For one application two platforms were designed and constructed to seismically isolate two pharmaceutical fill-finish lines. Based on business interruption analysis it was determined that the filling lines were critical to operations and that damage to the equipment was not acceptable. Isolation platforms were the perfect solution – providing the desired protection and easily adaptable to the existing construction.

The platforms limit the lateral accelerations on the equipment to less than 15% of gravity and are recessed into a slab depression to avoid changes in manufacturing operations. Figure 10 shows a photo of one of the partially completed platforms in the slab depression during installation.

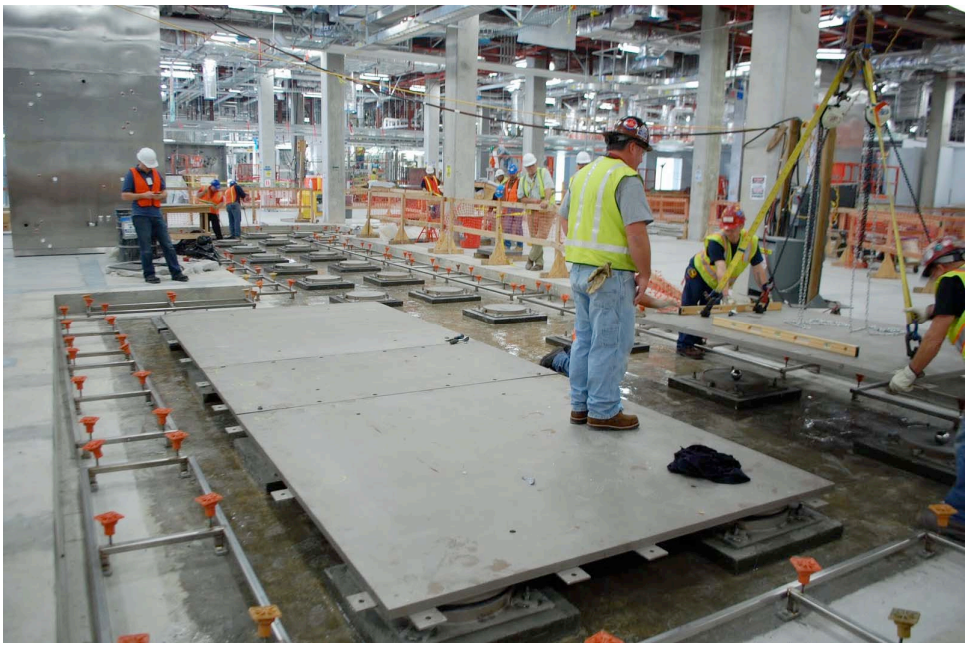

Figure 10. Partially Completed Isolation Platform

To minimize the depth of the slab depression, the platform was designed using a 1.5-inch thick top plate as the primary structural element. The top dishes of the Ball-N-Cone isolators were attached directly to the bottom of the plate in the shop by welding. The bottom isolators were field installed using leveling nuts, grout, oversized holes with welded plate washers and adhesive anchors. To minimize installation time, the platform was constructed with all bolted connections, allowing one platform to be installed in a single day (base dishes were already in place). The location and relative elevation of every dish attached to the top plate was surveyed during fabrication so that the base dishes could be accurately located in the field to minimize any field modifications. Out of 32 isolators on one line, only two isolators required minor adjustments in elevation.

The installation of the isolated platforms in a pharmaceutical clean room environment represents the strictest of criteria. The platform could not interfere with the manufacturing operations, the materials had to meet strict cleanliness requirements, which required the use of AIS 304L stainless steel for all platform components, except for the ball bearings, which were made from hardened AISI 440C stainless steel, the slab depression had to be water tight, yet allow movement of the platform in a seismic event.

A simpler application of the isolated platform is the system designed and constructed for The Bowls project in San Francisco, California. The project consists of the base isolation of a temporary art installation, which is composed of unreinforced masonry domes. Because the domes could be occupied by visitors, the installation had to meet the requirements of the building code. The team came up with the innovative solution of base isolating the domes and then conducting a full scale test for the building department. The Bowls project, which is described in detail in another paper submitted for this conference, uses similar isolators connected by a modular steel frame of wide flange beams. The platform is then created by infill wood joists topped with plywood. The steel frame and isolators is shown in Figure 11 and the final completed project in Figure 12.

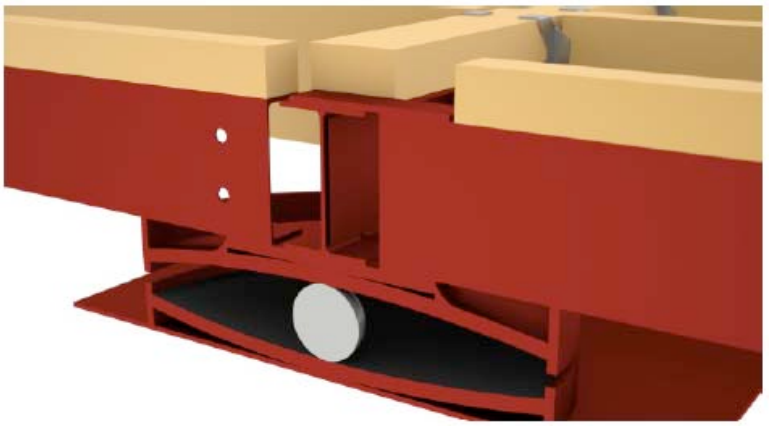

Figure 11. Section Through Isolator and Steel Frame

Figure 12. The Bowls Project

One unique feature of both the pharmaceutical installation and the Bowls project is that they could both be relatively easily tested to demonstrate that the design meets the performance objective, providing further assurance to both owners and building officials that the system provides the protection intended.

FUTURE APPLICATIONS

Given the relatively low cost of Ball-N-Cone isolators and the ease with which they can be configured into a variety of structural systems there are many opportunities for their use in seismic protection. One area that the system could easily be extended to is low-rise light-framed construction, such as residential. The Ball-N-Cone isolators are ideal for supporting the relatively low vertical loads associated with this type of construction and the cost per isolator is very affordable. The application of Ball-N-Cone isolators is well suited to high-end residential or for any owner who is looking for improved protection compared to standard construction.

CONCLUSIONS

WorkSafe Technologies Ball-N-Cone isolators provide a simple, effective, and low cost alternative to traditional base isolation systems. The Ball-N-Cone isolators are best suited for applications with relatively low vertical loads, such as nonstructural components or low-rise light-framed construction. Currently the technology has been applied for the protection of computer racks, entire data centers, and for large equipment and even fragile art installations. There are numerous other applications that the technology can be extended too in the future.

Probabilistic and Deterministic Seismic Soil Structure Interaction Analyses for the Lotung Quarter-Scale Containment Model

ABSTRACT

The seismic responses for nuclear facilities are required to consider soil-structure interaction (SSI) effects. The upcoming revision of ASCE 4 establishes a goal of developing seismic responses with an 80% probability of non-exceedance. It is important to ensure the widely used deterministic analysis results to be in an 80th-percentile level response or higher as compared to the probabilistic analysis.

The SSI analysis of the Lotung quarter-scale containment model is repeated using the probabilistic method using the computer program SASSI2000. The experimental Lotung results are used to evaluate the merits of the probabilistic approach and to make an assessment of the 80th-percentile responses with the responses obtained from recoded motion.

The analysis is subsequently repeated at three sites with different soil depths and with modifications to the input parameters to observe their effects on the probabilistic analyses. Probabilistic analysis considers the variation of soil properties, layer thicknesses, and structural parameters. For all cases, a comparison of the seismic loads and in-structure response spectra (ISRS) at the 80th-percentile level is made with the envelope of three deterministic SSI analyses, demonstrating that the deterministic method envelopes the probabilistic ISRS, but probabilistic structural forces may exceed the deterministic. This paper further examines the effects of Monte Carlo and Latin Hypercube sampling methods and of the number of samples on the accuracy of results for the probabilistic analyses.

INTRODUCTION

The seismic responses for nuclear facilities are required to consider dynamic soil-structure interaction (SSI) effects. SSI effects are typically considered by the use of computer programs such as SASSI or CLASSI and account for the behavior of the free field soil, modeled building structures, and the interaction of these components. The upcoming revision to ASCE 4 establishes a goal of developing seismic responses with approximately an 80% probability of non-exceedance for the given mean input motion. The mean input motion is typically developed using probabilistic site

response analyses. The same techniques used for probabilistic site response analyses can be expanded to SSI analyses or even combined into joint probabilistic analyses. Use of probabilistic SSI analyses can provide the required output with 80% probability of non-exceedance along with significant additional data on sensitivity of results to input variations. The recommended probabilistic SSI analysis is a robust method that can be integrated in the probabilistic site response analysis for development of the design motion, and also used for probabilistic risk assessment (PRA) for the structure and its components.

While probabilistic methodologies provide many benefits, they are not widely used due in part to the computational expense in performing the analyses. SASSI analyses calculate impedances in the frequency domain and are computationally expensive to run for large models, particularly for large embedded structures in soft soil, where wave-passage requirements demand the use of refined models. To reduce the computational expense, the response is calculated directly only at user-selected frequencies, and the intermediate frequency responses are calculated using an interpolation technique. The use of interpolation techniques requires additional effort on the part of the engineer to ensure that the analyses produce accurate results.

The deterministic methodology presented in ASCE 4 is intended to achieve the same goal of 80% probability of non-exceedance for the same mean input motion. Deterministic analyses consider uncertainties through variations in the soil profile to produce a lower-bound, mean, and upper-bound profile with a minimum soil shear modulus coefficient of variation of 0.5. The results of the three deterministic analyses are enveloped. Additional uncertainty is accounted for in the calculation of in-structure response spectra (ISRS) by broadening the results by ±15%. It is important to ensure the widely used deterministic analysis results in an 80th-percentile-level response or higher as compared to the probabilistic analysis.

In the following sections, this paper presents deterministic and probabilistic analyses of the Lotung experiment using SASSI2000 for three different soil sites: one site consistent with the Lotung experiment data, one deep-soil site, and one shallow-soil site. In each case, the enveloped deterministic responses are compared to probabilistic 80th-percentile responses to determine if the deterministic responses meet the intent of ASCE 4. For the shallow-soil site, the effect of probabilistic sampling methods and sample size are examined to determine their effect on the accuracy of the probabilistic results.

LOTUNG EXPERIMENT MODEL DESCRIPTION

The Lotung experiment was conducted by the Electric Power Research Institute (EPRI), Taiwan Power Company (TPC), and U.S. Nuclear Regulatory Commission (US NRC) in Lotung, Taiwan (EPRI 1987). The experiment considered a quarter-scale containment model (Figure 1) constructed with reinforced concrete cylinder containment walls 1 ft thick and 50 ft high. The structure is embedded 15 ft into the soil, with a 3 ft thick flat base slab and a 4 ft thick flat roof slab, and the structure supports a steam generator. Motions in the structure and at adjacent free field locations were recorded for the experiment. This structural model was selected for use in all analyses used in this paper because of the availability of recorded data to evaluate the results.

The SASSI2000 User's Manual provides a SASSI analysis considering a model of the Lotung Experiment using the recorded site motions and comparing the analyses results to the in-structure recorded motions as part of the program validation (Ostadan 2007). The SSI model is a half model with a plane of symmetry (Figure 2). The below-grade walls are modeled with thin-shell elements and the base slab is modeled with 3-D solid elements. The above-grade containment structure is modeled with a lumped mass stick model connected to the subsurface walls by rigid links. The internal steam generator and support structures are modeled with beams and lumped masses. The fixed-base containment structure has modes around 10.8 Hz and above 30 Hz, and the steam generator has modes around 5.5 Hz, 10.5 Hz, 15 to 20 Hz, and above 30 Hz. For use in the analyses presented herein, ISRS will be examined at the base slab (Node 178), top of the containment structure (Node 311), base of the steam generator (Node 300), and the top of the steam generator (Node 302); and structural shear force examined at the containment structure stick just above grade (Beam 1). All analyses are performed for vertically propagating shear waves excited in the Y-direction of motion using the direct method for calculation of impedances.

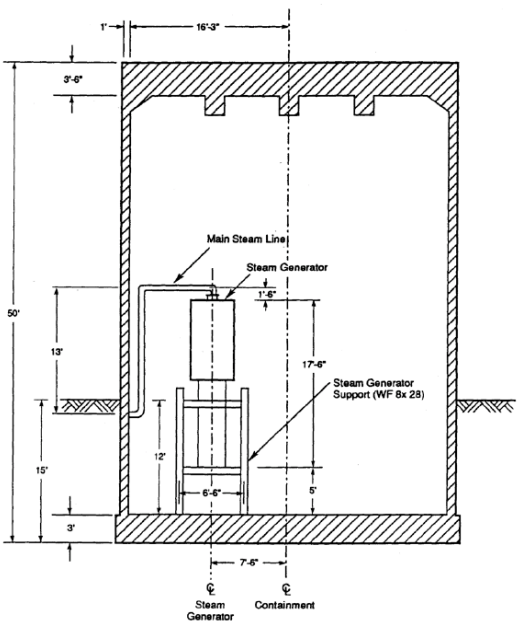

Figure 1. Vertical section of Lotung experiment.

DETERMINISTIC METHODOLOGY

The deterministic analyses follow the guidelines of ASCE 4 including variation of soil shear modulus by one standard deviation but not less than a coefficient of variation of 0.5 and considering no structural variation. Three soil profiles are considered, a lower-bound, mean, and upper-bound soil cases. Typically, the same soil layering was used in all three profiles. For the shallow soil profile, the deterministic analysis was performed, including variation in soil layer thicknesses to account for the significant effect these thicknesses play on the responses for shallow soil sites. The results of the three deterministic soil cases are enveloped, and the ISRS are broadened by 15% frequency shift at all frequencies. No peak clipping is performed.

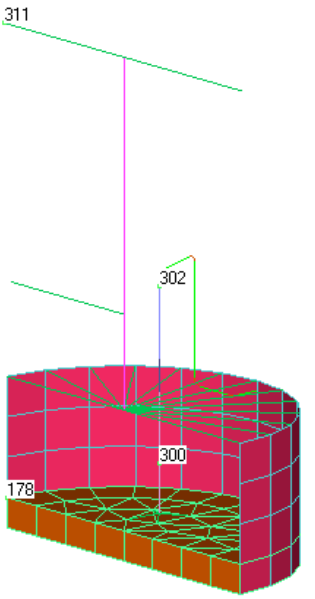

Figure 2. Lotung SSI model.

PROBABILISTIC STRUCTURAL VARIATION

For probabilistic analyses, the structural properties are varied. The mean and probabilistic distributions used are based on "Methodology for Developing Seismic Fragilities" (EPRI 1994), with the exception of steel damping where a lower mean value was used to avoid unconservative results compared to the deterministic analyses. Concrete elastic modulus, concrete material damping, steel elastic modulus, and steel damping are modeled with truncated lognormal distributions using the parameters indicated in Table 1. The variations used are similar to those proposed by ASCE 4.

Table 1. Probabilistic Structural Properties.

		Probabilistic		
	Deterministic	Mean	Cv (Used)	Cv (ASCE 4)
Concrete Elastic Modulus	518,400 ksf	518,400 ksf	0.32	0.35
Concrete Damping	4%	3%	0.5	0.4
Steel Elastic Modulus	2,088,000 ksf	2,088,000 ksf	0.32	0.35
Steel Damping	2%	2%	0.5	0.4
Structural Mass Coefficient	100%	100%	5%	–

SOIL SITES

Lotung site- The Lotung soil site was developed based on the geotechnical properties. The soil consists of 154 ft of soil over a linear elastic half space with shear wave velocities of 3,000 ft/s. Uncertainties in the soil profile included variation in shear-wave velocity, strain-dependent shear modulus degradation and damping curves, and layer thicknesses. Low-strain shear wave velocity was varied with a coefficient of variation of 0.2 with a lognormal distribution truncated at two standard deviations; thickness considered a beta distribution within ±20% variation bounds; and strain-dependent property curves considered a logarithmic variation based on a model by Darendeli (2001). Shear wave velocities of adjacent layers were correlated based on a model by Toro (1995), resulting in interlayer correlations between 0.55 and 0.7. Furthermore, a correlation of –0.7 was imposed between G/Go values and damping curves and 0.7 between G/Go and shear wave velocity. Sixty soil profiles were developed using the Latin Hypercube sampling method. Each of the sixty soil profiles were subjected to the ground-surface motion recorded at the Lotung site using an equivalent linear site response analysis performed using P-SHAKE to calculate the strain-compatible soil profiles for use in

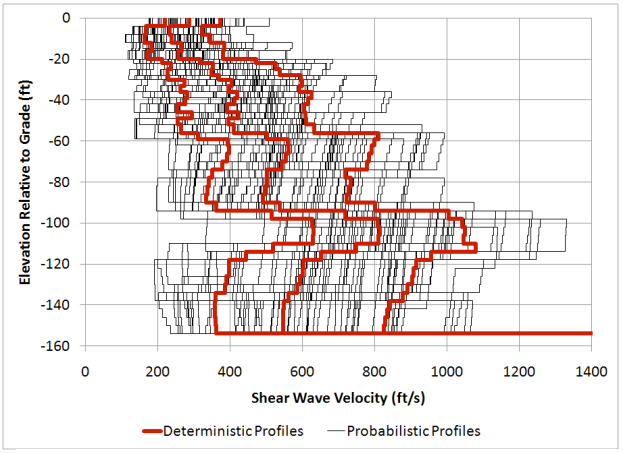

Figure 3. Lotung soil site Vs

SASSI analyses. The shear wave velocity profile of all sixty profiles plus the three deterministic profiles are shown in Figure 3.

Deep soil site- A deep soil site consists of 524 ft of soil modeled using ninety-five layers over a soil half space. Mean strain compatible shear modulus was varied with truncated lognormal distribution with a coefficient of variation Cv = 0.5 truncated at 3 Cv. The mean soil damping was varied with truncated normal distribution considering the calculated a standard of deviation of each soil layer and truncated at three standard deviations. A correlation coefficient of –1.0 was applied between the shear wave velocity coefficient and the damping deviation applied to each soil case. A correlation coefficient of 1.0 was applied between the shear wave velocities of all soil layers. Sixty soil profiles were developed using the Latin Hypercube sampling method. The shear wave velocity profile of all sixty profiles plus the three deterministic profiles are shown in Figure 4.

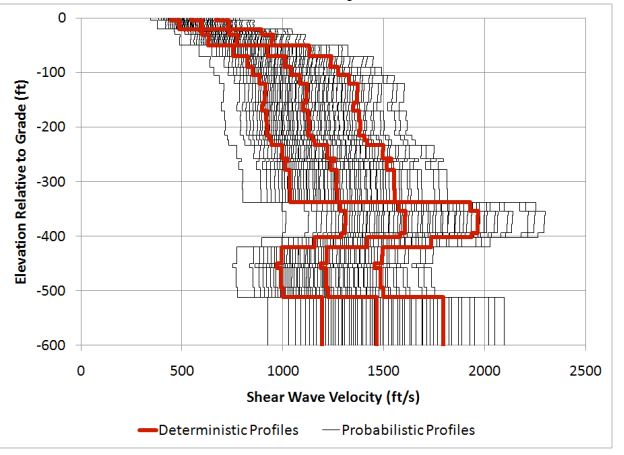

Figure 4. Deep soil site Vs

Shallow soil site- The shallow soil site consists of between 40 and 48 ft of soil over hard rock. The soil consists of three layers, an upper layer of relatively soft soil (Layer A), a lower layer of stiffer soil (Layer B), and a layer of clay (Layer C) over a stiff rock. Soil profile uncertainties considered variation in shear-wave velocity, strain-dependent shear modulus degradation and damping curves, and layer thicknesses. Variation of layer thicknesses considered uniform distributions for total depth to rock, Layer A, and Layer B with thickness of Layer C calculated from the other three parameters. Low-strain shear moduli were varied based on the layer coefficient of variation with a lognormal distribution truncated at three standard deviations. Variation of layer thicknesses considered uniform distributions for total depth to rock, Layer A, and Layer B with thickness of Layer C calculated from the other three parameters. Strain-dependent dynamic property curves considered a logarithmic variation similar to that used for the Lotung site. All soil properties were considered uncorrelated. Sixty low-strain soil profiles were developed using the Latin Hypercube sampling method.

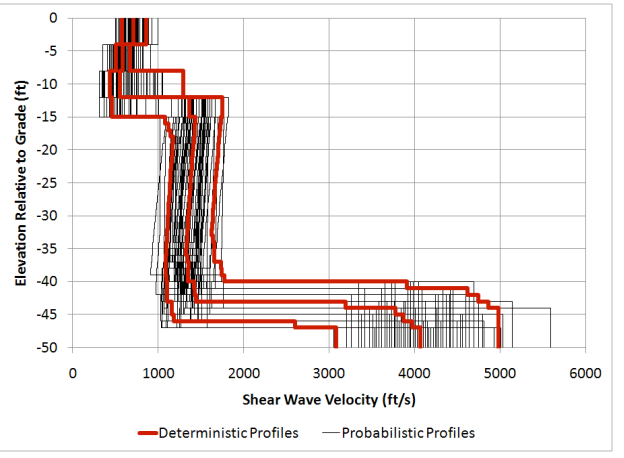

Figure 5. Shallow soil site Vs

Each of the sixty soil profiles were subjected to the PSHA rock outcrop motion in an equivalent linear site response analysis performed using SHAKE91 to calculate the strain-compatible soil profiles for use in SASSI analyses and the ground-surface motions. The shear wave velocity profile of all sixty profiles plus the three deterministic profiles are shown in Figure 5. The mean ground surface response spectra (GMRS) was calculated from the sixty profiles.

SASSI ANALYSES

Each analysis case was performed in SASSI2000 using the direct method for determining foundation impedances. The input motion for the Lotung site analyses was the recorded site ground motion for the Lotung experiment. The deep soil site input motions closely resemble a RG 1.60 response spectra scaled to 0.13 g. The shallow site input motions is a time history matched to the calculated site GMRS described above.

Three sets of analyses were run for each soil case. First, a set of three deterministic analyses were run, and the analyses enveloped to calculate the deterministic responses. Second, a set of sixty structural models were developed using the Latin Hypercube sampling method and the structural variations described above. The sixty structural models were randomly paired with the sixty strain-compatible soil profiles without replacement. The results of these analyses were processed to determine the 80th-percentile response by taking the twelfth-highest response value from the sixty cases. Third, additional sixty probabilistic analyses were performed using the deterministic base structure without variation and the sixty strain-compatible soil profiles. These sets are identified as deterministic, probabilistic, and probabilistic soil, respectively.

RESULTS

Lotung site- Comparisons of the Lotung experiment input motions and recorded ISRS to the probabilistic and broadened deterministic ISRS are shown in Figure 6. The calculated ISRS demonstrate that the motion at the base is well represented by the probabilistic responses. At the top of the containment structure, the probabilistic ISRS are near or exceed the recorded motions, and exceed the recorded motions by a large margin between 2 and 5 Hz. At the top of steam generator, the probabilistic ISRS provide close match with the recorded motions with a conservative response around 2.5 Hz. These results demonstrate that the probabilistic ISRS provide a conservative match to the recorded motions. Comparisons of the probabilistic ISRS with the broadened deterministic envelope ISRS shown in Figure 6 also show that the deterministic envelope is similar to, or greater than, the probabilistic response. The probabilistic structural variation causes a slight reduction and broadening of the spectra peak around 5.5 Hz at the top of the steam generator.

Comparisons of the probabilistic shear force with the deterministic shear force (Table 2) show that the probabilistic forces are enveloped by the deterministic results. The structural variation increases the response slightly.

Deep site- Comparisons of probabilistic ISRS with and without structural variation with the deterministic envelope and the broadened deterministic envelope ISRS are shown in Figure 7. Deterministic and probabilistic ISRS are similar at the base and top of the containment structure, indicating that both methods produce similar SSI responses. At the base and top of the steam generator, the ISRS is greatly amplified because the peak of the containment structure ISRS aligns with the natural frequency of the steam generator. For the steam generator, the deterministic ISRS is similar to the probabilistic response without structural variation. However, when the structural variation is included, the peak reduces and the spectra widens. This reduction and broadening occurs due to the variation in structural frequency and the resulting shifting in peak response. Regardless of whether structural variation is included, the deterministic envelope provides a reasonable, conservative response compared to the 80th-percentile probabilistic ISRS. The broadened envelope provides adequate broadening to envelope the probabilistic response.

Comparisons of the probabilistic and deterministic shear forces also show that the forces obtained from the probabilistic result including structural variation exceed the deterministic result slightly.

Shallow site- Comparisons of probabilistic ISRS with the deterministic envelope and the broadened deterministic envelope ISRS were examined and shown with additional sampling technique study curves (Figure 8). In nearly all cases, the deterministic envelope is similar to, or greater than, the probabilistic ISRS. The probabilistic peak response exceeds the deterministic over a narrow frequency range at the top of containment and top of steam generator. The broadened envelope provides adequate broadening to cover the structural variations.

Comparisons of the probabilistic and deterministic shear force demands show that the forces obtained from the probabilistic demands including structural variation exceed the deterministic demands by 17%. The 80th-percentile case has concrete damping of 1.2% and a mass adjustment factor of 1.03%. The damping value of 1.2% is very low and while appropriate for inclusion in probabilistic analyses to calculate response spectra, this value is lower than would be consistent for elements stressed to near their design strengths. Higher levels of damping may be justified but are not further examined herein. Excluding structural variation, the probabilistic shear demands exceed the deterministic by only 7%.

Table 2. Shear Force.

Shear (kips)	Lotung	Deep	Shallow
Deterministic Envelope	122	139	229
Probabilistic with No Structural Variation	113	139	244
Probabilistic with Structural Variation	118	143	269

EXAMINATION OF SAMPLING TECHNIQUES

All previously examined probabilistic analyses were performed considering the Latin Hypercube sampling method and sixty samples. This methodology was selected to

be consistent with current practice for sampling to obtain the mean input motions. Proposed ASCE 4 recommends at least thirty-two samples using either Monte Carlo or Latin Hypercube sampling. To examine the sampling effect, two thousand Monte Carlo analyses were performed using the same techniques as discussed above for the shallow soil site with structural variation. The 80th-percentile results from these two thousand analyses form the baseline against which other analyses are evaluated. The same analysis was performed using the Latin Hypercube sampling method with sets of sixty and thirty-two samples.

To evaluate the accuracy of the sixty-sample Monte Carlo analyses, one hundred sets of sixty results were randomly sampled, and the 80th-percentile response was calculated from each. These mean and standard deviation of these 80th-percentile ISRS were calculated at the top of containment and top of steam generator for comparison to the deterministic and baseline results (Figure 8). At all locations, the deterministic results envelop the probabilistic results, and the two thousand samples are closer to the deterministic envelope than was the sixty-sample case previously discussed. The mean of the one hundred samples is nearly identical to the baseline, and the standard of deviation is less than 7% of the mean value at each frequency for ISRS at the top of the containment structure and less than of the mean value at each frequency for ISRS at the top of the steam generator. Six of the one hundred cases at the top of the containment and twenty cases at the steam generator have spectral values more than 10% below the baseline any given frequency. The same technique was repeated with one hundred samples of thirty-two cases. The mean of these cases is also very similar to the baseline. At the top of the containment structure, the standard deviation is just under 10% of the mean with nineteen samples more than 10% below the baseline. At the top of the steam generator the standard deviation is just under 18% of the mean with thirty samples more than 10% below the baseline. Therefore, for this analysis, there is at least an 80% confidence that a Monte Carlo sampling of sixty cases is not more than 10% below the probabilistic ISRS, and this confidence reduces to 70% for a Monte Carlo sampling of thirty-two cases.

The comparison of the thirty-two- and sixty-sample Latin Hypercube cases demonstrates nearly identical ISRS to the two thousand Monte Carlo spectra except over a narrow frequency range (Figure 8). In this range, the sixty-sample case is within 87% of the baseline, and the thirty-two-sample case is within 79%. These results may be low due to failure of the small sample size to adequately represent the full subspace of probabilistic cases for the large number of variables. However, additional study is required to determine the cause of the discrepancy and how to improve the probabilistic results for analyses with relatively small sample sizes.

CONCLUSIONS AND RECOMMENDATIONS

This paper examined probabilistic and deterministic analyses of the Lotung experiment model considering probabilistic variation in soil profiles and structural properties. The deterministic analysis ISRS without peak clipping envelop the 80th-percentile probabilistic responses with minor exceptions. Where the probabilistic results exceed the deterministic results, they do so only by a small percentage and over narrow frequency ranges. Structural variation in the probabilistic analyses

typically reduces the peak value and broadens ISRS near structural frequencies. The effects of structural variation are adequately covered by the deterministic ±15% ISRS broadening.

Probabilistically determined force demands have been shown to exceed deterministic demands in some cases. Inclusion of structural variation increases probabilistic demands.

The study of probabilistic sampling methods demonstrated that increased sample sizes significantly improve accuracy of and confidence in the probabilistic responses. Care should be taken to avoid sampling bias through review of sampling or improved sampling techniques such as Latin Hypercube. Additional research is required to better define sampling required to accurately represent the probabilistic response with large number of variables and relatively small sample sizes and how to identify potentially unconservative probabilistic sampling.

ABSTRACT

The forthcoming update of ASCE 4 includes expanded provisions for analysis, design of seismically isolated nuclear structures and testing of seismic isolation bearings. The paper describes the provisions and their technical basis. The analysis and design provisions are consistent with the ASCE 43-05 performance objectives for nuclear structures, namely, 1) 1% probability of unacceptable performance for 100% Design Basis Earthquake (DBE) shaking, and 2) 10% probability of unacceptable performance for 150% DBE shaking.

INTRODUCTION

The implementation of a seismic isolation system at the base of a safety-related nuclear structure will serve to substantially reduce inertial forces on the superstructure and substructure as indicated in Figure 1. The increase in displacements shown in Figure 1 is accommodated by-and-large by the seismic isolators that are proportioned to support high axial loads at large lateral displacements as required by the draft Standard.

a. inertial forces b. displacements

Figure 1. Impact of seismic isolation on inertial forces and displacements

Figure 2 illustrates one of the benefits of seismic isolation, namely, a sharp reduction in spectral demand: increasing the fundamental period from 0.1 second (conventional

construction) to 2+ seconds (isolated construction) reduces the spectral demand by a factor of more than 10. The 5% damped spectrum presented in the figure is the design basis earthquake spectrum for the site of a nuclear power plant on rock in the Eastern United States.

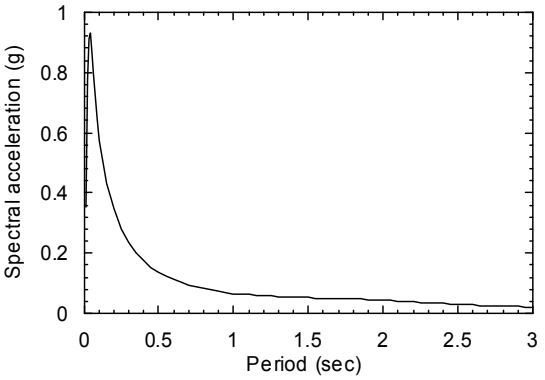

Figure 2. Design basis earthquake spectrum for a rock site in the EUS

The Provisions are written for three types of seismic isolator: low-damping and lead-rubber elastomeric bearings and Friction Pendulum™ sliding bearings. No other types of isolators are considered appropriate for nuclear structures.

Low-damping (LD) elastomeric bearings are composed of alternating layers of natural rubber and steel, and can be modeled as viscoelastic components. The shear modulus of the rubber ranges between 60 psi and 120 psi. The equivalent viscous damping is between 2 and 4% of critical. Lead-rubber (LR) elastomeric bearings are constructed similarly to low-damping rubber bearings but include a central lead core to dissipate earthquake-induced energy. The hysteresis loop for the LR bearing is bilinear per Figure 3 and defined by a zero-displacement force intercept, $Q_d W$, and a second-slope stiffness, K_d, where W is the supported weight.

Sliding bearings with restoring force provided by gravity have the hysteresis loop of Figure 3. In the Friction Pendulum™ (FP) family of bearings, the second-slope stiffness is equal to the supported weight divided by the radius of curvature of the sliding surface.

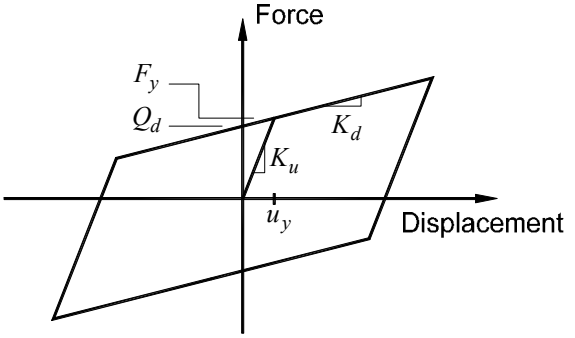

Figure 3. Mechanical properties of LR and FP bearings

The performance expectations of Section 1.3 of ASCE-43 (ASCE 2005) form the basis of the provisions in the seismic isolation section (7.7) of the draft ASCE Standard 4: 1) 1% probability of unacceptable performance for 100% DBE shaking, and 2) 10% probability of unacceptable performance for 150% DBE. More stringent criteria may be imposed by regulatory agencies, including the US Nuclear Regulatory Commission (USNRC), who require a plant-level HCLPF of 1% for 167% design basis shaking, noting that the plant-level HCLPF may not be dictated by a failure sequence involving seismic isolators (USNRC 2007, 2010).

Three performance statements for achieving the two performance objectives of ASCE-43 were assumed in the writing of Section 7.7 of the draft Standard, namely, 1) individual isolators shall suffer no damage in design earthquake shaking, 2) the probability of the isolated nuclear structure impacting surrounding structure (moat) for 100% (150%) design earthquake shaking is 1% (10%) or less, and 3) individual isolators sustain gravity and earthquake-induced axial loads at 90th percentile lateral displacements consistent with 150% design earthquake shaking. Performance statement 1 will be realized by production testing of each isolator supplied to a project for 80%-ile DBE displacements and co-existing gravity and earthquake-induced axial forces. Analysis can be used in support of performance statement 2 provided that the isolators are modeled correctly and the ground motion representations are reasonable. Performance statement 3 can be realized by prototype testing of a limited number of isolators for mean displacements and co-existing axial forces consistent with 150% of the design earthquake, noting that an isolation system is composed of 10s to 100s of isolators and that failure of the isolation system would have to involve the simultaneous failure of a significant percentage of the isolators in the system.

Diaphragms are required above and below the isolation system. In the draft Standard, the diaphragms above and below the isolation system are identified as basemat and foundation, respectively. These diaphragms are required to be stiff in the horizontal plane to effectively engage all of the seismic isolators in the seismic-force-resisting system. The basemat and foundation must be stiff out-of-plane to engage all isolators in the gravity load resisting system.

Constantinou et al. (2007) and Naeim and Kelly (1999) provide information on LD, LR and FP seismic isolators. Huang et al. (2008, 2009, 2010) provide data and information in support of the isolation of nuclear structures and the proposed isolation provisions in the Standard. Constantinou et al. (1999, 2007), Thompson et al. (2000) and Morgan and Whittaker (2001) provide the data used by Huang et al. (2009) to characterize the impact of variations in isolator material properties on the displacement response of seismic isolation systems.

GENERAL DESIGN REQUIREMENTS

Environmental and Operating Conditions

Best-estimate mechanical properties for the isolator units are used for DBE analysis. Analysis has been performed by Huang et al. (2009) to estimate displacements for LD, LR and FP bearing isolation systems at representative sites across the United States for DBE and 150% DBE shaking. These analyses considered variability in both the seismic input (i.e., a distribution in spectral demand; see Huang et al. 2009) and the mechanical properties of the isolation system. Factors were developed to relate the median design displacement in the isolation system in DBE shaking to a displacement with 1% probability of exceedance in DBE shaking and a 10% probability of exceedance in 150% DBE shaking. The greatest variability considered for isolator properties was ±20% from the best-estimate values with 95% probability.

Wind Loads

Lateral forces in seismic isolators under design wind loads should be a) less than the zero-displacement force intercept for a bilinear isolation system such as the lead-rubber bearing and sliding bearing per Figure 3, and b) small for low-damping rubber bearings.

Isolator Inspection and Replacement

Although isolators should likely not need to be replaced after DBE or 150% DBE shaking, the design of the structural framing system must provide for access to the isolators for periodic and post-earthquake inspection and possible replacement. Periodic inspection is required because seismic isolation has not been used for nuclear structures in the United States at the time of this writing. The isolators, isolation system, framing above and below the isolators and secondary systems crossing the isolation interface should be inspected after significant earthquake shaking. Components that are damaged should be replaced or repaired.

Spare isolators of each type used in the isolation system should be stored on-site and tested at 10-year intervals to build further confidence in the technology amongst structural engineers implementing isolators in nuclear structures. This requirement may be deleted if the isolators being implemented in a safety-related nuclear structure have a long track record of good seismic performance and no significant change in material properties with time.

Isolator Performance

Vertical load resistance

The vertical loads used to check the stability of an isolator should be calculated using the maximum positive and minimum negative values of a) dead load, b) live load, and

c) earthquake load associated with 80%-ile DBE shaking at the 80%-ile level and 150% DBE shaking.

No isolator damage is permitted for DBE displacements and forces calculated at the 80%-ile level. Isolator damage is permitted for 150% DBE shaking provided that it does not compromise the required vertical load resistance of the isolation system.

Minimum lateral restoring force

The restoring-force requirement is intended to limit residual displacement as a result of an earthquake, so that the isolated structure will survive aftershocks and future earthquakes. The rule is identical to that in ASCE 7 (ASCE 2010) for isolated buildings and other structures.

Basemat and Foundation Designs

The plan dimensions of foundations for nuclear islands are generally large. Vertical deflection of the basemat and/or settlement of the foundation below a small part of the isolation system will lead to a redistribution of gravity loads to the isolators that is generally undesirable. The basemat and the foundation should be sufficiently stiff in the vertical direction to engage all isolators in resisting gravity load effects. To provide a redundant gravity load resisting system, the basemat should be designed to span over one or more isolators in event of local settlement under an isolator.

DYNAMIC ANALYSIS

Response-history Analysis

General

Two procedures may be used for the analysis of seismically isolated nuclear structures. Each procedure is assumed to result in displacements in DBE shaking at the 80+%-ile level. Displacements in seismic isolators are calculated by time-stop as the vector sum of the two orthogonal horizontal displacements.

Time-domain analysis

The use of peak maximum values of isolator and superstructure response from analysis using three sets of three-component ground motions and three soil columns is assumed to meet the 80%-ile non-exceedance probability for DBE shaking.

Alternate calculations may be performed using 11+ sets of three-component ground motions and three soil columns (a minimum of 33 sets of calculations) to estimate the dispersion in the isolator and superstructure responses and thus the 80%-ile non-exceedance values.

Multi-step analysis

The horizontal and vertical envelope spectra at the foundation of the isolated structure calculated by frequency-domain analysis is assumed to represent 80%-ile spectral demands.

Three-component sets of ground motion time-series that are matched to these spectra are assumed to be 80%-ile ground motions. If less than five sets of ground motions are used for analysis, 80%-ile responses shall be taken as the peak maximum responses. If five or more sets of ground motions are used for analysis, 80%-ile responses may be taken as mean maximum responses.

Mathematical Modeling

Isolation system

The isolators shall be modeled using proven mathematical models with design parameters that have been validated by full-scale dynamic testing. Each isolator should be included in the mathematical model of the seismically isolated structure. The mathematical models of the isolators should account for changes in isolator properties associated with large-amplitude earthquake shaking (e.g., Kalpakidis et al. 2010).

For time-domain analysis, nonlinear models are required for lead-rubber and sliding bearings. Linear models are permitted for low-damping rubber bearings provided the computed shear strains for 150% design basis earthquake shaking are smaller than that associated with the onset of strain stiffening in the elastomer.

For frequency-domain analysis, equivalent linear properties shall be used for the isolators. The calculation of the equivalent properties should conform to the procedures of ASCE 7 for linear elastic analysis of seismically isolated structures. Multiple iterations may be required to validate the choice of isolator secant stiffness and equivalent viscous damping.

Superstructure

The superstructure can be modeled using elastic properties unless inelastic response is anticipated in components of the isolated superstructure at the level of shaking being considered. Simplified, validated elastic models of the isolated superstructure may be used for the purpose of calculating isolator displacements and floor accelerations if the superstructure remains elastic for the level of shaking considered.

Displacements and Forces for Design

Seismic Isolators

Values of the 80%-ile design displacement and the 80%-ile total design displacement from the response analysis for DBE shaking shall be calculated and reported for a)

establishing the scope of the isolator testing program, b) final design of the isolation system, and c) designing and detailing the seismic joints and the SSCs crossing the isolation interface.

Huang et al. (2009) showed that displacement demands (and thus transmitted forces) associated with 10% probability of exceedance (PE) in 150% DBE shaking are greater than those associated with 1% PE in DBE shaking. Accordingly, the connections of the isolators to the substructure and superstructure shall be designed to resist the forces associated with the 10% PE displacement for 150% of DBE shaking to ensure that inelastic action is confined to the isolators.

Seismic Joints

A performance objective for seismically isolated structures is the high probability of avoidance of impact with adjacent built and geo-structures. The width of a seismic joint that separates a seismically isolated structure from adjacent structures shall have a PE in 150% DBE shaking of 10% or less. The width of the joint shall be taken as 3 times the 80%-ile total design displacement if analysis is not performed for 150% DBE shaking. If analysis is performed for a distribution of ground shaking consistent with 150% of the intensity of the DBE, the width of the seismic joint shall be associated with a 10-% probability of exceedance.

SSCs Above the Isolation Interface

The design of the superstructure, systems and components above the isolation interface shall be based on the results of response-history analysis for DBE shaking and use the same procedures and standards adopted for non-isolated nuclear structures.

SSCs Below the Isolation Interface

The design of substructure, systems and components below the isolation interface shall be based on the results of response-history analysis for DBE shaking and use the same procedures and standards adopted for non-isolated nuclear structures. Systems and components bridging the isolation interface shall not be damaged or lose function in DBE shaking (1% PE). The probability of damage or loss of function in 150% DBE shaking shall be 10-%.

DESIGN REVIEW

A peer review of the design of an isolated nuclear structure should follow the requirements of the draft Standard for non-isolated structures and also address those aspects of the design and specification related to the seismic isolators, isolation system, and SSCs that cross the isolation interface.

Review of the design and analysis of the isolation system and design review of the isolator-testing program is mandated by the draft Standard because 1) the

consequences of isolator failure could be catastrophic, and 2) isolator design and fabrication technology is evolving rapidly and may be based on technologies unfamiliar to many design professionals.

The draft Standard requires that a team of registered design professionals perform the design review. The peer review team should be independent of the design team and other project contractors. The review team should include individuals with special expertise in one or more aspects of the design, analysis, testing and implementation of seismic isolation systems.

TESTING OF PROTOTYPE AND PRODUCTION ISOLATORS

General

The draft Standard describes the two types of tests to be performed on seismic isolators: 1) prototype, and 2) production. Prototype bearing tests are performed on a small number of isolators of each type planned for use in the isolation system. These tests are conducted prior to isolator production for the project. The purpose of the tests is to ensure that the isolators perform as anticipated by the design team for DBE and 150% DBE shaking. Production (or quality control) tests are performed on each isolator fabricated for a project. The production-testing program is less onerous than the prototype-testing program: dynamic tests are not required and the peak test displacement is that computed for the DBE.

Prototype Testing

Test specimens

Two isolators of each type and size in the isolation system are fabricated for prototype testing. This requirement is identical to that for building structures per ASCE 7.

Record

The minimum data to be recorded in a prototype test should enable the calculation of axial force, axial displacement, horizontal force and horizontal displacement histories, and the generation for force-displacement hysteresis loops. A sampling rate of 200 Hz is sufficient to resolve the response of isolators that are tested at frequencies of between 0.5 Hz and 0.01 Hz.

Sequence and cycles

The draft Standard specifies a minimum sequence of tests for prototype isolators. Other tests may be specified on a project-specific basis, including tests to compute vertical stiffness. ASCE 7 (ASCE 2010) and the AASHTO Guide Specification for Seismic Isolation Design (AASHTO 2010) include tests for isolators in buildings and

bridges, respectively. The number of cycles of loading is conservatively based on the data of Warn and Whittaker (2004).

Test specimen adequacy

The acceptance criteria used for prototype bearing tests should be consistent with the assumptions made for the design of the seismic isolators and seismic isolation system, and must therefore be developed on a project-by-project basis. Basic acceptance criteria for the three prototype tests are provided in the draft Standard for inclusion in the prototype-isolator acceptance criteria developed by the engineer of record. Sample criteria can be found in ASCE 7 (ASCE 2010) and the AASHTO Guide Specification for Seismic Isolation Design (AASHTO 2010).

Production Testing

Test specimens

Each production isolator shall be tested.

Sequence and cycles

Project-specific acceptance criteria will generally be developed for the production testing of isolators. For each type and size of bearing, shearing force-lateral displacement relationships should range between limits specified by the engineer of record. A minimum vertical stiffness for each type and size of isolator should be specified. The reader is referred to ASCE 7 (ASCE 2010) and the AASHTO Guide Specification for Seismic Isolation Design (AASHTO 2010) for additional information.

Test specimen adequacy

The acceptance criteria used for production bearing tests should be consistent with the assumptions made for the design of the seismic isolators and seismic isolation system, and must therefore be developed on a project-by-project basis. An acceptance criterion for production testing is provided in this section for inclusion in the production-isolator acceptance criteria developed by the engineer of record.

ABSTRACT

The subject of development of site specific performance-based design motion and its application to soil-structure interaction (SSI) analyses has been discussed in a number of guidance documents developed for both the Nuclear Regulatory Commission (USNRC) and Department of Energy (USDOE). NRC's Regulatory Guide 1.208 and upgrade to Sections 2.5.2, 3.7.1, 3.7.2 and 3.7.3 of NRC's Standard Review Plan (NUREG-0800) and DOE Standards (DOE Std 1020-94) have emphasized probabilistic approaches to development of seismic hazard and site response. These procedures are now used to estimate seismic response of critical facilities for design and evaluation purposes.

Chapter 2 of the new revision of ASCE 4 attempts to captures all significant changes to the recommended site response analysis procedures with the goal of providing an industry consensus on this process. This paper summarizes the interpretation of the regulations and guides, and the industry agreement on the details of the development and application of the ground motion for SSI analysis. The objective of the recommended methodologies is to maintain consistency from development of the design motion from site response analysis to its application to SSI analysis and evaluation of results. Consistent use of soil property data and input motions developed based on the recommendations in Chapter 2 of ASCE4 for application to SSI analyses described in Chapter 5.

Issues currently being emphasized in probabilistic site response analyses include (a) development of Foundation Input Response Spectra (FIRS) to be used as input to deterministic SSI analyses, (b) development of appropriate description of nonlinear soil properties to accommodate the incorporation of nonlinear behavior in the site response evaluation, and (c) consideration of layer-to-layer velocity correlation models in the column realizations

INTRODUCTION

With the introduction and acceptance of the probabilistic procedures for seismic analyses of SSC's described in ASCE 43-05, a number of modifications have been introduced into the design and evaluation process for critical facilities. Using the procedures for site response evaluation that are described in NUREG/CR-6728 and 6769, the development of surface design ground motions to be used for facility design were modified to incorporate probabilistic concepts, including the potential strong

influences of site response on these estimates. The issues described in this summary are primarily concerned with issues of site response only and do not consider other aspects of seismic hazard development. The primary presumption made is that a Probabilistic Seismic Hazard Assessment (PSHA) is available at the top of hard rock (velocity of about 9200 fps) and the remaining issue is to estimate the potential impact of the site specific configuration on the corresponding PSHA at the ground surface.

Most critical facilities being constructed in the USA (particularly in the EUS) are sited on or in relatively soft soils or rocks. Local site-specific conditions must therefore be considered. It is presumed that a significant site investigation program is conducted so as to characterize geotechnical and geophysical properties for the entire site column from hard rock to the ground surface. Unfortunately, for deep soil sites, this is not always the case. Depths to which adequate geophysical data and (relatively) undisturbed samples can be obtained are usually severely limited. One purpose of the probabilistic study is to attempt to incorporate this uncertainty in site data into the evaluation as well as the impact of normal variability in geotechnical and geophysical properties that occurs at all sites.

In addition to these limitations on determining the data required to define the entire site column from hard rock to the ground surface, the results of the probabilistic site response analyses must be put into a form that is suitable for incorporation into the deterministic process that is used to assess soil-structure interaction (SSI) effects. This process is currently defined in relatively subjective terms and much more work needs to be conducted to ensure that the current recommendations for target performance goals are attained for systems of interest.

In the descriptions presented herein as well as in Chapter 2 of ASCE4, it is presumed that the seismic input motions at the rock outcrop are defined in terms of a given UHRS defined at the appropriate return period. The input rock UHRS is defined for a given characteristic event determined from deaggregation of the seismic hazard at the site. Spectral site amplification for this input is then used to define the corresponding surface motions. If the hazard indicates that two spectra have significant contributions at low and high spectral frequencies (to be discussed later), then two or more rock characteristic events can be used to determine site amplification factors. This process is referred to as Method 2 in NUREG/CR-6728. The most accurate method of determining surface motions is to perform the entire site response calculation for every source contribution to the hazard. This is referred to as Method 4 in the document but has the disadvantage of being computationally intensive. Approximations to reducing the extent of computations (Bazzuro & Cornell, 2004) can be used, leading to Method 3 of the site response assessment.

PROCEDURES FOR FIRS DEVELOPMENT

The process currently recommended for determining near-surface ground motions to be used for SSI analysis lead to the development of Foundation Input Response

Spectra (FIRS) in the free-field at the depth of the foundation. The process is aimed at determining the mean estimate of the spectra as noted in Figure 1. The use of the mean foundation spectra ensures that the reduction in motions at depth in any one realization of the site response does not overly dominate the calculated input motions to the building.

Unfortunately, two different methods are currently accepted in NRC's Interim Staff Guidance (ISG) document to develop FIRS as noted in Figure 2, One method (so-called BNL approach) uses the definition of the foundation outcrop motion as a geologic outcrop wherein the section of the soil column above the foundation depth is removed from the profile. Using the input outcrop rock motions at depth, two separate sets of column responses need to be performed, one for the full column to the ground surface, and one stopping at the foundation depth. This process correctly incorporates the fact that the mass of the layers above the foundation is properly captured.

In the second approach (the NEI approach), an approximate outcrop motion is calculated from the convolutions by using the incoming wave solutions. However, although simpler, the process does not correctly account for the mass effect and the results for each realization are different since the surface layers are different for each realization. It should be noted that in place of the FIRS, a mean in-column motion can be developed at depth and this is the same for each of the two FIRS definitions. This mean in-column motion also satisfies the requirement of smoothing the dip in the motions at depth so that no one large decrease can dominate the calculations.

The FIRS or in-column spectra are then determined at the mean (Best Estimate, BE), minus one-sigma (lower bound, LB) and plus one-sigma (upper bound, UB) levels. Corresponding BE, LB and UB soil columns are also determined from the realizations used in the site response. It is typical to use at least 60 soil columns to get reasonable estimates of the UB and LB responses. An example of amplification factors are shown in Figure 4 for two input characteristic rock spectra at a low frequency (1-2.5 hz) and high frequency (5-10 hz) motions from the PSHA. These spectral shapes are then scaled to the target rock UHRS and used as input to the soil columns. The envelope of each set of amplification factors is then used to determine the surface and FIRS spectra. The FIRS (or in-column motions) are then used deterministically to determine SSI motions for the BE, LB and UB profiles. The envelope of the corresponding surface motions must be shown to exceed the surface PSHA. Otherwise inputs must be suitably scaled to ensure that the SSI inputs are adequate. It should be noted that the same process (BNL or NEI) must be used for the site response and SSI calculations.

An example of FIRS calculations for a variable site profile of Figure 5 (incorporating velocity inversions in the profiles) is shown in Figure 6 in which FIRS motions were developed at a variety of depths in thee profile. As can be noted, the FIRS calculations are exceedingly sensitive to the profile.

NONLINEAR SOIL PROPERTY DESCRIPTIONS

The issue of selection of nonlinear properties for foundation materials is obviously a serious consideration in the determination of site response. These properties are typically defined in terms of strain dependent modulus reduction and hysteretic damping properties used in the equivalent linear analysis methodology used in the one-dimensional analysis process used in the various site response codes (SHAKE, RASCAL, CARES) often used in these calculations. Examples of these properties are shown in Figures 7 and 8 for different soils. The recommendations presented in thee EPRI93 guidelines are often referred to, although their applications to a particular soil material must be shown to be appropriate. Unfortunately, for many site profiles, these properties are often unavailable, particularly for depths below about 125' due to difficulties in obtaining even reasonably undisturbed samples to bring to the laboratory.

The approximations used to define these properties often lead to the use of large values of uncertainty than appears warranted. The larger the uncertainty, the broader the computed surface amplification tends to become. Unfortunately, the amplification functions also tend to decrease in magnitude, not the most conservative of result desired. It is probably more appropriate to use more base case profiles based on the few samples typically available with smaller uncertainty parameters.

LAYER-TO-LAYER CORRELATIONS

An issue that is becoming of more interest recently is the layer-to-layer correlation models used to develop individual velocity and damping properties for each soil layer of the computational site profile. There are several approaches that can be used to develop these multiple realizations. One method can use the assumption that the layers are fully correlated; that is, if one layer is randomly selected to be at a given fractile (either stiff or soft of the BE velocity profile), all layers can be chosen to be at the same fractile. The selected velocities of each realization have the same shape of the BE profile. The selection minimizes layer-to-layer variability but its appropriateness to arrive at a reasonable estimate of the mean site amplification may still be appropriate.

Another simple-minded approach is to assume that the selected velocity for each computational layer is fully uncorrelated. Thus, two adjacent computational layers, which may be part of the same material zone of the profile, could have widely different velocities, leading to what appears to be a more unreasonable assumption. The larger swings in velocities would also be expected to lower site response since the alternate velocities add computational damping to the system.

Recently, the Toro model has been used at a number of sites where in layer-to-layer variability is assumed to decrease with depth. This model is based on the extensive velocity data available at the Savannah River site. This site is a deep soil site of essentially silty sands and may be appropriate for application to similar sites.

However, most sites are not similar to SRS and its application needs to be shown to be appropriate.

Figure 9 presents a plot of velocity profiles for a given site based on the fully correlated model. Figure 10 presents plots of the velocity realizations for a Toro model assumption while Figure 11 presents a similar plot of a fully uncorrelated set of realizations. The amplification functions generated from these three different models are shown in Figure 12. As may be noted, above about 1 Hz, the fully correlated model yields the highest response, while the fully uncorrelated model, as expected, is significantly lower. The Toro model falls somewhere in between. The conclusion clearly indicates that more effort needs to be expended to define appropriateness of the selected correlation model used in the analyses.

CONCLUSIONS

This paper has intended to present some of the interesting issues that have developed in recent years with the advent of probabilistic site response approaches, particularly when coupled with deterministic SSI analyses. One of the most important developments that has been noted is the important coupling that needs to be maintained between geotechnical/geophysical and structural analysts and reviewers. It is essential that these different analyses be conducted in a consistent methodology.

[1] Structures Workshop, Inc. One Richmond Sq, Suite 147N, Providence, RI 02906; PH (401) 383-8988; FAX (401) 351-8788; email: ean@structuresworkshop.com

ABSTRACT

This article addresses engineering, detailing, and erection of shear connections which represent 95% of the connections on every steel project. While they are often unfairly regarded as simple, they are rarely simple. Shear connection are complex due to the many different types of connections, number of limit states to check, as well as geometry and erection complexity. This article will compare and rate the various methods the Engineer of Record (EOR) uses to provide shear demands. In addition, common types of shear connections will be presented and discussed. Shear connections are rarely controlled simply by the number and capacity of the bolts, and this paper will examine all limit states and discuss what to look out for during shop drawing review.

1.0 Introduction

There has been an ongoing debate as to the responsibility for the design of steel connections for building projects. As a result, different practices are used in design office varying across the country. For instance, on the west coast, the connections are often fully designed by be EOR as part of the construction documentations. Whereas, on the East coast, the connection design criteria and requirements are specified on the construction documents, but the final design is delegated to a licensed professional engineer (often hired by the fabricator) in the state of jurisdiction.

The author has the rather unique experience of seeing both sides of the issue of connections design, first as an EOR designing buildings, specifying connection criteria and checking the shop drawings for conformance. And now for the past three years the author has worked for fabricators to design connections based on the requirements specified by the EOR. It through seeing this issue from both sides, that the author has an appreciation for the importance of the proper attention to shear connection design.

The 2010 edition of the AISC Code of Standard Practice outlines three options for the responsibility of the connection design. It presents a new (albeit already established and widely used) third option where by the EOR delegates the connection design to a professional engineer hired by the fabricator. This article is not a review of these options, but rather a presentation of the various practices used by the EOR to specify the shear connection requirements as seen by the author in review of hundreds of Construction Documents. It is the hope that through the presentation of these practices, it becomes clear that this new third option should become the industry standard for all connections including simple shear connections.

2.0 Why Every Shear Connection Must be Checked

Most often, at least on the East Coast, the steel connection design is relegated to the fabricator and the EOR provides demand criteria and typical details for the design of the connections. The fabricator either has an in house engineer or hires a connection engineer to design the connections (typically the shear, moment and bracing connections). .

However, in some cases the EOR does not always require the shear connections to be designed by an engineer, only the moment and bracing connections. This is a mistake in the opinion of this author. While shear connections are perceived as simple, they often are not. Take for instance the most common type of shear connection - the beam-to-beam connection, which is actually pretty complicated. As is commonly known, all beam-to-beam shear connections have a top cope, which can make the design tricky. In addition, the cope varies based on the size of the

girder – so it is not uncommon for the same size beams with the same type of connection material (shear tabs, bolts, etc) will have very different capacities. For example, a W12x14 framing into a W16x31 has a very different capacity than a W12x14 framing into a W12x53 even if the shear connection is identical, see Figure 1.

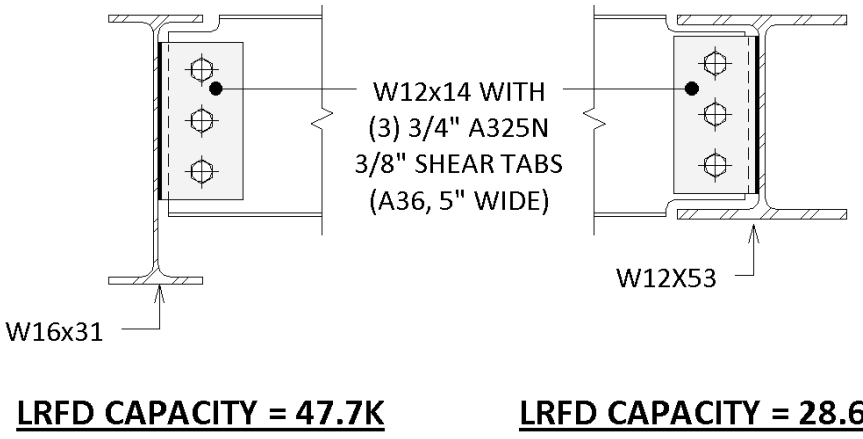

Figure 1. W12x14 beams with same Connection but different Shear Capacity

Not only is the W12x14 double coped when framed into the W12x53, but the copes are larger (both deeper and wider due to the thicker and wider girder flange) in comparison with the W12x14 framing into the W16x31. The reduced section due to the large copes significantly decreases the shear capacity of the connection by nearly half. Often times shear connections are not controlled by the bolt shear capacity (especially light beams with double angle shear connections). They may be controlled by bolt bearing, shear rupture of the web, block shear capacity of the web or coped section capacity. In the following sections we will explore the various ways the engineer of record specifies shear demands in addition to clarifying the different shear connection types.

3.0 EOR Methods of Supplying Shear Demand on Drawings

There are a variety of methods that are used by engineers to provide the fabricator the shear demands for the design of shear connections, and based the author's experience, some are good and some should be avoided.

3.1 **Method 1**: Provide Actual Shears on Each Beam on the Plans

This method is when the EOR provides the actual shear on the plans for every beam. This provides a uniform reliability in all of the members and the most accurate and efficient connections result.

Advantages	**Disadvantages**
Results in Least Expensive / Most Efficient Connections	Most work for EOR but can be automated. EOR does not and will not get paid for this work.
Most Reliable Shear Demands and Fewest RFIs from Fabricator	Can sometimes lead to very small connections that make the beam appear oversized (for example having only 2 bolts within a W30 looks strange even if it works)
Lower and More accurate bids from Fabricator	
OVERALL GRADE: A	

3.2 **Method 2**: Provide a Table of Shear Values

This is method can work but it may be overly conservative for some beams on the project if done improperly. The table on the left is too simplistic and greatly overestimates the shear demand on lighter sections. For example, a W18x35 will have the same demand as a W18x76. The author derived the right table based on the plastic modulus of the beam and studied each connection type and number of bolts required. The right table is a good one and feels free to use it on your project if appropriate. You can select the ASD or LRFD method, it really doesn't matter to a connection engineer and it doesn't affect the connection.

.

Beam Size	Required Shear Capacity, ASD / LRFD
W8	20 k / 30 k
W10	30 k / 45 k
W12	40 k / 60 k
W14	50 k / 75 k
W16	70 k / 105 k
W18	90 k / 135 k
W21	110 k / 165 k
W24	130 k / 195 k

Beam Sizes	Required Shear Capacity ASD / LRFD
W8x10-18 W10x12-15	10 k / 15 k
W8x21-28 W10x17-26 W12x14-19	20 k / 30 k
W8x31+ W10x30-45 W12x22-30 W14x22-30	30 k / 45 k
W10x49+ W12x35-58 W14x34-48 W16x26-40	40 k / 60 k
W12x65+ W14x53-61 W16x45-57 W18x35-55 W21x44-50	50 k / 75 k
W14x68+ W16x67+ W18x60-71 W21x55-62	70 k / 105 k
W18x76+ W21x68-73 W24x62-68	90 k / 135 k
W21x83+ W24x76-94 W27x84-94 W30x99	110 k / 165 k
W?? x100+	See Plans

Advantages	**Disadvantages**
Simple for EOR to add to General Notes	If table is not properly derived, it can lead to over (e.g. short infill beams) or under (e.g. transfer beams) designed connections depending on the framing condition.
More Reliable Shear Demands than providing demands based on AISC maximum uniform load tables (Method 3 in the next section)	EOR will need to verify chart on the very rare occasion the actual shear is higher.
Less RFIs from Fabricator	Connections are generally conservative and not cost effective
Less Cluttered Framing Plans compared to providing all the shears on the framing plans (Method 1 in the previous section)	
OVERALL GRADE: VARIES FROM 'F' (Left Chart) TO 'B' (Right Chart)	

3.3 **Method 3**: Shear demands based on Length of Beam

This is a very common method. It is provided in many different forms on the general notes but it is always based on the ***maximum total uniform load tables*** in the AISC manual. These tables are based on the moment capacity of the beam in which the max uniform load is "backed out" and the shear is determined. So these tables are based on the following: $M=wL^2/8$ and since $V=wL/2$, then $M=VL/4$ or $V=M/(L/4)$. Paradoxically, the longer the beam - the smaller the shear demands. Therefore, beams will have to be designed close to their flexural capacity for a connection to be reasonable. Figure 2 clearly describes the absurdity of this method. The shorter member requires much larger bolts and tabs, in addition to the welded doubler plate to meet the demand.

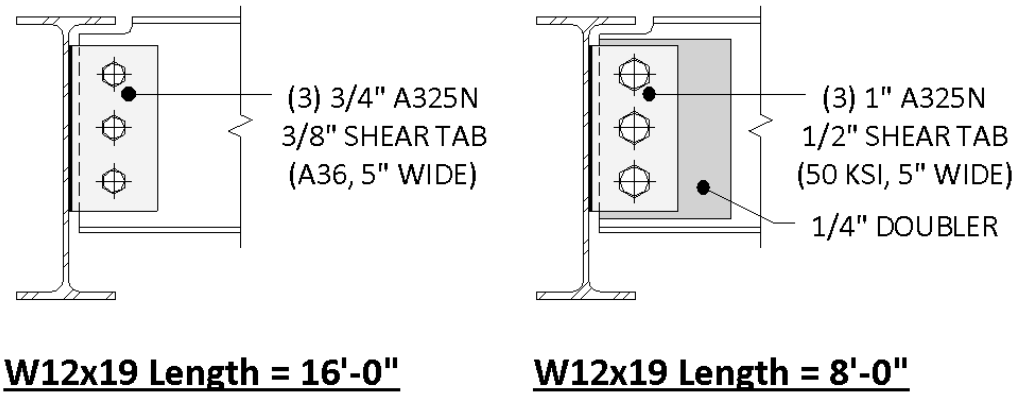

Figure 2. W12x19 (8ft Long) and W12x19 (16ft long)

For composite beams, the EOR will add a multiplier of anywhere between 1.5 and 2.3 on top of this shear to account for the increased moment capacity due to composite action with the concrete slab. For cantilevers, the EOR should be careful because this method is inappropriate, since the maximum total uniform load tables are based on simple span and cantilevers are usually not governed by strength.

For the EOR, this is the simplest method, just a quick note on the drawing. The EOR knows that as long as the beam works in bending (often from their analysis model), the shear connection will work. So the connection is designed for the maximum load it can support. This is often very conservative and inapproiate. It is a very costly method for the owner and fabricator and always leads to larger connections than necessary.

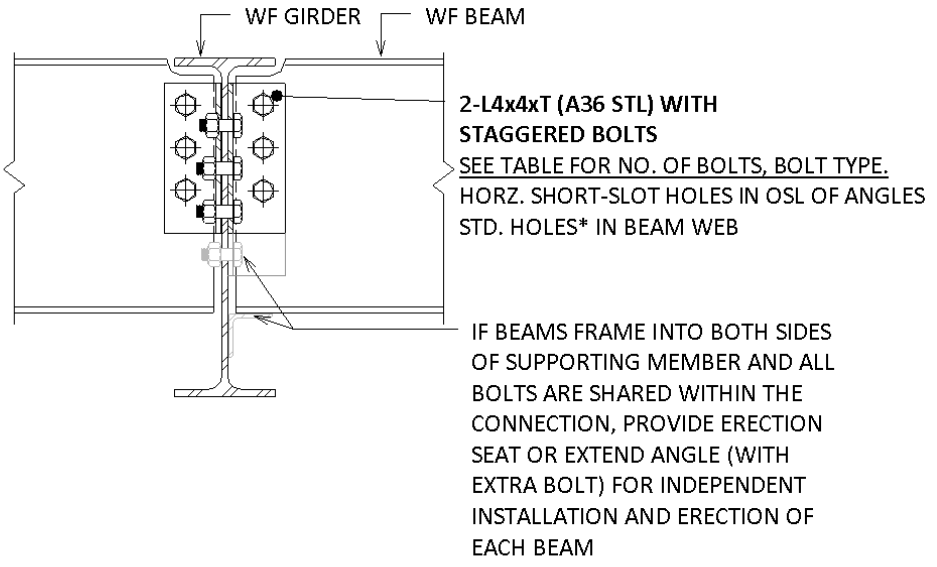
Advantages	Disadvantages
Simple for EOR to add to General Notes	Often leads to overly conservative and costly connections
	Least reliable since it is often a general criteria, broadly applied to most (if not all) conditions on the project.
	Short beams and composite beams often unnecessarily require doubler plates and/or web extension plates
	Many RFIs will result to verify shears
	Fabricator can lose money on a project because of unforeseen connection costs
	This method is derived for simple span members that are governed by flexure only. Beams that are governed by deflection, vibration, or overly designed are severely penalized.
OVERALL GRADE: F	

4.0 Types and Capacity of Shear Connections

4.1 Type 1: Beam to Beam Connections

Generally beam–to-beam connections have at least a top cope. Therefore, the capacities are difficult to calculate (cope section, block shear, etc). These are the most common connection on a project, yet they are often deemed as insignificant and "simple". This is not the case.

Another complexity is when double angles are required on a project. If all the bolts are shared on each side of the girder web, an erection bolt (or other aid) must be added to the connection to be able to build and meet OSHA requirements. This can lead to problems with fit up and erection sequencing.



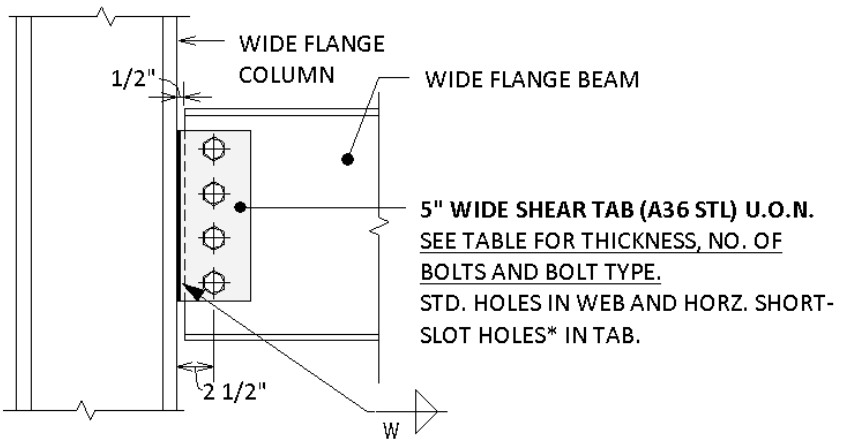


Figure 3. Double Angles can be a Problem

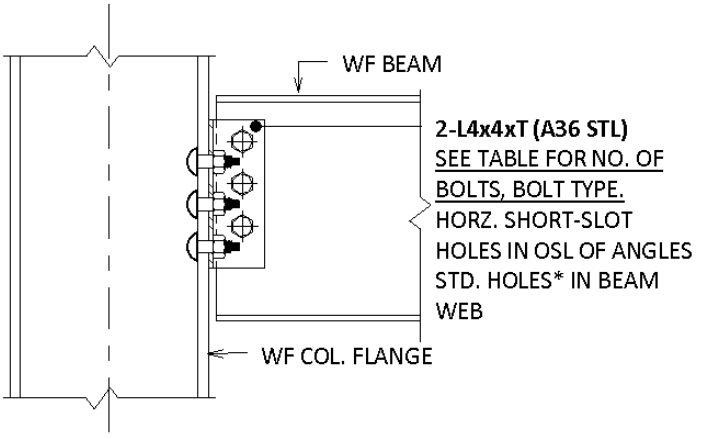
The EOR may not realize this, but when requiring the use of double angles for beam-girder connections, it is forcing the detailer to add erection bolts and often to extend the connection angles. In addition, it may affect the erection sequence and force the erector to place the floor beams in a specific sequence. For example, in the case where beams of different depths frame on either side of a girder and share bolts, the deeper beam may have to be erected before the shallower beam on the opposite side of the girder web (so the lower bolts can serve as the erection aid). This can cause delays. A clever detailer will stagger the angles on each side of the same beam web such that either beam can be erected first, but these angles may not fit due to the greater web clearance height required.



An example of inefficient use of connection material is the use of double angles to connect light beams with thin webs. Using 5/16" thick angle legs on each side of a beam web when the web is only a quarter inch is wasteful, yet very common. Furthermore, for beams with weights less than 30plf, it is not the connection angles that control the capacity; it is usually the web in block shear, coped section, or shear rupture (or bolt shear). Therefore, it is the author's opinion that the EOR should allow the fabricator the freedom to use shear tabs for these reasons. Please note, the bolts in Figure 3 do not need to be staggered for 4" angle legs. If not staggered, this connection will be easier to erect if the shop installs the bolts to the beam web such that the orientation of the tail end of the bolts never meet (spiral pattern in plan).

4.2 Type 2: Beam to Column Flange Connections

The simplest connection for an erector to a column flange is a shear tab as shown in Figure 4.

BEAM TO WF COL FLANGE SHEAR TAB

WF BEAM TO WF COL FLANGE USING DOUBLE ANGLES, BOLTED - BOLTED, STAGGERED

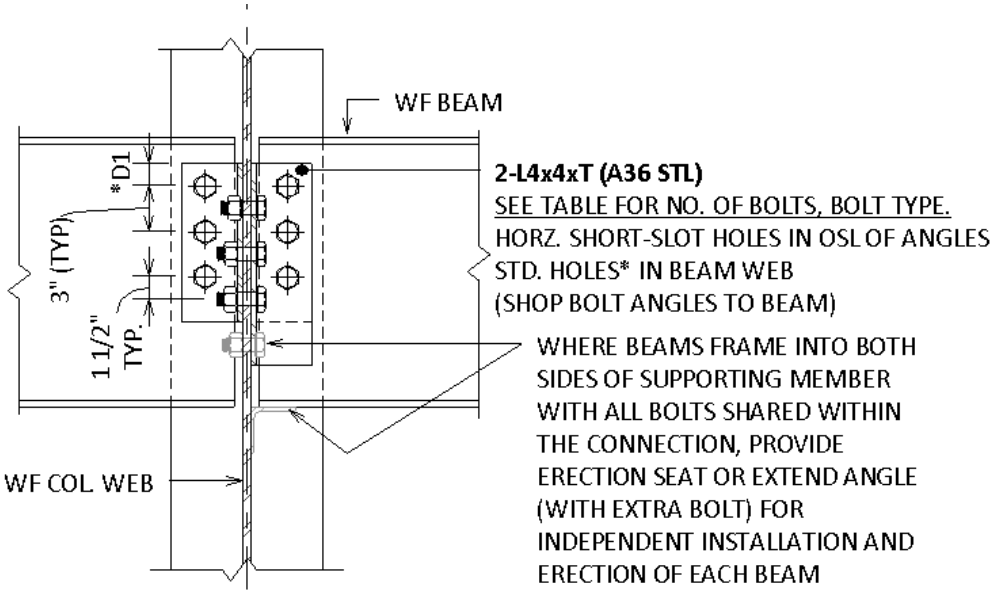


Figure 4. Connections to Column Flange I

If double angles are used, it may be important to stagger the bolts in this configuration. For the erector to have access to the tails of the column bolts using the TC bolt gun, the tails will always be facing out. This could cause interference with the shop installed bolts on the beam when two tails are on the same side of the beam web. Therefore, the author stronger recommends shear double angle shear connections to column flanges have staggered bolts.

4.3 Type 3: Beam to Column Web Connections

Double angles are best for beam-to-column web connections. Erectors that like the use of TC bolts in the field do not like shear tabs since the column flange interferes with the bolt gun.

Bla bla

WF BEAM TO WF COL WEB USING DOUBLE ANGLES, BOLTED - BOLTED, STAGGERED

5.0 Key Takeaways for EOR

- If the EOR is not designing all the shear connections, then require calculations by a PE registered in the state of the project for all connections, including shear connections, to be submitted for approval (similar to all connections). Do not put a table indicating the number of bolts only without checking every limit state of every connection.
- Try to add shears to the plans (method 1) or provide good table (method 2) – do not use note about the uniform load table method (method 3).
- Do not require double angles when shear tabs work
- Let the fabricator and/or fabricator's engineer select the type of shear connection. Shear tabs are generally preferred for beam-to-beam and beam-to-column flange connections.
- It is more efficient and cost effective for the fabricator to hire or staff an engineer to design connections specific to their shop and erection standards and practices (e.g. shop bolted, staggered bolts for double angle connections, shop standards for connection material...).

Designing and Detailing Welded Skewed T-Joints

T. Green[1] and T. Schlafly[2]

ABSTRACT

In the last 20 years, computer aided drafting and analysis software has allowed steel structure geometries to become more complicated. As the steel structure geometries become more complicated, the use of skewed t-joints for both tubular and nontubular connections has become more common. The American Welding Society Structural Welding Code - Steel (AWS D1.1) provides design and detailing requirements for skewed t-joints. Depending on the skewed t-joint geometry, designers are required to define the required weld leg or effective throat size. However, many designers are unaware of the AWS D1.1 skewed t-joint requirements and apply typical 90 degree fillet weld details to skewed connections. Contradiction between these 90 degree and skewed details in combination with the variety of AWS D1.1 prequalified joint configurations can lead to confusion and fabrication inefficiencies. AWS D1.1 design and detailing requirements for skewed t-joints are summarized and discussed.

INTRODUCTION

AWS D1.1 Annex K defines a t-joint as "a joint between two members located approximately at right angles to each other in the form of a T." A skewed t-joint, as the name suggests, is a joint where the two members may not form a right angle (see Figures 1 and 2). Skewed t-joints can be used to connect tubular as well as nontubular members. While some of the details discussed here may apply to the heel and toe of tubular skewed joints, tubular joints have many more topics to consider that are not discussed here. In the last 20 years, steel structure geometries have become more complicated, and therefore, the use of skewed t-joints has become more common.

Skewed t-joint welds typically consist of fillet welds or partial joint penetration (PJP) groove welds. Skewed t-joint geometric variables include dihedral angle, leg and throat dimensions, z-loss, groove angle and root opening. The dihedral angle (Ψ) is the angle at which the two surfaces meet - this angle will be acute or obtuse depending on the side of the connection being considered. Leg (b) and throat (t) dimensions define the weld geometry while z-loss accounts for potential lack of fusion and slag inclusions at the root of small included angle welds (i.e. welds on the acute side of a joint). The groove angle, which is used in PJP groove welds, is the angle between the two base metal faces at the weld. The root opening is the distance,

or gap, between the two surfaces at the weld root. The gap between the parts at the toe of the weld is not given a name in normal welding terminology but it is a critical variable used in selecting the appropriate weld joint detail in skewed t-joints. In Annex B, it is referred to as a root gap relative to the obtuse fillet type weld. Again, the purpose of this paper is to raise awareness and discuss AWS D1.1 skewed t-joint requirements.

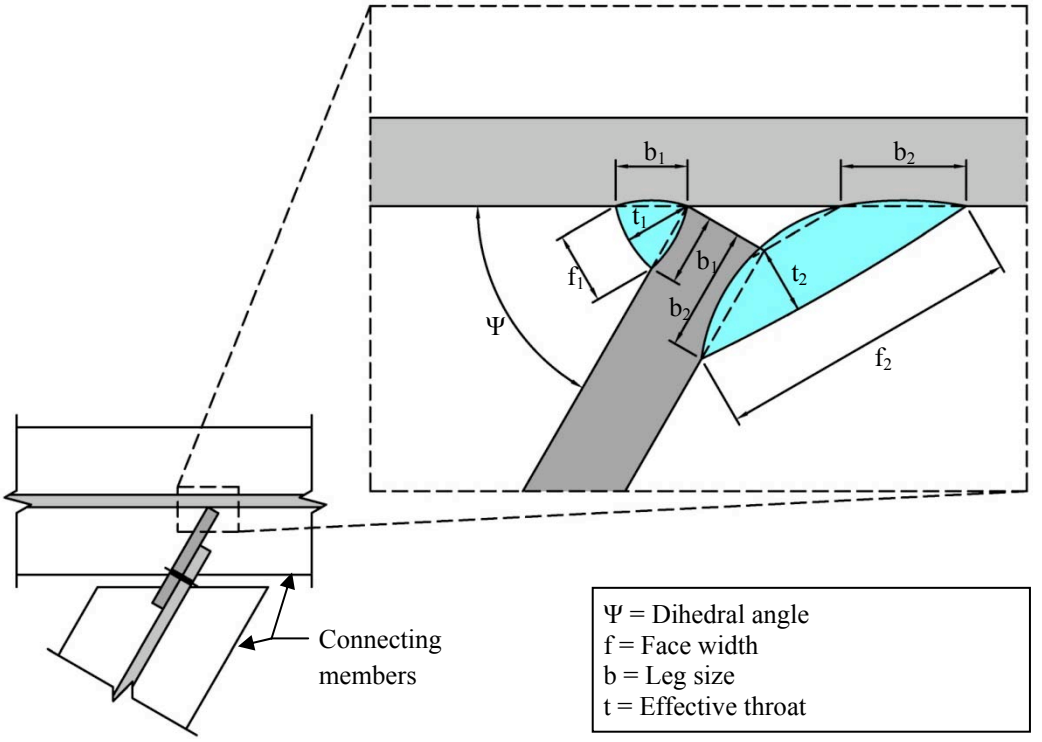

Figure 1. Skewed single plate connection with square edge.

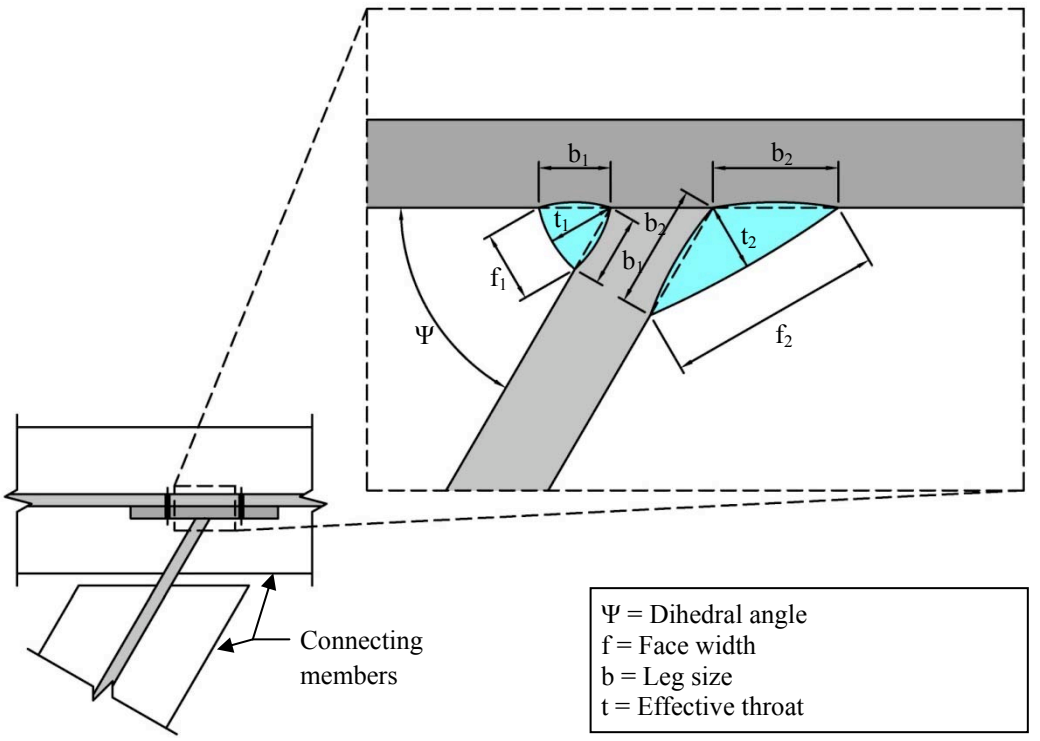

Figure 2. Skewed shear end-plate connection with beveled edge.

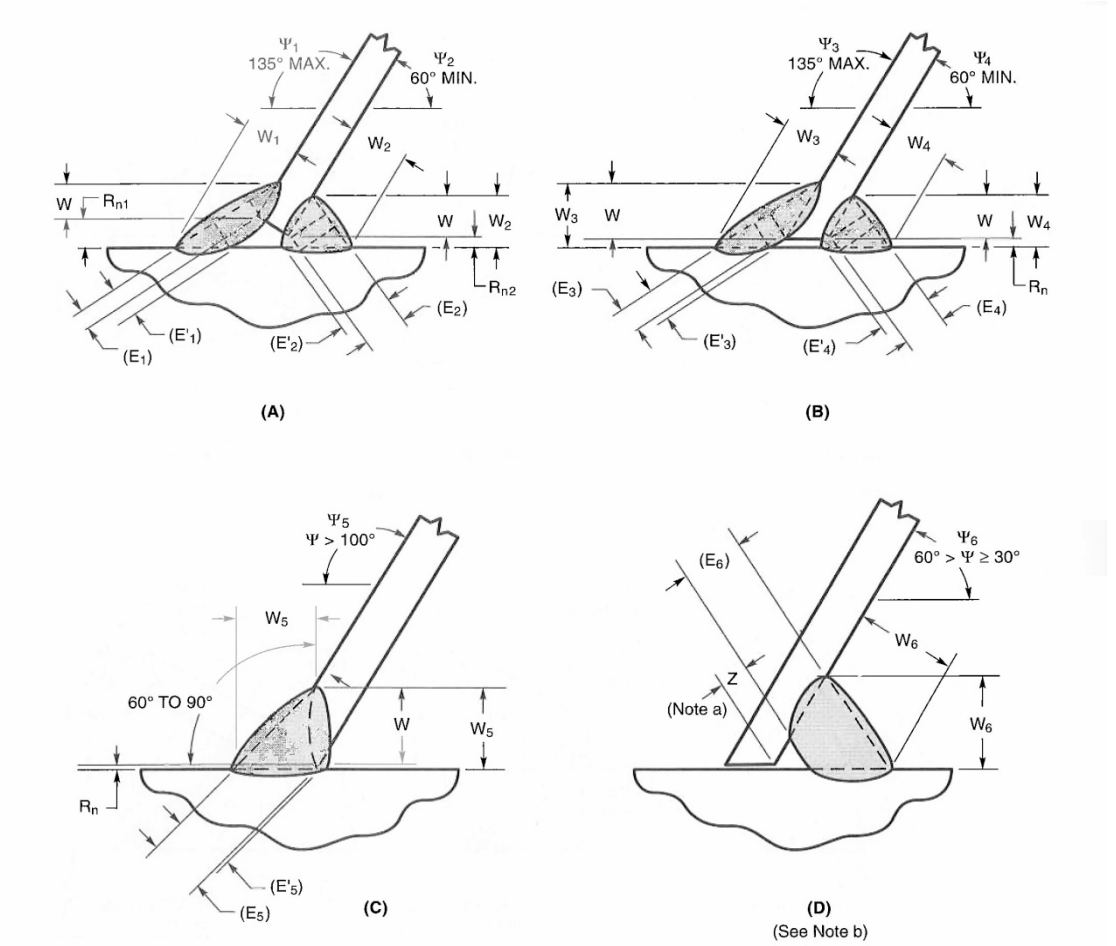
AWS REQUIREMENTS



Previous Codes. In 1980, fillet welds could be used in skewed t-joints having dihedral angles between 60 and 135 degrees. For dihedral angles smaller than 60 degrees, the joint was considered a PJP groove weld. In 1985, Note Q2 was added to the prequalified PJP groove weld figures indicating that "the member orientation may be changed provided that groove dimensions are maintained as specified." In the 1998 code, skewed t-joint design and prequalification requirements similar to the 2010 requirements were incorporated.

2010 Code. Skewed t-joint requirements are defined in Clause 2 - *Design of Welded Connections*, Clause 3 - *Prequalification of WPSs* and Annex B. For clarity, Clause 2 includes information related to applied stresses, allowable stresses and joint configurations for both tubular and nontubular members subject to static and cyclic loads. Clause 3 defines important variables that must be satisfied for a welded joint to be considered prequalified. Prequalified joints, in general, utilize materials and joint configurations that have a long history of good performance. Annex B Table B.1 helps geometrically convert 90 degree fillet weld leg size to skewed fillet weld leg size. Table 10-13 in the American Institute of Steel Construction (AISC) Manual of Steel Construction also provides design guidance for these welds.

The following provides a summary of several current skewed t-joint requirements:

1. Design Drawings
    a. Provide fillet weld leg size for surfaces meeting at 80 to 100 degrees.

   b. Provide weld effective throat size for surfaces meeting at less than 80 degrees and greater than 100 degrees.
2. Shop Drawings
   a. Provide fillet weld leg size for surfaces meeting at 80 to 100 degrees.
   b. Provide weld leg size, including z-loss and additional weld to account for the gap between the parts, for surfaces meeting at less than 80 degrees and greater than 100 degrees.
3. Calculation of Effective Throat and Leg Size
   a. Fillet welds at surfaces meeting at 80 to 100 degrees - effective throat is the shortest distance between the root and weld face of a 90 degree diagrammatic weld (Annex A). The effects of the 10 degree skew are neglected in accordance with AWS Clause 2.
   b. Fillet welds at surfaces meeting at 60 to 80 or greater than 100 degrees - effective throat is calculated based on leg size and dihedral angle. Leg size is calculated based on the root or face opening and effective throat (Annex B).
   c. Fillet welds at surfaces meeting at 30 to 60 degrees - effective throat is calculated based on leg size and dihedral angle. Leg size is calculated based on root opening, effective throat and z-loss (Annex B and Table 2.2)
   d. Fillet welds at surfaces meeting at less than 30 degrees - these welds are typically not considered to be effective in transmitting applied forces (some tubular joints are an exception). This can present problems in some geometries that are driven by architectural demands.
4. Prequalified Joint Details
   a. AWS Figure 3.11 (Figure 3) provides four different prequalified joint details. Details A, B and D depict fillet weld details fused to the side of the skewed part while Detail C depicts a weld fused to the edge of the skewed part. Note that the plate in Detail A is not beveled while the plate in Detail B is beveled parallel to the main member. In Detail C, the plate is beveled 60 to 90 degrees to the main member. Detail D is shown beveled parallel to the main member but this is irrelevant to the weld and unnecessary. Also note that Detail D represents a one-sided fillet weld for dihedral angles between 30 and 60 degrees.

[a] Detail (D). Apply Z loss dimension of Table 2.2 to determine effective throat.
[b] Detail (D) shall not be prequalified for under 30°. For welder qualifications, see Table 4.10.

Notes:
1. (E_n), (E'_n) = Effective throats dependent on magnitude of root opening (R_n) (see 5.22.1). (n) represents 1 through 5.
2. t = thickness of thinner part
3. Not prequalified for GMAW-S or GTAW.

Figure 3. AWS D1.1 2010 Figure 3.11 illustrating prequalified skewed t-joint details for nontubular applications.

EXAMPLES

Example 1. An engineer has a skewed t-joint with an acute dihedral angle (Ψ) equal to 60 degrees. The equivalent 90 degree fillet weld size (b) is 0.25 inches on both sides of the part. Note that the designer would show the effective throat on the contract drawings (0.707*0.25 inches=0.177 inches or, when rounded up, 3/16 inch).

The fabricator can utilize Figure 3.11 Details A, B or C. Since no end preparation is typically more cost effective than installing a bevel at the end of the plate, the fabricator selects Detail A with no root opening. Note that for most applications, the weld toe gap on the obtuse side needs to be equal to or less than 5/16 inch to comply with AWS D1.1 fit-up requirements. Using Annex B, the equivalent acute side skewed leg dimension (b) is equal to 0.71*0.25 inches=0.178 inches. Rounding up to a practical dimension, the acute side skewed leg dimension is equal to

3/16 inch. For the obtuse side, the equivalent skewed leg dimension is equal to 1.23*0.25 inches=0.308 inches. Again, rounding up to a practical dimension, the obtuse side skewed leg dimension is equal to 5/16 inch. Note that the opening or gap at the weld toe must be added to the 5/16 inch leg dimension. On the shop drawings, the fabricator would provide a 3/16 inch dimension on the acute side fillet weld and 5/16 inch plus the weld toe gap dimension on the obtuse side fillet weld.

For this example, both the designer and fabricator illustrate fillet welds but the dimensions shown on the contract and shop drawings are different. While the joints are equivalent from a structural performance perspective, modifications between contract and shop drawings should be clear to the designer and fabricator.

Example 2. An engineer has a skewed t-joint with an acute dihedral angle (Ψ) equal to 45 degrees. The equivalent 90 degree fillet weld size (b) is 0.25 inches. Again, note that the designer would show the effective throat on the contract drawings (0.707*0.25 inches=0.177 inches, or when rounded up, 3/16 inch).

The fabricator can utilize Figure 3.11 Details C or D but given the desire to avoid one sided fillets where possible, elects to use Detail C with no root opening. Due to groove angle limitations, the end of the plate must be beveled an additional 15 degrees to provide a 60 degree groove angle. Since there is only one PJP groove weld instead of two fillet welds, the total effective throat must be equal to 3/8 inch. On the shop drawings, the fabricator would provide a 3/8 inch PJP groove weld with a 60 degree root opening.

For this example, the designer specified fillet welds and the fabricator produced a PJP groove weld. Again, while the joints are equivalent from a structural performance perspective, modifications between contract and shop drawings should be clear to the designer and fabricator.

In addition, note that many of the existing prequalified, single bevel, PJP groove welds require groove angles equal to 45 degrees with minimum root face dimensions equal to or greater than 1/8 inch (see joint designation BTC-P4 in AWS D1.1 Figure 3.3 for reference). Comparing the example skewed joint with joint BTC-P4, the 45 degree groove angle (prior to beveling) for the skewed joint is not acceptable based on Detail C in Figure 3.11 even though a 45 degree bevel is acceptable for BTC-P4. In addition, no minimum root face dimension is required on Detail C in Figure 3.11 which contradicts the 1/8 inch minimum root face allowed for joint BTC-P4.

POTENTIAL AREAS FOR CONFUSION AND INEFFICIENCY

Weld symbol. In most structural drawings, designers provide a design load at each connection and reference typical connection details. Assuming that the typical details illustrate 90 degree, welded, single plate or end-plate connections, the fillet weld leg size would be provided for a range of plate lengths - typically 1/4 to 3/8 inch. For skewed t-joints between 80 and 100 degrees, these typical details are clear and work well.

However, when the two surfaces meet at less than 80 or greater than 100 degrees, a fillet weld symbol (with the required leg size) does not always adequately portray the required weld. For these welds, the detailer will typically select one of the AWS prequalified welds in Figure 3.11, design the connection, and produce shop drawings to be approved by the designer. Note that as part of this process, the fabricator may have to modify the fillet welds to PJP groove welds. In order to make sure that designers and engineers both understand that skewed t-joints are slightly different than typical fillet weld joints, a unique weld symbol clearly indicating whether the leg or throat dimension is given may be useful.

Drawing requirements. For skewed t-joints, fillet weld effective throat information is provided on the contract drawings and leg size is provided on shop drawings. For designers, lack of knowledge related to this requirement can lead to confusion. For example, if the contract drawings indicate that the size of a particular fillet weld is 1/4 inch for a 60 degree skewed t-joint, the fabricator assumes that the 1/4 inch dimension is the effective throat, not the fillet weld leg size. The fabricator converts the 1/4 inch effective throat value back into a 90 degree leg size and uses Annex B to determine the required skewed fillet weld leg dimension. The skewed fillet weld leg dimension is then provided on the shop drawing.

If the fabricator incorrectly assumed that the contract drawings specified a 90 degree fillet weld with 1/4 inch leg size, they could use Annex B to convert directly to the required skewed fillet weld leg size. However, this would result in the installed weld being smaller than the required weld which might reduce the overall strength of the connection. Knowledge of the information required on contract and shop drawings is critical to producing a safe, cost-effective structure.

Joint details. The prequalified skewed t-joint details include numerous variables which provide designers and fabricators with the flexibility to use geometries that produce the most reliable, cost-effective joint. However, there are several variables in the prequalified details that can cause confusion.

First, Details A and B define maximum and minimum dihedral angles (135 and 60 degrees, respectively). It is not clear why the dihedral angle does not range from 60 to 120 degrees or 45 to 135 degrees. Second, Detail C allows a PJP groove

weld to be installed at dihedral angles greater than 100 degrees. However, it also requires that the groove angle be greater than 60 degrees which would require beveling of the plate for all dihedral angles less than 60 degrees. Since previous codes allowed PJP groove weld configurations to be modified provided the groove dimensions were maintained and current prequalified, single bevel PJP groove welds allow for groove angles equal to 45 degrees, the 60 degree groove angle limitation may lead to additional joint preparation resulting increased overall cost.

Finally, Annex B is intended to facilitate designer and fabricator conversion from 90 degree fillet weld leg size to skewed fillet weld leg size. Annex B Table B.1 includes conversion information for dihedral angles from 60 to 135 degrees. Since Detail D in Figure 3.11 allows acute side fillet welds with dihedral angles as small as 30 degrees, is unclear why the conversion values in Annex B are limited to 60 to 135 degrees. In addition, a new table in Annex B that converts the required effective throat value directly to the skewed leg dimension may also be useful to the fabricator.

POTENTIAL CLARIFICATIONS

The following provides a brief summary of potential clarifications that may result in more efficient, safe, and cost-effective skewed t-joints.

1. Weld Symbol - Clarify fillet or PJP groove weld symbols so that weld type is clear to the designer and fabricator.
2. Design Requirements - Clarify fillet and PJP groove weld size designations so that effective throat or skewed leg dimensions are clear to designers and fabricators. Part of this effort may be to publicize the information required on the contract drawing to designers.
3. Joint Details - For Details A and B, clarify the two dihedral angles shown on each drawing. For Detail C, allow groove angles less than 60 degrees to be used particularly when being used in combination with a root opening. In all details, clarify joint angle requirements and permit less restriction on dihedral angle. In Annex B, include dihedral angles from 30 to 150 degrees. In addition, consider adding a new table to Annex B that will convert the designer's effective throat information to the fabricator's skewed leg size information.

PERMISSIONS

AWS D1.1 2010 Figure 3.11 and the definition of a t-joint were reproduced with the written authorization of AWS.

SUMMARY

Skewed t-joints have a long history of good performance and their use is increasing as the geometry of our steel buildings becomes more complex. The information presented in this paper is intended to clarify skewed t-joint design and

fabrication requirements while highlighting several topics that may have proven slightly confusing to designers and fabricators. The potential clarifications suggested above are for general consideration in order to produce more efficient, safe, and cost-effective skewed t-joints.

ABSTRACT

This paper presents the design, and the examination of ductile structural behavior through finite element analyses, of super composite columns and their connections to the outriggers, double belt trusses, and mega bracing members of the Ping An International Financial Center Tower in Shenzhen, China. When completed, this 660m-tall structure will be the tallest building in China and the second tallest building in the world.

Many complicated steel connections were analyzed and designed. Finite element analyses were performed on the super column, outriggers, double belt trusses, and mega bracing connections to evaluate the performance of the as-designed connections under 100 year wind forces and three levels of seismic action: frequent earthquake, moderate earthquake and severe earthquake.

This paper also briefly presents the design of the steel connections; describes the ABAQUS finite element analyses model; presents the major results of the finite element analyses; and evaluates the performance of the connections based on the analysis results.

PROJECT DESCRIPTION

The 660-meter tall Ping An Tower is sited on lot B116-0040 in the central business district of the Futian district of Shenzhen, China. Within its 115 stories, Ping An Tower contains mainly Class A office space, with some retail stores, entertainment venues, conference centers and trading areas (See Figure 1). The complex also includes an 11-story podium housing deluxe retail stores, offices, dining and lobby space. Beneath the tower and podium a five story deep basement mainly contains retail stores and parking. Occupying a total site area of about 12,000 m^2, the Ping An Tower has a total gross floor area (GFA) of approximately 462,000 m^2.

