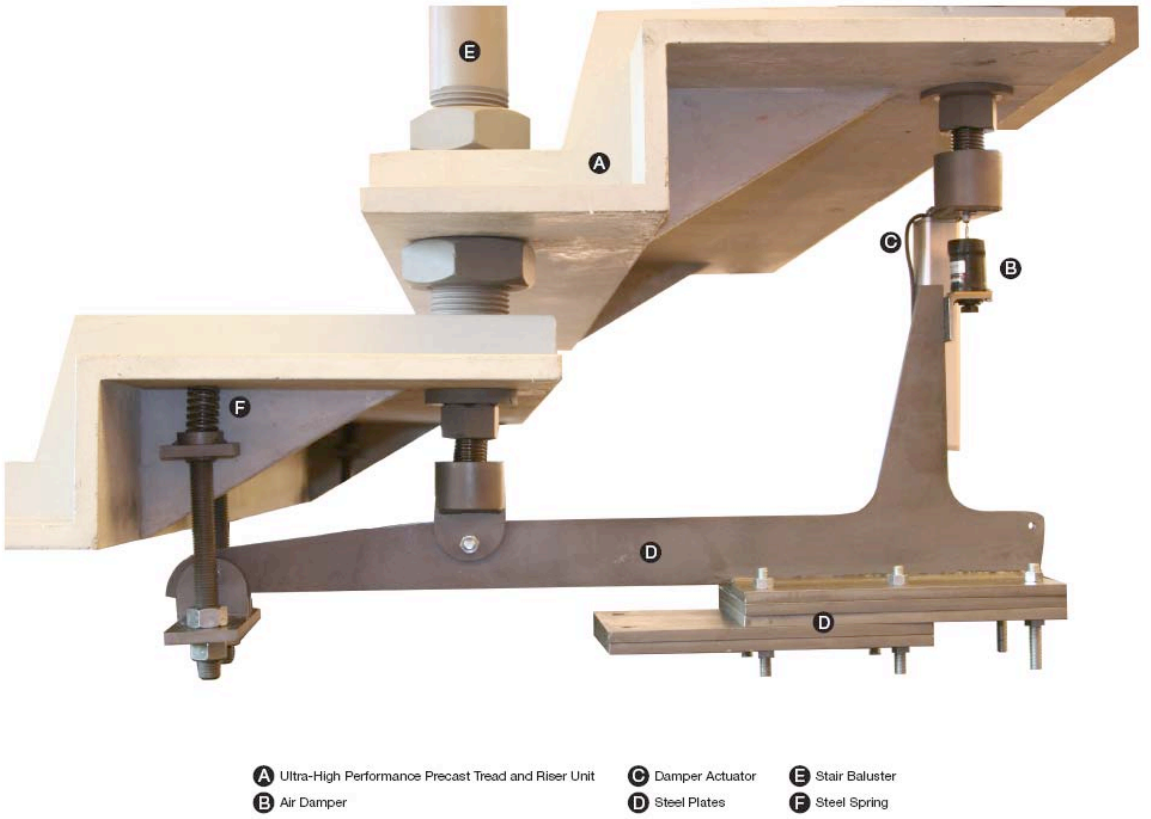

Figure 5: Tuned Mass Damper

Conclusions

The Walter P Moore Houston office stair has been conceived to defy all conventional notions of how a stair behaves. The inverted structural form replaces a conventional spanning notion, and budget normally spent on expensive architectural finishes is vastly reduced by the use of high performance structural materials. Conventional notions of a rigid feeling stair experience are replaced by celebrating the experience of traversing the stair through a real time read out of the participant's effect on the structure. After completion, the stair has proved to be a highly entertaining feature for both staff and clients, and has provoked extensive discussion on its inner workings.

ABSTRACT

Feature staircases are very popular in the architectural design of institutional and commercial buildings in North America and elsewhere. Generally, the iconic staircase is constructed from steel, has long unsupported spans and often consists of unique geometries. The gravity design of such staircases is trivial; however, designing the staircase to be insensitive to vibrations due to human activity is often challenging. The long spans, low mass, in conjunction with a low damping ratio, can result in a low-frequency system that responds with high human-induced accelerations. The damping ratio and the pace frequency have a significant influence on the vibration behavior of the structure. The AISC 11 design guide, which is the document used predominantly in North America for vibration design, does not contain any specific requirements for staircases. The UK design guide SCI P354, however, provides some specific information pertaining to their design. This paper examines the approaches of different vibration design guidelines and, along with the assumptions used in the analytical model, presents their application to the design of a feature staircase at a prominent academic institution in Toronto, Ontario, Canada. The four-story steel staircase, analyzed for vibrations using the finite element program SAP2000, has a nine meter cantilever span, with stone finishes and composite steel landings. To determine the best estimate for the actual damping ratio needed to be used in the analysis, acceleration measurements were performed on an existing staircase with similar characteristics. The study demonstrates that a large and inconsistent scatter of accelerations is obtained using the approaches specified in the different guidelines. It also emphasizes that the damping ratios recommended in the guidelines may not be indicative of the actual values and should be used with caution. Recommendations for damping ratios and pace frequencies for staircases are also provided.