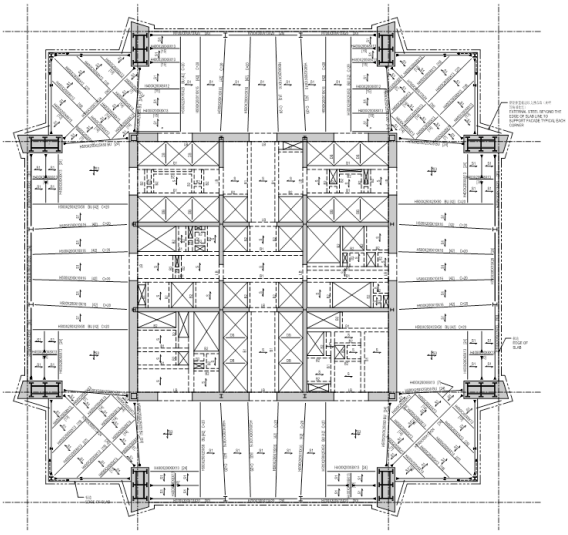

Figure 1 – Ping An Tower Site Plan, Typical Floor Plan and 3D Rendering (courtesy of KPF)

STRUCTURAL SYSTEM

The tower floor plate is typically square in plan with recessed corners. Floors reduce in size at upper levels. The tower primary lateral force resisting system

consists of a hybrid concrete core linked by steel outrigger trusses at four levels to eight super composite perimeter columns. The tower secondary lateral system consists of a mega frame with super columns, belt trusses and diagonal braces on each face, working together through chevron braces wrapping around the corners. While the hybrid concrete core, super columns, and outrigger trusses can be designed to resist the lateral forces by themselves, the perimeter mega frame and chevron braces improve lateral system redundancy and help decrease deflections.

The hybrid concrete core starts as a 32m by 32m square with 1.5m thick flange walls and 0.8m thick web walls. At upper floors, wall thicknesses decrease. At the top, flange walls are 0.5m thick and web walls are 0.4m thick. Steel shape columns embedded at wall corners and intersections increase core stiffness and ductility.

The super columns are approximately rectangular in plan, with corners shaped to suit the architecture. The super columns start as 6.0m by 3.2m and reduce in size with height to a minimum of 2.9m by 1.4m at the top. Steel built-up columns are also embedded in the super columns to reduce column sizes and increase column ductility. The steel ratio of the columns is 6% at the bottom and 4% at the top.

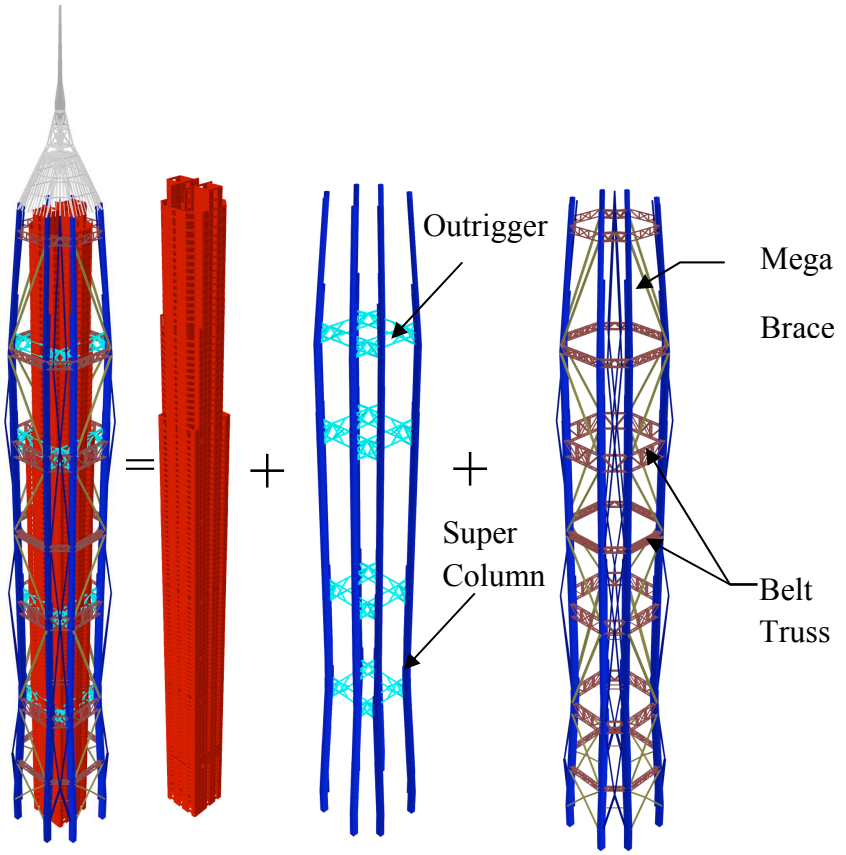
The tower is divided into nine stacked zones separated by MEP/refuge floors. Two-story tall steel outrigger trusses at the MEP/refuge floors above zones 1, 3, 5, and 6 connect the core and the super columns. The outriggers also help to increase system ductility and decrease story drift. A steel belt truss is located at every MEP/refuge zone. The belt truss, together with diagonal braces and super columns, forms the secondary lateral force resisting system. Mega bracing around each corner of the building increases mega frame integrity and stiffness. Complicated connections occur at refuge floors where outrigger trusses, belt trusses, and mega braces are connected to the super columns. Figure 2 shows the tower lateral force resisting system.

Tower gravity load on every floor is shared by the core, super columns and much smaller gravity columns. The gravity forces in the gravity columns are collected by belt trusses at the MEP/refuge floors and transferred to the super columns. This load path not only reduces the accumulated gravity forces taken by the gravity columns, but also helps to reduce tensile forces in the super columns due to lateral loads. At the top of each zone, gravity columns are connected to the bottom of belt trusses with vertically slotted connections to release potential stresses due to creep, shrinkage and differential movements.

SUPER COMPOSITE COLUMN MODEL

Due to the very large scale of the Ping An Tower super columns and their critical role in both the tower lateral force resisting system and gravity system, their behavior is very important to overall tower performance. The super columns must have adequate strength to sustain the applied loads, adequate stiffness to control

tower drift and adequate ductility to prevent tower brittle failure under extreme conditions. This paper will concentrate on super composite column ductility analysis.



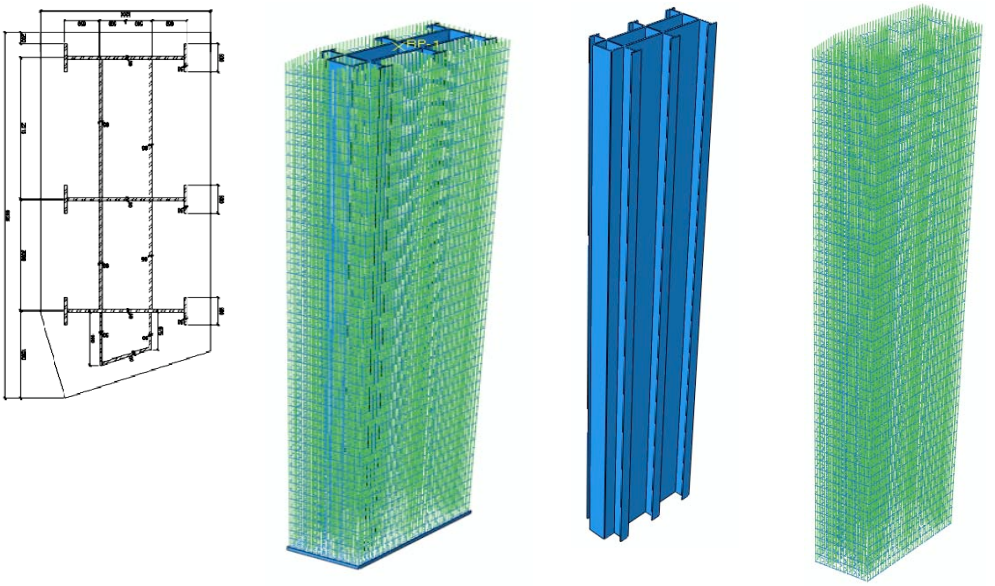


Figure 2. Lateral Force Resisting System = Core + Outriggers + Perimeter Braced Mega Frame

Super composite column ductility analysis was performed using the commercial finite analysis software ABAQUS Version 6.9 (Dassault Systemes, 2009). The load was applied using the displacement-control method. The super column of the podium zone at the bottom of the tower was modeled. From a buckling analysis, equivalent length of the modeled column is about 25m. Overall column plan dimensions were about 6.5m by 3.2m. The model included column concrete, embedded steel shapes and plates, and typical longitudinal reinforcing steel and stirrups (Figure 3). The model considered material nonlinear behavior to follow the specifications of the China Building Codes (GB50010-2002, 2002).

Concrete in the super composite column was modeled with solid elements. The concrete is China grade C70 with design compressive strength of 31.8 MPa (GB50010-2002, 2002). Concrete stress-strain curves were derived from the China concrete code as shown in Figure 4. Nonlinear concrete behavior was modeled using the versatile “Damaged Plastic Model” module of ABAQUS.

Embedded steel was also modeled with solid elements, while both longitudinal and stirrup reinforcement was modeled as truss elements. Both the steel shape and the regular steel reinforcement bars were "embedded" in the concrete by forcing the two parts to have the same displacements at common nodes. Steel materials were modeled as ideally elastic-plastic with no material strengthening beyond yielding.

Figure 3. Perspective View of the Super Column Model

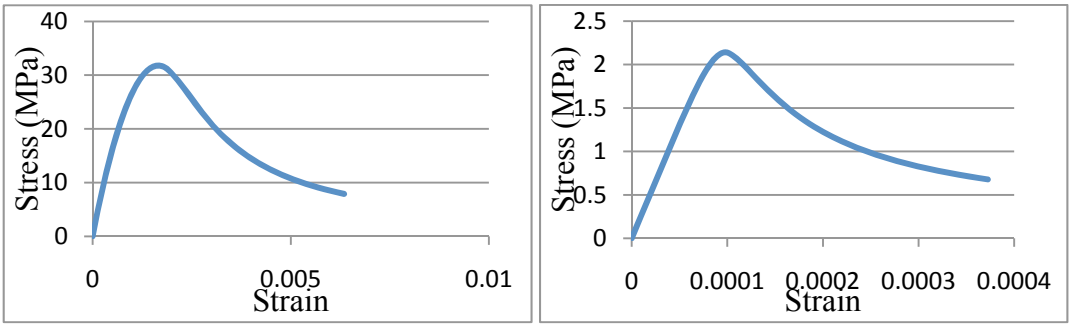

Figure 4.a Concrete Compressive σ-ε Curve Figure4.b Concrete Tensile σ-ε Curve

SUPER COMPOSITE COLUMN ANALYSES RESULTS

The super composite column analyses demonstrated that the column has satisfactory ductile performance. As an example, Figure 5 shows the moment – rotation of the super composite column with respect to the weak axis. The curve shows that the super composite column is able to develop significant displacement

after the capacity of the column is reached. When rotation of the column reaches 0.03 radian, the member still has about 85% of the maximum capacity. And the capacity of the member decreases gradually with no abrupt drop. Therefore, no brittle failure is expected.

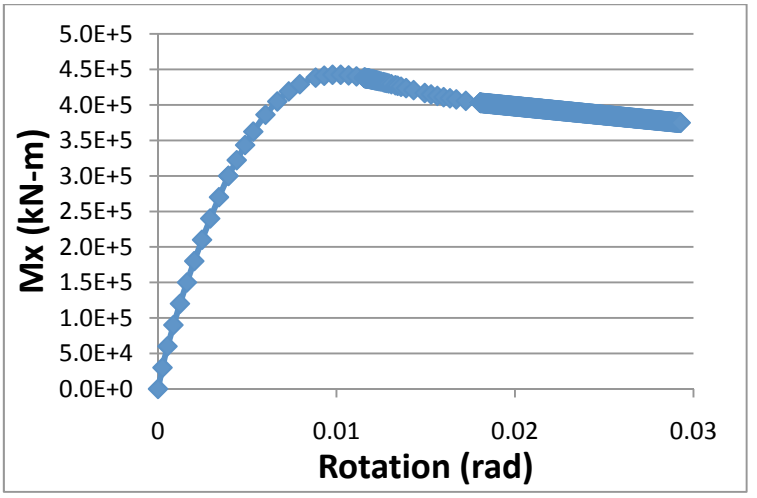

Figure 5. M-Φ Curve of the Super Composite Column with Respect to the Weak Axis

Figure 6 shows the stress contours of the steel shape and the longitudinal reinforcement at the ultimate stage. At the ultimate stage, both the embedded steel shape and the longitudinal reinforcement start to yield. The yielding of the steel helps to dissipate energy and therefore helps provide a ductile design of the super composite column.

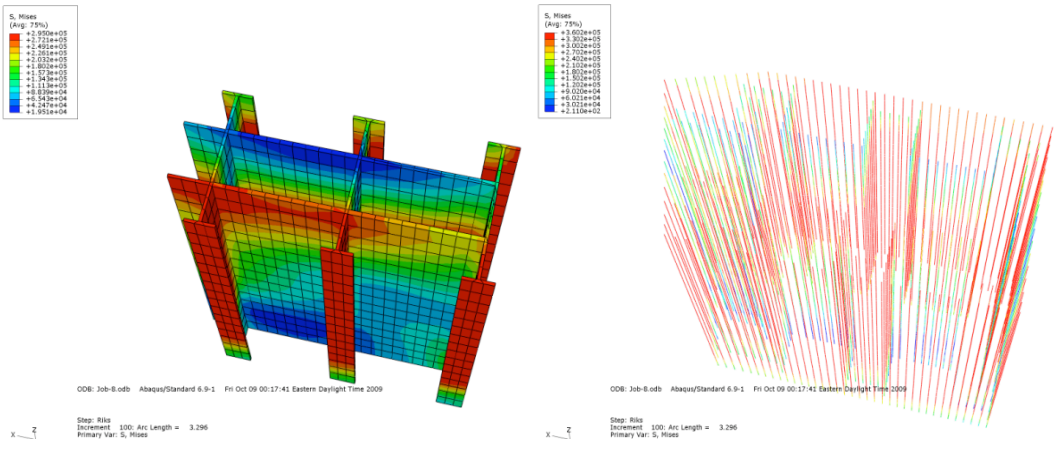

Figure 6 Stress Contour of the Steel Shape and the Longitudinal Reinforcement (The stress is in MPa. The red color steel shape stress contour indicates 295MPa, while for longitudinal reinforcement the red stress contour indicates 360MPa.)

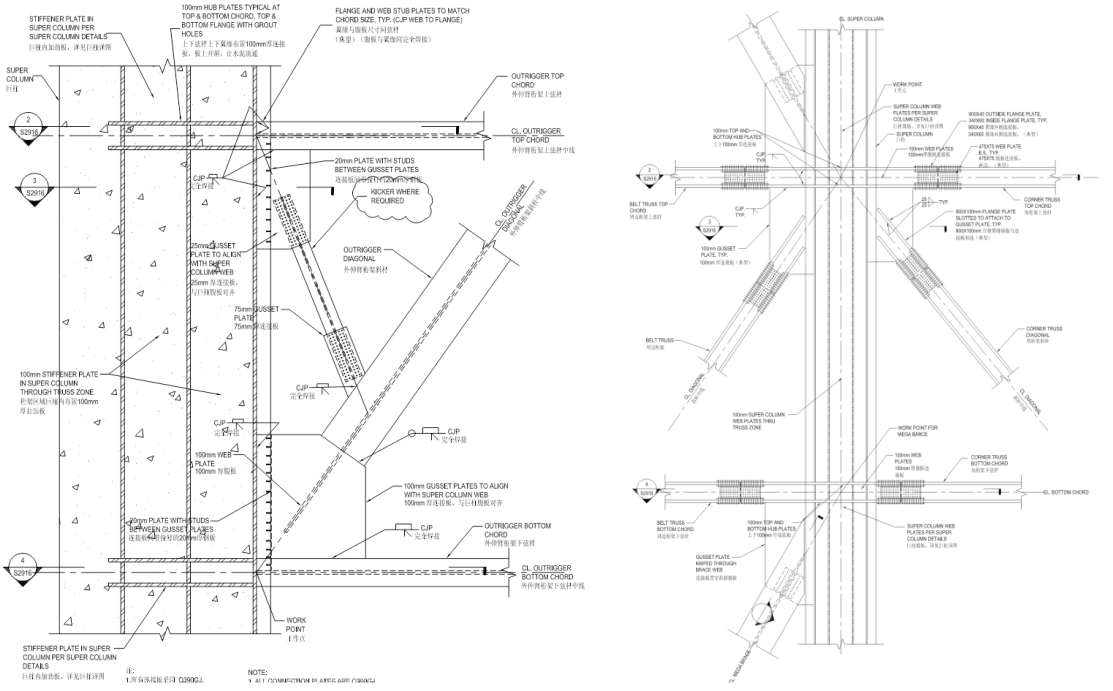
CONNECTION DESIGN AND FINITE ELEMENT MODEL

Tower structural performance depends on good connection performance. The complex building structure results in complex loading conditions at connections, especially those super column connections where outrigger trusses, belt trusses, and mega diagonal braces all frame in.

The building is not located in a severe seismic area. The peak ground seismic acceleration of the area with a return period of 50 years and 10% probability of being exceeded is 0.10g (the Response Modification Coefficient as used in the International Building Code does not apply in the China building code) (GB50011-2001, 2008). However, tower seismic design was considered critical due to the significance of this landmark building and the huge potential impact of any failure on the surrounding community. A mandatory expert panel formed by the Chinese Bureau of Construction consulted with the designers and approved project-specific seismic design criteria.



Seismic design criteria of the connections between the super composite columns and the trusses aimed at connection performance at three seismic levels:

a) Connections should remain elastic under gravity and wind load combinations.
b) Connections should remain elastic under Frequent Earthquake load (63% probability of being exceeded in 50 years) combinations.
c) Connections should remain elastic under combinations with gravity and Medium/Moderate Earthquake loads (10% probability of being exceeded in 50 years). Considering the way members are designed, this means connection capacities should be higher than those of the members.
d) Connections can yield, but should not fail under combinations with gravity and Severe Earthquake loads (2~3% probability of being exceeded in 50 years).
e) Conservatively assume that the embedded steel must take all connection loads because local congestion from reinforcing bars, steel shapes and plates, gusset plates and stiffeners means concrete quality at the column joint zone cannot be satisfactorily controlled.

Since China building codes have prescriptive requirements related to strength design only under the Frequent Earthquake level, finite element analyses (FEA) were used to evaluate performance of the connections under Medium and Severe Earthquake loads. As an example, this paper presents the modeling process and analytical results of a connection including a super composite column (SC), an outrigger truss (RT), a double belt trusses (DBT) including one interior truss and one exterior truss, and two diagonal mega braces (MB). Design details of the connection are shown in Figure 7.

The finite element analyses were performed with ABAQUS. In addition to the above-mentioned assumptions, it was assumed that welds and bolts will not fail before connection elements, so they were not specifically modeled. This assumption is consistent with the usual design strategy that welds and bolts have capacities at least equal to the capacities of the members connected. The finite element models

also conservatively ignore any contribution by typical reinforcing bars since many of them are potentially subject to being interrupted at the joint by steel connection plates.

Connection between SC and RT Connection between SC, DBT, and MB

Figure 7. Design Detail of the Connection between SC, RT, DBT, and MB

Figure 8 shows the finite element model of the connection. All steel members are modeled with solid elements. The outrigger trusses are made of China Q460GJ steel with yield strength of 395 MPa. The embedded steel shape in the super composite column, the belt trusses, and the diagonal mega braces are made of China Q345GJ steel with yield strength of 295 MPa. And the gusset plates are made of China Q390GJ steel with yield strength of 330 MPa. Young's Modulus of all steel is 2.06 X10^5MPa. The steel material is modeled as ideally elastic-plastic with no strengthening beyond yielding.

All gravity loads, wind loads and seismic loads are considered in combinations in the analyses. Member forces applied to the connection model were extracted from the tower ETABS model based on both time-history analyses and China code spectrum analyses.

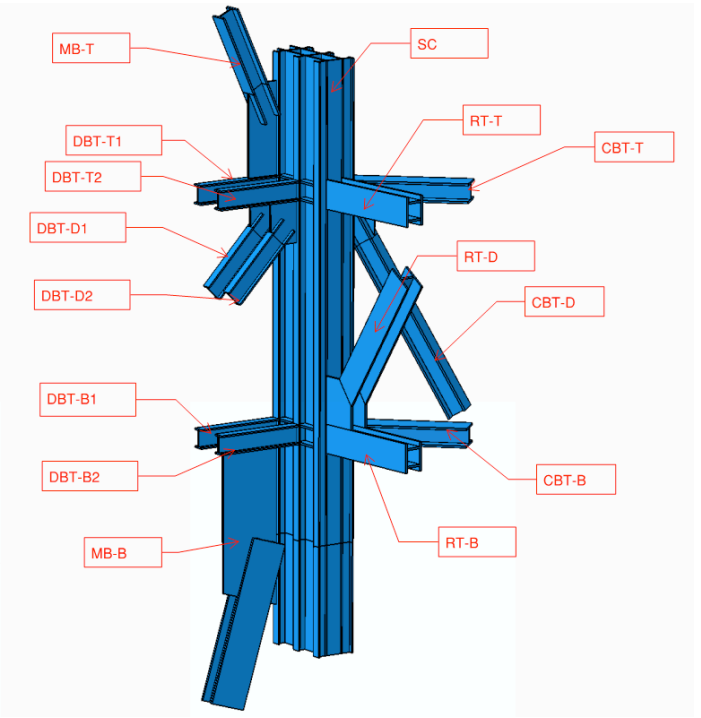


Figure 8. Finite Element Model of the Connection

CONNECTION ANALYSES RESULTS

Connection analyses were performed using member forces under load combinations with Frequent Earthquake, Medium/Moderate Earthquake, and Severe Earthquake forces. Since stress in the connection was expected to be lower than material yield stress under the Frequent Earthquake load combination, linear analyses were performed for this seismic level. Connections were designed to remain elastic under Medium Earthquake load combinations, but nonlinear analyses were performed for both Medium Earthquake and Severe Earthquake load combinations. Maximum stresses in components were evaluated using their respective material strengths and the Von Mises yield criterion.

Maximum stress under the Frequent Earthquake load combination is located at the local point where the bottom chord of the outrigger truss frames into the super column. While the maximum stress is around 340 MPa, this localized high stress spot can be eliminated by rounding of sharp corners. Other than at localized stress concentrations, maximum stress in most members is lower than 250 MPa. Therefore, the connection is elastic under the Frequent Earthquake load combination.

The Medium Earthquake ground acceleration used is about three times that of the Frequent Earthquake. However, gravity and wind loadings do not change. Other than localized stress concentration, maximum stresses in all components are lower than yield so the connection is still elastic under Medium Earthquake load combinations.

The Severe Earthquake ground acceleration used is about twice that of the Medium Earthquake or six times that of the Frequent Earthquake. However, the Severe Earthquake is an extreme load case so load factors in load combinations including it can be taken as 1.0. As a result, the overall design forces of members under Severe Earthquake load combinations are not necessary much higher than those of Medium Earthquake load combinations, especially where member design is mainly controlled by gravity loads and wind loads.

Under Severe Earthquake load combinations most member maximum stresses do not exceed 260 MPa. However, the connection components start to yield at the outrigger diagonal member, at top and bottom outrigger chords framing into the super column, and at the flange of the super column. Since the steel material was defined as ideally elastic-plastic, maximum stress tops at 395 MPa and yielding does not penetrate the whole section of the members. Hence the connection will still be able to take more load. There are also some localized stress concentrations reaching 395 MPa at concave corners where members intersect with the gusset plates. These hot spots could be eliminated by optimized detail design. Figure 9 shows an example stress contour of the connection under the controlling Severe Earthquake load combination.

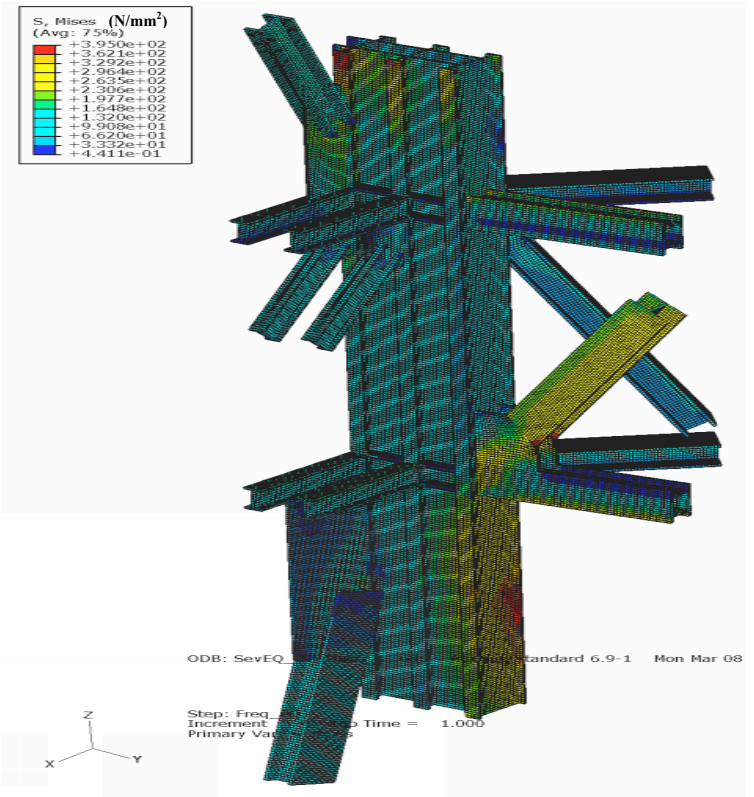

Figure 9. Stress Contour of the Connection under Severe Earthquake Load Combination (The red color stress contour indicates that stress exceeds yield of the specific material.)

CONCLUSION

Due to the super-tall nature of the Ping An Tower, performance of the super composite columns and related connections under extreme load cases is of great interest as fundamental to the overall performance of the 660m tall tower. To evaluate stress levels and ductility of the super columns, related connections and embedded steel shapes, detailed finite element analyses were performed under load combinations considering three levels of seismic loading.

Analysis results indicate that the super column is able to develop significant displacement before failure, with only a moderate decrease in capacity beyond yielding. Therefore it is concluded that the super column has a satisfactory level of ductility. Under Frequent and Medium Earthquake load combinations maximum stresses from the connection studies are less than the material yield point. Under Severe Earthquake load combinations the connection reaches yield at various places, but still has additional available capacity before failure, which is satisfactory. These analyses demonstrate that the Ping An Tower design meets performance criteria established in conjunction with the project expert review panel.

Steel Detailing Practices: Using Global Variation to Envision Innovation

K. Simonen, RA, SE[1]

[1]Department of Architecture, University of Washington, P.O. Box 355720 Seattle, WA 98195-5720; PH (206) 685-7282; email:ksimonen@uw.edu

ABSTRACT

While architecture, engineering and construction continue to become more globally integrated, significant regional differences in practice continue. This paper explores the regional differences in structural steel detailing. There is significant global variation in who typically takes responsibility for the detailing (both for structural strength and for specifics of fabrication) of steel connections. Interviews with over thirty professionals (architects, engineers, fabricators and others) with expertise in ten countries and three regions of the US were completed to characterize four distinct methods of designing and detailing steel connections for construction.

Case studies of three practices are presented to demonstrate established practices in which the distinction between engineer and fabricator is reduced or eliminated, explore the challenges and opportunities of the practice methods, provide examples for engineers, detailers and fabricators considering adaptation of their roles in an evolving market and present a framework for challenging basic assumptions and exploring alternate methods of project delivery.

INTRODUCTION

While architecture, engineering and construction continue to become a more global industry, significant regional differences in practice continue. These cultural and procedural differences impact both the social character and technical work processes between architects, engineers and builders. This paper explores the regional differences in structural steel design and fabrication processes and explores the potential use of regional variation as models for local innovation. Particular attention is paid to the interface between design and construction teams during the creation of fabrication (shop) drawings.

There is broad support for the idea that more effective collaboration is needed to improve building practice (CURT 2004, Smith and Tardif 2009). Currently much work is being done to develop new contractual agreements to promote a more collaborative practice (AIA 2007, Sakal 2005). The changes to responsibilities and processes needed to improve collaboration also require study (Dossick 2008). Participants are often reluctant to change fearing either increase risk (scope) or reduce responsibility (fee) without a clear understanding of the potential benefits of the altered work process (Allen et al. 2005). Often unaware of the wide variety of practice models successfully in use, people can be skeptical of changing methods to which they have become accustomed to (Moore 2002).

With limited understanding of differing processes, innovation happens based on individual intuition or unique local conditions. Understanding of the implications and value of innovation is essential for a more comprehensive transformation of the

industry. The established regional differences in the practice of steel detailing provide a unique opportunity to systematically compare differing established work processes and identify unique conditions. This paper summarizes key findings presented elsewhere (Simonen, 2010) and presents developed case studies of unique global practices and speculates on if and how these methods can be models innovation.

BACKGROUND

Expectations have been that advances in digital design, analysis and manufacturing capabilities will facilitate effective collaboration and the creation of more integrated buildings designs (CURT 2005, AIA 2006, Smith and Tardif 2009). However, the reality of practice is still far from this idealized concept. The limited interoperability of digital platforms most often results in transfer of little more than basic geometry. Multiple models are built for multiple needs such as design, analysis, representation, fabrication and construction usually resulting in a 'loosely coupled network' rather than a single master model (Dossick 2008). The tools of collaboration may have changed (3D digital models vs. 2D paper drawings) but without a culture of collaboration, using a digital model will not guarantee a collaborative or integrated practice.

The use of 3D digital modeling is prevalent in all phases of steel design and construction. In nearly all cases the structural engineering analysis model (e.g., ETABS, and SAP2000) is different than the representation model used for communication (e.g. REVIT, ArchiCAD, or AutoCAD) and is different again from the detailing model that defines detailed geometry for fabrication (e.g. Tekla or SDS2). Significant effort is being expended to enable interoperability between these formats, however the author has found it common that assumptions critical for one model render the model data inaccurate from another's perspective. For example, engineers create multiple analytic models of structures that must represent structural behavior of elements (lateral system, floor system etc) but are often abstractions of physical reality to optimize modeling effort and accurately predict structural performance. In addition, engineering judgment and approximations lead to simplified structural performance models, which efficiently represent complex and slightly varied physical conditions accurately enough to reflect structural performance but not accurately enough for construction.

Historically, steel fabricators had in house drafters creating the fabrication drawings. Over the past 20 years most steel detailers (at least in Australia and the US) have become independent consultants working under contract to different fabricators.

RESEARCH METHOD

This research was completed primarily through interviews with structural engineers, architects, steel fabricators/detailers, and other industry experts with experience working in ten countries and three regions of the US. Initial interviews were supplemented with follow up interviews with engineers and fabricators to develop more detailed case studies of unique practice conditions. These discussions focused on specifics of individual practices within the context of regional standards and the following questions were addressed in the interviews: What is the most effective way to integrate fabrication and design expertise? Are there unique regional conditions that

make one practice method superior to others? Who is motivated/empowered to initiate change? How is the balance between efficiency and performance maintained? How are risks and rewards allocated?

GLOBAL VARIABILITY IN ROLES & RESPONSIBILITIES

The design and construction of the structural components of a steel building typically require input from a wide number of contributors including the perspectives of the client (developer and end users), the design team (architects and engineers) and the builders (fabricators, erectors, general contractors). The roles and responsibilities at the beginning and end of projects are most consistent throughout global practice. There is significant variety in who takes responsibility for specific portions of the work during the detailing (both for structural strength and for specifics of fabrication) of steel connections. Summaries, described in more depth elsewhere (Simonen, 2010), of the primary characteristics of the identified methods are as follows:

Method 1: Steel fabricator's engineer configures and sizes entire steel structure

In this method, the structural steel subcontractor is responsible for design and detailing of the structural system. This method is common for industrial buildings (e.g. portal frame sheds) worldwide. However, with an increase in design-build contracts in the UK, companies have expanded their services to include more complex/architecturally significant projects. The UK design standards (BCSA 2007) include this as one of the three standard levels of service provided by a fabricator (in addition to methods 2 & 3 described below).

In some instances a consulting design engineer participates in the schematic design, configuration and coordination of the structure. When preliminary configuration (e.g. column locations and beam depths) is established, the project is bid to steel subcontractors who subsequently perform the final calculations, sizing members as well as connections. In these instances the consulting design engineer helps to establish any unique performance criteria that the project should be built to.

Method 2: Steel fabricator's engineer designs and details connections

In this process method, the design engineer establishes performance standards, sizes the members and determines the connection loads and delegates the design and detailing of connections to the fabricator. Typically the connection loads are either scheduled based on member sizes or with forces noted explicitly on the plans. The fabricator selects and configures the connection type typically using standardized connection methods. The fabricator's engineer prepares structural calculations and finalizes the connection design (number of bolts, size of plates and welds etc). This is what would be considered 'East Coast' style in the US.

Although similar in general description, the UK and US practices have significant differences. UK design standards (BCSA 2007) are explicit in assigning engineering responsibility to the fabricator. The design engineer is expected to deliver a clearly defined project scope to the fabricator. US design standards (AISC 2005) explicitly maintain that the design engineer retains full responsibility for the design and assume that assessment of the connection design and capacity takes place during the shop drawing review phase. Interviews with engineers with experience in both the US and

UK confirmed that there is significantly more design work done during shop drawing production in the US than in the UK. Typical European methods were described as similar to the UK with some regional variability.

Method 3: Structural engineer designs and details connections

In this process method the engineer prepares prescriptive connection details: specifying the sizes of plates, bolts and welds etc of details. Often, 'typical' details are developed that cover a range of member sizes with variables developed in a schedule. The fabricator must extrapolate from these details to determine the exact configuration of each detail and develop the fabrication and assembly drawings.

The structural engineer of record prepares the calculations to verify connection details, capacity and ultimate performance. If fabricators propose alternate methods, the engineer must review and approve the change. This may inhibit the fabricator from proposing alternate methods given the risk of being rejected. This method is common in the Western US, Australia and New Zealand.

Method 4: Structural engineer designs, details and creates steel shop drawings

In this process method the engineer completes a comprehensive design of the details including the creation of the fabrication drawings. The fabrication model (all interviewed utilized Tekla) is a database driven model that can be used to drive digitally controlled fabrication equipment. Thus fabrication drawings, rather than more schematic representation drawings, can then be priced and produced by competing fabricating shops. The engineer takes responsibility for the structural performance, geometric configuration and constructability of the structure. This method is the norm in Finland. A British engineer with experience in Hungary noted that there too the engineers develop full details often building up sections from welded plates as rolled sections are not easily available.

CHALLENGING ASSUMPTIONS

The initial assumptions of both the author and early interviewees were that the origins of the differences in work processes would be traced to seismic/non-seismic technical requirements and Germanic/Anglo cultural differences. However, as the interview pool expanded, interesting contradictions to the preliminary justifications emerged.

Outside of the US, there does not seem to be a relationship between the detailing system and the seismicity of the region. It seems likely that differences have more to do with the power structure and technical sophistication of the steel industries in select regions than on cultural engineering practices. In areas such as the UK, Germany and Eastern US where structural steel industries originated in the 1800's, the major steel suppliers developed proprietary member capacities and details (Gillette 1980, BCSA 2006). The manufacturers led the way to adoption of what was then an innovative and new structural system. In areas farther from steel manufacturing plants local fabricators imported steel shapes and it seems likely that the local structural engineer had the dominant technical expertise needed to develop the details. The Finnish steel industry developed primarily after World War II. Within that community there are a limited number of structural engineers and fabricators. Perhaps in select regions the

engineers developed the expertise in fabrication detailing out of necessity.

INNOVATION CASE STUDIES

In the course of the research three unique industry practices were identified: a unique region, Finland; unique expansion of scope by fabricators in the UK; and an innovative architect/owner in Australia. What follows is a description of and commentary upon these case studies.

Finland: unique region

Knowledge of the unique conditions in Finland was the spark that initiated this research. The author worked in a structural engineering firm in Finland in the 1990's where the structural and reinforcing steel shop drawings were all produced in house. Eliminating a step in the conventional US documentation process (bypassing 'construction documents' and going straight to 'shop drawings') appeared efficient and practical. As noted above, initial speculation that this was a European and/or German method was found not to be true but rather that Finland appears to have independently developed distinct process differences.

A Finnish engineer, Ragnar Wessman (interviewed November 24, 2009), has led the development of one of three-dimensional detailing program, Tekla. The program had originally been developed for structural engineers using the 'Finnish method' however the actual creation of the details does not change significantly when using other practice methods. He found the wide global variation in work practices and typical details was surprising and could not attribute this variation to anything other than 'happenstance in history'. He noted that historically the Finnish fabrication shops have been set up to be flexible and willing to fabricate whatever is designed. The relatively late development of structural steel in Finland along with the smaller market (when compared to the UK or Eastern US) may have made flexibility a necessity for an emerging steel industry. Wessman noted that in order to do good detailing, one must obey certain rules. While these rules are not that complex, applying them correctly does require a good understanding of fabrication and construction methods. He foresees greatest opportunity in exploring the links between subcontractors, contractors and operators in enabling more efficient delivery and operation of integrated facilities.

Timo Koivisto (interviewed January 12, 2010) a fabricator with experience in the UK and Finland noted that Finnish engineers have an intense culture of efficiency, optimizing individual member sizes to lower overall weight. The two main steel fabricators in Finland do work across Europe and take on additional detailing responsibilities when working outside of Finland. Antti Pekkala (interviewed December 15, 2010), a practicing structural engineer, confirmed that engineers take significant pride in reducing the overall weight of their structures and noted that this 'efficiency training' was done in the workplace not in University. He also noted that given the scale of the country, standards and reputations are easily communicated which could account for the effectiveness of the method.

Engineers with experience in this method expressed confidence that the 'rules' of detailing appropriately for fabrication/construction are not difficult to learn. They identified that the most important requirements is for the person in charge of detailing for fabrication to maintain adequate dimensional control. Some interviewed questioned

whether this method would be applicable outside of Finland with a larger and more diverse group of engineers and fabricators.

UK: fabricators expanding role

British steel subcontractors are expanding their services to offer comprehensive engineering for projects beyond the simple industrial portal sheds they have been engineering since the 1970's. Steve Mason (interviewed Nov 24, 2010), the technical director at a UK steel subcontractor, noted that the scope of their engineering responsibility can vary from conventional Method 2 to Method 1. Expanding their scope to develop full engineering designs enables them to improve their market share and 'keep (their) structural engineers motivated and committed'. He acknowledged that consulting engineers are better suited to spend long periods of time iterating through design development but felt that integrated design build typically resulted in lower weight/lower cost structures. In great part the services they provide are dictated by the demands of the client looking to shift risk and take advantage of a competitive market.

Richard Shuttleworth (interviewed December 15, 2010) is a practicing structural engineer who has worked in both methods 1 and 2. He noted that the primary driver for adopting Method 1 is coming from institutional clients looking to reduce risk and identify costs up front. In response, builders are putting together fixed price bids before the construction documents are complete. In these instances design teams put together schematic documents and specifications that the contractor uses to price and complete. Given the competitive nature of the UK steel industry, it is his opinion that the steel suppliers must be very aggressive in reducing material and detailing costs in order to achieve economically viable results. When asked about the challenge of balancing performance and efficiency he reflected that consulting engineers often deliver designs that provide flexibility and redundancy to support commonly occurring (but not guaranteed) irregularities (e.g. providing torsional stiffness to support potential cladding loads). Consulting engineers contracted to the architect are more likely to integrate these conditions into the design but specifying criteria for others to meet can be more challenging. Shuttleworth noted that developer clients are more likely to keep the structural engineering consultant as prime engineer (method 2) as developers have a better understanding of project risk and would like to maintain more control over the process.

AU: architect as innovator

Project Services is a unique consulting firm in Brisbane Australia. Established in 1992 as an AEC firm with public as shareholder it is expected to be commercially viable and support and lead the AEC industry. Tom Fussell (interviewed December 1, 2009) is the executive director and chief architect and is looking to enact change in a 'measured' way. Conventional practice in Australia is similar to the Western US/method 3 noted above. In 2001 Project Services purchased ArchiCAD and a 'pre-Autodesk' version of Revit and began integrating 3D BIM into their design process. The North Lakes Police Station project (CRCCI, 2009) was selected to test the generation of integrated interdisciplinary 3D models to be shared with the contractor for construction. Project Services hired BDS Group (now BDS Viracon) to create fabrication ready contract documents for the structural steel using Tekla. For portions of the design work a detailer co-located with the structural engineering team to create the model and collaboratively resolve design and constructability issues. The Tekla model was exported

and integrated into the architectural model and shop drawings were issued directly from the architectural/engineering team.

This is similar to the Finnish model/Method 3 except that the detailing expertise is not integrated into the structural engineering practice but rather brought in as a consultant. Independent steel detailing companies can use global labor pools to create cost-effective labor-intensive models and have developed methods to adapt to the varying standards of different steel fabricators. In this instance the architect/structural engineer took on added responsibility and risk by hiring the steel detailer directly in order to develop a more integrated proposal. The architect noted that this required the design team to take greater care in checking dimensional coordination than typical. Given the lack of CNC capabilities of local fabricators, traditional printed shop drawings were used to direct the work.

The end result of the process used by Project Services is very similar to the Finnish model. However, utilizing consultant detailers minimizes concerns about design engineers understanding and ability to detail for construction because the team integrated standard industry knowledge and expertise. Given Project Services unique role as an industry leader, they were willing to take on added risk to explore potential larger scale benefits and were able to alter the project fees to reflect this reorganization. This is similar to design assist and IPD methods currently being tested in the US.

CHALLENGES

Although the goal of improving quality and efficiency can be easily supported, empowering and motivating effective change can be elusive. While collaboration between structural engineers and detailers and/or expanding one disciplines roles to encompass the others may be effective at reducing time, cost and translational errors, structural engineers and steel detailers are rarely in a position to shape the contract or redistribute resources as both are subcontracted out by disciplinary 'primes'. In order to implement innovative methods, leadership must often come from owners with the ability to redistribute fees, risk and responsibility.

Multiple interviews included interesting discussions about the varying methods of establishing professional responsibility and the legal and building code structures that provide unique constraints. Even as international codes such as the IBC and Eurocode develop, individual jurisdictions execute and implement generalized requirements with unique local requirements.

CONCLUSIONS

The roles and responsibilities with regard to steel design, detailing and fabrication is an important area of the building process currently in a stage of significant flux. Regional variability in industry expertise and standards is significant and must be considered when proposing innovations in work processes and project delivery methods. As the industry actively explores improving the design process and product, there is a strong need for both qualitative understanding and quantitative assessment of different processes and their results. Having established different regional work processes provides a unique opportunity for quantitative research comparing performance

measures of costs, time, error etc. among regions to better understand the relative merits of different processes.

The case studies presented here are qualitative assessments of different practices. With a more comprehensive quantitative study, interesting comparisons could be made on effectiveness of collaboration and work processes and differences in structural efficiency and performance and construction cost, errors and time. Additional information about the successes and challenges of different processes would be valuable for professionals looking to evaluate options and establish what work processes should be optimum given an individual projects demands and constraints.

ACKNOWLEDGEMENTS

The author would like to thank the many professionals (only a small portion of whom are identified above) who participated in the interviews and whose time and interest made this research possible. Their diverse experience and insightful input provided significant valuable information and the seeds for future research beyond the scope of this project. They are greatly appreciated.

ABSTRACT

Large-scale shake table tests were performed to examine the out-of-plane stability of buckling-restrained braces (BRBs). Two specimens were subjected repeatedly to a near-fault ground motion with increasing magnitude. The test specimens comprised a single-bay, single-story steel frame and a pair of BRBs placed in a chevron arrangement. The chevron braced frame specimens were not braced at the point of intersection in the beam, and was therefore susceptible to out-of-plane instability. Standard BRBs were used in the first specimen, while unique BRBs with a flexible segment at each end of the steel core were used in the second specimen. A simple stability model predicted the BRBs in the second specimen to fail due to out-of-plane buckling at a force smaller than the yielding strength of the steel core. The first specimen exhibited excellent ductility during the shake table tests, while the second specimen developed noticeable out-of-plane deformation. Observations from the tested are described along with design implications.

INTRODUCTION

Buckling-restrained braces (BRBs) refer to a class of axially loaded members that achieve stable hysteretic behavior under both tension and compression (AISC 2005b; Uang and Nakashima 2004). BRBs have been used extensively in Japanese building structures since the 1980's as a performance enhancement device that dissipates seismic energy while maintaining the rest of the structure damage-free (Wada et al. 2004). On the other hand, the US practice has incorporated BRBs into a new class of concentrically braced frames (CBFs), named buckling-restrained braced frames (BRBFs) which exhibits excellent ductility (AISC 2005b).

Previous studies by Inoue et al. (2001) and Black et al. (2004), among others, established a design procedure to preclude flexural buckling of the BRB, local buckling of the steel core, or instability of the bracing element outside of the buckling-restraining system. The stable and predictable cyclic behavior of BRBs has been demonstrated by numerous tests (e.g., Saeki et al. 1995; Black et al. 2004). Meanwhile, Tembata et al. (2004) and Takeuchi et al. (2004) noted that BRBs with a flat-plate steel core require special attention to avoid out-of-plane instability. Such BRBs include relatively flexible segments between the end of the steel casing (of the buckling-restraining system that contain mortar) and the termination of stiffened segment. Because the flat plate is generally oriented parallel to the plane of the frame and parallel to the gusset plates for fabrication and constructability considerations, BRBs with a flat-pate steel core may be

usceptible to out-of-plane instability. This instability issue pertains primarily to BRBs placed in a chevron arrangement (or "inverted-V" arrangement).

Previously, Tembata et al. (2004) and Kinoshita et al. (2007) derived a comprehensive set of analytical solutions to the out-of-plane stability problem of BRBs, and validated the solutions against static, cyclic loading tests. Further, Kinoshita et al. (2008) performed a combined computational and experimental study to evaluate the rotational stiffness of standard BRB bracing connections in Japan. Experiments by Takeuchi et al. (2004) demonstrated how flexible bracing connections can trigger instability of BRBs.

A research project was conducted to further examine the stability requirements for BRBs subjected to dynamic loading and to examine how the BRBs may behave after the instability occurs. This paper defines the stability problem, describes analytical solutions to a mathematical stability model, and reports a large-scale shake-table test program. Findings and observations are described, followed by a discussion of practical implications.

STABILITY MODEL

The following four assumptions are introduced to derive an analytical expression for the out-of-plane buckling strength of BRBs placed in a chevron arrangement as shown in Fig. 1(a).

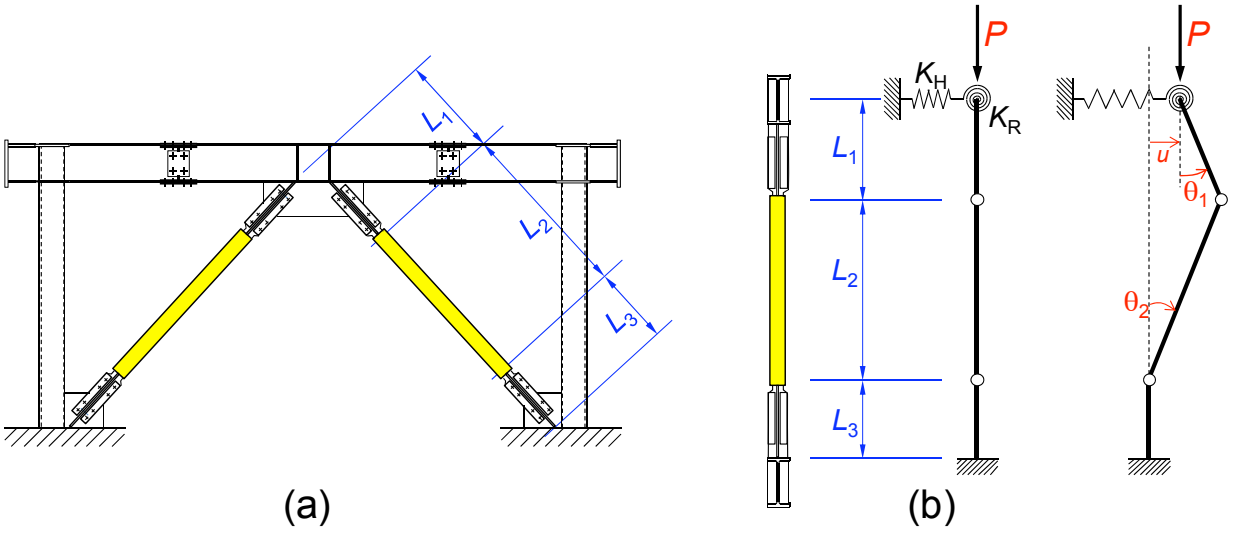

Fig. 1 Out-of-plane stability model: (a) chevron brace; (b) first-order buckling model.

1) The bracing member includes short segments which are flexible against out-of-plane rotation. The flexible segments are located at each end of the steel core, between the end of the steel casing and the termination of stiffened segment.
2) Yielding occurs only in the steel core while the segment outside of the BRB, the bracing connection, or the beam remains elastic. Distortion of the gusset plates and the beam section is negligibly small compared to out-of-plane rotation in the steel core.
3) The BRB is adequately designed such that flexural buckling of the BRB or local buckling of the steel core does not control the strength of the BRB.
4) Initial imperfection and out-of-plane drift is negligibly small.

Fig. 1(b) shows a first-order buckling model of the BRB based on the above assumptions, which is composed of rigid elements, internal hinges, and elastic end restrains. The internal

hinges are placed at the ends of the steel core. The top end of the system is the point of intersection of the BRBs which typically coincides with the centroid axis of the beam. The bottom of the system is assumed to be rigid because the bottom represents the brace-beam-column node that is well braced for translation and rotation. Initial imperfection is neglected.

It is noted that engineers may choose a different detail for the gusset plate connections, in which case assumption (2) may not be valid, and the buckling model shown in Fig. 1(c) may be adequate. The model may be viewed as a simplification of the elastic-perfectly plastic model proposed by Tembata et al. (2004) and Kinoshita et al. (2007), whose model considered elastic deformation of the gusset plates and BRB, and thus assumptions (2) and (3) do not apply. Tembata et al. and Kinoshita et al. justified assumption (1) only under the idealization that the steel core is an elastic-perfectly plastic material, and only when the BRB is subjected to a compressive force equal to the yield strength of the steel core.

The spring constants K_H and K_R may be evaluated based on the flexural and torsional stiffness of the beam and properties of lateral braces acting at the point of intersection. Fig. 2 shows all possible buckling modes. While three displacement parameters are shown (θ_1, θ_2, and u), the modes are defined in terms of two independent parameters. The critical loads, P_1 to P_3, corresponding to the first three modes are derived as follows.

$$P_1 = K_H \cdot L_2 \quad P_2 = \frac{K_R + K_H \cdot L_1^{\,2}}{L_1} \quad P_3 = \frac{K_R}{L_1} \qquad (1a-c)$$

Because $P_2 > P_3$ for $K_H \cdot L_1 > 0$, mode 2 never governs. The critical load, P_4, corresponding to mode 4 is determined as the smaller solution to the following quadratic equation.

$$(P - P_1)(P - P_3) - P \cdot \left(\frac{L_1}{L_2} P_1\right) = 0 \qquad (2)$$

The above equation suggests that mode 4 always governs and that mode 4 is a combination of modes 1 and 3. Denoting the solution to Equation (2) as P_{cr}, the buckling mode may be expressed as follows.

$$\frac{\theta_1}{\theta_2} = \frac{P_1}{P_3 - P_{cr} + \frac{L_1}{L_2} P_1} = \frac{P_1 - P_{cr}}{\frac{L_1}{L_2} P_1}, \quad \frac{u}{L_1 \theta_1} = \frac{P_{cr}}{P_1 - P_{cr}} \qquad (3a, b)$$

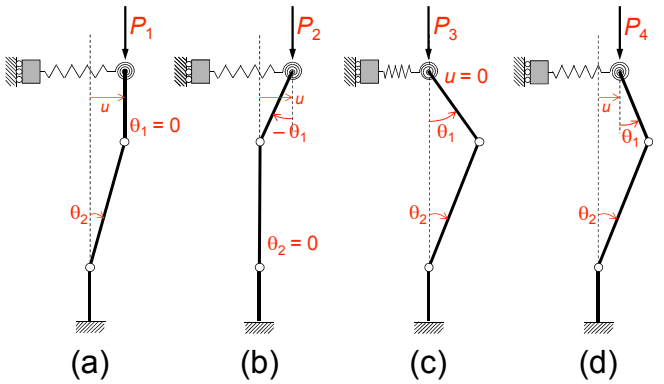

Fig. 2 Buckling modes: (a) to (d) indicate modes 1 to 4.

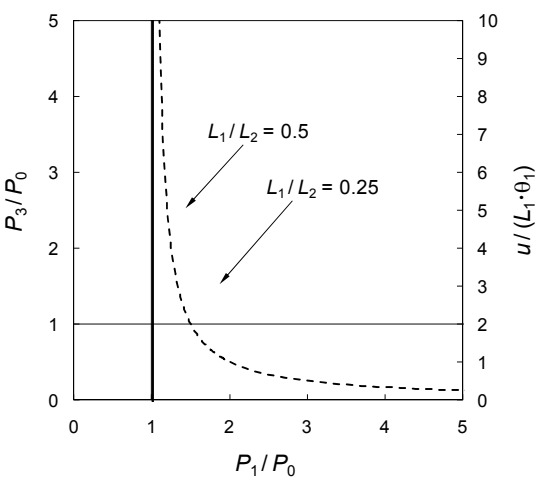

Fig. 3 Condition to achieve $P_{cr} = P_0$

Fig. 3 plots the combinations of P_1 and P_3 to achieve a fixed critical load $P_{cr} = P_0$. The domain in the P_1– P_3 space above the curve and opposite the origin defines the safe domain where the buckling strength is greater than P_0, and thus out-of-plane buckling of the BRB may be avoided. The curves are plotted for $L_1/L_2 = 0.25$ and 0.5. The case $L_1/L_2 = 0.25$ may represent BRBs with compact bracing connections, while $L_1/L_2 = 0.5$ may represent BRBs with larger bracing connections that uses bolted splices. The value P_3/P_0 approaches $(1 + L_1/L_2)$ as P_1/P_0 tends to infinity and P_1/P_0 approaches unity as P_3/P_0 tends to infinity. BRBs proportioned with larger bracing connections and shorter steel-core length requires somewhat larger restraints. The broken line in Fig. 3 indicates the transition of mode shape $u/(L_1 \cdot \theta_1)$ as a function of the P_1, given $P_{cr} = P_0$. Mode 1 ($\theta_1 = 0$) dominates when P_3 is significantly greater than P_1 and thus $P_{cr} \approx P_1$, and mode 3 ($u = 0$, $u = L_1 \cdot \theta_1$) dominates when P_1 is significantly greater than P_3 and thus $P_{cr} \approx P_3$.

TEST PLAN

Two braced-frame specimens were subjected to a series of strong earthquake ground motions to examine whether the out-of-plane buckling load of BRBs can be predicted based on the analytical solutions described above, and to examine how the system behavior may be affected by instability of BRBs. The tests were conducted at E-Defense, a three-dimensional, large-scale earthquake testing facility operated the National Research Institute for Earth Science and Disaster Prevention of Japan.

Specimens

As shown in Fig. 4(a), the specimens comprised a built-up wide-flange beam, two cold-formed square-tube columns, and a pair of BRBs. The 4.15-m span and 2.25-m height correspond to a 70%-scale building structure. After Specimen 1 was tested, the BRBs were replaced by a new pair of BRBs to prepare Specimen 2. The standard through-diaphragm detail (Nakashima et al. 1998) was used to achieve rigid beam-to-column connections. The bracing connections adopted a common Japanese detail that welds the fin plates (stiffener plates oriented perpendicular to the gusset plate) to the beam or column. The columns were rigidly connected to large base beams which were, in turn, fixed to the shake table. Table 1 lists the Japanese Industry Standards (JIS) designation and measured mechanical properties for each material used to fabricate the specimen. The specified minimum yield strength is 235, 295, and 325 MPa, respectively, for SN400, BCR295, and SM490 steel.

At the top side of the specimen, each end of the beam was connected to the test-bed system (described later) through a pin-ended load cell. The specimen was laterally braced along the columns and beam at discrete locations indicated in Fig. 4(a). No bracing was provided at the middle segment of the beam to intentionally reduce the torsional and translational restraint at the intersection point of the BRBs.

The two specimens were nominally identical except for the BRBs. As shown in Fig. 4(b) and (c), the BRBs used a 74 × 12 mm plate for the steel core and a square 125 ×125 × 2.3 mm steel tube casing filled with mortar for the buckling-restraining system. Unlike most standard BRB products, no capping steel plate was placed at either ends of the casing. The key difference between the two BRBs was the embedment length of the stiffened segment inside the buckling-restraining casing. While Specimen 1 used a standard embedment in current Japanese practice (110 mm as indicated in Fig. 4(b)), Specimen 2 used a shorter embedment length (30 mm).

Because out-of-plane restraint of the BRB is developed by bearing between the stiffened segment and mortar, and the steel core itself possesses little out-of-plane stiffness, the shorter embedment length in Specimen 2 was expected to promote out-of-plane stability of the specimen.

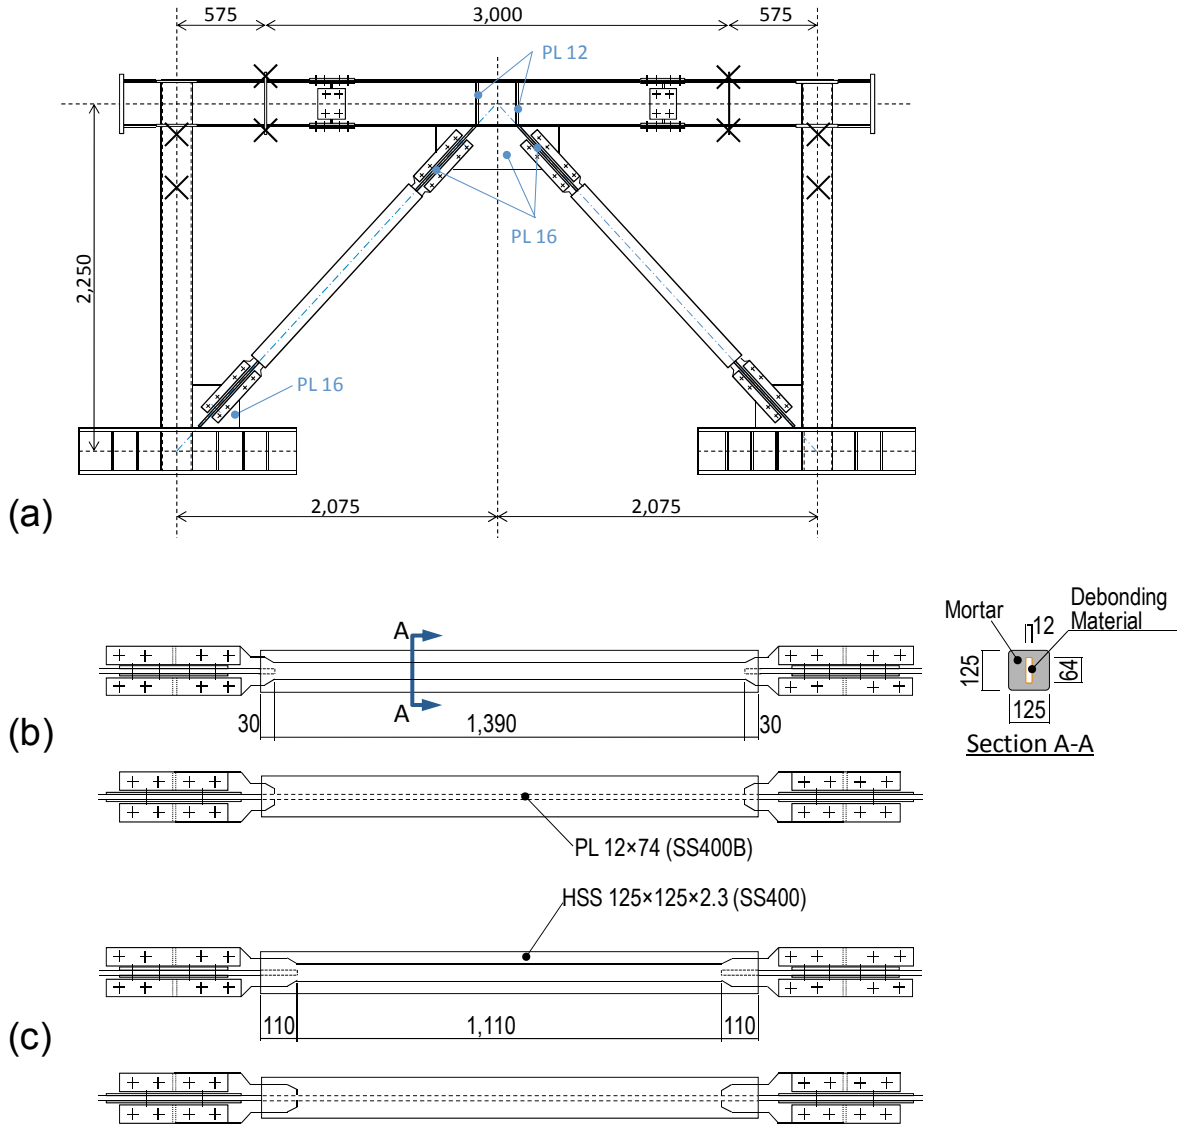

Fig. 4 Test specimen: (a) elevation and out-of-plane bracing points; (b) BRBs in Specimen 1; and (c) BRBs in Specimen 2.

Table 1 Material properties

Material	JIS designation	Yield strength (MPa)	Tensile strength (MPa)	Elongation (%)
Steel core (12 mm)	SN400B	297	421	35
Beam flange (9 mm)	SN400B	327	456	27
Beam web (6 mm)	SN400B	376	472	29
Column (9 mm)	BCR295	434	518	19
Gusset plate (12 mm)	SM490A	315	441	32

In other words, assumption (1) of the stability model in Fig. 1 was valid for Specimen 2 but not for Specimen 1.

A simple, rigid-plastic analysis using the measured material properties estimated the lateral strength of the specimen to be 798 kN, and suggested that the BRBs and underlying moment frame provide 58 and 42%, respectively, of the lateral strength.

Stability Design Check

The elastic stiffness of the beam between bracing points B and C determine the spring constants K_H and K_R shown in Fig. 1(b). Assuming that the beam is simply supported at the bracing points B and C and at the beam-to-column connections (A and D) and neglecting the stiffness added by the gusset plate, K_H = 5,530 kN/m and K_R = 330 kN·m/rad. From Fig. 4, L_1 = 1.39 m and L_2 = 0.83 m. Consequently, from Equations (1) and (2), P_1 = 4,590 kN, P_3 = 238 kN, and P_4 = 88 kN. While P_1 is substantially larger than the yield strength of the steel core based on the measured yield strength, P_y = 263 kN, P_3 and P_4 are smaller than P_y. Therefore, the instability model predicted Specimen 2 to experience substantial out-of-plane buckling and predicted that mode 3 would dominate over mode 1.

The *AISC Seismic Provisions* (2005b) require both flanges of the beam to be braced at the point of intersection of bracing unless the beam provides the required brace horizontal strength, P_{br}, and stiffness, β, defined as follows:

$$P_{br} = 0.01 P_r \tag{4}$$

$$\beta = \frac{1}{0.75}\left(\frac{8P_r}{L_b}\right) \tag{5}$$

In the above equations, P_r = required compressive strength of the BRB, L_b = the distance between the bracing point and point of intersection of the BRBs, and 0.75 is the resistance factor. The required translational stiffness according to Equation (5) is β = 19 kN/cm. Consequently, because K_H is nearly three times β, the *AISC Seismic Provisions* do not require lateral bracing at the middle of the beam.

Test Bed

The specimens were subjected to ground shaking at the E-Defense facility using the "test bed" system developed by Takeuchi et al. (2008). The test beds are multi-purpose devices that supply horizontal mass to the specimen while adding minimal lateral force resistance. As shown in Fig. 5, a pair of test beds was used for this program, one at each side of the loading plane of the specimen. At the base, the test bed was connected to the shaking table through a set of linear bearings which produced minimal friction (the friction coefficient was estimated as 0.0033 by Takeuchi et al. (2008)) for motion in the loading plane, and which restrained out-of-plane motion. At the top, the test bed was connected to each end of the specimen, with a load cell placed in the load path. The two test beds and additional test rigs supplied a combined 69.4 ton mass to the specimen. The test bed was also used to anchor the out-of-plane bracing indicated in Fig. 4(a). Consequently, the test beds were arranged to permit planar motion of the planar specimen.

Test Procedure

As mentioned above, the dimensions of the specimen was 70%-scale of typical building structures. The scaling rules for the shake table test are summarized in Table 2, where λ indicates the inverse of the dimension scaling factor for dimensions. In this case, λ = 1/0.7 = 1.41. Time

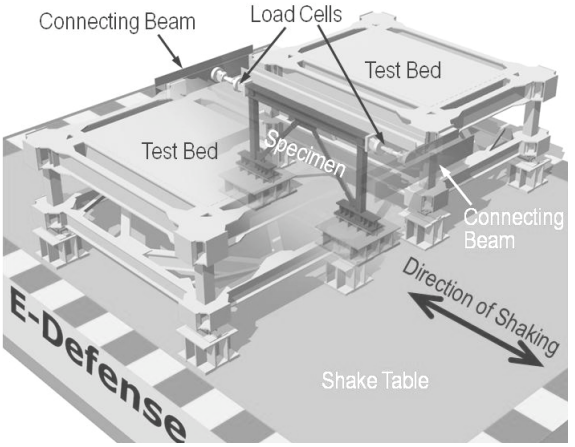

Fig. 5 Specimen and test-bed system

Table 2 Scaling rule

Parameters	Scaling Factor	
Dimension	$1/\lambda$	0.7
Mass	$1/\lambda$	0.7
Acceleration	$1/\lambda$	0.7
Time	1	1
(Inertia) Force	$1/\lambda^2$	0.5
Velocity	$1/\lambda$	0.7
Stress	1	1

and stress are not scaled.

The East-West component of the JR Takatori motion was introduced in the direction parallel to the primary plane of the specimen. The JR Takatori motion is a strong motion record from the 1995 Kobe earthquake, measured immediately adjacent to the fault. The EW component is characterized by a peak acceleration of 6.6 m/s^2 and strong velocity pulses. Fig. 6(a) shows the acceleration history of the motion while Fig. 6(b) shows the response acceleration spectrum obtained for 2 to 10% of critical damping (h = 0.02 to 0.1). The spectral response for h = 0.05 was between 17 and 23 m/s^2 for periods between 0.15 and 0.4 seconds. The natural vibration period of the specimen was predicted as 0.2 sec. After adjusting for the scaling factors, the JR Takatori motion was three times as large as the design basis earthquake in the Japanese design code. The shake table tests were conducted by introducing the motion repeatedly with increasing intensity. Table 3 lists the target excitation levels. Specimen 1 was tested with nine excitations, targeting between 14 and 120% of the JR Takatori EW motion. Specimen 2 was tested with seven excitations, targeting between 14 and 150% of the JR Takatori EW motion, with the 28% motion introduced twice.

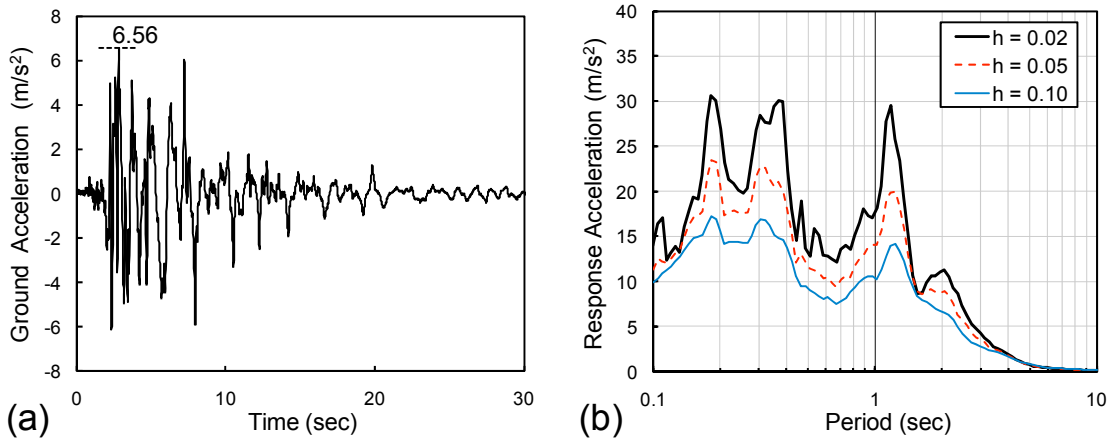

Fig. 6 JR Takatori EW motion: (a) ground acceleration history; and (b) response spectra.

Table 3 Excitation levels

Target Level	Specimen 1		Specimen 2	
	Max. acc. (m/s^2)	Averaged RSA (m/s^2)	Max. acc. (m/s^2)	Averaged RSA (m/s^2)
14%	1.21	4.8	1.16	4.6
21%	1.54	6.6	—	—
28%	1.99	8.6	2.06 / 2.09	9.0 / 9.2
42%	3.45	16	—	—
56%	4.40	20	—	—
70%	4.43	20	4.48	20
84%	5.58	25	—	—

120%	7.98	35	8.40	38
150%	—	—	10.2	46

Instrumentation

The load cells were used to evaluate the story shear. Displacement transducers were used to monitor the story drift and the out-of-plane deformation of the beam and BRBs. The force distributions in the beam, columns, and BRBs were evaluated based on strain gauges placed at selected sections of the beam and columns. Elongation of the BRB steel core was measured from the change in relative distance between the end of steel casing and connection region of the BRB. Data was collected at a rate of 1,000 Hz. All data was passed through a low-pass filter to eliminate frequency content above 50 Hz.

RESULTS

Based on unidirectional white noise excitation, the natural vibration period was determined as 0.18 sec for Specimen 1 and 0.19 sec for Specimen 2. The vibration period of the specimens was equivalent to that of a single or two story building.

Table 3 lists the maximum measured acceleration of the shake table. The table also lists the response spectral acceleration averaged over a period of 0.17 to 0.2 seconds, evaluated from the measured table motion and assuming a damping ratio h = 0.02. The corresponding values from the JR Takatori EW motion (i.e., target 100% motion) were 6.56 m/s^2 and 29 m/s^2, respectively. Therefore, the listed values indicate that the table motion was accurately amplified according to the targets.

Both specimens exhibited very similar response up to the 70% motion. Fig. 7 shows the story shear versus story drift response of the two specimens under the 100 and 120% motions. Specimen 1 exhibited very stable and ductile behavior even under the largest 120% motion, developing a maximum drift ratio of 0.013 radians and leaving a residual drift ratio smaller than 0.001 radians. Minimal yielding was observed in the framing members after testing of Specimen 1 was completed. On the other hand, Specimen 2 experienced substantial degradation in elastic stiffness during motions 100% and larger, recording a maximum drift ratio of 0.015 radians during the 100% motion and 0.03 radians during the 120% motion.

Fig. 8 shows the maximum drift and residual drift measured from each motion. The figure indicates very similar response of the two specimens under motions up to 70%. Motions larger than 100% caused minimal damage to Specimen 1 but severe damage to Specimen 2.

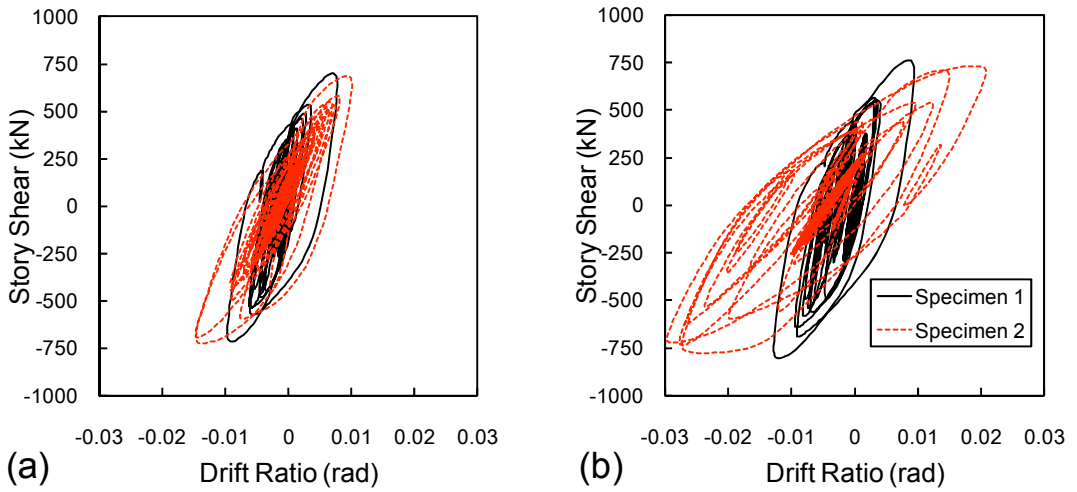

Fig. 7 Frame response at: (a) 100% motion; and (b) 120% motion.

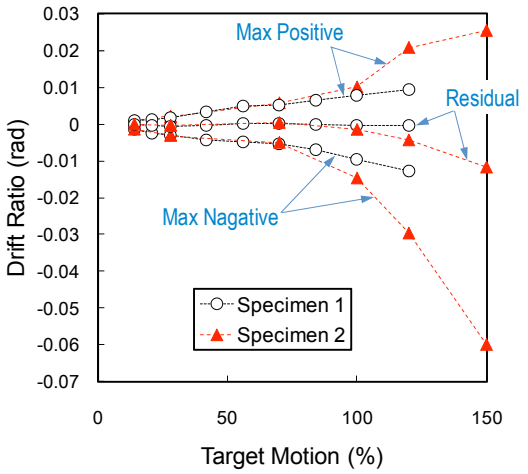

Fig. 8 Maximum drift and residual drift from each motion

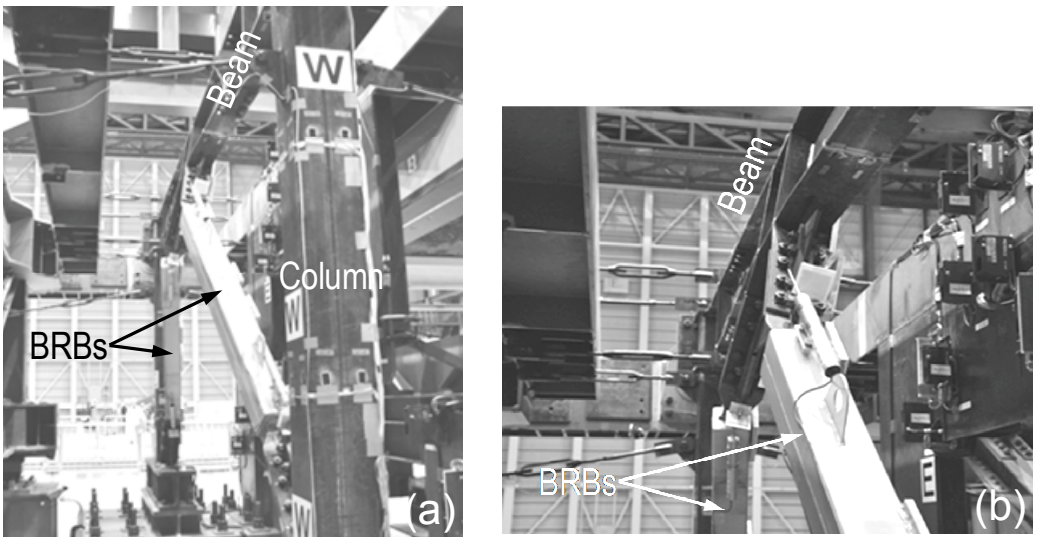

Fig. 9 Specimen 2 after 120% motion: (a) side view; and (b) close-up view.

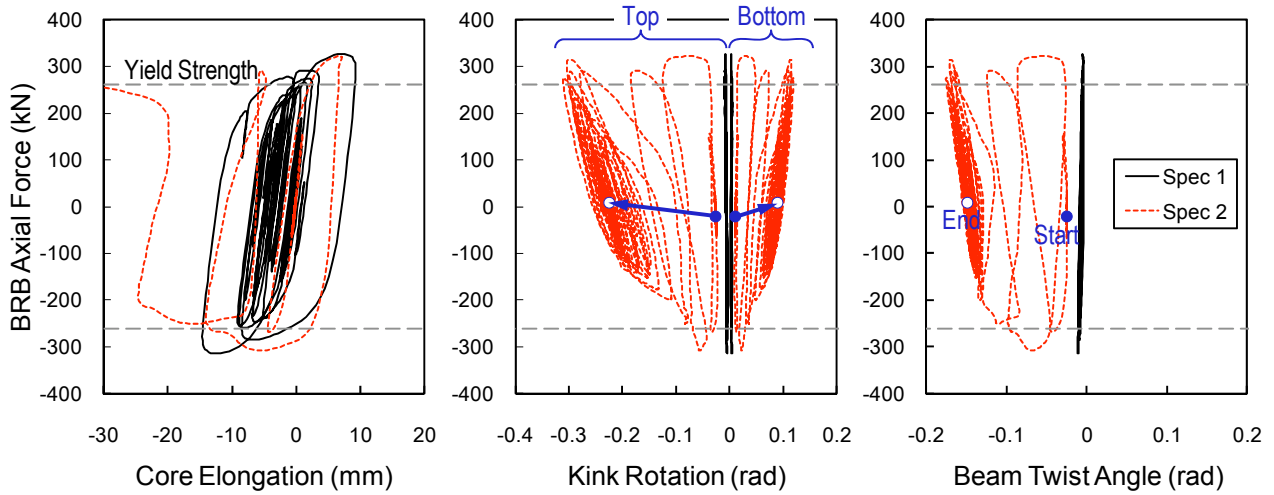

Fig. 10 BRB response at 100% motion: (a) BRB elongation; (b) BRB kink rotation; and (c) beam twist angle.

While the 150% motion produced extremely large drift ratios between -0.06 and 0.025 radians, the residual drift ratio after this motion was fairly small at 0.012 radians. The large deformation history did not cause collapse of Specimen 2. It is noted that P-Delta effects were not incorporated in the tests.

Fig. 9 shows photographs of Specimen 2 taken after the 120% motion. Fig. 9(a) views the elevation of the specimen from an angle. Kinking deformation is seen at the top and bottom ends of both BRBs, between the bolted gusset plate connection and steel casing. The kink rotation angle is notably larger at the top end of the BRB than at the bottom end, and the direction of kink rotation is opposite between the top and bottom. Fig. 9(b) is a close-up view of the middle portion of the beam where the top ends of the two BRBs connect to the beam. The close-up view indicates that the kinking deformation of the BRBs is accompanied by twisting of the beam between the two braced sections. The deformation seen in the photos agrees with the buckling mode illustrated in Fig. 2(c). As predicted by the analytical model, instability of Specimen 2 was promoted by lack of bracing of the beam at the work point of the two BRBs, and the lack of out-of-plane rotational stiffness at both ends of the BRBs.

Fig. 10 compares the BRB performance during the 100% motion, plotting the elongation of the BRB steel core, kink rotation at the top and bottom ends of the BRB, and twist angle of the beam immediately above the BRB, respectively, against the BRB axial force. The response is taken from the BRB placed on the closer side as viewed in Fig. 9. The direction of measured rotation is consistent with the visual observation in Fig. 9. The broken horizontal lines indicate the yield strength of the BRB steel core, P_y, based on the measured yield strength. The maximum tensile and compressive force was 1.25 and 1.20P_y, respectively, for Specimen 1 and 1.23 and 1.18P_y, respectively, for Specimen 2. The BRBs tested in this program exhibited similar behavior in tension and compression, although the BRBs in Specimen 2 were affected by instability and severe distortion of the frame during large motion.

Specimen 1 exhibited very stable cyclic behavior, with the BRB developing steadily larger forces with larger elongation, little kink rotation in the BRBs, and minimal twisting of the beam. Specimen 2 was able to exceed the yield strength. However, it could not effectively develop the full strength of the BRB due to instability of the system. Fig. 10(b) indicates that the kinking rotation at the top and bottom ends of the BRB formed in opposite directions, and the

rotation at the top end was twice the rotation at the bottom. Residual kinking rotation was present after the 84% motion. The 100% motion caused a very large residual rotation of 0.2 radians at the top and 0.1 radians at the bottom. Fig. 10(c) indicates that the kinking rotation of the BRB was accompanied by very severe twisting of the beam.

The occurrence of out-of-plane buckling was predicted by the first-order buckling model in Fig. 1(b). However, the BRB was able to sustain a much large force than predicted by the model. The study is continued by the authors to identify the reason for this discrepancy between predicted and measured BRB strength.

CONLUSIONS

A series of large-scale shake table tests were conducted to examine out-of-plane instability of BRBs. Two chevron braced-frame specimens were repeatedly subjected to the JR Takatori EW motion with increasing amplification. Both specimens implemented oddities from the Japanese practice to promote instability of the specimen: no lateral bracing was provided at the middle of the beam where two BRBs connected to the beam; and no steel cap was provided at the end of the steel casing. In addition, the BRBs in Specimen 2 had an unusually short embedment length of the stiffened segment into the steel casing. Key findings are summarized in the following.

1) Specimen 1 exhibited excellent performance despite the above mentioned measures to promote instability of the BRBs. After nine excitations from 14 to 120% motions, Specimen 1 was left with negligible residual drift. Even under the largest 120% motion, the specimen experienced minimal yielding in the framing members.
2) Specimen 2 was intentionally designed to exhibit out-of-plane instability of BRBs. This specimen exhibited excellent behavior until instability of the system led to severe kinking deformation at both ends of the BRBs, which was accompanied by severe twisting of the beam intersecting the top ends of the BRBs. Due to distortion of the BRBs and the beam, Specimen 2 was unable to develop the full strength of the BRBs during the 100, 120, and 150% motions.
3) Despite the severe out-of-plane distortion of the system and stiffness reduction, Specimen 2 exhibited minimal strength degradation at a very large drift of 0.06 rad. At the end of the test, no fracture was observed at the bracing connections.
4) The severe frame distortion observed in Specimen 2 would compromise serviceability of the structure and replacement of the BRBs following a seismic event. Therefore, out-of-plane instability of BRBs should be prevented. The first-order buckling model presented in this study offers a conservative estimate of the condition that causes the instability.

ACKNOWLEDGEMENTS

The project presented in this study was funded by the National Research Institute for Earth Science and Disaster Prevention of Japan. Mr. Naomiki Suzuki and Dr. Makoto Ohsaki provided guidance to the overall project and specimen design. The authors thank Dr. Toru Takeuchi and Dr. Yuji Koetaka for sharing their views and latest research findings. Ms. Sachi Furukawa, Mr. Ryo Umehara, and Mr. Xuchuan Lin helped processing the data. The steel frame components were fabricated by Sakamoto Industrial Iron Works Co. Maekawa Co., Ltd. managed specimen fabrication and construction of the test setup. Special thanks are extended to

ABSTRACT

Large-scale shake table tests were conducted to examine the dynamic response of steel concentrically braced frames. The specimen was a single-bay, single-story frame with a pair of square-tube braces placed in a chevron arrangement. The gusset plates connecting the brace to the framing elements were provided with an elliptical clearance to permit free out-of-plane rotation. The specimen was subjected repeatedly to unidirectional ground motion with increasing magnitude until the braces fractured. The test results demonstrated excellent performance of the gusset plate connections. The specimen response was reproduced by a numerical model using fiber elements. This model was able to predict the occurrence of brace fracture and post-fracture behavior of the frame. Observations from the shake table tests and aspects of the numerical analysis are reported in this paper.

INTRODUCTION

Concentrically-braced frames (CBFs) are an efficient structural system to achieve the lateral stiffness and strength required by modern seismic design provisions. The design rules in the *AISC Seismic Provisions for Structural Steel Buildings* (AISC 2005b) are based on an extensive body of research conducted since the 1970's (Popov et al. 1976; Astaneh-Asl et al. 1986; Nakashima and Wakabayashi 1993), which suggest that the seismic performance of axially loaded members degrade with the width-to-thickness and slenderness of the brace. Recent tests by Uriz and Mahin (2004), Lehman et al. (2008), and Roeder and Lehman (2009) indicate that secondary bending in the framing members caused by frame deformation can significantly affect bracing connections. Based on such observations, Lehman et al. (2008) developed a design procedure that promotes compact and thin gusset plates. While much improvement has been made in the design and detailing of CBFs, evaluating the behavior of CBFs under severe ground motions remains a challenging problem due to their complex nonlinear behavior following brace buckling and ultimately fracture.

This paper describes a research program that involved shake table tests of a large-scale braced frame specimen. The test results were used to evaluate the accuracy and reliability of state-of-the-art nonlinear analysis. The experimental and analytical study was used to examine the dynamic behavior of CBFs detailed according to the most recent recommendations.

TEST PLAN

A single story, single span, chevron-braced (or "inverted V-braced") frame specimen was subjected to a series of strong earthquake ground motions. The tests were conducted at E-Defense, a three-dimensional, large-scale earthquake testing facility maintained and operated by the National Research Institute for Earth Science and Disaster Prevention of Japan.

Specimens

Fig. 1 shows an elevation view of the braced-frame specimen. The 4.15-m span and 2.25-m height correspond to 70%-scale of a typical building structure. The braces were arranged to frame into the beam and column in an angle close to 45 degrees. The beam was rigidly connected to the columns. This frame comprised a built-up wide-flange beam (d = 300, b_f = 150, t_w = 6.5, t_f = 9 mm), two cold-formed square-tube columns (d = b = 200, t = 9 mm), and a pair of square tubular braces (d = b = 75, t = 3.2 mm) connected to the beam-to-column joints through 4.5-mm gusset plates. Table 1 lists the Japanese Industry Standards (JIS) designation and measured mechanical properties for each material used to fabricate the specimen. The specified minimum yield strength is 245, 235, 295, and 245 MPa, respectively, for STKR400, SN400, BCR295, and SS400 steel. The table also indicates the measured yield strength established from tension coupon tests. The measured yield strength for the beam and columns and tubular braces was 50% stronger than the specified minimum value. Interestingly, the measured yield strength for the gusset plate, 204 MPa, did not meet the specified minimum value of 245 MPa.

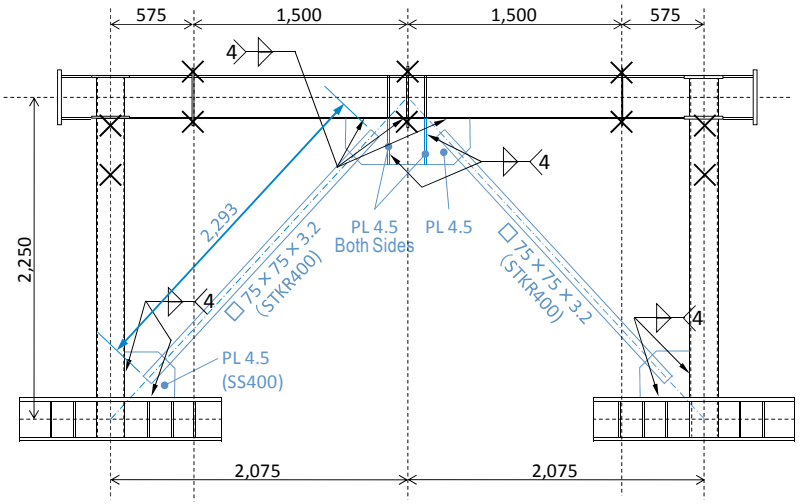

Figure 1. Test specimen and out-of-plane bracing points

Table 1. Material Properties

Material	JIS designation	Yield Strength (MPa)	Tensile Strength (MPa)	Elongation (%)
Brace	STKR400	383	452	36
Beam flange (9 mm)	SN400B	327	456	27
Beam web (6 mm)	SN400B	376	472	29
Column (9 mm)	BCR295	434	518	19
Gusset plate (4.5 mm)	SS400	204	291	54

The standard through-diaphragm detail (Nakashima et al. 2000) was used to achieve rigid beam-to-column connections. The gusset plate at the bracing connections was detailed according to the elliptical clearance rule proposed by Lehman et al. (2008). The gusset plate at the top end of the braces, between the braces and beam, was further provided with a pair of vertical stiffener plates to control interaction between the two braces. The columns were rigidly connected to large base beams which were, in turn, fixed to the shake table. At the top side of the specimen, each end of the beam was connected to the test-bed system described later. The specimen was laterally braced along the columns and beam at the discrete locations indicated in Fig. 1.

Compliance to Code Requirements

The tubular braces had a width-to-thickness ratio of b/t = 19.4 and member slenderness ratio of L/r = 103, where the member length L is the diagonal distance between beam-to-column nodes. The b/t ratio slightly violates the seismically compact limit of $0.64(E/F_y)^{1/2}$ = 18.5,while the L/r ratio is within the limit of $4(E/F_y)^{1/2}$ = 116 specified for Special CBFs per the *AISC Seismic Provisions*. The member slenderness ratio based on the length L measured between the elliptical fold lines was L/r = 91. The nominal strength based on the *AISC Specification for Structural Steel Buildings* (AISC 2005) was $0.658^{(Fe/Fy)}F_y$ = 143 kN for L/r = 103 and 161 kN for L/r = 91, using F_y = 245 kN.

Per the *AISC Seismic Provisions*, the bracing connections were detailed to develop the required tensile and compressive strength of the tubular braces. The elliptical clearance rule proposed by Lehman et al. (2008) was adopted for sizing the gusset plates.

Test Bed

The specimens were subjected to ground shaking at the E-Defense facility using the "test bed" system developed by Takeuchi et al. (2008). The test beds are multi-purpose devices that supply horizontal mass to the specimen while adding minimal lateral force resistance. As shown in Fig. 2, a pair of test beds was used for this program, one at each side of the loading plane of the specimen. At the base, the test bed was connected to the shaking table through a set of linear bearings which produced minimal friction (friction coefficient was estimated as 0.0033 by Takeuchi et al. (2008)) for motion in the loading plane, and which restrained out-of-plane motion. At the top, the test bed was connected to each end of the specimen, with a load cell placed in the load path. The two test beds and additional test rigs supplied a combined 69.4 ton mass to the

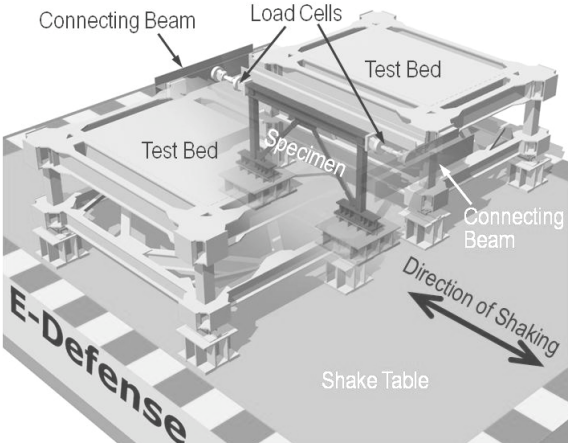

Figure 2. Specimen and test-bed system

specimen. The test bed was also used to anchor the out-of-plane bracing indicated in Fig. 1. Consequently, the test beds were arranged to permit planar motion of the planar specimen. The test-bed system has been used previously in a similar fashion for two experimental programs (Takeuchi et al. 2008; Ma et al. 2010).

Test Procedure

The East-West component of the JR Takatori motion (Nakamura et al. 1996) was introduced in the direction parallel to the primary plane of the specimen. The JR Takatori motion is a strong motion record from the 1995 Kobe earthquake, measured immediately adjacent to the fault. The EW component is characterized by a peak acceleration of 6.6 m/s^2 and strong velocity pulses. Fig. 3(a) shows the acceleration history of the motion while Fig. 3(b) shows the response acceleration spectrum obtained for 2% of critical damping (h = 0.02). The shake table tests were conducted by introducing the Takatori EW motion seven times, with target amplification level increasing from 10, 12, 14, 28, 28 (second time), to 42, and finally 70%. Fig. 3(b) also shows the acceleration response spectra constructed from the measured table motion assuming h = 0.02. The targeted amplification was achieved over a wide range of periods between 0.1 and 3 seconds, although the 70% motion exceeded the target in the short period range between 0.1 and 0.5 sec.

The load cells mentioned above were used to evaluate the story shear. Displacement transducers were used to monitor the story drift and the out-of-plane deformation of the beam and braces. The force distributions in the beam, columns, and braces were evaluated based on strain gauges placed at selected sections of the beam and columns. Elongation of the braces was measured based on the relative distance between the ends of tubular brace. Data was collected at a rate of 1,000 Hz. All data was passed through a low-pass filter to eliminate frequency content above 50 Hz.

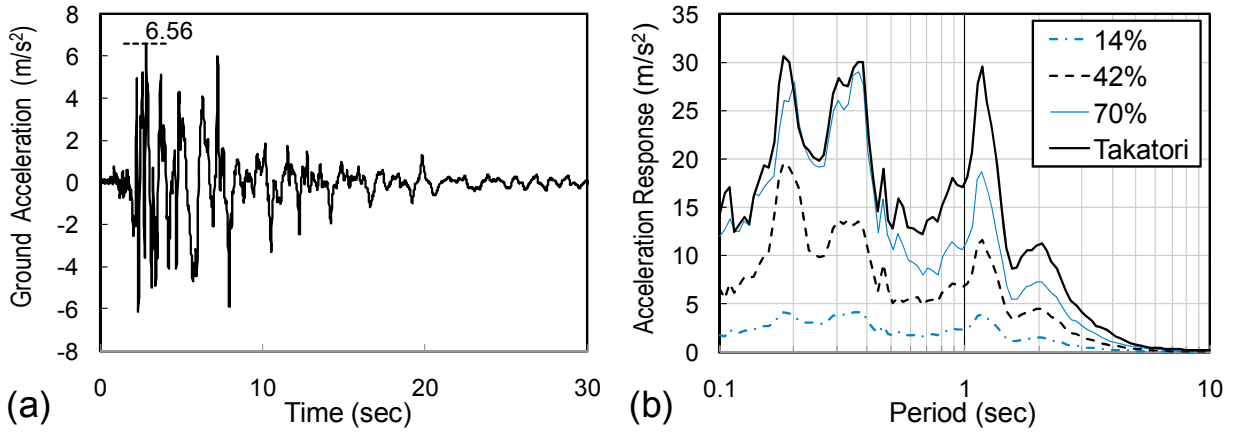

Figure 3. Ground motion: (a) JR Takatori EW acceleration history; and (b) response spectra for h = 0.02.

RESULTS

Global Behavior

Based on unidirectional white noise excitation, the natural vibration period was determined as 0.21 sec. The vibration period of the specimens was equivalent to that of a single or two story building.

Fig. 4 shows the story shear versus story drift response measured for the three tests using

the 28, 42, and 70% Takatori EW motions. The figure indicates that the structure remained elastic during the 28% motion, but some inelasticity occurred during the 42% motion. The response from the 70% motion plotted in Fig. 4(c) indicates that the stiffness of the system suddenly reduced after experiencing two and one-half drift cycles of -0.015 to +0.01 rad. During these drift cycles, the strength of the system dipped notably at rather small drifts.

Brace Performance

Fig. 5 shows the axial force (tension taken as positive) versus elongation relationship measured from a brace for the 28, 42, and 70% motions. The horizontal lines indicate the tensile yield strength and compressive strength of the brace member. The compressive strength was computed based on the measured yield strength, the AISC design equation, and a slenderness ratio L/r = 91. It is noted that beyond the deformation range where the beam yielded near the connections to the columns, the accuracy of brace force estimation based on strain gauge measurements is eroded. Nonetheless, Fig. 5 clearly illustrates the key characteristics of buckling

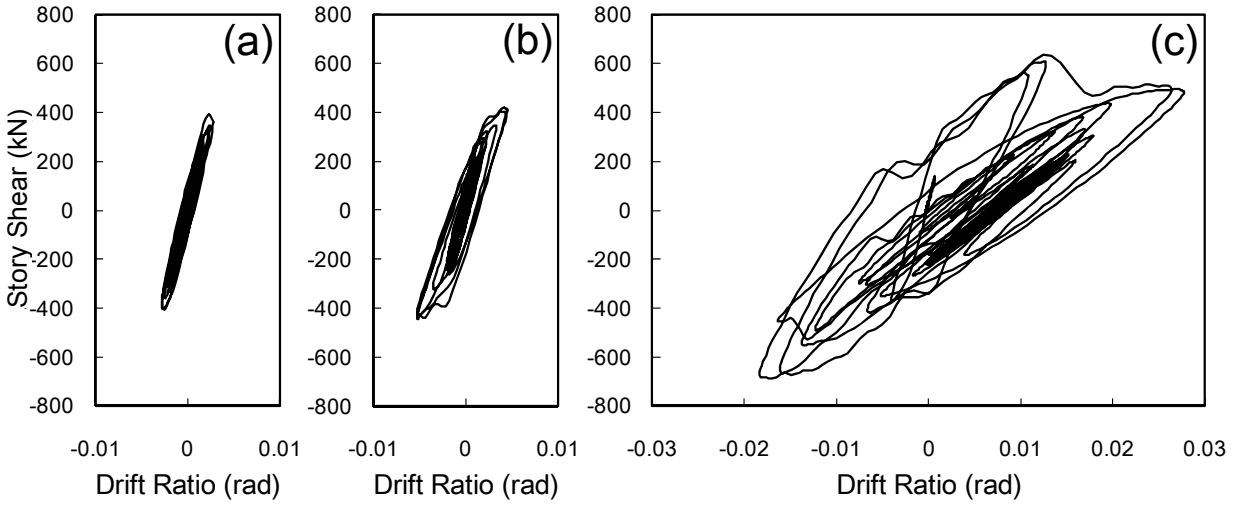

Figure. 4 Frame response at: (a) 28%; (b) 42%; and (c) 70% motion.

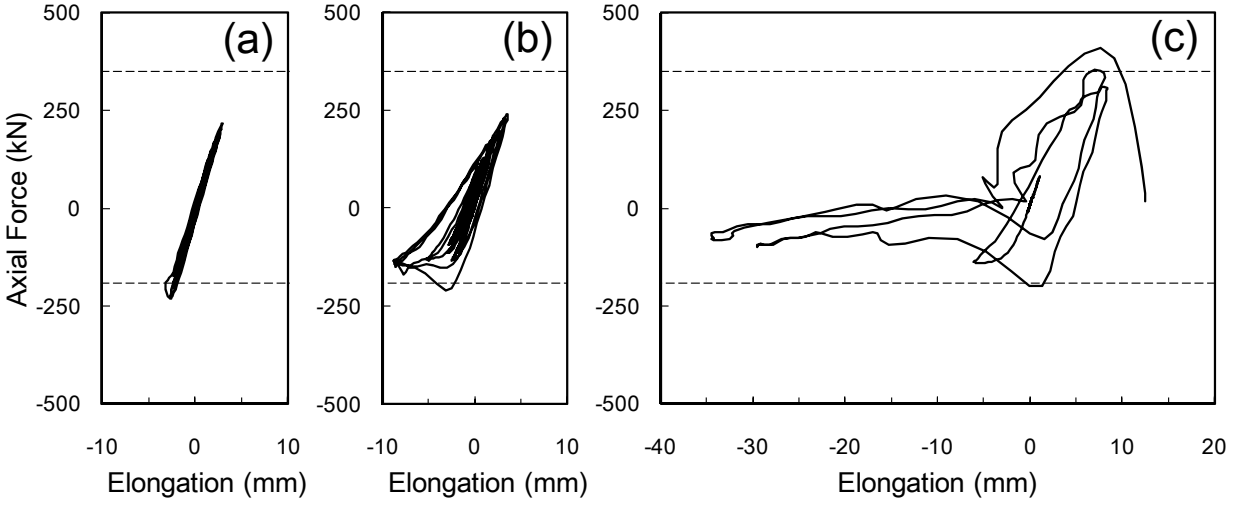

Figure. 5 Brace axial response at: (a) 28%; (b) 42%; and (c) 70% motion.

brace behavior. While the compressive force exceeded the estimated buckling strength during the 28% motion, no sign of instability was observed at this stage. A clear indication of buckling and degradation in compressive strength was observed from the 42% motion. No sign of residual deformation was visible in the brace member after the 42% motion test. During the 70% motion, the brace shown in Fig. 5(c) fractured after experiencing two and one-half loading cycles of -30 to 10 mm (1% contraction and 0.25% extension). The other brace fractured similarly shortly afterwards. The drift ratio of the specimen was smaller than 0.02 rad. when the fracture occurred. After both braces fractured, the underlying moment frame developed a story drift ratio approaching 0.03 rad.

Fig. 6 shows photographs of the specimen taken after the 70% motion test was completed. Fig. 6(a) shows the fractured brace. Both braces fractured near mid-length of the member. Indication of local buckling and ductile tearing was evident near the fractured section. Figs. 6(b) and (c) demonstrate that the gusset plates, either at the column base or at the middle of the beam, folded nicely along the elliptical clearance. No discernable damage was observed at the bracing connections, suggesting that the performance of the bracing connections was excellent.

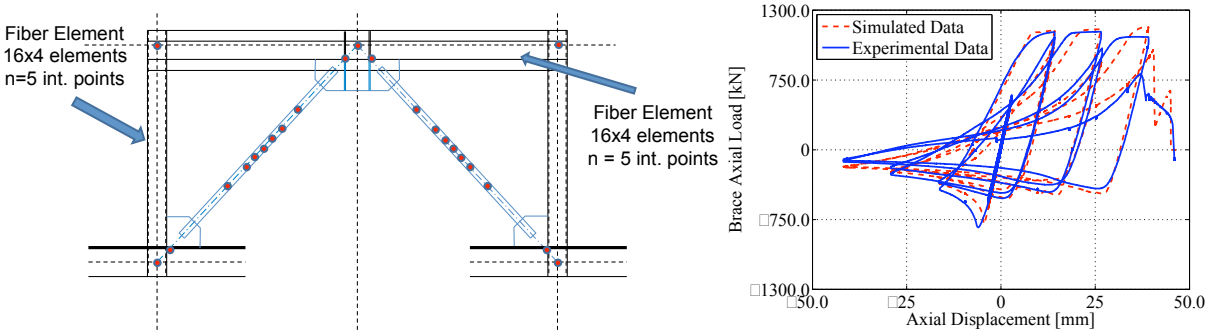

Figure. 6 Specimen after 70% motion: (a) gusset plate at the column base; (b) gusset plate at the beam; and (c) fractured brace.

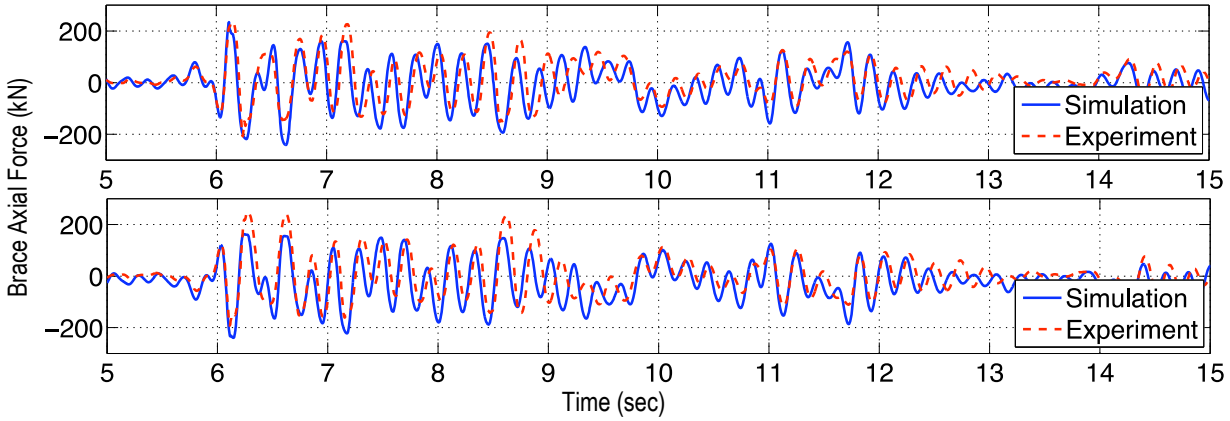
NUMERICAL SIMULATION

A numerical model of the specimen was constructed in the OpenSees platform (Mazzoni et al. 2009) using fiber elements. Figure 7a illustrates the analytical model of the test specimen. The geometry of the test specimen was modeled based on centerline dimensions, i.e. panel zones were not considered since they behaved elastically during the shaking table tests. To simulate inertia forces a leaning column was used that was connected with an axially rigid rod to the frame model. Since large P-Delta effects were not applied to the test specimen due to the sliding masses, only small P-delta effects were considered in the analysis. Corotational transformation was utilized. Steel beams and columns were modeled with fiber elements (16x4 elements) with five integration points along the length of each steel component. The brace members of the test specimen were modeled with a center node and an application of initial imperfection in accordance with the techniques summarized in Uriz et al. (2008) and Chen and Mahin (2008) in order to simulate overall buckling of the brace. The integration points along the brace element were based on Gauss-Lobatto quadrature rule (two integration points at the element ends). The material properties used for all steel components of the test specimen were

the ones previously summarized in Table 1. Three percent mass proportional damping was assumed at the first mode period of the test frame (T_1=0.20sec) since it was a single degree of freedom system. The 3% damping is justified based on the fact that friction damping due to sliding of the seismic masses was not simulated in the analytical model. Cumulative damage effects from phase to phase were considered in the numerical simulation since the scaled Takatori motions were analyzed sequentially. Further, the analytical model of the test frame incorporated fracture of the steel braces that can initiate according to a rain-flow-counting rule. The fracture model was calibrated against previous quasi-static experimental data on tubular steel braces by Fell et al. (2009). These steel brace components had similar slenderness ratios (L/r_y = 80, D/t =16) with the steel braces of the test specimen. An example of calibration of the fatigue model is shown in Figure 7b, including modeling of fracture at the center of the brace. a



(a) Test specimen (b) fatigue model calibration

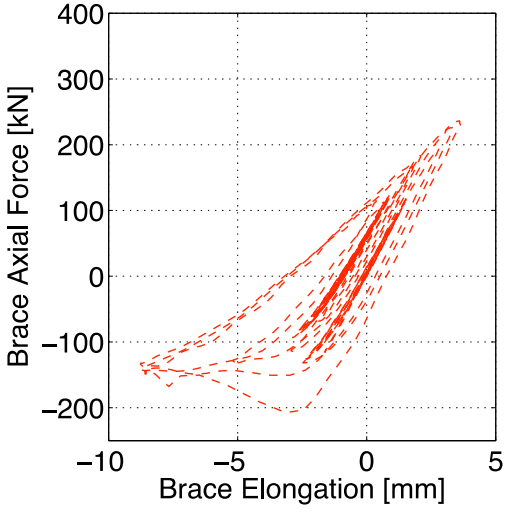


Figure 7. Modeling scheme

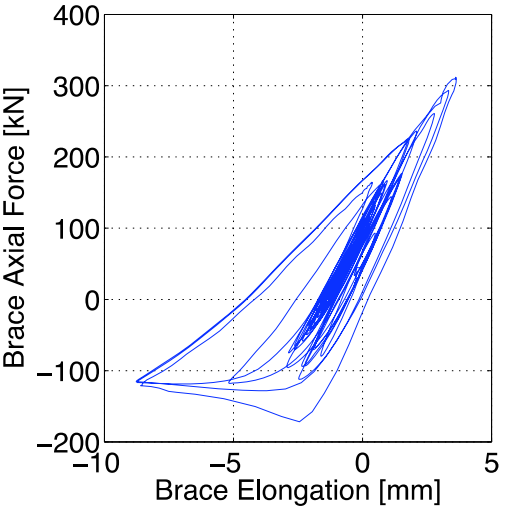
Figure 8a shows the axial force distribution history of the two braces of the test specimen for the 42% JR Takatori record. The force distribution of the braces is predicted fairly accurately prior to fracture. The same can be seen from Figures 8b and 8c that compare the recorded simulated brace force versus elongation with the simulated one for the same ground motion intensity. The base shear versus story drift ratio for the 42% motion is shown is Figure 8d. The base shear is normalized with respect to the total seismic weight of the test specimen. The figure superimposing the simulated response over the experimental response indicates that the global response is traced fairly accurately, indicating that the numerical model of the test specimen is reliable.



During the 70% motion, the two braces fractured. This resulted to a loss of lateral stiffness of the test specimen. However, the numerical model is able to simulate the loss of stiffness due to fracture of the braces since fracture is accurately traced for both braces. This can be seen in Figure 8e that shows a comparison of the simulated versus recorded normalized base shear versus story drift ratio of the test specimen. The model was able to predict the post-fracture behavior of the frame after the occurrence of brace fracture. This can be seen in Figure 9 that shows the base shear history of the test specimen as predicted by the numerical model compared to the experimental data. The phase difference between simulated and experimental results after the first 9 seconds of the ground motion is attributed to the fact that the predicted fracture time of the second brace occurred about 2 seconds earlier than in the experiment as can be seen from the same figure.

CONCLUSIONS

A series of large-scale shake table tests were conducted. The specimen was a 70%-scale, single-bay, single-story moment resisting frame with a pair of square tube braces placed in a chevron arrangement. The braces had a width-to-thickness ratio of 19.4 and member slenderness ratio of 103, where the brace length was taken as the diagonal distance between beam-to-column nodes. The width-to-thickness ratio was slightly greater than the seismically compact limit per the AISC Seismic Provisions. The gusset plates connecting the brace to the framing elements were provided with an elliptical clearance to permit free out-of-plane rotation. The specimen was subjected to a number of unidirectional ground motions with increasing intensity. During the final excitation, both braces experienced large inelastic loading cycles, and subsequently fractured in the middle at a drift ratio smaller than 0.02 rad. After the brace fractured, the underlying moment frame developed a story drift approaching 0.03 rad. After all tests were completed, no discernable damage was observed at the bracing connections.

A numerical model was constructed using fiber elements and incorporating fracture that can initiate according to a rain-flow-count rule calibrated against previous experimental data. The story drift, story shear, brace elongation, and force distribution recorded from the shake table tests was traced fairly accurately by the numerical model. The model was able to predict the occurrence of brace fracture and subsequent behavior of the frame.

ABSTRACT

Although conventional earthquake-resisting structural systems provide adequate life safety when properly designed, they rely on significant structural damage to dissipate the seismic energy. This structural damage and the residual drift that may result from the inelastic response can make a building difficult, if not financially unreasonable, to repair after an earthquake. As a result, development of systems that return to their initial position (i.e., "self-center") following an earthquake and minimize structural damage is a crucial need. This research aims to address this need by creating an innovative self-centering brace for advanced seismic performance.

In the present study, the seismic behavior and performance of self-centering buckling-restrained braces (SC-BRBs) is investigated. A SC-BRB consists of a typical BRB component, which provides energy dissipation, and pre-tensioned superelastic NiTi shape memory alloy (SMA) rods, which provide self-centering. The SMA rods are attached to the BRB portion of the brace using a set of concentric tubes and free-floating end plates that cause the SMA rods to elongate when the brace is in both tension and compression. Half-scale SC-BRBs are designed and fabricated for experimental validation. To characterize hysteretic response, the braces are subjected to a cyclic loading protocol adapted from the AISC Seismic Provisions for Structural Steel Buildings. The results of the experiments are used to validate a SC-BRB numerical model, which is used to conduct further parametric studies of SC-BRB behavior and to perform system studies of concentrically-braced frames with SC-BRBs.

INTRODUCTION

Although conventional earthquake-resisting structural systems, such as moment-resisting frames (MRFs) and concentrically-braced frames (CBFs), are generally deemed to provide adequate seismic safety, they depend on significant structural damage to survive strong ground shaking. Thus, protection against economic loss is not guaranteed owing to repair costs and associated business downtime. Distributed inelastic response in structural members and residual drift are two critical issues that can make a building difficult, if not financially unreasonable, to repair after an earthquake. As a result, development of systems that return to their initial position (i.e., self-center) following an earthquake and minimize structural damage is needed.

This research aims to address this need through investigation of an innovative self-centering brace for advanced seismic performance.

BACKGROUND

Two important topics provide context to the development of the present research: the buckling-restrained brace (BRB) and structural self-centering (SC).

Buckling-Restrained Braces: The BRB is a robust structural component with excellent hysteretic behavior. In the last few years, steel CBFs with BRBs, commonly called buckling-restrained braced frames (BRBFs), have been used extensively in the U.S. since the first application in the Plant and Environmental Sciences Building on the campus of the University of California at Davis (Clark et al. 2000). A BRB has two basic components: a steel core element that carries the entire brace axial force, and a restraining exterior element that prevents the core from buckling in compression allowing it to yield in both tension and compression. The restraining element is typically a concrete filled steel tube, and the steel core is not bonded to the concrete. BRBs have stable, predictable hysteretic behavior and provide significant energy dissipation and large ductility capacity.

BRBFs have been adopted rapidly since they offer significantly better performance than traditional steel CBFs, they are easier to design, and there is little to no additional effort required in construction. Although BRBFs address one of the critical requirements of high performance earthquake-resistant structural systems (i.e., they offer robust performance and concentrate structural damage in distinct locations that can be easily accessed for repair while preventing structural damage elsewhere), they are still susceptible to residual drift. Thus, although the BRB concept offers advantages over traditional steel braces, the lack of self-centering is still a shortcoming.

Self-Centering Systems: Self-centering (SC) earthquake-resisting structural systems, which have the ability to dissipate energy and also return to their original position after ground shaking, are a relatively new and promising concept for seismic design. SC system approaches can be grouped broadly into three categories: 1) systems with horizontal post-tensioned (PT) steel elements (bars or strands) that develop flexural gap opening at specified connections when lateral load is applied; 2) rocking systems, with or without vertical post-tensioned steel elements, that allow uplift at the base of the structure when lateral load is applied; and 3) braced-frame systems with SC braces that return to their initial length after undergoing shortening and elongation due to lateral load.

SC braces offer a significant advantage over the first two classes of SC systems since they lack the challenges associated with connection to the gravity system and transfer of inertial forces. SC braces can be substituted for conventional braces and the remainder of the braced frame system does not need to change. Recently, a SC brace was developed using PT high-strain-capacity aramid-fiber tendons to clamp the brace together (Christopoulos et al. 2008b, Tremblay et al. 2008). Inner and outer steel tubes are configured such that self-centering forces are produced when both tensile and compressive deformations are imposed on the brace. Energy dissipation is

introduced using friction pads clamped together with tensioned bolts. Several studies (e.g., Dolce and Cardone 2006, Zhu and Zhang 2008) have also considered SC braces using shape memory alloys (SMA) elements, both to create the self-centering force and to dissipate energy.

SMAs possess unique characteristics that are particularly suited to application in high-performance earthquake-resisting systems. The distinctive SMA characteristic that is most valuable for such applications is typically called "superelasticity" referring to the fact that very large strains (up to 10%) can be recovered elastically upon the removal of load. The superelastic region exhibits a stress plateau after a phase transition from austenite to martensite, which researchers have noted could be used to limit the forces transferred to other parts of the structure and concentrate deformation in the SMA (McCormick et al. 2007). As described below, this research takes advantage of the superelasticity of SMA to develop a brace with deformation capacity well beyond what even a large earthquake could require.

SELF-CENTERING BUCKLING-RESTRAINED BRACE BEHAVIOR

The self-centering buckling restrained brace (SC-BRB), shown in Figure 1, uses the widely accepted BRB concept as the energy dissipating mechanism and pre-tensioned NiTi SMA rods to create the self-centering force. The SC-BRB is a brace that can be substituted for a conventional steel brace or a buckling-restrained brace without changing the rest of the structure. It does not require any unusual detailing, or construction methods, but instead could be easily implemented using current design and construction practice. Unlike PT moment frame or rocking braced frame systems, there are no additional challenges associated with accommodating connection gap-opening or rocking displacement and interfacing the lateral-load-resisting frames with the gravity system and the rigid floor diaphragms.

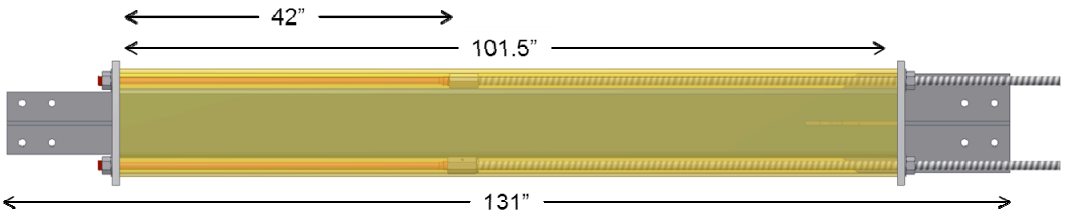

Figure 1 – SC-BRB with dimensions for a half-scale specimen

SC-BRB Components: The SC-BRB configuration is shown in Figure 2 and consists of the following key components:

1) The BRB core is a continuous steel element from the bolted connection at one end to the bolted connection at the other end. As the brace deforms, the core yields in tension or compression and dissipates energy.
2) The inner tube is nominally unstressed and provides buckling restraint for the BRB core. Grout is placed between the inner tube and the BRB steel core, with a bond break and small gap provided between the core and the grout to allow for uninhibited movement of the steel core.

3) The middle tube is welded to the left end of the BRB core and remains fixed with respect to the left end bolted connection.
4) The outer tube is welded to the right end of the BRB core and remains fixed with respect to the right end bolted connection.
5) Anchorage plates at each end have cross shaped slots through which the BRB core passes. The anchorage plates are not connected to the BRB core or to the tubes.
6) SMA rods are post-tensioned, clamping the anchorage plates against the middle and outer tubes and creating an initial compression in these two tubes.

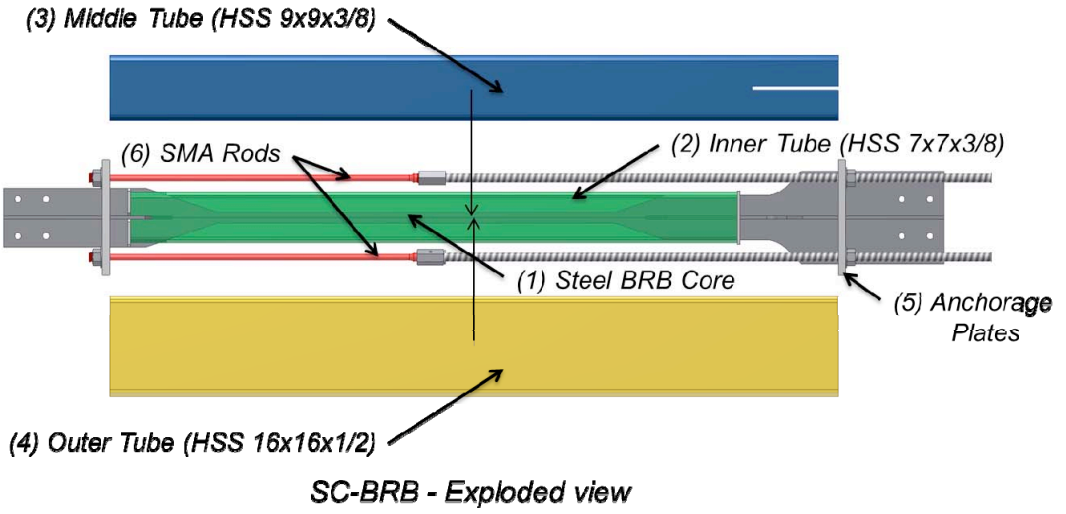

Figure 2 – SC-BRB components

The middle and outer tubes act as struts that push the anchorage plates apart as the brace deforms. As shown in Figure 3, both compression and tension brace forces cause the anchorage plates to move apart, resulting in additional SMA elongation and increasing self-centering force. The BRB core dissipates energy as it yields in tension and compression. The SMA pretension is selected to overcome the BRB yield force, including strain hardening, and thus produces self-centering.

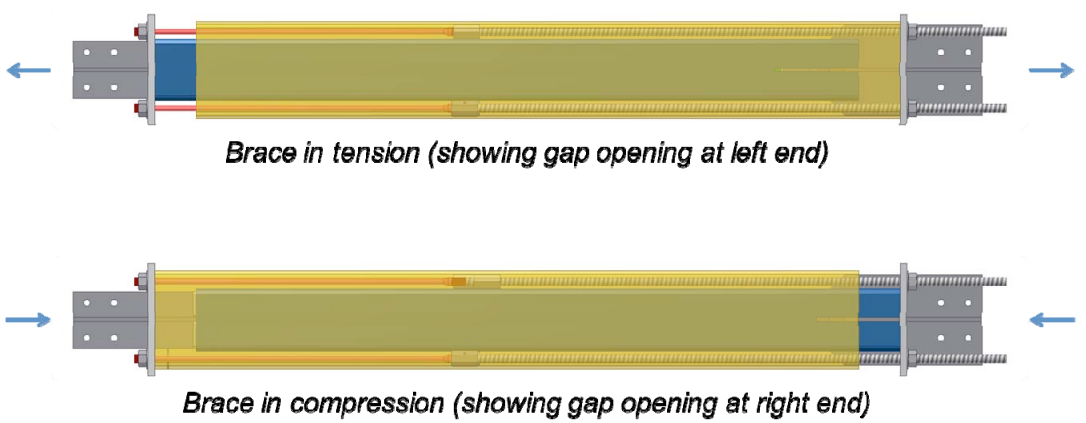

Figure 3 - SC-BRB functionality

SC-BRB DESIGN AND NUMERICAL MODELING

Preliminary analyses were conducted to examine the validity of the proposed brace. A prototype building was chosen to match a five-story BRBF design example (SEAOC/ICC 2006). Proportioning and detailing were carried out using a preliminary capacity design methodology, which will be examined and refined as the research continues. The initial design and detailing suggest that the SC-BRB can be reasonably proportioned and constructed for the design loads and geometry of this prototype building.

A numerical model was created in OpenSees (Mazzoni et al. 2009) to predict the response of the SC-BRB that was designed for the prototype building described above. The model uses gap elements to represent the contact between the tubes and the anchorage plates. The model is assembled in stages to allow for the pretensioning of the SMA (Figure 4).

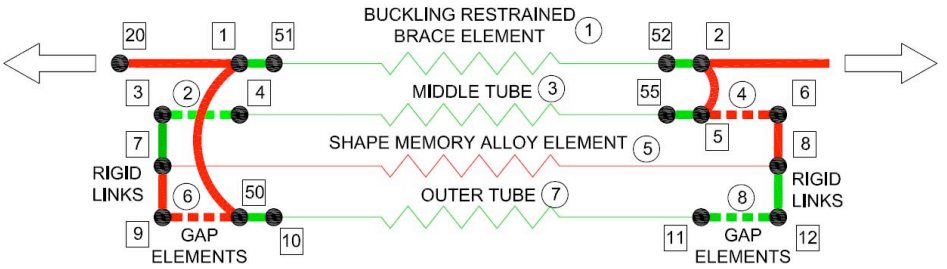

Figure 4 - Preliminary numerical model of the SC-BRB

The results of the preliminary analysis are shown in Figure 5 and Figure 6. Figure 5 illustrates the contribution of the BRB and SMA elements individually, whereas Figure 6 shows the total hysteretic response of the brace. At the end of the loading history, the brace is predicted to experience only a trivial amount of residual deformation.

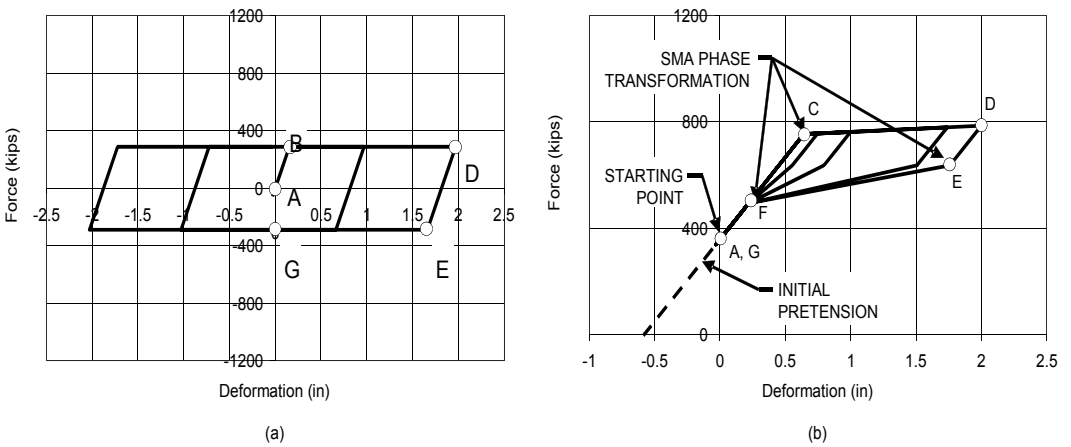

Figure 5 – Numerical simulation results demonstrating component response: (a) BRB; (b) SMA

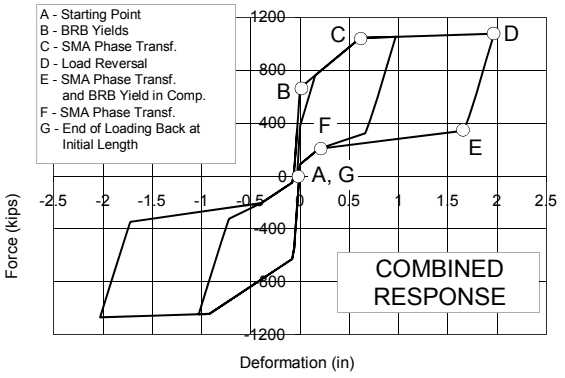

Figure 6 – Total SC-BRB response from numerical simulation

MATERIAL TESTING

A series of quasi-static cyclic tensile tests was performed on four sample specimens of NiTi SMA to measure the following mechanical properties (ASTM International 2008) of the bars that will be used in the SC-BRB:

1) Lower Plateau Strength – the value of stress at 2.5% strain during unloading
2) Upper Plateau Strength – the value of stress at 3% strain during initial loading
3) Residual Elongation – difference between strain at a stress of 7.0 MPa during loading and unloading
4) Uniform Elongation – elongation when maximum force is reached just before necking or fracture

Prior to testing, each bar was heat treated to achieve superelastic behavior in the SMA. The two variables studied in these tests were the length of time of the heat treatment and sequence of machining and heat treatment. The details of machining and heat treatment for each specimen are summarized below. All tests were performed using a 600-kip MTS uniaxial hydraulic testing frame.

Table 1 - Summary of SMA specimen heat treatment

Specimen	Time (min.)	Temp (°C)	Before/After Machining
1	30	375	Before
2	30 + 30	375	Before
3	90	375	After
4	60	375	After

Specimen Fabrication: The test specimens were proportioned according to ASTM E8 (ASTM International 2009), and had identical gage lengths and diameters. Specimens 1 and 2 were heat treated prior to machining, and specimens 3 and 4 were

heat treated after machining. Additionally, specimens 3 and 4 were threaded after heat treatment to ensure that the heat would not affect the thread dimensions. The fabrication details of each specimen are summarized in Table 1.

Loading Protocol: The specimens were tested using increasing strain cycles of 0.5%, 1.0%, 2.0%, 3.0%, 4.0%, 5.0%, and 6.0%. Figure 7 shows the loading protocol used for the test, a modified version of the testing protocol used by DesRoches et al. (2004).

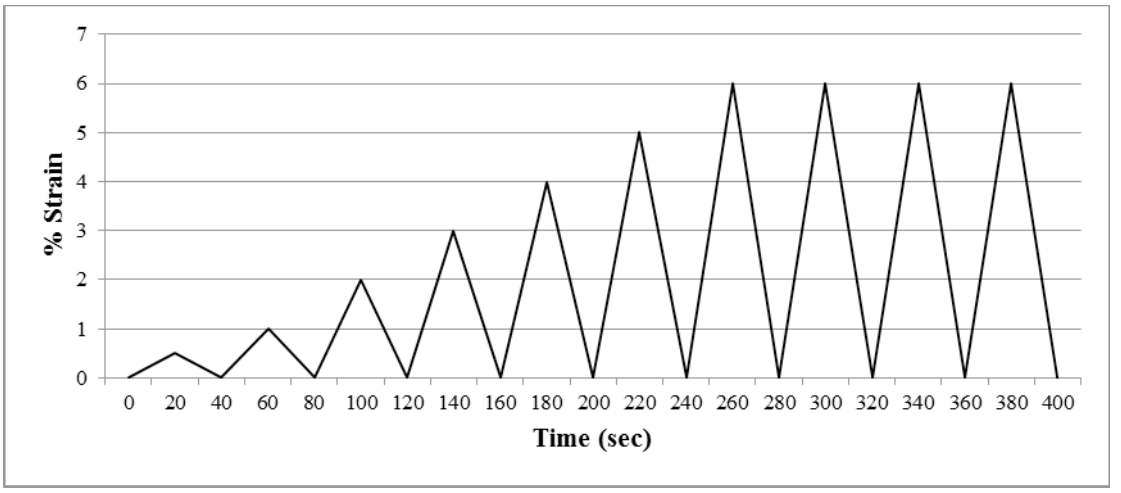

Figure 7 - Loading protocol used for cyclic testing of NiTi shape memory alloy bars

Tensile Test Results: The stress-strain curves from each specimen are presented in Figure 8 through Figure 11. Figure 8 shows that Specimen #1 had much larger residual deformation than representative tests from prior SMA research (Desroches et al. 2004) with a residual strain of approximately 3.5% after the fourth 6% cycle. Further investigation into the heat treatment process was performed by the manufacturer of the bar, and it was determined that the heat treatment performed by the manufacturer was insufficient. Therefore, the stock material for the second specimen was heat treated for an additional 30 minutes at 375° C prior to machining.

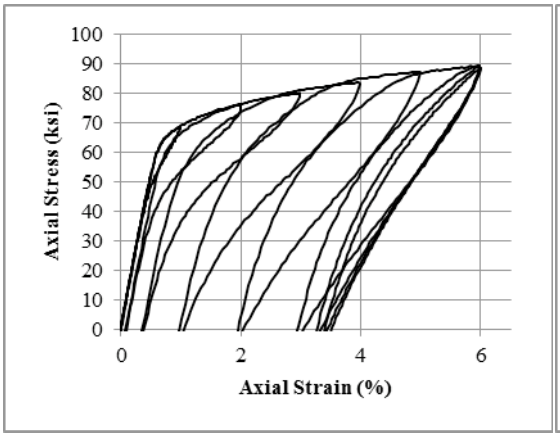

Figure 8 –Stress-strain curve for 0.75 in. diameter SMA bar (Specimen #1)

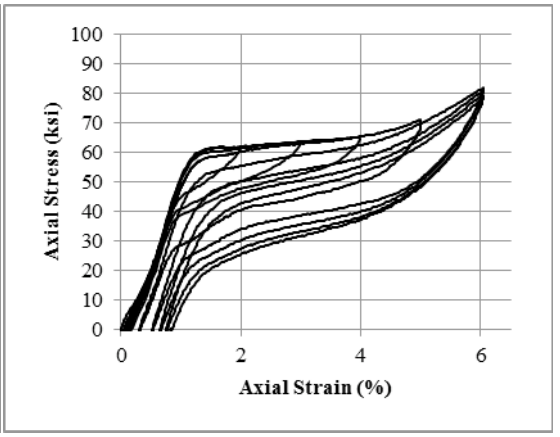

Figure 9 –Stress-strain curve for 0.75 in. diameter SMA bar (Specimen #2)

The initial cycles of testing on Specimen #2 show very little residual strain in the bar (Figure 9). After the 4% cycle, the residual elongation was only 0.20%, much lower than the 1.06% seen at the same point in the testing of Specimen #1. After the final 6% cycle, the residual elongation was 0.87%, a value much closer to reported values from prior studies (Desroches et al. 2004). There was a notable increase in the residual elongation after unloading the bar from the 5% cycle, and there was a drop in the upper plateau strength in subsequent cycles.

The initial cycles of testing on Specimen #3 show very little residual strain in the bar (Figure 10). After the 4% cycle, the residual elongation was only 0.01%, much lower than the 0.20% seen at the same point in the testing of Specimen #2. After the final 6% cycle, the residual elongation was 0.29%, a value less than that measured in the testing of Specimen #2. There was a notable increase in the residual elongation after unloading the bar from the 5% cycle, and there was a drop in the upper plateau strength in subsequent cycles. The upper and lower plateau strengths for Specimen #3 were considerably lower than those for Specimen #2.

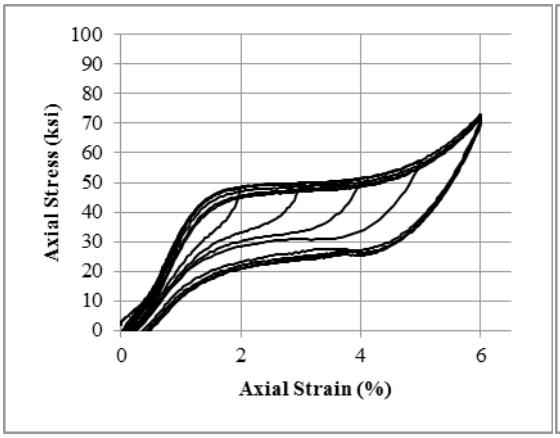

Figure 10 –Stress-strain curve for 0.75 in. diameter SMA bar (Specimen #3)

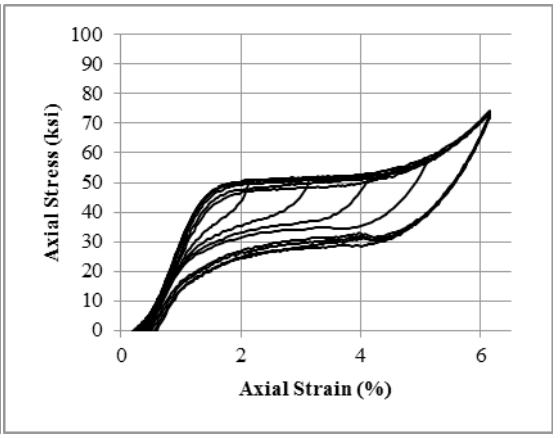

Figure 11 –Stress-strain curve for 0.75 in. diameter SMA bar (Specimen #4)

After the 4% cycle for Specimen #4 (Figure 11), the residual elongation was only 0.10%, which is higher than the 0.014% seen at the same point in the testing of Specimen #3, but lower than the 0.18% seen at the same point in the testing of Specimen #2. After the final 6% cycle, the residual elongation was 0.35%, a value that was the smallest of the four tests. Again, there was a notable increase in the residual elongation after unloading the bar from the 5% cycle, as well as a drop in the upper plateau strength in subsequent cycles. The upper and lower plateau strengths for Specimen #4 are greater than those for Specimen #3, but still considerably lower than those for Specimen #2. Table 2 summarizes the mechanical properties of all specimens tested.

Table 2 – Mechanical properties of SMA bars

Specimen	1	2	3	4
Lower Plateau Strength (ksi)	66.7	52.5	36.9	38.6
Upper Plateau Strength (ksi)	81.1	63.5	49.5	51.1
Residual Elongation (%)	6.26	0.87	0.54	0.35
Uniform Elongation (%)	9.44	6.99	6.87	9.01

CONCLUSIONS

Heat treating the bars for 60 minutes after machining resulted in the smallest amount of residual elongation. Additionally, machining the bars prior to heat treatment was easier. Strength decreased as heat treatment time increased. Since the SMA provides self-centering in the SC-BRB, control of residual elongation is very important. As a result, it is preferable to reduce the residual elongation even if it means that strength is reduced slightly. The results of the tensile tests also show that the superelastic SMA bars exhibit very little residual elongation when the maximum strain is 5% or lower. Therefore, the length of the bars in the final brace design was chosen to limit the overall strain in the SMA to less than 5%.

CONTINUING RESEARCH

Half-scale SC-BRB specimens will be tested at the University of Illinois using a 600-kip MTS uniaxial servo-controlled testing frame. The proposed loading protocol shown in Figure 12 is a modified version of the qualifying cyclic tests of BRBs given in the AISC *Seismic Provisions* (AISC 2005).

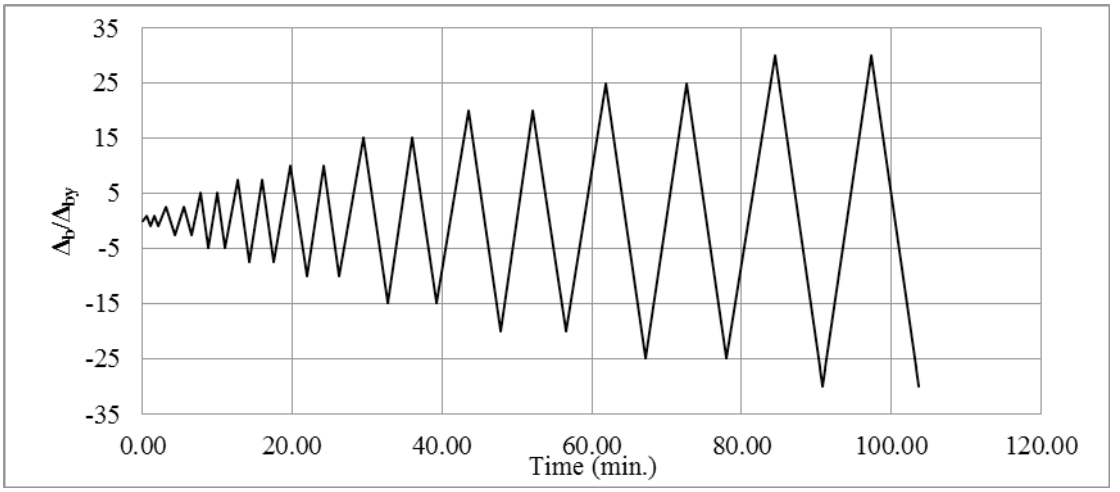

Figure 12 – Planned testing protocol for SC-BRBs

The tests will measure the performance of each brace and compare the effect of the relative pretension force to the brace core capacity. Data collected from the experimental studies will be used to validate and refine the brace numerical model,

which will be used for nonlinear dynamic system analyses. Ultimately, the results from the experimental and numerical studies will be used to develop design, detailing, and modeling guidelines for self-centering buckling-restrained braced frames.

ACKNOWLEDGEMENTS

This study is supported by the National Science Foundation through the Hazard Mitigation and Structural Engineering Program (Grant No. CMMI-0856555). The authors would like to thank SAES Smart Materials for advice on machining and heat treating the SMA, and the Newmark Structural Engineering Laboratory staff for assistance with fabrication and testing. Opinions, findings, and conclusions expressed in this paper are those of the authors and do not necessarily reflect the views of those acknowledged here.

A Celebration of Structure as Architecture - The Cathedral of Christ the Light

Mark Sarkisian[1], Peter Lee[2], Eric Long[2]

[1] PE, SE, Director, Skidmore Owings & Merrill LLP, San Francisco, CA
[2] PE, SE, Associate Director, Skidmore Owings & Merrill LLP, San Francisco, CA

ABSTRACT

The Cathedral of Christ the Light is an artistic celebration of modest and common building materials used to transform a site on the north end of Lake Merritt in Oakland California. The structure uses the most advanced geometric and scientific approaches to created a building that satisfied the Diocese of Oakland's need to construct a new cathedral with the service life of at least 300 years; a request that was not unexpected considering the venerable cathedrals of the Catholic Church that have survived for centuries. The project site exists only 4.6 km from the Hayward Fault, one of the most active seismic faults in the world, making the request substantially more challenging. Ground motions expected at the site could result in an earthquake of magnitude 7.0 or more on the Richter Scale.

The approach to design embodies lightness (both visually and structurally) and luminosity, hence its name, The Cathedral of Christ the Light. The structure is defined by sacred geometries and designed for lightness by using seismic isolation to manage ground motions and reduce the demand on the superstructure during an earthquake. It is the light that transforms the structure and its material throughout the day creating what the cathedral's lead architect and SOM Design Partner Craig Hartman calls a space of "ephemeral lightness" with a "primordial connection to the earth." In developing the design, Hartman thought that "the cathedral must be in the architectural language of our time. The Catholic Church has historically applied the most advanced architectural thinking to create architecture that illuminates, inspires and ennobles the human spirit."

The cathedral incorporates a highly innovative use of natural, yet ordinary, materials with an ethos of sustainability. Glued-laminated timber from sustainable forests, exposed reinforced concrete using replacement slag and fly ash, recycled high-strength steel, aluminum, and glass create the symbolic form.

The 1,350-seat cathedral, located on the northern edge of Lake Merritt, is the centerpiece

Figure 1. The Cathedral of Christ the Light

of a 224,000-square-foot complex with a complement of facilities that includes a mausoleum, a conference center, administrative offices, bishop and clergy residences, a bookstore, a café, and community-serving ministries. A landscaped public plaza, accessible from all directions, firmly links the center with the city's commercial downtown and surrounding neighborhoods. As a whole, the structure honors its religious and civic obligations to both the Catholic Diocese and the city of Oakland.

SACRED GEOMETRY

Vesica Piscis, or "vessel of the fish," is important to early Christian symbolism and the language of sacred geometry. Formed of two interpenetrating circles of the same diameter, the shape represents the fusion and reconciliation of opposites. These interpenetrating circles are related to one another through the square roots of 2, 3, and 5, the first three digits of the Fibonacci Sequence (other than unity). The height and width of the shape resulting from the intersecting circles are related by the square root of 3. Thus, the height or the longitudinal length of the Cathedral is equal to the diameter times the square root of 3 or 1.73205, and the width or the transverse length of the Cathedral is equal to the longitudinal length divided by the square root of 3. The geometric and mathematical applications of the resulting shape are the same as those commonly occurring in nature and in the order of the universe itself.

The vesica piscis conceived in plan is translated three dimensionally into the Cathedral's superstructure. Two intersecting spheres define the interior volume, while creating truncated vesici at the Alpha (beginning and the first letter of the Greek alphabet) and Omega (ending/everlasting and the last letter of the Greek alphabet) Windows. The architecturally exposed reinforced concrete reliquary walls used to create both the inside and outside of the structure are formed by overlapping circles with the same radii, simply offset in plan. The interior spherically-defined volume supported on the inside face of the reliquary wall is enclosed with a conical form supported on the outside face of the reliquary wall. The conical form, if continued to its apex, would close, but is instead truncated symbolically referring to the Cathedral's openness to the sky and, by extension, the heavens.

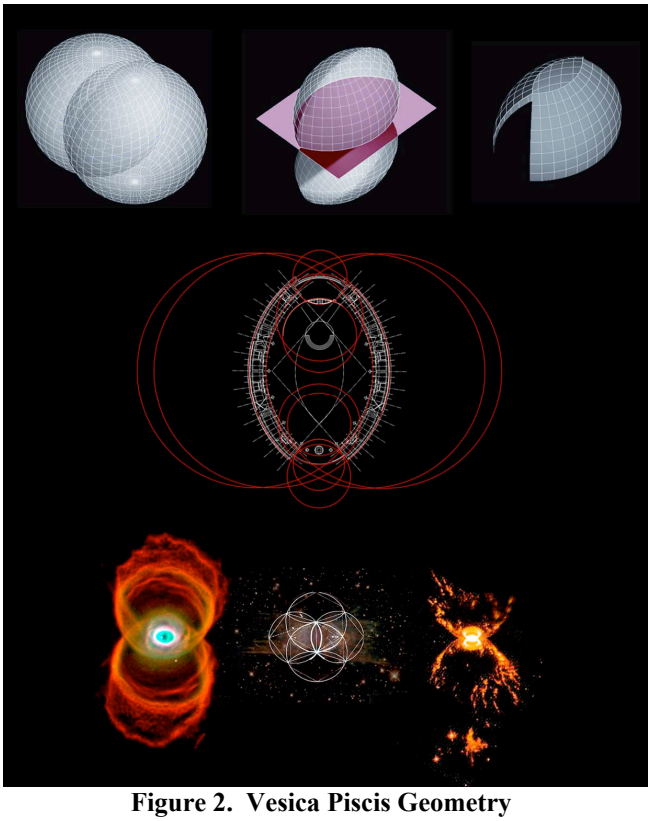

Figure 2. Vesica Piscis Geometry

DELICACY OF STRUCTURE

Drawing on the tradition of light as a scared phenomenon, Design Partner Craig Hartman envisioned the Cathedral to transform throughout the day as changing patterns of light interacted with the structure. In order to accommodate both the design concept and the potential seismic motion caused by nearby faults, a delicate structure was required to enable the play of light within the sanctuary and manage ground motions reduce the demand on the superstore during an earthquake. The main Cathedral superstructure consists of a hybrid structural system composed of reinforced concrete, pre-fabricated glued-laminated wood timber members, high-strength structural steel rods paired with glued-laminated wood compression struts, and a steel friction-pendulum seismic base isolation system.

Curved, tapered glued-laminated wood timber rib members form the framework of the sanctuary superstructure. A total of 724 closely spaced glued-laminated timber "louver" members interconnect and provide lateral bracing for inner rib members. The louvers also serve an integral role in the casting of natural daylight into the Sanctuary space. Louver orientation and widths change over the height of the structure. Louvers are wider with steeper angles near the base and narrower with flatter angles near the top. Light reflects off of the upper louver surfaces and illuminates lower surfaces of neighboring louvers. The size of the louvers directly corresponds to the structural demand in forming the inner shell of the sanctuary. Other than nighttime events, the Cathedral is lit entirely with natural daylight.

Inner curved rib members are 10-3/4 inches wide and vary from 30 inches deep at the base to 19-5/8 inches deep at the top connection to the oculus roof framing. These ribs form a spherical shape in plan and section. Exterior sloping straight glued-laminated outer rib members 10-3/4 inches wide and 15 inches deep form a conical shape in plan and are aligned on a radial geometry with inner ribs. A total of 13 sets of inner and outer vertical glued-laminated ribs form each half of the superstructure. Gravity loads are resisted by a total of 52 vertical glued-laminated wood timber elements.

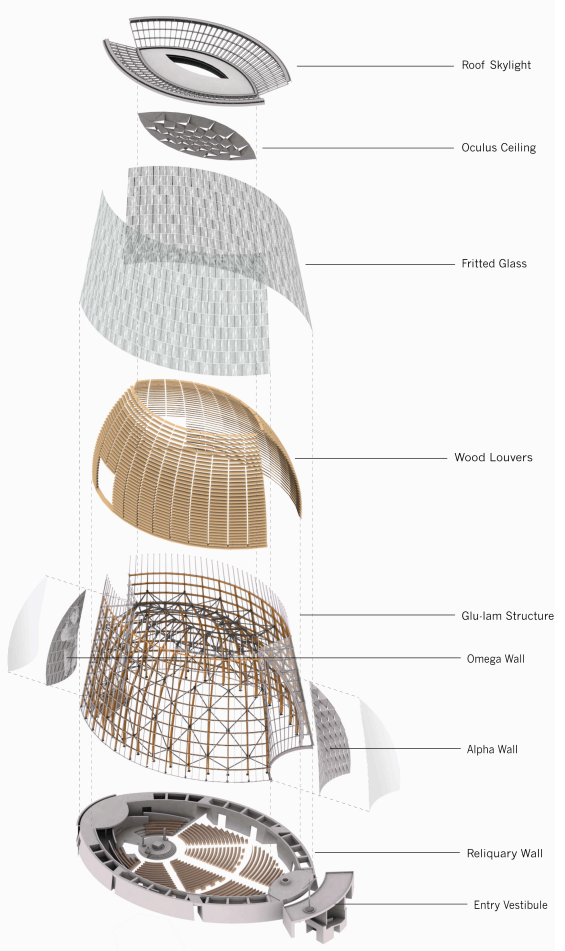

Figure 3. Model of main Cathedral showing primary superstructure elements

High-strength steel rods and tapering, turned glued-laminated wood struts interconnect the inner and outer ribs forming a hybrid steel-timber braced frame structure, which provides stability under both vertical and horizontal loading. Steel rods are designed to resist both wind and seismic forces. A total of 224 steel rods and 104 glued-laminated wood timber compression struts provide redundancy and reserve ductile capacity in the lateral load resisting system. The high-strength steel rods and glued-laminated wood struts are connected to the glued-laminated wood ribs with hidden steel knife plates and steel dowels from the backside of the ribs.

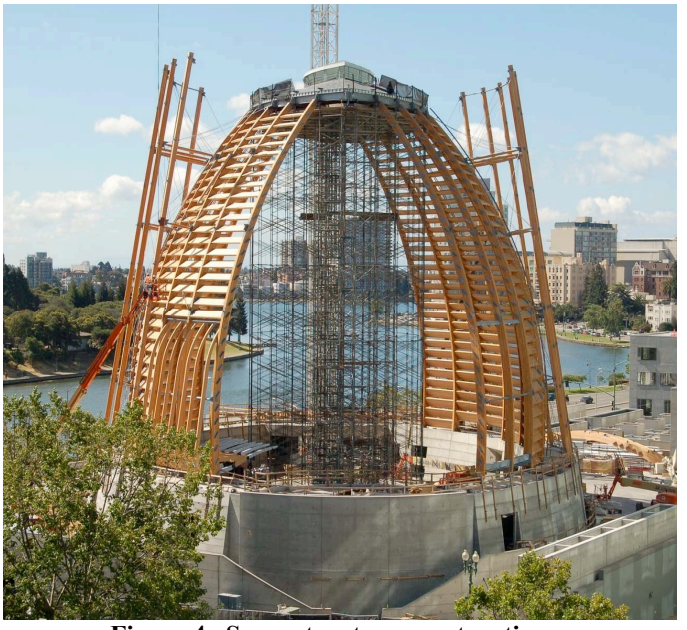

Figure 4. Superstructure construction

Figure 5. Interior View from altar looking south

Symmetric about the longitudinal centerline axis of the sanctuary, two sets of inner and outer ribs support the oculus roof structure comprised of structural steel framing and metal roof deck. In addition, the steel framing acts as a compression ring and diaphragm interconnecting the hybrid steel-timber braced frame elements from all sides of the Cathedral at the roof elevation.

Horizontal tubular steel members provide lateral bracing for exterior outer ribs and provide support for the exterior wall system. Structural steel and steel pin / bolted connections are used to connect primary structural members. Tubular structural steel framing is also used to support the north, “omega”, and south, “alpha”, end walls of the main Cathedral. These glazed end walls are supported by the roof compression ring, end glue laminated timber ribs, and reliquary wall reinforced concrete elements. All hybrid frame timber and steel elements and their connections are shop welded and hot-dipped galvanized allowing for field bolted erection.

The superstructure system of timber and structural steel is supported by 14 in. thick cast-in-place ductile reinforced-concrete reliquary walls. The architecturally exposed concrete reliquary walls extend 15 ft above the sanctuary floor and provide both gravity and lateral load support for the superstructure above. The walls are curved in plan and slope in section, and they contain highly articulate openings or "carvings" for doorways into side chapels, speakers, niches, and other programmatic elements. The reliquary walls were constructed with high density overlay plywood formwork and self-consolidating concrete, allowing for the natural formed finish to serve as the permanent architectural appearance. The base of the reliquary walls are interconnected by a horizontal two-way 12 in. thick reinforced-concrete diaphragm slab at the sanctuary floor. The top of the reliquary walls are interconnected by reinforced-concrete framing beams and slabs providing support for the 4-inch diameter steel pin connections to the glued-laminated wood timber ribs above.

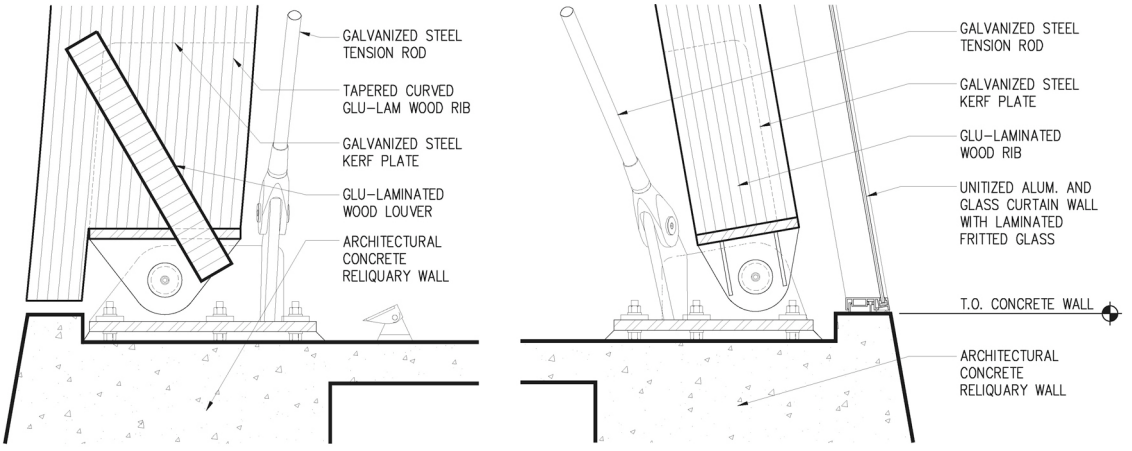

Figure 6. Detail of interior timber louvered wall and exterior glazed wall at base

Figure 7. Reliquary wall formwork construction and finished wall

BASE ISOLATION SYSTEM

The reliquary walls and sanctuary floor diaphragm are supported by a steel friction pendulum seismic base-isolation system provided by Earthquake Protection Systems, Inc., of Vallejo, California. Twenty isolators are located directly beneath the reliquary walls with 16 additional isolators located beneath the sanctuary diaphragm floor slab for a total of 36 isolation bearings provided throughout. The double concave friction pendulum-type isolation bearings provide 30 in. of displacement capacity under the expected maximum capable earthquake (MCE) events.

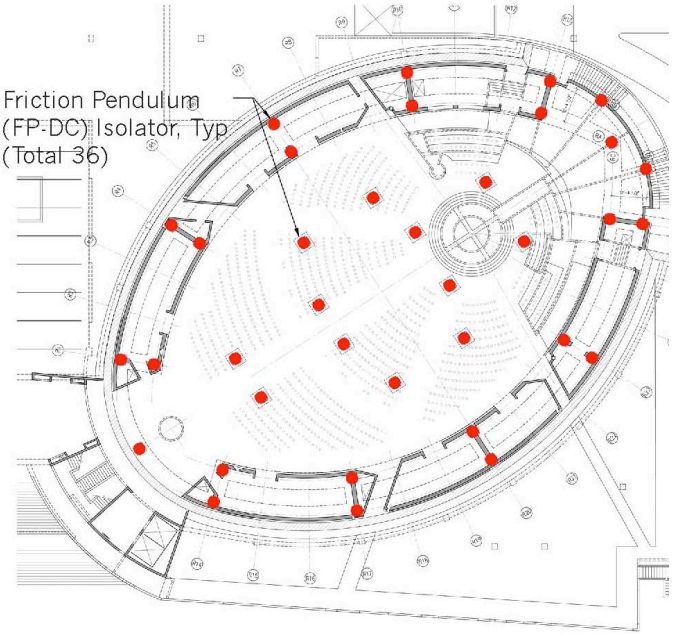

Figure 8. Level 1 Plan / Isolator Layout

The typical steel bearing assembly is 47 inches square in plan and 12.5 inches high. A bounded dynamic non-linear analysis to capture extremes of seismic performance is undertaken for analysis and design. Bounds of sliding friction are established based on a range of expected vertical loading conditions defining the seismic isolation system design properties. The analysis is then "bounded" by the lower bound friction (4.7%) to calculate maximum displacement demands under MCE, and by the upper bound friction (7.7%) to calculate maximum force demands under DBE. From analysis modeling, bearing design criteria was then established for both prototype and production bearing testing for typical bearing types. Weighted average values of friction are then established for both lower and upper bound coefficients of friction. A free body diagram (Fenz & Constantinou, 2006) of the articulated slider on the upper concave surface in the deformed configuration at horizontal displacement illustrates equilibrium in both the horizontal and vertical directions including the eccentric effects of both gravity and lateral overturning loads.

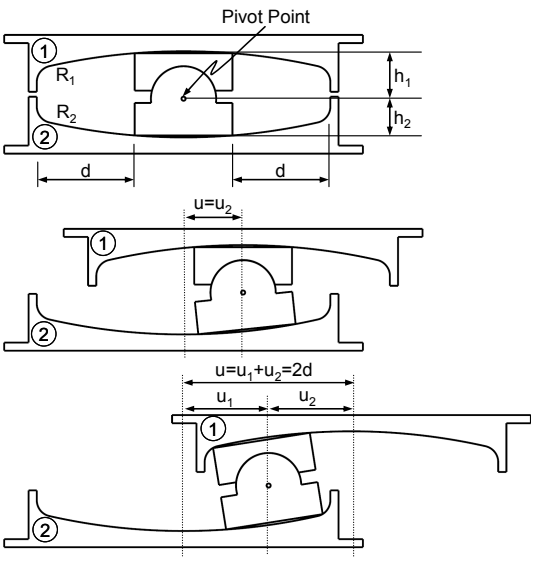

Figure 9. Section through isolator at Various stages of motion (Fenz & Constantinou, 2006)

The substructure below the seismic isolation system consists of a series of 12 in. thick ductile reinforced-concrete bearing walls located below the sanctuary within the mausoleum and under the perimeter reliquary wall supports. These walls extend to a 5 ft thick reinforced-concrete mat slab and perimeter basement wall foundation. The top of the mausoleum walls as well as the walls located directly below the sanctuary reliquary walls are interconnected with a continuous 6 in. thick reinforced-concrete diaphragm. This diaphragm is located directly below the isolation plane. The cellular structure of the mausoleum has an integral role in supporting the isolation plane.

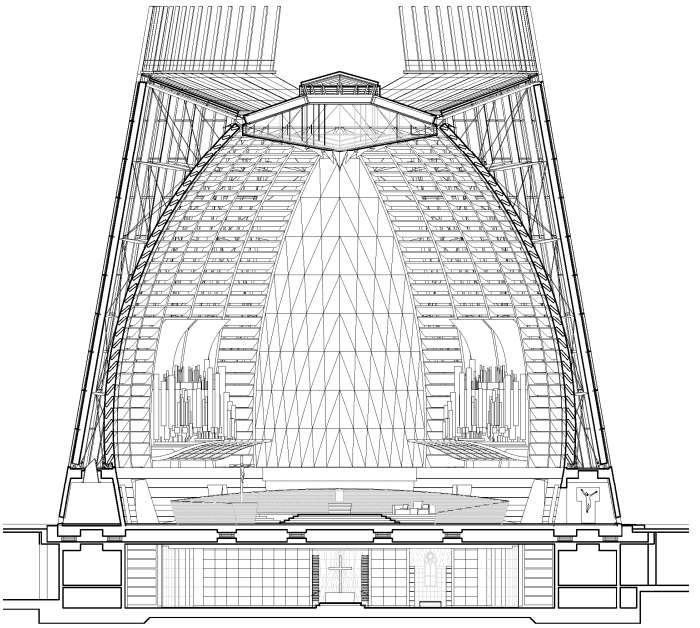

Figure 10. Transverse section through main Cathedral superstructure and substructure

EXTERIOR ENCLOSURE

The exterior envelope is defined by 2 custom designed enclosure systems. The primary system consists of 1,028 shop-fabricated unitized curtain wall panels. Each panel is a parallelogram frame and contains two layers of ¼" clear glass, laminated together with a 0.030 PVB translucent interlayer. A custom designed ceramic frit coating is baked on the inner surface of the layer of glass. This translucent frit coating modulates daylight within and captures the natural shifting of light throughout the day. The panels are nominally 10'-3" in height and vary in width from bottom to top based on the conical geometry of the outer exterior wall surface. The extruded aluminum mullions extend past the top of the enclosure to give a sense of verticality to the tapering conical form. The expressed mullions are clad in stainless steel. Multiple glass assemblies were reviewed in the design phases. Laminated glass was selected for increased acoustic performance. Each unitized curtainwall panel is supported from a tubular steel structural subframe. The unitized system frames and joinery are designed and sized to accommodate seismic movement and return to their original position without damage after a seismic event.

The South and North enclosure walls are named the "Alpha" wall and "Omega" wall respectively. The variable plan dimension from base to top and the segmented curved jamb conditions resulted in a design of varying sizes of triangular shaped clear laminated glass. The triangular glass lites are supported with stainless steel point fittings with universal joints to accommodate the geometrical

configuration. Triangular aluminum panels mounted on the interior side form the petal-shaped Alpha Window, which diffuses light above the Cathedral's entrance. The Omega Window rises behind the altar. Mounted on the interior side of the Omega wall enclosure are triangular aluminum panels perforated with 94,000 laser-cut holes. As points of light shine through the holes in varying levels of brightness, a 58-foot-tall image of Christ is visible from the sanctuary interior. The image is displayed in varying levels of contrast as light naturally shifts from bright sunlight, to overcast shadows, and to interior lighting at night.

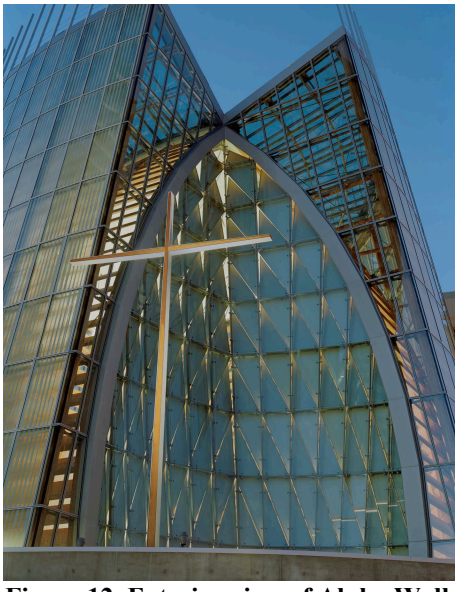

Figure 12. Exterior view of Alpha Wall

LONGEVITY AND DURABILITY OF GLUED-LAMINATED TIMBER

While wood is an important unifying architectural, structural and spiritual design element of the Cathedral structure and space, consideration of its use as a primary structural element in the Cathedral's glued-laminated superstructure was of tantamount importance with respect to the Oakland Diocese's desired long-term performance objectives of the Cathedral.

Longevity and durability design considerations in the use of glued-laminated wood timber for the project included historical development and state-of-the-art standards and codes, durability and exposure to ultraviolet light, effects of temperature and relative humidity, fire resistance, structural design factors dependent on conditions of use, wood species, structural redundancy, protective treatments, as well as, monitoring and long-term maintenance issues. Glued-laminated wood timber construction has had a long history of successful and economical implementation in the design of structures with significant advancements made in the design, production and fabrication technology over the last 30 years.

It is expected that the glued-laminated wood timber construction will see no detrimental effects as a result of exposure to ultraviolet light other than a natural darkening in the color of the wood material over time. Wood timber's natural cellular

structure of lignin and cellulose fibers make it an excellent insulating material that is also highly resistant against acids, alkali, salts and most other chemical substances.

Although the main Cathedral volume is enclosed by weather-tight exterior walls and roof system, fluctuation of air temperature and relative humidity will vary depending on the level of insulating materials, infiltration, thermal mass, ventilation, and type of heating and air conditioning systems employed. Within the main Cathedral volume, for an average sustained peak ambient air temperature of 80 deg F and a relative humidity range of 60 to 65 percent, wood will reach equilibrium at a wood moisture content of 11.7 percent. This is well below a 20 percent threshold of potential formation of decay, and therefore, there will be no impact on the primary glued-laminated wood members. The dimensional stability of wood is considered detrimental only when affected by large ranges and variations of both temperature and relative humidity that are sustained for longer periods of time under service conditions. For a controlled environment within the main Cathedral volume that allows the glued-laminated wood timber to reach equilibrium at a wood moisture content of 8 to 12 percent and peak extreme variations in the range of 4 to 6 percent, it is expected that the dimensional stability of the glued-laminated wood timber construction will be sufficiently maintained without adverse conditions.

The glued-laminated heavy timber construction is inherently resistant to fire due to the natural structure and insulating properties of wood. Under fire load, the charring of the exterior surface of wood acts to create an insulating layer that protects the core of the structural element and can achieve a minimum One Hour Fire Resistive Timber Construction fire rating.

The large majority of glued-laminated wood timber construction in the United States is typically comprised of various softwood species. Douglas Fir was selected as the most appropriate for the project because of its production availability on the West Coast, economical considerations, strength, stability, consistency and natural architectural appearance.

The reliability of wood timber structures and their connections rely on proven design standards and methods which include “condition of use” design factors that account for short-term and long-term load duration, volume, curvature, and beam/column stability.

SEISMICITY

Because the cathedral features a bracing system that relies on steel tension—which under the 2001 CBC’s prescriptive code for an occupied structure in Zone 4 would have limited the height of the church to just 65 ft.—the building had to be considered an “undefined” structure under the 2001 CBC. This meant that the design team had to provide rigorous proof that the structure has the strength and ductility to resist some of the strongest potential ground motions in the world. It was an unavoidable challenge because the tension members were critical to the design, providing a three-dimensional tie between the inner curved glued-laminated members and the outer straight glued-laminated members. These members maximize structural efficiency and provide superior performance even when subjected to the most severe seismic motion.

To prove the structural performance of this system, the design team utilized advanced computer modeling techniques to capture the behavior of seismic isolation combined with the glued-laminated superstructure interconnected with pre-stressed high-strength steel rods and timber compression struts supported on a base of reinforced-concrete reliquary wall and sanctuary floor structure. In addition, additional nonlinear analysis modeling was used to assess the unique structure's ability to resist strength and ductility demands beyond the maximum-considered earthquake levels.

To develop the cathedral's the complex superstructure, a full 3-dimensional nonlinear structural analysis model was developed using the SAP2000 computer analysis program, manufactured by Computers & Structures, Inc., in Berkeley, California. For final analysis, the base-isolated superstructure and the substructure were modeled separately using tri-directional response history analysis. Additionally, both isolated superstructure and substructure models were analyzed and designed to meet minimum 2001 CBC equivalent static provisions.

Two levels of site-specific probabilistic earthquake hazard ground motion criteria—consistent with CBC requirements—were provided by the project geotechnical engineer, Treadwell & Rollo, Inc. The seismic performance objectives were defined for both the 2001 CBC's "design basis earthquake" (DBE) and the "maximum capable earthquake" (MCE) levels of ground shaking. The lower bound DBE is defined as an event with a 10 percent chance of exceedance in 50 years based on a 475 year return period with a peak ground acceleration of 0.683g. The upper bound MCE is defined as an event with 10 percent chance of exceedance in 100 years based on a 972 year return period with a peak ground acceleration of 0.827g.

These performance objectives were used to further define expected levels of performance with expected levels of seismic ground motions. In consideration of the important design aspects of the cathedral—including the location of the site in close proximity to two so-called "near faults," the uniqueness of the design of the superstructure, and the use of a seismic isolation system to achieve enhanced seismic performance objectives—the design team took particular care in the development of site-specific spectra with input from the seismic isolation peer review panel for the project with an emphasis on state-of-the-art ground motion criteria which addressed proximity to near-faults, directivity effects, depth to rock, as well as, vertical ground accelerations.

Near-fault and directivity effects were incorporated in the development of horizontal fault normal, fault parallel and fault average site-specific response spectra at both the DBE and MCE levels. For both the DBE and MCE levels, a suite of seven pairs of horizontal fault normal and fault parallel acceleration time history ground motions were "matched" to the site-specific horizontal fault normal and fault parallel response spectra. It should be noted that the use of fault normal and fault parallel site-specific response spectra to address fault directivity and other near-fault directionality issues is not addressed explicitly by the 2001 CBC. The 2001 CBC assumes that site-specific spectra is independent of fault directionality and provides near-fault factors based on proximity to faults.

Because vertical site-specific response spectra were also required for this project under the 2001 CBC, a suite of seven vertical acceleration time history ground

motions were generated by the geotechnical consultant, Treadwell & Rollo, Inc. The vertical acceleration records were also scaled to match the site-specific vertical response spectra at both the DBE and MCE levels.

The non-linear dynamic time history analyses for the main cathedral superstructure was undertaken using methodologies from a 2003 study, "Earthquake Probabilities in the San Francisco Bay Region: 2002–2031," that was developed by the Working Group on California Earthquake Probabilities, a comprehensive analysis lead by the U.S. Geological Survey and involving input from a broad group of geologists, seismologists, and other earth scientists representing government, academia, and the private sector. For the North Hayward Fault segment, in particular, the seismic source segments and slip rates were considered. The spectrally matched DBE and MCE fault normal and fault parallel ground motion response histories were rotated and applied with respect to the primary transverse and longitudinal axis of main cathedral.

ENHANCED SEISMIC PERFORMANCE

For the main Cathedral superstructure, the owner elected to provide "enhanced" seismic performance objectives. An "enhanced" seismic performance objective provides better performance, or lower risk, than minimum "life-safety," or "collapse prevention" objectives of the CBC. This enhanced seismic performance is achieved by employing a seismic base isolation system and limiting the response of superstructure and substructure elements to achieve elastic behavior under the DBE with negligible structural damage, and, essentially elastic behavior under the MCE with minimal structural damage. To ensure elastic behavior under the DBE with negligible structural damage, the isolated superstructure was designed using maximum force demands calculated based on maximum stiffness (upper bound friction) of the isolation system and R_I=1. The superstructure drift was limited to $0.010/R_I = 0.01$ vs. a CBC limit of $0.020/R_I = 0.02$. To ensure essentially elastic behavior under the MCE, ductility demands were limited to be less than 1.0 and the superstructure drift was limited to $0.020/R_I = 0.02$.

Non-structural components and exterior wall elements are designed and detailed to accommodate the MCE movement without damage or permanent deformation. Nonstructural exterior wall, roof enclosure and interior components were designed for the DBE and MCE force levels, including peak horizontal and vertical accelerations to a life-safety criterion where limited component damage without failure may be expected.

WIND

Under the CBC's design wind loads, the base-isolated main cathedral superstructure is expected to provide stability to resist wind loading and to provide sufficient stiffness—and minimum friction—to resist maximum resultant wind loads at the base of the structure to resist potential sliding of the superstructure at the seismic isolation plane.

In considering the effects of wind, the site was modeled including a 1,200 ft. radius environment with 285 pressure taps to assess the exterior wall cladding pressures. Pedestrian level wind tunnel studies were also conducted along with an estimation of the base resultant forces that included base shears, overturning moments, base torques, load case combinations, and the dynamic effects of wind gusts. Rowan Williams Davies & Irwin Inc., of Guelph, Ontario, performed wind tunnel tests that among other factors, examined a 50-year fastest-mile wind speed of 70 mi/h.

SUMMARY

The cathedral honors the devotion and craftsmanship that unifies the world's great religious landmarks, using advanced technologies to achieve a luminous and evocative architecture with modest materials while minimizing the building's ecological footprint. The thermal mass of the cathedral's base—made of resource-conserving slag and fly-ash concrete—helps to efficiently heat and cool the occupied, lower strata of the interior volume. The Diocese challenged the design team to create a building for the ages. Through the highly innovative use of renewable materials and advanced seismic techniques, including base isolation, the structure has been designed to withstand a 1,000-year earthquake while using minimal energy and natural resources. As a result, the Cathedral of Christ the Light will endure for centuries rather than decades.

ABSTRACT

This paper discusses the analysis procedure adopted for performance evaluation of Ping An International Finance Center in Shenzhen, China. Upon completion, the 115 story tower 660 meters tall will become the world's second tallest building and tallest building in China. The selected structural system consists of a composite concrete core, seven exterior double layer belt trusses, four sets of steel outriggers, eight super columns and super diagonal braces between super columns.

Given the scale and importance of this building, a rather sophisticated evaluation of seismic performance during a rare earthquake (2% probability in 50 years or 2475 year return period) was performed. Two synthetic and five recorded ground motions were selected for the nonlinear time-history analysis. These ground motions were scaled to meet the provisions in China Seismic Code; BG50011-2008. The performance levels for immediate occupancy, life safety and collapse prevention were set based on ASCE 41-06 "Seismic Rehabilitation of Existing Buildings" (2006). Complex 3D computer models with geometric and material nonlinearities were generated for nonlinear dynamic time-history analyses.

The detailed performance assessments of main structural elements such as coupling beams, core walls, super columns, outriggers, belt-trusses and super-diagonal braces are presented in this paper.

Introduction

Located in Shenzhen, Peoples' Republic of China, the Ping An International Finance Center Tower will become the world's second tallest building and the tallest in China, at 660 meters. This building is a 115 story office tower consisting of offices, support facilities, a conference center, retail and parking. The building has a total gross floor area of 385,000 square meters plus a basement area of 77,000 square meters. The project also includes a steel-framed 11-story podium with high-end shopping arcades, restaurants and roof-top cafes.

Figure 1, Rendering of Ping An Tower (Courtesy of KPF)

Structural System

The selected structural system consists of a reinforced composite concrete core with steel outriggers connecting to eight composite super-columns at four levels as shown in Figure 3.

The exterior frame is composed of seven double layer belt trusses located at the mechanical and refuge floors as shown in Figure 2: Main Lateral Force Resisting System and Figure 4: Belt Truss. The exterior belt trusses are connect to a super diagonal at each exterior face of the building.

Core wall thicknesses range from 1500mm at the base to 400mm at the top. Super column plan dimensions range from 6.0m by 3.2m at the base to 2.9m by 1.4m at the top. The main lateral force resisting system is designed for a 100 year return period wind (Strength limit state) and 50 year return period wind (Serviceability limit state) based on wind loads determined by wind tunnel testing done by RWDI, Ontario, Canada. Based on the current China Seismic Code (GB50011-2008), the Tower will be designed for different performance goals under three levels of seismic hazard:

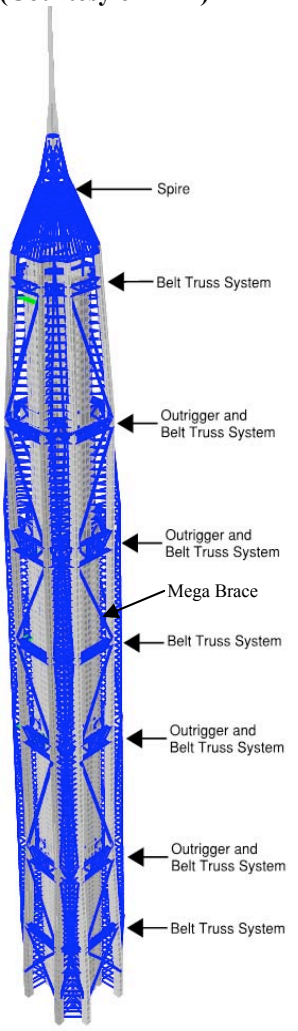

Figure 2: Main Lateral Force Resisting System

- Elastic Stage I: “No damage” under Frequent Earthquake (63% probability of exceedance in 50 years).
- Elastic Stage/Plastic II: “Minor Damage, but Repairable” under Moderate Earthquake (10% probability of exceedance in 50 years).
- Plastic Stage: “No Collapse” under Severe Earthquake (2% probability of exceedance in 50 years).

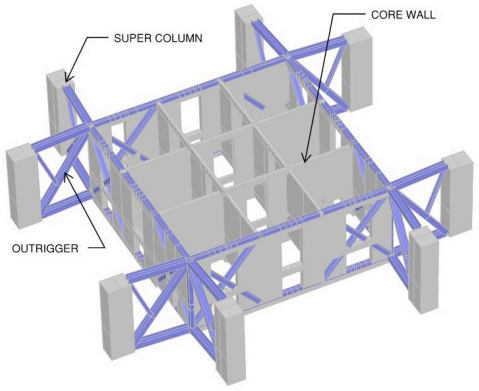

Figure 3: Outrigger, Super Column & Core Wall

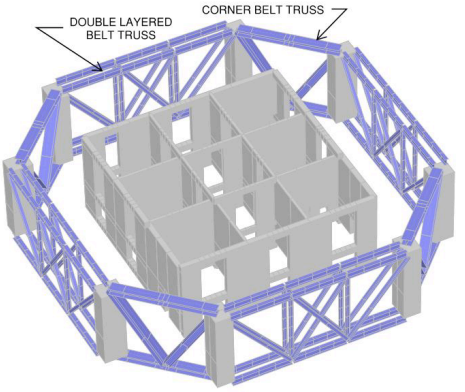

Figure 4: Belt Truss

Seismic Evaluation Process

During the design development phase of the project, while the building was being designed for 50 year (for serviceability checks), 100 year wind (times 1.4 load factor for strength check) and frequent and moderate earthquakes, a seismic evaluation process was started to study the behavior of various structural members under a severe earthquake.

The objective of this performance based seismic evaluation was to verify the inter-story drift demand of the structure, shear demand in the core and performance of link beams, core wall, super column, belt truss, outrigger and super diagonals under a severe earthquake. For this purpose, a three dimensional direct integration nonlinear time-history analysis was performed in PERFORM 3D software.

Analytical Model

Complex analytical models with detailed material and geometric nonlinearities (P-Δ effects) were generated in PERFORM-3D; a CSI Product. The modeling parameters for nonlinear response were in accordance with ASCE 41. Material characteristics were based on the China Building Code. All of the elements that are part of the main lateral force resisting system were modeled. Core wall elements and super columns were modeled as wall fiber elements. Outriggers were defined as frame elements with nonlinear fibers. Strains in these fibers can be monitored at any time-step of the analysis to evaluate member performance. Coupling

beams were modeled as frame elements with plastic hinges at both ends. Nonlinear behavior of these plastic hinges was defined using moment-curvature curves obtained from XTRACT (Imbsen). Belt trusses, chevron braces, mega braces and moment frame beams seen in Figure 5 were assumed to remain elastic. For each set of ground motions, these elements were checked to verify the assumption.

The seismic weight was calculated as $W = D_{exp} + L_{exp}$, where, D_{exp} and L_{exp} are realistic expected dead and anticipated realistic live loads (50% of total live load), respectively. Floor mass was assigned as a lumped mass and torsional mass on each floor diaphragm.

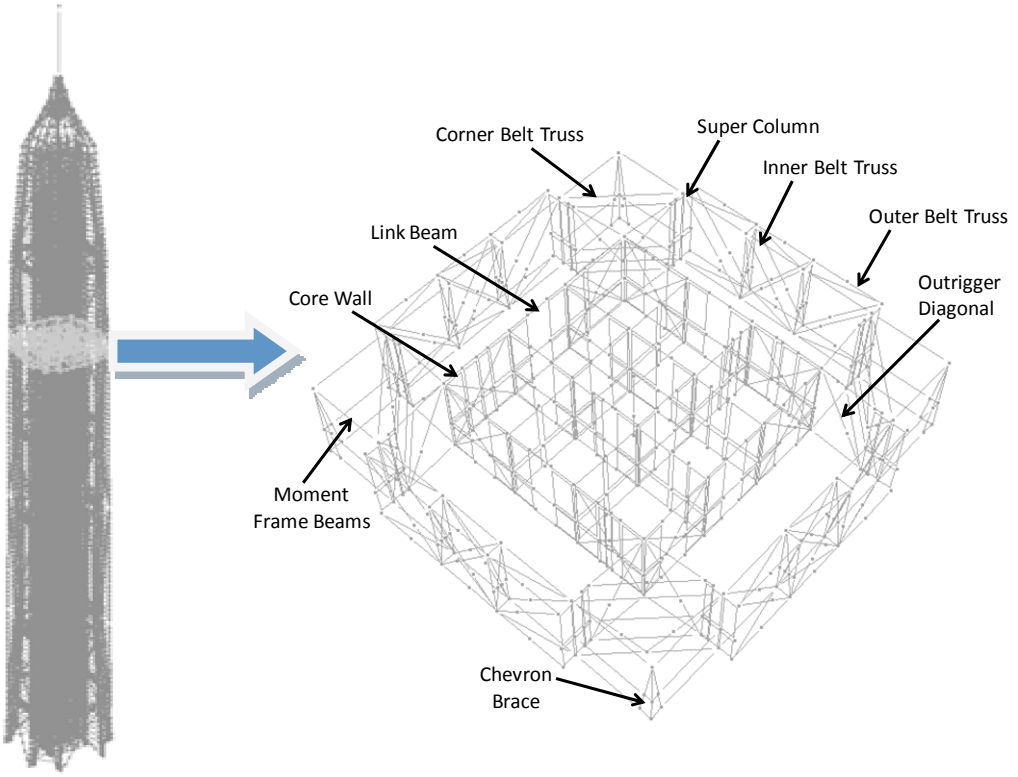

Figure 5: Analytical Model in PERFORM-3D

Damping

A key aspect of seismic behavior is the flow of energy as it is transformed from base input motions to tower movements, structural deformations and absorption as damping. Time history modeling with material nonlinearity can determine energy stored and absorbed by the structural frame. In addition, some

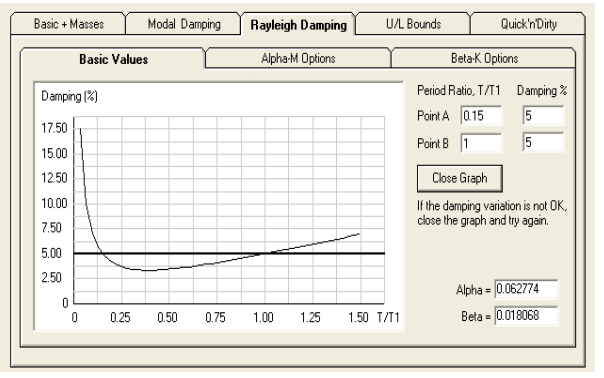

Figure 6: Rayleigh Damping

energy dissipation in a structure occurs through behaviors of various non-structural and structural components that are not explicitly modeled. To reflect energy dissipation not explicitly modeled, Rayleigh damping is specified for the structure as shown in Figure 6: Rayleigh Damping. The damping ratio for the more dominant periods of the structure is between 3.5% and 5%.

Selection of Ground Motions

Nonlinear time history analysis requires that earthquake records be used as input. Records were selected to reflect geological conditions at the site, and then scaled. Based on the China Seismic Code, three requirements should be met by the selected ground motions after scaling:

a. The lowest base shear shall be higher than 65% of China Seismic Design Code (GB50011) spectrum base shear for severe earthquake level.
b. The average base shear shall be higher than 80% of China Seismic Design Code (GB50011) spectrum base shear for severe earthquake level
c. Peak ground acceleration in major direction cannot be lower than 220 gal (cm/sec2).

Two synthesized and five recorded sets of time history curves equivalent to the severe earthquake hazard were selected satisfying the criteria above. Each set consisted of three time histories: two horizontal and one vertical.

Analysis Directions

For each of the seven sets of ground motions a major and minor component was identified. Analysis was performed by applying 100% of the major component motion along the X direction, 85% of the minor component along the Y direction and 65% of the vertical component along the Z direction. The analysis was repeated while applying 100% of the major component along the Y direction, 85% of the minor component along the X direction and 65% of the vertical component along the Z direction. A total of 14 analyses were run on this structure to evaluate the global and member performance.

Analysis Results

Gravity load was first applied to the structure to cause initial stressing of the members and then the nonlinear time history analysis was performed. The results obtained from the nonlinear direct integration time history analysis enabled us to understand global structural behavior as well as behavior of individual members during a severe earthquake. It identified any locations that should be strengthened during the design development stage of this project. A summary of maximum roof displacements, roof drifts and interstory drifts is shown in Table 1: Summary of Maximum Roof Displacements, Roof Drifts & Interstory Drift.

Table 1: Summary of Maximum Roof Displacements, Roof Drifts & Interstory Drift

Earthquake	Maximum Roof Displacement (m)	Maximum Roof Drift/H	Maximum Inter-story drift/h
L7552	1.4	1/386	1/232
L7555	1.4	1/386	1/227
US256	1.27	1/425	1/254
US335	0.89	1/607	1/213
US640	0.8	1/675	1/318
US689	0.74	1/730	1/304
US787	1.36	1/397	1/235

Maximum interstory drift of story height/213 is seen for the US335 ground motion. Since maximum allowable interstory drift according to the China Code is height/100, the interstory drifts are within the code prescribed limits.

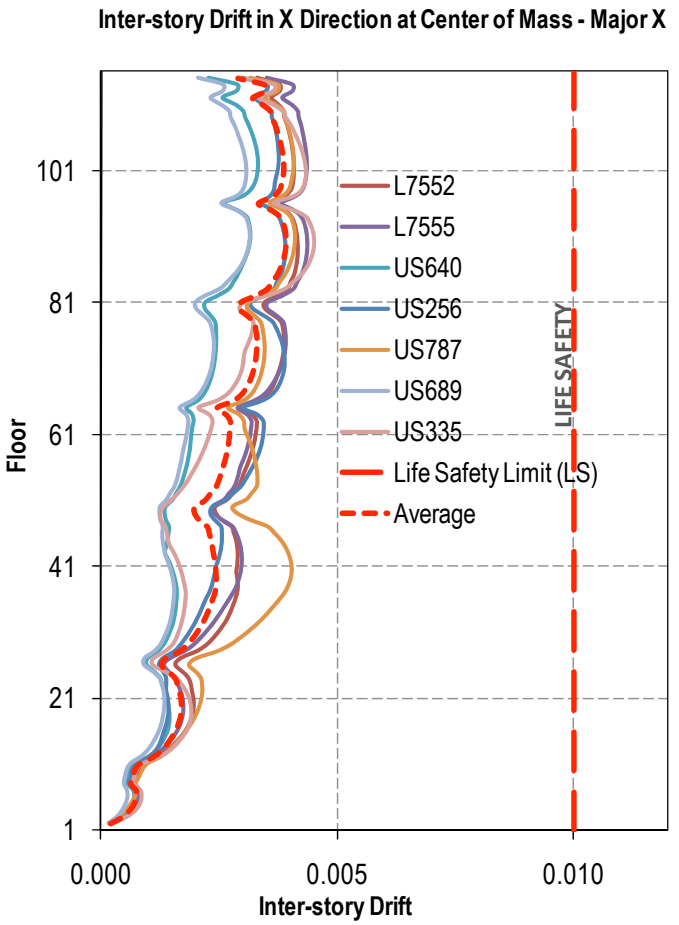

Figure 7: Maximum Inter-Story Drift

Plastic end rotations in the link beams were monitered and the link beams were categorized based on three performance levels; Immediate Occupancy(IO), Life Safety(LS) and Collapse Prevention(CP) as defined within ASCE 41.

Figure 8: Link Beam Performance based on ASCE 41 shows the percentage of link beams exceeding a particular performance level for each of the seven ground motions. It is seen that only 2% of link beams exceed the life safety performance level for one of the sets of ground motions (US787) while all other link beams perform within the life safety performance level or better.

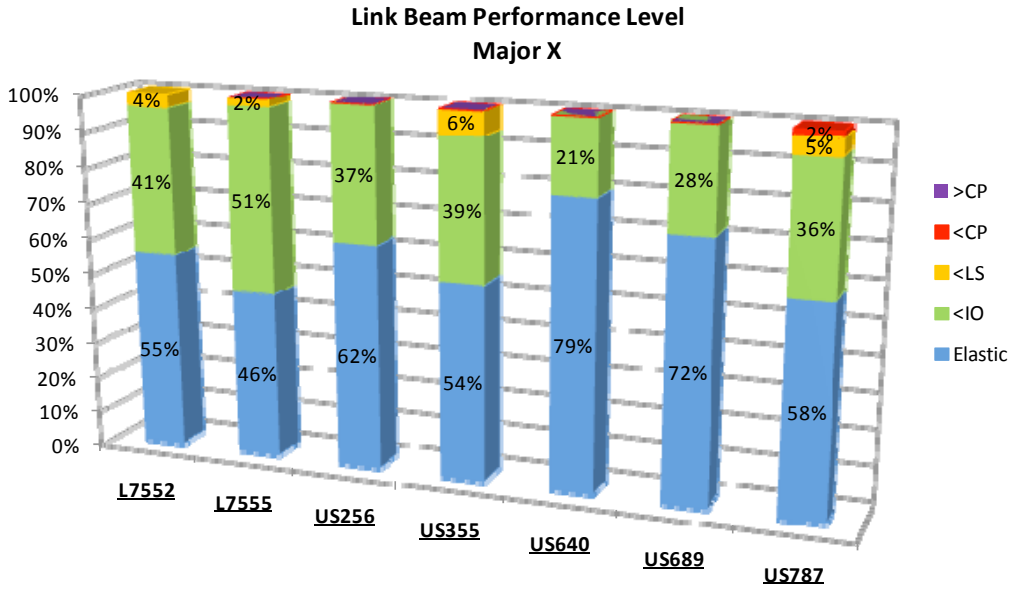

Figure 8: Link Beam Performance based on ASCE 41

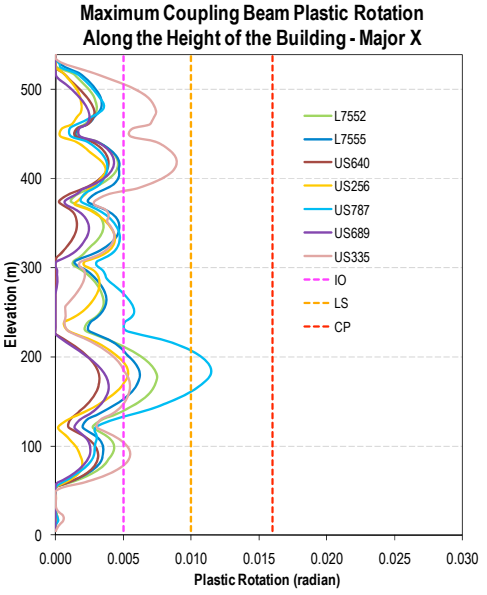

Figure 9: Maximum Link Beam Rotation

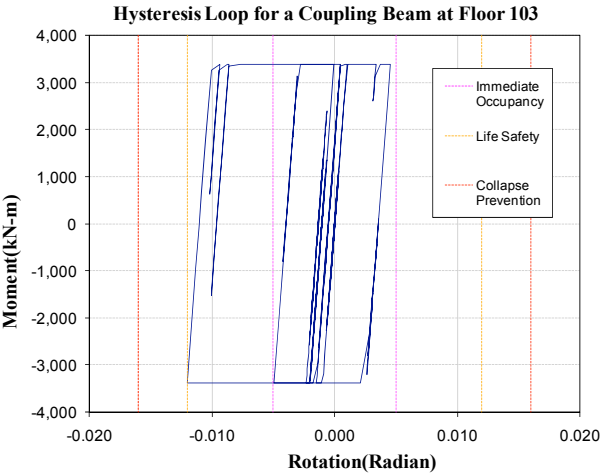

Figure 10: Hysteresis Loop for Link Beam

Figure 9 shows the maximum plastic rotations in the link beams located at different elevations of the building. Figure 10 shows the hysteresis loop for a link beam at floor 103 for the US335 ground motion. This shows the cyclic end rotations in the link beam and the ability of the link beams to dissipate energy hysteretically while undergoing plastic deformations as the building is subjected to ground acceleration. Appropriate link beam detailing can provide stable and reliable

hysteretic energy dissipation through this mechanism while limiting the plastic rotations such that link beams perform within the Life Safety performance level.

Strains in the core wall were monitored for all seven sets of ground motions. As shown in Figure 11, compressive strains in the core wall do not exceed the elastic material behavior limit for concrete. Figure 12 shows the tensile strains in the core wall along the height of the building. The presence of tensile strain exceeding the cracking limit indicates that some cracking of concrete occurs in the upper stories of the building but there is no yielding of steel rebar in the core wall.

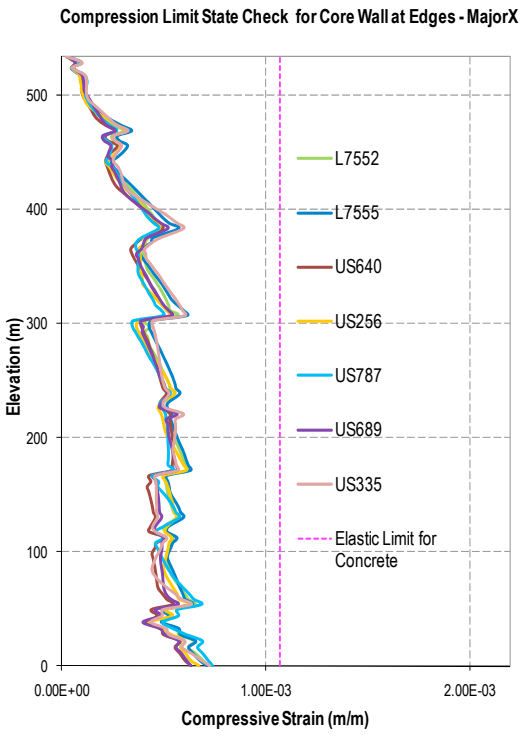

Figure 11: Compressive Strains in the Core Wall

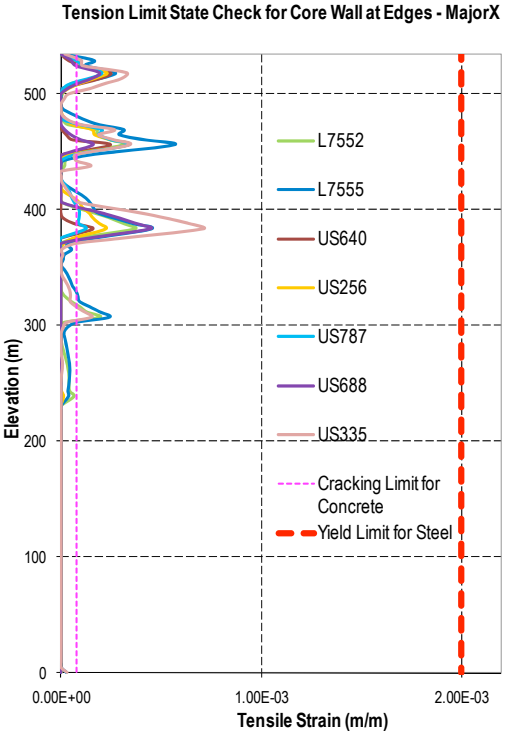

Figure 12: Tensile Strains in the Core Wall

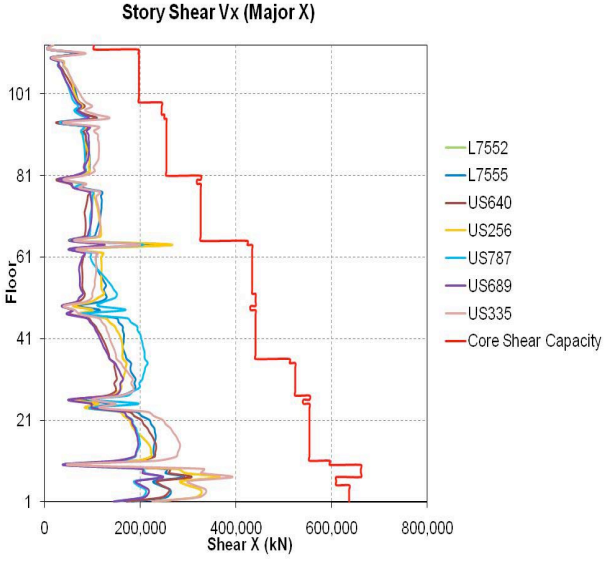

Figure 13, Core Shear Capacity Check

Shear force in the core wall from the nonlinear time-history analysis was checked against shear capacity of the core wall as calculated per the China Code. Figure 13 shows the shear demand in the core does not exceed the shear capacity of the core wall.

Similarly, the strains in the super columns were monitored for all seven sets of ground motions. Figures 14 and 15 show peak strains at the regions where outriggers connect the core wall and super columns.