INTRODUCTION

Over the past decades, resonance due to human activity has been typically ignored in the design of floors, staircases, and footbridges. Recently however, several analytical procedures have been proposed to evaluate the behavior of structural elements for human comfort arising from a specific activity and for suitability for sensitive equipment (AISC 1997, SCI 2007, FIB 2005). Such analytical tools require, in general, the calculation of the first natural frequency of the element under consideration and the maximum amplitude of acceleration for a specific human-induced excitation. The damping in the structural system is an important parameter that has to be estimated in order to obtain meaningful results. An acceptance criterion for human comfort or sensitive equipment is then used to determine whether the structural system meets serviceability requirements.

Feature staircases are very popular in the architectural design of institutional and commercial buildings in North America and throughout the world. Generally, the iconic staircase is constructed from steel, has a long unsupported span and often includes unique geometries. The structural design for gravity loads of such staircases is trivial; however, designing the staircase to be insensitive to vibrations due to human activity is often a challenging task. The long spans, low mass, in conjunction with a low damping ratio, can result in a low-frequency system that responds with high human-induced accelerations. While the mass influences both the frequency of the system and the response, the damping ratio and the pace frequency also have a significant influence on the vibration behavior of the structure (Kerr 1998, Kerr and Bishop 2001).

Three main parameters are required to properly evaluate the vibration sensitivity of staircases for human-induced vibrations: the damping ratio, the forcing or pace functions, and the acceptance criteria for human comfort. At present, there is no clear consensus in the research community on the determination of these values. The vibration behavior of a staircase based on two widely used design guides, AISC (1997) and SCI (2007), is examined herein.

DESIGN GUIDES REQUIREMENTS

Generally, vibration problems involve repeated forces caused by machinery or human activities such as walking, dancing, or fitness activity. In general, a repeating force can be represented by a combination of sinusoidal forces whose frequencies, f, are multiples, or harmonics, of the base frequency of the force repetition, e.g., the step frequency, f_{step}, in the case of human activities. The time-dependent repeating force can be represented by Fourier series as follows (e.g., AISC 1997):

$$F = P\left[1 + \sum_{i=1}^{n} \alpha_i \sin(2\pi i f_{step} t + \phi_i)\right]$$

where,

P is the person's weight
α_i is the dynamic or Fourier coefficient for the i^{th} harmonic force component
i is the harmonic multiple of the step frequency
f_{step} is the step frequency
t is time
ϕ_i is the phase angle for the i^{th} harmonic
n is the total number of contributing harmonics

The step or forcing frequencies, Fourier coefficients and other requirements of the two most widely used vibration design guides, AISC (1997) and SCI (2007), are presented below for footbridges and staircases, respectively.

1. AISC Guidelines

The American Institute for Steel Construction (AISC) design guide 11 "Floor Vibrations Due to Human Activity" (AISC 1997), which is the document used predominantly in North America for the design against vibration, contains no specific requirements for staircases. However, it provides requirements for footbridges which, for the purpose of this study, could be assimilated for the design of staircases. In this guide, the walking person is assumed to have a weight of 0.7 kN and the recommended damping ratio for footbridges is 1% of critical. The footbridge system is satisfactory if the peak acceleration due to walking excitation, as a fraction of the acceleration of gravity, g, does not exceed the acceleration limit of 1.5% for indoor footbridges and 5.0% for outdoor footbridges. The excitation (or forcing) frequency ranges and the dynamic (or Fourier) coefficients are given in Table 1.

Table 1. Forcing frequencies, f, and Fourier coefficients, α_i, for walking excitation (AISC 1997).

Harmonic, i	f (Hz)	α_i
1	1.6-2.2	0.5
2	3.2-4.4	0.2
3	4.8-6.6	0.1
4	6.4-8.8	0.05

2. SCI Guidelines

In contrast, the design guide prepared by the UK Steel Construction Institute (SCI 2007) provides specific requirements for the design of staircases. According to this guide, the walking person weight is assumed to be 0.746 kN and the recommended damping ratio is 0.5% of critical for fully welded steel structures, such