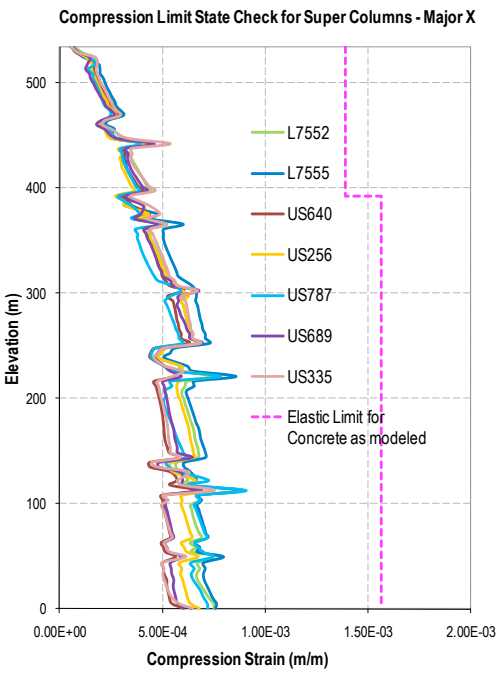

Figure 14: Compressive Strains in Super Column

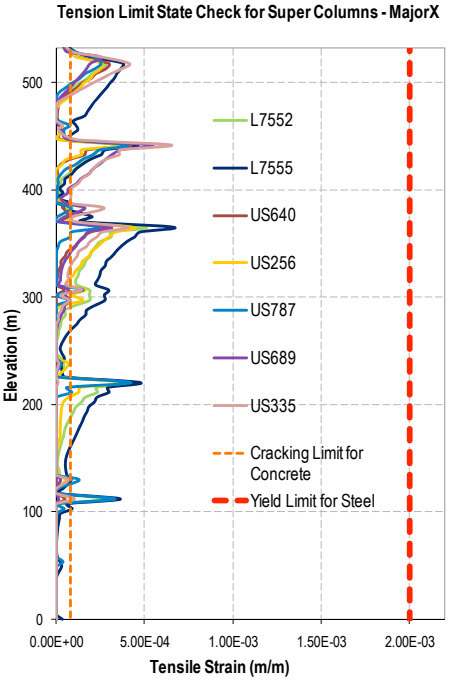

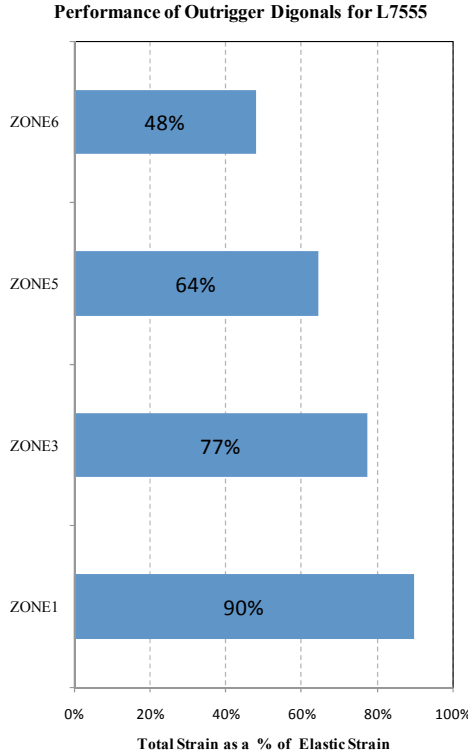

Figure 15: Tensile Strain in Super Column

Performance of outrigger diagonals was evaluated by monitoring the strains. As shown in figure 16, none of outriggers experience inelastic deformations. For L7555 ground motion, maximum strain in the outrigger diagonal was noted to be 90% at, the lowest-most outrigger level.

Forces in the belt truss and super diagonal member obtained from the nonlinear time-history analysis were used to calculate the stress ratio based on the strength limit state check per the China Code. Figures 17 and 18 show the maximum stress ratios in the belt truss and super diagonals for L7555. All the members behaved satisfactorily for the strength limit state check for all seven ground motions.

Figure 16: Performance of Outrigger Diagonals

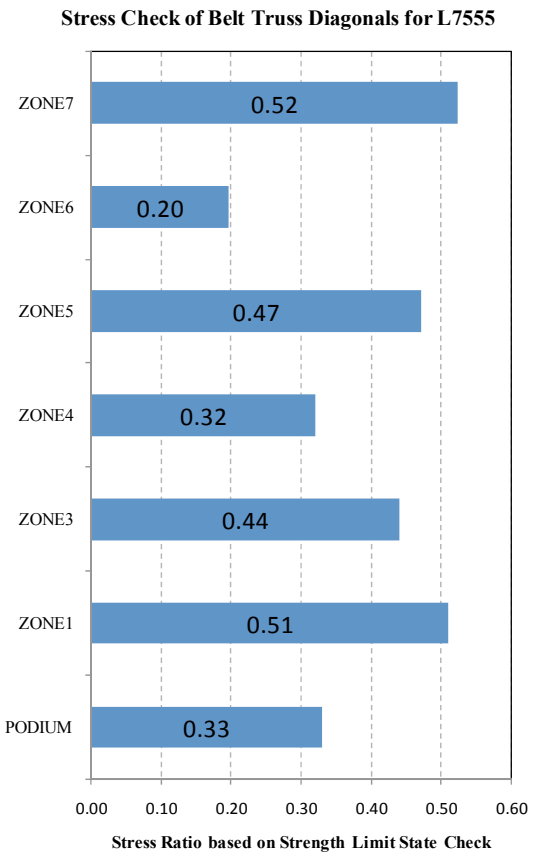

Figure 17, Stress Check of Belt Truss Diagonals

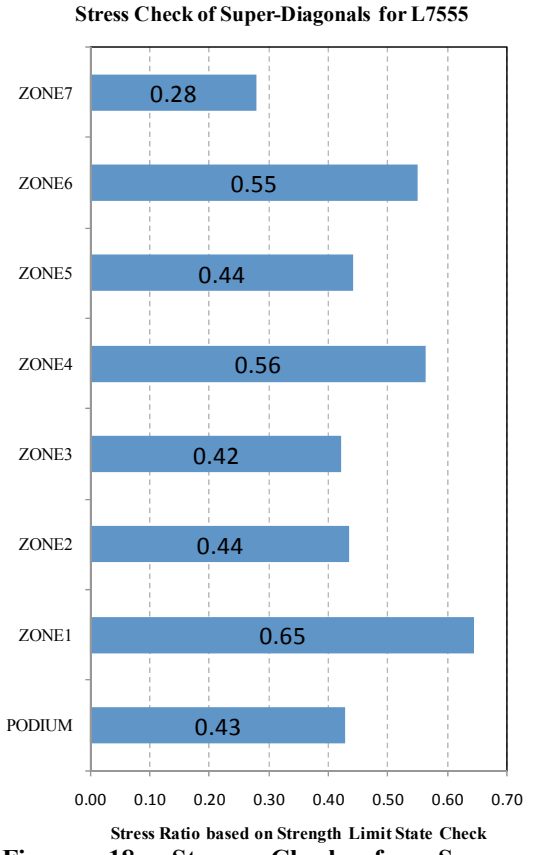

Figure 18, Stress Check for Super Diagonals

Conclusion

Performance-based seismic evaluation of Ping An International Finance Center aided the design team in obtaining approval of the seismic design from the national panel of experts. Complex analytical models were used to study structural behavior under the severe earthquake level (a rare event with 2% probability of exceedance in 50 years). The analytical results provided the design team with very useful information on building performance that helps provide the desired level of safety within an economical building design.

ABSTRACT

This paper presents an overview of the "Enhanced" seismic design of the New San Bernardino Court facility. Designed for the Judicial Council of California under the jurisdiction of the Administrative Office of the Courts, the state-of-the-art Superior Court facility will be located in the City of San Bernardino, California – a region of high seismicity in close proximity to active earthquake faults. The 12-story structure with one below grade level was designed to meet "Enhanced" seismic performance objectives of the 2006 California Trial Court Facility Standards in accordance with the 2007 California Building Code. The final design features a cost-effective steel-framed superstructure with special moment-resisting frames and supplementary viscous damping devices supported on a triple-concave friction pendulum seismic isolation system. This paper focuses on the overall progression of the final design from early design phases through final construction documents. This includes architectural design development, site-specific seismic hazard evaluation, structural system options considered, as well as, seismic risk assessment and life-cycle cost analysis to help inform decision making and system selection.

INTRODUCTION

This paper describes the seismic design procedure used for the New San Bernardino Court building. The seismic performance objective for this building is to provide "Enhanced" seismic performance objective of the California Trial Court Facilities Standards (AOC, 2006) using the 2007 California Building Code (CBC) and ASCE/SEI 7-05 requirements in response to project site-specific seismic hazard and ground motion criteria resulting in approximately two times greater than CBC minimum building code requirements. The lateral force resisting superstructure system (LFRS) consists of steel special moment-resisting frames (SMRF) with viscous damping devices (VDD) supported on a seismic isolation system. The SMRF are sized and designed with the strength requirements under Design Earthquake (DE) criteria while beam and column SMRF elements are prequalified per AISC 358-05. VDDs are provided to control horizontal displacement of the superstructure, rotational demands at SMRF connections and vertical column uplift demands at the isolation plane. The VDDs are designed to strength requirements under the Maximum Considered Earthquake (MCE). The seismic isolation system, including the frame members used for the stability of the isolation system at the isolation plane, was designed for displacement demand and strength requirements under the MCE.

The structural response was estimated through a series of nonlinear response-history analyses using a suite of 7-pairs of bi-directional time-history records developed based on the site-specific seismic hazard analysis results. The design of the fully CBC compliant steel framed ductile superstructure, supplemented by a fluid viscous damping system and supported by the isolation system provides an "Enhanced" seismic performance objective which minimizes damage to structural elements, non-structural components, and building contents under expected maximum peak earthquake ground motions. While minimizing potential business interruption and loss of use, the "Enhanced" seismic design seeks to protect the functionality, long-term investment and sustainability of the critical courthouse facility.

Figure 1. 3D Building Rendering

BUILDING DESCRIPTION

The New San Bernardino Court building, a state-of-the-art 36-courtroom facility, is comprised of approximately 400,000 square feet of administrative, clerk, jury, security operations, holding and building support spaces. The 12-story above grade structure includes an interconnected low-rise 3-story podium and one below grade detention level allowing vehicular access on the sloping site. The architectural exterior wall system consists typically of a combination of precast wall panel and glazed curtain wall system.

Superstructure Gravity Framing. The gravity composite steel-framed structure consists typically of a 3¼-inch lightweight concrete fill over a 3-inch 20-gauge metal deck slab. A typical podium level structural framing plan is shown in Figure 2. Composite steel floor framing at mechanical, roof penthouse, Level 1 and below grade levels consists of 4½-inch normal weight concrete fill over a 3-inch 18-gauge metal deck slabs. The typical story height of 16 feet accommodates the typical courtroom floors with clear ceiling heights of 12 feet. The story height of 17 feet at first floor and below grade level accommodates holding access, parking and general administration. The roof/penthouse mechanical level has a story height of typically 20 feet 6 inches to accommodate the mechanical systems.

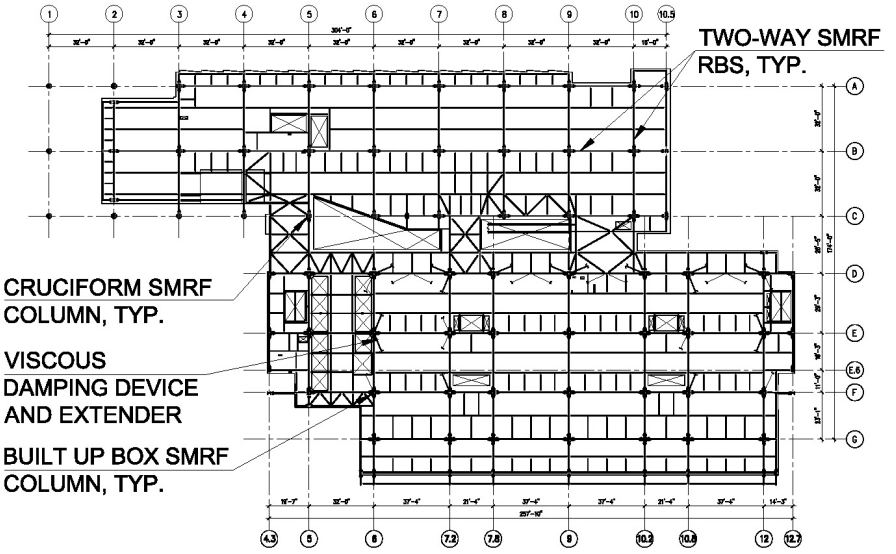

Figure 2. Typical Framing Plan at Podium Level 3

Superstructure Lateral Frame. The lateral force resisting system features a steel-framed superstructure with two-way special moment-resisting frames on essentially all frame lines in each direction utilizing both steel WF cruciform and built-up Box column with 184 distributed supplementary viscous damping devices (VDD) with extender brace elements supported on an energy dissipating seismic isolation system above the lowest mat foundation level. The VDD brace elements have a 440-kip design force with a +/- 5-inch stroke capacity. Pre-qualified steel moment frame connections include reduced-beam section ductile detailing. The uppermost two levels of the building have only two-way special moment-resisting frames to allow for future flexibility in future courtroom and office administration planning. A typical frame elevation in the transverse (N-S) direction is shown in Figure 3.

Seismic Isolation System. The seismic isolation bearing system, as manufactured by Earthquake Protection Systems, Vallejo, CA, consists of 69 Triple Concave-Friction Pendulum (TC-FP) bearings located above the base mat foundation. The TC-FP isolation bearing system will accommodate up to 42 inches of lateral movement at the seismic isolation plane and perimeter moat walls. The TC-FP bearings transfer gravity and lateral forces to the supporting foundation subgrade via reinforced concrete pedestals and mat foundation slab system. The isolation plane was carefully selected at below the lowest occupied level and at perimeter building perimeter conditions to minimize number of building utilities and service elements required to be detailed to accommodate movements across the seismic isolation plane. Locating the isolation plane above the mat foundation required approximately 55,000 sq ft of additional steel framing at the lowest building level.

Courthouse Security. Additionally, the design of the building superstructure incorporates physical security measures to further protect the facility and its

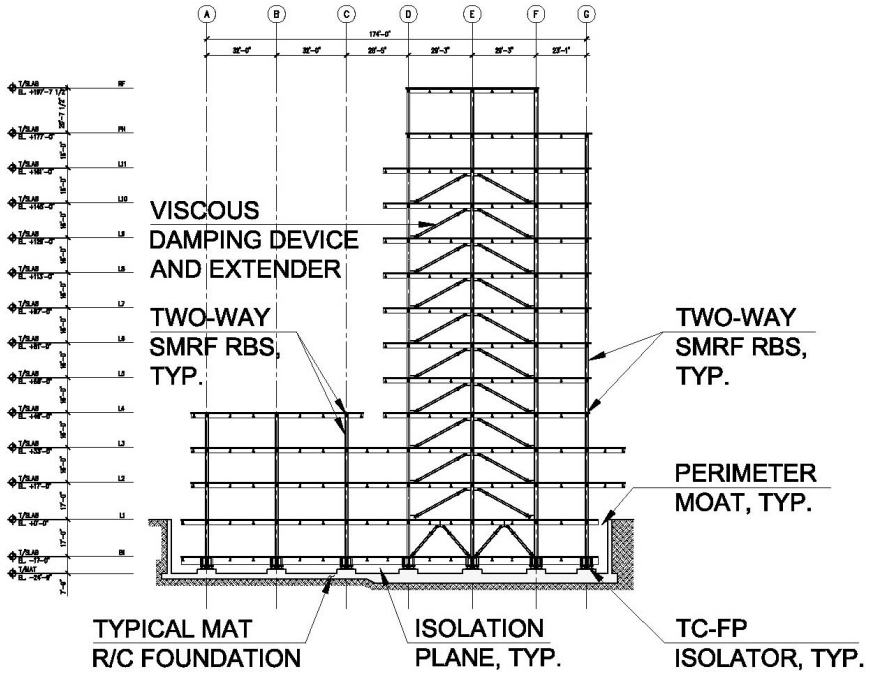

Figure 3. Typical Frame Elevation (N-S Trans Dir)

inhabitants to provide for courthouse security consistent with AOC (2006) requirements to provide security and blast resistant mitigation strategies. Redundant perimeter two-way moment frames at the grade level are designed to reduce the potential for progressive collapse. Interior columns in uncontrolled areas not subject to progressive collapse design are encased to provide hardening, as well as, blast resistant soffit framing slabs at exterior overhangs are provided. Other measures include perimeter building setbacks at grade, bollards protection and blast resistant exterior wall systems.

SEISMIC HAZARD

The facility is located southeast of the intersection of West 3rd Street and North Arrowhead Avenue in the City of San Bernardino, California, in close proximity to active earthquake faults including the San Jacinto (3.9 km), the San Andreas (9.1 km) and the Cucamonga (16.1 km) as shown in Figure 4. At a depth of about 20 feet and below, the site soil consists of dense to very dense sandy layers. The site is classified as "D" based on the measured shear-wave velocity (V_{s30}) of ranging between approximately 1,060 ft/sec and 1,530 ft/sec. The seismic design response spectra was prepared (GeoPentech, 2009) based on the CBC "mapped" USGS 2002; and the site-specific seismic design response spectra was developed based on the seismic hazard analysis and Chapter 21 of ASCE 7-05. The Maximum Considered Earthquake

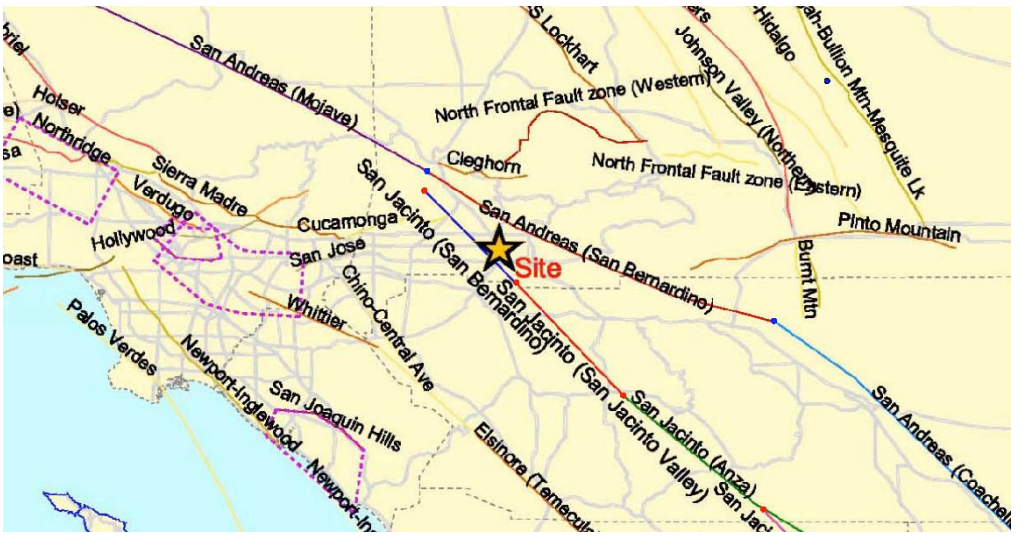

Figure 4. Seismic Source Map (GeoPentech, 2009)

(MCE) are developed based on the lesser of the deterministic 84th percentile "geomean" response spectra (5% damping) without directivity effects associated with the San Andreas Fault (M 7.8) and San Jacinto Fault (M 7.4) and the probabilistic seismic hazard analysis (PSHA) reflecting multiple-segment rupture scenarios corresponding to an average return period of 2,475 years (2% exceedance probability in 50 years). The PSHA reflects the "geomean" NGA attenuation relationships, as well as, near fault directivity effects to provide the Fault Parallel (FP), Fault Normal (FN) and vertical components of ground motion. Figure 5 presents the comparison between the CBC "mapped" and site-specific MCE response spectra including design response parameters. The site-specific spectra for Design Earthquake (DE) is calculated as 2/3 of MCE spectra. When the fault-normal component of spectra is

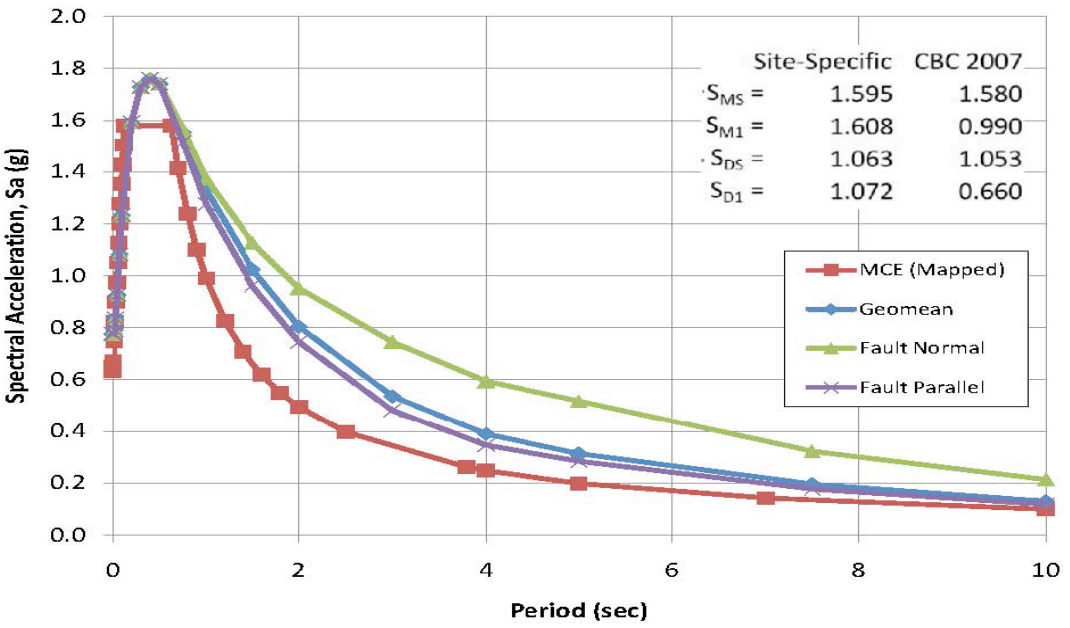

Figure 5. MCE (CBC) vs. Site-Specific Response Spectra (GeoPentech)

compared to the mapped spectra, the site-specific response spectral acceleration is estimated almost 40%, 100% and 2.6 times higher than the corresponding mapped values at 1-second, 2-second and at 5-second period respectively. Due to the AOC "Enhanced" seismic performance objectives, the adoption of the site-specific spectra, without reduction per CBC / ASCE 7-05 provisions, represented a significant design challenge. For the response-history analysis, based on the site-specific spectra, seven time-history records were selected considering the fault rates, magnitude and distance with scaled matching at the period range of interest of 0.2*T to 1.5*T (T is the natural period of the structure) for a fixed base building as required in Chapter 16 of ASCE 7-05. These ground-motion response time histories were further adjusted for the final period of interest of $0.5*T_D$ to $1.25*T_M$ (T_D and T_M are the effective period at Design Displacement and Maximum Displacement) as required for seismically isolated structure provisions of Chapter 17 (ASCE 7-05) based on final selected isolation system properties.

SEISMIC PERFORMANCE CRITERIA

The building is designed to achieve "Enhanced" seismic performance objectives of the California Trial Court Facility Standards (AOC, 2006) based on the governing site-specific seismic hazard and ground motion criteria, as noted above, designed to 2007 California Building Code (CBC) requirements. As shown in Figures 6 and 7,

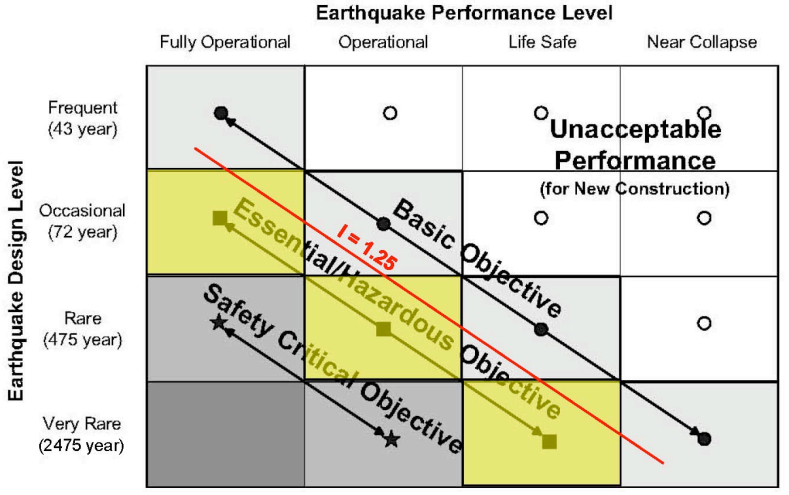

Figure 6. Seismic Performance Objectives (SEAOC, 1999)

this implied that the minimum seismic performance objectives of the building were now required to be higher than the "Basic Objective" earthquake performance objectives of the CBC as illustrated in SEAOC Blue Book (1999) and FEMA 356 (FEMA, 2000) provisions. With these "Enhanced" seismic performance objectives, it is expected that the structure may experience minor to moderate inelastic demands allowing economical repairs, while damage to non-structural components, contents, as well as, potential loss of functionality and business interruption is expected to be significantly reduced.

Nonstructural Performance Levels	Structural Performance Levels and Ranges					
	S-1 Immediate Occupancy	**S-2** Damage Control Range	**S-3** Life Safety	**S-4** Limited Safety Range	**S-5** Collapse Prevention	**S-6** Not Considered
N-A Operational	1-A Operational	2-A	Not recommended	Not recommended	Not recommended	Not recommended
N-B Immediate Occupancy	1-B Immediate Occupancy	2-B	3-B	Not recommended	Not recommended	Not recommended
N-C Life Safety	1-C	2-C	3-C Life Safety	4-C	5-C	6-C

Figure 7. Seismic Performance Objectives (FEMA, 2000)

STRUCTURAL SYSTEM OPTIONS

CBC "Mapped" Ground Motion Baseline Options. During Schematic Design and Design Development phases, the several levels of seismic performance objectives and corresponding lateral force-resisting system options were investigated in consideration of both first construction and long-term life-cycle costs. Serving as a baseline for relative cost and performance evaluations, CBC "mapped" ground motion LFRS options were developed based on CBC seismic importance factors of I=1.0, 1.25 and 1.5. Structural systems considered included steel special moment resisting frames (SMRF), dual systems with steel buckling-restrained braced frames (BRBF), special reinforced concrete moment frames, and dual systems with special reinforced concrete shear walls.

Site-Specific Ground Motion "Enhanced" Options. Using site-specific ground motion criteria, LFRS options were developed for "Enhanced" seismic performance objectives (I=1.25) only. Additionally, for "Enhanced" systems, reinforced concrete systems were not further considered based on least cost evaluations. Technologies considered for "Enhanced" seismic performance included seismic base-isolation systems for both elastomeric (Lead Rubber Bearing) and sliding (Triple Concave-Friction Pendulum System) bearings, as well as, superstructure frame energy dissipation systems including viscous damping devices (VDD), BRBFs and SOM patented Pin Fuse Frames. "Fixed-Base" structural system options considered included steel SMRFs dual systems with BRBFs in comparison with supplementary VDDs. These "Fixed-Base" options were further expanded by introducing the seismically "Isolated" systems to achieve "Enhanced" performance objectives. Based on evaluations with very large lateral displacement and overturning demands at the isolation plane, the Triple Concave-Friction Pendulum (TC-FP) bearings were considered as a more economical seismic isolation system considering extreme project site-specific ground motion criteria.

SEISMIC RISK ASSESSMENT AND LIFE-CYCLE COST ANALYSIS

Seismic risk assessment and long-term life-cycle cost analyses were performed on Design Development options to compare the relative seismic performance and cost of potential structural systems under consideration. The results were used to further help inform structural system selection decision making consistent with Life-Cycle Cost Analysis objectives as prescribed in the California Trial Court Facilities Standards (AOC, 2006). Based on HAZUS (FEMA) seismic risk assessment methodologies using a large range of earthquake ground motion return periods, nonlinear analyses and project specific damage fragility parameters were utilized to estimate building damage – including structural and nonstructural components, contents loss and business interruption – over a 25 year building lifetime (Certus/SOM, 2009). Performance of structural system options was compared with the mean annual loss that is expected in the fixed base structure ("baseline" option). The reduction in expected losses in the "Enhanced" system options was compared with the added initial investment. The analysis results, an approximate 19% Return on Investment with a Cost/Benefit ratio of 8, indicated that mean annual losses are expected to be significantly less for the "Enhanced" scheme with the seismic isolation system compared to the additional initial investment for the seismic isolation system and related costs. Throughout the risk assessment and LCCA, the additional initial costs of the complete base-isolated system were justified in terms of reducing potential future losses in earthquakes through improved performance, while implementing the "Enhanced" system within original projected budgets.

SELECTED LATERAL FORCE-RESISTING SYSTEM

Superstructure SMRF and VDDs. The final selected LFRS consists of steel SMRFs on essentially all frame lines in each direction at each level with 184 distributed superstructure VDDs supported on an energy dissipating seismic isolation system. The steel SMRFs consist typically of WF beam/girder two-way moment-connected to box and cruciform columns, as well as, rolled W14 columns in conformance with prequalification connection criteria of AISC 341-05 (AISC, 2005). The viscous damper and extender brace elements are located at each level with typically 8 damper elements in each frame direction, integrated with standard courtroom layouts and supporting areas, were utilized to control lateral drift are shown in Figures 2 and 3. The viscous damper devices are located at the top of each damper extender brace element in both chevron (Figure 8) and single diagonal configurations.

Seismic Isolation System and Isolation Plane. The superstructure is supported by the seismic isolation system above the horizontal isolation plane located directly above the mat foundation over entire building podium and tower footprint. The isolation system is comprised of 69 TC-FP isolation bearing units located at each column. Typical detail of the TC-FP isolation bearing at interior condition is shown in Figure 9. Units are located approximately 4'-0" below the top of slab and placed on concrete pedestals to allow access for utilities, construction, maintenance, testing and inspection. The total clearance from the underside of the metal deck to the top of

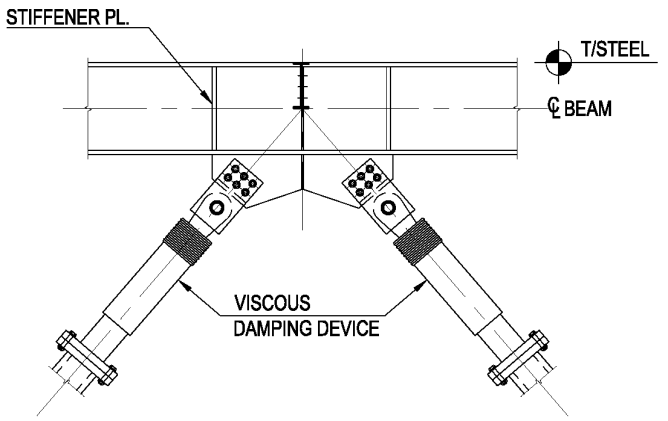

Figure 8. Typical Viscous Damper Frame Detail

mat is approximately 6'-0". Cantilevered retaining walls are provided at building moat wall conditions. The perimeter moat, which allows for free-seismic movement of the isolated superstructure, is provided with a clear distance of 42 inches as shown in Figure 10. At lower level vehicular access conditions, a reinforced concrete slab and/or steel closure plate cover the moat space making up the seismic joint assembly and allowing for functionality under relative seismic movements of the isolated superstructure.

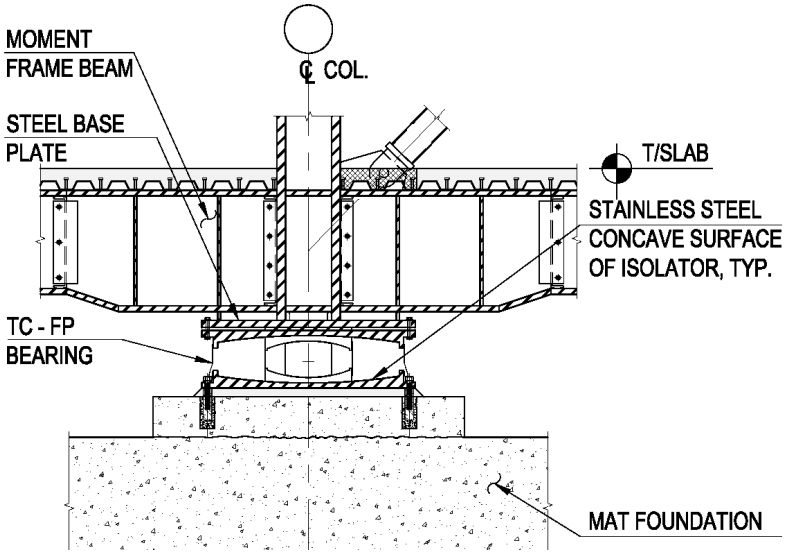

Figure 9. Typical TC-FP Isolator Detail at Mat Foundation

To maintain stability during lateral movement of the isolation system, structural steel framing elements and connections at the isolation plane are designed to remain elastic under MCE level ground motion response design criteria. Moment-connected girders to columns at the isolation plane were designed considering gravity and overturning axial loads, additional moments developed from the P-Δ effects, horizontal shear due to the friction at isolator surfaces, as well as, the restoring force equilibrium. The concrete pedestals which support the isolator units are designed for the MCE level ground motion responses and the additional moment due to P-Δ effects, axial loads and the horizontal shear. The reinforced concrete mat foundation was designed for

the DE level structural response with R_I = 1 and also evaluated for punching shear requirements including the additional strength demands to maintain stability under MCE level responses.

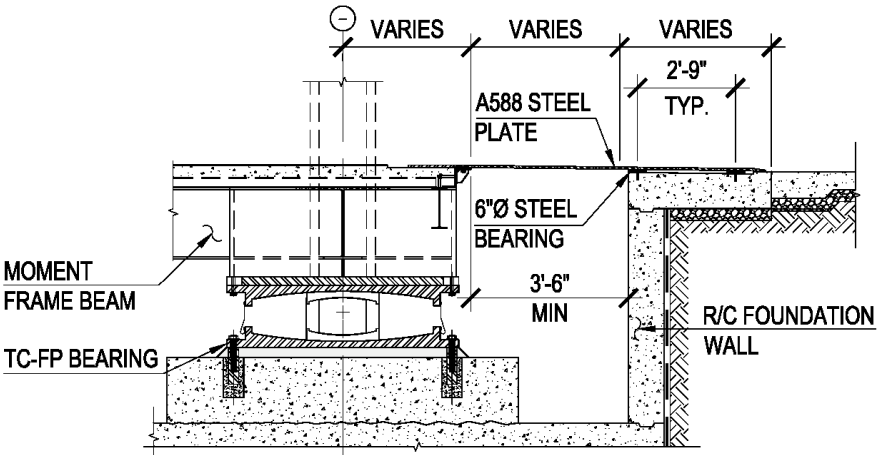

Figure 10. Typical TC-FP Isolator Detail at Lower Level Perimeter Moat

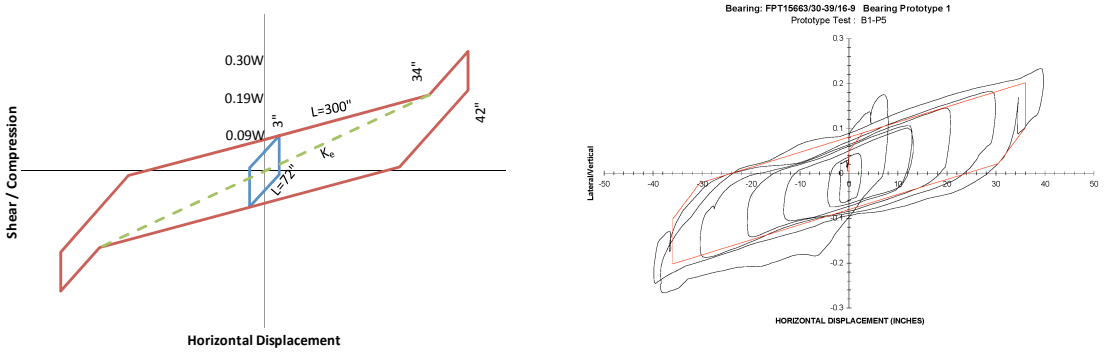

STRUCTURAL ANALYSIS AND DESIGN

Nonlinear Analysis Modeling. The ETABS computer program was used to prepare 3D analysis models of the building. All pertinent stiffness of structural members, mass and gravity loads were included in the models. The beams and columns were modeled as elastic frame elements. The composite floor decks were modeled as one-way deck elements and rigid diaphragms were applied to them. Seven sets of time-history ground motions were used in the nonlinear response-history analyses performed while accounting for nonlinearity in the damper elements of the superstructure, the seismic isolators and capture uplift on seismic isolators where occurs. The analysis cases included the bounded properties of the seismic isolator friction coefficients and the viscous damping devices in order to capture the governing structural responses as prescribed by ASCE 7-05 Ch. 17 & 18. The analyses with DE ground motion sets were used to calculate design lateral forces and displacements of the lateral-force resisting systems above the seismic isolation plane. The structural elements in the superstructure were designed to remain essentially elastic. The MCE ground motion sets were used for the analyses to calculate the total maximum displacement, D_{TM}, of the isolation system, the vertical displacement and the stability demands of each isolator, as well as, to estimate maximum damper axial force and displacement demands.

Viscous Damping Devices. The VDDs have a velocity exponent (α) of 0.5, a damping constant (C) of 150 kip-(sec/in)$^{\alpha}$, a maximum stroke of ± 5 inch and a maximum design force capacity of 440-kip. The structural analyses included the bounded analysis of (± 15%) the upper and lower bound damper properties. The VDD elements are modeled using nonlinear damper elements in ETABS. The damping devices were designed to have displacement and design force capacities for MCE level demands. The connections and components, including the damper

extenders, transferring the damper forces to the structural members were designed to develop the capacity of the VDDs. Since the damper forces are substantially out-of-phase with elastic forces, they do not significantly increase loading on the structural members.

Isolation Bearing System (TC-FP). Analysis modeling of each bearing was developed on the basis of assumed mechanical properties of the TC-FP bearings as provided by bearing manufacturer, EPS, with target nominal properties as shown in Figure 11(a), as later verified by prototype testing, Figure 11(b)

(a) Nominal Bearing Properties

(b) Prototype Bearing Tests (EPS)

Figure 11. TC-FP Isolation System Bearing Properties

The effective radii (L) of the outer and inner concave surfaces are 300 and 72 inches, respectively. The friction coefficients of Breakaway, Target, Lower Bound (LB) and Upper Bound (UB) are 5.0%, 9.0%, 7.5% and 10.5%, respectively. UB and LB properties included adjustments for potential aging and contamination effects. EPS (2010) confirmed analysis parameters based on the results of prototype bearing testing as conducted during the CD design phase under direction of SOM and Design Review panel. Modeling of TC-FP is based on the equivalent bilinear model to represent the breakaway friction coefficients of inner and outer surfaces. Equivalent bilinear modeling of TC-FP represents the actual hysteretic behavior without significant loss of accuracy. The TC-FP mechanical properties are averaged based on the global behavior of entire building, as well as, in establishing prototype testing acceptance criteria. The TC-FP was idealized using a combination of isolator2 link element and gap/hook elements of ETABS program. The isolator2 link elements are used to model the equivalent bilinear model to represent the breakaway friction coefficient of inner and outer surfaces. The gap/hook elements are used to model later stage stiffening effects of isolator. The structural analyses included the bounded analysis the upper and lower bound friction coefficients to determine maximum force and displacement demands.

Isolation Plane Framing. The isolation plane seismic force resisting system consists of all the structural elements between the top of the isolators and below the top of

basement floor slab. The elements in this plane was designed to have a capacity for 100% of the required seismic story shear under DE with $R_I = 1.0$. When the elements are required to have a strength for the stability, which are the girders and columns directly connected to the isolator, the elements are designed to have a capacity for 100% of the required seismic story shear under MCE with $R_I = 1.0$, including secondary moments developed from the large lateral displacement of the isolator.

Superstructure Frame. The superstructure, defined as the structural system above the top of the basement floor slab, consists of steel SMRFs with supplementary VDDs with the SMRF beams and columns assembled with fully ductile prequalified connections per AISC 358-05. The members were designed to the structural responses under DE events with $R_I = 2.0$. Additionally, the superstructure members were evaluated per FEMA 356 to meet the structural Life Safety seismic performance criteria and estimated SMRF connection rotational demands under MCE level events. Based on the series of nonlinear response-history analyses, the maximum average drift ratios are about 1.4% under DE level ground motions and about 1.7% under MCE level ground motions.

DISCUSSION AND CONCLUSIONS

The seismic isolation system was an appropriate design strategy for the courthouse to limit earthquake damage and to protect facility function. Since the building is located in a region of very high seismicity and is subject to particularly strong ground motions, the large seismic demands posed a challenge for the design of seismically isolated structure in terms of the displacement capacity of the isolation system and the strength capacity of the superstructure while attempting to achieve AOC "Enhanced" seismic performance objectives.

The viscous damping devices were used to supplement isolation system damping and to reduce the displacement demand. As a result of the installation of supplementary dampers at the superstructure in line with SMRF system, it was able to reduce the interstory drifts and isolator vertical, as well as, horizontal displacement demands. By reducing drifts, the rotational demands on the SMRF beam-column connections were also reduced to an essentially elastic level.

The lateral force resisting system utilizes both seismic isolation and viscous damping systems along with fully ductile prescribed LFRS system. The resulting system achieves an "Enhanced" seismic performance level by protecting the structural elements, non-structural components, and building contents against damage, as well as, loss of use under expected severe demands of MCE ground motions. It is also considered that the "Enhanced" seismic design provides a sustainable low-carbon footprint with significant benefits on the environment while protecting the long-term investment and continued use of the critical courthouse facility.

ACKNOWLEDEMENT

The authors gratefully acknowledge the support of the Judicial Council of California, and the Administrative Office of the Courts (AOC) during the design development of this project. Additionally, AOC project oversight was provided by Afshar Jalalian, and, CBC Design Review was provided by Robert Bachman (Chair), Professor Michael Constantinou, and Dr. Norman Abrahamson. Contributions are gratefully acknowledged.

ABSTRACT

This paper summarizes the case study of a four-story building with three additional levels below grade in the Pacific Northwest of the U.S. consisting primarily of precast and cast-in-place concrete elements. The lateral force resisting system consists of eight reinforced concrete shear wall towers located around the perimeter of the building and four shear walls down the centerline of the building. The building was analyzed and a retrofit scheme was developed using both linear and nonlinear static analysis procedures conforming to the requirements of ASCE 31 and 41. The retrofit scheme had to meet a number of criteria set forth by the owner. The retrofit had to visually promote the owner's commitment to seismic safety while embodying sustainability. The building had to remain occupied and operational while the retrofit construction took place; which required noise, dust and vibration be minimized. The HVAC system also had to remain in operation while it was modernized. To satisfy these constraints, the retrofit employed a mostly exterior strengthening scheme that included large horizontal steel trusses and steel collectors in order to engage previously unused exterior tower walls. Four strips of new roof over the existing roofs were added to confine the existing gypsum concrete roofs and provide support for a new HVAC system. Collectively, the retrofit scheme was a tailored solution which optimized use of the existing structural elements while providing the owner with an economical retrofit which is expected to meet or exceed the established performance goals.

INTRODUCTION

Facility managers and government representatives are becoming increasingly aware of the life-safety risk posed by older buildings not designed and constructed to meet the requirements of current building codes. This problem is compounded in geographic areas where the understanding of seismicity has evolved in recent years

and is now understood to represent an increased risk. In response to this risk, a university located in the Pacific Northwest of the United States has undertaken a program to improve the seismic safety of their campus facilities. The state's legislature, also wishing to support and promote the goals of seismic safety, employed a matching funds program to help promote seismic safety in the local community.

One such example of this combined state and university objective to improve the seismic safety of existing buildings is a pre-1975 non-ductile concrete building used for a large portion of the university's science and technology lab space. The building houses teaching and research laboratories for chemistry, biology, physics, environmental engineering, and structural engineering. A preliminary Tier 1 seismic evaluation per ASCE 31 (ASCE, 2003) indicated several Life-Safety concerns; and subsequent Tier 2 and Tier 3 evaluations indicated retrofit strengthening would be required for the building to achieve the desired seismic performance of the Basic Safety Objective including Life-Safety performance in the BSE-1 (the Design Basis Earthquake with a 10% probability of exceedance in 50 years) and Collapse Prevention in the BSE-2 (the Maximum Considered Earthquake with a 2% probability of exceedance in 50 years) per ASCE 41 (ASCE, 2006).

Additionally, both the state and the university wanted to use the renovation of this building to demonstrate their commitment to promoting seismic safety and sustainability statewide. This project also served to showcase their commitment to attracting top-notch faculty, students and support research and workforce development for their healthcare, advanced manufacturing and high-technology industries.

However, the strengthening had to be carefully coordinated out of respect for the occupants and uses of the building. The laboratories for the various university departments contain active research that cannot be interrupted or compromised. Furthermore, the university could ill afford to lose precious classroom space inside the building as that was already scarce. Therefore, because the building would need to remain occupied and operational, any construction work to seismically strengthen and modernize the building would need to be carefully coordinated to minimize noise, vibration, and dust. Furthermore, the HVAC system would need to remain online for the full duration of construction to support the research and teaching functions.

BUILDING DESCRIPTION

The building was constructed in 1970 and has four stories above grade, with three levels below grade; with two levels containing offices and labs and a third level for mechanical and HVAC systems. The building is rectangular in plan, and has dimensions of 280 feet by 146 feet at most of the levels (see Figure 1). At the fourth and roof levels, the plan steps back to 208 feet by 146 feet in plan (see Figure 2).

Story heights are approximately 18 feet for the mechanical level, 12 feet for the two lower levels, and 13 feet 9 inches for the levels above grade (see Figure 3).

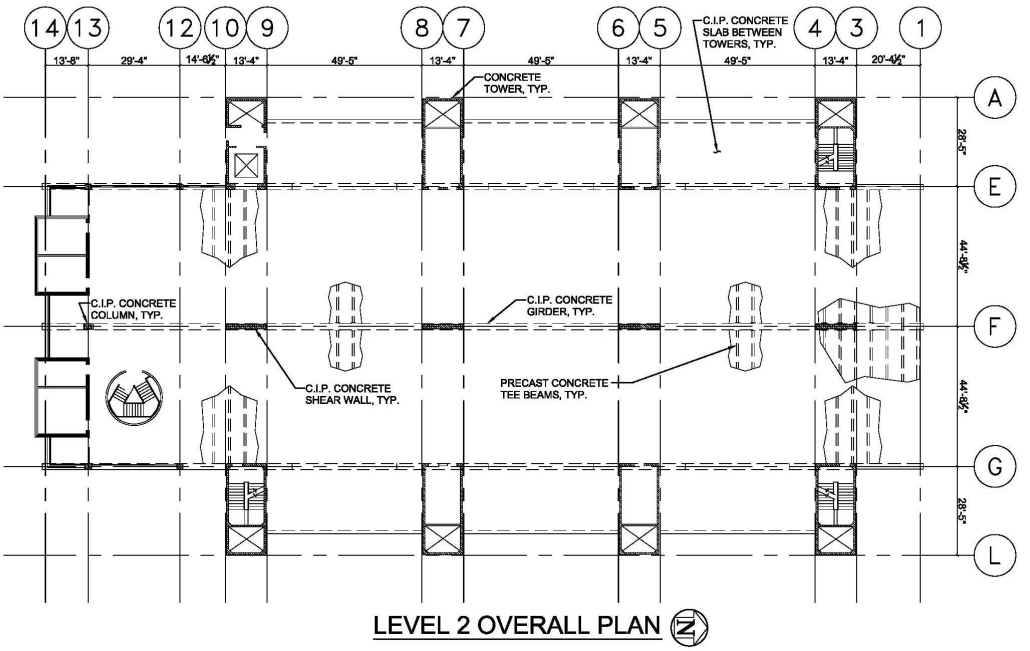

Figure 1. Typical floor plan

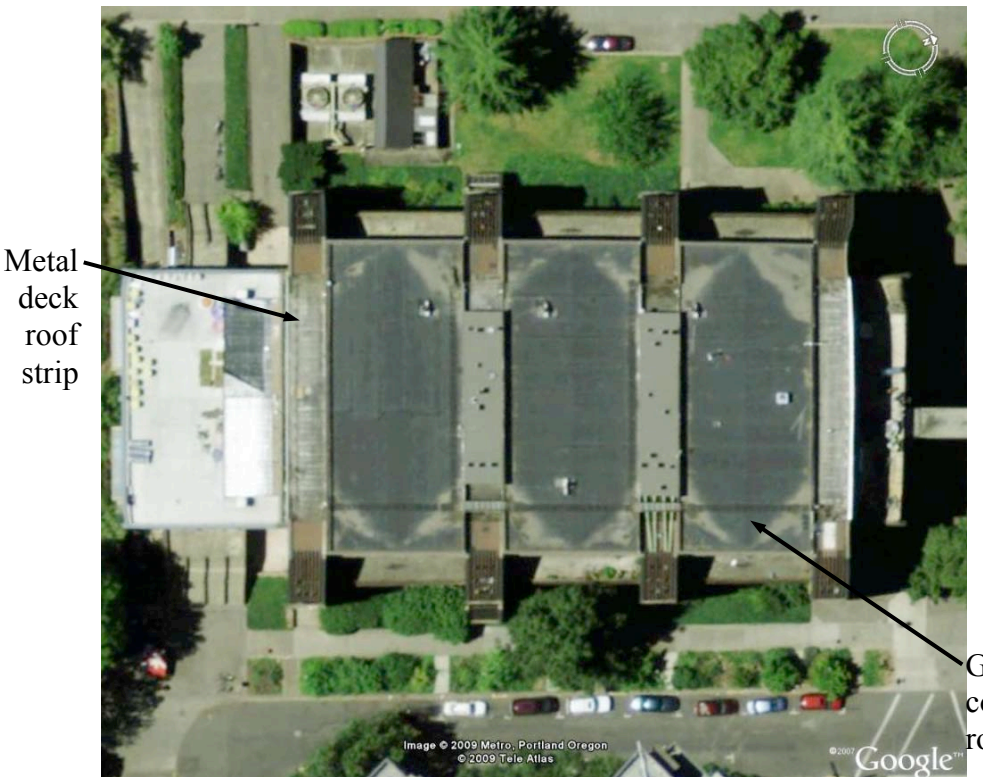

Figure 2. Roof view (Google, 2007)

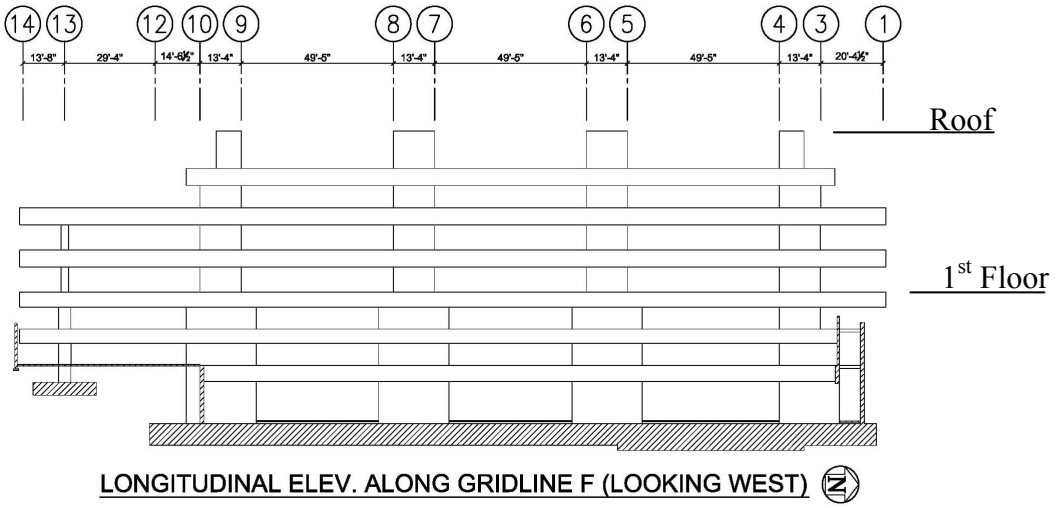

Figure 3. Elevation along gridline F

The gravity-load-resisting system consists primarily of precast and cast-in-place (CIP) concrete elements. There are eight stair and elevator cores in the building (four on both the east and west sides), all consisting of reinforced concrete bearing walls. There are also four large shear walls situated along the centerline of the building along gridline F (see Figure 1 for gridlines). The stair towers are founded on four-foot-thick concrete footings, and the centerline walls are founded on a seven-foot-thick strip footing. The foundation walls surround the levels below grade and do not have a strip footing, but span between the adjacent tower footings.

The majority of the roof consists of two inch thick gypsum concrete over form board, supported by open-web steel joists. The steel joists span in the east-west direction to wide flange girders. These girders span between the reinforced concrete bearing walls at the building centerline and between the towers on the sides of the building. Small strips of the roof consist of a metal deck supported by open web steel joists spanning in the east-west direction between the towers and the centerline walls. These strips are three feet lower in elevation than the gypsum concrete roof areas. A portion of the metal deck roof supports a penthouse with miscellaneous mechanical equipment.

The floors consist of precast tee sections, with a minimum three-inch reinforced topping slab, spanning east-west to cast-in-place and precast girders. The girders are cast in place along gridline F and span to concrete bearing walls at the building centerline. The girders along gridlines E and G consist of both cast in place and precast portions. The cast in place portion is cast integrally with the interior face of the tower wall and cantilever from the tower. These cantilevered girders support a precast middle portion between the towers. Between the towers on the east and west sides of each floor are one-way concrete slabs spanning between the precast girders and edge beams.

The lateral force-resisting system of the building consists of the gypsum concrete and metal deck diaphragms of the roof, reinforced concrete topping slabs and one-way slabs at the floors, and reinforced concrete shear walls around the eight stair and elevator cores, as well as down the centerline of the building. The tower walls are eight inches thick. The walls on the north and south sides of the towers are mostly solid; however, the walls on the east and west sides of the tower on the interior side have many openings for doorways. The centerline walls are eighteen inches thick. Below the first level, the perimeter retaining walls substantially increase the amount of shear wall in both directions. However, due to floor penetrations for the building ventilation system, the basement wall on the north side of the building is not effectively connected to the rest of the diaphragm.

COMPUTER MODEL AND MODELING ASSUMPTIONS

The computer modeling for the building was carried out in two phases. First, a linear static model was utilized to gain a quick preliminary understanding of the building behavior. This provided the design team with an understanding of the cost of the structural retrofit portion of the project and therefore an approximation of how much money remained for modernization of the architectural and MEP systems so that these disciplines could plan their portion of the project. A nonlinear static analysis was then utilized to improve the understanding of the building behavior and reduce the scope of required strengthening. This improved understanding of building performance and reduced strengthening allowed the project team to save approximately $1.4M in construction costs while also reducing the corresponding construction impact on the occupants of the building.

The computer program ETABS (CSI, 2008) was used to perform the linear static analysis of the building. The tower walls, centerline walls, basement walls and lower level diaphragms were modeled with shell elements as seen in Figure 4 and all major openings from doorways and duct penetrations were included. The girders along the centerline of the building were modeled with frame elements along centerline dimensions. Cracked section properties were used for flexural stiffness for all concrete elements. The bases of all the walls were fixed. The seismic demands were based on site-specific response spectra provided by the geotechnical engineer, and all seismic loads, including horizontal accidental torsion, were applied at the center of rigidity for the fixed diaphragms and distributed point loads for the shell modeled diaphragms.

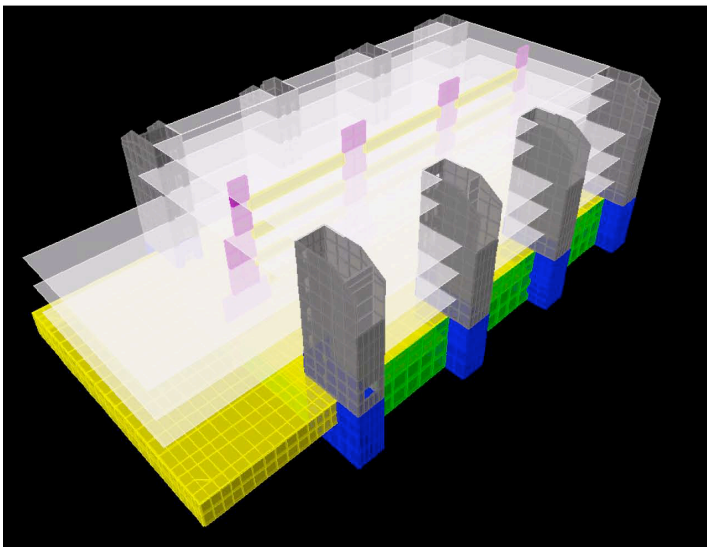

Figure 4. Linear static model

The computer program ETABS was also used to perform the nonlinear static analysis of the building. The nonlinear model required the centerline walls and tower walls be modeled with frame elements in order to capture their inelastic shear and flexure performance. Each centerline wall was simply modeled with a vertical frame element. However, the tower posed a more interesting challenge. The nonlinear tower model needed to capture the composite flexural action of the tower as well as the potential yielding of the portion of the tower wall above the doorways on the interior faces of the towers.

To accomplish this, each tower was divided into four discrete elements to enable modeling the tower section with vertical line elements. The four vertical line elements were connected with horizontal rigid link elements at each floor level and at the roof, except at the doorway penetrations in the towers. At these penetrations, the horizontal element was a frame element with section properties to represent the wall (and integral beam) between the door penetrations. Geometric section properties for each of the vertical elements and for each story were determined using the computer program RC-Section (Pikaso, 1994).

The tower shell element model from the linear static analysis was used to calibrate the tower line element model global stiffness in the N-S and E-W directions. These models are shown in Figure 5. Equivalent stiffness was achieved by modifying the line element tower plan dimensions. The story displacements for the shell element and calibrated line element models were compared.

The use of the four separate vertical frame elements to model the towers required a modified approach to capture the flexural plastic hinging of the composite tower sections. Equivalent axial plastic hinges were defined based on the chord reinforcing steel axial capacity and moment arm of the tower section tension-compression couple between the corresponding vertical frame elements. The axial hinges were defined as

tension only hinges because the area of concrete in compression had adequate capacity to remain elastic. Different axial hinge properties were defined for the N-S and E-W directions to account for the different moment arms of the tension-compression couple in the two directions.

Shear hinges were modeled in the tower vertical line elements at mid-height of each story. The shear areas of these elements included only the section of wall parallel to the direction of loading (i.e., neglecting the perpendicular leg of the L shape). Shear hinges were also modeled at midspan of the horizontal elements over the tower doorways. The capacity of these shear hinges was calculated based on the portion of the tower wall over the door and CIP beam along gridlines E and G. Proper activation of tower plastic hinges was verified before incorporating the towers into the overall building model.

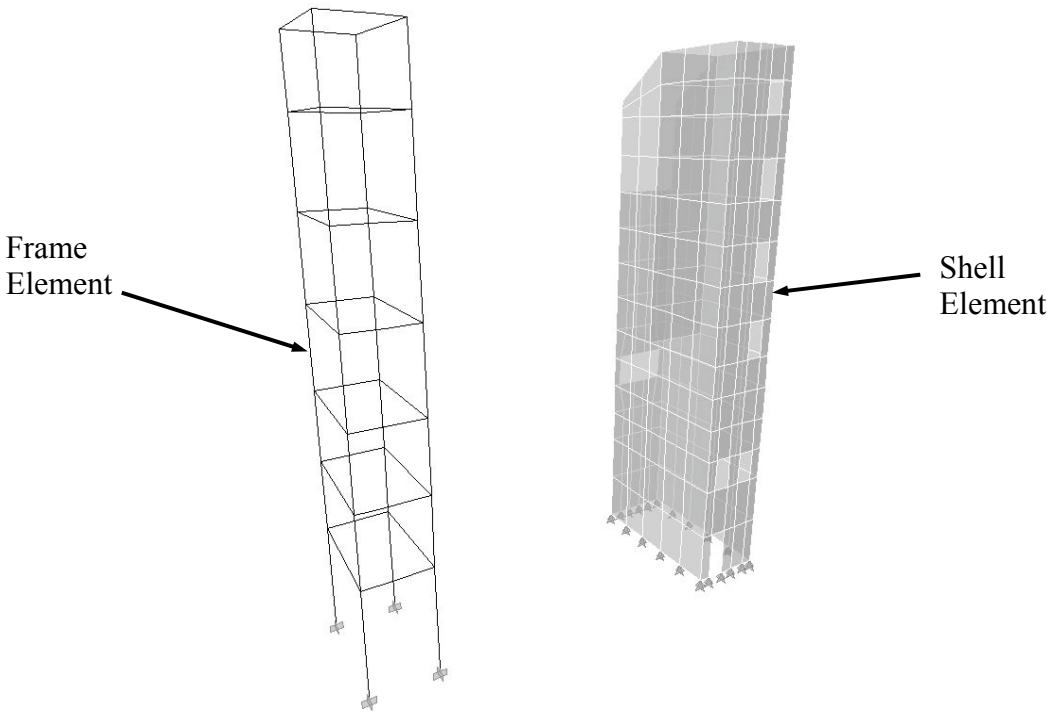

Figure 5. Comparison between frame model and shell model of tower

BUIDING EVALUATION RESULTS

The linear static analysis indicated that the as-built configuration of the building did not allow for the transfer of force to all of the existing walls. In the north-south direction, the exterior walls of the towers were unable to resist north-south seismic loads since the towers extended beyond the diaphragms. This significantly overstressed the walls along the centerline of the building and the interior face of the towers where penetrations for doorways into the towers drastically reduced the available wall. In the east-west direction, no collector was present to drag load into

the tower walls along gridlines 3 and 10. Therefore, it was determined that either these load paths would need to be created or additional walls would need to be added.

Both options were considered. Ultimately, the option to extend the floor diaphragms and add wall collectors along gridlines 3 and 10 were chosen because it would result in less impact to the occupants of the building during construction and the usability of floor plans. However, even with this retrofit approach, the elastic analysis still indicated that the walls were potentially overstressed. Even with the diaphragms extended to the outside face of the tower walls, some of the centerline shear walls and interior face tower walls were overstressed in shear at the lower levels. Additionally, even with the tower collectors, the tower walls were also overstressed in flexure and shear. Therefore, given that only some of the shear walls were overstressed in the north-south direction, and the tower walls were not significantly overstressed in the east-west direction based on the linear static analysis, it was felt that a nonlinear static analysis would verify that the shear walls would be adequate with only minor infilling of existing penetrations.

As shown in Figures 6 and 7, the nonlinear static analysis indeed showed the retrofitted building could satisfy both the Life Safety performance objective at the BSE-1 target displacement and the Collapse Prevention performance objective at the BSE-2 target displacement. In the north-south direction, the building could reach the Life Safety performance objective at the BSE-1 target displacement with shear yielding in only some of the walls. The building could reach the Collapse Prevention performance objective at the BSE-2 target displacement before the building formed the governing mechanism of shear yielding above the basement walls, as seen in Figure 8. In the east-west direction, the building could reach the BSE-1 level performance objective with some initial flexural yielding of the towers followed by shear yielding after the BSE-2 level target displacement was reached as seen in Figure 9.

Even with the use of advanced analysis, there were several deficiencies that required remediation. In particular, at the roof, while the gypsum was reinforced with weld wire fabric, there was a lack of shear connection between the gypsum concrete diaphragm and the steel girders in the north-south direction. Furthermore, the connections of the steel girders in the north-south direction to the centerline walls and tower walls were insufficient to resist the cross-tie loads for the roof. Finally, the open web steel joists were insufficient to resist the cross-tie loads for the roof in the east-west direction.

SPECIFIC DEFICIENCIES AND RETROFIT SOLUTIONS

While the replacement of the roof was a possible solution to the deficiencies in load path and cross-ties, the impact to the occupants would have been extensive. Alternatively, the fact that the metal deck strips of roof between the towers was lower than the gypsum concrete roof was used to good effect in adding new concrete over metal deck strips of roof over each of the existing metal deck roof strips. This new strip of roof was supported by new steel girders spanning from the interior corners of the towers at gridlines E and G to the walls along gridline F. The new roof was connected to the existing open web steel joists at the sides of the gypsum concrete roofs, transferring the east-west seismic loads from the gypsum concrete into the concrete strip and, ultimately, to the tower walls through the new steel girders. The new roof strips also served as beams to confine the gypsum concrete roofs through bearing in the north-south direction and transferring the seismic loads to the centerline walls along gridline F and the interior walls of the towers along gridlines E and G. Also, the new steel girders that support the roof strips between gridlines 5 to 6 and 7 to 8 served to support raised mechanical platforms which contained new mechanical equipment for the building, part of the modernization of the HVAC systems.

As previously mentioned, the tower walls along gridlines 3 and 10 were capable of resisting the lateral loads of the building as there were no collectors for these walls in the original design. Therefore, vertical steel plates were bolted to the outside face of the concrete tower walls and behind the brick facade as the brick was removed and replaced. These vertical plates were spliced with horizontal plates inside the building which were through-bolted to the precast tee beam that spans in the east-west direction between gridline F and either E or G. These horizontal plates were recessed into the 3” topping slab on top of the precast tee beams, the topping slab was then repaired flush with the surrounding floor so as not to interfere with the use of the floor.

The remediation of one of the main seismic deficiencies of the building involved the need to increase the amount of shear wall in the north-south direction. The centerline shear walls were inadequate when simply combined with only the interior face of the tower walls given the numerous door openings in these walls. The exterior face of the tower walls needed to be engaged, and the diaphragm needed to be extended to these walls for this to occur. While extending the floor slabs out to the outside face of the towers was considered, it was not attractive due to the high cost and impact to the occupants from the associated construction. Therefore, a horizontal steel truss solution was developed that would be less costly and faster to construct, would have much less impact on the building occupants, and would integrate with the aesthetic look the architect was designing for the modernized building. The trusses, some measuring as much as 17 by 50 feet, were designed to be fabricated off-site, trucked in, and then lifted into place as one complete unit. The connections to the edge beams and the sides of the towers were designed to receive the trusses as the trusses were

slid into place by a crane. The brick was repaired around these connections giving a clean, modern look to the trusses and the building as shown in Figure 10.

Figure 10. East elevation showing exterior trusses

CONCLUSIONS

Through the use of nonlinear static analysis and creative problem-solving, a seismic retrofit for the building was designed to achieve the desired seismic performance using primarily the existing structural components. The addition of new structural elements was kept to a minimum, and most of the work involved strengthening connections and utilizing existing structural framing. The new elements that were added served multiple purposes, beyond the basic seismic structural purposes. The new roof, while strengthening the roof diaphragm, also supported the new mechanical equipment that was part of the modernization of the research labs. Placing the new equipment and associated ductwork on the roof allowed the existing equipment and ductwork in the basement to remain operational for the continued use of the lab spaces while most the rest of the construction project progressed. The horizontal trusses, while capturing the exterior tower walls for lateral resistance, also featured prominently in the architect's modernization of the overall appearance of the building.

Central to all of the seismic strengthening work was the theme of minimizing the impact to the occupants; the important research in the science facility was conducted and student lessons continued uninterrupted during construction. This was accomplished through keeping as much of the construction work outside the building

as possible and modifying the envelope of the building as little as possible; thus minimizing the dust, vibration, and noise inside the building during construction.

Ultimately, the approach taken to analyze and strengthen the building satisfied the university and state's goals for this project. The new building stands as a prominent example of the university and state's desire to promote seismic safety and sustainability. Accordingly, the building has already hosted a tour for representatives from nearly 20 Pacific Rim countries, which was organized by the U.S. State Department, World Affairs Council, for the purpose of showcasing the state's commitment. Additionally, the building has been featured by National Geographic in a filmed segment focusing on the state's proactive steps to implement seismic safety and sustainability. On a local level, through a presentation to the student chapter of ASCE, the building has recently served the engineering students of the university as an example of a seismic retrofit project. This project also will continue to serve as a teaching example for future engineering classes.

ABSTRACT

The unfortunate collapse of the I-35W Bridge in Minneapolis, Minnesota in August 2007 has brought bridge safety to the forefront of the public. The immediate reaction to the incident was focused on highway bridge inspection and evaluation practices, especially related to inspection and evaluation of gusset plates on truss bridges. There were several directives from federal and state authorities to address these issues in the short-term and long-term. The short-term directives were to address the inspection and evaluation of gusset plates on truss bridges similar to the collapsed I-35W bridge. For the long-term, Congress and the bridge industry have focused on reviewing current practices in bridge inspection and bridge management, identifying gaps and issues with current practices and policies that can be improved in the future, and providing methodologies to effectively utilize available limited resources using risk based methodologies. This paper will discuss these issues from the owners' perspective based on the authors' involvement and experience in working with state and other transportation agencies on such issues.

INTRODUCTION

The deck truss of the eight-lane I-35W Highway Bridge over the Mississippi River in Minneapolis, MN collapsed on August 1st of 2007 causing 13 deaths and 145 injuries (see Figure 1). The detailed studies by the National Transportation Safety Board (NTSB) attributed the collapse to inadequate load capacity of a gusset plate that failed under a combination of substantial increase in the weight of the bridge due to previous modifications and the traffic and concentrated construction loads on the bridge on the day of the collapse (National 2008). The gusset plate was under-designed and did not have adequate load capacity. But before this was made clear, the immediate focus of the owners and regulating agencies had been on inspection and evaluation aspects and possible improvements.

As a reaction to any failure, the immediate focus of bridge owners and the government (both federal and local) is to assure the public that these types of bridges in their jurisdiction are safe and take appropriate actions to avoid such failures in the future. This involved identification of all such structures, initial quick visual

inspections, followed by detailed inspections and evaluations as more and more information became available. Issues were resolved by incorporating appropriate policies and initiating research required to make the programs better in the long-term.

This paper briefly discusses the major studies conducted after I-35W Bridge collapse to prevent such failures in the future with emphasis on efforts by the New York State Department of Transportation (NYSDOT) and the American Association of State Highway and Transportation Officials (AASHTO).

Figure 1. I-35W Bridge Failure (Courtesy: Minnesota DOT Web site)

MAJOR STUDIES AND OUTCOMES

This section briefly describes some of the efforts by NTSB, Government Accountability Office (GAO), American Society of Civil Engineers (ASCE), AASHTO, and Federal Highway Administration (FHWA) in the bridge inspection and evaluation area.

NTSB Study. NTSB has investigated the I-35W failure to determine the probable cause of the accident and made recommendations to prevent similar failures from occurring in the future. Based on their study, NTSB identified five safety issues in the investigation (National 2008): 1) Insufficient quality control procedures by the bridge design firm for designing bridges and insufficient federal and state procedures for reviewing and approving bridge design plans and calculations. 2) Lack of guidance for bridge owners in regard to the placement of construction loads on bridges during repair or maintenance activities. 3) Exclusion of gusset plates in bridge load rating calculations. 4) Lack of inspection guidance for condition of gusset plate distortion. 5) Inadequate use of technologies for accurately assessing the condition of gusset plates on deck truss bridges. NTSB made several recommendations to FHWA and AASHTO and urged them to take action on these safety recommendations in order to prevent failures in the future.

GAO Study. After the I-35W Bridge collapse, the GAO prepared a report to Congressional Committees on the U.S. Department of Transportation's ability to prioritize resources for bridges (United 2008). The Highway Bridge Program (HBP) is considered one of the primary sources of federal funding for bridges and this study examined the use and effectiveness of this funding based on the review of program documents, bridge data analysis, and meetings with transportation officials in states that have high levels of HBP funding and large bridge inventories. The report concluded that the current HBP program, while generally helping to improve bridge conditions (see Figure 2), does not have goals and performance measures that align with federal funding. The report also found no-ties between the HBP funding and bridge performance and lack of data to ascertain the effectiveness of HBP. The report made several recommendations to improve the focus, performance, and sustainability of the HBP.

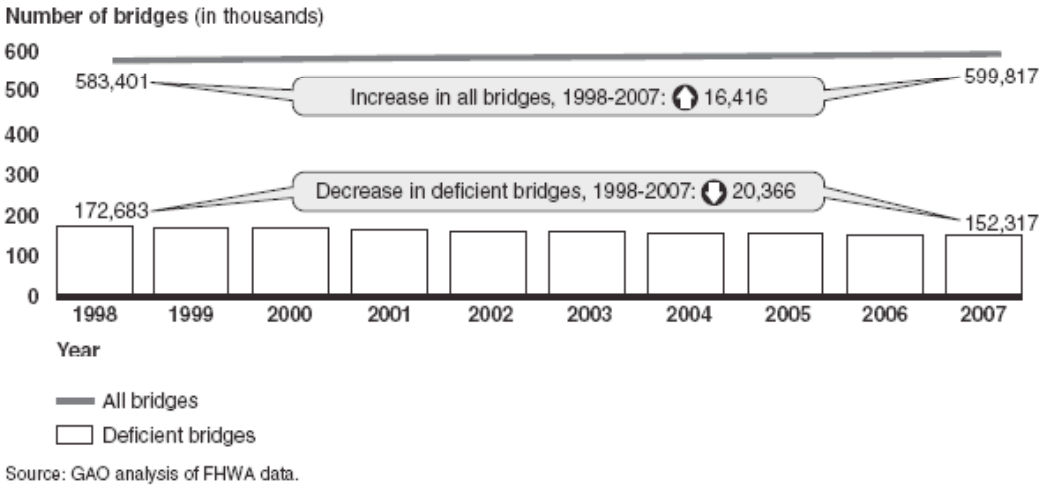

Figure 2. Trends in Numbers of Bridges and Deficient Bridges, 1998 through 2007 (Source: GAO-08-1043, Page 26)

Structural Engineering Institute (SEI) of ASCE. There were several non-government efforts on identifying the gaps in bridge inspection and management practices. One such effort was initiated by SEI. SEI formed a joint ad-hoc group with members from SEI and AASHTO. (Authors of this paper were part of this ad-hoc group.) This group discussed bridge inspection and rating methods and practices used to ensure the safety of highway bridges in the United States. The group concluded that, in general, the current National Bridge Inspection Standards (NBIS) and programs developed to address those standards have adequate policies and procedures in place to ensure public safety (White Paper 2009). The group also concluded that the current system can be improved and identified gaps and needs to improve bridge safety and ensure uniformity, consistency, and reliability of bridge inspections nationwide. Four of these are listed here: 1) A more rational, risk-based approach considering factors such as the design, details, materials, age, and loading of specific bridges to determine the appropriate inspection intervals for bridges as opposed to a set 24 month cycle. 2) New and more assertive types of quality control and assurance, such as performance testing of inspectors that could be used to encourage consistency

of inspections. 3) Close collaboration between those responsible for maintenance and repair of a bridge and those responsible for bridge inspection. 4) Accurate definitions of terms such as structurally deficient, functionally obsolete, and fracture critical to make public perception of bridge safety consistent with the facts.

AASHTO. AASHTO, representing all state transportation agencies, provided the required information and data to investigators of all the above studies, as well as providing information to the public and to politicians through testimonies and hearings. They also collected, as needed, information from all the states through questionnaires and surveys.

NTSB made several recommendations to AASHTO regarding bridge inspection and management issues (National 2008); and AASHTO took appropriate actions as noted below.

H-08-21: Revise AASHTO Manual for Bridge Evaluation (MBE) to include guidance for conducting load ratings on new bridges before they are placed in-service: AASHTO Subcommittee on Bridges and Structures (SCOBS), at their annual meeting, approved changes to the MBE which includes language that further clarifies the purpose of load rating. The new language includes information stating that as-built construction and shop drawings should be used rather than design drawings to calculate load ratings, and emphasizes that load ratings should be reviewed and updated if necessary during every inspection cycle. These updates to the MBE are available as an Interim as of January of 2010 (Manual 2010).

H-08-22: Modify the guidance and procedures in MBE to include evaluating the capacity of gusset plates as part of the load rating calculations performed for non-load-path-redundant steel truss bridges: The AASHTO SCOBS approved changes to the MBE that outlined inspection methods of gusset plates and connections as well as methods for load rating of gusset plates. Also included in the updates to the MBE is reference to the FHWA memorandum addressing guidance on load rating of gusset plates. These updates to the MBE are available as an Interim as of January of 2010 (Manual 2010).

H-08-23: When the findings of the FHWA/AASHTO joint study on gusset plates become available, update the MBE: Upon completion of the NCHRP Project 12-84, "Guidelines for the Load and Resistance Factor Design and Rating of Riveted and Bolted, and Welded Gusset-Plate Connections for Steel Bridges," AASHTO will review and consider incorporating appropriate recommendations from this study into AASHTO specifications as soon as practical.

H-08-25: Include gusset plates as a commonly recognized structural element (CoRe) and develop guidance for bridge owners in tracking and responding to potentially damaging conditions in gusset plates, such as corrosion and distortion; and revise the AASHTO Guide for Commonly Recognized (CoRe) Structural Elements to incorporate the new information: The CoRe document (Guide 2010) was amended with an Interim, and now includes gusset plates.

In addition to the response to the NTSB recommendations, AASHTO has also recognized the need for a better, easier to use document outlining Element Level Bridge Inspection Practices. In 2010, a new Guide Manual for Bridge Element Inspection (Guide 2011) was developed and accepted by SCOBS. This manual will supersede the *CoRe* Manual in the future and will be available in print in January

2011. The new element guidelines will also be incorporated into the PONTIS bridge management software in 2011.

FHWA. The immediate efforts of Federal Highways was for their division offices to offer support to the states during the mandated immediate inspections and to provide communication channels from the federal government. The FHWA Office of Bridge Technology also worked closely with AASHTO participating in immediate conference calls with all the states to discuss reactions to the collapse.

Also in response to the I-35 W Bridge collapse, on January 15th 2008, FHWA issued Technical Advisory 5140.29 "Load-carrying Capacity Considerations of Gusset Plates in Non-load-path-redundant Steel Truss Bridges" giving guidance for load rating of gusset plates. Since then, webinars and support have been given to the states to enact these methods.

After NTSB completed their investigations the following recommendations were made to FHWA concerning bridge inspection and management.

H-08-18: Require that bridge owners assess the truss bridges in their inventories to identify locations where visual inspections may not detect gusset plate corrosion and where, therefore, appropriate nondestructive evaluation technologies should be used to assess gusset plate condition: The FHWA concurred with this recommendation to supplement visual inspection with appropriate nondestructive evaluation methods to more thoroughly assess gusset plate condition as necessary. The FHWA evaluated feasible alternatives for nondestructive evaluation of locations where visual inspections may not detect gusset plate corrosion. FHWA also cooperated and collaborated with AASHTO and bridge owners to study options that are practical and could be effectively put into practice in compliance with this recommendation and NBIS. These findings are now being shared with the states.

H-08-19: Modify the approved bridge inspector training as follows: (1) update the National Highway Institute training courses to address inspection techniques and conditions specific to gusset plates, emphasizing issues associated with gusset plate distortion as well as the use of nondestructive evaluation at locations where visual inspections may be inadequate to assess and quantify such conditions as section loss due to corrosion; and, (2) at a minimum, include revisions to reference material, such as the Bridge Inspector's Reference Manual, and address any newly developed gusset plate condition ratings in the American Association of State Highway and Transportation Officials commonly recognized (CoRe) structural elements: The FHWA has begun the process of updating and revising the inspection training courses offered through the National Highway Institute and other reference documents, such as the Bridge Inspector's Reference Manual, to emphasize inspection issues associated with gusset plates, including corrosion and distortion.

National Highway Bridge Reconstruction and Inspection Act of 2008 (S. 3338): After the I-35W Bridge failure, a legislation at the national level was proposed in the previous Congress to authorize additional funding to improve bridge infrastructure condition. The legislation proposed strengthening bridge inspection standards, adopting a risk-based prioritization process for certain bridge rehabilitation and replacement projects, required that states develop 5-year performance plans for bridge

inspections and for the rehabilitation or replacement of deficient bridges, and required states to develop and implement a bridge management system. The proposed legislation had several implications on the bridge inspection and evaluation program, but was never acted upon.

STATE EFFORTS

The immediate reaction of most states has been to check their inventories for number, location, and condition of bridges similar to I-35W (i.e. deck truss bridges) to review their condition and to provide this data to the public. Most of these structures were inspected as soon as possible with their load ratings reviewed. As the details of the failure and gusset plate issues surfaced, the policies governing the construction loads, including gusset plates in detailed bridge inspections, and inspection procedures were reviewed with appropriate changes made to assure safety and adhere to mandates. New York State experience is given below. It is the authors' opinion that similar actions might have been taken in other states, but exact actions might vary depending on the structure of the State Transportation agencies, local practices, bridge ownerships, etc.

NY State Efforts. (Annual 2008 and 2009) In response to the tragic collapse of the I-35W Bridge in Minneapolis on August 1, 2007, the Governor of New York State established a Task Force, chaired by the NYSDOT Executive Deputy Commissioner and comprised of participants from the New York State Department of Transportation, New York State Thruway Authority, New York State Bridge Authority, and the Metropolitan Transportation Authority. The Task Force was directed to determine whether bridges in New York State of similar design and type as the I-35W bridge continued to be safe to use, to review the State's bridge inspection standards and procedures, and to report back to the Governor in 30 days.

There are 49 deck truss highway bridges in New York State. Of the 49, twenty are State-owned, 12 are locally owned, 15 are owned by authorities, and 2 are highway bridges owned by railroads. All 49 bridges had visual inspections completed by August 31, 2007. Detailed, hands-on inspections were also completed on each of these bridges by October 17, 2007. The visual inspections and the more detailed inspections found that these structures are safe and the current inspection protocols are adequate to ensure the safety of the traveling public. The Task Force concluded that all the public highway bridge owners are meeting or exceeding the standards for bridge inspection and safety assurance that were established by NYSDOT pursuant to Federal regulations, 23 CFR Part 650, and Article 9 of the Highway Law as amended by the State's Graber Law -- Chapter 781 of the Laws of 1988.

Two reports summarizing Task Force activities were prepared and submitted to the Governor: an initial report issued on August 31, 2007 and a final report issued on November 30, 2007. These reports (New York 2007a and 2007b) may be viewed on the Department's Website at www.nysdot.gov/bridgedata.

Following the National Transportation Safety Board recommendations and a related Federal directive, all the truss bridges were screened to ensure that the gusset plates had been adequately designed. An implementation plan was developed to achieve this result with specific guidance and direction developed and issued for

reviewing the adequacy of existing bridge gusset plates in accordance with FHWA's Technical Advisory. The Department developed software for analysis of gusset plate capacity and also organized a training session on the use of the developed software and associated methodology. All of the 132 truss bridges identified as meeting the criteria outlined in the Federal Advisory were analyzed to ensure that the gusset plates had been adequately designed. These efforts found no design related deficiencies. At the same time, these efforts revealed some deterioration related deficiencies in about 10 of the bridges and these were addressed through repairs, postings, or closure of the bridges.

Due to public awareness and interest in bridge data, a website (www.nysdot.gov/bridgedata) was created with the latest bridge inspection and condition data that is updated periodically. This website also gives relevant information on bridge condition definitions, the bridge inspection program, and bridge statistics.

A research project is also in progress to document quantitatively the variability of condition scores associated with the New York State Bridge Inspection Program, suggesting improvements to policy and procedures and areas requiring further training, if needed, to reduce the variability and improve the reliability/consistency of the program. The project is expected to be completed in 2011.

SUMMARY

The unfortunate collapse of the I-35W Bridge, similar to other past bridge failures, brought bridge safety to the forefront of public attention. Several studies were conducted by public and private agencies to review the failure and take steps to avoid such failures in the future. Connections have always been included as part of the primary members, but generally were designed to be stronger than the primary members. Thus, they normally do not control the design and hence, were not included in most load rating analyses. These will be included by the owners in the future load rating analyses as they could be a controlling factor when deterioration affects them. Considerable research is on-going on the use of advanced technologies for bridge health monitoring and risk based evaluations that may be incorporated into practice in the coming decade.

ABSTRACT

The failure of a large steel truss bridge in Minnesota has been, in part, attributed to overstressed and buckled gusset plates. This catastrophic event signaled concerns of the potential for a similar overstressed state in gusset plates in steel truss bridges across the county. To provide guidance to bridge engineers, the Federal Highway Administration released FHWA Bridge Design Guidance No. 1 Load Rating Evaluation of Gusset Plates in Truss Bridges; however, the somewhat complex evaluation methods make rapid assessment costly for DOTs. A study supported by the Washington State Department of Transportation and FHWA has developed a procedure for rapid and reliable evaluation of the state of gusset plates, including the maximum stresses and likelihood of yielding. The development utilized a parametric study of several gusset plate configurations performed using advanced nonlinear finite element analysis. Parameters such as plate thickness, yield stress, and load distribution were considered for actual gusset plate connections from bridges primarily in Washington State. The selected gusset connections also had different geometries to ensure the resulting evaluation approach is sufficiently broad in applicability. The new approach should enable bridge engineers to more expediently evaluate the capacity of gusset plates, allowing gusset plates with near critical demand-to-capacity ratios to be identified for further, more refined analysis or retrofit. The paper and presentation will detail the analyses and resulting rapid gusset plate evaluation procedure.

INTRODUCTION

A Federal Highway Administration report (Ocel and Wright 2008) has demonstrated that several of the gusset plates on the collapsed I-35 Mississippi River Bridge in Minneapolis were significantly over stressed and has identified the inelastic buckling of one of the plates in particular as a likely cause of the collapse. Thus, there is an urgent need to evaluate the safety of gusset plates on such bridges across the county. In response, FHWA has released *Load Rating Guidance and Examples for Bolted and Riveted Gusset Plates in Truss Bridges* (FHWA Guide, FHWA 2009) which provides Departments of Transportation (DOTs) with guidance for gusset plate evaluation. In addition to checking the resistance of fasteners, the recommended approach includes four plate checks: compressive buckling, tension, shear and block shear. The shear check requires point-in-time truss element loads (denoted concurrent loads) for consistent estimation of the shear stress rather than envelope loads, which can make the check cumbersome

and time consuming. While it is important that gusset plates be evaluated, the number of truss bridges that have failed relative to the total number of truss bridges in service suggests that the number of over stressed gusset plates on steel truss bridges throughout the U.S. is small. Thus, a rapid evaluation procedure that is appropriately conservative but can be easily and cost-effectively applied is warranted. The procedure should identify gusset plates that are highly stressed and warrant more detailed investigation while quickly demonstrating that many others are not of concern.

This paper describes analytical research that develops a rapid procedure to identify highly stressed gusset plates, denoted the Triage Evaluation Procedure (TEP). In the process of this development, extensive nonlinear analyses are performed which show the relationships between the TEP, the procedure in the FHWA Guide, and expected gusset plate performance. Three bridges in the Washington State Department of Transportation (WSDOT) inventory were selected for this research, each with different geometries and gusset plate configurations. Global analysis of each bridge was performed to establish realistic gusset plate loads and load distributions. Results of the global bridge analyses were used to select gusset plate geometries from each bridge for high resolution finite element analysis. Finite element (FE) models of the three selected gusset plates and the suspect gusset from the I-35 bridge were developed and used to study the onset of yielding, the interactions of gusset plate stresses generated from loads in the truss elements, and gusset buckling. For each gusset plate model several analyses were conducted with different gusset plate thicknesses and load distributions to clearly establish initiation of yielding and buckling

BRIDGE AND GUSSET PLATE DESCRIPTIONS

Elevations and photographs of the three bridges from the WSDOT inventory selected for use in this research are shown in Fig. 1. Two are deck truss bridges that cantilever off inner piers and have simply supported drop-in trusses in the middle (BR 31-36 and BR 101-217) and one is a simply supported through truss (BR 90-134N). Open circles in Fig. 1 indicate locations where hinges were included in the trusses via large pins to allow the center portions of the deck trusses to remain simply supported and to allow for thermal movements. Each bridge carries two lanes of traffic, with BR 90-134N carrying two lanes that travel in the same direction. The bridge shop drawings are dated 1930 for BR 101-217, 1949 for BR 90-134N, and 1950 for BR 31-36.

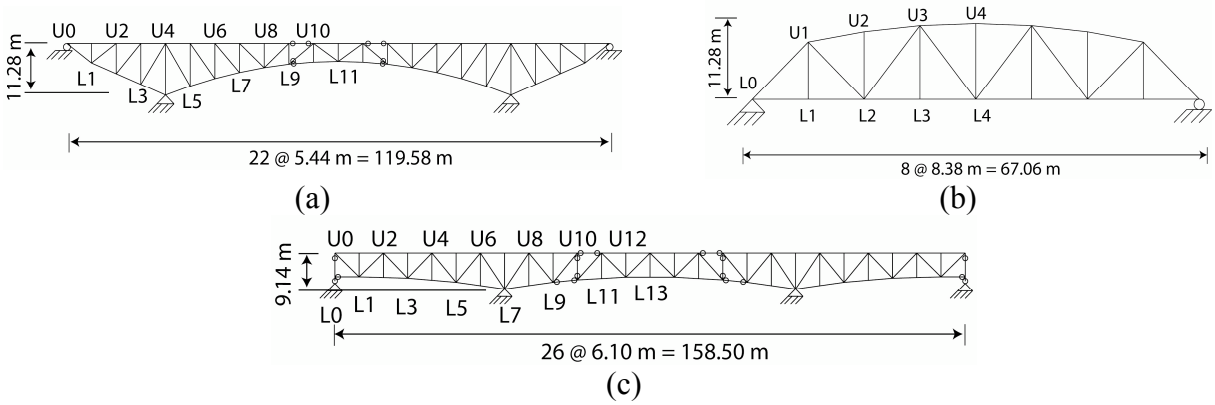

Figure 1. Elevation schematics and photographs of WSDOT bridges: (a) BR 101-217, (b) BR 90-134N, (c) BR 31-36.

Global two-dimensional analysis of each truss was performed for dead load and the HS-20 live loads (AASHTO Manual for Bridge Evaluation, AASHTO 2008) to identify gussets with high stresses and unique geometry for detailed FE modeling. Tension and compression Whitmore stresses for all members connected at a joint were used as indicators of gussets with relatively high stresses**.** One gusset plate connection from each bridge described above was selected for detailed.

Each selected joint is shown in Fig. 2. Joint L5 from BR 101-217 (Fig. 2a) is a lower chord connection with 9.5 mm (3/8 in.) thick gusset plates positioned between the back-to-back channels and the diagonal and vertical members pass between the gusset plates with the vertical member extending through to the bottom flange of the chord. The steel is specified as "Structural O.H. Steel", which for the purposes of this research was taken to have a specified yield stress of 207 MPa (30 ksi). Joint L9 from BR 31-36 (Fig. 2b) has two 13 mm (1/2 in.) thick gusset plates that are riveted to the outer faces of the truss members. This connection is at a hinge location in the truss and has a zero force chord member attached (L9-L10) with a large pin along where secondary plates increase the bearing strength of the pin hole for construction loads. All steel for this bridge was specified as A7 with a specified yield stress of 228 MPa (33 ksi)**.** Joint L2 from BR 90-134N (Fig. 2c) has two 13 mm (1/2 in.) thick gusset plates located on the outer faces of the members that were specified as silicon steel, for which a specified yield stress of 310 MPa (45 ksi) is assumed. The gusset also serves as a chord splice, where the splice is offset from the midpoint of the gusset, with the connection for Chord L2-L4 being longer. Joint U10 from the I-35 Bridge in Minneapolis (Fig. 2d) was also considered, since it serves as a baseline and comparison to other analytical studies. It is described in detail in Ocel and Wright (2008).

The selected gusset plates provide considerable variation in geometry and gusset plate layout as may be encountered in practice. The distribution of load between members attached to the gusset plates and the thickness of the gusset plates were additional parameters considered in the analytical research.

A suite of load distributions was considered because of the wide variability in dynamic bridge loading and necessity that loads satisfy equilibrium in FE analysis. These variations evaluated their impact on the stress distribution, occurrence of yielding, and buckling capacity of the gusset plates. The load distributions for the gusset plates from the three WSDOT bridges were determined by moving an HS-20 live load over the bridge in the global analyses and factoring the results to be consistent with the Load Factored Rating (LFR) Operating Rating Level per AASHTO (2008), including impact.

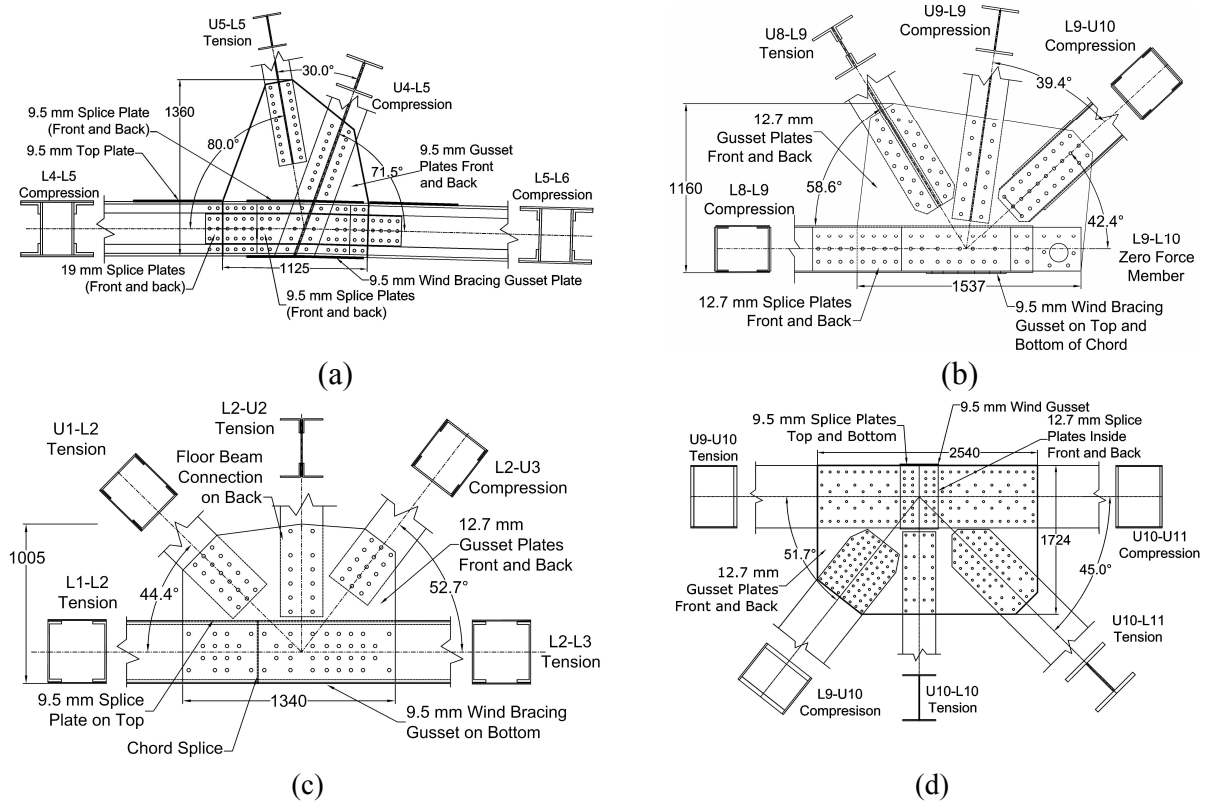

Figure 2. Selected gusset plate connections for detailed evaluation: (a) Joint L5 BR 101-217, (b) Joint L9 BR 31-36, (c) Joint L2 BR 90-134N, and (d) Joint U10 I-35.

FE MODELS

Detailed FE models of each connection were developed using the ANSYS software package (ANSYS 2008) as shown in Fig. 3 for Joint U10 of the I-35 Bridge. All models had similar features except as noted in this discussion. Four-noded reduced integration shell elements were used to model the gusset plates, splices, wind bracing plates and truss members in the vicinity of the gusset plates, as shown in Fig. 3. A mesh refinement study found that a 25 mm (1 in.) average element edge length was adequate and produced similar stress distributions and stress magnitudes at key points as models with smaller mesh sizes. At a distance of twice the member depth, *d*, from the gusset edge the truss members were transitioned to beam elements. A plane-sections-remain-plane master-slave constraint was applied at this transition. The beam elements ended at adjacent panel points where all degrees of freedom except translation in the member's axial direction were restrained. Loads were applied in the axial direction of the members at these adjacent panel points. Restraint was provided against out-of-plane gusset displacement at the locations where wind bracing and/or floor beams connected to the gusset. Gusset L2 of Bridge 90-134N had a floor beam attached to it via a riveted web angle connection. In this case, floor beam loads were applied to the modeled connection at the rivet line of the floor beam web. The web angles were modeled completely and were riveted to the inner gusset plate of the joint.

All rivets were modeled as rigid fasteners. Translational degrees of freedom of nodes at rivet locations were constrained to be equal for members and gussets plates. Contact or gap elements were not used at the surfaces to simplify the modeling process and minimize computational time. This leads to conservative estimates of the gusset plate buckling load, since contact between

plates and members provides additional buckling restraint. All gusset plate and splice plate steel was modeled as bilinear kinematic hardening materials that had an initial modulus of 200 GPa (29,000 ksi) and 3% strain hardening. The strain hardening was found by linearizing the stress-strain results from tests on the I-35 Bridge gusset plate material reported in Ocel and Wright (2008). All shell and beam elements modeling truss members were assigned elastic material properties so that their nonlinear response would not influence the gusset plate response.

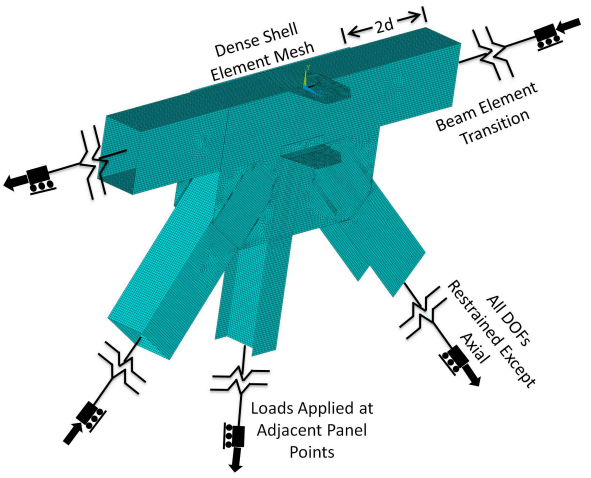

Figure 3. Finite element mesh for Joint U10 I-35 shown with schematic of typical boundary conditions.

DEVELOPMENT OF THE TRIAGE EVALUATION PROCEDURE

Based on the progression of gusset plate yielding described in Berman et al. (2011), the onset of yielding in a gusset plate is defined here to be when 0.5% of the gusset plate area has Von Mises stress above the yield stress of the material. It is important to note that this clearly does not constitute gusset plate failure; however, it is a stress state that may be of concern for bridge owners, since they would not want to exceed this stress too many times in the bridge's life. As a result, bridge engineers would require further investigation of a gusset plate which exceeded this stress state when it occurs under service loading.

To predict the onset of gusset plate yielding the interactions of the stresses generated from the connected truss members must be considered. Fig. 4 illustrates how the stresses from the two diagonal members connected to a gusset plate may interfere with each other. Here, a simple method for combining stresses is developed. While more complex and accurate methods may be possible and are the focus of future research by the authors, the objective of the current endeavor is to develop a conservative, simple and straightforward process for evaluating gusset plates for the onset of yielding.

The Whitmore method conservatively predicts the maximum uniaxial stresses in the gusset at the end of a riveted member connection, which are denoted σ_{11} and σ_{22} in Fig. 5. The TEP conservatively assumes these uniaxial stresses to be principle stresses. The most adverse condition occurs when these stresses for different members are orthogonal to each other and opposite in sign. When these conditions occur, the two dimensional Von Mises yield criterion can be used to demonstrate that yielding occurs when the Whitmore stress at the end of a member, σ_{11}, exceeds $\sigma_y/\sqrt{3}$, where σ_y is the yield stress of the gusset plate (Berman et a. 2011).

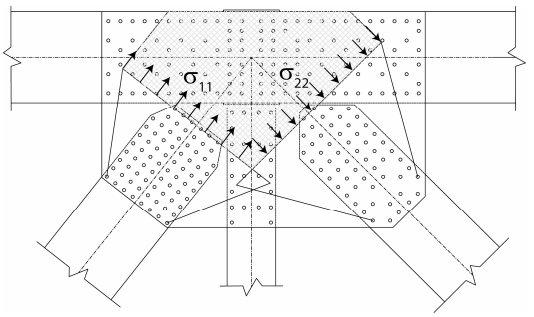

Figure 5. Interference of stresses in truss bridge gusset plates.

COMPARISON OF THE TEP AND FHWA GUIDE PROCEDURE

For each analysis that did not exhibit elastic buckling (typically gusset plates above 3.2 mm (1/8 in.) thick) the truss member loads at the point in the analysis where 0.5% of the gusset plate is yielding was recorded. Those loads were then used to compute the values shown in Table 1, which include the maximum uniaxial stress on the Whitmore section (considering all members) and the maximum gross shear stress (considering multiple shear sections), the latter calculated per the approach in the FHWA Guide. The values shown are for the gusset plates at their actual thicknesses and are shown for only one load distribution, although similar results were observed for other thicknesses and load distributions where elastic buckling did not occur. For Joint L5 of BR 101-217 no shear stress is shown because both possible shear lines pass through either a chord or vertical hanger since the chord is continuous through the gusset and the vertical hanger goes completely through the gusset to the bottom of the chord as shown in Fig. 2. The stresses shown Table 1 demonstrate that in all cases the maximum uniaxial stress on the Whitmore section and maximum shear stress are both below yield and in some cases are as much as 40% below yield when the onset of gusset plate yielding occurs. This result clearly shows that both the shear stress and Whitmore stress evaluations in the FHWA Guide do not identify the onset of gusset plate yielding. This result is not surprising since: (i) the shear stress evaluation assumes full shear yielding over the entire selected shear section, and (ii) yielding along the entire Whitmore width at the end of a truss member implies that the critical stresses are uniaxial and are not influenced by the stresses generated by other members, which was shown above to not be the case.

Table 1. Maximum shear and Whitmore stresses per the FHWA Guide at the onset of significant gusset plate yielding for Load Distribution Case 1.

	Gusset L5 BR 101-217		Gusset L9 BR 31-36		Gusset L2 BR 90-134N		Gusset U10 I-35 Bridge	
	τ_{max} (MPa)	$\sigma_{w,max}$ (MPa)	τ_{max} (MPa)	$\sigma_{w,max}$ (MPa)	τ_{max} (MPa)	$\sigma_{w,max}$ (MPa)	τ_{max} (MPa)	$\sigma_{w,max}$ (MPa)
1	107	133	85	140	101	262	148	237
F_y	207		228		310		345	
$F_y/\sqrt{3}$	119		132		179		199	

Examining the maximum uniaxial stresses along the Whitmore section at yield shown in Table 1, indicates that in all cases, it is greater than $F_y/\sqrt{3}$. Therefore, the proposed yielding check in the TEP is conservative with respect to indicating gusset plate yielding. The TEP

yielding check is a single stress check is made that accounts for the worst possible stress interactions without considering stresses at multiple sections and eliminating the need for concurrent point-in-time loads. The proposed yielding check is significantly faster to employ than the checks in the FHWA guide and should save DOTs considerable resources.

IMPLEMENTATION OF THE TRIAGE EVALUATION PROCEDURE

Here, the TEP and procedure from the FHWA Guide are used to evaluate various gusset plates, including those on the selected WSDOT bridges and Joint U10 of the I-35 Bridge. The fasteners are not evaluated since the focus of the TEP is to identify gusset plates that may be yielding and/or buckling. However, an evaluation of fastener capacity would be necessary as part of a complete joint evaluation. Further, a compression buckling check has been developed for the TEP but is not presented here for brevity (see Berman et al. 2011 for complete details).

Three loading conditions were considered for Joint U10 of the I-35 Bridge: (i) the loads denoted Step 2 in Ocel and Wright (2008), which are an estimate of the forces at the joint due to the dead loads when the bridge first opened for service, (ii) the loads denoted Step 3 in Ocel and Wright (2008), which are an estimate of the forces at the joint due to the dead loads after modifications were made to the bridge in 1999 and (iii) the estimated loads at the time of collapse as given in Ocel and Wright (2008). Table 3 shows demand-to-capacity ratios (DC ratios) for these three loading conditions for Joint U10, where the demand is the maximum Whitmore stress in the gusset considering all members and the capacity is $F_y/\sqrt{3}$ per the TEP. As shown in Table 2 the DC ratio is 1.04 for the Step 2 loading, which indicates this gusset plate was likely to be yielding under only dead loads when the bridge opened for service. With the addition of the construction and traffic loads estimated to be on the bridge at the time of collapse the DC ratio climbs to 1.42 for the TEP. Yielding of the gusset plates at both load levels has indeed been confirmed by finite element analyses conducted as part of this research and by those conducted by Ocel and Wright (2008). DC ratios are also shown for the limit states in the FHWA Guide with resistance factors per the LRFR procedure. For the three loading conditions the horizontal shear governed the capacity of the gusset plate with the factor Ω taken as 0.74 (see the FHWA Guide), resulting in DC ratios above 1.0 for both Step 3 and 4 loads. The values indicate the TEP is conservative relative to FHWA Guide.

Table 2. Capacity-to-demand ratios for Joint U10 of I-35 for Load Steps 2, 3, and 4 from Ocel and Wright (2008).

	Step 2 (Dead Loads 1965)	Step 3 (Dead Loads 1999)	Step 4 (Loads at Collapse)
Triage	0.96	0.78	0.70
FHWA Guide	1.02	0.83	0.78

Rating factors for legal loads for all joints were calculated for the three WSDOT bridges per the AASHTO Manual for Bridge Evaluation (AASHTO 2008) using the HS-20 live load as the legal load and assuming unknown average daily truck traffic. Rating factors (RFs) were calculated per LRFR using factored loads for the Service II load combination for the TEP and the Strength I load combination for procedure from the FHWA Guide and are shown in Tables 3, 4, and 5 for BR 90-134N, BR 31-36 and BR 101-217, respectively. The Service II load combination was selected for the TEP because the yielding check derived is not a failure mode,

but rather indicates the onset of yielding. In all cases, gusset plate yielding governed in the TEP over gusset plate buckling. Comparing the RFs from the TEP and FHWA procedure indicates that the TEP is conservative for all gussets considered.

Table 3. Rating factors for BR 90-134N gusset plates from the proposed Triage Evaluation Procedure with Service II loads and the approach in the FHWA Guide with Strength I loads.

	Joint Identification			
	U1	U3	L2	L4
Triage RF	2.33	1.41	2.20	2.00
FHWA RF	3.51	4.09	2.59	2.75

Table 4. Rating factors for BR 31-36 gusset plates from the proposed Triage Evaluation Procedure with Service II loads and the approach in the FHWA Guide with Strength I loads.

	Joint Identification						
	U2	U4	U6	U8	U10	U11	U13
Triage RF	1.02	2.81	1.95	1.84	5.24	1.08	2.61
FHWA RF	1.24	2.83	2.19	1.90	5.44	1.49	4.85
	Joint Identification						
	L1	L3	L5	L7	L9	L10	L12
Triage RF	1.13	1.82	2.10	3.75	0.78	2.48	1.50
FHWA RF	1.23	1.96	2.12	5.32	0.95	3.14	1.95

Table 5. Rating factors for BR 101-217 gusset plates from the proposed Triage Evaluation Procedure with Service II loads and the approach in the FHWA Guide with Strength I loads.

	Joint Identification								
	U2	U3	U4	U5	U6	U7	U9	U10	
Triage RF	0.93	1.07	1.92	1.68	2.14	1.50	1.15	2.38	
FHWA RF	1.35	1.55	2.47	2.29	2.79	2.02	2.86	2.94	
	Joint Identification								
	L1	L2	L3	L5	L6	L7	L8	L9	L11
Triage RF	1.83	2.25	0.98	1.50	1.74	1.25	1.31	1.24	2.40
FHWA RF	1.84	2.56	1.78	2.47	2.34	2.79	2.53	2.25	3.39

As shown in the tables only a few gusset plates have RFs less than 1.0 from the TEP and will require further investigation. This demonstrates that the procedure is not overly conservative when checked against Service II loads. No joints on BR 90-134N have an RF less than 1.0. On BR 31-36 only Joint L9 has an RF less than 1.0 from the TEP, and also has an RF less than 1.0 from the FHWA Guide procedures. This joint has stresses at Whitmore sections that approximate the assumptions used in the derivation of the yield check for the TEP, i.e., there are Whitmore stresses that are nearly orthogonal, equal in magnitude and opposite in sign. Therefore, this joint would require further investigation and may indeed be yielding under Service II loads. BR 101-217, has two joints, U2 and L3, with RF's less than 1.0 from the TEP and serves as an example

of the limitations of both the TEP and the FHWA procedure. Examining Joint L3 reveals that the RF from the TEP is governed by stresses at the Whitmore sections of the compression chords, which are milled-to-bear. Thus, if these chords are verified to still be bearing against each other they may be neglected and this joint will have an RF greater than 1.0. The RF values all demonstrate that the TEP is conservative relative to the FHWA Guide.

CONCLUSIONS

The currently recommended FHWA procedures for gusset plate evaluation may not identify all gusset plates in steel truss bridges that may be yielding under service loads. Analysis results indicate that a complex interaction of stresses is generated in gusset plates by connecting members and that this interaction can initiate gusset plate yielding when the uniaxial stresses on Whitmore sections associated with those connecting members are well below yield. A conservative and considerably simpler process for identifying gusset plates that may be yielding was developed and is recommended for identifying gusset plates that may need more detailed evaluation.

ACKNOWLEDGEMENTS

This work was supported in part by the Washington State Department of Transportation and the Federal Highway Administration. However, any opinions, findings, conclusions, and recommendations presented in this paper are those of the authors and do not necessarily reflect the views of the sponsors. The authors would like to specifically thank Washington State Bridge Preservation Engineer Harvey Coffman and Load Rating Engineer Mohamad Al-Salman for their invaluable contributions to this research.

Lessons Learned from the Utah Experience: Suggestions for Implementing a Structural License and Practice Act in Your State

Author
Barry Kay Arnold, P.E., S.E., SECB *(**barrya@arwengineers.com**) has a Master of Science Degree from Utah State University. He is a Vice President at ARW Engineers in Ogden, Utah. Barry is a Past President of the Structural Engineers Association of Utah (SEAU) and serves as SEAU's Delegate to the National Council of Structural Engineers Associations (NCSEA). He is a member of the NCSEA Licensing Committee and the NCSEA Board of Directors.*

Abstract
Wading through the mechanics of writing a bill and getting support for structural licensing and practice acts can appear to be an overwhelming, difficult, and time-consuming experience. Working through the political process can especially be a challenge if you are unfamiliar with the motivating factors and back-room negotiations that typically influence a legislative decision. However, a number of Structural Engineers Associations (SEAs) have successfully worked through the legislative process and effectively lobbied for structural licensing and practice acts. Learning from their experience will provide you with the essential background information that you need to ensure success as you move forward toward structural licensing and practice acts in your state.

Because the specific methods of changing the licensing laws will vary from state to state, this session will focus on general topics that each state should have in common. Specifically, this session will include important information about establishing a firm foundation of support, emphasizing the reasons for a practice act, creating a vision that will motivate and inspire, developing strategies for success, presenting talking points that will have impact, and explaining why structural licensing and practice acts are essential. Additional topics will include understanding your legislators and actually writing the bill.

Discussion
Because a change in current licensing laws will be required to incorporate structural licensing and practice acts in most states, a review and understanding of the process and terms are beneficial. This paper provides any SEA and/or SEI Chapter that is pursuing structural licensing and practice acts some insight into the legislative and internal process to help create a winning strategy that will ultimately lead to success and better protection for the public.

The Three Components of the Bill to Change the Licensing Law

Structural Licensing

Structural licensing is a means of defining the credentials an individual must have in order to use the title, "structural engineer." Once these requirements are codified in each state's licensing laws, the term "structural engineer" will be protected such that only those engineers who have met them will be allowed to use it. This is called a title act; it does not create any restriction on the practice of structural engineering by other engineers, but does define the education, experience, and examination requirements of those using the title "structural engineer."

Practice Act

A practice act defines the types of buildings and structures that a structural engineer, as defined by the title act, must be responsible for designing. Restrictions based on structure size, height, use, occupancy, and proximity to high-risk regions are common.

Transition Clause (Grandfathering)

The transition clause, or Grandfathering as it has been called in the past, allows currently licensed and qualified professional engineers the opportunity to continue practicing structural engineering without conforming to the revised examination, education, and/or experience requirements defined in the title act. This is an important component of the process of changing the licensing laws and must be included when a change is made to the law. The purpose of the transition clause is to avoid restricting any existing business or individual from practicing in an area of engineering they have previously practiced in.

Writing the Bill to Change the Licensing Law

Writing the proposed changes to the current licensing laws may appear daunting, but it need not be. In fact, it is a simple process when it includes input from the division responsible for professional licensing and a legislative analyst. It involves taking the existing licensing language and adding to it or deleting portions from it.

Title Act Language

An example of a title act might look like this:

> Each applicant for licensure as a professional structural engineer shall meet the requirements for licensure as a professional engineer and:
>
> (a) submit an application in a form prescribed by the division;
>
> (b) pay a fee determined by the department under Section XX-XX-XX;
>
> (c) provide satisfactory evidence of good moral character;
>
> (d) have graduated and received an earned bachelors or masters degree from an engineering program meeting criteria established by rule by the division in collaboration with the board;

(e) have successfully completed three years of licensed professional engineering experience established by rule by the division in collaboration with the board;
(f) have successfully passed examinations established by rule by the division in collaboration with the board;
(g) meet with the board or representative of the division upon request for the purpose of evaluating the applicant's qualification for licensure.

Item (d) is the education requirement. Item (e) is the experience requirement. Item (f) is the examination requirement. The examination, that has been "established by rule," and in this case, is the NCEES 16-hour structural exam.

The specific examination requirement is generally contained in the rules and not in the law so that a change in the type of allowed examinations can be made by the licensing board and will not require legislative action.

In the above example, the Structural Engineering license (SE) is a post-Professional Engineer (PE) credential. This is a stance recommended by ASCE/SEI. Some states have opted instead to have SE applicants take either the PE exam or the SE exam, but not both.

Practice Act Language

An example of a portion of a practice act might look like this:

"Professional structural engineering or the practice of structural engineering" means a service or creative work in the following areas, and may be further defined by rule by the division in collaboration with the board:
(a) providing structural engineering services for significant structures including:
(i) buildings and other structures representing a substantial hazard to human life, which include:
(A) buildings and other structures whose primary occupancy is public assembly with an occupant load greater than 300;
(B) buildings and other structures with elementary school, secondary school or day care facilities with an occupant load greater than 250;
(C) buildings and other structures with an occupant load greater than 500 for colleges or adult education facilities;
(D) health care facilities with an occupant load of 50 or more resident patients, but not having surgery or emergency treatment facilities;
(E) jails and detention facilities with a gross area greater than 3000 square feet; or

(F) an occupancy with an occupant load greater than 5,000;

(ii) buildings and other structures designated as essential facilities, including:

(A) hospitals and other health care facilities having surgery or emergency treatment facilities with a gross area greater than 3000 square feet;

(B) fire, rescue and police stations and emergency vehicle garages with a mean height greater than 24 feet, or a gross area greater than 5000 square feet;

(C) designated earthquake, hurricane, or other emergency shelters with a gross area greater than 3000 square feet;

(D) designated emergency preparedness, communication, and operation centers and other buildings required for emergency response with a mean height more than 24 feet, or a gross area greater than 5000 square feet;

(E) power-generating stations and other public utility facilities required as emergency backup facilities with a gross area greater than 3000 square feet;

(F) structures with a mean height more than 24 feet, or a gross area greater than 5000 square feet containing highly toxic materials as defined by the division by rule, where the quantity of the material exceeds the maximum allowable quantities set by the division by rule;

(G) aviation control towers, air traffic control centers and emergency aircraft hangars at commercial service and cargo air services airports as defined by the Federal Aviation Administration with a mean height greater than 35 feet, or a gross area greater than 20,000 square feet; and,

(iii) buildings and other structures requiring special consideration, including:

(A) structures or buildings that are:

(I) normally occupied by human beings; and

(II) five stories or more in height; or

(III) that have an average roof height more than 60 feet above the average ground level measured at the perimeter of the structure;

(B) all buildings over 60,000 aggregate gross square feet in area; and

(b) includes the definition of professional engineering or the practice of engineering provided in Subsection (X).

In the above example specific restrictions are defined regarding which categories of structures must be designed by a licensed structural engineer based on building size and height, occupancy, and use. Additional categories could include building use, high wind speed zones, high snow loads, seismic site class, and problematic soil conditions like liquefaction or expansive clays.

Transition Clause Language

An example of a transition clause might look like this:

(f) have successfully passed examinations established by rule by the division in collaboration with the board, *except that prior to (DATE), an applicant for licensure may submit a signed affidavit in a form prescribed by the division stating that the applicant is currently engaged in the practice of structural engineering;*

The above portion of the transition clause is intended to be incorporated as part of the title act section (f) described above. The text in italics specifically defines the exception to the proposed rule for professional engineers desiring to utilize the transition clause to acquire the title of structural engineer in lieu of taking an additional examination.

It is important to understand that the title act, practice act, and transition clause noted above are intended to be examples only and are not intended to be viewed as guidelines or recommendations endorsed by any national organization.

Keep in mind that the wording of the proposed changes is important. All words have a legal definition(s) that may differ from the common usage or ordinary dictionary definition of the word. Watch for words with double or multiple meanings to avoid ambiguity.

Although the initial process of writing the title act, practice act, and transition clause may be completed by a structural licensing committee within the SEA, it is imperative that the proposed changes be circulated to all organizations that may have an interest in the matter. The process should be open and fair and sincerely consider all input and recommendations from any source. The benefit of having a variety of organizations provide input is to minimize the possibility of having unintended consequences. Contractors, building owners, architects, and engineering organizations can provide a variety of valuable perspectives, useful assistance, and insights.

It is imperative throughout the bill-writing process that you are willing to negotiate, compromise, and acquiesce. As with all bills that go through the legislative process, the single best way to get your bill defeated is to be inflexible. On the other hand, the single best way to get your bill passed is to be willing to give and take a little.

Getting the Public Relations Machine Rolling

Many structural engineers tend to avoid publicity and take a back row seat behind the owner, contractor and architect when a project on which they have worked is in the limelight. That type of passive behavior is unproductive when you are trying to get a bill for structural licensing and practice acts passed. Because many structural engineers are seldom seen in the spotlight, it is likely that some of your legislators and the general public may not fully understand the important role that structural engineers play in protecting their health, safety and welfare.

It is imperative that structural engineers raise awareness about the structural engineering profession and the potential problems and hazards that the public faces because of unqualified individuals attempting to perform structural design.

Populate Boards and Committees

There are a variety of boards, organizations, or committees to which the media and your legislators turn for advice and recommendations. It would be beneficial if members of the local SEA and/or SEI Chapter populated those groups to offer advice and provide a voice from the structural engineer's perspective.

Does a representative from your SEA/SEI regularly attend your state's licensing board meetings? Is there a structural engineer on the licensing board? Does your state have other appointed advisory boards to which they turn for advice? A structural engineer should volunteer to sit on every board that may be consulted by the legislature while debating the issue of structural licensing and practice acts to provide input and clarify the motivation and reasons behind the bill.

There are a variety of local engineering-related associations such as ASCE and ACEC that have boards and committees that may support changes to the current laws. Members of the SEA should volunteer to be involved in those organizations to keep them abreast of developments and progress, and to be a conduit for information and input back to the SEA/SEI.

Increase Awareness of What Structural Engineers Do for the Public

Journalists from local television stations, magazines and newspapers are always looking for interviews and articles of local interest and concern. Publishing an opinion piece or appearing on television is a great opportunity to increase the public's awareness about structural engineering. If it is appropriate, emphasize what structural engineers do and what sets them apart from other branches of engineering.

Remember that the media are looking for local interest stories that will grab the public's attention and provide useful information that they can use and from which

they can benefit. When you discuss or write on a topic for the media, keep this question in mind: "What is in it for their viewers, listeners, or readers?" That is the question they are asking themselves, and it will ultimately be a deciding factor in whether you are published or interviewed.

To be of use to the general public, any interview that is given or article that is written should use non-technical language, such that it is void of jargon, and should emphasize why the public should be concerned about the topic.

A sample of article titles that may be of interest to the public and media include:

- Why Did My Neighbor's House Fall Down? (after a hurricane, earthquake, or snow storm)
- Is My House Safe Against Earthquakes?
- Things to Consider When Building in Earthquake Country.
- What to Look for Before You Buy a House in Hurricane Country.
- How Much Snow is Too Much Snow on My House?
- The Hurricane is Gone, but the Damage Remains – What You Can Do to Prevent This from Happening Next Time

The White Paper and the One-Pager

Writing a white paper is a good starting point to help the SEA/SEI Structural Licensing Committee members collect their thoughts and firm up their positions regarding structural licensing and practice acts. A white paper is generally three to five pages in length and emphasizes the reasons for structural licensing and practice acts.

A white paper is good, but a one-pager is even better. A one-pager is, as the name suggests, one side of one sheet of paper. The one-pager is a concise summary of the contents of the white paper. The one-pager should be easy to read and have bullet points to emphasize important aspects of structural licensing and practice acts. The one-pager is a great way to introduce the public, legislators, and media to the topic of Structural Licensing and Practice Acts.

The value of a well crafted one-pager is that it is likely to be read, while the lengthier white paper will generally *not* be read in its entirety. A sample one-pager is included at the end of this paper.

Making the Case for Structural Licensing and Practice Acts

From the national arena there has been a variety of investigations and studies that have highlighted the problem of member failure, building collapse, and–in some cases–death as a result of an engineer practicing outside the area of his or her competence. As informative as those cases are, it is more beneficial to document similar problems within your state. Making the problem more of a local concern and issue carries more weight and impact with the legislature and media than to highlight the problems with poor-quality structural design nationally.

Know Who May Resist SE Licensure

As obvious as the need for structural licensing and practice acts are for many, there are those who are wholly unaware of the magnitude of the problem of licensed engineers practicing outside the areas of their competence and the potential life-threatening consequences that may result. States that require a plan check review before issuing a building permit have firsthand knowledge about the magnitude of the problem. Many contractors, owners, architects, insurance companies, and fabricators and manufacturers of products used on structures are also keenly aware of the magnitude of the problem and its consequences. Unfortunately, there are those in the legislature and within some engineering organizations who choose to turn a blind eye to the situation, preferring to wait and "count the bodies" before they are willing to do something about it.

Some of the groups that have had, in the past, some concern about structural licensing and practice acts include:

- The National Society of Professional Engineers (NSPE) and its state-level affiliates. They prefer to have engineers unrestricted and left to decide for themselves what work they are competent to perform. Unfortunately, some engineers who may not be competent to perform structural engineering genuinely believe that they are competent to do this work.
- Commercial Contractors. They are concerned about having to pay higher fees for structural engineering services and higher building costs. This is only speculation and is not the intent for a SE licensing act.
- Residential Contractors. They are concerned that if a residential building is designed correctly by a knowledgeable structural engineer that the cost of a home will go up and may cause a potential home buyer not to build. This is only speculation and is not the intent for a SE licensing act.
- Some Engineers. Some engineers are concerned about the low pass rate on the NCEES structural exam and a lack of adequate resources for preparing for it. There are several courses available to prepare engineers to pass the structural engineering exam requirement.

Common questions, accusations, and misconceptions that surround structural licensing and practice acts include:

- "Won't buildings cost more?" No, buildings should not cost more. The code establishes the minimum requirements for a safe building. This bill makes sure that certain structures comply with the code by requiring them to be designed by those who have the appropriate education and experience, and who have passed a structural exam.
- "PEs and SEs, aren't they all the same?" Experience, education and examination separate and differentiate SEs from PEs.
- "Are we currently having a problem?" Although, as noted above, the problem of engineers practicing outside the areas of their competence is a real danger and threat to the public, there are some who are unaware of it. It is important to emphasize that we would rather take action now than "count bodies" later.

- "Ethics shouldn't be legislated." We are not trying to legislate ethics; this is about protecting the public - like drivers' licenses, speed limits and seat belt laws.
- "Aren't all professional engineers intelligent and capable?" Sure, but this is about having engineers demonstrate their knowledge and understanding of structures by passing the requisite examination. History is full of people that were intelligent and capable but—knowingly or otherwise—did not work for the public good.

Some people, including engineers and legislators, may never understand the importance of structural licensing and practice acts as a means of protecting the health, safety, and welfare of the public. Ignorance and ego will be unfortunate obstacles, but they are not insurmountable. Patience and a desire to educate others are virtues that will be invaluable throughout the process.

Generating Support

There are a variety of organizations and individuals that support structural licensing and practice acts. They include:

- National Council of Structural Engineers Associations (NCSEA)
- American Society of Civil Engineers (ASCE)
- Structural Engineering Institute (SEI)
- Council of American Structural Engineers (CASE)
- Local chapters of ACEC
- Some local chapters of the American Institute of Architects (AIA)
- Building officials and those who perform structural plan reviews
- The state Division of Professional Licensing (or equivalent)

All of these organizations should be informed about the proposed changes to the licensing laws and be given the opportunity to offer input and advice.

All members of the SEA/SEI Chapters and the supporting organizations should be kept fully informed about the progress and changes that may be made to the proposed changes to the licensing laws. The SEA/SEI's membership will appreciate monthly newsletter articles or emails that keep them fully informed. Some of the groups listed above may find it more advantageous to receive frequent emails.

When the proposed changes to the licensing laws are being debated in the legislature, it is advantageous to have the legislators receive email from their constituents declaring support for the bill. Declaring support is not always as clear-cut as it seems. Legislators must receive email, or other forms of communication, clearly noting that the sender "supports the bill as it is currently written." Emails that state, "I support the proposed bill …….. but suggest the following changes….." or "I agree with structural licensing and practice acts in principle but would request the following changes…" are viewed as non-support of the bill and will be counterproductive.

Emails and letters sent to legislators should be short, direct, and to the point to ensure that they are read. Lengthy correspondence is often not read by busy legislators. The first few paragraphs should be short, perhaps no more than two to five sentences in length, and should explicitly declare support for the bill. The correspondence should be cordial and avoid name-calling, fault-finding, and digging up past disagreements. A paragraph or two highlighting why you support the bill would be appropriate and acceptable.

It is important, but not critical, to have support emails from across the state, because most Legislators will not read or be swayed by any correspondence unless it is from their actual constituents. This does not mean that a person sending an email to every legislator is ineffective or useless, but it means that such a tactic is not as effective as every legislator receiving correspondence from their own constituents.

Working with Your Legislatures

Most states have a brief outline published or posted online that spells out the legislative process. Some states require a bill to go through an interim committee and/or legislative analyst review, receive a fiscal note, be reviewed by a Senate committee, be read and be voted on twice in the Senate, be reviewed by a House committee, and finally be read and voted on twice in the House. The process can be lengthy, catching the uninformed off-guard. It is a good idea to have a firm grasp on how the legislative process works in your state.

In addition, it is important to know something about the state leadership in the House and Senate. The leadership typically has the power to stall or throw out any bill that they deem of low importance or that they do not support.

It is also important to know something of the quality and character of the legislators with whom you are dealing. When asked by a legislator why the SEA of Utah was pursuing this course of action, I stated: “We’re proposing this bill on its own merits - because it’s the right thing to do.” To that, the legislator responded: “We don’t pass bills based on their merits or principle. Right has nothing to do with the decisions that are made.” Did he misspeak? Maybe. Was he right? Unfortunately, yes. A state’s legislature has many pressing and important problems to deal with and usually has a limited time frame within which to complete their work. What seems right and necessary to you may not be important to particular legislators based on the overall scope of the many issues that they face.

Working with a Legislator

Most states have information online about each legislator. Often the information includes a resume, the district that he or she represents, background information, committee assignments, contact information and past successful legislation. It is important to have as much information as you can about every legislator so that you can decide which one(s) to approach about sponsoring the bill.

Factors that influence the effectiveness of a legislator include, but are not necessarily limited to:

- Whether he/she belongs to the majority or minority party.
- His/her relationship with the Senate and House leadership.
- His/her longevity; senior legislators are generally more effective than freshmen.

Once you choose a legislator and that person accepts the responsibility of sponsoring the bill in either the Senate or House, he/she can assist you in choosing a legislator to co-sponsor the bill in the other legislative branch. It is important to review the credentials of all the legislators before asking one to sponsor the bill. Those who are eager to sponsor it may not be the best choice for getting it through the legislative process.

Legislators are good people who believe strongly in what they are doing and the notion that they are making a positive difference in the world. They also have to worry about getting re-elected. Because of that, no legislator wants to sponsor a bill that may fail because it could be bad for their campaign and image.

Important considerations that a legislator may entertain before agreeing to sponsor the bill may include:

- Will the bill result in a cost to the state? (The legislator will not want to increase taxes. Generally, the fiscal note for a bill on structural licensing and practice acts will be zero or very small.)
- Will the bill result in a cost to their constituents? (No.)
- Does the bill restrict or adversely affect existing businesses? (No. The transition clause ensures that the Bill will not affect existing businesses.)

Do not be afraid to interview your legislators to determine their level of commitment to the bill and assess their ability to assist you in seeing it successfully through the legislative process. This is probably the most important part of the whole effort – choose the sponsors carefully.

Once the sponsors have been selected, it is vital to educate them and help them fully to understand the reasons and purpose behind the bill. Your legislator must stand alone on the floor to speak in support of the bill and answer any questions that arise. It is important to make sure that they are well–prepared for this task.

When the Bill is being reviewed in committee or discussed on the floor, it is important to have the one-pager readily available and distribute it to every legislator so that they can read the main points of the Bill and perhaps gain a greater understanding of the importance of structural licensing and practice acts.

Closure

Licensing structural engineers separately and establishing a practice act will raise the bar for structural engineers above that of a Professional Engineer. However, we

should keep in mind that the purpose of structural licensing is not to create a group of elitist snobs. An open process and clear purpose will demonstrate our willingness to work with all interested parties and our desire to create a better future for our profession. The push toward structural licensing and practice acts in all states should be viewed for what it is: an expression of our desire to serve the public better and fulfill our ethical obligation to hold paramount the safety, health, and welfare of the public.

A Structural Practice Act for the State of Utah

IN A NUTSHELL

- Need for greater public safety in the structural design of significant buildings and structures
- Those presently qualified and competent to practice structural engineering as defined will remain qualified to do so
- Six month window for transitioning professionals to apply for S.E. licensing
- Administration changes for DOPL are minimal

PROPOSED STRUCTURAL LICENSE ACT FOR UTAH

The current Utah law concerning the practice of structural engineering does not define which structures or buildings require structural design other than to suggest that they are complex.

A proposal by the Structural Engineers Association of Utah (SEAU) would better define the practice of structural design by explicitly stating which buildings and structures would be considered not only complex, but also of sufficient importance to warrant the added expertise of structural engineers.

The International Building Code (IBC) classifies structures according to their occupancy with the intent of requiring increased care in the design of certain buildings. Hospitals, schools, and structures housing large numbers of occupants are deemed important and the code requirements for their structural design are consequently elevated.

These structures are among those defined in the proposed structural practice act for Utah.

Why Is A Structural Practice Act Necessary?

With the adoption of the 2006 International Building Code, Utah is leading the way in public safety. There is an increasing complexity requiring higher levels of competence and experience for structural design of significant structures

Reasons for improving structural practice:

- *Education Requirements:* Bachelor of Science degree requirements have steadily decreased from 140 to 150 semester hours to as little as 124 hours.
- *Complex Codes:* Structural engineering design and building code requirements have become increasingly complex
- *Computerization:* Use of advanced software by less competent engineers to design structures
- *Hidden Problems in Existing Buildings:* Many potential problems will only be evident when an earthquake or design snow load is applied
- *Plan Checking:* Many jurisdictions do not have the resources to perform sufficient structural plan reviews. Reliance on the "engineers stamp" does not always assure quality performance
- *Insurance Costs:* Poor design and construction can affect many different insurance policies
- *Cost Effective Design:* A structure can be designed which may be safe and meets the building code, yet is not the most cost effective structural solution

How Will the Current Practice of Structural Engineering Change?

Those presently qualified and competent in the areas defined by the act will continue to be able to practice structural engineering. If not presently licensed as an SE in Utah, they will submit application to DOPL for review together with an affidavit attesting to their competence and experience.

How Will It Be Implemented?

Beginning July 1, 2008, those professional engineers not holding a valid S.E. license in Utah and desiring to be transitioned will have six months to make application to the Division of Occupational and Professional Licensing (DOPL).

After January 1, 2009 licensing as a S.E. in Utah will follow the requirements presently established by the state and administered by the DOPL.

Benefits

- Increased public safety for the structural design of significant buildings and structures
- Clearly defines the responsibilities for the practice of structural engineering
- Maintains and improves upon the standards established by the state of Utah for the practice of structural engineering and the qualifications of license holders.

ABSTRACT

In April 2011, National Council 0f Examiners for Engineering and Surveying (NCEES) will begin offering a new 16-hour Structural Examination to replace the Structural I and Structural II examinations. This new exam will also replace the state specific seismic structural examinations currently offered by California, Oregon, and Washington.

The first half of this paper will focus on how and why the changes were made, including discussion of how different states use the current structural examinations, difficulties in mobility of structural licenses, the NCEES Structural Task Force, the NCEES Professional Activities and Knowledges Survey for the new 16-hour Structural Examination, and the new Test Specification.

The second half of this paper will discuss the format of the new 16-hour Structural Examination, the new 16-hour Structural Examination writing committee, and how the new 16-hour Structural Examination is graded.

INTRODUCTION

The first administration of the new 16-hour Structural Examination which replaces the Structural I and Structural II examinations was April 8-9, 2011. This paper will discuss the history of structural examinations in the United States and its Territories, the reasons for the change from the Structural I and Structural II examinations to the new 16-hour Structural Examination, and the process of the change.

HISTORY OF NATIONAL STRUCTURAL LICENSURE

The states of California, Illinois and Washington wrote state specific structural engineering examinations in the later half of the twentieth century. Illinois suggested that the National Council of Examiners for Engineering and Surveying (NCEES) write a national exam and that Illinois would use that exam rather than continue to write a state specific exam. In 1986 NCEES offered the first Structural I Examination (SE I) as the first day of a 2 day exam. In 1986 NCEES offered the first Structural II Examination (SE II) to complete sixteen hours of examination. In 1993, at Illinois request, NCEES added seismic content to the afternoon portion of the Structural II Examination.

In 1932 California passed a Structural Engineer title authority act. This was the year before the 1933 Long Beach Earthquake. After the 1933 Long Beach Earthquake the Field Act was passed to require a Structural Engineer for schools. Modifications to this act added a requirement that a Structural Engineer be engaged to design a hospital. California subsequently started writing state specific structural engineering examinations.

The structural engineering examination in Washington was first offered in 1950 following the 1949 Olympia Earthquake. This examination was initially an 8-hour exam. In 1963 it was changed to a 16-hour exam

In 1986 California, Hawaii, Oregon and Washington cooperated in writing the 16-hour Western States Examination. Idaho and Nevada subsequently joined this exam. In 1993 Hawaii, Oregon and Nevada left the Western States exam and went to the NCEES SE I and SE II exams because NCEES had added seismic content to the afternoon problems on the SE II Exam. Washington left the Western States Exam in 1998.

STRUCTURAL EXAMINATION USEAGE AND MOBILITY

As shown in Table 1, after 1998 different U.S. states and territories have granted structural licenses using a variety of examinations.

Table 1. U.S. States and Territories Which Used 16-Hour Licensing Examinations

STATE OR TERRITORY	EXAMINATIONS USED
Arizona	SE I + SE II
California	SE II + CA SE III
Guam	SE I + SE II
Hawaii	SE I + SE II or Civil/Structural + SE II
Idaho	SE I + SE II
Illinois	SE I + SE II
Louisiana	SE I + SE II
Nebraska	SE I + SE II
Nevada	SE I + SE II
Northern Mariana Islands	SE I + SE II
Oregon	SE II + WA/OR SE III
Utah	SE I + SE II
Washington	SE II + WA/OR SE III

Forty-seven states and territories offered the NCEES SE I, but thirty-four of them did not require the SE II exam. The forty-seven states and territories include the 13 states and territories listed in Table 1. Some of these thirty-four states and territories which did not require the SE II exam offered the SE I so that engineers in their jurisdiction could apply for comity in other jurisdictions. Other jurisdictions offered the SE I in lieu of another PE exam, such as the civil exam with the structural module.

California, Guam, Idaho, Nevada, Oregon, Utah and Washington required a PE license prior to allowing candidates to sit for the structural examinations.

These various permutations of examination usage made comity and mobility difficult. For example, recently licensed structural engineers from Oregon, Washington, and in some cases, recently licensed structural engineers from California or Hawaii would have to take the NCEES SE I examination to obtain a license in Illinois. Similarly, licensed structural engineers from Arizona, Guam, Idaho, Illinois, Louisiana, Nebraska, Nevada, the Northern Mariana Islands and Utah would have to travel to California, Oregon or Washington to take one of the two state specific seismic examinations. Candidates from other states and territories would have to take both the SE II and one of the two state specific seismic examinations to become licensed in any of the states or territories listed in Table 1.

THE NCEES STRUCTURAL EXAMINATION TASK FORCE

In 2006 NCEES established a Structural Examination Task Force to address these examination, comity and mobility issues. The Task Force developed three recommendations.

The first recommendation was that it is desirable and appropriate to have a single 16-hour structural engineering examination that would be accepted by all jurisdictions listed in Table 1 and other jurisdictions that might currently be using the NCEES SE I examination as a stand alone licensing exam.

Illinois pointed out to the Task force that the SE I was always intended to be the breadth portion of a 16-hour breadth-depth examination. Using the SE I examination as a stand alone licensing exam, had the effect of licensing structural engineers without a depth portion of the licensing examination.

At the end of the last century, there were three legacy codes used to design building structures in the United States. Usage of these legacy codes was on a regional basis as shown in Figure 1. By the time that the NCEES Structural Examination Task Force was created, the International Building Code (IBC) was the single dominate building code for the United States as shown in Figure 2.

The IBC used the new United States Geologic Survey seismic maps. These maps showed that even with low to moderate seismicity, sites with poor soil conditions in most states and territories qualify as Seismic Design Category D. Structures designed for sites in Seismic Design Category D generally have to be designed using “Special” seismic force resisting systems; such as Special Reinforced Concrete Moment Frames; Special Reinforced Masonry Shear Walls; or Special Steel Concentric Braced Frames. Design of these “Special” systems triggers an additional body of knowledge which includes the AISC Seismic standards; all of Chapter 21 of ACI 318; the high seismic portions of the “Building Code Requirements and Specification for Masonry Structures”; and the high seismic portions of the NDS “Special Design Provisions for Wind and Seismic”. The use of this high seismic body of knowledge in many more U.S. states and territories meant that it was

appropriate that structural engineers in more states and territories be examined on these high seismic systems. Further, to maximize licensing mobility and protect life safety, structural engineers should be examined on these high seismic systems since even if they do not have sites which qualify as Seismic Design Category D in their home state or territory; they are likely to encounter such sites when they seek comity in other states and territories.

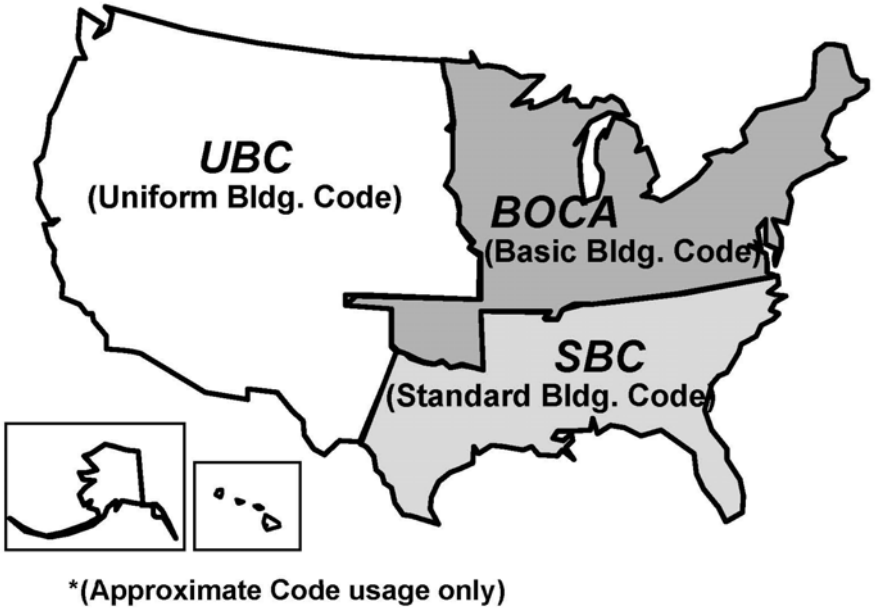

Figure 1. Building code usage under the legacy codes

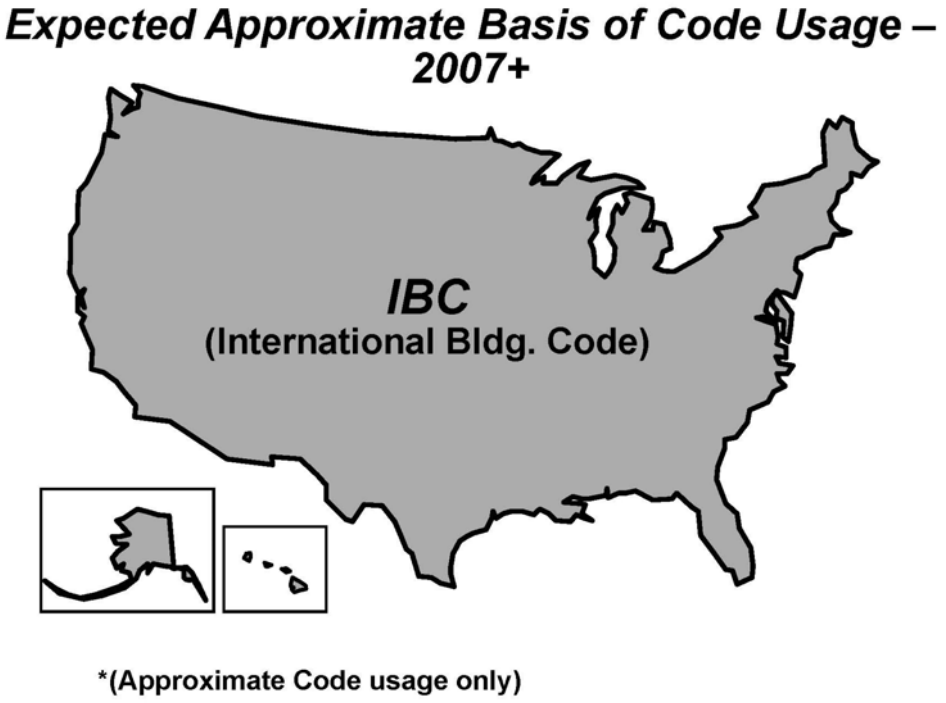

Figure 2 Building code usage in 2010 and beyond

The second recommendation was that moving to a structural engineering examination based on the IBC triggered the need for a new structural Professional Activities and Knowledges Study (PAKS). NCEES conducts a PAKS for all of the examinations that it writes. PAKS are generally conducted on a six to nine year cycle. The Task Force concluded that while a new structural PAKS was not yet required for the SE I and SE II examinations based on timing, it was required based on the major changes in design created by adoption of the IBC as the reference code for building structural design.

The third recommendation concerned specific format suggestions for the new 16-hour structural engineering examination. These suggestions included ways to address the breadth/depth requirements and ways to group the knowledges and abilities for the new structural examination. These will be addressed below in the section titled "FORMAT OF THE NEW 16-HOUR STRUCTURAL EXAMINATION".

PROFESSIONAL ACTIVITIES AND KNOWLEDGES SURVEY

NCEES established a committee to create the Professional Activities and Knowledges Study for the new 16-hour structural examination. The structural PAKS committee membership included members of the Structural Engineering Task Force; representatives from all 16-hour structural examination jurisdictions; representatives from the Civil/Structural exam module; representatives from the existing SE I and SE II examinations committee; representatives from the Structural Engineering Institute (SEI); and representatives from the National Council of Structural Engineering Associations (NCSEA).

The structural PAKS committee created a survey with fifty-five abilities, one hundred fifty-six knowledges and seventeen codes and standards. Abilities include the development of concepts, calculations and drawings. Knowledges include design of specific elements and systems.

The structural PAKS was administered as an on-line survey. News about the survey was distributed to all licensed structural engineers in the states and territories listed in Table 1; all licensed structural engineers on mailing lists obtained from NCEES Member Boards; practicing structural engineers on mailing lists obtained from SEI and NCSEA; and through articles appeared in professional engineering journals and NCEES member board newsletters. Recipients of postcard announcements and the articles also requested that structural engineers inform their colleagues (non-members of SEI and NCESEA) about the survey and urge them to participate in the on-line survey.

A total of 1,019 structural engineers completed the survey. This was considered to be quite a robust response, compared to the response on other NCEES examination PAKS. The respondents represented almost all of the U.S. states and territories. The majority of respondents were licensed professional engineers, currently practicing structural engineering, who devoted more than 75% of their

current work time to hands-on structural engineering. Most of the respondents worked in private consulting practice.

Of the respondents who were licensed structural engineers in the states and territories listed in Table 1, the number of respondents ranged from four who were licensed to practice in the Northern Mariana Islands to two hundred fifty-five who were licensed to practice in California. As Figure 3 shows, no state or territory dominated the survey.

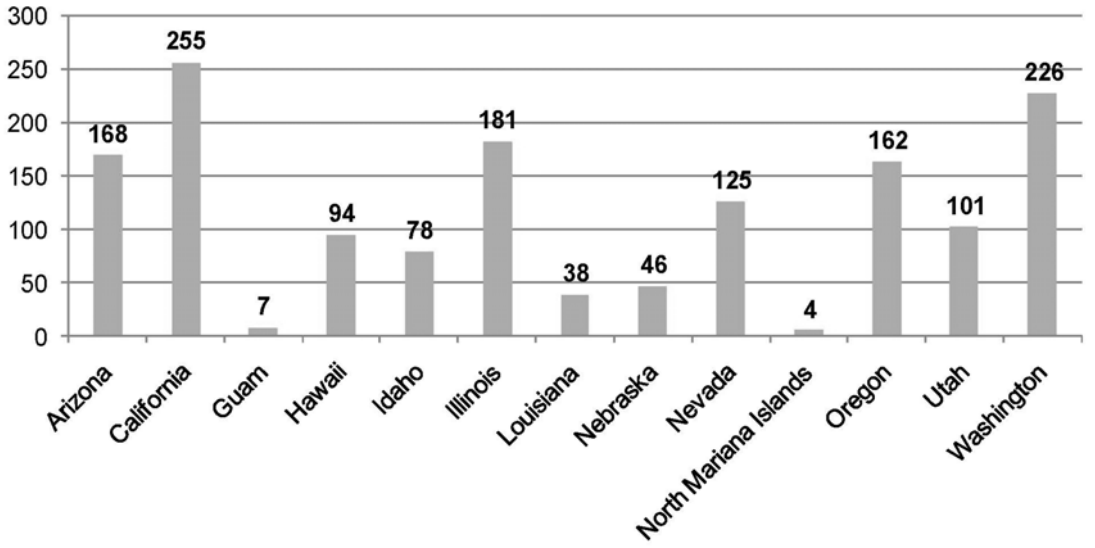

Figure 3. States of respondent licensure

In general, as Figure 4 shows, there was an even distribution of number of years of practice of the respondents, with the exception of a slight increase by the respondents who reported that they had been practicing between six and ten years. Since this is near the point in a structural engineers career where they would sit for the licensing examination, this slight increase was viewed as a positive outcome.

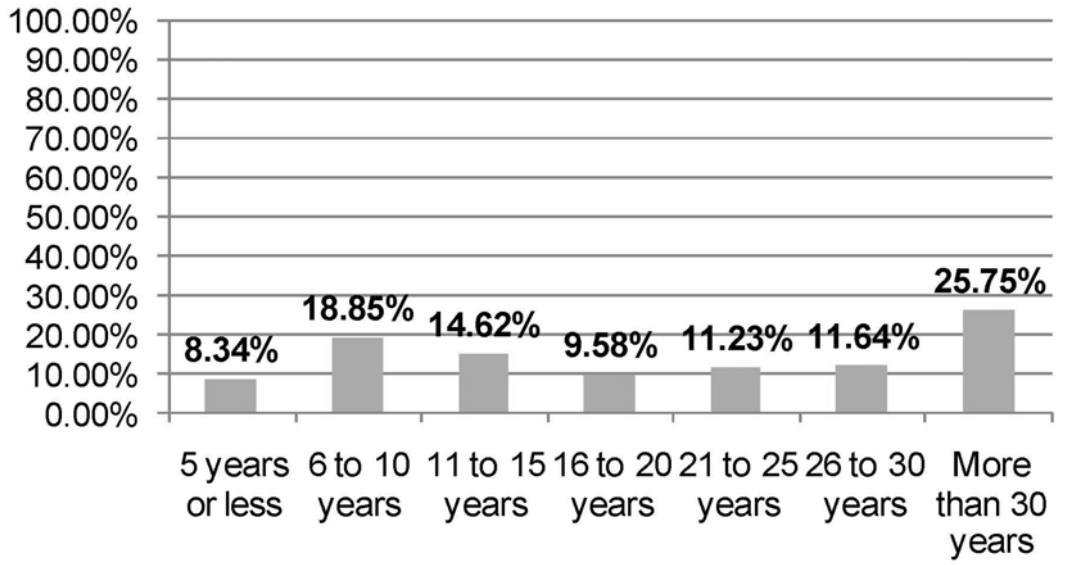

Figure 4 Survey respondents' years of practice

Fifty-three of the fifty-five professional activities on the survey achieved high importance ratings. The respondents indicated that the survey covered the important professional activities adequately to well.

One hundred thirty-two of the one hundred fifty-six knowledges on the survey achieved high importance ratings. Respondents indicated that the survey covered the important knowledges adequately to well.

Eight of the seventeen codes and standards on the survey achieved high importance ratings.

The NCEES Structural Professional Activities and Knowledges Survey conducted in 2008 and 2009 asked the profession specific questions about the importance of knowledge of design for systems of moderate seismicity versus systems the importance of knowledge of design for systems of high seismicity. All of the high seismic systems achieved high importance ratings. This result did not change when the survey responses were sorted by states with high seismicity versus states with moderate to low seismicity. Thus the profession clearly stated that it was essential that candidates for structural licensure be examined on these "Special" systems. This result was notably different from the previous PAKS and reflects the changes brought about by adoption of the IBC and the new seismic maps. The PAKS also gave high importance ratings to the design for high wind forces.

TEST SPECIFICATION

Once the PAKS results were analyzed, NCEES established a committee to create the Test Specification for the new 16-hour structural examination. The Structural Test Specification Committee membership added one new member to the structural PAKS Committee.

Based on the results of the PAKS a test specification was created for each component of each module of the new 16-hour structural examination. These components are described in the next section. Each ability or knowledge on the PAKS had a numeric importance rating of 1 to 5. The test specification reflects all abilities and knowledges which achieved an aggregate importance rating higher than 2.6.

The new Test Specification is presented in four parts, one for each component of each module of the new 16-hour structural examination. The Test Specification is available as a free download on the NCEES web site at **www.ncees.org**.

FORMAT OF THE NEW 16-HOUR STRUCTURAL EXAMINATION

The new 16-hour Structural Examination consists of two 8-hour components both of which include breadth and depth modules. The components contain integrated design, analysis and detailing questions. NCEES has been very clear that no single portion of the exam is a sufficient stand-alone exam for any purpose.

Component one examines candidates on the "Analysis and Design for Gravity Forces and Incidental Lateral Forces from soil, ice, etc." It contains a 4-hour multiple choice problem module which is administered in the morning. There are forty questions in this multiple choice module. The multiple choice module is comprised of both building and bridge questions.

Component one also contains a 4 hours objectively scored (essay) problem module which is administered in the afternoon. The afternoon module of component one will have a building track and a bridge track. The building track will contain four 1-hour building problems. The bridge track will contain two 1-hour and one 2-hour bridge problems. Candidates must declare whether they are going to attempt the building track or the bridge track in the afternoon when they register for the examination.

Component two examines candidates on the "Analysis and Design for Lateral Forces – High Wind and High Seismic." It contains a 4-hour multiple choice problem module which will be administered in the morning. There are forty questions in this multiple choice module. The multiple choice module is comprised of both building and bridge questions.

Component two also contains a 4 hour objectively scored problem module which will be administered in the afternoon. The afternoon module of component two will have a building track and a bridge track. The building track will contain four 1-hour building problems. The building problems will include at least two problems in Seismic Design Category D or above and at least one wind problem with wind speeds of 110 mph or higher. The bridge track will contain two 1-hour and one 2-hour bridge problems. Candidates must declare whether they are going to attempt the building track or the bridge track in the afternoon when they register for the examination. They must select the same track, buildings or bridges on both components.

PASSING THE NEW 16-HOUR STRUCTURAL EXAMINATION

Each 8-hour component of the exam may be taken on consecutive days in the same exam administration, or each component may be taken in separate exam administrations. Candidates must achieve an acceptable result on both vertical and lateral components to pass the exam.

If a candidate does not achieve an acceptable result on one of the two 8-hour components, that 8-hour component can be retaken. Due to the changing nature of the design codes, some states or territories may impose a limit of five years during which the candidate must achieve an acceptable result on the second 8-hour component. If the candidate does not achieve an acceptable result on the second 8-hour component within five years, the first 8-hour component (on which the candidate had previously achieved an acceptable result) must be retaken.

NCEES has prepared a sample questions and solutions book for the new 16-hour Structural Examination. It can be ordered online.

NEW 16-HOUR STRUCTURAL EXAMINATION WRITING COMMITTEE

The NCEES structural committee whic h writes the new 16-hour Structural Examination is comprised of subject matter experts who can legally practice as structural engineers in the jurisdiction in which they have been licensed. In general, for the thirteen states and territories which are listed in Table 1, these subject matter experts have passed a sixteen-hour structural exam. Subject matter experts from other states or territories may have only passed an eight-hour licensing exam. Nonetheless, they can legally practice in their jurisdiction. This same guideline was adopted by the Structural Engineer's Certification Board (SECB) when it set it's guidelines for acceptance of applicants.

In some cases, subject matter experts also serve on standards development organizations or code advisory committees.

With the increased emphasis on high wind and high seismic forces, new committee members have been recruited from regions of the country where design for these forces is common practice.

GRADING THE NEW 16-HOUR STRUCTURAL EXAMINATION

The multiple choice sections of both m odules are machine scored. Statistics of each problem are examined for anomalies and problems which appear to have anomalous results are given an additional review by subject matter experts prior to the release of scores.

The objectively scored portions of both modules are graded in workshop scoring sessions. Teams of graders who are subject matter experts and who can legally practice as structural engineers in the jurisdiction they are licensed in are assembled, trained, and certified. Each candidate's solution to a given problem is graded by at least two graders on the team. In fairness to the candidates, the training and certification process is robust.

CONCLUSION

The new 16-hour Structural Examination which replaces the Structural I and Structural II examinations has been developed through a robust process which included direct input by the structural engineering profession through the NCEES Structural Professional Activities and Knowledges Study. The test specification was based on activities, knowledges and codes which the profession rated to be of high importance in the PAKS. These include lateral design of high seismic and high wind systems.

The new 16-hour Structural Examination will protect public safety of structures and promote mobility of licensure throughout the United States and its Territories. As Boards of Registration understand the increased seismic risk in their jurisdiction, it is anticipated that the use of the new 16-hour structural exam will expand to more of these jurisdictions.

ABSTRACT

Science is widely perceived as an especially systematic approach to knowing; engineering could be conceived as an especially systematic approach to willing. In science, although the will is implicitly involved, the intellect is primary, because the goal is ideal—additional "objective" knowledge. In engineering, although the intellect is implicitly involved, the will is primary, because the goal is pragmatic—some "subjective" outcome, which is often selected by a manager or client, rather than the engineer. Furthermore, engineering problems are rarely well-defined; uncertainties and resource constraints dictate that they be conceptualized and solved heuristically. As a result, different engineers will follow different design procedures and develop different models, none of which is uniquely "correct." Because tradeoffs are always necessary, engineering decision-making—and human behavior in general—is more intentional than rational. Recognizing this can help today's society to engage engineers more explicitly in addressing the many challenges that it faces, technological and otherwise.

INTRODUCTION

What is engineering? At first glance, it appears that engineers would simply be those who operate engines. However, in other languages—such as French, German, or Spanish—the word for "engineer" starts with the letter I, not the letter E. This reflects the etymological fact that "engineers" are fundamentally people who exercise *ingenuity*.

The classic definition of engineering reflects this somewhat. It is attributed to Thomas Tredgold and dates to the 1828 charter of the Institution of Civil Engineers in Great Britain. It says, "Engineering is the art of directing the great sources of power in nature for the use and convenience of man." This certainly sounds important and impressive, but the problem is that it does not really capture what engineers do on a daily basis. Few would seriously claim that their professional activities constitute "directing the great sources of power in nature."

There is another definition, specific to structural engineering, which is perhaps less familiar and has been attributed to various individuals. It is so pithy, and has been

repeated so often, that apparently no one really knows for sure who originally uttered it. The earliest documented instance was in a structural analysis textbook (Brown 1967): "The art of moulding materials we do not really understand into shapes we cannot really analyze, so as to withstand forces we cannot really assess, in such a way that the public does not really suspect." This seems much closer to the mark.

One of the interesting things about both of these definitions of engineering is that, contrary to popular usage, neither refers to it as a *science*. Instead, both refer to it as an *art*. What is the difference? The dictionary (*Merriam-Webster's*, 1993) provides three relevant definitions of science:

- "a department of systematized knowledge as an object of study;"
- "a system of knowledge covering general truths or the operation of general laws;" and
- "principles and procedures for the systematic pursuit of knowledge."

Notice the one word that is common to all three: knowledge. Apparently science is all about knowledge. Is engineering all about knowledge? In light of these definitions, is engineering a science? Should engineers also call themselves scientists?

What about the definition of art? Once again, the dictionary (*Merriam-Webster's*, 1993) provides three definitions that are potentially relevant:

- "skill acquired by experience, study, or observation;"
- "an occupation requiring knowledge or skill;" and
- "the conscious use of skill and creative imagination."

Once again, notice the one word that is common to all three: skill. Apparently art is all about skill. Is engineering all about skill? In light of these definitions, is engineering an art? Should engineers also call themselves artists? Do engineers perceive what they do for a living as "the conscious use of skill and creative imagination"? Is that how non-engineers typically perceive what engineers do for a living?

KNOWING AND WILLING

To explore this distinction a bit further, consider that science primarily has to do with *knowing*, while art primarily has to do with *willing*—that is, making conscious decisions that may or may not have a rational justification. In particular, just as science is widely perceived as an especially systematic approach to knowing, so engineering could be conceived as an especially systematic approach to willing.

This becomes evident if we simply compare the scientific and engineering methods. Scientists observe natural phenomena, propose hypotheses in an effort to explain them, and conduct careful experiments to test their theories. Although the will is

implicitly involved, the *intellect* is primary, because the goal is ideal: additional knowledge that is supposed to be objective.

By contrast, as Koen (2003, 2010) has long been arguing, engineers use "state-of-the-art heuristics to create the best change in an uncertain situation within the available resources." Note that this definition of the engineering method invokes the "state of the *art*," not the "state of the *science*," and explicitly acknowledges that engineering is a *creative* activity. Although the intellect is implicitly involved, the *will* is primary, because the goal is pragmatic: some outcome that is usually subjective. Knowledge serves mainly as a necessary but insufficient means to that contingent end—"the best change," which is usually not something that is up to the engineer to determine.

In fact, as Goldman (1991) has observed, engineering is a captive enterprise. For one thing, it is widely—and wrongly—perceived as nothing more than *applied* science. In addition, the practice of engineering has been limited in terms of what problems engineers are allowed to address and what solutions are considered acceptable. The autonomy of the profession is restricted by the need for someone to retain an engineer before he or she can undertake a specific project. Engineers rarely have the opportunity to influence the process that leads a manager or client to decide that a certain product or facility is necessary or desirable. Furthermore, a variety of constraints are imposed on engineering designs by others as a result of aesthetic, functional, or other considerations, which are often non-technical.

These two types of captivity—one intellectual, the other social—are not separate, but interdependent; the first anchors the second, which in turn reinforces the legitimacy of the first. Goldman's thesis was (and still is) that technology and innovation are generally dominated by market-driven value assessments, rather than by technical knowledge. Even when managers or clients are engineers by training, the decisions that they make inevitably reflect the agendas and priorities of the organizations that they serve—not necessarily the capabilities and limitations of the engineers whom they supervise or retain. As a result, engineering tends to be *instrumental* in nature; it is exploited by non-engineers to achieve their own objectives, which may be quite arbitrary. In other words, the willfulness of engineering is both enabled and restricted by the willfulness of the institutions that appropriate it.

This has significant ethical implications. Mitcham (2009) has argued that engineering is "philosophically inadequate" because it does not have an integral ideal that is "good in itself" and well-embedded in its curriculum and practice. Physicians pursue health and lawyers seek justice, but engineers solve whatever design problems are presented to them and leave the use (or misuse) of the resulting technology up to others. Although they are explicitly charged with holding paramount the safety and welfare of the public, engineers are not especially well-qualified to determine exactly what satisfies that obligation.

Goldberg (2009) has responded to this assessment. His view is that Mitcham is properly differentiating occupations that are ethically simple vs. ethically complex,

based on whether serving the client's interests will align naturally and consistently with serving the interests of society as a whole. In this sense, engineering is clearly ethically complex, because it can be utilized for malevolent purposes; and even when this is not the case, the uncertainties involved are such that good intentions can still lead to unfortunate consequences.

HEURISTICS AND DESIGN PROCEDURES

In fact, Koen (2003) holds that heuristics are central to engineering practice—and everything else, for that matter. A heuristic is "anything that provides a plausible aid or direction in the solution of a problem but is in the final analysis unjustified, incapable of justification, and potentially fallible." Familiar examples include rules of thumb and factors of safety. Why is the stress at 2% strain considered to be the yield strength? Why are most structural designs based on this particular value? Why do engineers typically divide it by something like 1.67 in order to determine a member's capacity to resist service loads? The short answer to all of these questions is: Because it usually works. There is no timeless truth waiting to be discovered here, something embedded within the essence of reality.

With this in mind, Goldman (1984, 1990, 2004) has pointed out that science is supposed to be concerned with necessity, certainty, universality, abstractness, and theory. It seeks objective knowledge of timeless truth that is based on reality, for the purpose of intellectual contemplation and understanding. By contrast, engineering is characterized by contingency, probability, particularity, concreteness, and practice. Engineers rely on subjective know-how and historical opinions that are derived from experience, with the goal of willful action and use. Heuristics cannot be "proven" in the absolute sense, but their utilization is legitimately warranted, frequently on the grounds of successful past implementation.

In fact, each individual engineer has a unique collection of relevant heuristics at his or her disposal, along with "meta-heuristics" for selecting which heuristics are most appropriate in a given set of circumstances. When these are combined to facilitate converting a client's technical and non-technical requirements into a viable solution that adequately accounts for the unknowns and satisfies all applicable constraints, they constitute what Addis (1990) calls a design procedure. This is analogous to a hypothesis in the scientific method; however, a design procedure does not lead inevitably to a particular outcome. In fact, Addis notes "that it is possible to produce very similar structural designs using different design procedures and that similar design procedures can lead to significantly different structures—there is no logical connection between the two."

Most design procedures include the development of mathematical *models* that are supposed to capture the important aspects of reality. The engineer’s challenge is to ascertain what those features are and what assumptions and simplifications can safely be incorporated in order to keep everything manageable, while still yielding a meaningful assessment of likely performance. As de Vries (2010) has observed, two

common strategies are abstraction and idealization. Abstraction involves neglecting certain aspects of reality in order to gain a better understanding of the remaining aspects. Idealization involves replacing a complicated aspect of reality with a simplified version.

Fundamentally, models are approximate representations that serve as epistemic tools (Boon and Knuuttila 2009)—they help engineers learn about the parameters of a design problem and evaluate possible solutions. Although analysis of a model is usually straightforward, conforming to fundamental principles derived from *science*, its initial construction and subsequent adjustment require "the conscious use of skill and creative imagination"—which, as you may recall, is one of the dictionary definitions of *art* (*Merriam-Webster's*, 1993).

ENGINEERING INTENTIONALITY

The bottom line here is that engineering is not deterministic; it routinely requires setting priorities and selecting the best way forward from among multiple options when there is no one "right" answer (Addis 1997). Consequently, attempts to apply a theory of *rationality* to engineering are probably misguided (e.g., Kroes et al. 2009); *intentionality* seems like a more appropriate concept. Take the example of a bridge. Is there a single optimal span for a particular location? You can make an argument for the one across the Golden Gate. But the reality is that there is a staggering array of variables that influence what will ultimately be constructed. For example:

- What kind of traffic will the bridge carry—cars, trucks, or trains?
- What type of bridge will it be—suspension, cable-stayed, or box girder?
- What primary material will be used—wood, steel, or concrete?

Tradeoffs are inevitable, and not just for technical reasons—there are often budget constraints, legal restrictions, or political considerations that come into play. As Goldman (2010) has discussed, these kinds of tradeoffs—both technical and non-technical—are at the heart of the design process, and therefore constitute the essence of engineering intentionality.

In the end, how does a bridge designer settle on the final form of the structure? There is no rigid and inerrant formula that will provide the "proper" outcome. This is the challenge that engineers face—they routinely have to make and justify seemingly arbitrary decisions with an understanding of the situation that is incomplete, at best. The contrast here is really between deduction and induction. *Deduction* reaches conclusions that are absolutely certain, because they contain no new information that was not already present in the premises; accepting the premises requires accepting the conclusion. *Induction* reaches conclusions that are *not* certain, because they *do* contain new information; the argument has to add something to the premises.

With this in mind, which approach do engineers most commonly employ? Consider the question this way: Is every design a foregone conclusion, derived deductively

from the specified criteria and other project requirements? Of course not! Engineering is clearly an *inductive* activity—it requires the addition of information along the pathway from thought to thing, or from concept to completion. In other words, engineers are *information creators*. In fact, one definition of information is "the actualization of one possibility to the exclusion of others" (Dembski 1997)—which is exactly what engineering is all about.

There is no law of nature or mathematics that dictates a particular design. There are constraints, to be sure. There are decisions made by others that limit the engineer's options. In the end, though, the engineer makes certain choices; and another, equally competent engineer might well go in a different direction. Each designer has a singular point of view that informs how he or she "sees" a problem and its (potential) solution. Certain concepts, especially within a particular discipline, are familiar to all; but each individual also develops and refines a certain amount of technical intuition through professional experiences—"tacit" knowledge that is difficult to capture and communicate to others.

As a consequence of all this, two models of the same system can both be "correct," yet yield different results. The advantage that an engineer has over a scientist is the ability not only to adjust the model to represent reality better, but also to adjust *reality* to suit the model better—yet another example of engineering practice being more of an art than a science. This is especially true for unconventional projects that go beyond standard designs and details, requiring the engineer to develop *custom* designs and details using first principles. In such cases, it is often the model that dictates reality, rather than the other way around.

In this way, engineering practice involves reinterpreting an inductive situation to facilitate deductive analysis. Once the model is set up, the results follow inexorably; but setting up the model is the real work of the engineer. In other words, engineering includes problem *definition*, not just problem solution. Engineers have to convert all of the relevant design criteria—which are often dictated by clients, codes, and other authorities—into the "language," so to speak, of engineering.

And as in the case of natural language translation, the formulation of engineering problems and their solutions is inherently indeterminate. They tend to be ill-structured (Simon 1973) or even "wicked" (Rittel and Webber 1969). Consequently, design—in fact, all human behavior—is not ultimately governed by *reasons*, but by *motives*. Although common usage treats these two terms as virtually synonymous, the prevalence of the first one in both ordinary and philosophical discourse reflects an ancient prejudice—going all the way back to Plato—that subordinates action to contemplation; that is, willing to knowing.

CONCLUSION

As members of the profession that exemplifies willing, engineers should strive to resist and reverse this tendency. For example, although it is common in many

fields—including engineering—to perceive a "gap between theory and practice," Addis (1990) advocates abandoning this widespread notion in favor of an alternative classification: engineering *science* vs. engineering *design*. The essential difference between these two activities is not in the types of *knowledge* that they employ, but rather in their distinct *purposes*—further understanding and explaining the natural world vs. efficiently producing useful artifacts in a context of uncertainty.

The outcomes of engineering are rarely black and white, right or wrong. Managers and clients give engineers their problems and expect them to solve them, even though there are no *objective* solutions—there are simply too many parameters and too many criteria. They depend on engineers to exercise good *judgment*, grounded in their formal education and honed by their subsequent experience. As Vick (2002) wrote, "The novice begins with data and ends with a number; the expert begins with knowledge and ends with understanding."

There is a widespread perception that engineers are little more than number crunchers. This is not only inaccurate, it is *dangerous*. Data and numbers are meaningless—unless and until they are *properly* interpreted by someone who *knows* where they came from and *understands* what they mean.

With this in mind, consider the motion made by Florman (1997): "I propose that we take the time to think about who we are, as citizens living in a 'technological society,' and—for engineers—as the profession most essential to the well-being of that society." After all: Is there any situation in human existence that is *not* subject to uncertainty and resource constraints? Or that does *not* require the use of successful heuristics? Or that does *not* demand willing, as well as knowing? It is precisely when there is more than one path to follow that it is possible and desirable to exercise *wisdom*.

This being the case, in light of their training and temperament, engineers are uniquely suited to help society wrestle with the many challenges that it faces—not only in the technological realm, but across all aspects of human existence.

ABSTRACT

Structural building codes serve a number of purposes, but the primary one is to provide minimum standards of design that protect human health and safety. Codes have grown more complicated over the past 25 years primarily by providing increasing numbers of explicit provisions for the design of most structural members. Explicit provisions appear to be a good way to encode design knowledge, but too many of them will make the code difficult to decode. Encoding and decoding of design knowledge is best performed by a combination of implicit and explicit provisions providing general design principles and optimizing the number of explicit provisions in order to minimize the noise in the encoding/decoding process.

INTRODUCTION

The authority of building codes is granted by a common appeal to public safety. These codes are identified as minimum standards to safeguard the health, safety, property, and welfare of the public, which seems like a reasonable foundation upon which to build a set of regulations or to formulate a philosophy of how the public can best be served and protected. Building codes contain both explicit and implicit directives that identify minimum standards of building performance with which engineers must comply in structural design. Viewed from an information theory perspective (Pierce 1980), the provisions in a building code are an encoding of some portion of the design knowledge space. The designer's job is then to decode this encoded design knowledge.

Viewed this way, it is apparent that enhancements to a building code can come from doing a better job at encoding the design knowledge, enhancing the decoding process, or a combination of the two. Arguments for simplification of the building code often seem to be arguments to reduce the portion of the design knowledge space that is encoded, or just to do a better job encoding the portion of the design knowledge space that has been chosen (Hess 2009). Of course, another option is to enhance the decoding process by educating engineers better. However, no matter how well

engineers are educated, the decoding will be a personal process that will guarantee, in some cases, different interpretations of the building code directives.

It seems appropriate at this point to list some of the goals of building codes. The list is loosely ordered by relative importance of the goals, and some of the goals are not mutually exclusive.

- Define minimum standards
- Document legal requirements
- Enhance safety
- Protect property
- Assist engineers
- Assist code officials
- Enhance consistency across designs
- Reduce uncertainty
- Maintain heuristics

All of these goals are best met when the encoding and decoding processes are as optimal as possible. This paper considers some of the forms that the encoding takes, how it might be possible to encode in a way that reduces noise, and how the decoding process might be enhanced.

ENCODING DESIGN KNOWLEDGE

One form of design knowledge encoding is the use of explicit and implicit requirements; both kinds are necessary in order to meet the overall goal of safety. Building officials charged with enforcing the regulations often do not possess adequate training to interpret the appropriate response to an implicit code requirement, whereas they are generally suited to enforce explicit directives. Implicit requirements permit a range of solutions based on the engineer's experience and creativity, whereas explicit instructions allow limited or no leeway.

An example of an explicit requirement is that an anchorage of a concrete wall to a roof diaphragm must be able to carry 200 pounds per linear foot (plf) for allowable stress design under seismic load combinations (ICC 2006, Section 1604.8.2). Thus, if a minimum anchorage force of 200 plf is required, then 190 plf is insufficient and would be in violation of the building code. An example of an implicit criterion (ICC 2006, Section 1604.4) is that structural systems must provide a complete load path capable of transferring all loads from their point of origin to the load-resisting elements (e.g., walls and roof diaphragms). The implicit requirement for a complete load path, however, would allow an engineer to design a system based on actual loads (possibly less than 200 plf) and select components that are better suited for smaller loads, yet retain the characteristics of ductility so important in seismic design. The engineer is thus allowed broader latitude with which to judge the performance of a specific structure. From an informational standpoint, explicit requirements would appear to encode the design knowledge with less noise than do implicit requirements,

where noise here means that the requirement can be interpreted in more and varied ways.

Over the years, codes have become more explicit, and implicit instructions are often overshadowed. Granted, implicit directives are more difficult to enforce, but a greater amount of explicit requirements does not necessarily lead to safer structures. It is often difficult to decide how heavily to weigh the importance of these two elements (Shapiro, 1997; Coeckelbergh, 2006). If building codes are too explicit, innovation can be hampered and engineers may be viewed as simply instruction-following technicians (Coeckelbergh, 2006). Furthermore, as the number of explicit requirements increase, so does the noise in the code. If codes are too implicit, then proper enforcement of construction requirements for safe structures can be difficult to perform and the likelihood of a structural failure may be increased (Elms, 1999).

Many engineers argue that modern building codes do not adequately achieve a balance, typically tilting too far in the direction of prescription, as the ever-increasing thickness of the printed code documents suggests (Hess, 2009). The intent of the code often gets lost as it grows in size, and explicit provisions that were simple at one time become more complicated, which reduces the effectiveness of the code, increases noise, and stifles innovation and creativity on the part of responsible designers. Codes that are too complicated (often overly explicit) make it difficult for a designer to know how many of the requirements must be met to justify a specific design. So although explicit requirements may at first make for a better encoding, using a large number of explicit requirements that are strongly interconnected will make the decoding process more difficult. Codes that are too simple (overly implicit) can cause a similar decoding problem, except in this case the question is what should be used that is not specified to justify the design (Addis 1990). In summary, in the overly explicit case, the engineer will have difficulty determining what the code writers had in mind; and in the overly implicit case, the engineer will have to choose directly from the design knowledge space without help from the code writers.

In ASCE 7 (ASCE 2010), there are now three ways to approach designs: strength procedures, allowable stress procedures, and performance-based procedures. The designer is even allowed to choose among these procedures for different members in the same structure. In other words, there are three fairly explicit requirements that are strongly connected because different procedures can be used for different parts of a structure and for different load combinations (ASCE 2010). These provisions make the overall result implicit since the engineer has the discretion to choose among the three procedures.

However, the provision allowing choice among the three procedures presents a problem for an engineer who has a good understanding of these procedures: Is it safe to optimize a structure by choosing among the three procedures for various elements? Under most conditions, building codes are member–based, meaning that if you designed each member to the minimum standards throughout the structure, it could possibly behave in ways that are not safe due to system effects. This limitation is true

for designs performed within a single procedure, and thus may be magnified if the designer could design each member by choosing the smallest outcome from the three procedures for each element in a structure. The safety question does not have an answer in this case, so a knowledgeable engineer would be unlikely to blend the procedures in a single structure. An engineer with less understanding of the background of these procedures could, if time and money permitted, attempt the type of optimization described above. Allowing selection among the three procedures increases the noise in the code and increases uncertainty about the safety of structures designed under these provisions.

Other explicit requirements are heuristics. A heuristic is, to quote Koen (2003), "anything that provides a plausible aid or direction in the solution of a problem, but is in the final analysis unjustified, incapable of justification, and potentially fallible." Koen would argue that all provisions in a building code are heuristics, but some provisions appear to be more heuristic that others. An example from ACI 318 (ACI 2008) is the procedure for determining the effective flange width of reinforced concrete T-beams, which has been in use for over 90 years (Chen et al. 2007). This design procedure is a crude but effective way to deal with shear lag, thus a heuristic for shear lag design. Heuristics of this type are common in building codes, have a history of adequate performance, and allow engineers to solve problems in fairly simple, consistent ways across a range of designs.

Brenner (2007) discusses the manner in which a code can change when a relatively simple heuristic is replaced with a more rigorous approach. The AASHTO LRFD provisions (AASHTO 2007) for determining the live load distribution factor for bridge stringers changed from a simple heuristic in terms of one parameter, the stringer spacing, to a formula with up to eight parameters. Is the new, more complicated heuristic really worth the additional time required to use it? Is the previous, much simpler formula still adequate? Was the simpler heuristic a minimum standard? If so, why is the new one necessary? The encoding of the design knowledge has become noisier and decoding has become more difficult. The value of the change for the design engineer is unknown.

DECODING ENCODED DESIGN KNOWLEDGE

Decoding building codes has become increasingly more difficult over the past 25 years or so. Part of the difficulty is due to the significant increase in the size of the codes and the number of provisions contained within them, particularly ones that direct the engineer down a range of possible paths depending on certain criteria related to the structure and the load. Examples include seismic design and wind design, and criteria like that described above for design procedures that allow the engineer to choose between and even mix and match a few provisions. As stated previously, in an overly explicit code, the engineer has difficulty determining what the code writers had in mind; and in the overly implicit code, the engineer must

choose directly from the design knowledge space without help from the code writers. Erring too much in either direction increases the noise in the code.

The length of building codes has increased significantly. Considering ASCE 7, the size of the code has grown as follows: 1988, 94 pages; 1993, 134 pages; 1995, 214 pages; 1998, 330 pages; 2002, 376 pages; 2005, 388 pages; and 2010, 608 pages. Even accounting for the fact that some of these page changes are due to font size, the code has grown significantly. Over the 25-year period from 1983 to 2008, ACI 318, combining code and commentary, grew from 266 pages to 436 pages. This growth is not nearly as explosive as that for ASCE 7, but is still significant. Writing nearly twenty years ago about design codes, Galambos (1992) stated: "In the opinion of this writer, the present generation of codes has probably reached the limit of tolerable bulk and complexity. More of this complication will make the codes a modern dinosaur. Future design codes should concentrate on providing general principles and deemphasize detailed requirements." The present code structures are generally complicated encodings that force an engineer into a difficult decoding process. Complicated code structures can increase the chance of human error (Galambos 1992).

So what kinds of encodings would make the building codes more readily decoded? If we consider the list of goals for these documents, then clearly the code must provide minimum standards. Present codes seem to go beyond minimum standards, although the term 'minimum standard' is "in the eye of the beholder." For example, an engineer in Alaska once wanted to know why shear wall design could not be simplified, and in the same breath asked why a portion of the walls perpendicular to the shear wall at its ends could not be used as part of the chord members of the shear wall to make it an I-section.

Minimum standards do not necessarily provide the most economical design, and in most cases will not provide it. Building codes should be minimum standards; designing to more rigorous standards in order to make a structure more economical and/or innovative is beyond the minimum. Codes should assist engineers in their designs and assist code officials in making sure that designs are safe. Assisting engineers beyond the minimum standards is outside the code. Certainly it might be in a commentary, but that itself is outside the code. Assisting code officials and the other goals of design codes would seem to be best performed by making a code as explicit as possible, but an explicit code can itself cause confusion and increase noise in the decoding process.

Design codes should be just explicit enough to define minimum standards, which should assist both engineers and code officials. Most existing codes imply that the procedures in the code are the exclusive way to design that type of structural member. The change described above for live load distribution in stringer bridges would seem to be an unnecessary change, at least as far as minimum standards go. The old simple heuristic had been working well for years, and unless the new formula is a necessary

change from a safety standpoint, it should not be replaced. The new one would be appropriate in a commentary, but seems inappropriate as a requirement.

BALANCING ACT

Engineers who call for building code simplification are often calling for a reduction in explicit provisions in the code and, consequently, a smaller and less complicated document. A simplified code with essentially no explicit provisions may also prove to be inadequate, because engineers would need to depend on their own resources, which would likely decrease design consistency and increase uncertainty in the safety of structures. A balance needs to be found that reduces the noise in the code to its minimum. There will never be zero noise, because design of a structure is an individual process, and each engineer's interpretation of the code provisions will be potentially different (Bucciarelli 2003).

Perhaps there is a better way to blend explicit requirements with implicit provisions so that codes do not become increasingly burdensome, and yet the intent is clear enough to meet the goals of design codes and permit innovative approaches to solving structural engineering problems. An approach to future code updates that might serve society and the engineering profession better would reduce explicit provisions and expand on implicit directions in the code and include a commentary that gives suggestions to an engineer for achieving the stated goals, including suggested explicit provisions. For instance, the design code could consist of a *specification* that is mostly implicit, but may include longstanding, simple heuristics; a *commentary* that gives suggestions about how the specification could be met, including more complicated explicit provisions; and a *supplement* that includes aids for designs prepared in accordance with the commentary methods. The specification could be written such that use of the commentary techniques would lead to a deemed-to-comply design. This approach would not reduce the information available to an engineer, but would make it clear that most of the presently explicit procedures are suggested for use, rather than required. It would be up to the engineer to choose the design method that will best meet the implicit requirements in the specification.

CONCLUSION

Structural building codes have become increasingly more complicated over the past 25 years. Although at first it might appear that adding more explicit design requirements will make for better and safer designs, there is reason to believe that codes that are overly explicit reduce safety. Codes are an encoding of the design knowledge space, and overly explicit requirements increase the noise in the code, making decoding more difficult for the engineer. Overly implicit codes would also cause noise, but present codes are clearly not too implicit. An ideal code would minimize the noise in the encoding/decoding process by finding a balance between explicit and implicit requirements.

What does it mean to be sustainable?

Tonatiuh Rodriguez-Nikl[1]

[1]M.ASCE., Ph.D., P.E., Oregon State University, School of Civil and Construction Engineering, 220 Owen Hall, Corvallis, OR, 97331. Email: rodrigto@engr.orst.edu, Phone: (541)737-2057, Fax: (541)737-3052

Abstract

Most engineers today have heard of sustainability, but there are probably few who would feel comfortable defining what it means. Even well-intentioned and well-read practitioners struggle with a useful definition of sustainability. Depending on who is asked topics that fall under the umbrella of sustainability can include green materials, energy independence, pervious pavement, the heat island effect, health of local waterways, social justice, etc. The scope of topics is extremely broad and can create a lack of focus that is a barrier to making progress on technical issues and communicating an effective message about sustainability.

In civil engineering, perhaps the two viewpoints on sustainability most commonly offered are a quote from the Brundtland Commission: "meeting the needs of the present without compromising the ability of future generations to meet their own needs" and the Triple Bottom Line of people, planet, and profit. These and other approaches contribute to our understanding of sustainability, sometimes from radically different points of view. In this paper the different approaches are discussed. Commonalities and differences are noted and a generalized framework of sustainability is developed. This framework can serve as a guide to analyzing some of the more popular topics in the discourse surrounding sustainability as related to civil engineering, to determine which do not fall within the scope of sustainability, which are the most important, and where we as technical practitioners should be focusing our efforts. Ultimately, the goal of this paper is to help engineers actively discuss and answer these questions for themselves.

Introduction

The word "sustainability" has gained significant popularity in recent years. It has become a common concept both in everyday life and in the profession. The American Society of Civil Engineers (ASCE) has released books on the topic (ASCE 2004, Kestner et al. 2010) and its leadership considers this a central topic. In January 2010 ASCE convened five roundtables in Washington, D.C. One of these was centered on the theme of promoting "sustainability and resilience in infrastructure to protect the natural environment and withstand natural and man-made hazards" (Powell 2010). Sustainable development even appears in the First Cannon of the ASCE Code of Ethics as "the process of applying natural, human, and economic resources to enhance

the safety, welfare, and quality of life for all of society while maintaining the availability of the remaining natural resources."

Despite the popularity of sustainability, or perhaps because of it, there is still considerable skepticism surrounding the idea. Paul Jowitt (2004), former president of the Institution of Civil Engineers and a proponent of sustainable development wrote that "the problem with sustainability and sustainable development is not a lack of definitions – there are very many. It is easy to see why some are so skeptical." Certainly there are many disingenuous misuses of the term for purposes of blatant marketing with no underlying substance. A similar although perhaps unintentional misuse is equating sustainability with being "green" (environmentally less invasive) as in the phrase "our project was sustainable because we reduced noise, reduced construction waste, and used recycled materials." More troubling is the seeming preponderance of well-intentioned technical presentations and articles that use "sustainability" superficially without providing the audience or the reader a clear idea of what it really means. While this may simply be done in the interest of space and time, not through ignorance, the proliferation of superficial and different uses of "sustainability" carries the danger of making the term practically meaningless.

In no way should these arguments and examples be taken as reason to dismiss sustainability out of hand. The motivations for promoting sustainability are based on significant and important considerations. At stake is whether it is possible to maintain the social benefits provided by the recent centuries of industrialization in the face of the detrimental impacts that have accompanied such development. As civil engineers – entrusted with designing, building, and maintaining much of the physical infrastructure that supports modern society – we are intimately bound to this question. In addition to the social benefit it might bring, our work contributes in a negative way to pressing global challenges such as climate change and natural resource depletion. How important or pressing these issues are is out of the scope of this paper, but whatever the final verdict, the questions are of significant consequence and merit serious, careful, and rational consideration.

This paper is an attempt to respond to the skepticism that often surrounds the mention of "sustainability" by providing a theoretical framework that captures its essential features and allows for meaningful and rational dialogue. The ultimate hope for this framework is that it be useful for making well informed decisions by providing a clear way to think about the relevant issues involved. Thus, although this topic is necessarily broad and theoretical, the motivation is practical: enabling the profession to identify the most important problems and to find the most effective solutions to those problems.

In the remainder of the paper the more common definitions of sustainability are reviewed, the theoretical framework is proposed and discussed, and finally the question posed in the title of the paper is answered and a list of questions is provided to help determine whether something can genuinely be called sustainable.

Common Definitions of Sustainability

Within the civil engineering profession there are two definitions almost invariably offered for "sustainability". One is often referred to as the "Brundtland Definition" and stated as "meeting the needs of the present without compromising the ability of future generations to meet their own needs". The other common definition is the "Triple Bottom Line", which defines sustainability as the intersection of social needs, economic needs, and environmental needs. It is sometimes referred to as "People-Planet-Profit" or the "Three Pillars of Sustainability". With no further elaboration both definitions are overly general and vague and admit a variety of competing interpretations. These definitions sound good at first glance but become difficult to use as decision criteria when attempting to analyze a concrete scenario. For instance, when applying the first definition, what exactly is a "need"? When applying the second, how little weight can be given to any of the three factors (people, planet, and profit) while still being considered "sustainable"? To understand these questions better, it is important to reflect briefly on the context surrounding each of them.

The Brundtland Definition arose in 1987 in a report of the United Nations World Commission on Environment and Development (WCED 1987). It became known as the Brundtland Report because of its chair, Gro Harlem Brundtland of Norway. The report provides a rich vision of the problems and solutions surrounding their definition of sustainable development, addressing such issues as population, food security, ecosystems, energy, industry, and urban environments. It calls for responsible economic growth as a means of eliminating poverty. An extended quotation provides a more honest interpretation of the intentions of the report: "Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs. It contains within it two key concepts: the concept of 'needs', in particular the essential needs of the world's poor, to which overriding priority should be given; and the idea of limitations imposed by the state of technology and social organization on the environment's ability to meet present and future needs." It is interesting that these issues are often ignored or contradicted by people who use the shorter version of the passage.

The Triple Bottom Line (TBL) was coined in 1994 by John Elkington of the British consultant firm SustainAbility (Elkington 2004). The intent of the term was to present ideas such as those of the Brundtland Report to the business world. Elkington (1998, ch. 4) identifies the traditional accounting framework in which one (1) identifies what counts as capital (physical, financial, etc.), (2) accounts for this capital, (3) identifies relevant issues of concern (e.g., profit/loss and balance sheets as well as long term financial issues), (4) conducts audits to determine the performance in these areas, and (5) reports these results to the appropriate audience (e.g., stockholders). This same framework is then adapted to environmental and social issues. As Elkington clarifies, environmental accounting is more than just "counting the trees and trying to put a price tag on the lumber they represent"; it is important to capture the "underlying natural wealth". Environmental capital includes global resources such as natural resources, but because TBL speaks to individual firms, the scope of interest is

only with those resources affected by the firm. Similarly, while social capital represents broad issues as public health, education, social friction, and society's wealth-creation potential, the scope of interest is with those issues that the firm affects directly. These are issues such as "community relations, product safety, training and education initiatives, sponsorship, charitable donations of money and time, and employment of disadvantaged groups." While identifying the need for measurable metrics for environmental and social issues, Elkington admits that this is an area in which much work is needed.

Before proceeding to the new proposal one more topic is discussed because of its popularity in the building industry. LEED (Leadership in Energy and Environmental Design) is an increasingly popular approach to sustainability in buildings. In part because of its success for buildings it is being piloted for neighborhoods and similar approaches are being developed by others for infrastructure (ASCE 2010, Greenroads 2010). LEED identifies the following areas of concern: sustainable sites, water efficiency, energy & atmosphere, materials & resources, indoor environmental quality, and locations & linkages. In addition to these are awareness & education, innovation in design, and regionally important issues. LEED establishes basic design requirements in those areas and suggests optional improvements. Each of the optional improvements can earn points and a minimum number of points is required. Additional points can be earned to obtain higher certifications.

Some themes run through all these frameworks; others through just one or two. Environmental issues are paramount and social issues are at least addressed by all three. All three focus on a long-term future and expect at least maintenance of the status-quo during this term. The proposals differ in geographical scale; the Brundtland definition is global while TBL is applied at the scale of an individual business and LEED is applied at the level of an individual facility. The Brundtland definition focuses on the poor and demands a marked improvement in their situation; the other two do not discuss issues of poverty. LEED has a detailed measurement system not found in the other two.

Proposed Framework

A generalized framework is now proposed to capture concisely the important aspects of these and other definitions to provide a generalized notion of sustainability and a way of evaluating new developments, be they theoretical and broad or technical solutions to specific problems. A dictionary definition of "sustainable" provides a suitable starting point. The Oxford English Dictionary defines it as "capable of being maintained at a certain rate or level". Other definitions are similar. One can construct a graphical interpretation of this definition as shown in Figure 1 on the following page. The vertical axis in this figure represents Quality, a term that will be used here in a general sense to refer to how good something is. It can refer to the financial standing of a firm, the functionality of a car, the reliability of a bridge, or the level of social inequality in a society. The horizontal axis represents time t and Quality is represented as the function $Q(t)$. The quantity t_f represents a time threshold beyond

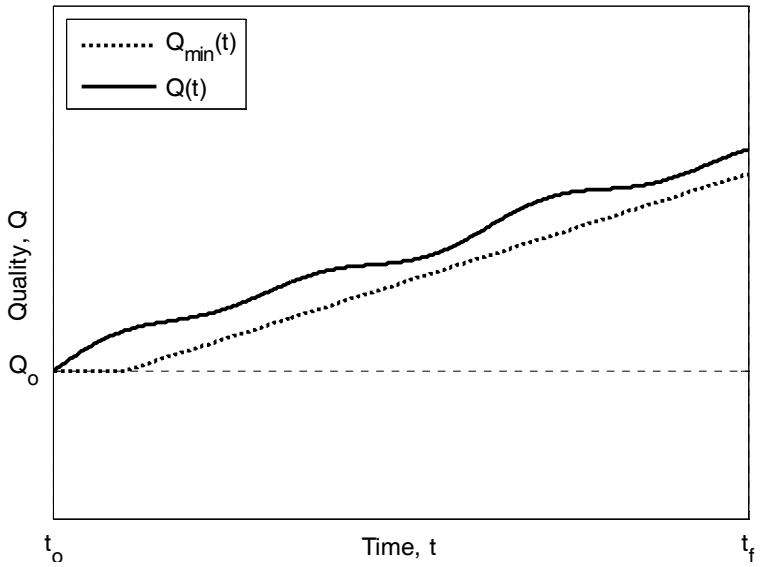

Figure 1. Graphical representation of proposed sustainability framework.

which we are no longer concerned. A function $Q_{min}(t)$ is defined to determine the limit below which $Q(t)$ cannot drop. With this framework it is possible to define sustainability in mathematical terms. A process is said to be sustainable if

$$Q(t) \geq Q_{\min}(t) \forall t \in [t_o, t_f].$$

This idea will be illustrated in an example that is intentionally simple, but that is familiar to structural engineers and provides a springboard for talking about more general ideas. While this example does not capture the whole of what people mean when they say "sustainability", a term that tends to be attached to global problems at long time scales, it will lead directly to a generalized framework.

Consider a reinforced concrete bridge in a seismic region with cold winters. Once the bridge is in service, the primary concerns are earthquakes, freeze-thaw, and chloride ion penetration from de-icing salts. The seismic robustness of the bridge is measured by its reliability index β, which is related to the probability of exceeding a defined damage state in an earthquake. With no maintenance and mitigation plan the reliability index of the bridge might decrease in time as shown by the solid line in Figure 2 on the following page. The pristine bridge has a relatively high reliability index but after a certain initiation time, rebar corrosion begins and the reliability index decreases indefinitely, at some point dropping below β_{min}, the lower limit. In this case, applying the definition above, we can say that the seismic robustness of the bridge as measured by its reliability index is not sustainable over its intended service life. With a maintenance and mitigation plan in place, the reliability index of the bridge might progress as shown by the dashed line. The plan is to use cathodic protection to delay the initiation time. At a later time the bridge is retrofitted to make up for the steel rebar lost to oxidation. This does not stop further loss of rebar but does increase the strength sufficiently for the bridge's reliability index to remain above the required

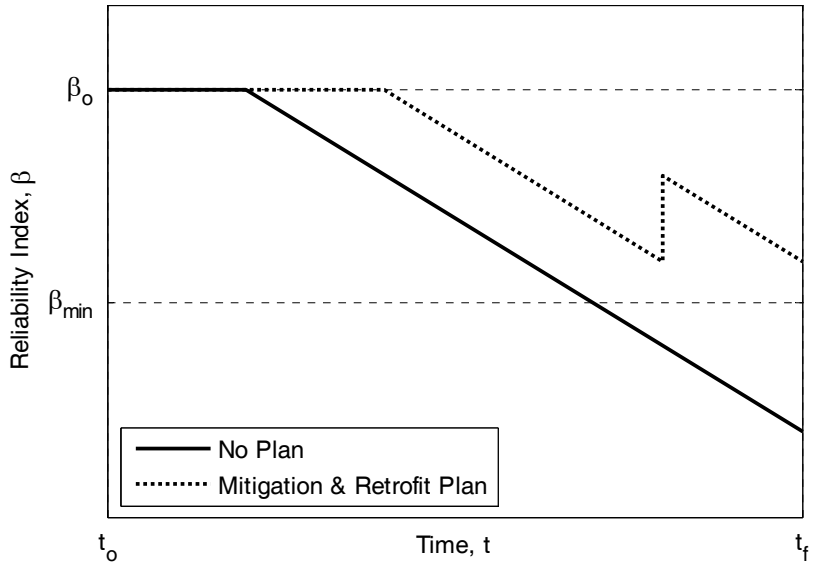

Figure 2. Reliability index of a bridge with and without mitigation and retrofit plans

minimum before the end of it service life. In this case we can say that the seismic robustness of the bridge as measured by its reliability index is sustainable over its intended service life. The following important issues are observed in this example:

1) There is a salient topic of concern, in this case the seismic robustness of the bridge.
2) The seismic robustness is measured by a numerical metric, the reliability index.
3) Some of the parameters are determined a-priori, namely t_f (the service life) and β_{min} (the minimum allowable reliability index).
4) The evolution of the reliability index is affected by natural laws (e.g., corrosion, weather, and seismicity) that are beyond the control of any individual.
5) The evolution of reliability index with time is also affected by the chosen maintenance and rehabilitation plan.
6) Once the maintenance and rehabilitation plan is chosen and the natural laws understood, the evolution of reliability index is determined by our physical models.
7) The predicted and required performance are compared to determine whether the seismic robustness is sustainable.

These seven steps can be generalized as follows:

1) Clearly identify the issues pertinent to the problem at hand.
2) Establish a method of assessing the Quality of these features. These are preferably numerical metrics.
3) Determine the performance requirements in the form of the minimum level of Quality $Q_{min}(t)$ and the time horizon t_f. Depending on the scenario these re-

quirements are determined by the engineer, the individual, the political system, etc.
4) Identify the natural laws that will govern $Q(t)$, i.e., the evolution of the features identified in step 1.
5) Determine the policies that will also govern $Q(t)$.
6) Determine the evolution of $Q(t)$ given the natural laws and processes.
7) Compare the predicted Quality to the required minimum level $Q_{min}(t)$.

Discussion

To illustrate how this framework can be applied, in the remainder of this section it is used to discuss the three common visions of sustainability presented above. Using the framework in the context of sustainable development not just as discussed in the Brundtland Report but including additional developments as summarized by Brandon and Lombardi (2011), we observe the following:

1) Human development is a complex issue that depends on such different factors such as standard of living, education, and public health among many others. One of the main tasks of the Brundtland report is to identify the relevant issues and describe them in detail. Despite the age of the document its findings are still relevant today.
2) The Brundtland report discusses the metrics used to measure these relevant issues. Others have attempted to establish a single summary metric to help in measuring changes in development. One such example is the human development index (HDI), which depends on more fundamental metrics such as gross domestic product, literacy rate and infant mortality.
3) The time horizon (t_f) and the development goals $Q_{min}(t)$ are issues subject to intense debate, but it is possible to establish them. Regarding t_f the Brundtland Report speaks of elimination of poverty in the time span of "several generations". Researchers have suggested 500 years (Hansen 2007) to 1000 years (MacKay 2008, 157) as suitable time scales.
4) The issues identified in step 1 are governed by laws and models from a wide variety of disciplines that include economics, public health, and climate science, to name a few.
5) The course of human development is affected by public policies at all geographical scales. The intention of the field of sustainable development is to influence policies to make the goals in step 1 more easily attainable.
6) Although the analysis might prove too complex, in theory predictions of the evolution of human development could now be made. Given the complexity of the problem and the number of assumptions that must be made, many analyses should be made to establish lower and upper bounds and our level of certainty in the predictions.
7) Having obtained predictions and measures of uncertainty, it would be possible to gauge whether the development goals could be reached. Because the answer depends on the social sciences, whose predictive abilities are not as accurate as those in the natural sciences, this is a difficult step.

As shown in this brief analysis, efforts in sustainable development are complex, perhaps too complex to obtain meaningful answer, but these efforts do address all the areas that have been identified as relevant. In contrast, when the Brundtland definition is decontextualized and reduced to simply "meeting the needs of the present without compromising the ability of future generations to meet their own needs", the relevant features are no longer clearly identified. Reference is made to the needs of the present and future generations, but what these needs are is not elaborated further. Because the needs are not identified it is impossible to assess their Quality in any objective way; anybody is able to provide their own definition of needs to suit their own agendas. Because Quality cannot be assessed, it is impossible to establish useful limits, or to identify evolutionary processes, even in theory.

A similar story can be told for the Triple Bottom Line (TBL). The detailed description provided by Elkington (1998) addresses the seven points identified by the framework proposed in this paper, although it is admitted that environmental and social accounting are areas in need of development. However, if one makes the simple claim that sustainability means accounting for economic, social, and environmental considerations, this removes any chance at a rational analysis. Interpretations can differ wildly, from taking the point of view of a business to being global in scale and political in scope with radical social justice and environmentalist goals. With a vague definition and a range of interpretations this wide, it is again not possible to develop a meaningful way of assessing Quality nor of determining the evolution of the economic, social, and environmental considerations.

Applying the proposed framework to LEED we observe the following:

1) The overarching goals of the LEED program are "improving performance" in "energy savings, water efficiency, CO_2 emissions reduction, improved indoor environmental quality, and stewardship of resources and sensitivity to their impacts" (USGBC 2010). These are typical of goals proposed by the green building community. There are no specific targets such as reducing CO_2 emissions by 30% in 50 years. The goal is simply to "improve performance".
2) LEED has a detailed measurement scheme. It is intended for use during design to influence the decisions of the design team. There is at present no requirement for long term performance measurement or modeling. Thus this score does not directly relate to the goals above. The items that are scored are practices that may (or may not) result in positive changes with regard to the stated goals. There are concerns that LEED certified buildings fail to perform as per the LEED program goals (Scofield 2009). While additional research is still needed this is an important concern.
3) There is no time horizon defined by LEED and while there are clearly defined point thresholds for different levels of certification, there are no defined minimum levels of Quality. This is due to the indirect relation between the goals and the measurement scheme. The only information that can be gathered by their requirement to "improve performance" is that $Q(t) > Q(0)$, i.e., that is that the performance be marginally better in some undefined time frame.

4) The knowledge does exist for determining the environmental impact of the building in the areas identified in the first bullet. Public and commercial life cycle inventories (databases) are available and software programs exist to calculate the impacts of a building project though its design life.
5) LEED makes no provisions for building operation, maintenance, or adaptability to the future. The typical LEED certified building will be operated in the same way as any conventional building.
6) Life cycle assessment (LCA) is a well established technique for determining the impacts in any given project through time (see e.g., ISO 2006). By using LCA one would be able to determine the performance of conventional and LEED certified buildings according to the goals stated in bullet 1. At present LEED is considering including LCA. It is too early to tell how it will be included or what changes this might bring.
7) It is not possible to use the LEED framework to determine whether a project can be called sustainable or not. This is due to two fundamental limitations: the vague statement of overarching goals and the disconnect between these goals and the system of measurement.

This analysis reveals that the point system offered by LEED is not a metric of sustainability. Although it may be a useful metric of something else, achieving LEED certification for a building provides no guarantee of performance that can be classified as sustainable.

What Does It Mean To Be Sustainable? The answer to this question follows from the structure of the proposed framework: (1) issues of concern are identified, (2) metrics are developed, (3) desired performance through time is determined, (4-5) forces governing the evolution of these issues are identified, (6) the evolution is modeled with sufficient accuracy, and (7) it is determined whether the predicted performance meets the desired performance.

While identification of an issue may be a matter of opinion, the choice should be defensible. Why are the chosen issues important? Why should these issues take precedence over all others? This is the most important step since without it it is not clear what question is being answered, if the proposed question is relevant, or even if a question is being answered. This step is also often ignored and people seem to assume that others share their views, creating a major source of miscommunication. This is a source of the ambiguity mentioned in the introduction between the many uses of "sustainability".

An important consideration that must be made when defining the issue of concern is the geographical scale of the issue; is it local like a bridge, a firm, or a building; is it regional like a watershed or the heat island effect in an urban area; is it national like calls for energy independence; or is it global like climate change? As in the example above, it is possible to refer to the sustainability of the bridge, as measured by its reliability index, under seismic loading and a particular de-icing and maintenance plan. Yet this does not capture what most people mean when using the stand-alone term

"sustainable". If this term is to be given the importance of a stand-alone term it should carry with it grandiose assumptions; it should refer to issues that are global in scale and relevant over long time spans. These issues would be those that affect the whole of humanity and its ability to at least maintain a level of development near what we have achieved so far. These are issues such as those discussed in the Brundtland Report.

Only an evolving process can be called sustainable. Something unchanging is tautologically sustainable. Thus, a technological innovation cannot be called sustainable without understanding the ways in which it will be used and applied, i.e., the ways in which it will effect change and be changed. A single building cannot be sustainable, but it can be an example of methods that when applied over a wide sector of society can contribute to sustainable urban development.

How well we can predict an evolving process depends on our knowledge about the natural forces that govern it as well as the influential practices within human control, e.g., public policies, standard industry practices, maintenance procedures, etc. The human-controlled practices must match the scale of the issues of interest. For instance, a new "green" (environmentally less invasive) material may use large amounts of recycled materials and result in significant reductions in CO_2 emissions, but if the availability of those materials is limited to small geographical regions, if the mechanical properties of that material limit its use to a few special applications, or if practices in the construction industry are such that they cannot produce or use the material extensively, then the impact of that innovation will be negligible. This material cannot fall under the banner of sustainability because its influence does not match the global, long term scale of resource depletion and climate change that would have made use of recycled materials and reduction of CO_2 emissions worthwhile goals to pursue.

Once the issues, the proper evaluation metrics, and the natural and human forces affecting those issues are identified, the evolution of the issues can be predicted. The nature of the analysis may look vastly different depending on the field of study, but because the problems are multidisciplinary and large (both spatially and temporally) most analyses will have in common the need to consider complex systems and significant uncertainty. Engineers may not be accustomed to considering such matters. Rodriguez-Nikl and Brown (2011) offer guidance for conducting such analyses.

In considering the distant future, it is important to determine the discount rate that accounts for the tendency for people to discount risks in the future, i.e., to fear a risk today more than the same risk in the future. It has been argued that when considering long term decisions that the smallest possible discount rate should be used (Brandon and Lombardi 2011, 47-49; Weitzman 1998). It can be shown that introducing even a very small discount rate can result in drastically different conclusions about the future, e.g., without a discount rate one may predict a net degradation whereas with even a small discount rate one may predict net modest improvement. For this reason,

it is suggested not to use a discount rate when making predictions about the distant future.

Once this analysis is conducted to satisfaction, determining whether a course of action is sustainable is a simple matter of determining whether the predicted performance of the issues of concern is within the stated limits. *For something to be sustainable means that it is a globally relevant and significant process that can be maintained within stated limits over long time scales*. If a claim of sustainability is being made the following questions need to be satisfactorily addressed:

1) Are the issues of concern clearly identified, well argued for, and global in scope?
2) Have appropriate metrics been developed for analyzing these issues? Are the chosen metrics directly relevant to the issues of concern?
3) Are appropriate limits chosen for these metrics? Is the time horizon long enough?
4) How well are natural laws understood? What does this imply about the uncertainty in our analyses?
5) Are human practices that influence the issues of concern well understood and defined? Do these practices allow for action at the same global scale as the issues of concern?
6) Is the evolution of these issues known with sufficient accuracy and certainty?
7) Is the predicted performance within the stated limits?

If one is a potential user of a technology and wants to determine whether that technology can honestly be called sustainable, if one wishes to invent a new technology that can honestly be called sustainable, or if one simply wants to evaluate their personal practices at home with regard to sustainability, this list of questions will help guide one's thinking to allow action consistent with one's values.

Summary

The aim of this paper is to present a comprehensive general definition of sustainability that can bring clarity to contemporary discussions and provide a way of assessing proposed solutions for the pressing problems of the day. The more common paradigms for sustainability are first presented. These are the Brundtland definition: "meeting the needs of the present without compromising the ability of future generations to meet their own needs" and the Triple Bottom Line of people, planet, and profit. LEED is also discussed because of its popularity in the building industry. Following this a general theoretical framework of sustainability is proposed for discussing the issues involved and a list of questions is provided to help determine whether something can genuinely be called sustainable.

ABSTRACT

There is widespread concern among practicing engineers that the clarity and usability of the building codes have radically diminished as the size and complexity of the codes have increased. One tool for assessing the ability of practicing engineers to consistently and reliably implement the code is the use of Trial Design Problems. The Trial Design Problem process consists of (a) developing a common engineering problem, (b) enlisting practicing engineers to complete the engineering problem using the code, (c) evaluating the engineering solutions submitted by practicing engineers, and (d) conveying the results of the problems to the engineering community and code development committees.

The Design Practices Committee has recently completed evaluating two different Design Problems. One design problem was for the application of ACI 318 Appendix D cracked concrete anchor bolt design. The second problem was the analysis and detailing specification of Wall-to-Roof anchorage in masonry construction intended to be per ACI 530-08. These problems have exhibited and proved that new code sections are routinely misinterpreted or not applied by practicing engineers. The application of these important and more recently instituted code sections has proved to be a subject that can cause confusion and misapplication as will be evidenced in the session. A movement is in progress to encourage greater collaboration between Code writing authors, and application and interpretation of code sections by the practicing engineers. The purpose of this session is to present the results of these trial problems and encourage further collaboration to advance the practice of structural engineering as it relates to code interpretation and design of elements and components. The objective is to improve clarity regarding current issues in the profession such as application of code sections, the complexity of codes and their detailed application. Presentations will introduce these topics, allowing time for comments, questions, and further discussion with members of the audience in attendance.

INTRODUCTION

Is the code written for practicing design engineers or for researchers? Are practicing design engineers able to keep up with the fast pace of code changes? Is the code

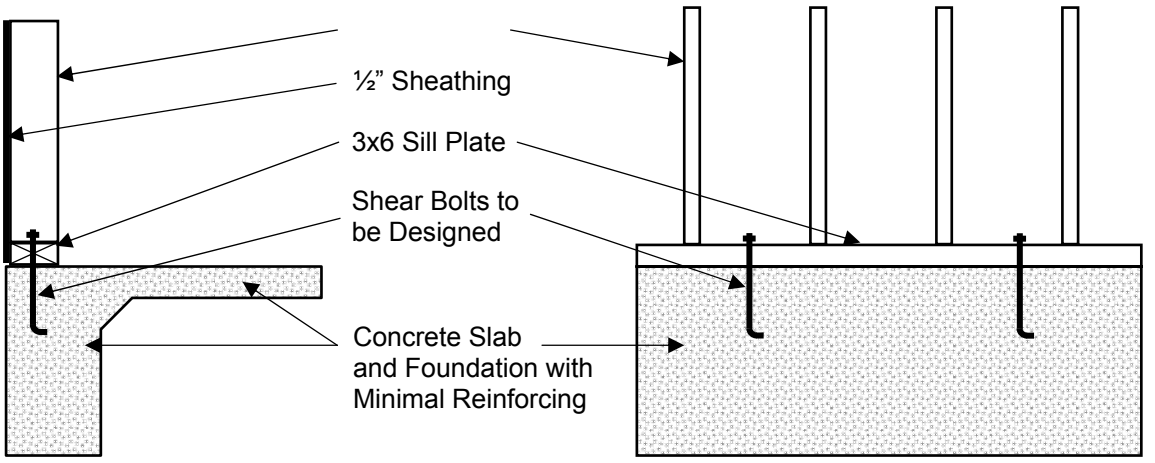
being properly and consistently applied in practice? With the introduction of a national building code (IBC), there has been growing concern among practicing engineers that the complexity of the code has significantly increased while the clarity and usability of the code has radically diminished. This paper describes the activities being performed by the Design Practices Committee of the Structural Engineering Institute (SEI) to evaluate the impact of code complexity on the practice of structural engineering by soliciting solutions to Trial Design Problems.

Trial Design Problems – Two Trial Design Problems were recently completed that quantitatively evaluated the effectiveness of the ACI 318 Appendix D, ACI 530-08 and ASCE 7-05 codes in producing reliable, safe and consistent engineering design applications. The results of the Trial Design Problems presented in this paper quantitatively demonstrate that unnecessarily complex code provisions result in less reliable, less safe and less consistent design practices.

In general, Trial Design Problems are intended to:

1. Investigate how practicing engineers interpret and apply current code provisions.
2. Investigate the consistency of engineering judgment of practicing engineers.
3. Promote dialog and continuing education among practicing engineers.
4. Identify and promote needed improvements in the code requirements.

The Trial Design Problem process consists of:



1. Developing a problem based on code provisions,
2. Enlisting practicing engineers to complete the engineering problem,
3. Evaluating the engineering solutions submitted by practicing engineers, and
4. Conveying the results of the problems to the engineering community and code development committees.

Trial Design Problem #1 - ACI 318 Appendix D

You are designing a new wood framed residence located in San Diego, California. You have already determined the lateral forces on the wood shear walls and that the house is classified as Seismic Design Category D. You have also determined that you will be using a 3x sill plate of pressure treated Hem Fir lumber and 2,500 psi normal weight concrete for the slab and foundation. The maximum in-plane shear force on the wood shear walls is as follows:

υ_{wind} = 600 plf ultimate / 420 plf allowable
$\upsilon_{earthquake}$ = 500 plf ultimate / 350 plf allowable

Design the shear anchor bolts connecting the 3x wood sill plate of the shear wall to the cast-in-place reinforced concrete foundation.

SOLUTION - ANCHOR DESIGN PROBLEM 2009

Time to Complete: **Way, way, way too much time.**

Bolt Type: ***Cast-in-Place 'J' Bolt***
(e.g. cast-in-place 'J' bolt, post-installed expansion anchor, etc.)

Bolt Grade / Material: ***A307***
(e.g. A307, etc.)

Bolt Capacity Sources: ***ACI Appendix D, NDS***
(e.g. IBC Bolt Capacity Tables, ACI Appendix D, NDS, Bolt Vendor Information, etc.)

Bolt Diameter: ***5/8" diameter***

Bolt Embedment: ***7"***

Bolt Spacing: ***48"***

Solution

ACI Shear Anchor Design (ACI D.4.1)

- $\phi V_n \geq V_{ua}$ (Eq. D-1)
- ϕV_n equals lesser of ϕV_{sa} or ϕV_{cb} or ϕV_{cp}

Steel Strength of Anchor in Shear (ACI D.6.1)

- Use 5/8" diameter A307 Hooked Anchor Bolts
- $V_{sa} = n0.6A_{se,v}f_{uta}$ (ACI Eq. D-20)
    - $A_{se} = 0.226in^2$ (Threads considered)
    - $f_{uta} = 58{,}000psi$ (A307)

- $V_{sa} = (1)(0.6)(0.226in^2)(58{,}000\,psi) = 7{,}860lbs$
- $\phi V_{sa} = (0.65)(7{,}860lbs) = 5{,}110lbs$
    - $\phi = 0.65$ (ACI D.4.4)

Concrete Breakout Strength in Shear (ACI D6.2)

- $V_{cb} = 2\frac{A_{Vc}}{A_{Vco}}\psi_{ed,V}\psi_{c,V}\psi_{h,V}V_b$ (ACI Eq. D-21 & D.6.2.1.c)
    - $A_{Vc} = A_{Vco} = 4.5(c_{a1})^2 = 4.5(2.5")^2 = 28.1in^2$
        - $c_{a1} = 2.5"$
    - $\psi_{ed,V} = 1.0$ (ACI D.6.2.1.c)
    - $\psi_{c,V} = 1.0$ (ACI D.6.2.7)
    - $\psi_{h,V} = 1.0$ (ACI D.6.2.8)
    - $V_b = \left(7\left(\frac{l_e}{d_a}\right)^{0.2}\sqrt{d_a}\right)\lambda\sqrt{f_c'}(c_{a1})^{1.5}$ (ACI Eq. D-24)
        - $l_e = h_{ef} = 6"$
        - $d_a = 0.625"$
        - $\lambda = 1.0$
    - $V_b = \left(7\left(\frac{6"}{0.625"}\right)^{0.2}\sqrt{0.625"}\right)1.0\sqrt{2{,}500\,psi}(2.5")^{1.5} = 1{,}710lbs$

- $V_{cb} = (2)\left(\frac{28.1in^2}{28.1in^2}\right)(1.0)(1.0)(1.0)(1{,}710lbs) = 3{,}420lbs$
- $\phi V_{cb} = (0.70)(3{,}420lbs) = 2{,}390lbs$
    - $\phi = 0.70$ (ACI D.4.4)

Concrete Pryout Strength (ACI D.6.3)

- $V_{cp} = k_{cp}N_{cb}$ (ACI Eq. D-30)
    - $k_{cp} = 2.0$
        - $h_{ef} = 6.0" > 2.5"$
    - $N_{cb} = \frac{A_{Nc}}{A_{Nco}}\psi_{ed,N}\psi_{c,N}\psi_{cp,N}N_b$
        - $A_{Nc} = (c_{a1} + 1.5h_{ef})(2\times 1.5h_{ef})$ (ACI Fig. Rd.5.2.1)
        - $A_{Nc} = (2.5"+1.5(6.0"))((2)(1.5)(6.0"))=207in^2$
        - $A_{Nco} = 9h_{ef}^2 = (9)(6.0")^2 = 324in^2$
        - $\psi_{ed,N} = 0.7 + 0.3\frac{c_{a,\min}}{1.5h_{ef}}$ (ACI Eq. D-11 for $c_{a,min}<1.5h_{ef}$)

- $\psi_{ed,N} = 0.7 + 0.3\dfrac{2.5"}{1.5(6.0")} = 0.78$
- $\psi_{c,N} = 1.0$ (ACI D.5.2.6)
- $\psi_{cp,N} = 1.0$ (ACI D.5.2.7)
- $N_b = k_c\lambda\sqrt{f_c'}h_{ef}^{1.5} = (24)(1.0)(\sqrt{2500\,psi})(6.0)^{1.5} = 17{,}636lbs$

  - $N_{cb} = \dfrac{207in^2}{324in^2}(0.78)(1.0)(1.0)(17{,}636lbs) = 8{,}790lbs$

- $V_{cp} = (2.0)(8{,}790lbs) = 17{,}580lbs$
- $\phi V_{cp} = (0.70)(17{,}580lbs) = 12{,}310lbs$
  - $\phi = 0.70$ (ACI D.4.4)

Wood Sill Plate (NDS)

- $Z' = ZC_DC_MC_tC_gC_\Delta C_{eg}C_{di}C_{tn}$
  - $Z = 1{,}170lbs$ (NDS Table 11E)
  - $C_D = 1.6$, $C_M = 1.0$, $C_t = 1.0$, $C_g = 1.0$, $C_\Delta = 1.0$, $C_{eg} = 1.0$, $C_{di} = 1.0$, $C_{tn} = 1.0$
- $Z' = (1{,}170lbs)(1.6) = 1{,}870lbs$

Wind Design

- Concrete
  - $\phi V_n = \phi V_{cb} = 2{,}410lbs$
  - $V_u = 600\,plf$
  - $Spacing = \dfrac{2{,}410lbs}{600\,plf} = 4.0\,ft$
- Wood
  - $Z' = 1{,}870lbs$
  - $V = 420\,plf$
  - $Spacing = \dfrac{1{,}870lbs}{420\,plf} = 4.5\,ft$

Earthquake Design

- Concrete
  - $0.75\phi V_n = 0.75(2{,}410lbs) = 1{,}810lbs$
  - $V_u = 500\,plf$
  - $Spacing = \dfrac{1{,}810lbs}{500\,plf} = 3.6\,ft$ (Governs Design, Use 32" o.c.)
- Wood
  - $Z' = 1{,}870lbs$
  - $V = 350\,plf$

- $Spacing = \frac{1{,}870 lbs}{350 plf} = 5.3 ft$

Final Selection

- Use 5/8" diameter cast-in-place hooked anchor bolts with 7" embedment spaced at 32" on center.

The Design Practices Committee of the Structural Engineering Institute recently completed the above Trial Design Problem related to the application of ACI 318 Appendix D with an anchor bolt problem for wood frame construction. The quantitative analysis of the Trial Design Problem solutions indicated serious concerns with the ability of practicing engineers to reliably and efficiently implement several provisions of the ACI 318 Appendix D procedures including:

- Significant variation in the application of Appendix D sections, variable values and variation in the interpretation of NDS sections and values. Specifically values for the seismic capacity of the anchor bolts in the concrete varied from a low of 521# to a high of 41,800#.
- Experience is essential as engineers with less than 5 years experience consisted of only 11% of respondents and one utilized only off the shelf software to complete the solution and did not check the wood capacity.
- Selection of Appendix D as the governing code for the concrete portion was made only 61% of the time even though ACI 318 Appendix D was referenced right on the problem statement.
- Short embedment depths for the 5/8" diameter anchors were selected many times that shows a lack understanding of the behavior of materials to keep connections ductile and not have brittle shear failures of the concrete. Over 60% of the embedments specified were 6 inches or less.

Recommendations going forward indicate efforts can be made to increase engineer's awareness to ductile behavior of anchorage into concrete construction. Increase professional development seminars, and increase training. Considering the Trial Design Problem results, training should include various options for working through practical examples of ACI 318 Appendix D problems, including the use of software.

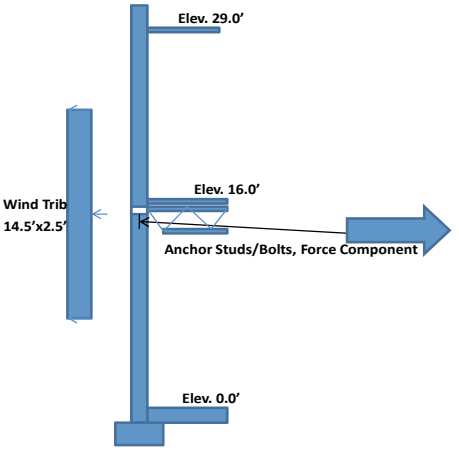
The demographics of the participants were as follows:

Highest Educational Degree	28% Bachelors	50% Masters	22% Unknown	
Years Experience	11% 0-4 Years	38% 5-10 Years	28% 11-20 Years	0% 21+ Years
Professional License	17% EIT Only	61% PE	17% SE	
States	33% Virginia	11% Minnesota	56% Other	

Experience is Essential - This is the first lesson learned (or reinforced) from the trial design solutions. Education alone is not adequate to ensure practicing engineers are able to safely and consistently design elements of structures. As an example, the concrete capacity from the published solution was 2.41 kips. The answer submitted by engineers with less than 5 years experience varied from 1.5 kips to 3.5 kips. While having experience certainly did not eliminate all errors, having at least 5 years of experience seemed to give engineers enough judgment to recognize unreasonable answers that were grossly incorrect. As a result of the large variation in results for those with less than 5 years of experience, findings for subsequent portions of the assessment were based on data gathered from those engineers with 5+ years of experience.

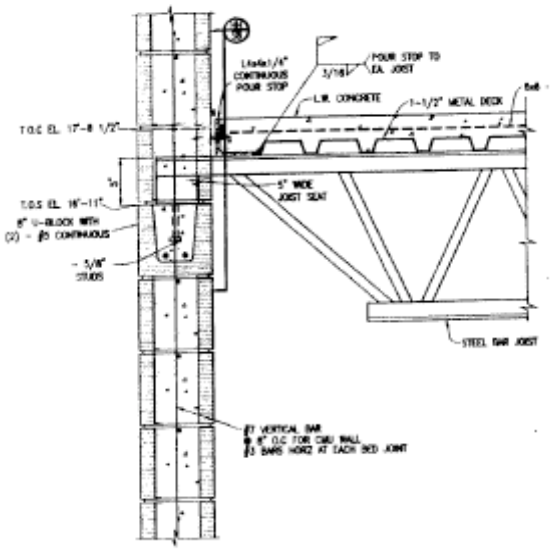
Use of ACI 318 Appendix D to solve for the concrete strength vs. Not solving for this at all or using IBC – Over 60% of the submitted solutions used the ACI 318 Appendix D Method to solve for the concretes wind and seismic capacity.

Degree of Difficulty on arriving at the solution - The average time to complete the analysis was approximately 2 hours.



Recommendations – The results of this problem indicate that efforts should be made to:

1. Increase engineer's awareness of the ACI 318 Appendix D Design Procedures. These efforts could include: (a) increased referencing to ACI 318 in the IBC and ASCE 7 code requirements, (b) increased exposure in ASCE 7 professional development seminars.



2. Increase training in and education in both younger engineers and among experienced senior engineers (10+ year's experience). The training should include ACI 318 Appendix D anchorage problem solutions for both concrete and steel elements and include applicable software solutions.

Trial Design Problem #2 – Wall to 2nd Floor Anchorage in Masonry Construction per ACI 530-08

You are designing a new concrete block masonry wall Fire Station in New Orleans, Louisiana that is approximately 100'x100' in plan and in a flat urban area. You need to determine the component wind lateral out-of-plane wall force based on the Code required 150 mph basic wind speed. The second floor open web joist framing will be anchored to the grouted 8-inch, f'm = 2000 psi reinforced concrete block masonry wall at joist pockets every 2.5' feet on center. The tributary height contributing to the 2nd floor wind out of plane load is 14.5 feet so the out of plane wind load area is 2.5' x 14.5' to be attached to the floor framing. The Roof is at elevation 29 feet as shown in the wall section below.

WALL SECTION

DETAIL AT SECOND FLOOR

Determine the wind out-of-plane lateral force (leeward side) and the proposed number of 5/8-inch diameter anchors connecting the joist bearing plate to the masonry wall for the force. The governing Building Codes are IBC 2009, ASCE 7-05 and ACI 530-08.

Solution

Time to Complete: **Averaged about 2 hours**
Wind Resultant Force Component: ***2016#***

Anchor Type, Grade, Material: ***Cast-in-Place Headed Stud (Nelson Stud), ASTM A108***
(e.g. Headed Anchor Stud, cast-in-place 'J' bolt, post-installed expansion anchor, A307 Anchor Bolt, etc.)
Anchor Capacity Sources: ***ACI 530-08/ASCE 7-05***
(e.g. Code, Bolt Vendor Information, etc.)
Number of 5/8" diameter anchors per attachment: **2 @ *5/8" diameter***
Bolt Embedment and Spacing: ***7"embedment and 8 inch spacing***

Solution

Wind Resultant Force Component for lateral out-of plane load.
ASCE 7-05 Wind Components (ASCE 7-05 6.4.2.2)

- $p_{net} = \lambda K_{zt} I p_{net30}$ (EQ 6-2)
- In the City of New Orleans, Exposure B, Urban Area, $\lambda = 1.0$ for Urban Area
- Topographic Factor K_{zt} for the flat site is 1.0
- Fire station is an Occupancy Category IV structure per ASCE 7-05 Table 1-1
- Importance Factor per ASCE 7-05 Table 6-1 for Category IV in Hurricane Prone regions is 1.15
- End Wall Zone 5 used as 10% of the building length is = 100' (0.10) = 10'
- Tributary Wind Area on each joist anchor location component = 2.5'x14.5'= 36 ft^2
- p_{net30} from ASCE 7-05, Figure 6-3, Components and Cladding, Wall, End Zone 5, Greater than 20ft^2 but less than 50ft^2,
  Straight line Interpolate between the value for 20ft^2 of 50.5 psf and 50ft^2 of 45.7 psf for 36 ft^2.
- (50.5 psf – 45.7 psf) / 50ft^2 – 20ft^2 = 4.8 psf/ft^2
- (4.8 psf/ft^2) (36ft^2 -20ft^2 / 50ft^2 – 20ft^2) = 2.56 psf
- p_{net30} = 45.7 psf + 2.56 psf = 48.26 psf
- p_{net} =1.0 (1.0) (1.15) 48.26psf = 56 psf
- Wind Resultant Force Component = 56 psf (36ft^2) = 2016 #

ACI 530-08 Shear Design (ACI 2.1.4.3)

- Use 5/8" diameter A307 Headed Anchor Bolts
- L_{bc} = 7.625/2 = 3.81" which is governed by half the thickness of the 8" inch thick CMU wall
- $A_{pv} = \pi L_{bc}^2 / 2 = \pi 3.81^2 / 2$ = 22.8 sq. in.
- $A_{pt} = \pi L_{bc}^2 = \pi 3.81^2$ = 45.6 sq. in
- B_v is the lesser of $B_{vb} = 1.25\ A_{pv} \sqrt{f'm}$ (Eq. 2-6)

  -or-

  $B_{vc} = 350\ \sqrt[4]{f'mA_b}$ (Eq. 2-7)

  -or-

  $B_{vpry} = 2.0\ B_{ab} = 2.5\ A_{pt} \sqrt{f'm}$ (Eq. 2-8)

  -or-

  $B_{vs} = 0.36\ A_b f_y$ (Eq. 2-9)
- $B_{vb} = 1.25\ A_{pv} \sqrt{f'm}$ = 1.25 (22.8) $\sqrt{2000}$ = 1275# <u>GOVERNS</u>

- $B_{vc} = 350\ \sqrt[4]{(2000 psi)(0.31 in2)} = 1746\#$
- $B_{vpry} = 2.0\ B_{ab} = 2.5\ A_{pt}\ \sqrt{f'm} = 2.5\ (45.6)\ \sqrt{2000} = 5100\#$
- $B_{vs} = 0.36\ (0.31)\ 30{,}000 = 3350\ \#$
- B_{vb} Masonry breakout controls
- Check overlap if bolts spaced at 8 inches on center.
  $A_{pv} = 22.8 + 8"x3.81" = 53.2$ sq. in.
  $B_{vb} = 1.25\ (53.2)\ \sqrt{2000} = 2974\#$ OK
- Number of 5/8" diameter Anchors Needed = 2016# / 1275# per anchor = 1.6 anchors

Final Selection
- Use (2) 5/8" diameter cast-in-place headed anchor bolts located in the center of the wall with 7" embedment spaced at 8" on center (one anchor each cell, 12 bolt diameters on center for the anchors.)

The demographics of the 27 participants were as follows:

Highest Educational Degree	63% Bachelors	37% Masters	0% Unknown	
Years Experience	18.5% 0-4 Years	37% 5-10 Years	18.5% 11-20 Years	26% 21+ Years
Professional License	26% EIT Only	74% PE	26% SE	
States	44% Virginia	11% Oregon	7.5% each NC, WI, GA	22.5% Others

Experience is Essential - This is the first lesson learned (or reinforced) from the trial design solutions. Education and number of years of experience alone are not adequate to ensure practicing engineers are able to safely and consistently design buildings. As examples, 4 participants arrived at only needing one 5/8" diameter anchor to secure this connection. Typically the answer of needing only one anchor bolt was arrived at due to a low wind force resultant and not checking for wind forces at the edge of the structure where the force can be higher. The answers submitted by engineers with less than 5 years experience varied from 1 kips to 2 kips for the wind force resultant on the detail. However even very experienced engineers arrived at wind force demands as low as 500 pounds. While having experience certainly did not eliminate all errors, having at least 5 years of experience seemed to give engineers more judgment to recognize unreasonable answers that were incorrect. Additionally the use of only one anchor is very impractical and can be irresponsible. The use of only one anchor will most likely result in an eccentric loading condition between the joist and the anchor that can result in unaccounted for torsion and failure of the anchor when loaded.

Central vs. End Wall Zone Wind Force – 55% of the submitted solutions did not calculate the end wall zone wind force component. Given the simplicity of the

problem and the fact that many of the engineers that submitted solutions were from regions of the Atlantic or Gulf Coast, it is interesting to observe the omission of the End Wall Wind Zones from the calculations.

Revision of ACI 530-05 to ACI 530-08 Section 2.1.4.3.2 - The determination of correct number of anchors changed from 4 to 2 by using the newer ACI 530-08 code section 2.1.4.3.2 as opposed to the previous version in ACI 530-05. The change in the code away from linear interpolation once 12 diameter edge distance was not achieved resulted in a significant change in the calculations and results. Most all respondents stated they used the ACI 530-08 code. However, one respondent stated they were using the ACI 530-08 code but upon examination of the submitted calculations they had actually used the ACI 530-05 section and arrived at the need for the 4 anchors instead of only 2. The practicality of 4 anchors in this type of detail would almost be prohibitive.

Bolt/Anchor Embedment – 52% of respondents have an anchor embedment of 4 inches or less. Further 22% of respondents had an embedment depth of only 2.5 inches. This shallow embedment does not allow for much if any ductility in the anchorages performance and can lead to a more brittle failure of the anchorage. This was not recognized by the respondents ion their solutions by upsizing the anchor embedment depths. With only a 2.5 inch embedment often times the bearing plates for such anchorage require the use of leveling grout that could truly jeopardize the true embedment in the masonry.

Headed Shear Stud Usage as opposed to Anchor Bolts – 22% of respondents utilized headed anchor studs that would need to be welded to the bearing plate above prior to either wet setting these bearing plates and anchors or carefully prepositioning and grouting around and underneath. The recognition that the placement of the prewelded headed shear studs to the underside of the bearing plates and then the difficulty of placing this in the grouted cell was assumed to take place by the other 78% of respondents and their use of cast in place anchor bolts. This observation by the majority of participants is encouraging. However having 22% of the respondents not recognize this also indicates more experience and judgment would be beneficial in the applications of the right materials for the right application.

Recommendations – The results of this problem indicate that efforts should be made to:

1. Increase engineers awareness of the ASCE 7 wind load requirements for end zones especially. These efforts can include increased exposure to ASCE 7 wind loading professional development seminars.

2. Increase engineer's awareness of the AVI 530-08 procedures. These efforts could include: (a) increased referencing to ACI 530–08 Section 2.1.4.2.2.1 in ASCE 7 code requirements, (b) increased exposure in ACI 530-08 and ASCE 7 professional development seminars.

3. Increase training in practical detailing of connections for constructability and ductility. Often this training is best done in offices where experienced engineers can mentor junior engineers to avoid the lessons learned over the years. The training should include the various options and consequences for detailing critical connections in alternative ways. A good quality control program instituted by senior engineers reviewing junior engineers work can also yield these benefits from a training manner.

Conclusions

An evaluation of the data presented in the trial design problems leads to the following conclusions:

Trial Design Problems – Trial design problems are an important tool in assessing the ability of practicing design engineers to safely and consistently apply the code provisions. We encourage code committees to consider expanding the use of this tool in assessing the efficacy of future code changes.

Experience Matters – The trial design problem results clearly indicate that engineers with at least 5 years of experience produce much safer and more consistent designs. Perhaps increased experience requirements for licensure should be considered with more emphasis on pre-licensure mentorship.

Code Complexity and Safety – The perceived accuracy of complex codes is overshadowed by a significant increase in errors. The trial design problems quantitatively demonstrate that complex codes, such as the current ASCE 7-05 wind provisions, and few years of experience produce results that are less accurate, less consistent and less safe. We applaud the efforts of ASCE 7 and ACI 530 for revising the codes sections to determine anchorage in a more reasonable manner. When this problem was solved using the ACI 530-05 code an impractical four 5/8" diameter anchors were needed to provide adequate anchorage. ASCE and ACI are consciously developing better provisions that reduce design errors and increase building safety, while decreasing the amount of time needed for design.

Code Committees need Practicing Engineers – Practicing design engineers must be adequately represented on code committees to insure that codes do not become unnecessarily complex.

Using Failure Case Studies to Teach Reinforced Concrete Design

Norbert Delatte, M.ASCE[1]

[1]Professor and Interim Chair, Civil & Environmental Engineering Department, Stilwell Hall Room SH 121, Euclid Avenue at East 24th Street, Cleveland State University, Cleveland, Ohio 44115, Tel: 216-687-9259, Fax: 216-687-5395
Email: n.delatte@csuohio.edu

ABSTRACT

The study of failures, particularly in a design course, can help teach students how to ensure the satisfactory performance of buildings and bridges. Some of the shear design provisions in the current ACI 318 Building Code can be traced back to two collapses of Air Force warehouses in the mid-1950s. Three building collapses in the 1970s and 1980s showed the importance of punching shear. There is also much to be learned from reinforced concrete building performance under extreme conditions, such as the terrorist attacks on the Oklahoma City Murrah Building and the Pentagon (9/11). Another classic case is the collapse of a major section of the Ronan Point apartment towers in the UK in 1968, illustrating the need to properly tie precast building elements together. The relatively recent collapse of the Laval, Quebec concrete bridge abutments in Canada shows the importance of providing continuity of reinforcement.

INTRODUCTION

The study of failures, particularly in a design course, can help teach students how to ensure the satisfactory performance of buildings and bridges. A number of failure case studies have been developed for use in courses teaching reinforced concrete design, as outlined in the book "Beyond Failure." These include failures in the construction process and in formwork, such as the collapse of the Willow Island Cooling Tower. Some of the shear design provisions in the current ACI 318 Building Code can be traced back to two collapses of Air Force warehouses in the mid-1950s. Three building collapses in the 1970s and 1980s showed the importance of punching shear. These were the 2000 Commonwealth Avenue collapse in Massachusetts, the Skyline Plaza/ Bailey's Crossroads collapse in Virginia, and the Harbour Cay Condominium collapse in Florida. The latter two were investigated by the National Bureau of Standards, NBS (now the National Institute of Standards and Technology, NIST). There is also much to be learned from reinforced concrete building performance under extreme conditions, such as the terrorist attacks on the Oklahoma City Murrah Building and the Pentagon (9/11). Another classic case is the collapse of a major section of the Ronan Point apartment towers in the UK in 1968, illustrating the need to properly tie precast building elements together. The relatively recent collapse of the Laval, Quebec concrete bridge abutments in Canada shows the importance of providing continuity of reinforcement. This case study also offers the

opportunity to illustrate the application of strut and tie models to the analysis of complex reinforced concrete structures.

In the U.S., a typical first course in Design of Reinforced Concrete Structures (such as CVE 422 at Cleveland State University) focuses on basic theory and design of reinforced concrete structures according to the American Concrete Institute (ACI) 318-08 (ACI 2008) code. Often the course is taught using a textbook based on that standard, such as Wight and MacGregor (2009). In most cases, only about half of the textbook material is covered in an introductory course, although some universities offer a subsequent advanced course on topics such as torsion, slender columns, plastic design, yield line theory, and so forth.

For the past two years the course at Cleveland State University has included a number of failure case studies selected to illustrate the behavior of reinforced concrete structures and members. In addition to the course text (Wight and MacGregor, 2009) and code (ACI 2008), the course included excerpts from Chapter 5 (Reinforced Concrete Structures) of the book *Beyond Failure* (Delatte, 2008).

CONCRETE MATERIALS AND CONSTRUCTION

Although construction methods are not the focus of the CVE 422 course, the designer is also responsible for construction specifications, and an understanding of material behavior and construction practices is of considerable value.

One case study of this type is the collapse of the Willow Island Cooling Tower at Willow Island, West Virginia, on April 27, 1978. Because this collapse case study focuses on concrete strength and formwork practices, it is more of a construction case study and is found in Chapter 9 (Construction Materials) of *Beyond Failure* (Delatte, 2008). This case study is not covered in the CVE 422, because the same principles are addressed in the 2000 Commonwealth Avenue collapse case study, which will be discussed shortly.

SHEAR MECHANISMS AND FAILURES

Shear in reinforced concrete can be a complex subject for students to grasp. First of all, the flow of forces can be difficult to envision. Second, while the need to use stirrup reinforcement to enhance shear strength is straightforward, the need to provide minimum stirrups when the calculated forces show that they aren't necessary is not so obvious.

The roof collapses of the Air Force Warehouses at Wilkins Air Force Depot in Shelby, Ohio, on August 17, 1955, and at Robins Air Force Base near Macon, Georgia, on September 5, 1956, are often used to show the need for minimum stirrup reinforcement (e.g. p. 234 of Wight and MacGregor, 2009). These collapses are generally attributed to combined load, shrinkage, and thermal effects. In each case,

400 foot lengths of roof girders functioned as single units due to defective expansion joints (pp. 130 – 133, Delatte, 2008).

Three case studies illustrate the collapse of buildings under construction due to punching shear and similar mechanisms. The first of the three was the January 25, 1971 collapse of the 2000 Commonwealth Avenue apartment building under construction in Boston. Four workers were killed in this collapse. The project was characterized by an almost total lack of construction control and inspection. The floor plan and the extent of collapse are shown in figure 1.

This building used flat plate construction. A plate is a slab of uniform thickness supported on columns. This is a very economical type of construction for short spans and light loads because formwork is very simple and the absence of beams reduces the floor-to-floor height (p. 606, Wight and MacGregor, 2009). However, the problem with the system is that it is subject to two-way or punching shear of the slabs, which can be a brittle failure mechanism. Despite the importance of this failure mechanism, textbooks often suggest that the material not be covered in an introductory course but be deferred to an advanced course.

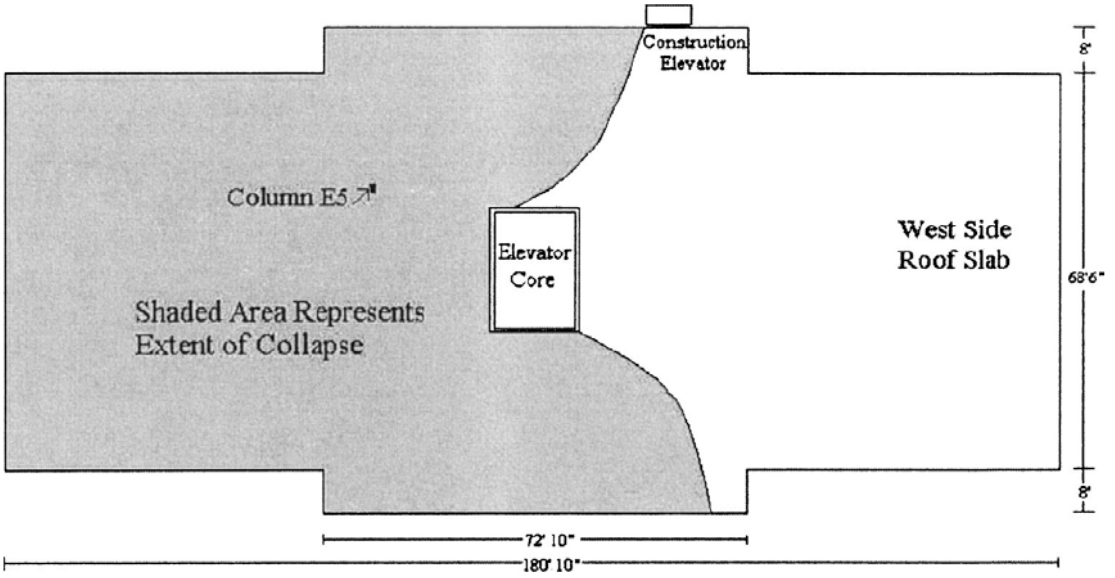

Figure 1: Collapsed Section of 2000 Commonwealth Avenue (King and Delatte, 2004, Delatte, 2008)

The punching shear mechanism is illustrated in figure 2. The slab breaks away and the column "punches" through the slab. The resistance to punching shear depends on the strength of the concrete, the effective depth of the slab, and the perimeter of the failure plane around the column. Clearly, the loads applied to the slab and the removal of shoring under the slab are also important. In the collapse at 2000 Commonwealth Avenue, the strength of the concrete was low and strength

development was impaired by cold weather. Some of the reinforcement was improperly placed and poorly developed. The roof slab of the building held heavy mechanical equipment, and there was evidence that shoring had been removed prematurely. Details are provided in King and Delatte (2004) and Delatte (2008). The City of Boston published a detailed report (Granger et al., 1971).

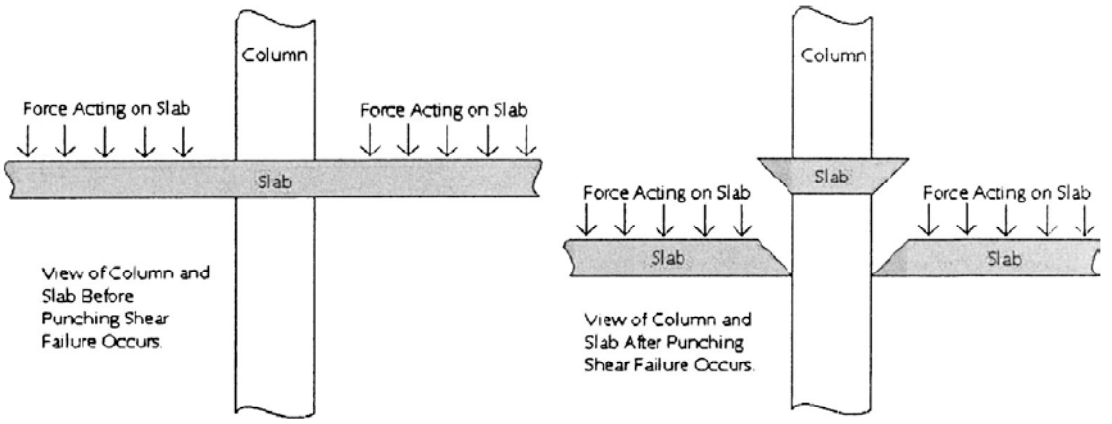

Figure 2: Punching shear failure mechanism (King and Delatte, 2004, Delatte, 2008)

Only a few years after the 2000 Commonwealth Avenue collapse, a similar collapse occurred at Skyline Plaza, Bailey's Crossroads, Virginia. On March 2, 1973, a section of the apartment building under construction collapsed to the ground. The collapsed structure is shown in figures 3 and 4. This collapse was investigated by the National Bureau of Standards (NBS) which is now the National Institute of Standards and Technology (NIST) (Leyendecker and Fattal, 1977, Carino et al., 1983).

Once again, punching shear was the culprit. An entire section of the building collapsed to the ground, so that the structure looked like two separate buildings (figure 4). The rate of construction was approximately one floor per week, but in cold weather (e.g. March) rate of concrete strength gain was severely retarded. NBS used the maturity method to estimate that the compressive concrete strength was only about 1,000 – 1,500 psi at the time of the collapse. The investigation also found that the collapse occurred while shoring was being removed several floors below a fresh concrete placement. The NBS published a full report on their investigation (Leyendecker and Fattal, 1977, Carino et al., 1983).

The third punching shear case study was the collapse of the Harbour Cay Condominium on March 27, 1981 in Cocoa Beach, Florida. Eleven workers were killed and 23 were injured. The condominium was five stories tall, with shoring at all levels (figure 5). When the forms were removed, the structure collapsed completely with all floors pancaking to the ground (figure 6).

Figure 3: Skyline Plaza/ Bailey's Crossroads Collapse, (Delatte, 2008, photo courtesy Nick Carino of NIST)

Figure 6 shows an important clue to the collapse. The column standing up shows a telltale sign of punching shear where the slab used to be attached to the column. This collapse was also investigated by the NBS (Lew et al., 1981, Lew et al., 1982).

The investigation found that the slabs were considerably thinner than the ACI minimum typically used for deflection control. Moreover, the reinforcing steel had been placed too low in the slab because chairs of the wrong height had been used, which made the effective depth of the slab too small. The column sizes were too small. In addition to causing the problem of column reinforcement congestion and poor consolidation of concrete, this meant that the perimeter around the columns to resist punching shear was too small. The concrete, however, had been of adequate strength.

This failure was due to design error. Critical calculations had never been performed, including those for slab minimum thickness and for punching shear.

PERFORMANCE UNDER EXTREME CONDITIONS

One early case study of concrete building performance under extreme conditions was the partial collapse of the Ronan Point apartment tower in London, U.K., on the morning of May 16, 1968. Ronan Point was 22 stories tall and was built using a system of precast panels fastened together. As the occupant of one apartment lit a stove to brew her morning tea, leaking gas exploded and blew out an exterior load-bearing wall. An entire corner of the building collapsed to the ground, killing four. Subsequent investigations showed that the connections between the panels were very poorly constructed (figure 7). A very light explosion was able to cause a disproportionate collapse of the structure. This case study led to changes in building codes to improve structural integrity and robustness. The U.K. government published a thorough investigative report (Griffiths et al. 1968).

In recent years, reinforced concrete structures have been tested under extreme events, including terrorist attacks. These include the bombing of the Oklahoma City Murrah Federal Building on April 19, 1995, and the attack on the Pentagon on September 11, 2001. Although neither building was designed for this type of event, there are lessons to be learned by contrasting the performance of the two structures.

By pretty much any criterion the Murrah Federal Building performed poorly. Approximately half of the floor plan was destroyed and 169 people were killed. A detailed analysis is provided by Hinman and Hammond (1997).

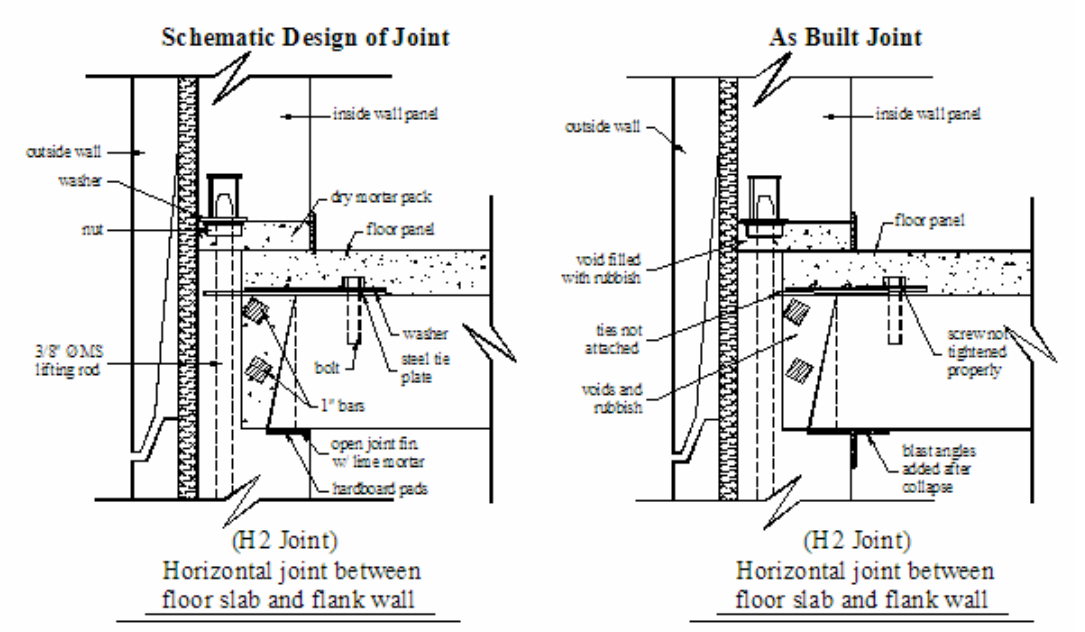

Figure 7: Ronan Point connection (Pearson and Delatte, 2005, Delatte, 2008)

Once a critical column was shattered, the continuity of the structure was severely disrupted. Floor slabs were blasted upwards and shattered, and then fell downward and pancaked to the ground.

On the other hand, the performance of the Pentagon to the September 11, 2001 attack is generally considered to be very good. The building had been constructed during World War II, and the original design concept called for it to store records after the war, so it was designed for high floor live loads of 150 psf. Circular columns with spiral reinforcement were used, and beam bottom reinforcement was continuous through the columns. The building was also in the process of being renovated to improve safety against blast.

As a result, the collapse of the building was localized to the immediate area of the aircraft impact, and the damage did not spread disproportionately. Columns continued to carry loads even though severely bent. A comprehensive building performance report has been published (Pentagon 2003).

CONTINUITY OF REINFORCEMENT AND STRUT-AND-TIE MODELS

Although collapses of structures in service without an immediate, obvious triggering cause are rare, one such case was the failure of the Autoroute 19 de la Concorde Overpass in Laval, Quebec, on September 30, 2006. This bridge collapse killed five people and injured six.

The bridge consisted of parallel prestressed concrete box beams resting on cast-in-place concrete cantilevers extending out from the abutments. The supports doubled

as expansion joints, and were subjected to unpredictable tension forces from the expansion and contraction of the bridge.

The cantilever supports relied on a complex reinforcement detail to transfer bearing forces to the top bars of the cantilevers through stirrups. However, the tops of the stirrups were placed slightly below the top reinforcement, leaving a horizontal plane of weakness. The support peeled away along that plane of weakness.

This case study offers the opportunity to illustrate the use of strut-and-tie models in design and analysis of reinforced concrete structures. The provincial government of Quebec published a lengthy report, with versions in both French and English (Commission 2007).

SUMMARY AND CONCLUSIONS

The case for the inclusion of case studies in engineering courses, particularly design courses, has been made elsewhere – for example, in Chapter 1 of Delatte (2008). There are a number of case studies, as outlined in this paper that could be used in a reinforced concrete design course. More information on these cases and others may be found in the references cited below, in Delatte (2008), and in the failure case studies project web site http://matdl.org/failurecases/ (Delatte, 2011).

Obviously, too much of a good thing can quickly become too much. The author uses five case studies in the CVE 422 Reinforced Concrete Design course. These are the Air Force Warehouses, 2000 Commonwealth Avenue, Skyline Plaza/ Bailey's Crossroads, Harbour Cay Condominium, and the Laval Quebec Bridge collapse.

Lessons Learned through the Development of an Undergraduate Course on Civil Engineering Failures

K.A. Salyards, P.E., Ph.D.[1]

[1]Department of Civil and Environmental Engineering, Bucknell University, 302 Dana Engineering, Lewisburg, PA 17837; PH (570) 577-1757; FAX (570) 577-3415; email: kas046@bucknell.edu

Abstract

A new undergraduate course was developed to introduce civil engineering students to the field of forensic engineering and foster an awareness of how engineers can and should learn from failures. Several other individuals and engineering departments have made commendable efforts to integrate information about specific failure cases within civil engineering courses while others have developed graduate-level courses designed to teach the students to become forensic engineers. This undergraduate course was designed to fit somewhere in between. The goals were two-fold: to improve the general knowledge base of historic and common failure modes and to introduce the field of forensic engineering and what it requires in an effort to encourage continued education in the field. The development of such a course was difficult for a number of reasons including the vast scope of the field, the scarce supply of teaching materials, and the disparity between the level of student knowledge at an undergraduate level and that required to fully understand an engineering failure. This paper describes the educational objectives and resources utilized in the preparation of the course, the variety of teaching methods and techniques undertaken during the course of the semester, and the successful components of the course as well as the difficulties and challenges encountered. Several considerations and suggestions are presented for others in the development of similar courses and recommendations for improving future offerings of this course are also presented.

Introduction

Numerous engineering educators, practitioners, and professional organizations have long recognized the need for integration of engineering failures into civil engineering curriculums. Methods for accomplishing this and the benefits of such integration have been the subject of professional discussion over the past two decades (Bosela 1993, Rendon-Herrero 1993, Delatte 1997, Delatte and Rens 2002, Reynolds 2003, Parfitt 2006, Prevatt 2010). In support of these needs, the Committee on Education of the Technical Council of Forensic Engineering, ASCE, continues to study engineering curricula (Rens et al. 2000) and develop and distribute educational resources including workshops for faculty on teaching with failure case studies.

Several approaches for integrating engineering failures into a civil engineering curriculum are possible depending on the needs of the individual department or college. In most cases, it is not viable to add another core course to a curriculum that is already full. Integration of short failure case studies into other required courses, such as mechanics, soil mechanics, structural design, or senior capstone courses is perhaps the best alternative (Delatte and Rens 2002). These case studies can be used to reinforce technical concepts while providing an opportunity for discussion of engineering ethics and professional development. The details for individual case studies are now available through several sources, including ASCE's Journal of Performance of Constructed Facilities and manuscripts (Delatte 2009, Frost 1995).

This approach integrating failure case studies into a variety of engineering courses has the advantage that it can be undertaken by almost any instructor. This approach can evolve over time as the instructor examines individual case studies and develops instructional activities to accompany each case study and technical concept. The level of expertise of the instructor will influence the level of detail with which the case study can be presented, but an in-depth analysis is not often required if the goal is to simply reinforce basic engineering concepts and introduce the concept of learning from failures. It is believed that this approach is even more effective if failure case studies are consistently incorporated across the curriculum.

A review of this approach has identified the instructor's lack of time to research and prepare case studies as the main obstacle impeding more widespread application (Delatte and Rens 2002). However, numerous sources are available for historic case studies (Nicastro 1996) and improvement in this area continues through the periodic publication of case studies in journals, news articles, internet sites (Delatte 2008, Parfitt 2009), and new books (Delatte 2009). These sources provide instructors with the pertinent information and references, while removing the difficulty associated with uncovering potentially confidential information.

Another approach, albeit rare, involves the development of an upper-level elective or graduate-level course in failure analysis and forensic engineering. Survey results (Delatte and Rens 2002) indicate that less than 10% of universities offer such a course. The availability of an instructor with sufficient practical engineering or failure investigation experience is rare. Many of these courses rely on support and involvement from external industry professionals involved in forensic work. In addition, these courses are primarily offered at the graduate level minimizing the likelihood that undergraduate students would be able to enroll because of prerequisites. Despite the appropriateness and success of such courses at the graduate level, the infrequent availability and preclusion of undergraduate enrollment falls short in realizing the learning opportunities available from engineering failures.

Although both of these approaches have been effective in expanding the awareness and educational perspectives of their target audiences, there seems to be a void in between. Integration of failure case studies into the curriculum reinforces technical

concepts and exposes students to select engineering failures but it doesn't directly address the field of forensic engineering. A stand-alone graduate-level course is likely to encompass both aspects, but the availability is limited by both instructor expertise and prerequisite requirements. The development of an undergraduate course to encompass both a review of a variety of case studies and the lessons learned from them as well as an introduction to the field of forensic engineering is described herein.

Motivation for Course Development

The motivation for the development of an elective course in building failures is multi-faceted and influenced by the educational environment at Bucknell University. Bucknell University is a private, liberal arts university in central Pennsylvania with 3600 undergraduate students. Approximately 900 students are enrolled in the College of Engineering with 170 in the Department of Civil and Environmental Engineering (CEE). As a predominately undergraduate university, the students do not have access to many graduate-level courses and the rural location also limits the involvement of local practitioners and professional organizations. The combination of both factors precludes the educational approach of a stand-alone course in forensic engineering.

The student population also influenced the development of the course. Less than 30% of all applicants are accepted into the CEE program yielding a selective student population and a large number of graduating students subsequently enter graduate degree programs. The student population is generally strong academically and the majority of students have broad interests in the field of civil engineering. Both undergraduate research and graduate-level education are strongly encouraged. Alumni of the department are frequently employed in non-traditional engineering positions, as exhibited by numerous working in the forensic engineering profession. Exposure to a variety of alternative career paths within civil engineering including forensic engineering is fitting for all students, especially those with an inclination for non-traditional careers.

Bucknell's civil engineering curriculum requires core courses in the traditional areas of civil engineering: geotechnical, water resources, environmental, structural, and transportation. Electives are offered in each of the subdisciplines as well as construction. This breadth of required courses coupled with the small size of the student body allows for few electives which require significant background. To populate an elective, it must be sufficiently broad to attract students interested in a variety of subdisciplines and not require advanced coursework in any one particular discipline. An elective focusing on engineering failures therefore must be sufficiently broad, while requiring a solid base in engineering fundamentals. For this reason, the course registration was restricted to fifteen engineering students in their senior year.

From the author's perspective with education and experience in architectural engineering, an introduction to building and architectural systems, building science and construction issues as they relate to building failures was also desirable. It is also

the author's opinion that an introduction to the field of forensic engineering is valuable to encourage further education and specialization.

Resources Utilized

In the preliminary stage of course development, references describing both approaches were consulted. Delatte and Rens (2002) proposed a variety of methods for utilizing case studies within the context of required engineering courses including topic introductions, class discussions, example problems, and group or individual projects. General case study approaches (Pietroforte 1998, Russell and McCullouch 1990) and individual accounts of case studies used in a specific course (Delatte 1997, Sutterer 2003) were referenced. Case histories from a variety of sources were reviewed (Delatte 2008, Delatte 2009). Publications describing the organization of stand-alone forensic engineering courses were also consulted (Delatte and Rens 2002, Ratay 2005, Wang 2005, Parfitt 2006).

Learning Outcomes and Objectives

Based on the motivations and references discussed above, a course in civil engineering failures and forensic engineering was developed for its first offering in the spring semester of 2009. The overall learning outcomes for the first offering of the course were:

1. To improve the general knowledge base of historic engineering failures, common failure modes and the lessons learned from them.
2. To introduce and encourage continued education in the field of forensic engineering or related fields

To achieve these general learning outcomes, the following learning objectives were established. "At the conclusion of the course, students will be able to:

1. Demonstrate an awareness of a variety of civil engineering failure case studies
2. Summarize the technical, ethical and professional issues involved in a variety of failure case studies incorporating structural, serviceability, building envelope, transportation, geotechnical and environmental issues
3. Describe the typical stages involved in the forensic engineering process for civil engineering and describe some of the investigative methods and tools available including non-destructive evaluation
4. Compose a proposal for forensic engineering services, a final written report, and present an oral summation of your findings
5. Recognize the limits of your knowledge; identify and locate the appropriate sources for the information sought; and utilize the information in a suitable manner
6. Develop improved observation skills and recognize possible indicators of issues that may warrant further investigation
7. Perform as an effective contributing member of an investigative or research-oriented team"

Course Details

To gauge the appropriateness of the course development and preparation, a survey was distributed to determine the incoming awareness of engineering failures and the student expectations for the course. The results clearly indicated that the students' awareness of both historic and current engineering failures was nearly nonexistent. Even such prominent cases as the Kansas City Hyatt Regency collapse were not universally recognized. In light of this revelation, the course was modified to incorporate more case history presentations by both instructor and students. The topics introduced in the class included:

- Case histories
- Forensic engineering process
- Contract language and legal issues
- Common failure types and related investigative techniques
    - Building envelope failures
    - Material deterioration and maintenance
    - Structural failure
- Historic preservation
- Accident reconstruction
- Ethics in engineering practice

The class met three hours a week with an additional weekly two hour lab period. The hourly meetings were typically utilized for traditional lecture, instructor case history presentations, and class discussions. The lab period was reserved for student presentations on assigned case histories, guest speakers, and class discussions.

Teaching techniques

To address a range of learning styles, several educational approaches were incorporated.

Traditional Classroom Lecture
The traditional classroom lecture was utilized to introduce new material and provide the pertinent technical information required for comprehension. In this manner, the material was structured in a logical manner and related discussions were directed. This approach was most suitable for topics such as the forensic engineering process and contract language and legal issues. Questions were designed and utilized to stimulate individual thinking and prompt short class discussions. Shorter periods of traditional lecture were used to counteract the typically negative implications of a passive audience.

Guest lectures
To emphasize forensic engineering as a possible career path, practicing professionals were invited to participate in the course as guest presenters throughout the semester. The practitioners offered a personal perspective and firsthand experience with current

industry practices, recent investigation case studies, and represent the diversity of opportunities involved in some type of forensic investigation. During the first offering of this course, practitioners from the following firms offered a guest lecture:

- Simpson Gumpertz & Heger, Inc. (SGH)
- Thornton-Tomasetti, Inc.
- Masonry Preservation Services, Inc. (MPS)
- Architectural Testing
- ENVIRON International Corporation

In addition, practitioners from Wiss, Janney, Elstner Associates, Inc. (WJE) have presented on the field of forensic engineering as part of the senior capstone course in the semester following the first offering of this course.

Class discussions – current issues

Each week, a class discussion was planned to incorporate relatively recent failures, articles, or investigations of interest to the students. Students were required to contribute articles or topics in preparation for these weekly discussions. Topics were wide ranging, including the controlled demolition of a local smoke stack tower, the failure of wood roof trusses under construction at a local site, legal issues relating to engineering failures as posed in NCSEA's Structure magazine, review of both media coverage and forensic reports of the recent I-35 Minneapolis Bridge collapse, and ethical dilemmas relating to engineering failures as posed in the "A Question of Ethics" section of ASCE News.

Simulated Client Interaction - Proposal

To improve observation skills and professional writing, a mid-semester assignment was developed incorporating the façade condition assessment of a campus building. The University had previously completed an investigation for the restoration of an aging masonry façade exhibiting significant cracking at certain locations. The assignment required the students to visually examine the façade, research material and construction details, and prepare a proposal for engineering services for the project. This required research into non-destructive testing methods and possible underlying causes of the deterioration. The results of the University's condition assessment were discussed and the façade restoration was completed during the summer following this course offering.

Individual research report

Because of the diversity of student interest within the class, a final individual research report was incorporated for which each student selected an appropriate topic that was of interest to him/her. The research report was to be a synopsis and evaluation of a category or type of failure written in the form of a technical note. Examples of selected topics included fire damage investigation, failure modes of asphalt, accident reconstruction techniques, glass and glazing problems, and wood truss failure modes. This assignment promoted individual research, professional writing, and the summary and evaluation of information.

Case history presentations

The benefits of examining historic engineering failures and analyzing the details of the case are widely acknowledged. To introduce the principle of learning from failure, several noteworthy and detailed case histories were presented by the instructor or guest speakers. Examples included the Kansas City Hyatt, Citicorp Headquarters, John Hancock Tower, and L'Ambiance Plaza. The details of the construction, failure, and key players in each history were presented using all available sources, including figures, photographs, video, and reports. The ensuing investigation details and conclusions were presented along with the resulting legal consequences and industry changes, if applicable. Each case history presentation was followed with a discussion period about noteworthy details of each case, including ethical dilemmas, investigation techniques, and relevance of the case to current industry practices.

After several case history presentations by the instructor or guest speakers, the format of the presentation shifted slightly to engage the students after the basic facts of the construction and failure were presented. The students were prompted to analyze the given information and identify evidence to be gathered, tests to be performed, and potential causes of the failure. After a short discussion, the details of the investigation and likely cause of failure were unveiled. This approach forced the students to play an active role in the case history presentation and begin to develop their observation and analysis skills.

Student case history research presentations

To facilitate the introduction of a significant number of case histories, student groups were assigned a case history to research, summarize, and present every other week. Each thirty minute presentation was to be accompanied by a single 8 ½ x 11 synopsis handout highlighting critical details in a poster-like format. The student groups were required to reference several reliable sources and identify any conflicting reports or conclusions. These assignments provided opportunity for furthering research skills, improving team interaction, and enhancing both oral and graphic communication skills. Each student was also required to review every presentation for thoroughness of the case history and clarity of the presentation. Questions were posed to each team and they were responsible for further research if required.

After several weeks of weekly presentations, an additional component was incorporated into the case history presentations. Each group was required to develop a visual aid of the failure mode to supplement their presentation. The visual aid could be in the form of a physical model or a graphical animation. The goal of this assignment was to further the understanding of the case history and promote forms of communication beyond the traditional powerpoint presentation.

Course Assessment

For the first offering of the course, the student response was quite positive. Despite an 8:00 time period and a course restricted to second-semester seniors, fifteen students

enrolled, filling the course. The students were engaged by the wide variety of topics introduced and were particularly interested in the case histories. A survey, identical to that which was distributed on the first day of class, was also administered at the end of the class to gauge the effect that the course had on engineering failure awareness. The results indicated that the students were significantly more aware of engineering failures, even those not specifically addressed during the course. It is also noteworthy that two of the fifteen students are currently employed by one of the firms volunteering as guest speakers. Both students continued their education in a graduate program and are now employed in the building performance sector of the firm.

Several components were identified by both the students and instructor as particularly successful. The student case history research presentations were the most highly ranked component by the students. They enjoyed discovering the details of each case history and rather than passively absorbing the material. The inclusion of a physical model or animation component was also identified as a particularly effective tool in understanding the failure mode. In addition to the goal of educating the students about engineering failures and the lessons to be learned from each case history, the students were excited about the vast improvement in their presentation skills. After graduation, several students emailed back about positive feedback they had received from their employers about their presentation skills that they attributed to this course.

The second most highly ranked component of the course was the presentations made by industry professionals. As expected, the speakers were able to bring a different perspective and personal experience to a variety of topics. The guest speakers also elaborated on the industry and offered advice for those interested in entering the field of forensic engineering. Other highlights of the course noted by the students was the inclusion of Engineering Disaster videos to complement and illustrate case histories and the fortuitously timed field trip to watch the controlled demolition of a local smoke stack tower.

The development and delivery of this course for the first time was not without a fair number of challenges and frustrations. One of the main challenges for the course was the organization. The broad scope of the field and struggling to incorporate topics of interest for the diverse student population impacted the organization as it seemed to jump from topic to topic without consistently smooth transitions. The students perceived the difficulty in achieving an effective organization of the course and identified this as one of the weakest points of the course. This difficulty was compounded with the challenge of the timely scheduling of guest speakers to relate to recent topics. This struggle is not limited to this course and has been experienced by other instructors organizing and scheduling guest speakers.

A related challenge was the availability of industry professional able to travel to central Pennsylvania to offer a presentation. Unfortunately, the rural nature of Bucknell's location is unfavorable for effective participation of practitioners.

As the instructor, the most significant difficulty experienced was the level of supporting information necessary to bring undergraduate students to a level where a failure could be understood and discussed. Civil engineering students are rarely exposed to important details of construction, such as flashing location, material selection, joints, etc., through coursework. For example, a discussion of water infiltration in cavity wall construction or façade preservation requires a working knowledge of these subjects. It was difficult to foresee when additional material was required and to effectively prepare and plan accordingly. For the first offering of the course, this required a significant amount of time and probably factored into review comments that the organization of the course could be improved.

Summary

As expected for the development of a new course, several challenges were encountered in both the planning and delivery of the course. These difficulties, along with several successful components of the course, have focused the strategy for improving the course before its next offering. The author has begun to narrow the scope of the course to improve its organization and continues to gather additional case histories to expand upon this successful component. Support from practicing professionals continues to be garnered. Because it is likely to be several years before the course is offered again, the author endeavors to improve and expand the incorporation of short engineering failure case studies in core civil engineering undergraduate courses to raise the awareness and interest of forensic engineering as a potential career path. Case studies have been incorporated into the other courses taught by the author including Statics, Mechanics of Materials, and Design of Concrete Structures and the instructional activities are being shared with colleagues throughout the College of Engineering. The development and initial delivery of this course in engineering failures has not only enhanced the educational experience of the students enrolled in the course, but has also initiated an increased awareness and motivation for a broader integration of failures and the lessons learned into the civil engineering curriculum.

ABSTRACT

To this day, the 1981 skywalk collapse in the Kansas City Hyatt Regency resulted in the worst loss of life from a structural engineering mistake in United States history. While many important engineering lessons can be drawn from this disaster, it is just as important to recognize the broader lessons learned in the design and construction process as a whole that can be successfully brought into the classroom. Numerous organizations have undertaken the task of envisioning how engineering education can meet the demands of the future. ABET's baccalaureate degree accreditation criteria, ASCE's Body of Knowledge and Body of Knowledge 2 as well as the National Academy of Engineering have documented the need to change engineering education from its historical focus on technical content knowledge to include greater emphasis on professional issues and to integrate engineering practice into education. To this end teaching methods such as project based learning, active learning and the use of case studies are being explored to address these broader learning outcomes while actively engaging students. Because of the attraction students have in extraordinary events, the Hyatt disaster provides an ideal backdrop to introduce many of the professional issues needed to broaden the undergraduates' learning experience. This paper discusses the use of the Hyatt Regency skywalk collapse in design coursework with specific application to third and fourth year civil and architectural engineering student learning. Besides the traditional concepts of load flow analysis and member design, broader concepts relating to professional roles and responsibilities, design team interplay, the design process, the construction process and professional practice ethics are emphasized.

INTRODUCTION

Today's engineering graduates face a world more complex than ever before. Their engineering profession is being challenged by both technical complexities and societal complexities. Historically, engineering education has primarily focused on technical content to provide a strong theoretical foundation for future practicing engineers. Learning to *apply* their technical knowledge as well as *experiencing* the professional and societal issues was relegated to their early years of employment under the guidance of a mentor or watchful supervisor.

In a similar fashion, other professionals in the construction industry had apprentice and journeymen approaches to teach the broader professional issues on the job. However, in today's fast-paced society, with increasing job complexity and competing priorities for limited time, there has been less fostering within the engineering profession and more relying upon skills acquired during college education. The expectation has become that engineering graduates must be well prepared to meet the new challenges of not only heightened technical complexity but also escalating professional complexity.

As engineering students begin their career path, they are facing challenges of competing and conflicting demands. Exciting and dramatic projects must be economically feasible; durable materials must be sustainable, and more daring structures must be at the same time safer. Under this backdrop, the engineering office is often expected to meet unrealistic deadlines, for lower fees, while maintaining a high level of quality control to ensure human safety, health, and welfare. These professional and technical challenges require engineering students to be adept in interdisciplinary and teamwork skills, have refined communication skills, appreciate responsibility and accountability, and embark on lifelong learning. It has been well established that the education of the future engineer must incorporate these professional issues in the classroom as well as into the early years of employment to face these challenges (ASCE Body of Knowledge Committee, 2008).

The Kansas City Hyatt Regency skywalk collapse has at its heart non-technical issues of communication, interdisciplinary teamwork, and ethical challenges; and provides an excellent tool as a case study to engage students while teaching these boarder professional issues. This paper is not meant to educate the reader of the events that led up to and followed the disaster; but instead demonstrate the usefulness of this using this tragedy as a platform to engage engineering students and introduce broad professional issues into the classroom.

LEARNING OBJECTIVES

It is now widely accepted that the incorporation of both technical and professional issues is necessary in an undergraduate engineering education. The National Academy of Engineering (2005) and ABET's accreditation criteria (ABET, 2010) emphasize this objective, yet the need for integrating professional issues into the classroom is clearest in the ASCE's report *Civil Engineering Body of Knowledge for the 21st Century: Preparing the Civil Engineer for the Future* (ASCE Body of Knowledge Committee, 2008).

The objective of ASCE's Body of Knowledge report is to provide a guide to reform education and pre-licensure experience to shape the civil engineer of the future. The vision of the civil engineer in year 2025 is seen as being quite different from the past due to society's dramatic globalization with the complexities of sustainability demands, risk management, and the larger number of interested parties in a particular project. ASCE's Body of Knowledge report identifies the knowledge, skills and

attitudes necessary to enter the practice of civil engineering at the professional level, through education and early experience. It is ASCE's hope that engineering curricula and pre-licensing experience will change over time towards this model. And indeed, ABET education accreditation and National Council of Examiners for Engineering and Surveying (NCEES) engineering licensing criteria are working together with ASCE's Body of Knowledge for an integrated process towards licensing.

ASCE's Body of Knowledge guidelines contain the traditional instructional objectives in foundational and technical outcomes. These basics broadly include work in math and sciences, experimentation and problem solving. What have been more difficult to incorporate in existing curricula are the nine professional issue outcomes identified. Figure 1 lists the desired professional outcomes and their respective level of achievement to be reached upon completing an *undergraduate* education in civil engineering (on a scale of 6). In the ASCE's outcomes rubric it is interesting to note that none of the professional outcomes are assigned to the master's degree education process. The master's degree is recommended to focus exclusively on technical experimentation, problem solving and area specialization.

Level	*Professional Outcome*
4	Communication
2	Public Policy
2	Business and Public Administration
3	Globalization
3	Leadership
3	Teamwork
2	Attitudes
3	Lifelong Learning
4	Professional and Ethical Responsibility

Figure 1. ASCE's Body of Knowledge Professional Issue Outcomes at the Undergraduate Level

The level of outcome achievement is tied to the cognitive domain of Bloom's Taxonomy. The two highest professional issues on this cognitive achievement scale are Communication and Professional and Ethical Responsibility. While some educators may simply regard communications as being satisfied by their institution's general breadth requirements in speech or writing, the intent is far more extensive. Undergraduates are expected to understand communication issues *within* the professional practice, including graphic presentation, construction drawings, computer models, hand sketches, verbal instructions, technical and non-technical writing. Reinforcement of these professional issue outcomes are also addressed in ABET's *a-k* criteria for baccalaureate engineering degree programs. Criteria *f, g* and *h* specifically address: an understanding of professional and ethical responsibility, an ability to communicate effectively and the broad education necessary to understand the impact of engineering solutions in a global and societal context, respectively.

PROFESSIONAL ISSUES IN THE HYATT REGENCY COLLAPSE

The Kansas City Hyatt Regency skywalk collapse is a uniquely suited case study to engage and educate students in the more important professional outcomes desired by the Body of Knowledge. The two most significant professional issues identified by ASCE's Body of Knowledge are communications and professional ethics and responsibilities, both of which are spotlighted in the collapse.

The major issue at the heart of the Hyatt Regency disaster is the breakdown of communications (Banset, 1989). There was a failure for the structural engineer to clearly communicate his intent to the steel fabricator his role or responsibility in the design of the critical rod-to-beam connection. In addition, the failure of this connection was traced back to an inadequate design that was not properly communicated graphically in the construction documents or verbally in subsequent phone calls between the two disciplines.

The ambiguous communication between the structural engineer and the steel fabricator was identified in Missouri's Administrative Hearing as a major factor in the disaster (Deutsch, 1985). The Commission report states that the structural engineer "bears the burden of communicating his intent to the contractor and *assumes the risk* of confusion or noncommunication." The report also states, "…the burden and responsibility for clear communication lies with the engineer who assumes the risk of ambiguity in his design drawings."

In line with another learning outcome is the understanding of professional responsibility and its ethical implementation by the Hyatt's structural engineer. Despite making assurances to the owner and architect of doing so, the structural engineer never ran calculations on the flawed connection. In addition, the structural engineer and the steel fabricator did not properly coordinate their responsibilities in the connection design; and in their rush to complete the job, the critical shop drawings never got a proper review despite the engineer's review stamp. Valuable opportunities exist in such a teachable case study to highlight important professional issues in communications, professional responsibilities, professional ethics, and interdisciplinary teamwork.

TEACHING TECHNIQUES

Case studies lend themselves as a powerful tool for contextual learning of professional issues. These are real-life stories with characters, a setting, a plot with a struggle, and an outcome; and when presented in story form, students are immersed briefly into a chain of unfolding events with an underlying professional context. Weaving factual information into an emotional story has been shown to develop better comprehension and long-term memorization [Abrahamson, 1998; Haven, 2007]. In addition, a deeper emotional connection is made allowing the students to personally experience and internalize engineering judgment dilemmas and ethical decisions. This is very difficult to achieve in the classroom through any other method of instruction.

When case study events are presented in chronological order with a surprise ending, teaching tends to take an inductive approach rather than a traditional deductive style. Instead of first describing how mistakes were made along the way in the Hyatt disaster, an inductive approach reveals the disaster and then encourages the students to determine the cause by sifting through the facts. In general, the inductive approach first gives students the reason why they need to learn the material and then challenges them to make logical sense of a complex problem. This problem-solving skill is imperative to the success of life-long learning. The inductive approach to student learning is supported by the best research on learning currently available (Prince, 2006).

Another powerful teaching technique well-suited for the Hyatt Regency case study is the use of project-based active learning strategies. This is a dynamic approach to teaching with a high level of student engagement and participation. Research indicates that students are more likely to retain the knowledge gained through this approach than through traditional lecture-centered or textbook-centered learning. In addition, students develop confidence and self-direction as they move through both team-based and independent work. There are various approaches to implementing active learning strategies in conjunction with inductive learning and storytelling, and a few approaches considered by the authors will now be discussed.

HYATT REGENCY COLLAPSE CASE STUDY APPROACHES

Various approaches are available to introduce case studies to students. One author's approach to introducing the Hyatt Regency case study lesson involves only one or two days of class time. The students are first introduced to a "hypothetical" hotel project as an in-class exercise where the instructor challenges them to develop engineering ideas to span elevated walkways across a 120-ft wide atrium space. Students break into small groups and develop schematic design solutions for two stacked, visually floating, walkways across the atrium space. During the exercise, the instructor plays the role of the architect guiding and challenging students to make the walkways thin and visually floating. This is an excellent time to provide an overview of the entire design process from the developer's original concept to the completed construction drawings as the students experience a portion of this process. Additionally, the professional roles and responsibilities of the developer, architect and structural engineer are discussed in this context.

At the conclusion of the groups' schematic design exercise, the instructor compares and contrasts the different approaches developed. While some design solution differences may simply be a matter of different perspectives, other differences could be attributed to intentionally ambiguous communications from the instructor. An important lesson in clear communications and the pitfalls of inappropriate assumptions can be taught here, foreshadowing later parts of the case study.

It is at this point that the instructor explains that this exercise is actually based on a real design problem, and then unveils the *as-designed* solution with three pairs of continuous suspended rods supporting both stacked walkways. Once it is revealed that this is a real project, the instructor can engage the students further using the

actual setting and participants' names to begin to tell the story. The as-designed solution is discussed in general and contrasted with the student designs, and it is of some benefit to encourage the students to mentally adopt the as-design solution as reasonably appropriate.

Using the power of storytelling the instructor can slowly unveil the story with plot twists and emotional surprises providing drama, but importantly allowing the instructor to control the student's experience and to introduce key points in communication failures, ethical dilemmas, professional roles and responsibilities. The revelation that the adopted design detail led to 114 deaths provides an emotional attachment as the students search for causes. The process provides students with a self-motivated inductive learning approach.

Similar to an actual investigation, the instructor slowly reveals more information being learned of the collapse. Using an important active learning approach, students are periodically polled with a show of hands or electronic clickers to observe opinion shift as to perceived fault. Using the following hypothetical series of discoveries, the instructor gradually introduces many professional issues while students critically think of responsibilities and ethical challenges:

> *Investigation discovery #1:* The hanger rods pulled through the inadequately designed box beam flanges.
> *Teachable moment:* Basic technical design concepts may be introduced. Graphic communication methods of drawings and details are introduced.
> *Students' general opinion:* The structural engineer is at fault.
>
> *Investigation discovery #2:* The steel fabricator revised the single continuous rod design to a design using two separate rods, thus doubling the load on the failed box beam connection.
> *Teachable moment:* The roles and responsibilities of the engineer and fabricator are compared and contrasted.
> *Students' general opinion:* Fault has shifted towards the steel fabricator.
>
> *Investigation discovery #3:* The steel fabricator explains that the single rod design is impractical to build, as it requires a fully threaded rod design and mid-length nut assembly.
> *Teachable moment:* The issue of constructability is introduced and whose responsibility it is.
> *Students' general opinion:* Class split between the engineer and fabricator as to fault.
>
> *Investigation discovery #4:* The steel fabricator's shop drawings indicate the revised connection was communicated to the engineer who reviewed it and stamped his approval.
> *Teachable moment:* Introduction of the purpose of steel shop drawings, with roles and responsibilities of the involved disciplines.

Students' general opinion: Fault has shifted back to the structural engineer.

Investigation discovery #5: The engineer says he doesn't "approve" shop drawings but only provides a cursory review as indicated on the stamp.
Teachable moment: Ambiguous communications of responsibility and expectations are a major factor in this disaster. Additionally, the introduction of fast-track projects and this delivery mode's rushed nature are discussed.
Students' general opinion: Class becomes split as to fault assignment.

Investigation discovery #6: The steel fabricator's detailer and the architect testify that they had undocumented phone calls with the engineer regarding the connection revision, and that they were assured by the engineer that it was safe. Engineer admits to some of the phone calls, but denies assuming responsibility for the connection.
Teachable moment: Communications need to be clear and documented to avoid ambiguity and accountability.
Students' general opinion: Fault shifts more towards the engineer again.

Investigation discovery #7: During construction, a 2700 square foot portion of the atrium collapsed due to a poor connection, alarming the owner. The engineer assured the owner that every atrium detail would be checked for safety. Despite being compensated for checking the atrium again and writing a letter to the architect assuring safety of the suspended walkways, a review commission determined that engineering calculations of the box-beam and connection were never made.
Teachable moment: Ethical behavior serves an important purpose.
Students' general opinion: The engineer is at fault.

Additional hypothetical scenarios for discussion:

What if the steel fabricator dumped over 500 pages of shop drawings on the engineer for immediate review?

What if it was standard practice for the steel fabricator to complete the design of typical connections?

What if the engineer strongly suggested to the architect it would be safer to support the walkways with columns instead of suspended rods?

As this case study is presented with unfolding drama, students are immersed into different situations that challenge their perceptions and attitudes. This experiential approach can instill professional ethics very successfully, and gives the students the practice of making difficult judgments before beginning their careers. With both intellectual and emotional engagement, students are in a valuable learning environment to introduce ASCE's and NSPE's Code of Ethics and to introduce other

professional learning outcomes in communications, interdisciplinary teamwork, roles and responsibilities, and leadership.

Student response to the introduction of case studies has been overwhelmingly positive. During the exercises and discussions, student engagement is very apparent with insightful questions and full attention throughout the classroom.

Another instructor takes a different approach using the Hyatt walkway collapse within a professional issues module that is a part of a broad quarter-long design problem. The objectives of the module are to discuss an engineer's professional responsibilities and the relationship of these responsibilities to society; to discuss various engineering ethics codes; to identify the need for an ethics code; to emphasize the importance of communication – both written and verbal; and, within a setting – the Hyatt walkway collapse – identify ethical concerns, describe what action should be taken and discuss the ethical basis for these actions. The case works well within the context of a design project wherein the students are progressing from conceptual design through final design and developing a calculation package and set of construction documents. The lessons require limited class time but make use of asynchronous discussions conducted through a website.

The instructor begins the module by conducting an assessment of the students' understanding of what distinguishes engineering as a profession, what is an engineer's responsibility and to whom is an engineer responsible; and what if any is the distinction between professional ethics and personal ethics? The instructor then begins a discussion of the assessment topics along with an introduction to the steps to licensure as a professional engineer and structural engineer, the latter of which always elicits much student inquiry. The responsibility of engineers to the society as well as the public trust placed in the profession to establish standards of conduct and to enforce those standards highlights the importance of professional ethical tenets beyond personal opinions. The ASCE and NSPE codes of ethics are introduced along with some history of their development. A brief PowerPoint presentation is used to open the story of the Hyatt Regency design and construction – a project much larger but similar to the one they are undertaking. The context of practice in the 1980s is presented; the roles of individuals are described. The story is set in motion. The walkway collapse is not yet discussed.

The students are then divided into four teams; each team is assigned four technical papers (Gillum, 2000; Luth, 2000; Moncarz, 2000; Pfatteicher, 2000) for reading and discussion within their teams. Each team is given a list of questions for discussion on the technical / human / organizational / socio-cultural aspects of the case. Sample questions from each of these four areas follow:

> *Technical:* Describe the features of the critical detail that failed in the walkway collapse.
> *Human factors:* As an entry level engineer what steps will you take when new situations arise in a design project that you have not faced before? How

will you convey your knowledge and understanding and what you don't yet understand?
Organizational: What is the responsibility of the Engineer of record?
Socio-cultural: What do you believe should be the responsibility of building departments for projects such as the Hyatt Regency Hotel? How can building departments provide the level of review appropriate for such a project?

The students are also required to submit a question that they think should be answered regarding each aspect of the case.

Over a period of approximately two weeks the students answer the questions and undertake an asynchronous discussion with one another in the four areas via an electronic discussion board. During this period they are engaged in the structural detailing of a multi-story building in the classroom. The final task of the assignment is to compile a summary presentation of the team's perspective of what can be learned from these events. A post assessment on professional ethics follows sometime later in the term.

Student responses in the asynchronous discussion for each aspect of the case are evaluated based on their depth of inquiry and reflection of the reading. A team score is assigned. Some responses provided by students to posed questions include:

"[in new modes of delivery and contractual arrangements] early delineation of responsibilities should stimulate cooperation and communication."

"One thing that [is mentioned] that I have not considered is being open to everyone and letting them know that you are not completely familiar with the problem, this can help with avoiding any mishaps and it also reaffirms the team aspect of a project."

"…this situation shows that more structured communication between parties was necessary to avoid problems."

Suggested questions by students include:

"How can the lack of communication and ineffective collaboration between the design and construction professionals that characterized this project be prevented in the future?"

"…about having an onsite engineer…what should an onsite engineer be looking for and checking during construction?"

The concluding student PowerPoint presentation and final professional engineering ethics quiz administered following the case study module indicate that students develop a keen awareness of the responsibilities embodied in engineering practice. Future assessments will include a student survey evaluating the contribution of case

studies to both technical and ethics learning. The survey was developed by faculty at Cleveland State University for evaluating individual course learning with respect to ABET's *a-k* criteria as well as the impact of case studies, along with other course elements, in contributing to student interest in the course material.

OTHER APPROACHES

The two presented approaches are those most familiar to the authors. A myriad of other approaches are possible to achieve the similar learning objectives. The use of active learning strategies enhances student engagement and material retention, and should be strongly considered. Another such approach with strong potential is to have each student assume the role of a Kansas City Star newspaper reporter and write an article with the intended audience being the general public. This exercise challenges students to research complex events and then disseminate them into basic concepts and translate technical terminology into lay terms. Student then exchange the proposed articles with each other and then take on the role of newspaper editor for a peer review. To enhance the active learning and engagement, the articles are formatted similar to newspaper with multiple column formatting, headline, photograph, several figures, and notable quotes. With a restrictive word count it will be impossible for students to have a comprehensive discussion; thus students are challenged to prioritize the relevant information from the public's perspective, and to be as succinct as possible.

A similar role playing approach places the students into the uncomfortable position of representing Hyatt Hotels. In this exercise, students assume the role of Hyatt's public relations officer who must write a letter to the disaster survivors explaining what was determined to be the cause of the collapse. This style of letter will be quite different than a newspaper article in its demeanor. The use of analogies is strongly encouraged to help relate the mechanics of the collapse with everyday concepts the intended audience is familiar with. Another important aspect of this exercise is students' selection of language and disposition when communicating with survivors who are still healing physically and mentally from their experience. Students are challenged to be transparent and open, yet to experience the underlying fear of a disgraced corporate image and potential liability. These are real professional conflicts that occur in an engineering office, and the ethical implications of different courses of action can be discussed.

Another approach which has been shown to be very successful is the implementation of a mock trial or public inquiry (Jennings, 2000). Students form teams to research the disaster, form opinions, and then support or even argue their findings to the rest of the class. This student-based learning approach encourages students to be inquisitive about the roles, responsibilities, and priorities of the engineering profession. In addition, student-based learning as opposed to teacher-imparted learning fosters student self-discovery, an important trait for lifelong learning. These outcomes are core professional issues desired by ASCE's Body of Knowledge and ABET. An additional benefit of this approach is that student-based learning has less

reliance on the instructor's practical experience, thus making this case study approach more acceptable to the entire faculty. Detailed descriptions of the events from various perspectives are widely available for students to draw upon, especially five articles published in the Journal of Performance of Constructed Facilities (Gillum, 2000; Luth, 2000; Moncarz, 2000; Pfatteicher, 2000; Rubin, 1987).

Using approaches that involve teamwork, communications within a group, communications to lay people, and self-directed discovery creates an experiential learning environment that is similar to the engineer's practice environment. These approaches not only allow students to experience some of the professional issues in a design office, but also allow students to possibly connect with how these professional issues affected the initiation of the Hyatt Regency disaster.

CONCLUSION

Traditional classroom assignments involve a hypothetical situation with a single solution or obvious best answer. The engineering profession is far more complex with competing priorities, numerous uncertainties, and several feasible solutions, all subjected to various human factors such as communication, risk adversity, and our ability to work with others constructively. The vision of the future engineer has embraced the need to educate towards these professional issues for the benefit of the profession and society.

Using case studies, active learning techniques, and student-based approaches are powerful tools educators use to engage students and introduce professional issues. The Hyatt Regency skywalk collapse is well suited to assist educators towards the outcomes desired for the future engineer. Whether the instructor has practitioner experience or is more comfortable in academia, different approaches are available to match the instructor's level of involvement and past experiences.

It is especially rewarding as instructors to witness increased levels of student engagement and excitement while students learn an important chapter of our profession's past and interlacing the more mundane professional issues into the subject matter. Others are encouraged to find other significant events and engaging teaching approaches to reach the same outcomes.

Abstract

Reasons for including failure case studies within the undergraduate engineering curriculum have been made by various authors. Specific cases have been integrated into the syllabi of engineering mechanics, structural analysis, and structural design courses. The case studies used are typically catastrophic structural failures, where failure can be defined as a structural collapse, often with significant loss of life.

Many civil engineering undergraduate programs include a course in construction planning and management. The American Society of Civil Engineers (ASCE) Civil Engineering Body of Knowledge (BOK) for the 21th Century, Second Edition emphasizes a need for Civil Engineers to understand not only the technical areas of analysis and design, but also more of the project management issues that enable a project to go from design to fruition. Hence, it is likely that more programs will include construction management courses.

This paper deals with the integration of failure case studies into a construction planning and estimating course. In addition to structural failures, this course looks at the definition of "failure" from an engineering/construction perspective. It explains that failure includes the inability of an engineered facility to perform as designed. It further opines that failure to be constructed within reasonable time and budgetary constraints falls within the definition of failure. While most students may have the pre-conceived notion that failures are only caused by design deficiencies and perhaps natural hazards, the examples used in this course emphasize how many failures are caused by deficiencies in the design and/or construction process itself.

In addition to the use of more typical and catastrophic failure case studies, such as the Hyatt Regency Walkway Collapse (Kansas City, Missouri), and the L'Ambiance Plaza Collapse (Bridgeport, Connecticut), the course makes extensive use of the Montreal Olympic Facility design and construction to demonstrate how deficiencies in the design and construction process can lead to extreme constructability issues and exorbitant cost overruns.

The author also shows how the inclusion of the case studies addresses some of the more difficult areas to address in the Accreditation Board for Engineering and Technology (ABET) evaluation criteria, such as the understanding of the impact of civil and environmental engineering solutions in a global and social context.

Introduction

Reasons for including failure case studies within the undergraduate engineering curriculum have been made by various authors (Baer 1996; Carper 2000, Carpet et al 2008; Delatte 1997; Delatte 2000; Delatte and Rens 2002, Jennings and Mackinnon 2000; Pietroforte 1998; Rendon-Herrero 1993a). Barriers to using failure case studies in civil engineering courses were identified (Rendon-Herrero 1993a) as a lack of readily available case study information and an already overcrowded undergraduate curriculum built around ABET requirements (Rendon-Herrero 1993a). Although stand alone courses which deal with forensic engineering have also been developed (Bosela 1993) most are either senior elective or graduate level courses. One of the major factors identified is offering such courses as required undergraduate courses is the constraints already placed on the undergraduate program by the Accreditation Board for Engineering and Technology (ABET) and other general university requirements. Since that time, engineering failures and forensic engineering have received considerable attention, via publications such as the ASCE Journal of Performance of Constructed Facilities, and ASCE Forensic Congresses with published proceedings (Rens 1997; Rens et al 2000c; Bosela et al 2003; Bosela and Delatte 2006; Chen et al 2009). Case materials have been developed (Delatte et al 2007; Delatte et al 2008a,b; Delatte et al 2010) case study websites (Delatte et al 2008b; Delatte et al 2010; Parfitt 2010; Rens et al 2000a,b,c), text books (Delatte 2010; Shepherd and Frost 1995), and failure vignettes (Zickle 2000) etc., to enable faculty members to more easily include failure case studies in their undergraduate courses. Workshops have been held to assist faculty members in incorporating lessons learned from failure case studies into their courses (Delatte et al 2007). Typically, specific cases have been integrated into the syllabi of engineering mechanics, structural analysis, structural design, and geotechnical engineering courses (Delatte et al 2010). The case studies used generally fall into the classification of "engineering disasters", such as catastrophic structural failures, where such failure may result in a significant loss of life. In some cases, students have worked on an existing failure case as part of a class project (Rendon-Herrero 1993b; Sutterer 2003).

Many civil engineering undergraduate programs include a course in construction planning and management. The American Society of Civil Engineers (ASCE) Body of Knowledge (BOK) 2nd Edition (2008) emphasizes a need for Civil Engineers to understand not only the technical areas of analysis and design, but also more of the construction and project management issues (BOK Outcome 13) that enable a project to go from design to fruition. Hence, it is likely that more civil engineering programs will include construction management courses in their curricula.

Cleveland State University offers an ABET accredited undergraduate program in Civil Engineering, which includes the course CVE 403 Construction Planning & Principles of Estimating. It is a required three semester credit hour course, offered during the final semester of the senior year. The basic course objectives are as follows:

- basic understanding of construction procedures, equipment and details
- understand the roles and responsibilities of design and construction professional, and how they interact to construct a project
- show how probable cost of construction projects can be estimated

- show how he/she can best use systematic construction tools for improving project estimates, management procedures, & early identification of potential problems
- show how to use a detailed project schedule for project control
- provide an understanding of legal and professional practice issues related to the construction industry
- use lessons learned from failures to illustrate various professional practice issues, such as design responsibilities, importance of licensure & lifelong learning, etc.

In addition, ABET and the ASCE Body of Knowledge (BOK) include additional broader outcomes, such as

- *understand the principles of ethical behavior & society-serving role of practicing engineers* (BOK Outcome 24)
- *are motivated to continue their professional growth through graduate education and/or professional development* (BOK Outcome 23)
- *contemporary issues and historical perspectives* (BOK Outcome 11)

Over a period of time, the author modified what had been a traditional, broad-based construction management course, integrating lessons learned from failures throughout the course.

Although this course does use some case studies of structural failures, such as the Hyatt Regency Walkway, Kansas City, Missouri, Collapse, and the L'Ambiance Plaza, Hartford, Connecticut Collapse during construction, it also looks at the definition of "failure" from an engineering/construction perspective. It explains that failure includes the inability of an engineered facility to perform as designed. It further explains how failure to be constructed within reasonable time and budgetary constraints falls within the definition of failure. While most students may have the pre-conceived notion that failures are only caused by design deficiencies and perhaps natural hazards, the examples used in this course emphasize how many failures are caused by deficiencies in the design and/or construction process itself. This course makes extensive use of the Montreal Olympic Facility design and construction to demonstrate how deficiencies in the design and construction process can lead to extreme constructability problems and exorbitant cost overruns. An overview of the Montreal Olympic Case Study is presented at the very beginning of the course, and it is re-visited many times when specific management and estimating functions are later being discussed.

Montreal Olympic Complex

The Montreal Olympic complex consisted of a main stadium, velodrome, roads, walkways, practice fields, an Olympic Village housing facility, and other structures and landscaping, which were constructed for the 1976 Summer Olympics, held in Montreal, Quebec, Canada, commencing on July 4, 1976. It was nicknamed the "Big O", due to its name and the shape of the stadium, but it later became known as "The Big Owe" and "The Big Woe" (CBC 1999; CBC News 2006). Planning began in 1970, and preliminary estimates prepared at that time indicated a projected cost for the entire complex of $836 million dollars, including a projected cost for the main stadium of $40 million dollars. The final costs in 1976 were $1.5 billion dollars, with $120 million for the main stadium. In addition to the cost overruns, there were considerable time overruns, which meant that the complex was almost not completed in

time for the Olympics, and some of the final activities were still on-going at the time the Olympics started, and major components originally planned such as the retractable roof were not begun until after the Olympics (Neil 1979).

The original "owner" was the City of Montreal, Quebec, who contracted with architect Roger Taillibert to design the Olympic Park, including the Olympic Stadium and velodrome (Auf der Maur 1976). Mr. Taillibert lived and conducted business in Paris, France. Both the velodrome and Olympic stadium were relatively unusual, unique artistic creations. The Velodrome was comprised of three arches supported by abutments. It was designed to have the appearance of a cycling helmet. The Olympic Stadium was another ultramodern design which resembled an elliptical sea shell with a handle. The original design also included a retractable fabric roof, which was subsequently deleted for cost savings.

The contract for the Velodrome construction was awarded to Prime Contractor Charles Drunceau with a $12 million bid, based on half complete plans, and construction began in 1973. The City of Montreal had also promised to host the 1974 World Cycling Championship in the Velodrome, resulting in a very tight and unrealistic critical path. Soil problems due to low bearing capacity and the high loads on the abutments resulted in substantial time delays and cost overruns for the foundation work. A new foreign project engineer was hired and a new critical path schedule was developed. Due to the time constraints, most of the construction contracts were cost plus, rather than low bid fixed cost contracts. There were also a number of labor problems, such as tasks taking too long, strikes, overtime, and extra equipment, which themselves added about $12 million to the project cost. The deadline could not be met, and a temporary facility had to be constructed for the World Cycling Championships. The final cost for the 7,000 seat Velodrome was approximately $70 million, compared to a $60 million cost for a 60,000 seat domed stadium in Seattle, Washington, USA at the same time.

The Olympic Stadium design was extremely complex. The structure consisted of epoxy connected precast post-tensioned concrete ribs, which were connected to a hollow ring at the top. No more than two ribs were identical. This construction procedure (epoxy-glued, post-tensioned structural members) had been used in Europe, but not in North America. It was extremely difficult to align the ribs to perform the post-tensioning and make the connections. Scaffold could not be used, since it would restrict access. Hence numerous cranes had to be used to secure each rib. There was a slow and expensive learning curve for the contractor to become even somewhat proficient. All of which greatly extended the construction time, pushing much of the post-tensioning to the winter months, when water freezing in the post-tensioning tubes further increased the construction difficulty. The final cost for the Stadium was approximately $13,000 per seat, compared to approximately $2,400 per seat for the Superdome in New Orleans, Louisiana, USA constructed at approximately the same time.

The Main Road Viaduct also had a relatively high construction cost due to its design. Although the main road was straight, the Viaduct had a complex design, with curved faces and outstretched legs. The curved surfaces resulted in the in-ability to use standard, re-usable formwork. Whereas convention formwork would have cost approximately $27 per square foot,

the formwork cost for the Viaduct was approximately $400 per square foot. Hence, the final cost of the Viaduct was approximately $14 million, versus a projected cost of only $5 million if a conventional design would have been used.

During the construction of the Olympic Complex the cost and time overruns were spiraling out of control, and it became apparent that the City of Montreal was unable to complete the project, which would have been an embarrassment to not only the city, but to Canada. Hence, the Province of Quebec took over and completed the project. Labor problems remained rampant, as the fixed deadline and absence of no-strike agreements created an atmosphere of labor strikes, slowdowns, and sabotage. Eventually the Province of Quebec issued the ultimatum that either the construction workers get on with the work or the project would be cancelled, and the Olympic games would need to be held elsewhere. Following the ultimatum, productivity did increase, and the project was eventually completed.

The Montreal Olympic Village also experienced considerable problems and irregularities. Originally it was to provide low-cost housing units after the Olympics, and the federal government was going to provide 95 % of the clearance cost and 75 % of the construction cost. The deadline for bids for a developer was March 1, 1974, but in January of 1974 Joseph Zappia visited France and claimed to be the developer. At the bid deadline, none of the 53 bidders heard anything, and Joseph Zappia was chosen behind the scene. The developer went to French architect Andre Manangoy because he liked his design of condos at Bai des Anges, France. The design was ill-suited for Montreal's cold winters, and the Federal government chose not to provide the funding due to the elaborate design which was not comparable to low-cost housing. Zarolega received a generous cost-plus contract without a "not-to-exceed" clause. The "plus" was 12 % on the first $30 million, and 6 % on anything above. Zarolega estimated that the project would not exceed $45 million. Concerns about the potential cost led to the government committee hiring of a consultant for a second opinion. He predicted a project cost of $55-$58 million, with a possible $10 million overtime bill. Despite the second opinion, they went with the Zarolega estimate. A number of problems occurred during the construction, including outrageous sub-contracts, dangerous construction techniques, poor coordination, and theft. A new consultant was brought in to manage the construction. The actual cost for the Olympic Village was approximately $70 million.

There are a number of technical, procedural, and ethical issues that contributed to the problems experienced by the Montreal Olympics project (Neil 1979) including the following:

Extreme Time Constraints

There was an unrealistic deadline for the project. An additional two years would have been much more reasonable for the design and construction. The City of Montreal was so late with design documents that most work packages could not be bid. Instead, most of the contracts were negotiated.

Unrealistic Project Schedule

Project scheduling was forced to fit extremely tight deadlines. Hence the critical paths were much too optimistic, and did not allow for any normal problems which occur in all construction projects. The critical paths included a multitude of simultaneous activities, without considering

their negative impact on the productivity of each. Hence, almost everything took much longer because of the conflicts. A proper construction schedule is based upon normal crews and construction activity durations, so that individual activities on a critical path can be intelligently expedited, or "crashed", to prudently compensate for project delays while minimizing increased costs. The unrealistic nature of the schedules made it impossible to intelligently crash selected activities. The schedules were abandoned and everything became a daily crash.

Unusual design, one-of-a-kind components

As mentioned previously, it was extremely difficult and labor intensive to construct the stadium with the pre-cast, post-tensioned, epoxy connected ribs of varying sizes. The required use of one-of-a-kind, single-use formwork for the curved surfaces of the viaduct also resulted in increased costs.

Crowded Work Space

The time constraints and schedule compression resulted in even more simultaneous activities, and an extremely crowed work space. At one point, there were 80 different cranes trying to operate in the stadium. This resulted in cranes waiting for other cranes to finish their lifts, and crews standing around waiting for their turn. Doubling of the amount of cranes used on the job substantially increased the equipment cost, but only increased the productivity 25 %.

Shortage of Resources

Due to the size of the project, there was a shortage of local resources. Labor, material and equipment had to be brought in from other areas. This resulted in additional transportation costs. It also resulted in poorer quality labor, as well as non-local labor not having the same sense of "civic pride" as regular Montreal residents.

Organization and Relationship

The original client was the City of Montreal, which did not have the expertise and experience to manage a job of that magnitude. A change in client occurred when the Province of Quebec was forced to step in and assume that role. Although the change was necessary, additional difficulties, such as communication problems, typically occur when the major constituents change during a project.

In addition, the relationship of the design professionals hindered prompt communication. The design and engineering was done in France, and converted from metric to English units by Canadian engineers.

The client, architect, design engineers and project management did not function as a team. The architect was unwilling to consider value engineering ("Experts Slam the Olympic Structures of Montreal" 1976). He was primarily interested in the artistic value of his design, without consideration of any cost saving suggestions from the other parties, including the design engineers.

Weather

The weather contributed to the problems, particularly since weather protection and heating was needed, especially for the concrete work and installation of the post-tensioning tendons. The project delays pushed much of that work into the winter months.

Ethical Aspects

There were a number of ethical aspects brought out in this case, including the experience necessary for undertaking such a project, team goals and responsibilities, public safety (including the safety of workers when simultaneous work is being done in crowded conditions), as well as awarding of contracts (especially for the Olympic Village).

After the 1976 Olympics, the Olympic Stadium saga continued. The roof and tower are completed, but the retractable Kevlar roof failed (Wikipedia 2008), an "indestructible" Teflon roof also collapsed (CBC News 1999) and a fiberglass panel roof installed later suffered a partial collapse (Merron 2008).

Lessons Learned

In conclusion, the Montreal Olympics Complex is an excellent example of a failure, based upon the excessive cost overruns, attributable to the following:

- inadequate time available and improper project scheduling
- constructability issues
- organizational structure
- ethics

Based upon that experience, the following is a recipe for a construction cost/time failure:

1. Insufficient time
2. Unusual construction
3. Unrealistic critical path
4. Lack of experience/expertise
5. Lack of team approach (Every man for himself)
6. Constructibility issues
7. Shortage of resources
8. Poor organizational structure/communications
9. Lack of ethics (including lack of transparency of procedures)

Hyatt Regency Walkway

The Hyatt Regency Walkway Collapse is well known, and hence the details of the case will only have a cursory discussion in this paper. Suspended walkways supported by long threaded steel rods were used in a lobby/atrium of the hotel in Kansas City, Missouri, USA. The second floor walkways were suspended from the beams of the 4th floor walkways. The hotel had been completed the previous year, and on July 17, 1981, while between 1,500 and 2,000 people were attending a dance in the atrium, the walkways collapsed, killing 114 people (Carper

2001). The story most often told is that a blatant error was made in the design of the walkways, which resulted in them being extremely under-designed, causing the collapse. Detailed analysis of the structural system (Moncarz and Taylor 2000) showed that the connection was near failure at dead load only. However, the connection was never actually designed (Luth 2000). Hence, the failure should be classified as a process failure (Moncarz and Taylor 2000). In the classroom, our discussion goes beyond the inadequacy of the connection, and looks at the organization and procedural issues which led to the collapse, including the convoluted project delivery system, ethical issues (Pfatteicher 2000) and the roles and responsibilities of the engineer-of-record, steel fabricator and erector, particularly regarding the connection details, and whether those responsibilities can be contractually assigned to other parties. Detailed discussions of this case study are readily available in the literature (Delatte 2009), including a paper by the engineer-of-record (Gillum 2000).

L'AMBIANCE PLAZA – (1987)

This was a sixteen story apartment building in Bridgeport, Connecticut, USA, which was being constructed using the lift-slab method. when it suddenly collapsed, killing 28 construction workers. There were multiple theories on the cause of the collapse, including failures of the lifting mechanisms (shearhead collar deformation allowing a lifting rod to slip out (Scribner and Culver 1988, Culver 2002, McGuire 1992), rolling out of the wedges temporarily supporting the slabs (Cuoco et al 1992), foundation movement, improper design of floor slab post-tensioning tendons (Poston et al 1991), and general instability of the structure during construction (Moncarz et al 1992). These theories were never fully resolved due to a controversial mediated settlement of claims (Felsen, M. D. 1989). Details of this case study are available in the literature (Heger 1991; Martin and Delatte 2000).

This tragedy led to the development of guidelines for lift-slab construction , as well as perhaps the demise of lift-slab construction, which had an enviable safety record. It also illustrated how a convoluted project delivery system can make it unclear on who has the prime responsibility for structural safety. Students may understand the engineer-of-records responsibility for the completed structure, but they are typically unfamiliar with the lift-slab construction method and the engineer's responsibilities during construction. This is a particularly interesting case study for the students, as the engineer-of-record has supplied the author with his personal perspective (O'Kon 1993), including how he dealt with the tragedy and the controversial mediated settlement. It also graphically illustrates the relative instability of many structures during construction, lack of redundant load paths, and the need for temporary bracing. Following this tragedy, guidelines for lift-slab construction were developed (Zallen and Peraza 2003).

Assessment of Construction Planning and Estimating Course

An assessment of this course was done over a three year period, using survey forms and focus groups (Delatte et al 2008a,b; Delatte et al 2010). On a scale of 1-5, with 5 being strongly agree, the course received the following average scores:

Year	2007	2008
Understanding of professional and ethical responsibilities	4.75	4.88
Impact of engineering solutions in a global and societal context	3.75	4.38
Recognition of the need for, and an ability to engage in life-long learning	4.25	4.63
Knowledge of contemporary issues	4.0	4.0

Conclusion

Engineering failures are often the result of poor organization and process. This course effectively uses failure case studies, including failures as defined by extreme cost and time overruns, to address some of the required outcomes which are traditionally more difficult to quantify in most technical courses, particularly with respect to project management, professional and ethical responsibilities, and their impact.

ABSTRACT

Fully biodegradable composite materials fabricated using natural fiber reinforcements and biopolymeric matrices derived from poly(β-hydroxybutyrate) (PHB) and PHB-*co*-poly(β-hydroxyvalerate) (PHBV), are being investigated as potential alternatives to traditional residential construction materials. The materials are envisioned to be rapidly renewable by using biogas from their anaerobic biodegradation as the feedstock for microbial production of the biopolymer and using plant-based materials for composite reinforcement and fillers. These biobased composites are being engineered to satisfy acceptable stiffness, strength, ductility, and in-service durability performance criteria while maintaining the propensity for rapid out-of-service anaerobic biodegradation. In this paper a brief overview of research on material development, mechanical properties, and multiscale modeling, as well as moisture absorption and long-term durability of PHBV-wood fiber filled composites with and without fiber treatments is given. This research is an interdisciplinary collaboration between structural, environmental, and chemical engineers.

INTRODUCTION

Holistic characterizations of solid waste streams in the United States have attributed 40% (96 million tons) of all landfilled debris to building-related construction and demolition (C&D) activities (EPA 2008); typical residential construction materials, including wood, plastic, and drywall, constitute 45% (43.2 million tons) of landfilled C&D material waste (EPA 1998). Traditional residential construction materials seemingly possess a cradle-to-grave lifecycle and ostensibly lie recalcitrant in landfills, due to the predominantly idle rates of biodegradation.

Through the transformation of material lifecycles using a cradle-to-cradle design methodology which harnesses the power of naturally occurring bioprocesses, rapidly renewable, fully biodegradable composite materials fabricated using natural fibers as reinforcement in matrices derived from poly(β-hydroxybutyrate) (PHB), a

microbially synthesized biopolymer, and PHB-*co*-poly(β-hydroxyvalerate) (PHBV), a copolymer blend, are being investigated as potential alternatives to traditional residential construction materials in both structural and non-structural applications. As shown in Figure 1, the construction biomaterials are envisioned to be rapidly renewable by a) utilizing methane biogas captured from anaerobic degradation and biotransformation of the material as the carbon-based feedstock for microbial production of PHB and b) using plant-based materials for composite reinforcement.

Laboratory-scale research has investigated the mechanical characterization (Alvarez 2003, Luo 1999, Avella 2007), thermal stability (Li 2007), and water absorption behavior (Alvarez 2003, Alam 2006) of various natural fibers in matrices derived from starch, polyhydroxyalkanoates (PHB, PHBV), polylactides (PLA, PGA), soy-based resins, and other biorenewable resources. Potential applications of these materials range from automotive parts, interior trims and finishes, furniture, decking, fencing, and, of particular interest, both temporary and permanent building components (Humphreys 2003).

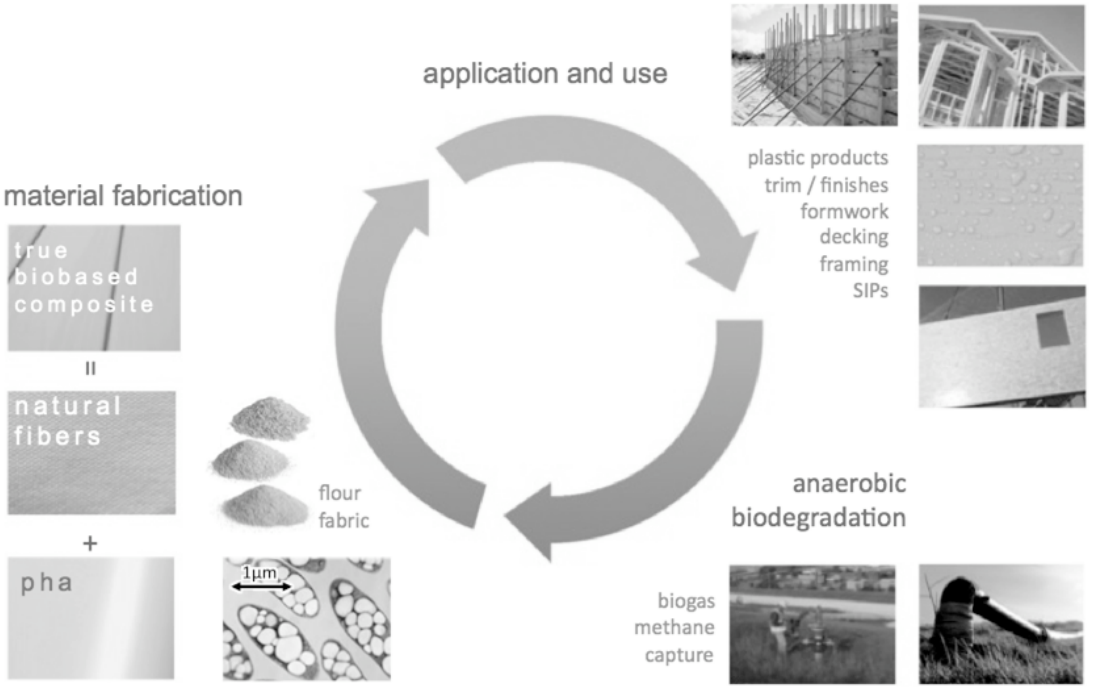

Figure 1. Envisioned closed-loop life-cycle for PHB-based composite materials

Material properties achieved by PHB-based composites are comparable to dimensional lumber (Christian 2009) and are being engineered to satisfy acceptable stiffness, strength, ductility, and in-service material durability performance criteria (low moisture absorption, thermal stability, UV resistance) while maintaining the propensity for rapid anaerobic biodegradation. To the authors' knowledge, no studies have comprehensively characterized a class of materials from a holistic composite systems engineering approach wherein the benefits of fiber reinforcements or fillers and interfacial modifications for increased in-service mechanical performance and durability are balanced with tradeoff effects of out-of-service biodegradation.

Material Durability. While biobased materials have demonstrated adequate initial mechanical properties for specific target applications, long-term durability concerns exist due to the inherent differences in morphology and chemical composition of natural fibers and PHB-based biopolymers. The hydrophilicity of the fibers, hydrophobicity of the matrix, and corresponding differences in surface energies of the two phases have been shown to decrease material stiffness and exacerbate water uptake in high humidity environments. Water absorption leads to fiber swelling, dimensional instability, matrix cracking, mass loss, susceptibility to fungal attack, and biodeterioration. To address fiber-matrix incompatibility concerns, various modification techniques have traditionally been employed to improve both the moisture resistance and mechanical performance of biobased composites.

For this preliminary study, engineered biobased composite specimens of PHBV and a reinforcing filler of natural, lignocellulosic oak wood flour (OWF) were fabricated using an extrusion-injection molding process. Degradation studies have shown that PHB-based polymers biodegrade more rapidly than other biopolymers (such as cellulose acetate and soybean oil-based resins) (Morse 2009); furthermore, it has been shown that the gaseous products of the anaerobic biodegradation of PHBV consist primarily of carbon dioxide and methane, the latter of which can be captured and used as a closed-loop carbon source for the production of new PHBV. OWF was selected as a lignocellulosic filler to: 1) utilize a waste material byproduct from commercial wood manufacturing and agricultural processes; 2) improve the mechanical stiffness of the matrix material; and 3) reduce the overall cost of the composite.

Mechanical and water absorption properties are being characterized as a function of wood fiber loading by volume percent. The effects of a silane coupling agent fiber treatment and a maleic anhydride matrix grafting technique are under investigation and are being correlated with the morphology of the altered fiber-matrix interface using scanning electron microscopy (SEM). Experimental results are being correlated with theoretical predictive models with consideration given to the phenomenological effects of the employed fiber-matrix interfacial compatibilization techniques. In addition, the effect of the modifications on both moisture absorption and anaerobic biodegradation are being studied. An overview of selected research results from this project is presented herein.

MATERIAL DEVELOPMENT AND METHODS

Materials. PHBV (ENMAT^{TM} Y1000P, Tianan Biological Materials Company, Zhejiang, China) was used as the matrix material and was measured to have a density of 1.21 g/cm^3. Prior to composite processing, the PHBV was dried in a 50°C oven for a minimum of 12 hours to remove moisture. OWF (2037-Oak, American Wood Fibers, Wisconsin, USA) was used as the natural fiber filler. Based on a sieve analysis and volumetric measurements, the OWF had a 20 mesh wood flour particle size <841μm and an apparent (bulk) density of 0.44 g/cm^3. Measurements using optical microscopy confirmed an average fiber aspect ratio (l/d) of 3.6. The OWF was preconditioned in an oven overnight at a temperature of 100°C prior to compound

extrusion. For the silanation and maleic anhydride reactive extrusion, trimethoxy-(octadecyl)silane ($C_{21}H_{46}O_3Si$), maleic anhydride (2.5-Furandione, $C_4H_2O_3$); dicumyl peroxide (bis(1-methyl-1-phenylethyl) peroxide, $C_{18}H_{22}O_2$), and phenolphthalein were obtained from Sigma-Aldrich.

Fiber-Matrix Compatibilization. The effects of a silane coupling agent and a maleic anhydride grafting technique were investigated for improving fiber-matrix compatibilization. For the silane treatment, a vapor deposition technique using foil-lined dessicators was employed to ensure silane was sufficiently chemisorbed onto the OWF particles. At the end of the thermochemical treatment, 1g samples of OWF were extracted from the bottom of the dessicator and tested with a drop of distilled water from a pipette to verify the hydrophobicity of the treated fibers. Maleic anhydride was grafted onto the PHBV polymer chains via a reactive extrusion technique using a Brabender Plasti-Corder single-screw extruder. A dry blend of PHBV pellets, maleic anhdride, and dicumyl peroxide (10% and 0.75% of PHBV by weight, respectively) was fed through the main hopper. The reactive extrusion was performed at a melt temperature of 160°C and an extruder screw speed of 20 rpm, which corresponded to a residence time of 150 seconds. The graft percentage of MA-grafted PHBV (mPHBV) in the extracted material was found to be 0.8% via an acid-base titration technique using phenolphthalein as an indicator.

Composite Processing. To investigate the effects of various fiber treatments, four families of PHBV/OWF composites were processed. These included pure PHBV/untreated OWF composites (P), pure PHBV/silanated OWF composites (PS), 1% mPHBV/untreated OWF composites (1M), and 2% mPHBV/untreated OWF composites (2M). The 1% mPHBV nomenclature indicates that 1% of the PHBV used in the composite was modified with maleic anhydride with the balance being unmodified PHBV. Each family of composite mixture formulations was reinforced with varying amounts of OWF. Target fiber loadings ranged from 0-40% in 10% increments by weight percent of filler.

Master batches of composite mixtures were fabricated by compound extrusion using an American Leistritz ZSE-18HP twin-screw extruder set at a processing temperature of 165°C and a main screw speed of 190 rpm. The extruded composite was fed from the die into a cooling water bath and immediately pelletized into uniformly sized pellets, using a Scheer Bay BT-25 pelletizer. Prior to injection molding, the compounded pellets were dried in an oven at 40°C for 12 hours. After oven-drying, ASTM standard specimens for testing of tensile (D638) mechanical properties as well as 3-mm-thick 50-mm-diameter disc specimens were prepared using an Arburg 320A injection-molding machine. Complete details on all materials and fabrication methods are reported in (Srubar 2011a).

Uniaxial Tension. The cross-sectional geometry (width, thickness) was measured on all samples. The densities of the PHBV/OWF composites were measured by immersion of oven-dry samples in water according to ASTM D792 and calculated based on Archimedes' Principle. ASTM D3171 was used to determine the constituent

content of fiber-reinforced polymeric composites with chloroform as the solvent. The existence of soluble organics in the pure OWF was found to be negligible. Although not reported herein, microscopy has been used to investigate filler morphology, fiber-matrix interfacial adhesion, and particle dispersion, and differential scanning calorimeter was performed to determine the thermal properties of the polymer composites (i.e., crystallization, melting, and glass transition temperatures).

Tensile specimens were tested according to ASTM D638 using an MTS 858 tabletop machine with a 13.5 kN capacity. Modulus of elasticity, ultimate strength, maximum elongation, and Poisson's ratio for the specimens were determined. The longitudinal and transverse strains were measured using a 50 mm gage length extensometer and a strain gage, respectively. Three specimens were tested for each variable.

For the sorption testing, disc samples were equilibrated in an oven at 70°C for 36 hours until a constant weight was achieved. Water sorption experiments were performed in a sealed room-temperature water immersion basin as per ASTM D570. Composite specimens were periodically removed from the water basin, bound surface moisture was carefully removed, and weights as well as radial and through-thickness dimension measurements were recorded to obtain both time-dependent mass gain and coefficients of hygroexpansion.

SELECTED EXPERIMENTAL RESULTS

Composite and Filler Density. The densities of the PHBV/OWF composites resulted in an increase in composite density from 1.21 g/cm^3 for the neat PHBV to 1.22-1.30 g/cm^3 dependent upon fiber loading. The experimental determination of filler density in the composite yielded an average value of 1.44 g/cm^3 whereas the overall density of preprocessed natural oak wood ranges from 0.32-0.72 g/cm^3 due to its tubular microstructure and porous anatomy (Clemons 2005). Similar results in terms of increased densities in both injection-molded and extruded wood flour composites have been reported in the literature (Anderson 2007) and are primarily due to the compressibility of wood flour particles. During processing, the wood flour fibers are exposed to elevated pressures, which results in the collapse of the wood fiber cell walls. Substantiating this phenomenon, the density of wood cell walls is well documented to be 1.40-1.60 g/cm^3 contingent upon the wood specie (Clemons 2005).

Uniaxial Tension Response. The uniaxial tension stress-strain response of representative samples of pure PHBV and PHBV/untreated OWF composites are shown in Figure 2. The modulus of elasticity calculated as the initial slope of the stress-strain relationship increased with increases in fiber loading. Initial stiffness increased neat PHBV stiffness from 3800±102 MPa to 4820±180 MPa for a 40% fiber loading. As the filler-matrix bond is expected to be weak, the increase in stiffness is attributed to the increase in the quantity of nucleation sites due to the added surface area of wood fibers in the reinforcement phase. These nucleation sites promote ubiquitous crystalline spherulite formation, which results in an overall increase in polymer crystallinity and, correspondingly, an overall increase in

composite stiffness. The increase in stiffness is expected to plateau with the addition of more OWF due to limitations related to the packing density of wood flour particles with an aspect ratio of 3.6. This plateau is apparent in Figure 3 where the effect of fiber loading on modulus of elasticity is shown.

In contrast, the addition of OWF systematically decreases the ultimate tensile strength of the composites as well as the elongation to break (Figure 2). The tensile strength of neat PHBV decreased from 34.8±0.7 MPa to 21.4±1.8 MPa with a fiber loading of 40%. This corresponds to an average strength decrease of 3.4 MPa with every 5% OWF added by volume. The decrease in tensile strength can be quantifiably predicted under the assumption of no interfacial adhesion between particle and matrix. The wood flour filler simply displaces matrix material; thus, the tensile strength is only dependent upon the tensile strength and volume fraction of PHBV (Srubar 2011a).

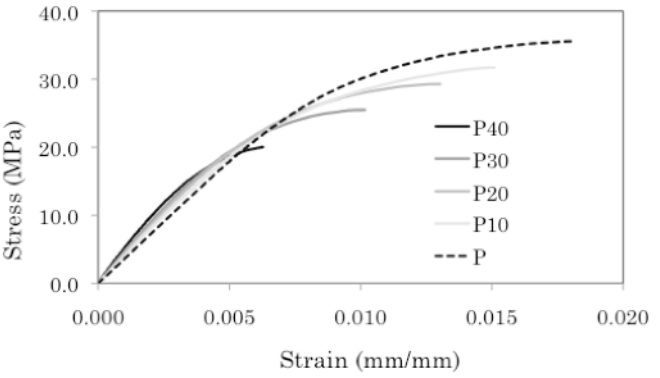

Figure 2. Effect of fiber loading on stress-strain behavior of PHBV/untreated OWF composites.

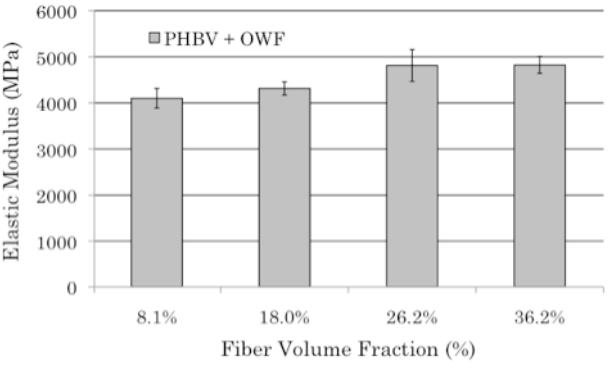

Figure 3. Effect of fiber loading on the tensile elastic modulus of PHBV/untreated OWF composites.

For all untreated and treated families of PHBV/OWF composites, the same increase in composite stiffness and decreases in strength and elongation to break were observed as the amount of filler increased. Initial comparisons between the effects of modification techniques on the material properties show that both fiber and matrix treatments do improve mechanical performance. Complete results of the effects and mechanisms governing interfacial improvements are reported in (Srubar 2011b).

Water Absorption Behavior. Figure 4 shows the water uptake behavior of PHBV/untreated OWF composites. An increase of fiber loading corresponds to an increase in water uptake as expected and as shown in other water absorption studies with natural fiber composites (Wang 2006). As can be seen in Figure 4, PHBV is primarily hydrophobic; the slight gain in moisture mass is the result of polymer plasticization and relaxation. The marked difference between the slopes of the 20% (shallow) and 40% (steep) composites suggest a volume fraction threshold that relates to the packing density of fibers in the composite. Percolation thresholds for ellipsoidal particulate fillers with an aspect ratio of 3.6 are being investigated for applicability to the moisture absorption behavior of PHBV/OWF composites.

Preliminary results also indicate that the modification techniques were not effective in reducing overall equilibrium moisture contents (Figure 5) particularly in the case of the silane treatment. It is believed that this is due, primarily, to the processing damage incurred during the injection-molding of the composites, where wood flour particles have collapsed due to elevated temperatures and pressures. The vapor deposition of silane onto fiber surfaces was a preprocessing technique and the collapse of the cell walls during processing would expose untreated fiber surfaces creating preferential pathways for water to enter the wood fibers. In addition, the low graft percent of maleated PHBV does not significantly affect the water absorption behavior in low volume fraction composites. Maleation improves fiber wettability and dispersion; however, in low filler fraction composites, good dispersion of particles can occur in untreated composites since there are appreciably fewer particles to disperse.

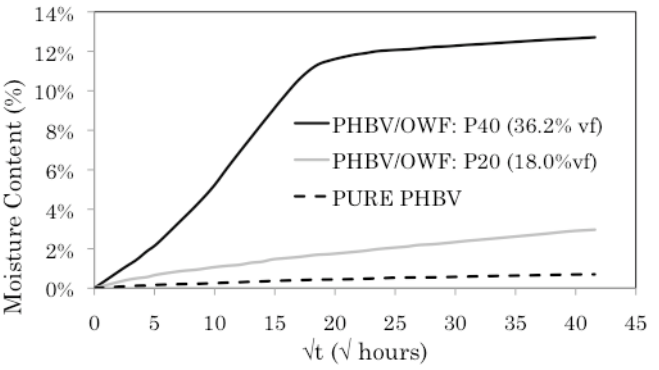

Figure 4. Water sorption of neat PHBV and PHBV reinforced with 20% and 40% OWF.

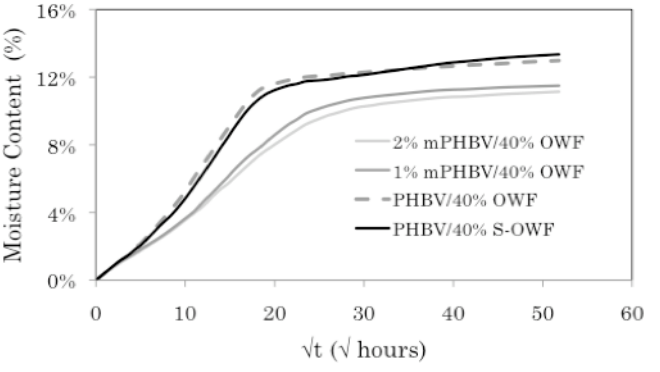

Figure 5. Water uptake profiles of four families of composites: untreated, silanated OWF, and 1% and 2% maleated PHBV.

However, there is noticeable impedance induced in the retardation of the rate of water absorption with high fiber loadings (Figure 5), especially by the maleic anhydride-treated polymer composites. As previously noted, maleation of the polymer improves fiber wettability, which corresponds to better fiber dispersion. The increase in fiber dispersion increases the hygrophobicity of the bulk composite by providing polymer-rich coatings on individual fibers. This phenomenon would explain the slight decrease in rate of water absorption coupled with the gradual inclination toward the same ultimate equilibrium moisture content as the untreated fiber samples.

PRELIMINARY MODELING

Experimental data obtained from fundamental tensile tests can be compared with the most commonly used theoretical models for initial composite stiffness. The Halpin-Tsai and Tsai-Pagano equations were developed to predict the global tensile modulus

of aligned short wood fiber reinforced biopolymeric composites using the micromechanical properties of the individual fiber and matrix phase constituents. Using experimentally determined parameters, this micromechanical modeling approach has been used previously in initial stiffness predictions of PHBV/wood flour composites (see Singh 2007).

Figure 6 shows the comparison of modulus of elasticity values determined experimentally with the initial composite stiffness predictions of the Halpin-Tsai / Tsai-Pagano Model for each of the four families of composites. As can be seen in the figure, the model provides a good estimation of composite stiffness for PHBV/untreated OWF, while it does not capture the enhanced improvement exhibited by the silanated and maleic anhydride treated families of PHBV/OWF composites.

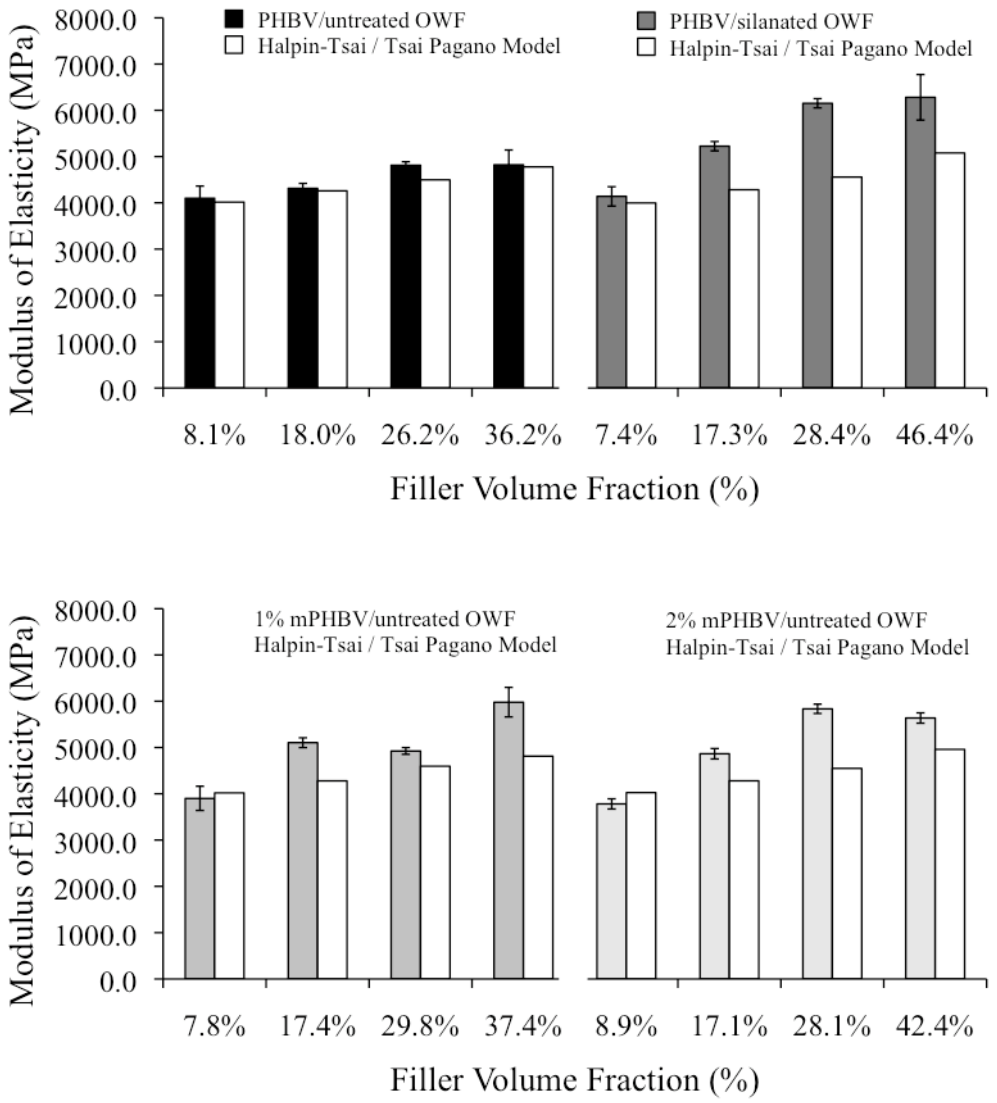

Figure 6. Comparison of experimental results with a micromechanical model for composite stiffness.

The inabilities of the model to provide a good estimation for the treated composites is attributed to its failure to incorporate improved fiber wettability and dispersion and the corresponding fundamental changes in crystalline matrix morphology that occur during processing. Current research investigations include further refinement and development of new models that account for these treatment-induced morphological changes in the matrix microstructure.

CONCLUSIONS

The introduction of OWF filler into PHBV led to increasing stiffness and decreasing strength with increasing filler content. The increased stiffness with increasing filler content is attributed to increased available fiber surface area and therefore nucleation sites for crystalline structure formation in the polymer matrix. This argument is further supported by an embrittlement of the composite and the reduction in elongation to break of tensile test data. Additional characterization techniques to support this conclusion are ongoing. In plain PHBV/untreated OWF composites, tensile strength can be predicted by considering only the matrix tensile strength and matrix filler fraction, indicating no interfacial adhesion between filler and matrix and, correspondingly, no contribution of tensile strength from the particulate filler.

The compatibilization techniques did not have a significant impact on reducing overall equilibrium moisture contents but did reduce the rate of moisture uptake relative to the composites with untreated wood fiber filler. In the case of the silane pre-treatment of the filler, it is believed (and confirmed through SEM imaging (Srubar 2011b)) that during extrusion and injection-molding, the wood fiber particles collapsed, exposing untreated fiber surfaces and thus creating preferential pathways for water to enter the wood filler. Untreated PHBV/OWF composite stiffness can be predicted with the conventional Halpin-Tsai / Tsai-Pagano Model; however, the model fails to account for alterations in the material microstructure induced by the employed chemical compatibilization techniques.

Acknowledgments. This research has been funded primarily by the National Science Foundation through CMMI Grant 0900325 with partial support from the California Environmental Protection Agency, Department of Toxic Substances Control under grant No. 07T3451. ABSTRACT

Many studies have shown that fiber-reinforced polymer (FRP) laminates are an effective alternative for structural retrofit and repair of insufficiently reinforced concrete members; however, achieving the full tensile capacity of the externally bonded FRP is often very difficult. This is especially true when FRP is used on elements where there is inadequate length to develop the full tensile strength of the FRP laminate, leading to premature debonding failure. Anchorage systems attempt to mechanically restrain the FRP or improve the FRP-to-concrete bond, thus reducing the length required to develop its full design strength. Many types of anchorage systems have been tested by different investigators, but mixed and inconclusive results have been presented. Additionally, no evidence exists to show that one particular type of anchorage system is completely effective in developing the full tensile strength of FRP. The lack of conclusive results is exacerbated by the absence of a consistent testing procedure for evaluating anchorage strength and a system for categorizing the purpose of the anchorage system, despite the current design guide's recommendation that anchorage testing should precede the strengthening of a structure with FRP. An overview of previously tested anchorage systems is presented along with applicable testing procedures from existing literature. The limitations of each anchorage system are mentioned with respect to specific structural strengthening applications. The existing anchorages are then categorized according to their specific application to FRP anchorage, and the applicability of testing procedures to each anchorage category is discussed. Finally, the need for systematic testing is discussed and potential research topics are explored.

INTRODUCTION

For the past several decades, strengthening of reinforced concrete (RC) elements with fiber-reinforced polymer (FRP) composites has been studied as an effective method of structural retrofit and repair of insufficient members. FRP has become an

attractive construction material for these purposes due to its high strength-to-weight ratio, corrosion resistance, and ease of installation. Despite the extremely high strength of FRP composites, specifically those bonded externally to RC members, premature failure modes and difficulties in detailing often prevent the design strength, which is a function of the rupture strength of FRP, from being reached. To solve this problem, various anchorage systems have been devised and tested in an attempt to allow the strength of the FRP to approach its ultimate capacity.

Performance of anchorages becomes critical in the design of FRP strengthening systems because the improved strength due to the anchorage still may not be high enough to develop the full tensile strength of FRP. Therefore, failure modes are most often anchorage failure, FRP rupture due to local stress concentrations imposed by the anchorage, or FRP debonding. Because FRP rupture and debonding are sudden and brittle, a thorough understanding of the behavior and strength of anchorage is crucial for designing a safe, reliable structure.

While a wide variety of anchorage systems have been created and tested, the process of choosing an anchorage system for a specific strengthening application is often difficult due to the difference in behavior and lack of categorization with respect to application or purpose. To date, all anchorage systems have been grouped together in the single category of "FRP anchorage" or a similar term, even though different systems are not entirely interchangeable. Therefore, categorization of anchorage purposes will be useful for designers and for the scholarly exchange of information.

Because of the critical nature of FRP anchorage performance, current design guidelines require that a proposed anchorage system be heavily scrutinized under representative physical testing. Test procedures that have been published recently by scholars, however, have limited applicability. Further, while test data for a specific type of anchorage system may be available, the data may not be relevant to a different application depending on the usage of that particular system.

This paper presents a review of existing anchorage systems and focuses on their physical characteristics, role as a part of an FRP strengthening system, and applications. Existing types of anchorage systems are briefly discussed, categorized according to strengthening application, and related to an applicable testing procedure. Finally, the need for further research and consistent testing procedures is discussed.

CHARACTERISTICS OF FRP ANCHORAGE SYSTEMS

FRP anchorage systems for strengthening RC members are typically fabricated from the following materials: metal, usually steel and sometimes aluminum; carbon fibers, glass fibers, or other composite materials; a modification of the original concrete surface; or a combination of the three. For laboratory purposes, the use of metal anchorages is an attractive option because innovative devices can be easily fabricated by non-specialized personnel. Additionally, they can be designed to fail in a ductile manner, whereas FRP failure is usually sudden and brittle. For many applications of

FRP strengthening, however, corrosion is a major concern, and the use of a steel anchorage system is not an option. Anchorage devices made from carbon fiber-reinforced polymer (CFRP) or glass fiber-reinforced polymer (GFRP) are attractive because they can be integrated seamlessly with the overall FRP strengthening system and do not have the potential for galvanic corrosion. A disadvantage to using FRP or other composite anchorage systems is that the geometry of the devices can be limited unless advanced production techniques are used.

Current design guidelines for FRP anchorage systems can be found in *ACI 440.2R-08*, "Guide for the Design and Construction of Externally Bonded FRP Systems for Strengthening Concrete Structures." Recommendations and guidelines for anchorage systems found in this document, however, are limited at best. Although the guide states that any proposed method of anchorage should be "heavily scrutinized" or evaluated through "representative physical testing," it does not specify types of testing procedures that are considered adequate. The document also states that an anchorage system's ability to restrain FRP "is believed to result from their ability to resist tensile normal stresses rather than enhancing interfacial shear capacity." While this statement is true for many types of anchorages, there are many more that do not rely on resisting the tensile normal forces.

It is worth noting that many FRP strengthening systems are constructed without the need for anchorage systems because sufficient space exists for the FRP design strength to be developed along an "active bond length" over which the majority of the bond stress is maintained. While this bond length can be considered a form of anchorage, the depth and complexity of determining this "active bond length" warrants much discussion and is beyond the scope of this paper.

CATEGORIZATION OF FRP ANCHORAGE SYSTEMS

The purpose of anchorage systems is to allow the FRP strengthening system to reach a higher design strength by accomplishing one or more of the following: (I) preventing or delaying a premature debonding failure by resisting tensile normal forces; (II) reducing the in-plane development length required to achieve a specified design strength by transferring load from the FRP to the anchorage via shear; or (III) transferring the force in the FRP laminate to another structural component where no development length is available. For the remainder of this paper, anchorages serving these purposes will be categorized as Type I, Type II, and Type III anchorages and are described in the following paragraphs.

Type I. Type I anchorages are often used at the termination of FRP sheets or plates, or sometimes throughout their entire length, to resist tensile forces normal to the plane of the FRP. An example condition is when the soffit of a beam is strengthened in flexure with FRP, and either plate-end debonding or intermediate flexural or flexural-shear crack induced (collectively referred to as I.C.) debonding is a concern. In this case, a Type I system is installed over/though the FRP to resist the normal forces as shown in Figure 1 and achieve a higher design strength. (For a thorough

description of FRP failure modes, the reader is referred to Teng et. al., 2002).

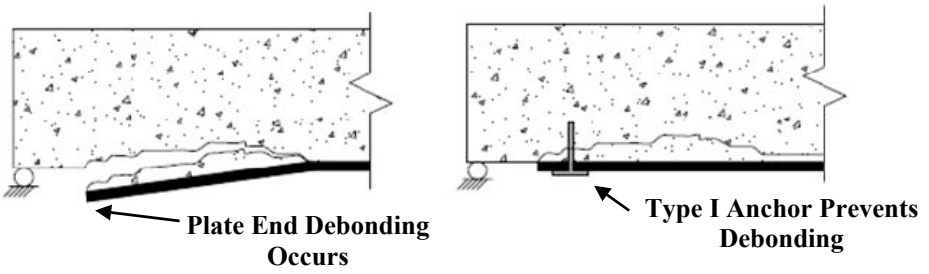

Figure 1: Type I Anchorage

Type II. Type II anchorages are used where insufficient space exists due to geometric conditions to allow the FRP to be developed to reach a specified design strength. In a Type II system, load is transferred in shear via bond between the FRP and anchorage system. This is distinguished from Type I anchorage because Type II anchorages do not include a mechanism to restrain plate-end or I.C. debonding. An example of this is a T-beam where an FRP U-Wrap (described later) is used for shear strengthening as seen in Figure 2. In this case, the beam flange requires the FRP to be terminated and prevents it from being fully developed. The installation of a Type II anchor in this situation would bond the end of the U-Wrap to the anchorage system and would result in a higher strength due to the increased bond transfer.

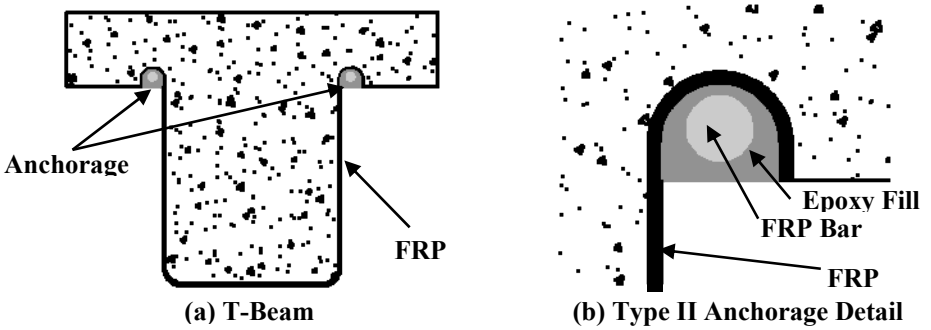

Figure 2: Example of Type II Anchorage on T-Beam

Type III. Type III anchorages are used in situations where the location of maximum FRP stress lies at sheet or plate end or near a change in direction in the fiber direction, such as the interface between two structural members. An example of this is vertical FRP strips installed on a concrete or masonry shear wall to increase flexural resistance. While Type III anchorages may include characteristics of Type I and Type II anchorages, Type III anchorages present a special and difficult challenge in that the FRP strengthening system can be considered to have no strength before their inclusion. While some Type III anchorages may have some debonding-preventing characteristics, they differ from Type I anchorages in that they must transfer the entire force in the FRP to another structural element instead of simply resisting the debonding normal force. Type III anchorages differ from Type II anchorages in that the demand on a Type II anchorage is less since some of the force is transferred along a "bonded length." Type III anchors do not benefit from a "bonded length."

Table 1: Summary and Categorization of Anchorage Systems

Type	System/Device	Study	Independent Anchorage Test?	Test Type	FRP Strengthening Application

EXISTING FRP ANCHORAGE SYSTEM TYPES

A wide variety of innovative anchorage systems have been used for structural strengthening applications or have been subjected to representative physical testing. Different anchorage system types are described and categorized in the sections that follow. Studies from the literature that use each system type are presented in Table 1.

Anchor Spikes. Anchor spikes are strands of bundled fibers that have one end embedded in the composite matrix and the other end embedded in the concrete below or adjacent to the FRP sheet being anchored. Anchor spikes made from CFRP, GFRP, or steel have been reported in the literature. Anchor spikes fall into all three anchorage categories. 90º anchor spikes, which fall into the Type I category, are embedded in a hole drilled into the concrete substrate and through the FRP sheet. Their means of force transfer is primarily through resisting the tensile normal forces associated with debonding. 180º anchor spikes can be considered Type II or Type III depending on the strengthening application. When a 180º anchor spike is inserted through the flange of a T-beam and bonded directly to an FRP stirrup, it is being used as a Type II anchor. If a 180º anchor spike is used to anchor an FRP sheet on a cantilever beam at the point of maximum moment, it is being used as a Type III anchor. Types of anchor spikes are shown in Figure 3.

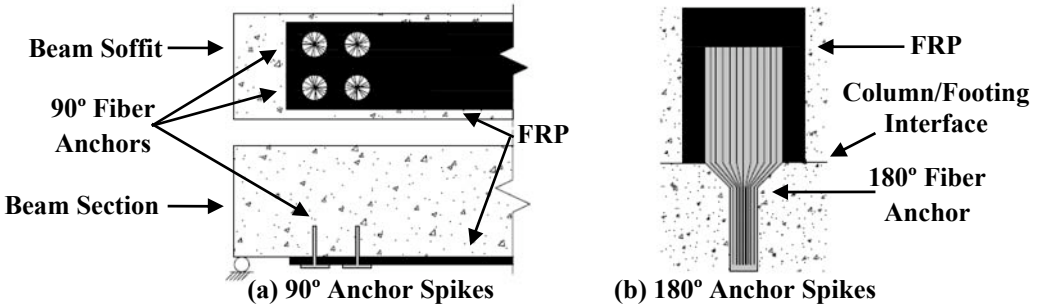

Figure 3: Types of Anchor Spikes

Transverse Wrapping. Transverse wrapping of flexural FRP reinforcement with shear or confining reinforcement, commonly referred to as a "U-Wrap", is an effective way to increase the debonding strain of the flexural FRP reinforcement. While detailed studies of the anchorage mechanics of transverse wrapping have been minimal, several studies have shown that they are an effective anchorage system. In fact, *ACI 440.2R-08* notes an improvement "of up to 30% increase in debonding strains has been observed." While transverse wrapping is typically not prestressed, a study by Zhuo et al. (2009) demonstrated a prestressed FRP strap that has potential for use as a transverse wrapping anchorage system.

FRP Strips. Anchoring at the sheet end with perpendicular strips of FRP is another method of anchorage. While this may seem similar to transverse wrapping, it can be distinguished because the strips do not provide a confinement effect. Because of this, the FRP strip anchorage must be loaded out-of-plane, or in other words, loaded in a direction other than that of the fibers, leading to an inefficient force transfer mechanism. While this type of anchorage has not been shown to be as effective as

other types, its major advantage is that the anchorage and strengthening materials are the same, allowing for easy construction and eliminating the potential for corrosion.

U-Anchors. U-Anchors increase the capacity of an FRP strengthening system by increasing the bonded area of FRP-to-concrete. U-Anchors are installed by cutting a groove into the concrete surface perpendicular to the FRP fiber direction at or near the end of an FRP sheet. The FRP sheet is then pressed into the groove and the remainder of the groove filled with polymer (see Figure 4). Increase in area is attributed to the FRP bond to the walls of the groove. In some cases, an FRP or steel rod is placed into the groove, although the inclusion of the rod serves only to ease the installation procedure and does not provide an increase in anchoring strength. Thus, inclusion of a rod in a U-Anchor groove is not necessary (Khalifa et al. 1999). U-Anchors have been used in Type II and Type III applications.

Longitudinal Chase. A study by Kalfat and Al-Mahaidi (2010) involved a "Longitudinal Chase" anchorage system, which is similar in behavior to a U-Anchor. Instead of anchoring the FRP sheet in a transverse groove at or near the plate end, a groove is cut in the concrete longitudinally, or in the fiber direction of the FRP, and filled with polymer (Figure 4). The inclusion of a bar in the groove is optional as its inclusion does not contribute to the strength of the anchorage system. Because FRP failure is rarely through the polymer matrix, the increased bond surface area provided by the walls of the chase allows for more force transfer along the length of the FRP.

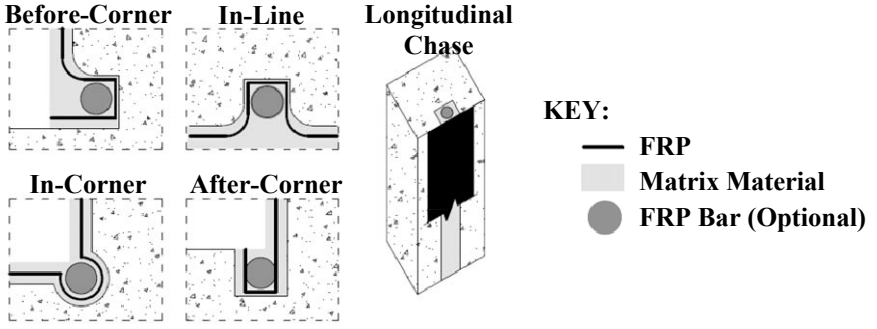

Figure 4: U-Anchors and Longitudinal Chase

Steel and FRP Plates. Steel and FRP plates have been used for several applications of FRP anchorage. The plates are usually placed at or near the FRP sheet end and bonded to the FRP. The plates are then either glued, or more often, bolted to the concrete surface. While the presence of the plates may help prevent debonding of the FRP sheet by resisting the normal debonding forces, their primary mode of load transfer is via shear between the plate and FRP. Therefore, plated anchorage devices can be considered to have both Type I and Type II anchorage properties. Detailing of plated anchorage systems varies widely in literature and often varies widely within a given study. Ortega (2009) studied plated anchorage systems used to anchor FRP U-Wraps on RC and PC T-beams at the web/flange interface. Plated devices included a continuous plate that spanned the length of the beam with bolts around the FRP U-Wrap strips, discontinuous plates that were bolted around the FRP strips, and plates that sandwich the FRP to transfer load in double shear. Ceroni et al. (2008) compared several glued and bolted plated anchorage systems through representative testing. In

this study, plates were used before and after a 90º joint for comparative purposes.

Steel Angles/Pipes. Steel angles have been used for FRP anchorage at 90º joints. Typically, the FRP is laid around the joint, the angle bonded to the FRP in the joint, and the angle bolted to the concrete either through or around the FRP sheet. Steel angles behave in a Type I & II manner and also can be used as a Type III anchorage system. Nagy-György et al. (2005) used a combination of a bolted angle and a U-Anchor in a Type III application. Despite wide use of steel angles as an FRP anchorage device, premature FRP failures due to local stress concentrations at the angle corner have resulted in limitations for their use.

Because of local stress concentrations developed in the FRP resulting from their steel angle anchorage devices, Hall et al. (2002) and Hiotakis (2004) developed similar alternative devices, both of which were used in Type III applications. The device used by Hall et al. involved a plate that was bolted to concrete after a 90º joint. Under this plate, a rounded angle or a quarter-section of pipe was placed immediately adjacent to the joint so that the FRP would lay tangent to the pipe or angle and cause the plate to bend as a cantilever about the line of the bolts. By placing the rounded angle or quarter-pipe at the joint, the stress concentrations are reduced. The system developed by Hiotakis, referred to as a "Cylindrical Hollow Section (CHS) Anchorage", involves a pipe or bar placed in the 90º joint with the pipe or bar anchored directly to the concrete using one of several bolt configurations. The Hiotakis system is currently protected by a U.S. patent. Detailing of the anchor bolts for this anchorage device must be carefully monitored to ensure they are not installed in the plastic hinge region of a member. This is an important consideration since Appendix D of *ACI 318-08* specifically excludes anchors in plastic hinge regions, and anchors qualified through *ACI 355.2-07* do not anticipate the level of crack widths typically developed in plastic hinge regions.

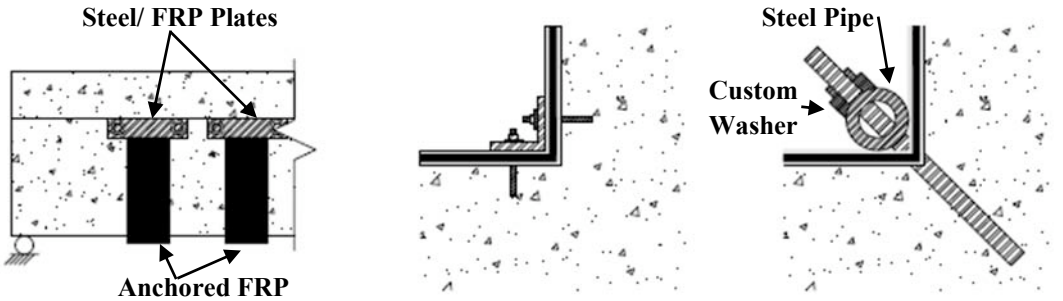

Figure 5: Plates, Angles, and CHS Anchorages

TESTING PROCEDURES FOR ANCHORAGE SYSTEMS

Most studies involving FRP anchorage systems involved tests that were one component of a larger strengthening system study, as indicated in Table 1. Also noted in the table are details about the FRP strengthening application studied. While these types of tests are very useful in demonstrating application-specific performances of these anchorage systems, the data they provide are difficult to use for design purposes

because of the complex variables that affect their response. As previously mentioned, *ACI 440.2R-08* requires that sufficient representative testing be performed before an anchorage system is used in field applications. Very little representative testing has been reported in literature, however, and most of the testing procedures reported have a limited range of applicability. Thus, the need exists for systematic, representative testing procedures based on the anchorage category. Further, these procedures should include enough applicable variables so that conclusions for design can be reached.

Type I and Type II anchorages should have similar testing procedures. With proper test design, the procedure may be duplicated for both monotonic or fatigue loadings. Testing procedures appropriate for Type I and Type II anchorages have been developed and reported by Hall et al. (2002), Teng et al. (2001), Ceroni et al. (2008), Kalfat & Al-Mahaidi (2010), Sadone et al. (2010), and Sami et al. (2010). Test procedures in Hall et al. (2002), Ceroni et al. (2008), and Sami et al. (2010) use double-sided specimens, which are attractive for use because of their initial loading symmetry. It is worth noting that while these tests have a simple design and testing procedure, they require that two sets of anchorages are tested to obtain one test result. Additionally, this testing procedure may tend to underestimate the ultimate strength of the anchorage in question. The test must be stopped when symmetry is lost in the test setup, which does not necessarily correspond to anchorage failure. Orton (2007) performed representative testing of Type I and Type II anchorages, but because the specimen construction and loading were designed to replicate a specific strengthening application, the data may not be applicable to other applications of the same type of anchorage.

Type III anchorage testing procedures can be similar to Type I and Type II procedures with the exception that the FRP-to-concrete bonded length between the anchorage and applied load must be zero. Any bonded length will transfer load to the bonded concrete, which will lead to an overestimation of the strength of the anchorage. Again, with proper test design the procedure may be duplicated for both monotonic or fatigue loadings. Very few representative testing procedures exist in literature for Type III anchorages. Studies by Eshwar et al. (2003) and Piyong et al. (2003) involving pullout tests for GFRP anchor spikes would be appropriate for Type III anchorage testing only if it is known that the bond between anchor spike and the anchored FRP is adequate.

CONCLUSION

Anchorage systems in existing literature have certainly shown that their presence can contribute significantly to the overall strength of an FRP strengthening system. Additionally, in the case of a Type III anchor, their presence is essential. Due to the limited amount of existing test results from independent anchorage tests, however, design of FRP strengthening systems containing anchorage systems becomes rather difficult. Therefore, it is recommended that future research establish a large database of simple anchorage tests, the results of which can be compared and correlated among large-scale FRP strengthening systems. While the many different applications of

anchorage systems each present their own challenges and limitations, the existence of a large database of simple test results will surely aid the development of new and improved anchorage systems and assist in the creation of design guidelines.

For example, data for Type I and Type II anchorages can be easily obtained through the creation of simple shear tests or a double-lap shear test. Important variables for Type I and Type II tests include, but are not limited to, bonded length of FRP to concrete between the anchorage and applied load, number of sheets anchored, applied load magnitude, width of FRP plate or sheet anchored, concrete substrate properties, and various other anchorage system-specific parameters that are dependent on anchorage design and detailing. Data from these tests could then be related to a control specimen with no anchorage system and compared to existing bond strength models to determine the strength enhancement resulting from the presence of the anchorage. Finally, results could be used to predict the strength of an FRP system used for large-scale strengthening, and the results used to prepare design guidelines.

Due to the nature of Type III anchorage systems, which do not benefit from a "bonded length" ahead of the anchorage system, a simple "pull-out" type test will suffice to obtain preliminary data. An example specimen for a Type III system test involves a concrete block onto which the anchorage system is installed. The FRP is then attached to the anchorage system and/or the concrete surface and an external force is applied to the FRP normal to the concrete surface. This creates a very simple test, and the only variables not involving anchorage detailing or concrete substrate properties would include applied load and number of sheets anchored. The results from this type of test would be immensely useful in determining a design strength for an FRP system needing Type III anchorage systems, although it must be noted that detailing at the joint is critical and should be evaluated further using representative testing of the entire FRP strengthening system.

ABSTRACT

Concrete has been used as the major construction material for many years in the field of civil engineering because of its high compressive strength and constructability. In order to restrict the growth of micro cracks, Carbon-Nanofibers (CNF's) were added to the concrete mix. The concentration of CNF in concrete mix also yields higher strength and ductility. Uniaxial compression tests on CNF concrete were conducted to find the best CNF concentration. To evaluate the performance of CNF concrete, experiments were conducted at the University of Houston (UH) and an inelastic non-linear fiber beam element with bending, shear and axial force interaction for the analysis of reinforced concrete structures was developed and evaluated to correlate with the experimental results.

INTRODUCTION

The use of carbon nanofiber composites began with the discovery of carbon nanotubes in the late 1980s (Lau and Hui 2002). Carbon nanotubes are over 100 times stronger than steel and only one-sixth of the weight in addition to its high thermal and electrical conductivities (Lau and Hui 2002). These properties make carbon nanotubes extremely attractive for engineering materials.

Since the 1990s, researchers have been adding carbon nanofibers (CNF) to cement paste (containing no aggregate), mortar (containing fine aggregate) and concrete (containing fine and coarse aggregate) (Chung 2000). The addition of CNF to cement-based materials has many advantageous mechanical and electrical properties including increased strength, ductility and conductivity (Chen and Chung 1993, Li et al. 2004, Li et al 2006, Li et al 2007). The most difficult issue during CNF concrete production is dispersion of the CNF. Well dispersed CNF results in uniform calcium-silicate-hydrate (CSH) gel formation, which improves the structural and electrical properties of the concrete (Chung 2005). It was discovered that CNF disperse better in Self-Consolidated Concrete (SCC) (Gao et al 2009). A carbon nanofiber self-consolidating reinforced concrete (CNFSCRC) column was built and tested under a reversed cyclic load (Howser 2010).

SHEAR-BASED FIBER ELEMENT FORMULATION

Shear-based fiber beam element with Timoshenko type displacement and force formulations were proved accurate in simulating the behavior of columns (Mullapudi and Ayoub 2010). So here the same approach was used for the analysis of Carbon-nanofiber reinforced concrete columns. Monotonic and cyclic constitutive relationships were modified based on the uni-axial stress strain relations derived by Gao et al (2009).

Axial force N; shear force V and section moment M (Fig. 1 b) are derived from the known kinematic variables axial strain ε_x, shear strain γ_{xy} and section rotation β (Fig. 1 a) as described by Mullapudi and Ayoub (2010).

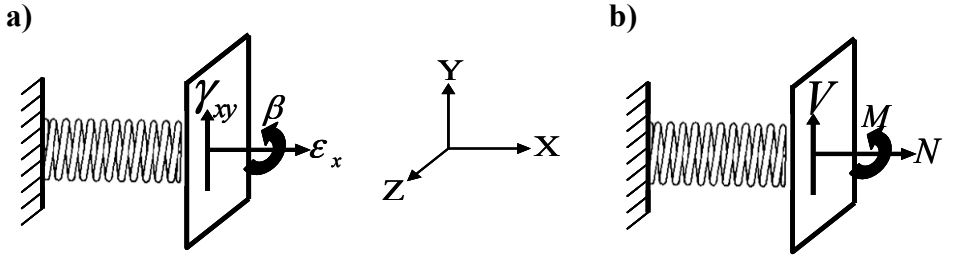

Fig. 1 (a) Section Deformations and (b) Section Forces

ORTHOGONAL STRESS STATE DETERMINATION

COMPRESSION-COMPRESSION REGION

Current research uses the Vecchio's (1992) simplified version of Kupfer et al. (1969) biaxial compression strength equation. The concrete compressive strength increase in the lateral direction depends on the confining stress in the orthogonal direction. Strength enhancement and increase in ductility are dependent on the biaxial compressive stresses. Concrete in compression exhibits lateral expansion and increase in Poison ratio. An upper limit of 0.5 has been considered for Poison ratio.

TENSION-COMPRESSION REGION

In this case, the uniaxial strain of concrete $\bar{\varepsilon}_1$ in principal direction 1 is in tension, and the uniaxial strain $\bar{\varepsilon}_2$ of concrete in principal direction 2 is in compression. Due to this condition, the uniaxial concrete stress σ_1 in direction 1 is calculated from $\bar{\varepsilon}_1$, and is not a function of the perpendicular concrete strain $\bar{\varepsilon}_2$. The compressive strength in direction 2, σ_2 will soften due to tension in the orthogonal direction. Hsu and Zhu (2002) derived a softening equation in the tension-compression region, which is implemented in the current model (Fig. 2). Based on panel testing as proposed by Hsu et al. (1995), Belarbi and Hsu (1995) also developed

a similar expression based on the softened concrete constitutive laws. The lateral tensile stress reduces the compressive strength in the orthogonal direction. The equation for compressive strength reduction factor proposed by Hsu and Zhu (2002) is:

$$\zeta = \left(\frac{5.8}{\sqrt{f_c^{'}(MPa)}} \le 0.9 \right) \left(\frac{1}{\sqrt{1+400\bar{\varepsilon}_1}} \right) \left(1 - \frac{|\alpha_{r1}|}{24^{\circ}} \right), \qquad (1)$$

The softening coefficient ζ value is limited to 0.9 because the uni-axial concrete compressive strength $f_c^{'}$ is calculated from standard cylinder tests, while from the panel experiments at the University of Houston, it was observed that concrete strength does not reach $f_c^{'}$; the reasons for this are due to size effect, loading rate, and shape factor, which have a significant effect on concrete compressive strength $f_c^{'}$. The ultimate stress in the orthogonal direction is therefore $\zeta f_c^{'}$ at a softened strain $\zeta\varepsilon_0$ (Fig. 2), where ζ is the softening coefficient and α_{r1} is the deviation angle in degrees. This is the difference between the applied stress angle α_1 and the rotating angle α_r; $\bar{\varepsilon}_1$ represents the lateral tensile strain while ε_0 is the concrete strain at peak compressive strength $f_c^{'}$, and $\zeta f_c^{'}$ is the softened concrete compressive strength.

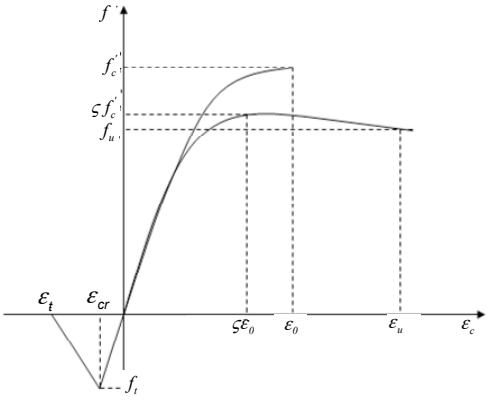

Fig. 2 Stress-Strain curve with softening

TENSION-TENSION REGION

In the current model, tensile strength is not affected by its orthogonal compressive or tensile stresses. Always the tensile strength is equal to the uniaxial tensile strength at cracking and tension stiffening is considered only after cracking.

ORTHOTROPY WITH UNIAXIAL STRESS STATE

The concrete model is simplified with plane stress orthotropic assumption. The model has perpendicular planes of elastic symmetry 1 and 2 with the local principal axes normal to these planes of symmetry.

The stresses in the orthogonal directions are:

$$\sigma = D_{LO}\varepsilon \tag{2}$$

where σ is the local stress vector, ε is the local strain vector and D_{lo} is the local material stiffness matrix in the principal direction (Chen 1976).

RC structures are considered orthotropic materials with axes oriented at an angel θ between the principal and x-axes. The rotational matrix R is introduced as:

$$R = \begin{bmatrix} \cos^2\theta & \sin^2\theta & \cos\theta\sin\theta \\ \sin^2\theta & \cos^2\theta & -\cos\theta\sin\theta \\ -2\cos\theta\sin\theta & 2\cos\theta\sin\theta & \cos^2\theta - \sin^2\theta \end{bmatrix} \tag{3}$$

The orthotropic stiffness matrix in global direction D_{gl} is:

$$D_{gl} = R^T D_{lo} R \tag{4}$$

The sectional stiffness $K_{Section}$ can be formulated by coupling the axial, shear and bending terms in $D_{gl.}$

STIRRUP CONSIDERATION

Transverse strains are internal variables determined by imposing equilibrium at each fiber between concrete and vertical steel stirrups. Transverse strains are not known in advance and due to the non-linear behavior of the concrete and steel, an iterative procedure is needed to satisfy the equilibrium in the transverse direction (Fig. 3), following the procedure proposed by Petrangeli et al. (1999).

$$\sigma^i_{y,c} A^i_{y,c} + \sigma^i_{y,s} A^i_{y,s} = 0 \tag{5}$$

where $\sigma^i_{y,c}$, $\sigma^i_{y,s}$ are concrete and steel stresses in the transverse direction at fiber i, and $A^i_{y,c}$, $A^i_{y,s}$ represents the areas of concrete and steel in the transverse direction at fiber *i*.

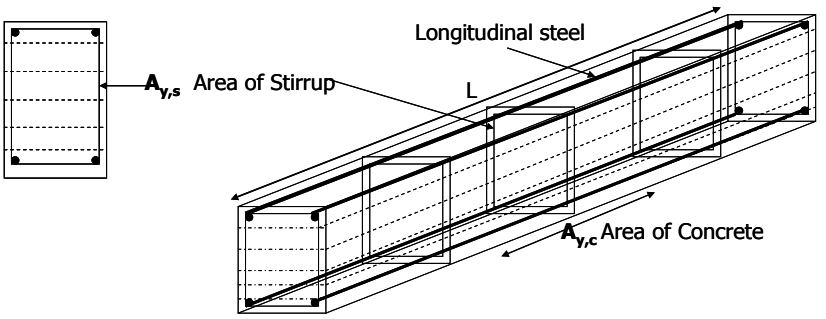

Fig. 3 Fiber element with stirrup

STIFFNESS AND FORCE RESULTANTS

The total stiffness of the section is the sum of concrete and steel stiffness, and is evaluated as follows.

$$K_{Section} = \sum_{1}^{nC} (K_{Section})_C + \sum_{1}^{nS} (K_{Section})_S \quad (6)$$

where the subscripts C, S denotes the parameters related to concrete and steel respectively, nC and nS are the number of concrete and steel fibers in the section and $K_{Section}$ is the section stiffness.

The total force of the section is the sum of concrete and steel forces in the respective direction, and is evaluated as

$$F_{Section} = \sum_{1}^{nC} (F_{Section})_C + \sum_{1}^{nS} (F_{Section})_S \quad (7)$$

where $F_{Section}$ is the section force.

CORRELATIONS WITH EXPERIMENT

SIMULATION OF ABOUTAHA ET AL. (1999) COLUMN SC3

The model was calibrated to simulate the behavior of a half scale cantilever frame column (Column SC3) tested by Aboutaha et al. (1999) at the University of Texas. The column has a length-depth ratio of 2.67.

The width of the specimen is 914.4 mm (36 in.), and its depth is 457.2 mm (18 in.). The longitudinal reinforcement consists of two layers of eight No.8 bars, uniformly spaced along each side of the width of the column with a concrete cover of 38 mm (1.5 inches). No. 3 steel stirrups are provided with a spacing of 406.4 mm (16 inches). The column is tested without axial loads.

A concrete compressive strength of f_c' = 21.9 MPa (3.2 ksi) was used to analyze the reinforced concrete column. A yield stress of longitudinal and transverse reinforcement of f_y = 434 MPa (63.0 ksi) and f_y = 400 MPa (68.0 ksi), respectively, was used in the analysis. The Young's modulus of concrete and steel are E_c = 21900 MPa (3200 ksi) and E_s = 200,000 MPa (29,000 ksi) respectively.

Column SC3 was the control specimen and was tested under cyclic uni-axial bending along the weak axis. The currently developed shear model was used to simulate the experimental cyclic force-displacement response, as shown in Fig. 4 and Fig. 5. The flexural element (Fig. 4) overestimated the shear capacity and did not

capture the pinching behavior well, but the shear element (Fig. 5) estimated well the energy dissipation and shear capacity. Column SC3 was reinforced with a very small amount of transverse steel (0.096%), and because of this small confinement, the transverse steel yielded early, and pinching occurred, which resulted in shear degradation.

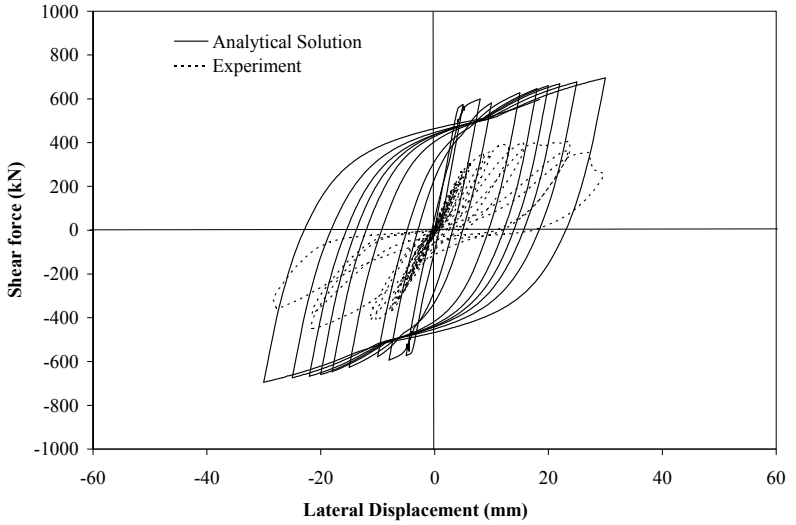

Fig. 4 Cyclic shear force displacement comparison with experiment and flexural element

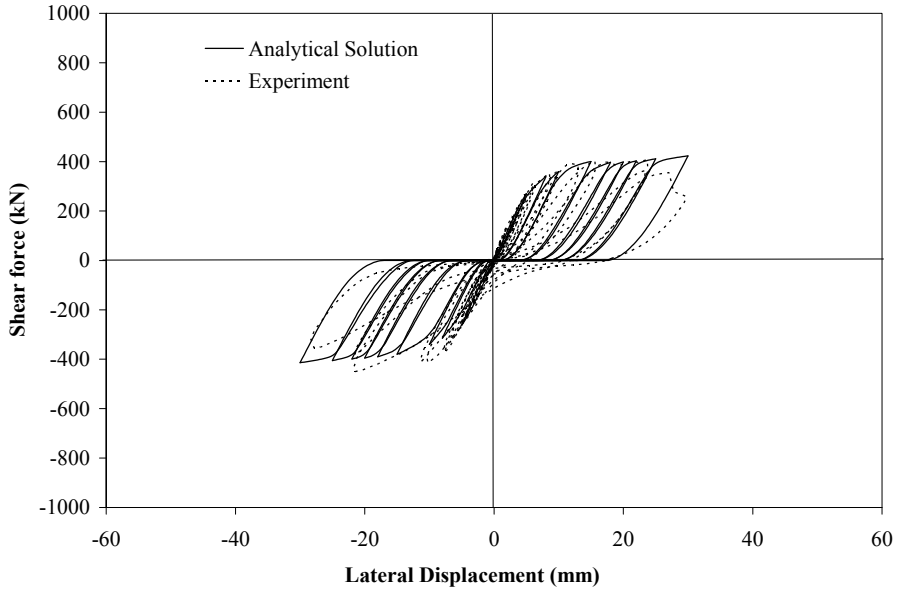

Fig. 5 Cyclic shear force displacement comparison with experiment and shear element

SIMULATION OF XIAO AND MARTIROSSYAN (1998) COLUMN HC4-8L 16-T6-0.2P

As shown in Table 1, six mixtures of Self Consolidated Concrete (SCC) were studied by Gao et al (2009) and used for the analysis of the column tested by Xiao and Martirossyan (1998) at the University of Southern California, Los Angeles. The binder weight is the total weight of cement and CNF. CNFSCC07-LO, CNFSCC10-LO, CNFSCC15-LO, CNFSCC20-LO and CNFSCC25-LO denote self-consolidating concrete containing the CNF PR-19- XT-LHT-OX in amounts of 0.7%, 1.0%, 1.5%, 2.0% and 2.5% by volume of binder, respectively.

The peak compressive strength varies as follows (Table 2): CNFSCC10-LO > CNFSCC15-LO > SCC > CNFSCC07-LO > CNFSCC25-LO > CNFSCC20 -LO and is increased 21.4% compared to plain SCC when the CNF concentration is 1.0%. This indicates the threshold of the concentration is around 1.0% and gives higher energy dissipation.

Table 1 Mixing proportions

Mix	Carbon nanofiber (vol% binder)	Water (kg m^{-3} concrete)	Cement (kg m^{-3} concrete)	Coarse aggregate (kg m^{-3} concrete)	Fine aggregate (kg m^{-3} concrete)	High-range water reducer (fl.oz./cw)	Antifoam (fl.oz./cw)
SCC	0	191	480	901	1005	11	0
CNFSCC07-LO	0.7	191	478	902	1008	7	11
CNFSCC10-LO	1	191	478	902	1008	11	11
CNFSCC15-LO	1.5	191	478	902	1008	19	11
CNFSCC20-LO	2	191	478	902	1008	23	11
CNFSCC25-LO	2.5	191	478	902	1008	35	11

Table 2 Carbon-nanofiber concrete destructive properties

Concrete	Strength MPa	Peak strain ε_0
SCC	45.5	0.0017
CNFSCC07-LO	44.7	0.0018
CNFSCC10-LO	55.2	0.0025
CNFSCC15-LO	51.2	0.0023
CNFSCC20-LO	43.8	0.0022
CNFSCC25-LO	44.3	0.0023

An axial load of 1068 kN (240 kip) was applied constantly on the column. Rotations were fixed at the column bottom and top so that the column deformed anti-symmetrically with respect to the mid-height under combined axial and lateral loading. In the numerical analysis, the column was divided into several finite elements until convergence was achieved. Column HC4-8L16-T6-0.2P had low shear reinforcement ($\rho_s = 1.63\%$), and was analyzed under monotonic uni-axial bending.

The width of the column section is 254 mm (10 in.), and its depth is also 254 mm (10 inches). The longitudinal reinforcement consists of eight No. 16 (15.9 mm (0.63-inch) diameter) bars, uniformly spaced along the perimeter, with a clear cover of 13 mm (0.51 inches). No. 6 (6.4 mm, 0.25-inch diameter) steel stirrups are provided with a spacing of 51 mm (2 inches).

Concrete compressive strengths and concrete strains at peak strength were taken from the test results of Gao et al (2009) which are given in Table 2. The ultimate strain of concrete was taken same for all types of mixtures for this example but actually the ultimate strain will be higher for the concrete with CNF. A yield stress f_y = 510 and 449 MPa (74 and 65.12 ksi) is being used for the longitudinal and transverse reinforcements. Young's modulus of concrete and steel are E_c = 45,500 MPa (6600 ksi) and E_s = 200,000 MPa (29,000 ksi), respectively.

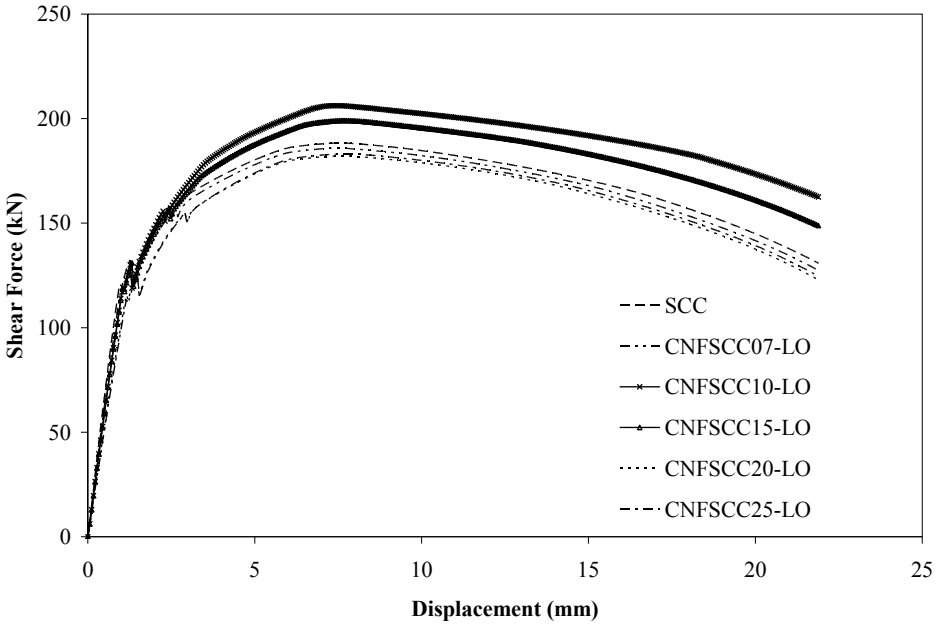

Fig. 6 Load-displacement relation of CNF with different mixtures

As shown in Fig. 6, the shear resistance of the column is in order of CNFSCC10-LO > CNFSCC15-LO > SCC > CNFSCC07-LO > CNFSCC25-LO > CNFSCC20 –LO. Shear resistance was increased 9% compared to plain SCC when the CNF concentration is 1.0%. Longitudinal and transverse reinforcement yielded early for the column made up of SCC compared to the column made up of CNFSCC10-LO. The column failed in shear after core degradation of the concrete.

CONCLUSIONS

This work represents a new approach to the numerical analysis of structures made up of non-linear carbon- nanofiber (CNF) concrete. A Fiber beam element was developed to analyze the CNF structure with the incorporation of mechanisms of shear deformation and strength. The emphasis of the paper is on the evaluation of the

effect of orthotropic model parameters to account for shear sensitive structures and the action of transverse reinforcement. The section deformations are determined from the strain state using the classical plane section hypothesis. The proposed model is able to capture the interaction between axial, flexural, and shear responses. The results of a numerical correlation with the experimental results of a bridge pier section show that the model is able to capture the shear failure and provides reasonable results.

ABSTRACT

Post-earthquake functionality of essential facilities, like hospitals, relies heavily on operation of its nonstructural components such as piping systems, fire suppressors, elevators, and medical equipments. This paper presents the findings from experiments performed on welded and threaded hospital piping subassemblies, with and without cable braces, subjected to various intensities of equivalent inter-story drift. The subassemblies were tested between a stationary frame and a biaxial shake table with an input motion compatible with ICC-ES AC156. A simplified computational model was developed in SAP2000 and calibrated with the experimental data. The model was used to investigate the dynamic characteristics of the piping subassemblies. The effective stiffness of the cable bracing system was found from the computational model to be approximately 10% of full stiffness due to initial looseness that typically exists in piping bracings.

INTRODUCTION

In recent earthquakes, nonstructural components of hospitals and medical facilities have suffered severe damage, consequently interrupting the functionality of these facilities (OSHPD 2010). The 1971 San Fernando Earthquake caused excessive damage to many hospitals and medical facilities, which led to evacuation of four of the eleven damaged medical facilities in the area (Wasilewski 1998). Due to this unacceptable performance, the State of California passed the Hospital Seismic Safety Act in 1973, which requires medical facilities to remain operational after earthquake events.

The costs of repair and replacement of non-residential buildings after the Northridge earthquake was $6.3 billion, with only $1.1 billion due to structural damage (Kircher 2003). Immediately after this earthquake, 88% of the hospital beds in the damaged area (13 hospitals) had to be evacuated because of nonstructural damage such as elevator failure, water damage, etc. (Ayres and Phillips 1998). Hospitals built in accordance with the 1973 Hospital Act were successful in resisting structural damage. However, damage to nonstructural components (plumbing, ceiling systems, etc.) in post 1973 construction was still extensive, emphasizing the urgent need to better understand the general seismic behavior of these systems and specifically that of piping systems.

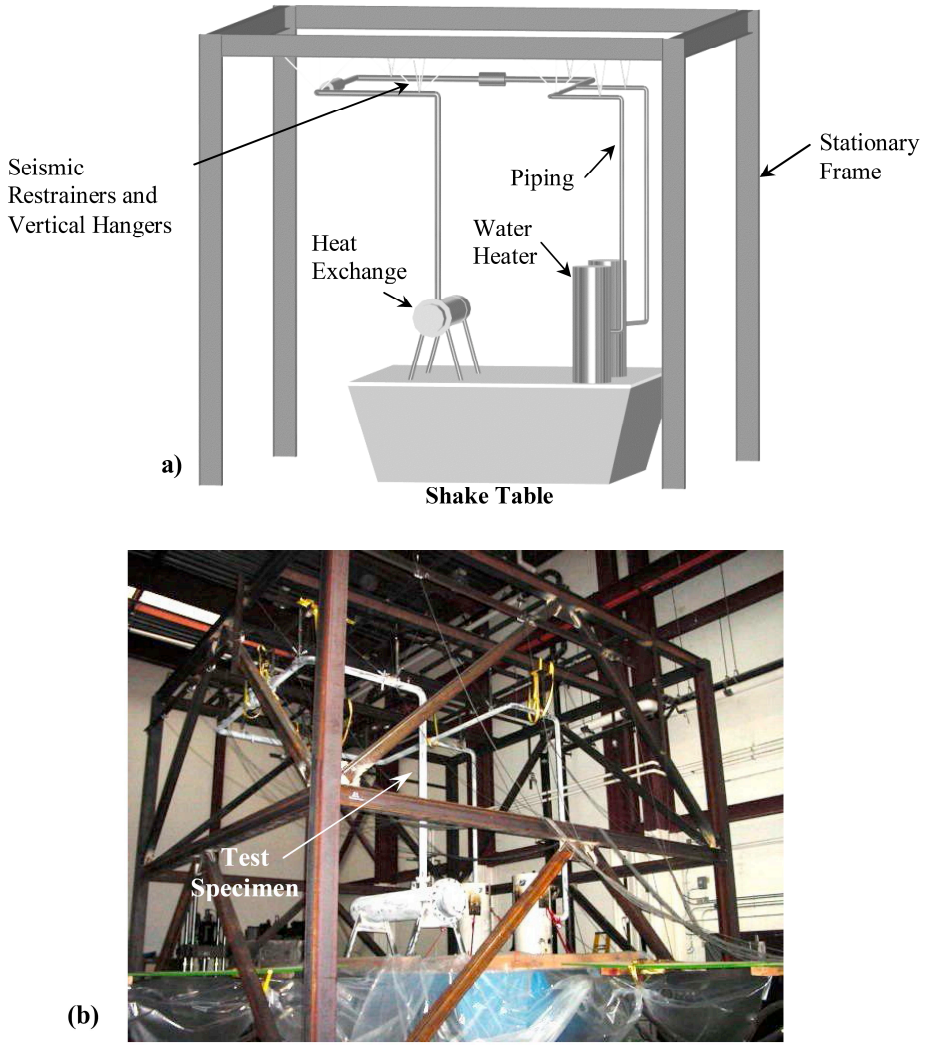
In an earthquake, inadequately or improperly restrained piping systems may suffer damage as a result of large differential movement of the system or from impacts with adjacent structural and nonstructural components. Several entities have provided seismic restraining guidelines and design provisions for piping systems and other nonstructural components: the National Fire Protection Association has had seismic restraint guidelines since 1939 (NFPA 2007); the Seismology Committee of the Structural Engineers Association of California (SEAOC) has published seismic restraint guidelines for fire sprinkler piping since 1959 (SEAOC Blue Book 2006); and the Sheet Metal Industry Fund of Los Angeles published the Guidelines for Seismic Restraint of Mechanical Systems in 1976 (SMACNA 2008) to restrict the movement of piping systems. As one of the most recent efforts, American Lifeline Alliance, a partnership between the Federal Emergency Management Agency (FEMA) and the American Society of Civil Engineers (ASCE), has published Seismic Design and Retrofit of Piping Systems (ALA 2002).

This paper presents the results of a series of experimental and analytical studies of typical hospital piping assemblies that was conducted at the Large Scale Structure Laboratory of the University of Nevada, Reno. Based on the results of these experiments, a simplified computational model was developed as part of this study using SAP2000 finite element analysis packages (CSI 2009).

EXPERIMENTAL INVESTIGATION

Welded and threaded piping assemblies were subjected to a series of simulated ground motions using a biaxial shake table at the *NEES Equipment Site* at the University of Nevada, Reno. These experiments were conducted on piping systems with and without seismic cable restrainers.

Test Setup. The piping assemblies were comprised of two water heaters, one heat exchanger, three riser branches, and horizontal runs. The assembly was fixed on the shake table and hung from, or restrained to, a stationary frame that was attached to the laboratory floor (Fig. 1a and 1b). The piping assemblies were tested under horizontal seismic excitations, allowing investigation of the response of the piping systems to the imposed inter-story drifts expected to occur between adjacent floors of a multistory building. This test setup was capable of imposing realistic differential inter-story displacements on the piping assembly; however, since the frame used to suspend the piping assembly was fixed on the lab floor, the accelerations were not representative of actual field responses in which the floors supporting a piping system also respond to the ground excitation. A computational model was developed to study the response characteristics of the piping assembly and their importance on the assembly's response to realistic inter-story drifts. This model was calibrated using the experimental results.



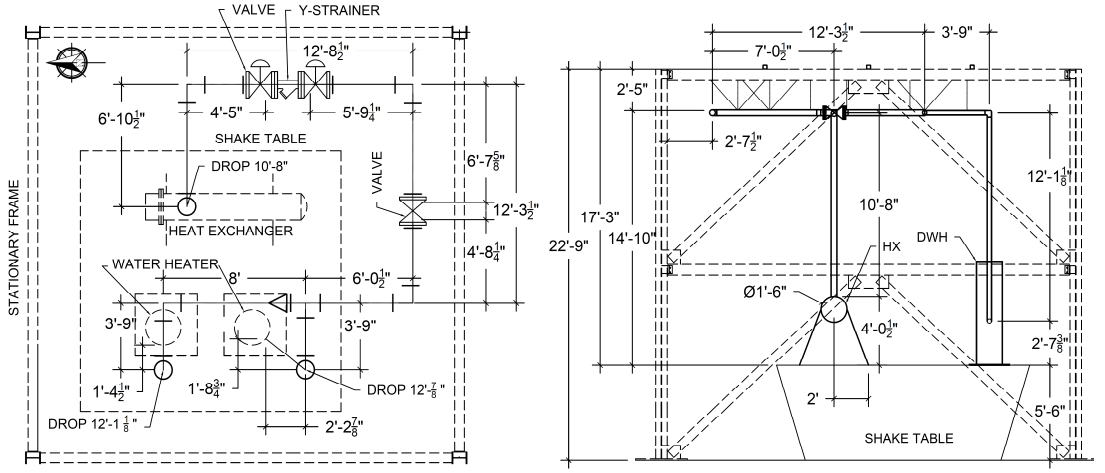


Figure 2. Experimental Setup a) Schematic of the Setup, b) Final Setup.

Piping Assembly Test Specimens. In consultation with California Office of Statewide Health Planning and Development (OSHPD) engineers, a partial system of hospital piping was selected to resemble a piping configuration used in the University of California, Davis Medical Center. The system was slightly modified to accommodate the dimensions and geometrical restrictions of the shake table. The system was tested with welded and threaded connections in separate test specimens with the same geometry, valves, and bracing layout.

Figures 2 and 3 show the plan and elevation view of the piping layout and major components. The piping assembly was made up of 3" and 4" schedule 40 ASTM A53 grade-B black steel pipe with outer diameter and thickness of 3.5 in and 4.5 in, and 0.216 in and 0.237 in, respectively. The specimen included a heat exchanger and two water heaters that were attached to the shake table. The water heaters were connected to the 3" pipes through four-bolt flanged connections. The heat exchanger and all valves were connected to the 4" pipes through eight-bolt flanged connections. A combination of one y-strainer (61 lbs) between two gate valves (83 lbs/valve) and a separate check valve (80lbs) were installed on the horizontal run.

(a) **(b)**

Figure 2. a) Plan View of Piping Subassembly, b) Elevation View of Piping Subassembly.

In the welded assemblies, all fittings, including the flanges and elbows, were made of forged steel. The fittings on the threaded assemblies were made of cast iron. The pipes with threaded joints were secured with enough torque to engage all of the threads in the fitting. The pipes were filled with water under hydrostatic pressure prior to the experiment to account for the additional mass of water and to detect any leakage in the system.

Hangers and Seismic Restraining. Each of the two test assemblies (threaded and welded) was tested with and without seismic restraining. Cable restrainers were used as seismic bracings as shown in Figure 3. Cable restrainers were originally designed to restrain displacements of isolated systems, but they have shown to be a preferred pipe restrainer system because of their effectiveness and ease of installation (Manson

2009). The restrainer cables used in the test setup were made of ⅛-in diameter galvanized 7 x 19 (number of strands x wires per strand) aircraft grade steel with a specified minimum break strength of 1700 lb. The vertical hanger rods were of two sizes: ⅝-in diameter all-thread rod for supporting the 4" pipe, and ½-in diameter all-thread rod for supporting the 3" pipe. The vertical hanger rods were braced laterally along their length with a 1⅝-in square, 12-gauge strut to prevent buckling of the hanger rods.

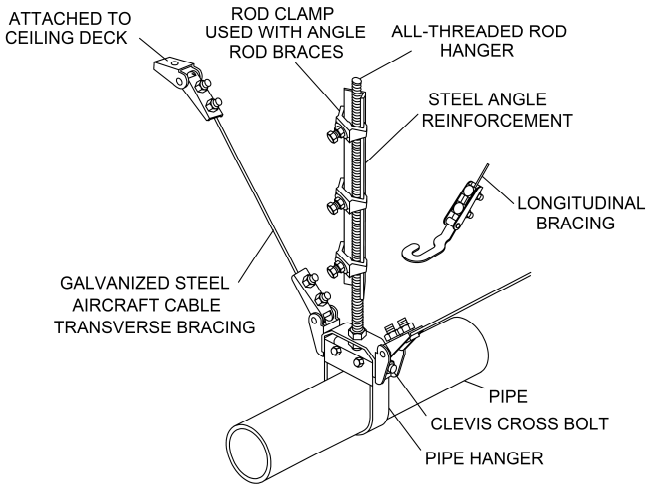

Figure 3. Seismic Bracing Details.

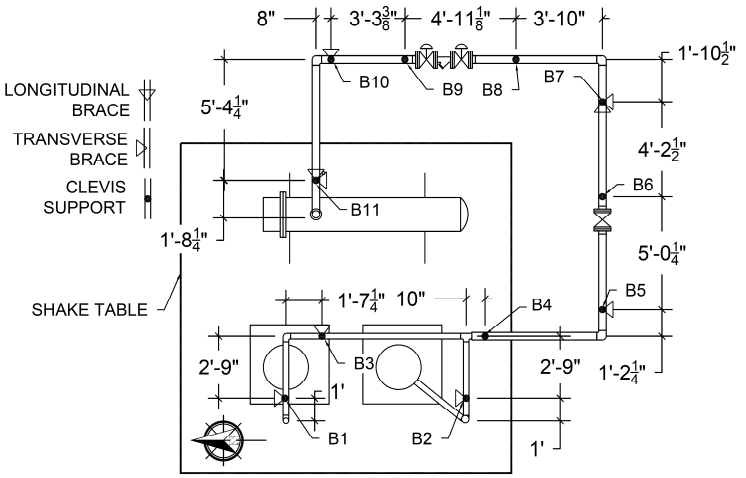
Of a total of eleven vertical support points, seven were used to attach cable restrainers and four were used only as hanger points. Two of the seven restraining points had cable restrainers in both the longitudinal and lateral directions. Figure 4 shows the bracing layout. In this figure, the letter "H" designates a point of vertical support (hanger) and the letter "B" tags a seismic restraining point. For unrestrained piping assemblies, all of the cable restrainers, the strut braces around the hanger rods, and the cross bolts in clevises (shown in Fig. 3) were removed to reflect the unbraced condition of piping systems seen in the field.



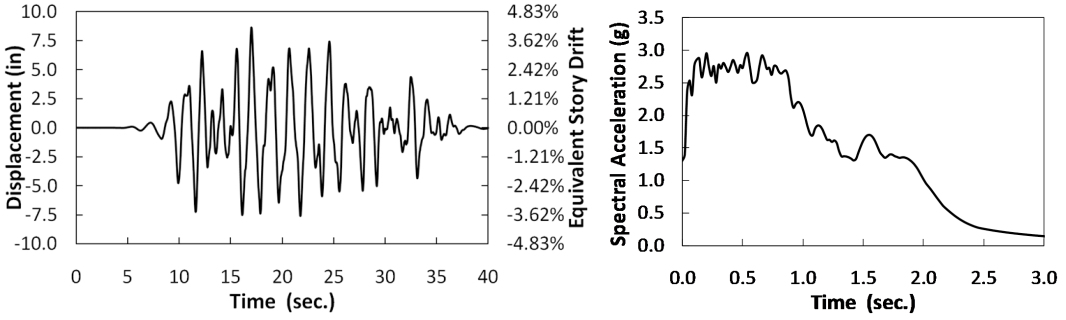


Figure 4. Bracing Layout.

Table Input Motion. The ICC-ES AC156 testing protocol (ICC Evaluation Service, Inc. 2007) was considered after consulting OSHPD engineers. The program SIMQKE (Gasparini 1976) was used to generate a synthetic table input motion compatible with the requirements of AC156 assuming conservative values that are typical of Seismic Design Category D. The peak acceleration and peak displacement of the full scale motion were 1.31g and 8.65 in, respectively. The achieved table motion is shown in Fig. 5a and the 5% damped pseudo-acceleration spectrum of the achieved motion is plotted in Fig. 5b. This input motion subjected the specimen to an equivalent maximum inter-story drift of 4.3%.

Each experimental model was subjected to increasing intensities of the input motion. These excitations were applied independently along each of the main axes, referred to as N-S, E-W. Biaxial excitation was also applied along 45° with respect to these axes (Goodwin et al., 2005).

Figure 5. a) Achieved Shake Table Motion, b) Spectral Acc. of the Table Motion

EXPERIMENTAL RESULTS

Dynamic Properties. Prior to the experiments, the models were subjected to sine sweep excitation in order to identify the dynamic characteristics of the system. The average of acceleration transfer functions between table and the pipe at each of the four corners of the piping assembly was used to identify the frequencies of the first three modes of vibration of each model.

Table 1 presents the frequencies of the four models. Higher frequency values of the braced system as compared to the corresponding values of the unbraced system are due to the effect of added stiffness of the cable restrainers. Dynamic characteristics of the welded and threaded system were comparable and indicated that the rigidity of the threaded connections was similar to that of welded joints.

Table 1. Frequencies of the Piping Subassembly Model.

Subassembly Type	Frequency (Hz)		
	1st Mode	2nd Mode	3rd Mode
Welded Braced	2.98	4.56	6.51
Threaded Braced	2.76	4.1	6.17
Welded Unbraced	1.63	2.61	3.66
Threaded Unbraced	1.61	2.33	3.86

Measured Data. An arrangement of different instruments was installed on the test assembly to measure its seismic response. Figure 6 shows the four representative points of measured responses. The measured displacements (or drifts) are denoted as Δ_1, Δ_2, Δ_3, and Δ_4, and the accelerations are denoted as Acc_1 and Acc_2. Drifts were calculated by dividing the measured displacements by the clear distance between table and stationary frame.

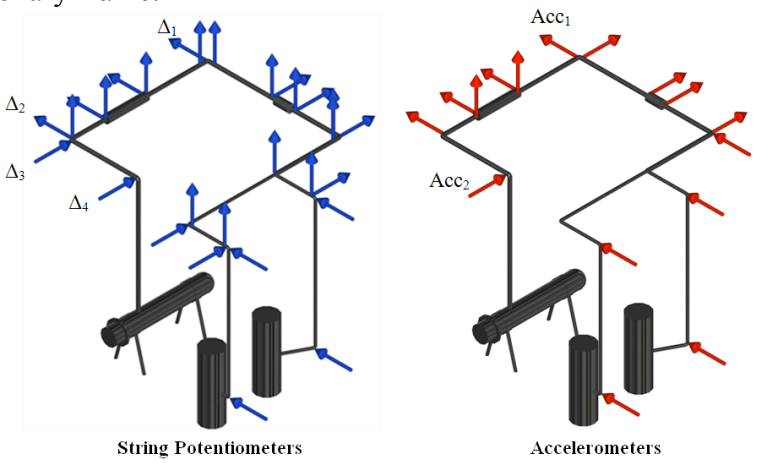

Figure 5. Instrumentation Configuration

Figures 6a and 6b show the maximum measured accelerations, Acc_1 and Acc_2, versus the corresponding maximum drifts, Δ_1 and Δ_4, in progressive biaxial motions of the welded assembly. Figure 11a shows that the maximum accelerations in E-W direction increased by increasing drifts. In contrast with E-W direction, the accelerations in N-S direction stopped increasing for drifts larger than approximately 2.5% as displayed in Fig. 11b, implying the piping assembly yielded thereafter. These figures also reveal that the accelerations of restrained and unrestrained systems are comparable.

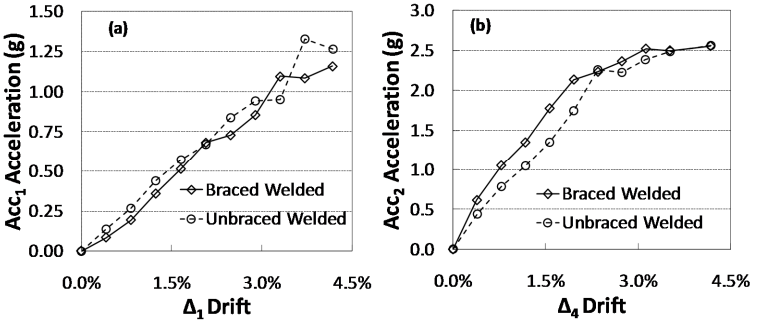

Figure 5. Acceleration Response versus Drift

In Fig. 7, Δ_4 in the restrained welded assembly is compared with the corresponding value of the threaded one at 70% IM that the system was still elastic. Responses of the systems were essentially similar, indicating that the type of fittings (threaded or welded) did not change the dynamic response of the piping system.

Figures 8a and 8b display Δ_1 and Δ_4 displacement histories of the welded assembly at 70% IM. The displacements of the unrestrained system were significantly larger than those of the restrained system. This observation signifies that seismic

restraining is necessary when the displacement of piping systems may impose damage to other adjacent components by impacting them.

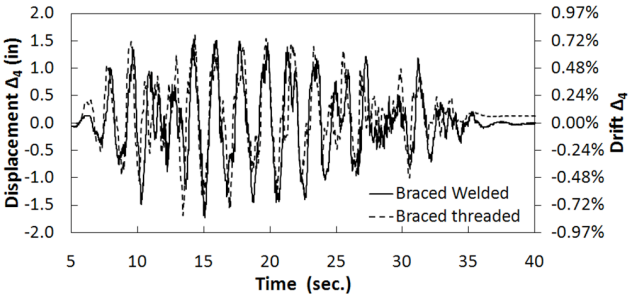

Figure 7. Comparison of Welded and Threaded Systems at 70% MI

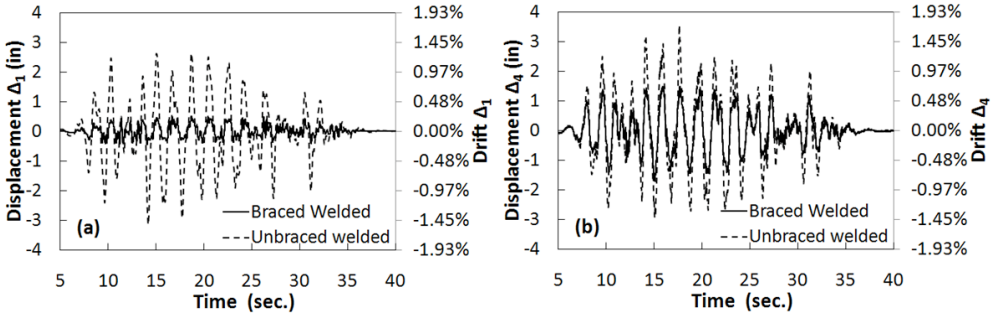

Figure 8. Comparison of Responses of Braced and Unbraced Systems at 70% MI

COMPUTATIONAL MODEL OF THE SPECIMENS

The purpose of the computational modeling was to develop a simplified method that can be employed in the design procedure of piping systems. The experimental data was used to calibrate the response of the seismic cable restrainers and validate the computational model.

Development of a Simplified Computational Model. The SAP2000 software (CSI 2009) was utilized for computational modeling. Pipes were modeled as linear elastic frame elements with gross pipe section properties. The mass of water inside the pipes was included in the model as additional distributed massed on the pipe members. The connections of the pipes to the heat exchanger and heaters were assumed rigid in all directions except rotationally about the longitudinal axis of these equipments. Joint areas were not explicitly modeled. The achieved table motion was defined as the support displacement history in the direction of shaking.

Preliminary analyses showed that if full stiffness of the cable restrainers is used, the computed response and dynamic properties are very different from the experimental results. The main reason was found to be the flexibility of the clamps and clevises and the initial slack in the cables. This initial slack in the restrainers was also discussed by Hoehler et al. (2009). To better represent the initial conditions of the seismic restrainers in the model, an equivalent effective axial stiffness was used for the cables. To keep the model simple, any sophisticated elements such as gaps or nonlinear links were not used.

Figure 9 shows the expected load-displacement relationship of an elastic system with an initial looseness. This figure shows that the maximum "effective" stiffness increases when displacement increases. The effective stiffness should be adjusted for the anticipated or target displacements.

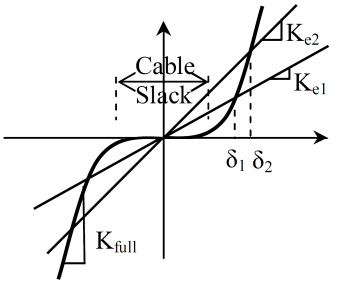

Figure 9. Effective Stiffness of Cable Restrainers Due to Looseness

By matching the dynamic properties of the computational model and the experimental specimen at 50% IM, the effective stiffness of the cable restrainers was discovered to be 1/10 of the gross section of the cables to account for the initial slack. By using 10% of full stiffness of the cable restrainers, frequencies of the first three modes of vibration for the restrained assemblies were calculated as 3.21 Hz, 4.15 Hz, and 6.02 Hz, respectively. The calculated frequencies for the unrestrained system were 1.81 Hz, 2.43 Hz, and 3.36 Hz for the first three modes.

Figures 10a, b compare the computational and experimental Δ_2 displacements for the restrained and unrestrained welded assemblies under 50% IM. The error differences between the analytical and computational displacement results are less than 10%. This is acceptable considering the simplicity of the analytical model.

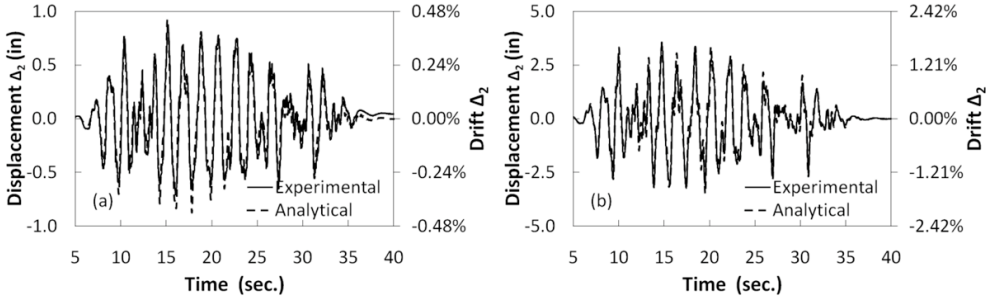

Figure 10. Δ2 under E-W 50% IM, a) Braced Welded System, b) Unbraced Welded System

Kinematic and Dynamic Responses. A piping system installed between two floors of a building is essentially a dynamic system that is subjected to differential support excitation during an earthquake. Figure 11 shows a mass-spring simplified SDOF model of the test assembly. In this model, K_p is the total lateral stiffness of the vertical pipe risers, and K_r is the total lateral stiffness of seismic restrainers that attach the piping to the stationary frame. The dynamic influence vector can be found from the partitioned stiffness matrix of the mass-spring system, according to the methodology described in Chopra (2007). The dynamic influence vector of the piping system is:

$$\iota = \left[\frac{K_p}{K_p + K_r} \quad \frac{K_r}{K_p + K_r} \right] \tag{1}$$

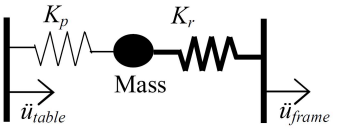

Figure 11. Equivalent Mass-Spring Model

The effective acceleration will be obtained by multiplying the dynamic influence vector by the support excitation vector. Accordingly, the effective inertial force is:

$$P_{eff} = \frac{m}{K_p + K_r}\left(K_p \ddot{u}_{table} + K_r \ddot{u}_{frame}\right) \tag{2}$$

In Equation 2, $\ddot{u}_{table}$ and $\ddot{u}_{frame}$ are the acceleration histories of the shake table and the supporting frame, respectively. The stationary frame was fixed in all experiments, and the test assembly was excited only through movement of the shake table; therefore, the second portion of Eq. 2 can be discarded. For such a system, the dynamic influence coefficient is the ratio of the pipe stiffness to the summation of stiffnesses of the pipes and restrainers. For the restrained assemblies this coefficient was about 0.25, which implies that the mass sensed 25% of table accelerations and displacements.

Response of a system under multiple support excitations is comprised of kinematic and dynamic effects (Chopra, 2007) as shown in Eq. 3; in this equation, ι is the influence vector as introduced in Eq. 1, u_g is the support displacement vector, and u is the dynamic response. The kinematic response is static deformations due to the imposed differential support displacements.

$$u_{total} = \iota u_g + u \tag{3}$$

The computational model was used to study the significance of the inertial effects shown in Eq. 2 on the total response of the piping system. To accomplish this, all the masses were removed from the model, and the model was subjected to 50% IM biaxial table motion and 100% IM biaxial roof motion to produce 2.17% inter-story drift in each direction. Response of the massless system (kinematic response) was compared to dynamic response, which was calculated by subtracting the kinematic response from the response of the system with real masses and subjected to the same support excitations.

Figure 12a, b shows the dynamic and kinematic portions of Δ_2 and Δ_3. For these points, the maximum dynamic responses were approximately 10% and 30% of the kinematic responses, respectively. Measured data show that the dynamic effects are insignificant compared to the kinematic deformations experienced by the tested restrained piping system. Therefore, for a similar piping system running between the adjacent floors of a building, the displacements imposed to the system due to the differential floor motions is larger than the dynamic responses. This conclusion may not apply to the piping systems that primarily run horizontally beneath the floors, or to systems composed of large diameter pipes that mobilize large inertial loads. Furthermore, considering the small spacing used between the restrainers in the test assembly, real piping systems with larger spacing between restrainers may experience large inertial forces.

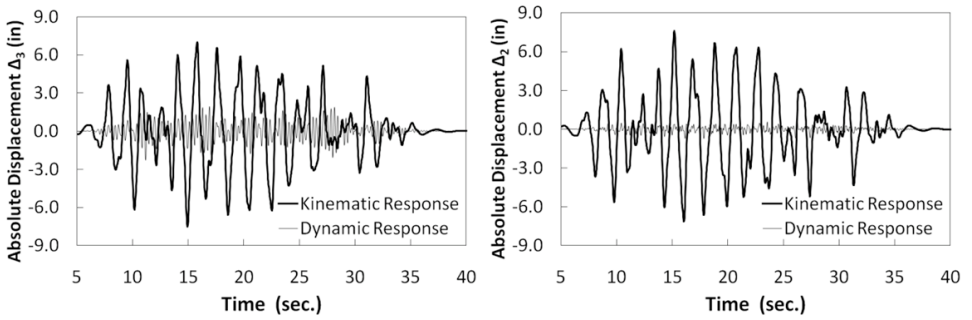

Figure 12. Analytical Dynamic and Kinematic Responses under 50% IM Table and 100% IM Roof Biaxial Motion

SUMMARY AND CONCLUSIONS

The objective of this research was to identify dynamic characteristics of typical hospital piping assemblies by subjecting them to different levels of dynamic inter-story drifts. One of the assemblies used welded connections whereas the other used threaded connections. The piping assemblies were hung from a stationary frame that was installed outside the table on the laboratory floor. The assemblies were tested using a synthetic input motion. Both assemblies were tested with and without cable seismic restrainers. Subsequent to the experimental studies, a simplified computational model was developed in SAP2000 to better understand the effects of different parameters on the response of the system.

The following observations and conclusions are drawn from the presented experimental and computational studies; however, designers should be mindful of the differences between the boundary conditions of the test assembly and piping systems supported by building floors.

- The seismic restrainers did not have a major effect on the acceleration response of the piping assemblies, though they were effective in limiting displacement responses.
- The flexural rigidities of the threaded and the welded joints were comparable.
- Due to the inherent slack of the cable restrainers, their effective stiffness was found to be one-tenth of the full stiffness.
- The kinematic response of the system comprised less than 23% of the total response. It showed that the dynamic response of a similar piping assembly could be insignificant compared to other structural systems due to the small associated masses.

ACKNOWLEDGEMENTS

This study was funded by the Multidisciplinary Center for Earthquake Engineering Research (MCEER) through a grant from the Earthquake Engineering Research Centers Program of the National Science Foundation (NSF) under NSF award number EEC- 9701471. Assistance from Dr. Patrick Laplace and Mr. Paul Lucas of the UNR Large Scale Structures Lab during the assembly and testing is appreciated.

ABSTRACT

As part of the project entitled "*NEESR-GC: Simulation of the Seismic Performance of Nonstructural System,*" a series of system-level full-scale experiments of ceilings-piping-partition systems will be conducted at the University of Nevada, Reno NEES Site. This project is aimed at understanding the seismic response of these systems and their interaction with each other and the parent structure. A two-story, two-bay steel braced frame spanning across three biaxial shake tables was designed as a Test-Bed structure to simulate a variety of dynamic environments. After introducing the design considerations of the Test-Bed structure within this paper, the method proposed to develop the shake table drive motions is explained. To obtain the drive motion, a transfer function (TF) was formulated for a multi-support dynamic system under differential support excitation and combined with a TF previously developed for target floor acceleration of a generic structure. A suitable high-pass filter was suggested to limit exerted demands on the shake tables.

1. Introduction

After an earthquake, the functionality of an essential facility, such as a hospital, relies heavily on the functionality of its nonstructural components, such as piping systems, fire suppression systems, elevators, and other equipment. In recent earthquakes, nonstructural components of hospitals and medical facilities have suffered severe damage, which consequently interrupted the functionality of these facilities (OSHPD, 2010). The 1971 San Fernando Earthquake caused excessive damage to many hospitals and medical facilities, which led to evacuation of four of the eleven damaged medical facilities in the area (Wasilweski, 1998). Due to this unacceptable performance, the State of California passed the Hospital Seismic Safety Act in 1973, requiring medical facilities to remain operational after earthquake events.

The repair and replacement costs of nonresidential buildings after the Northridge earthquake were $6.3 billion, with only $1.1 billion of the total in structural damage (Kircher, 2003). Immediately after this earthquake, 88% of the occupants of the hospital beds in the damaged area (13 hospitals) had to be evacuated as a result of nonstructural damage such as water damage, elevator failure, etc. (Ayres et al., 1998). Hospitals built in accordance with the 1973 Hospital Act, however, were successful in resisting structural damage. Nevertheless, nonstructural damage (plumbing, ceiling systems, etc.) in post 1973 construction was, and still is, extensive after strong seismic activities. This shows an urgent need to better understand the seismic behavior of nonstructural systems.

Extensive systematic experimental data is required as a supplement to previous experience to improve available nonstructural design provisions. Several studies have been conducted on the seismic response of nonstructural subassemblies and their components as early as 1980s on ceiling tiles and piping systems (ANCO, 1983; Hoehler et al., 2009; ATC, 2007); however, the understanding on the system-level response of these subassemblies is significantly limited necessitating the design of large-scale experiments on complete systems (Zaghi, 2010).

As a part of the NEESR Grand Challenge project "*Simulation of the Seismic Performance of Nonstructural Systems*," a large scale Test-Bed structure is constructed to conduct system-level experiments of full-scale, complex, nonstructural systems. The NEES earthquake simulator (three biaxial shake tables) at the Large Scale Structure Laboratory of University of Nevada, Reno will be used to subject the Test-Bed structure and nested nonstructural systems to desired levels of dynamic excitations.

Nonstructural components can be divided into two categories in terms of seismic performance: 1) acceleration sensitive elements such as ceiling and horizontal pipe runs; and 2) drift sensitive components, including partition and riser pipes. The Test-Bed structure is designed in a way that it can subject the nested subassemblies to large accelerations as well as large inter-story drifts.

Before describing the methodology used for the development of the shake table input motion, a brief review of the NEESR Grand Challenge is presented, followed by the design philosophy and provisions of the proposed Test-Bed structure.

2.NEESR Nonstructural Grand Challenge Project

The Grand Challenge Project entitled "Simulation of the Seismic Performance of Nonstructural Systems"(http://www.nees-nonstructural.org) integrates multidisciplinary system-level studies that develop, for the first time, the simulation capabilities and implementation process for enhancing the seismic performance of ceiling-piping-partition (CPP) nonstructural systems. This project is led by the University of Nevada, Reno in collaboration with the Consortium of Universities for Research in Earthquake Engineering (CUREE), Cornell University, Georgia Institute of Technology, North Carolina Agricultural and Technical State University, North Carolina State University, Rutherford & Chekene, State University of New York at Buffalo, and University of California, San Diego. In the first experimental phase of the project, a comprehensive testing program is using the University at Buffalo and the University of Nevada, Reno NEES Equipment Sites to conduct full-scale subsystem and system-level experiments, respectively. The main objective of the subsystem level test series is to characterize the seismic performance of CPP systems and to provide the input for the design and execution of system-level experiments at the University of Nevada, Reno. This paper reports on design considerations and characteristics of UNR Test-Bed structure.

3.Test-Bed Structure Design Philosophy

To achieve the objectives of system-level experimental investigation, several key requirements were identified, particularly with respect to the design of the Test-Bed structure. During the experiments, it will be utmost importance to simulate experimentally and to capture the various types of interactions that will take place among the subassemblies and the parent Test-Bed structure. Moreover, the Test-Bed structure should allow investigators to study the effects of structural yielding on the response of the subassemblies. A discussion of the performance design concepts were utilized in the design of the Test-Bed structure with the provisions follows.

A two-story, two-bay (61ft-long, 12ft-wide, 24ft-high) Test-Bed structure was designed. The dimensions are typical of spans and story heights in multi-story buildings and allow for the installation of full height partition walls as well as large ceiling areas. The longitudinal and transverse views of the frame are presented in Figure1.

Nonstructural components can be divided into two categories in terms of seismic response: 1) acceleration sensitive elements such as ceiling, horizontal pipe runs, and sprinkler heads, and 2) drift sensitive components, including partition and riser pipes. To study both categories, two designs were considered for the Test-Bed structure by implementing two sets of bracing systems. Elastic braces restrained against buckling, used to achieve large floor accelerations, and buckling resistant braces (BRBs), used to produce large inter-story drifts.

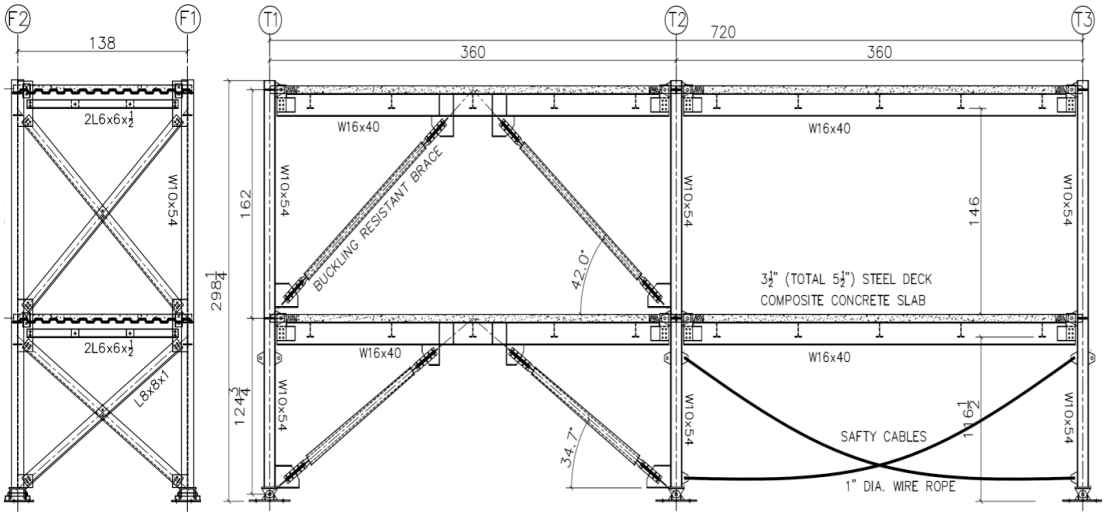

Figure 1: Longitudinal and Transverse Views of the Test-Bed Structure

Although the Test-Bed structure is a two-story frame, it may represent any two adjacent floors of a multi-story building (for instance, the $(j+1)^{th}$ and $(j+2)^{th}$floors) aspresented in Figure 2. This can be achieved by generating table acceleration that gives the first and second floor of Test-Bed structure motions most similar to $(j+1)^{th}$ and $(j+2)^{th}$floor motions of that multi-story building.

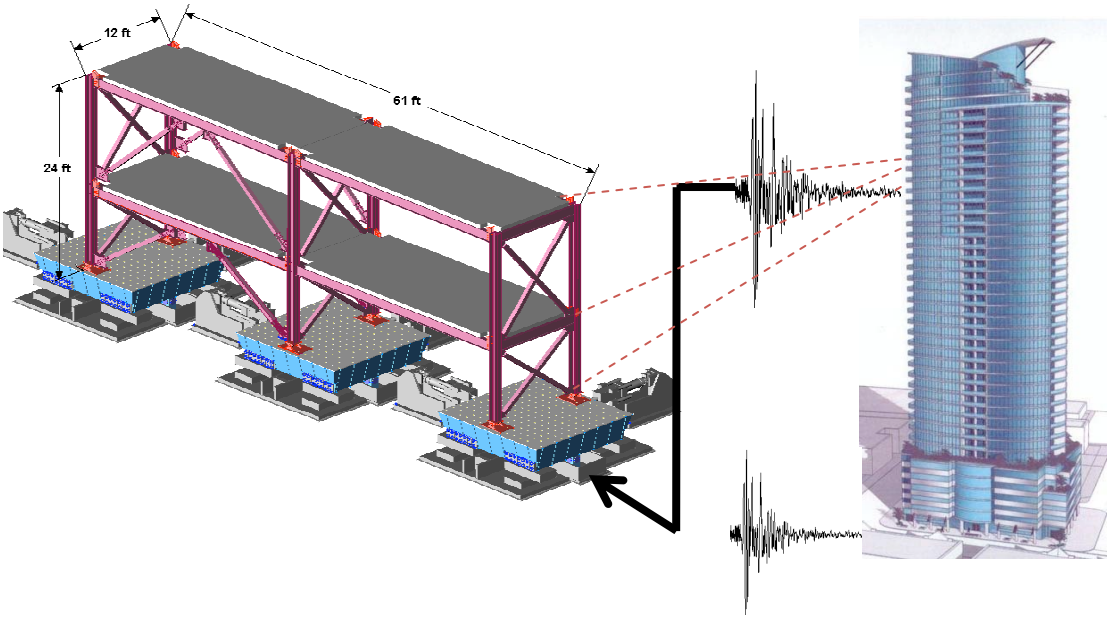

Figure2: Test-Bed Structure on Shake Tables and Two Adjacent Floors of Tall Building Concept

To understand the effects of the nonstructural subassemblies on the seismic response of structures (specifically stiffness, lateral strength, and added damping) structural dynamic characteristics of the Test-Bed structure should be well known,

predictable, and controllable. The Test-Bed structure was designed with 'frictionless' tight-fit hinges in order to avoid any possible deviation of the physical responses from that of numerical models. The column-base and beam-column connections were pinned, minimizing the rotational fixity. The lateral stiffness and strength of the frame is provided by a set of eight brace members that are installed in a chevron configuration. This design methodology allows yielding to take place in predefined members (BRB braces).

The Test-Bed structure is planned to be used for multiple experiments, and therefore, should remain linear-elastic during the shake table testing. Utilization of the buckling restrained members as lateral resisting members enables the Test-Bed structure to be used a number of times after replacement of the yielded braces. Furthermore, to allow for a safe assembly and disassembly of the structure, each floor is divided into two prefabricated 5.5-in thick steel deck concrete composite slabs panels that were built off-site and will be shipped to the laboratory. These floor panels as well as other structural members can be stored in a small area before and after the test.

4. Target Performance of the Test-Bed

Taking the limitations of the shake table into consideration, the Test-Bed was designed to reach the target inter-story drift and peak floor acceleration without exceeding the hydraulic system restraints. The target performances of linear and nonlinear Test-Bed structures are separately discussed in this section.

The test bed is designed for longitudinal excitation. Therefore, the transverse bracing system of the Test-Bed structure was significantly overdesigned to ensure that the longitudinal dynamic modes dominate vibration of the frame.

4.1Nonlinear Test-Bed

This setup was designed to achieve large inter-story drifts similar to that of nonlinear frame structure. This setup was aimed at the evaluation of drift sensitive subassemblies such as in-plane partitions, pipe risers, and riser ducts. Design target of the nonlinear Test-Bed was to achieve an inter-story drift larger than 3% on both stories.

The nonlinear BRBs were designed for 20kips yield force and stiffness of 70kips/in and 59kips/in in the first and second floors, respectively. On each floor 31kips of additional was provided using low profile lead baskets bolted to the floor to provide required inertial forces. The natural period of the structure was calculated as 0.43sec and the effective period of the structure at 3% drift was found to be 1.21sec.

4.2 Linear Test-Bed

This setup was designed to investigate acceleration sensitive subassemblies including ceilings, sprinkler piping, and out-of-plane partitions. The linear Test-Bed was designed to simulate linear or stiff structures in which large floor acceleration is expected. The target peak floor acceleration (PFA) was larger than 2.0g on both

floors.

Because conventional braces required a large cross-section area for local or global buckling requirements, buckling restrained elastic braces were used for the linear structure. This large area increases the elastic stiffness of the structure and as a consequence significantly reduces the effective periods. Although a high frequency Test-Bed experiences large floor accelerations, its period does not fall within the range of practical structures. To avoid yielding of the brace members in the linear structure, strength of the brace members was increased by using higher-grade steel for the brace cores to control the lateral stiffness. The linear BRBs were designed for a yield force of 60kips and stiffnesses of 186 kips/in and 176kips/in in the first and second floors, respectively. An additional mass of 7kips was provided on the first floor and 3.5kips on the second floor to achieve the target period. The natural period of the structure was found to be 0.19sec.

It should be mentioned that the Test-Bed structure may be designed to achieve other performance limits in accordance with the purpose of the experiment.

5. Development of the Shake Table Input Motion

It is evident that if a ground acceleration is used as the shake table input motion, the Test-Bed structure will simulate the response of a two-story building supported on the ground.However, the Test-Bed structure is meant to simulate the floor response of any multistory building: a method was developed as part of this project to allow simulation of floor acceleration responses of multistory buildingsby using the Test-Bed structure.The theory of a reduced-order earthquake demand assessment that is presented in detail by Taghavi and Miranda(2005) was adopted. The absolute acceleration transfer function (TF) was obtained by superposition of modal TFs. This TF was multiplied by the inverse of a TF for the Test-Bed structure that was formulated with theeffect of multi-support excitationin mind.To satisfy the displacement and velocity limitations of the shake-tables, a high-pass filter was added to TF of the system. This method is described in detail in this section.

5.1 Description of Generic Buildings

The dynamic characteristicsof multistory buildings are approximated (Taghavi and Miranda, 2005) by using an equivalent continuum model consisting of a flexural cantilever beam and a shear cantilever beam deforming in bending and shear, respectively (Fig. 3). These flexural and shear cantilever beams were assumed to undergo the same lateral deformation. Under a horizontal acceleration at the base, response of this continuum system can be expressed by the following partial differential equation(Taghavi and Miranda, 2005):

$$\rho(x)\frac{\partial^2 u(x,t)}{\partial(t^2)}+c(x)\frac{\partial^2 u(x,t)}{\partial(t)}+\frac{1}{H^4}\frac{\partial^2}{\partial x^2}\left[EI(x)\frac{\partial^2 u(x,t)}{\partial x^2}\right]-\frac{1}{H^2}\frac{\partial}{\partial x}\left[GA(x)\frac{\partial u(x,t)}{\partial x}\right]=-\rho(x)\frac{\partial^2 u_g(t)}{\partial t^2} \quad (1)$$

where $\rho(x)$ is mass per unit height, $u(x,t)$ is the displacement at normalized height $x$at time t(x variesbetween zero, at the base of the building, and one, at the roof level), H

is the total height of the building,*c(x)* is damping coefficient per unit height,*EI(x)* is flexural rigidity of the flexural beam along the height,*GA(x)* is shear rigidity of the shear beam and $u_g(t)$is the ground displacement at time *t*.

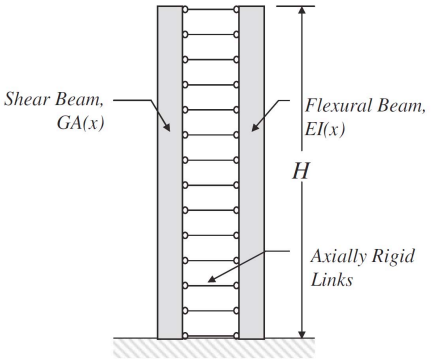

Figure3: GenericModel to Estimate Dynamic Properties of Multi-Story Buildings (Taghavi and Miranda, 2005)

By solving Eq.(1), the shape of the mode of vibration corresponding to the i^{th} mode, normalized to unity at *x=1* is found by:

$$\phi_i(x)=\frac{\sin(\gamma_i x)-\gamma_i\left(\gamma_i^2+\alpha_o^2\right)^{-\frac{1}{2}}\sinh\left(x\sqrt{\gamma_i^2+\alpha_o^2}\right)+\eta_i\left[\cosh\left(x\sqrt{\gamma_i^2+\alpha_o^2}\right)-\cos(\gamma_i x)\right]}{\sin(\gamma_i)-\gamma_i\left(\gamma_i^2+\alpha_o^2\right)^{-\frac{1}{2}}\sinh\left(\sqrt{\gamma_i^2+\alpha_o^2}\right)+\eta_i\left[\cosh\left(\sqrt{\gamma_i^2+\alpha_o^2}\right)-\cos(\gamma_i)\right]} \quad (2)$$

where,

$$\eta_i=\frac{\gamma_i^2\sin(\gamma_i)+\gamma_i\sqrt{\gamma_i^2+\alpha_o^2}\sinh\left(\sqrt{\gamma_i^2+\alpha_o^2}\right)}{\gamma_i^2\cos(\gamma_i)+\left(\gamma_i^2+\alpha_o^2\right)\sinh\left(\sqrt{\gamma_i^2+\alpha_o^2}\right)} \quad (3)$$

In Eq. (2), γ_i is obtained from the solution of the characteristic equation shown as Eq. (4):

$$2+\left[2+\frac{\alpha_o^4}{\gamma_i^2\left(\gamma_i^2+\alpha_o^2\right)}\right]\cos(\gamma_i)\cosh\left(\sqrt{\gamma_i^2+\alpha_o^2}\right)+\left[\frac{\alpha_o^2}{\gamma_i\left(\gamma_i^2+\alpha_o^2\right)}\right]\sin(\gamma_i)\sinh\left(\sqrt{\gamma_i^2+\alpha_o^2}\right)=0 \quad (4)$$

The dimensionless parameter α_o in Eq. (2) controls the degree of participation of overall flexural and overall shear deformations in the genericmodel of multistory buildings. A value of α_o equal to zero represents a pure flexural and a value larger than 30corresponds to a shear dominated deformation for a building. In these equations *i* represent the mode number.

For a continuum model with uniformly distributed mass, themodal participation factor of the i^{th} mode of vibration is given by:

$$\Gamma_i = \frac{\int_0^1 \phi_i(x)dx}{\int_0^1 \phi_i^2(x)dx} \tag{5}$$

Eqs. (2) and (5) were implemented to generate the TF for the absolute acceleration of q^{th} floor of generic building.A method that is discussed in detail in Maddaloni et al.(2010)was utilized to obtain theTFshown in Eq. (6):

$$H_q(\omega) = \sum_{im=1}^{k} \frac{-\left(2i\omega\xi_{im}\omega_{im} + \omega_{im}^2\right)}{\omega_{im}^2 - \omega^2 + 2i\omega\xi_{im}\omega_{im}} \phi_{im,q}\Gamma_{im} \tag{6}$$

Where ω_{im}^2 , Γ_{im} and ξ_{im} are the circular frequency,modal participation factor, and damping ratio of im^{th} mode of generic building, respectively.Only the first $k$significant modes were participated in this derivation. In this equation, $\phi_{im,q}$ corresponds to the value of the im^{th} mode in the q^{th} floor of the building.

5.2 Development of a TF for the Absolute Floor Accelerationof the Test-Bed Structure

The Test-Bed structure is supported on three shake tables.Each shake table respondsslightly different to the drive motion as can be explained by servo-valve control basics. The following formulation for a dynamic system with multiple support excitations wasextended to include the support degrees of freedom (DOFs) in the system TF equations. The matrix form of the equation of motion for the Test-Bed Structure with two dynamic DOFs and three support DOFs can be written as (Chopra AK, 2001)

$$\begin{bmatrix} {}_{2x2}M_{ss} & 0 \\ 0 & {}_{3x3}M_{tt} \end{bmatrix} \begin{bmatrix} {}_{2x1}\ddot{u}_s^t \\ {}_{3x1}\ddot{u}_t \end{bmatrix} + \begin{bmatrix} {}_{2x2}C_{ss} & {}_{2x3}C_{st} \\ {}_{3x2}C_{ts} & {}_{3x3}C_{tt} \end{bmatrix} \begin{bmatrix} {}_{2x1}\dot{u}_s^t \\ {}_{3x1}\dot{u}_t \end{bmatrix} + \begin{bmatrix} {}_{2x2}K_{ss} & {}_{2x3}K_{st} \\ {}_{3x2}K_{ts} & {}_{3x3}K_{tt} \end{bmatrix} \begin{bmatrix} {}_{2x1}u_s^t \\ {}_{1x3}u_t \end{bmatrix} = \begin{bmatrix} 0 \\ {}_{3x1}p_t(t) \end{bmatrix} \tag{7}$$

The total displacements include contributions from dynamic and static displacements as:

$$\begin{bmatrix} {}_{2x1}u_s^t \\ {}_{3x1}u_t \end{bmatrix} = \begin{bmatrix} {}_{2x1}u_s^s \\ {}_{3x1}u_t \end{bmatrix} + \begin{bmatrix} {}_{2x1}u_s \\ 0 \end{bmatrix} \tag{8}$$

Where[M], [C], [K] are the mass, stiffness, and viscous damping matrices, respectively. The vectors [$\ddot{u}$], [$\dot{u}$], [u] are the acceleration, velocity, and displacement, respectively.The superscripts t and s stand for the total and static responses, accordingly. The subscripts t and s are related to the shake table's and the structure's responses, respectively. The $P_t(t)$ is the table force vector.

Equation (7) can be reduced to Eq. (9) after satisfying static equilibrium.

$$_{2x2}M_{ss\ 2x1}\ddot{u}_s(t)+{}_{2x2}C_{ss\ 2x1}\dot{u}_s(t)+{}_{2x2}K_{ss\ 2x1}u_s(t)=-{}_{2x2}M_{ss\ 2x3}\iota_{3x1}\ddot{u}_t(t) \quad (9)$$

Where $_{2x3}\iota=_{2x2}K_{ss}^{-1}{}_{2x3}K_{st}$ describes the influence of support displacements (or accelerations) on structure displacement (or acceleration) at dynamic DOFs.

Dynamic response of the structure may be decomposed in modal coordinates, $q_i(t)$, that $u(t)=\phi_i q_i(t)$ and ϕ_i is the i^{th} mass-normalized mode shape.Assuming that response is composed of harmonic functions, Eq. (9)can be transformed to Eq. (10) infrequency domain:

$$-\omega^2 q_i(\omega)+2i\omega\xi_i\omega_i q_i(\omega)+\omega_i^2 q_i(\omega)=-{}_{1x2}\Gamma_{i\ 2x3}\iota_{3x1}\ddot{u}_t(\omega) \quad (10)$$

where $\left(\phi_i^T K_{ss}\phi_i\right)/M_{ss,i}^*=\omega_i^2$ is the circular frequency and $\left(C_{ss,i}^*/M_{ss,i}^*\right)/2\,\omega_i=\xi_i$ is the damping ratio of i^{th} mode of vibration.

The absolute acceleration response vector, $\ddot{u}_s^t$, for the Test-Bed structure with two horizontal dynamic DOFs is the summation of the relative acceleration vector and the influence of table acceleration:

$$_{2x1}\ddot{u}_s^t(\omega)=\sum_{i=1}^{2}-\omega^2{}_{2x1}\phi_i q(\omega)_i+{}_{2x3}\iota_{3x1}\ddot{u}_t(\omega) \quad (11)$$

Equation (11) was pre-multiplied by $\left({}_{1x2}\phi_i^T{}_{2x2}M_{ss}\right)=-{}_{1x2}\Gamma_i$ and combined with Eq. (10) to obtain:

$$_{1x2}\phi_i^T{}_{2x2}M_{ss\ 2x1}\ddot{u}_s^t(\omega)=\frac{-\left(2i\omega\xi_i\omega_i+\omega_i^2\right)}{\omega_i^2-\omega^2+2i\omega\xi_i\omega_i}{}_{1x2}\Gamma_{i\ 2x3}\iota_{3x1}\ddot{u}_t(\omega) \quad (12)$$

The mode shape is mass normalized, $\Phi^T M=\Phi^{-1}$, thus Eq. (12) can be manipulated to achieve the absolute acceleration of the j^{th} floor of the Test-Bed structureas:

$$\ddot{u}_s^t(\omega)_j=\left[\sum_{i=1}^{2}\frac{-\left(2i\omega\xi_i\omega_i+\omega_i^2\right)}{\omega_i^2-\omega^2+2i\omega\xi_i\omega_i}\phi_{i,j\ 1x3}\kappa_i\right]_{3x1}\ddot{u}_t(\omega) \quad (13)$$

The term shown in the bracket is a TF that relates the accelerations of shake tables to the absolute floor acceleration of the Test-Bed. The TF that relates motion of the n^{th} shake tableto the acceleration of the j^{th}floor is defined by Eq. (14).

$$H_{sn,j}(\omega)=\frac{\ddot{u}_s^t(\omega)_j}{\ddot{u}_t(\omega)_n}=\sum_{i=1}^{2}\frac{-\left(2i\omega\xi_i\omega_i+\omega_i^2\right)}{\omega_i^2-\omega^2+2i\omega\xi_i\omega_i}\phi_{i,j}\kappa_{i,n} \quad (14)$$

In this equation, parameter $\kappa_{i,n} = \left(_{1x2}\Gamma_{i\ 2x3}\iota\right)_n$ is a measure of the participation of n^{th} table on the absolute acceleration of the j^{th} floor in i^{th} mode of vibration. As was mentioned earlier, the achieved table motions may be different from the drive motion (or target motion) due to several factors including the servo valve's dynamic response, the compressibility of the actuator fluid, oil leakage through the actuator seals, and the influence of the mass and stiffness of the test specimen(Maddaloni et al., 2010). The achieved and target shake table motions are assumed to be related through a transfer function H_{tn} for the n^{th} shake table. The TF that relates acceleration of the j^{th} floor to the drive motion can be obtained from the summation of the multiplication of structure TFs, as shown in Eq. (14), with H_{tn}. Figure 4 shows the structure-table dynamic system.

$$H_j(\omega) = \sum_{n=1}^{3} H_{tn}(\omega) \cdot H_{sn,j}(\omega) \tag{15}$$

or

$$H_j(\omega) = \sum_{n=1}^{3} H_{tn} \cdot \left[\sum_{i=1}^{2} \frac{-\left(2i\omega\xi_i\omega_i + \omega_i^2\right)}{\omega_i^2 - \omega^2 + 2i\omega\xi_i\omega_i} \phi_{i,j}\kappa_{i,n} \right] \tag{16}$$

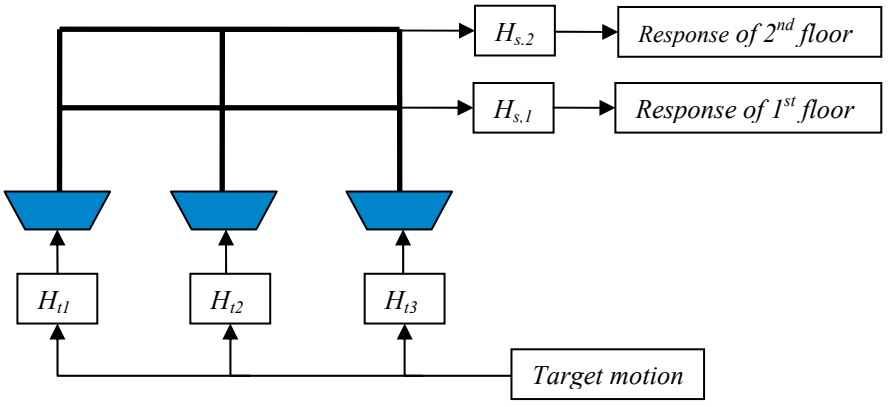

Figure4: Structure-Table Dynamic System

5.3 Development of Shake Table Drive Motion

The Test-Bed structure should simulate the specific floor responses of any target building. Floor response of a multistory building subjected to a ground motion, $\ddot{u}_g(\omega)$, can be obtained by using the TF presented as Eq.(6).

The drive motion of the shake tablesto achieve the target floor motion can be generatedby multiplication of the inverse of the TF of the Test-Bedshake table system shown in Fig. (4) and can express as:

$$\ddot{u}_{Drive}(\omega) = H_q(\omega) \,.\, H_j(\omega)^{-1} \,.\, \ddot{u}_g(\omega) \tag{17}$$

Or in its expanded form:

$$\ddot{u}_{Drive}(\omega) = \frac{\sum_{im=1}^{k} \dfrac{-\left(2i\omega\xi_{im}\omega_{im} + \omega_{im}^2\right)}{\omega_{im}^2 - \omega^2 + 2i\omega\xi_{im}\omega_{im}} \phi_{im,q}}{\sum_{n=1}^{3} H_{tn} \cdot \left[\sum_{i=1}^{2} \dfrac{-\left(2i\omega\xi_i\omega_i + \omega_i^2\right)}{\omega_i^2 - \omega^2 + 2i\omega\xi_i\omega_i} \phi_{i,j}\kappa_{i,n} \right]} \ddot{u}_g(\omega) \tag{18}$$

Expression of $\ddot{u}_{Drive}(\omega)$ in the time domain gives the time history ofthe drive motion of the shake tables. A suitable high-pass filter may be needed to insure thatthe demands on the shake tables are within acceptable limitsto permit continued use. This method allows for the simulation of floor accelerations of any type of structural system subjected to any set of ground motions.

This work will be continued to develop a similar formulation that can be used for simulation of the inter-story drifts of the generic building. A simplified method will be used to account for the structural nonlinearities.

6. Summary and Conclusions

A reusable Test-Bed structure was developed for shake table investigations of nonstructural systems. The Test-Bed structure simulates two adjacent floors of a multistory building. This two-story, two-bay frame can accommodate full-scale subassemblies and subject them to large drifts and/or accelerations. The design of this frame allows for reusing the Test-Bed.

The drive motion of the shake tables was obtained in order to achieve a target floor motion. This target floor motion was obtained from analysis of a continuum dynamic system representing a generic multistory building, offering a notable versatility to simulate floor acceleration of any type of structure. Nonlinearities will be included in this formulation in the extension of this study.

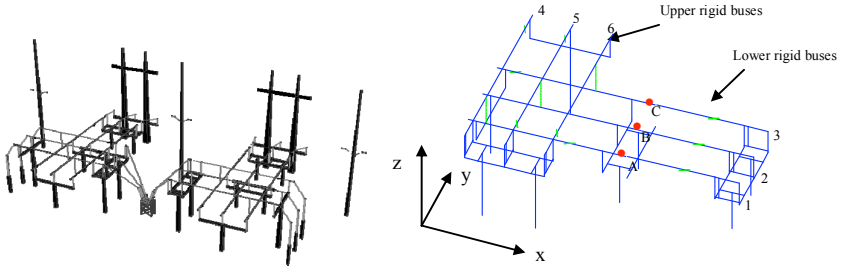
ABSTRACT

In this study, 38/ 34kV Highway N Substation, St. Charles County, Missouri was analyzed with a finite element model (FEM) for its vulnerability during earthquake excitations. Every component of the substation was modeled with due considerations of mass density, stiffness and geometries. Based on the FEM, modal analysis was conducted to identify the natural frequencies of structures along with their corresponding mass participation factors. In response spectrum analysis, the dynamic responses of main components such as 'rigid' buses and switches were evaluated. In time-history analysis, both site-specific synthetic ground motion and spectrum compatible ground motion were considered. The numerical results under both ground motions were compared and the magnitude and location of the maximum moments in each case were identified.

1 INTRODUCTION

In recent years, strong earthquakes have occurred in urban areas. They often lead to devastating damage of constructed facilities, such as lifeline systems, gas and water distribution systems, power transmission systems and communication networks, threatening the safety and security of citizens and impacting regional economy. For example, the El Salvador Earthquake that occurred on January 13, 2001, Japan, caused nationwide damage to the electric power system (Konagai, 2001). To minimize losses such as these, shortly after an earthquake, damaged substations must be repaired and resumed to full operation. Typical damages were observed in transformers, bushings, interrupters, connectors, radiators, circuit breakers, surge arresters and capacitor banks. This highlights the need to identify and strengthen the critical components of these systems so that their functionality during future earthquakes is ensured. A power substation is comprised of interconnected components including transformers, bushings, disconnect switches, interrupters, connectors, circuit breakers, surge arresters, etc.. Some



components of power substations such as porcelain insulators and bushings were quite susceptible to earthquakes and easily broken due to strong shaking. These equipment items are usually connected to each other through conductor buses or flexible cables. In the event of earthquakes, these connections may induce dynamic interaction among the items. Previous studies (Kiureghian and Sackman et al., 1999; Kiureghian and Hong, 2000) have indicated that the dynamic characteristics may have contributed significantly to the damage of power substations. However, design guidelines or analysis methods that account for this interaction effect are currently unavailable.

The objective of this paper is to evaluate the seismic performance of various components of the Highway N Substation with FEM, using a site-specific design response spectrum or a synthesized ground motions for the region.

2 FEM ANALYSIS

2.1 FEM Modeling

The SAP2000 finite element code was used to develop a model of the 138kV side of the power substation. The FEM of the main parts of the substation includes steel support structures, porcelain bushings, rigid bus, dampers, and cables, as shown in **Figure 1a**. ain focus of the analysis was to determine the seismic response of the 138kV rigid bus assembly. In particular, the goal was to obtain the 138kV disconnect switch seismic response (**Figure 1b**). The upper rigid buses (4, 5, and 6) are oriented in 90° with the lower rigid buses (1, 2, and 3). The sliding mechanisms such as sleeves in the rigid bus and the electric switches were modeled by constraining two sets of nodes at the two sides of each sliding mechanism except for their slippage along the centerline of a rigid bus and a switch arm. The 'rigid' bus and disconnect switch components in the FEM model, which is one of the critical parts of the power substation, were validated with a full scale shake table test on three Turner Electric's TMX switches (Chen, 2009).

2.2 Modal Analysis

The modal analysis of the Highway N rigid bus assembly structure wasconducted to determine the natural frequencies and mode shapes of the structure and evaluate its responses under dynamic loading. In general, the

dynamic responses of the structure are governed by a number of the lowest vibration modes.

How many modes of vibration must be included in analysis is a practical question. In building design, the accumulated modal participation mass factor (MPMF) in each horizontal direction must exceed 90%. For complex 3-D structures, it is often difficult to achieve that level of mass participation in all directions. In this study, an effort was made to include an accumulated MPMF of over 90% in each horizontal direction (X and Y directions in Figure 3). To this end, a total of 40 modes are specified in the initial analysis of the structure to ensure satisfied accuracy of the first 20 vibration mode characteristics.

The natural frequencies of the first 20 modes with modal mass-participant factors are listed in Table 1 along with a brief description of each dominant motion and its respective MPMF. Here, the significant modes are defined as those with an MPMR of 2% or higher in any single direction.

In Table 1, UX, UY, and UZ represent the translational motions along X, Y, and Z axes while RX, RY, and RZ, denote the rotational motions about X, Y, and Z axes, respectively. The MPMF value provides a measure of how important a particular mode of vibration is for the overall response to the acceleration loads in

each of the three global directions though a small MPMF value could correspond to a significant local vibration mode. It helps ensure a significant and required number of vibration modes are included in the seismic response analysis. Table 1 indicates that the accumulated MPMF exceeds 90% in X and Y directions as well as in rotational motions about the vertical axis. The MPMF in vertical direction is low since the critical components, rigid buses, participating in various vibration are relatively light in comparison with vertical members. The fact that a less mass participation is observed in the vertical direction is likely attributable to the presence of flexible cables in the model, where some of them vibrate independently of the remaining structure.

The first 6 mode shapes of vibration are presented in **Figure** 2. Most modes correspond to the coupled motion in X and Y directions. This observation indicates that the structure is flexible in the X and Y direction. Indeed, the fundamental period of 0.826s mainly corresponds to the X movement of the tall part of the structure together with the slight Y movement and the rotation around Y and Z, as shown in **Figure** 2(a).

(a) Mode No. 1 (b) Mode No. 2 (c) Mode No. 3

(d) Mode No. 4 (e) Mode No. 5 (f) Mode No. 6

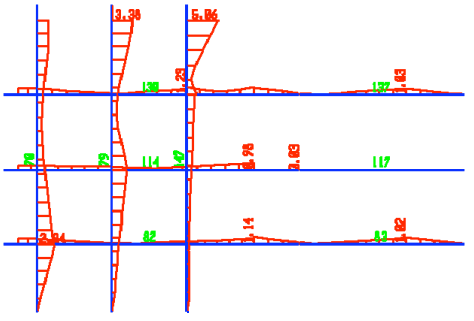
Figure 2 Mode shapes of the FEM

Figure 2(b) shows the second mode of vibration in the X direction at a period of 0.784 sec. The shape of the 3rd mode is shown in Figure 4(c); it mainly corresponds to the Y motion. The shapes of the 4^{th} mode and 9^{th} mode primarily correspond to the X motion while Modes 7, 11, 14 and 15 mainly correspond to the Y motion. Basically, the first 11 modes dominate the horizontal vibration of the substation structure. These modes are mainly related to the motion of the supports in the structure. After the 11^{th} mode, more and more rigid bus begins to participate in the motion. That is why the mass participant factors are relatively small for the several last vibration modes.

2.3 Response Spectrum Analysis

2.3.1 Response spectrum

Surface exploration at the project site was reported by Geotechnology (2004). Based on the soil condition, the project site was classified as Class D (IBC, 2003). In this case, the design spectral response accelerations (S_{DS} & S_{D1}) were calculated using the procedures outlined in Section 1615 of the 2003 IBC. The spectral parameters used for estimation of the ground accelerations at short period (S_{DS}) and at one second period (S_{D1}) were determined based on the site condition. The design spectrum was governed by S_{DS} = 0.45g, S_{D1} = 0.15g and T_0 = 0.1 sec.



2.3.2 FEM analysis

The FEM of the substation's 138kV side rigid bus assembly was analyzed under the design earthquake described by the response spectrum. The maximum relative velocity and displacement obtained at the three key points at lower rigid buses, as indicated in **Figure 1** (b) are listed in Table 2. The maximum relative displacements are approximately 2.24 in.

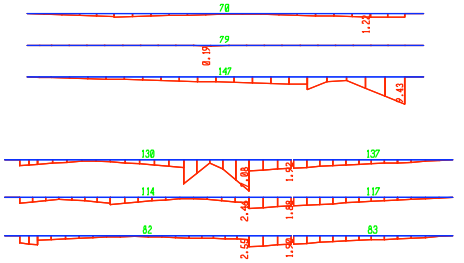


Table 2 Relative acceleration, velocity and displacement

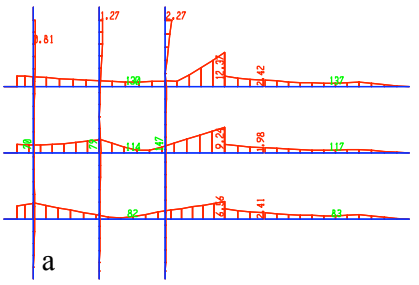
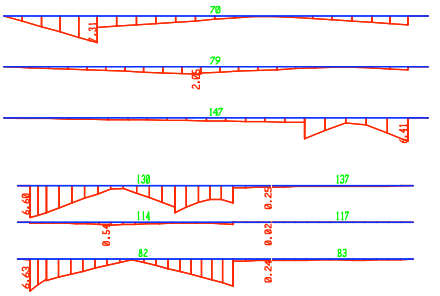
Location	Relative velocity (in/sec)	Relative displacement (in)
A	15.3	2.24
B	15.2	2.22
C	15.3	2.23



The flexural moment distributed along the six main buses are presented in **Figure 3**(a, b) are due to the earthquake excitation in X direction while **Figure 3**(c, d) result from the excitation in Y direction. It is evidenced that the maximum out-of-plane moment occurred in lower main buses (1, 2, and 3) as a result of the Y-directional earthquake. The maximum in-plane moment occurs in upper main buses (4, 5, and 6) due to the X-directional earthquake.



(a) Out-of-plane moment about vertical axis under X-directional earthquake

(b) In-plane moment about horizontal axis under the X-directional earthquake

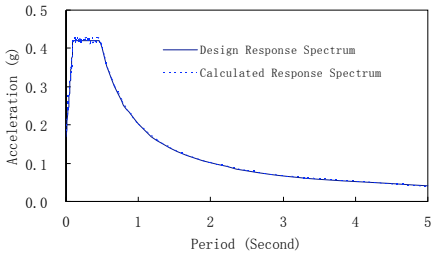
c)) Out-of-plane moment about vertical axis under the Y-directional earthquake

(d) In-plane moment under horizontal axis due to Y-directional earthquake

Figure 3 Moment distribution along main buses

Each main bus has at least one vibration absorber and a cable constraint between two levels of switch structures. It can be seen from Figure 3 that the maximum moment in various buses varies. The absolute maximum moment among all the buses occurs in bus #3. It is noted that the larger value of vertical and transverse moments does not necessarily happen in the same direction. This observation can be seen in **Table 3**. The maximum moment in bus 3 reaches about 12.4 kip-in out of plan due to the Y-directional earthquake. It is also observed that both the 30% and the square-root-of-the-sum-of-the-squared load combination rules give higher moments due to the combined effect of directional earthquake components.

Table 3 Maximum moment in each bus (kip-in)



Earthquake component	Moment	Bus #1	Bus #2	Bus #3	Bus #4	Bus #5	Bus #6
X	In-plane	1.14	0.98	1.23	2.84	3.38	5.06

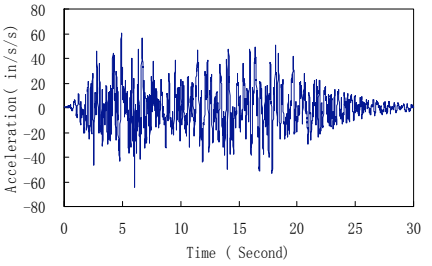
30%X + Y	In-plane	6.90	9.54	**12.7**	1.66	2.28	3.79
	Out-of-plane	7.40	1.28	8.72	7.68	2.11	9.24
$\sqrt{X^2+Y^2}$	In-plane	6.66	9.30	**12.4**	2.95	3.61	5.55
	Out-of-plane	7.10	2.52	9.68	7.41	2.06	**11.4**

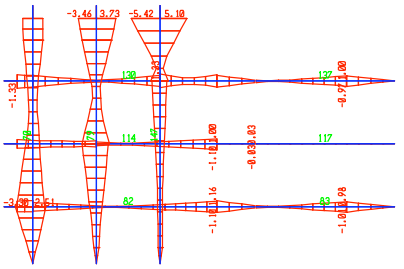
2.4 Time History Analysis

Two methods were employed to generate synthetic ground motions in this study. The first method is for the ground motions compatible with the design response spectrum as specified in the 2003 IBC. The second one is for site-specific ground motions generated with the point source model.

2.4.1 Spectrum compatible ground motions

Ground motions were generated to ensure their acceleration response spectrum compatible with that in **Figure 4**, taken from the 2003 IBC. First, 10 synthetic ground motions were generated to match the spectral accelerations, S_{DS} and S_{D1}. Their response spectra were then evaluated and compared with the design acceleration spectrum. The best matched spectrum is selected as illustrated **Figure 4** along with the design spectrum. Its corresponding time history is presented in **Figure 5**. It is observed from **Figure 4 and Figure 5** that the synthetic ground motion results in a response spectrum that matches well with the design spectrum.





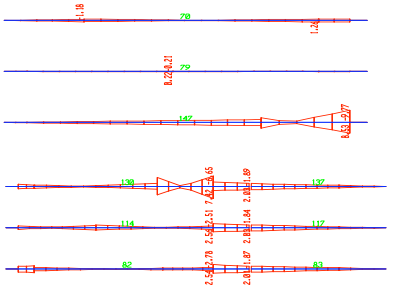


Figure 4 Response spectrum **Figure 5 Synthetic ground motion**

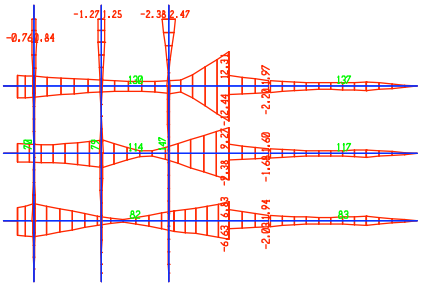
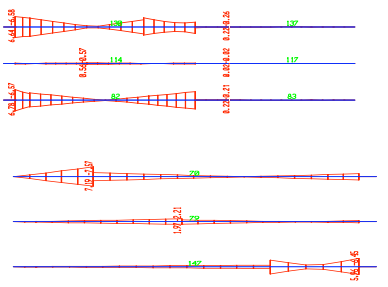


Time history analysis was also conducted with the FEM of the substation. Modal damping taken in this study was 0.05. The maximum moment is distributed along each bus as shown in Figure 6 for out-of-plane and in-plane moments in X direction (a and b) and Y direction (c and d), respectively.



(a)Out-of-plane moment about the vertical axis

(b)In-plane moment about the horizontal axis

(c) Out of plane moment about the vertical axis

(d) In-plane moment around the horizontal axis

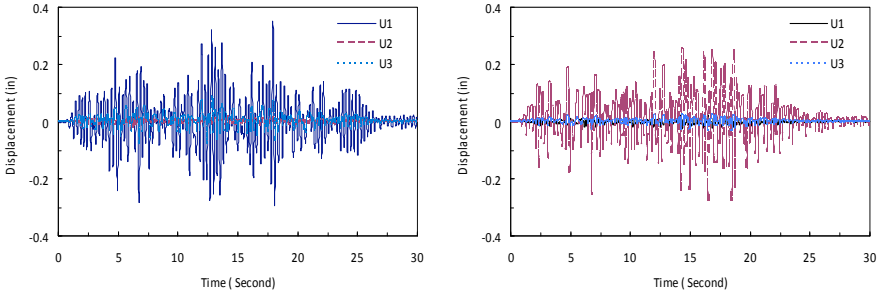


Figure 6 Moment envelop of main buses

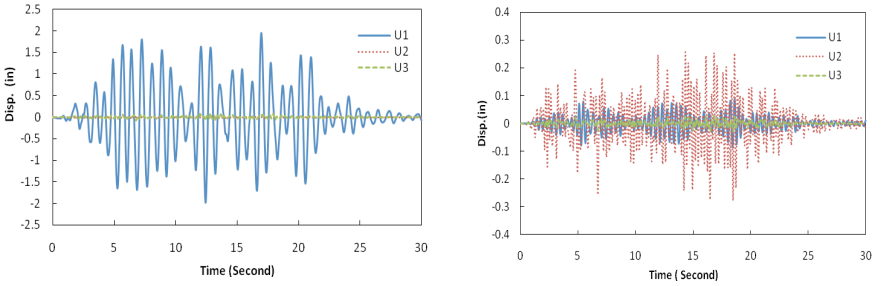
The maximum moments along each bus due to individual component earthquakes and their combination are summarized in **Table 4.** The absolute maximum moments due to X- and Y-directional earthquakes are 9.77 kip-in and 12.4 kip-in, respectively. They occur in bus #6 and bus #3. Both the magnitude and location of the absolute moments well correspond to those from response spectrum analysis.

Table 4 Maximum moment in each bus (kip-in)



Earth**quake component**	**Moment**	**Bus #1**	**Bus #2**	**Bus #3**	**Bus #4**	**Bus #5**	**Bus #6**
X	In-plane	1.16	1.10	1.33	3.30	3.73	5.42
	Out-of-plane	2.78	2.56	7.42	1.26	0.22	**9.77**
Y	In-plane	6.83	9.38	**12.4**	0.84	1.27	2.47
	Out-of-plane	6.78	0.57	6.64	7.57	2.21	6.45
X + 30%Y	In-plane	3.21	3.91	5.06	3.55	4.11	6.16
	Out-of-plane	4.81	2.73	9.41	3.53	0.88	**11.7**
30%X + Y	In-plane	7.18	9.71	**12.8**	1.83	2.39	4.10
	Out-of-plane	7.61	1.34	8.87	7.95	2.28	9.38

	Out-of-plane	7.33	2.62	9.96	7.67	2.22	**11.7**

The three-directional time history responses at joint "A" are presented in Figure 7 due to ground motions in X- and Y-direction, respectively. Since the main bus #1 with joint A is oriented along the X direction, the displacement at joint A (-X and +X sides) is the largest in the X- and Y-direction under the X- and Y-directional earthquakes, respectively. Note that U1, U2, and U3 in **Figures 7** and **8** represent the axiald is placement and the transverse displacements both in horizontal and vertical directions.

(a)Ground motion in X-direction (b) Ground motion in Y-direction

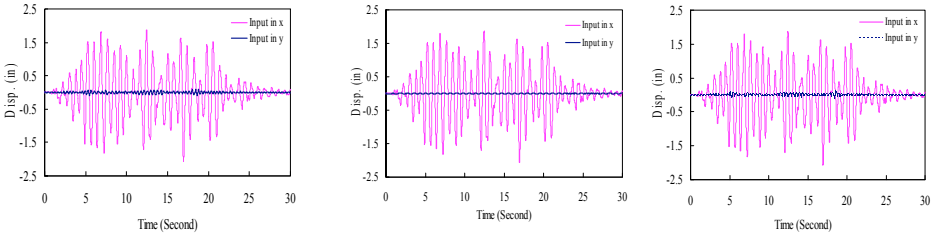

Figure 7 Displacement time histories at joint A (-X side) underground motions

(a)Ground motion in X-direction (b) Ground motion in Y direction

Figure 8 Displacement time histories at joint A (+X side) underground motions

The relative displacements at three slip joints (A, B, and C) are presented in **Figure 9** as the difference between the motions on two sides of each joint. It can be seen from the figure that the maximum relative displacement reaches 1.86 inches, which is slightly less than that obtained from the response spectrum analysis. The dominant excitation is in the X- direction and the influence of the excitation from Y direction can be neglected.

(a) Slip joint A (b) Slip joint B (c) Slip joint C

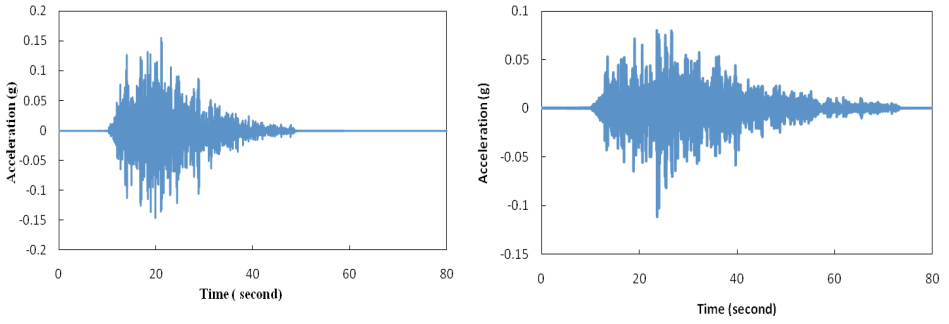

Figure 9 Open-and-close of the switches underground motions

2.5 Site-specific synthetic ground motion

The epicenter distance and the earthquake magnitude were selected for the synthesis of a site-specific ground motion. To match their spectral accelerations with S_{DS} & S_{D1}, several synthetic rock motions with a pair of distance and magnitude were first generated using the Boore's SMSIM method for the project site. A soil profile was then created using the boring log data reported by Geotechnology (2004), and the mean shear wave velocities (V_{sm}) of upper deposits (Karadeniz, 2007). Finally, site-specific response analyses were conducted with the SHAKE2000 software and the response spectra were examined to see how well they matched the design spectral accelerations, taken from the 2003 IBC. An appropriate rock motion was determined from the "best match" of these data.

For the project site located on the south side of the Old Highway "N" and east of the intersection with Highway K, the simulated rock motions predicted by the Boore SMSIM procedure were as follows: (1) M7.5 earthquake at a distance of 240 km, and (2) M7 earthquake at a distance of 100 km. These events result in

spectral accelerations of approximately 0.416g at 0.14 second and approximately 0.024g at 1 second periods. The time history of the ground motions induced by both earthquakes is depicted in **Figure 10.**

(a) M7.0 earthquake at 100 kim distance(b) M7.5 earthquake at 240 km distance

Figure 10 Synthetic ground motions at the project site

The maximum moments under one component and a combined action of two components of ground motions are presented in **Table 5** under an M7 earthquake at 100 km and in **Table 6** under an M7.5 earthquake at 240 km. In comparison with **Table 4**, **Tables 5** and **6** indicate that the maximum moment of the structure under the site specific ground motion is significantly smaller than that under the spectrum-compatible ground motion. This is attributed to different characteristics in the synthetic ground motions. The site specific ground motion depends upon the local geologic condition while the spectrum compatible ground motion was generated by following the design response spectrum that was developed based on the probabilistic seismic risk analysis.

Table 5 Maximum moment under an M7.0 earthquake at 100 km distance (kip-in)

3 CONCLUDING REMARKS

1. The three-dimensional responses of the electric substation structure are evident. Most of the vibration modes are coupled together. The dynamic characteristics (frequency and mode shapes) of the structure indicate that the rigid bus-stayed structure is flexible in both horizontal directions.

2. The 20 significant modes of vibration up to 7.08 Hz include more than 90% mass participations in both horizontal directions.
3. Based on the time history analysis with synthetic ground motions, the maximum moment is approximately 12.44 kip-in, comparable to that obtained from the response spectrum analysis. The maximum relative displacement at the slip joints is 1.86 inches, 17% lower than the result from the response spectrum analysis. This conclusion mainly results from the fact that the response spectrum analysis loses the phase information among various responses, thus amplifying the relative motion.

ACKNOWLEDGEMENT

Financial support to complete this study was in part provided by Ameren and by the Center for Transportation Infrastructure and Safety at Missouri University of Science and Technology. The assistances from Dr. Kazi R. Karim on the establishment of the initial FEM model and Drs. Jianbo Li and David Rogers on ground motion generations are highly appreciated.

ABSTRACT

Design, assessment and prediction of the performance of structures and infrastructures based on component analysis have been the conventional methodologies enforced by the specifications. Nevertheless, system-based performance indicators can provide more efficiency and dependability in performance-based design, assessment, and prediction of structures and infrastructures. The objective of this paper is to provide a general overview of performance indicators applicable to civil structures and infrastructures. Definitions and formulations of selected performance indicators are presented. Information on what level (section, component, system, system of systems) these indicators are useful is provided. Interaction between life-cycle cost and lifetime performance is presented.

INTRODUCTION

Civil infrastructural systems are subjected to deterioration in strength and performance due to the aggressive environmental conditions (e.g., corrosion) and aging of the materials they are composed of. Therefore, the safety of these systems is highly affected by this deterioration. In order to avoid the consequences of structural failures, maintenance programs are carried out by the responsible authorities. It is necessary to predict the life-cycle performance of these systems accurately to establish a rational maintenance program. However, difficulties arise in prediction of life-cycle performance because of the complexity and high uncertainty in loading and deterioration processes. Consequently, it is essential to use proper indicators to evaluate the structural performance in a quantitative manner.

So far, many researchers focused on quantifying structural performance with deterministic and probabilistic indicators such as safety factor and reliability index, respectively. National design codes take uncertainty into account by including specific factors in the computation of structural resistance and load. However, the prediction of structural performance under deterioration may require the use of several performance indicators. For example, system reliability index is an adequate

measure for quantifying the safety of a structure with respect to ultimate limit states, but system redundancy index is required to evaluate the availability of warning before final failure. Moreover, performance indicators related to damage tolerance of structures, such as vulnerability and robustness are essential to consider for structures under deterioration and local damage together with the indicators related to ultimate limit states. To provide a desired safety level of structures, the values of performance indicators under consideration shouldn't down-cross required threshold levels. On the other hand, life-cycle cost of structures is another measure which decision makers have to balance with the performance indicators. Nevertheless, it is evident that evaluating structural performance requires considering multiple indicators simultaneously. The purpose of this paper is to review several structural performance indicators used to evaluate the performance of civil structural and infrastructural systems. The formulation of these indices and several associated references are presented. Information on what level (section, component, system, system of systems) these indicators are useful is provided. Background of balancing cost and performance is also briefly indicated.

LIMIT STATES IN PERFORMANCE QUANTIFICATION

Performance evaluation of cross-sections, members, parts of structures, and overall structures is based on limit states defining the failure domain under specific loading conditions. The limit states defining the failure modes of components are included in design codes. For instance, AASHTO LRFD Bridge Design Specifications (2007), regardless of type and analysis used, requires that

$$\sum \eta_i \gamma_i Q_i \le \phi R_n \tag{1}$$

is satisfied for all specified load effects and combinations, where Q_i is the load effect, R_n is the nominal strength, γ_i is load factor, ϕ_i is resistance factor and η_i is load modifier. Eq. (1) applies to all strength limit states, service limit states and fatigue and fracture limit states. The factors multiplying the load effects and nominal strength exist to ensure a predefined safety level of the component. However, if the purpose is to evaluate the performance of an existing structure or design with respect to different target performance levels, the equation defining limit states must be in the pure form. A general representation of limit states which is used in reliability analysis in terms of a performance function $g(\mathbf{X})$ can be expressed as

$$g(\mathbf{X}) = g(X_1, X_2, ..., X_n) = 0 \tag{2}$$

where $\mathbf{X} = (X_1, X_2, \ldots, X_n)$ is a vector of random variables of the system, and the performance function $g(\mathbf{X})$ determines the state of the system as $[g(\mathbf{X}) > 0]$ = "Safe state", and $[g(\mathbf{X}) < 0]$ = "Failure state".

LEVELS OF PERFORMANCE QUANTIFICATION

In regard to the purpose and type of analysis, structural performance can be quantified at cross-section level, member (component) level, overall structure (system) level, and group of structures (system of systems) level. The strength of a component under different loading conditions can be expressed in terms of the capacity of its most critical section when stability problems are not accounted for. Under consideration of stability problems, the performance is quantified at component level. In most of the current building design codes, strength requirements are based on component strength. Although this kind of approach may ensure an adequate level of safety of components, it lacks the information about the interaction between the components and overall performance of the whole structure. However, performance at system level is of concern in performance-based design. Structural reliability theory offers a rational framework for quantification of system performance by also including the uncertainties both in the resistance and the load effects. Overall system performance for a limit state can be evaluated by assuming that the system limit state is series or parallel or series-parallel combination of component limit states (Ditlevsen and Bjerager, 1986; Hendawi and Frangopol, 1994). The domain Ω, representing the violation of system limit state can be expressed in terms of component limit states as (Ang and Tang 1984):

(a) for series system $\Omega \equiv \bigcup_{k=1}^{n} \{g_k(X) < 0\}$

(b) for parallel system $\Omega \equiv \bigcap_{k=1}^{n} \{g_k(X) < 0\}$

(c) for series-parallel system $\Omega \equiv \bigcup_{k=1}^{n} \bigcap_{j=1}^{c_n} \{g_{k,j}(X) < 0\}$

where c_n is the number of components in the n-th cut set.

The performance of a system which consists of a number of subsystems depends not only on the performance of the subsystems but also on the interaction of these subsystems. An example of a system of systems is a highway bridge network, where each bridge is a system itself and interacts with the other bridges for the performance of whole network by means of traffic flow.

DEFINITIONS OF COMMON PERFORMANCE INDICATORS

Safety factor. The simplest deterministic interpretation of the safety factor, when there is a linear relationship between the load and the stress produced by the load, is

$$SF = \frac{\sigma_u}{\sigma_{all}} \tag{3}$$

where SF represents the safety factor, σ_u is the maximum usable stress which can be either the yield stress or the ultimate stress, and σ_{all} is the allowable stress which is usually defined in structural design codes.

The most common use of safety factor is design at section and component levels. Allowable stress design is based on the concept that the maximum stress in a cross-section or a component shall not exceed a certain allowable stress under normal service conditions (AISC, 2005). The limiting stress, which can be yield stress or stress at instability or fracture, is divided by a safety factor to provide the allowable stress. The safety factor is used to provide a design margin over the theoretical design capacity to allow for consideration of uncertainty due to any components of the design process including calculations, material strengths, and manufacture quality.

Load and resistance factors. Load and resistance factor design is based on the ultimate strength of critical member sections or the load carrying capacity of members (Ellingwood et al., 1980). In Load and Resistance Factor Design (LRFD), the resistances R and the load effects Q are usually considered as statistically independent random variables. If the resistance R is greater than the load effect Q, a margin of safety exists. On the other hand, since resistance and load effect are random variables, there is a probability that resistance is smaller than load effect. This probability is related to the overlap area of the frequency distributions of the resistance and load effect and their dispersions (AISC, 2005). Figure 1 illustrates the probability density functions (PDFs) of the resistance and load effect. In this figure $E(Q)$ and $E(R)$ represent the mean values of load effect and resistance, respectively.

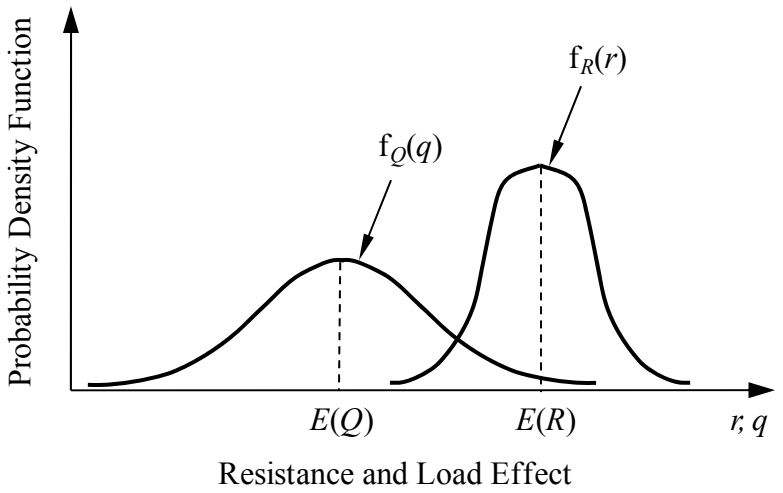

Figure 1 – Probability density functions of resistance and load effect

Load and resistance factors are used for design at section and component levels. LRFD suggests the use of resistance factor and partial load factors to account for the uncertainty in the resistance and the load effect. The partial load factor approach was originally developed during 1960s for reinforced concrete structures. It gives the opportunity for live and wind loads to have greater partial load factors than the dead load due to the fact that live loads and wind loads have greater uncertainty. The condition of safety with respect to the occurrence of failure mode i including the reduced resistance and factored loads using resistance and partial load factors can be written as

$$\phi_i R_i \geq \gamma_{Di} Q_{Di} + \gamma_{Li} Q_{Li} + \ldots \tag{4}$$

where R is the member resistance, ϕ_i is the resistance factor, Q_D and Q_L are the dead and live load effects, and γ_D and γ_L are the partial load factors associated with the dead and live load, respectively.

Probability of failure. The stochastic nature of the structural resistance and the load effects can be described by their probability density functions. The probability of failure of any section, component or system is defined as the probability of occurrence of the event that resistance is smaller than the load effects and can be evaluated by solving the following convolution integral:

$$P_f = P(g \leq 0) = \int_0^\infty F_R(s) f_Q(s) ds \tag{5}$$

where g is the performance function, R is the resistance in a certain failure mode, Q is the load effect in the same failure mode, F_R is the cumulative distribution function of R, and f_Q is the probability density function of the load effect Q.

Probability of failure is the basis for most probabilistic performance indicators. It is used at all levels (section, component, system, system of systems). In many cases, it is impossible or very demanding to evaluate P_f by analytical methods. Therefore, numerical methods such as Monte Carlo Simulations are used.

Reliability index. The reliability of a structure can be expressed in terms of either probability of failure or its corresponding reliability index. As a measure of reliability, reliability index can be defined as the shortest distance from the origin to the limit state surface in the standard normal space. For normally distributed independent variables reliability index can be calculated as

$$\beta = \frac{E(R) - E(Q)}{\sqrt{\sigma^2(R) + \sigma^2(Q)}} \tag{6}$$

where β indicates the reliability index, $E(R)$ and $E(Q)$ are the mean values of the resistance and load effect, and $\sigma(R)$ and $\sigma(Q)$ are the standard deviations of the resistance and load effect, respectively. For more complex problems, first and second order reliability methods (FORM and SORM) which approximately provide the reliability index by searching the most probable point on the failure surface (g_j=0), are the most common methods to compute reliability index. The probability of failure and reliability index are approximately related to each other as follows

$$P_f = 1 - \Phi(\beta) \tag{7}$$

where $\Phi(.)$ indicates the standard normal distribution function.

Cumulative time probability of failure. The probability of failure within a certain period of time is called cumulative time probability of failure. The basic approach considers only one random variable, the time at which the component or system fails. Cumulative time probability of failure up to time t_f can be calculated as (Frangopol and Okasha, 2008)

$$F(t_f) = P(T \le t_f) = \int_0^{t_f} f(u)du \tag{8}$$

where $F(t_f)$ is the area under the probability density function $f(u)$ of the time to failure to the left of t_f. Cumulative time probability of failure is a time-dependent performance indicator.

Survivor function. Survivor function is the probability that a component or system survives until time t. It is equal to the reliability function, which is the probability that a component or system is still functioning at time t. Survivor function is the complement of the cumulative time probability of failure and can be expressed as

$$S(t) = 1 - F(t) = P(T > t) = \int_{t_f}^{\infty} f(u)du \tag{9}$$

where $F(t_f)$ is the area under the probability density function $f(u)$ of the time to failure to the left of t_f. Survivor function is a time-dependent performance indicator.

Hazard function. Hazard function is a measure of risk associated with an item at time t. It is also known as hazard rate or failure rate. Hazard function also can be defined as the conditional probability of failure in a time interval $t+dt$, given that a component has survived until time t (Ramakumar, 1993). Hazard function is the ratio of probability density function to the survivor function and can be expressed as

$$h(t) = \frac{f(t)}{S(t)} \tag{10}$$

where $h(t)$ indicates the hazard function, $f(t)$ and $S(t)$ represent the probability density function and survivor function, respectively. Hazard function is a time-dependent performance indicator.

Redundancy. There are several definitions and indicators for structural redundancy in the literature. A measure of redundancy, in the context of availability of warning before system failure, was proposed by Frangopol and Curley (1987) as

$$RI_1 = \frac{P_{f(dmg)} - P_{f(sys)}}{P_{f(sys)}} \tag{11}$$

where $P_{f(dmg)}$ is the probability of damage occurrence to the system, and $P_{f(sys)}$ is the probability of system failure.

A measure of redundancy, as the availability of alternative load path after sudden local damage, was proposed by Frangopol and Curley (1987) as

$$RI_2 = \frac{\beta_{intact}}{\beta_{intact} - \beta_{damaged}} \tag{12}$$

where β_{intact} is the reliability index of the intact system and $\beta_{damaged}$ is the reliability index of the damaged system.

Redundancy is a system performance measure. However, it is also applicable at the section and component levels as a measure of warning with respect to failure. AASHTO LRFD Bridge Design Specifications (2007) considers redundancy in bridge structures based on the study of Frangopol and Nakib (1991). The load modifier η_i in Eq. (1), which accounts for redundancy level, is based on the redundancy definition in Frangopol and Nakib (1991). Application of redundancy concept to deteriorating structures can be found in Okasha and Frangopol (2009, 2010a).

Vulnerability and damage tolerance. In structural engineering, vulnerability is one of the key measures used to capture the essential feature of damage tolerant structures. A probabilistic measure of vulnerability was proposed by Lind (1995), defined as the ratio of the failure probability of the damaged system to the failure probability of the undamaged system

$$V = \frac{P(r_d, Q)}{P(r_0, Q)} \tag{13}$$

where r_d indicates a particular damaged state, r_0 indicates a pristine system state, Q is the prospective loading, $P(r_d, Q)$ represents the probability of failure of the system in the damaged state, $P(r_0, Q)$ represents the probability of failure of the system in the pristine state, and V refers to vulnerability of the system in state r_d for prospective loading Q. The value of vulnerability is 1.0 if the probabilities of failure of the damaged and intact systems are the same. Lind (1995) also defined the damage tolerance of a structure as the reciprocal of vulnerability. Vulnerability and damage tolerance are system performance indicators.

Risk. The most common formulation of risk in engineering is multiplication of probability of occurrence by the consequences of an event. Direct risk is the one associated with the damage occurrence itself while indirect risk is associated with the system failure as a result of the damage. Direct and indirect risks are formulated as (Baker et al., 2006)

$$R_{Dir} = \int_x \int_y C_{Dir} f_{D|E}(y \mid x) f_E(x) dy dx \tag{14}$$

$$R_{Indir} = \int_x \int_y C_{Indir} P(F \mid D = y) f_{D|E}(y \mid x) f_E(x) dy dx \tag{15}$$

where C_{Dir} and C_{Indir} are the direct and indirect consequences, and $f_Z(z)$ is used to denote the probability density function of a random variable Z. E, D and F represent the hazard occurrence, damage occurrence, and system failure, respectively. These integrals can be computed with numerical integration or Monte Carlo Simulation. Risk is applicable at component and system levels as well as system of systems level.

Robustness. Robustness is one of the key measures in the field of progressive collapse and damage tolerant structures. Although robustness is recognized as a desirable property in structures and systems, there is not a widely accepted theory on robust structures. Maes *et al*. (2006) defined robustness of a system as

$$R = \min_i \frac{P_{s0}}{P_{si}} \tag{16}$$

where P_{s0} is the system failure probability of the undamaged system, and P_{si} is the system failure probability assuming one impaired member i.

Baker *et al*. (2008) state a robust system to be one where indirect risks do not contribute significantly to the total system risk. An index of robustness is proposed as

$$I_{Rob} = \frac{R_{Dir}}{R_{Dir} + R_{Ind}} \tag{17}$$

where I_{Rob} is the index of robustness, and R_{Dir} and R_{Ind} are the direct and indirect risks, respectively. This index varies between 0 and 1.0 with larger values representing a larger robustness. Additional robustness indicators are indicated in Biondini and Frangopol (2010), Biondini et al. (2008), Ghosn and Frangopol (2007) , and Ghosn et al. (2010). Robustness is a system performance indicator.

Resilience. Bruneau et al. (2003) defined resilience as the ability of the system to reduce the chances of a shock, to absorb a shock if it occurs (abrupt reduction of performance), and to recover quickly after a shock (re-establish normal performance). According to their definition, a resilient system exhibits (a) reduced failure probabilities, (b) reduced consequences from failures in terms of lives lost, damage, and negative economic and social consequences, and (c) reduced time to recovery. The analytical definition of resilience is based on the concept of functionality, also called “serviceability” or “quality of infrastructure” (Bruneau et al. 2003; Cimellaro et al. 2010). Then, resilience is defined as the integral of the functionality in time as

$$R = \int_{t_0}^{t_h} Q(t) dt \tag{18}$$

where t_0 is the time at which the extreme event occurs, and t_h is the investigated time horizon. Resilience is a system performance indicator. Resilience is also applied to

system of systems such as highway bridge networks. Application of resilience concept to highway bridge networks can be found in Bocchini and Frangopol (2011), Frangopol and Bocchini (2011).

Life-cycle cost. One of the most important measures in evaluation of structural performance is life-cycle cost. The proper allocation of resources can be achieved by minimizing the total cost while keeping structural safety at a desired level. The expected total cost during the lifetime of a structure can be expressed as (Frangopol et al., 1997)

$$C_{ET} = C_T + C_{PM} + C_{INS} + C_{REP} + C_F \tag{19}$$

where C_T is the initial cost, C_{PM} is the expected cost of routine maintenance cost, C_{INS} is the expected cost of inspections, C_{REP} is the expected cost of repair, and C_F is expected failure cost.

BALANCING COST AND PERFORMANCE

Life-cycle cost and performance level of a structure are two conflicting criteria that should be balanced. Significant amount of research has been done in the area of optimum planning for life-cycle management of civil structures and infrastructures (Chang and Shinozuka, 1996; Ang and De Leon, 1997; Frangopol et al. 1997, 2001; Ang et al. 1998; Estes and Frangopol, 1999; Frangopol and Kong, 2001; Okasha and Frangopol, 2010b).

The interaction between the components of life-cycle cost and initial performance level (i.e., reliability index) is qualitatively illustrated in Figure 2. Higher performance levels require higher initial cost. However, if the initial performance level is high, failure cost, preventive maintenance cost and repair cost are lower.

CONCLUSIONS

In this paper, common performance indicators for civil structures and infrastructures are presented. Some indicators are used to define performance at cross-section and component levels while others are used to quantify performance of systems and groups of systems.

The matter of which indicators should be considered depends on the priorities and objectives of the decision makers. In most design processes, the main purpose is minimizing the life-cycle cost while maintaining safety at an acceptable level. If time-dependent analysis is required, time-dependent indices such as cumulative probability of failure, survivor function, hazard function or cumulative hazard function may be essential. Furthermore, structures are subjected to damage and deterioration during their lifetime. In this case, not only basic safety measures such as reliability index but also the measures related to damage tolerance of structures such as vulnerability, redundancy, and robustness may be beneficial.

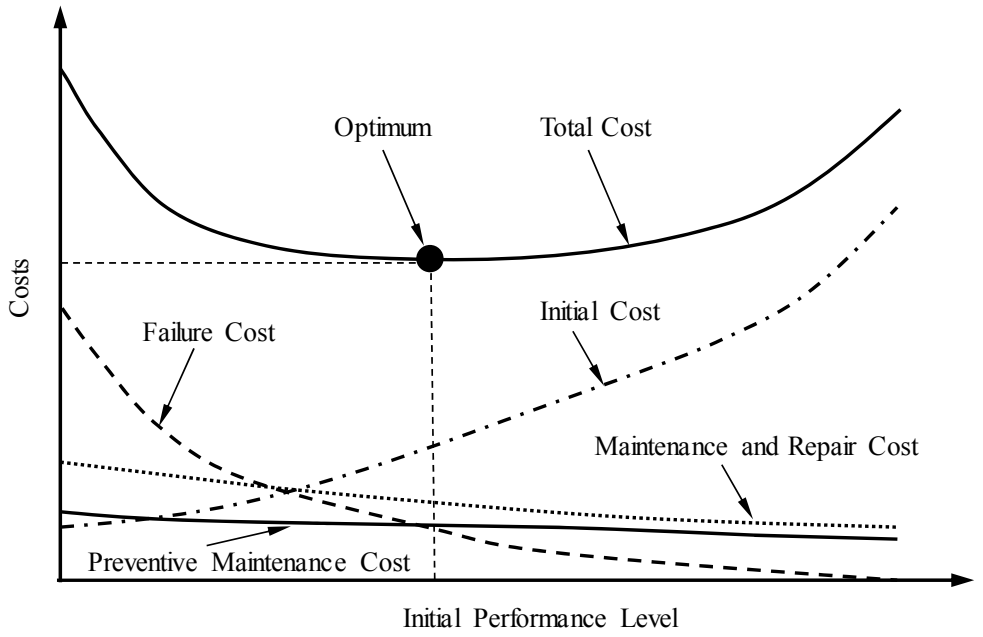

Figure 2 – Interaction between costs and initial performance level

The performance indicators for civil structures and infrastructures are not limited to those mentioned in this paper. More effort should be placed on determination of performance indicators and their use in risk communication and optimal decision making under uncertainty.

ABSTRACT

The drive for alternative energy sources has resulted in many proposals for offshore wind farms in the United Sates. Offshore wind turbines are subject to harsh environmental conditions including but not limited to simultaneous action of extreme wind and wave loading as well as hurricanes. From a structural reliability point of view, there are several failure mechanisms of a wind turbine such as blade or other component fatigue, tower local or global buckling and foundation failure such as sliding. In addition, there are several mechanical components and a control mechanism that could be studied from a traditional reliability point of view. Given the complexity of the problem which involves a combination of structural and electromechanical systems, an approach based on annual power generation is considered here to evaluate the performance of offshore wind farms.

INTRODUCTION

In recent years, the desire for renewable (green) energy resources has increased dramatically. One such source of green energy is wind. Harnessing the power of wind has been documented to ancient times. Those early beginnings used wind as a direct source of power to provide mechanical work. In the modern era, the need for electrical energy has resulted in the development of numerous wind turbine schemes designed for that purpose. Despite unlimited, yet intermittently available, wind resources, wind turbines, like all electrical power-producing devices, require maintenance and suffer failures from time to time. Wind turbines have the additional complication in that they need to be located near the best sources of wind. Often times, these locations are difficult to approach (for maintenance) depending upon the weather and time of year. To further exacerbate the situation, failures frequently occur during times of inclement weather and harsh seasons. For wind to become a desirable major source of energy, its cost must prove reasonable compared to other sources.

There have been many studies related to the reliability of offshore wind turbines (Sorensen and Toft, 2010, Agarwal and Manuel, 2009). Structural reliability has been a key consideration. However, reliability cannot be isolated from performance

of mechanical components, control mechanisms, etc. Eventually, in order to make a comparison between wind turbine power generation and other types of power generation, a cost-benefit analysis needs to be undertaken to provide a solid rationale for its implementation. The benefits associated with wind energy could be a function of factors including net power generated, cost of net power generation, reduction of direct greenhouse gas emissions, overall carbon footprint, reduction in fossil fuel dependence, etc. It could in general be a combination of factors with varying weights assigned to the individual benefits.

If the various benefits are to be related to power generation, their evaluation is most appropriately associated with performance indicators deemed relevant to power generation. Performance indicators for wind turbines could include gross available power at a specified location, structural performance of the individual components or the entire system, net available power at a specified location, net cost of power, etc. Some indicators that have been suggested have targets such as "reduce installation costs by 20% by 2020," or "wind energy production forecast with less than 3% uncertainty by 2020."

An exact assignment of a single performance index that may be used for all wind farms is not easily attainable, but a generalized relation or index can be developed that is usable across a wide range of potential wind farm locations. In the present study, a procedure for the determination of the performance of wind farm total net annual output is investigated.

WIND TURBINE SYSTEMS AND SUBSYSTEMS

To account for the performance of a wind turbine, one needs to be familiar with its main components which include the foundation, the tower structure, the nacelle, and the rotor. Each of these components is made up of many subcomponents and their design can differ radically depending upon the size of the turbine, its operating environment, and what the designer considers the ideal turbine configuration given the constraints of the individual project.

For offshore wind turbines, the design of the foundation and support structure could be one of several alternative types including gravity, pilings, guy wires, tension legs, ballast stabilization, and suction-based anchors. The choice of specific foundation depends upon the water depth at the wind farm and the geology of the sea floor. Very limited evidence of foundation failures has been found during the research of existing systems. It is possible that experience from the offshore oil and gas technology can be of benefit in this regard. However, given that we have had no experience to date in locating wind turbines offshore in the United States on either the East or West coasts, it is not possible to make definitive conclusions regarding foundation performance. Experience with European offshore wind turbines has offered far greater data in this regard, but both the metocean and the seabed conditions in Europe are quite different from that on either coast of the United States.

The tower structure of a wind turbine is typically made of rolled, tubular steel. It might be expected that the corrosive effects related to seawater would be of considerable concern. However, given adequate inspection and the experience with performance coatings associated with oil and gas platforms, corrosion is of a lesser concern than other factors associated with the long-term operation of the wind turbine as a complete system.

The nacelle and the rotor are the two most complex systems in a wind turbine. The complexity of the nacelle is due its housing of the majority of the subsystems required for the operation of the wind turbine, including power generation and control systems (mechanical, hydraulic, and electrical). The major subsystems include the transmission, generator, brake, and the yaw/pitch/stall controller and actuators. The transmission subsystem varies substantially depending upon the design selected. Its purpose is to convert the rotation rate of the shaft from the rotor to the speed necessary for the generator to convert rotational energy into electrical energy. Two principal designs for the transmission are direct-drive (i.e. gearbox-free) and conventional gearbox-based or indirect-drive. Direct-drive transmissions may have higher initial costs but may lead to lower maintenance costs. There is a trend towards direct-drive systems for offshore applications due to reduced maintenance needs.

The brake system for a wind turbine is comprised of a mechanical friction brake and a hydraulic system that stops the turbine blades during maintenance and overhaul. A braking system is also used in the yaw mechanism to maintain nacelle position. In addition to these two braking systems, there are controllers for yaw as well as blade pitch/stall. Yaw control rotates the turbine directly into the wind in order to generate maximum power.

Typically, four yaw sensors monitor the wind direction and activate the yaw motors to face the prevailing wind. A four-point bearing connects the nacelle to the tower. The yaw mechanism turns the blades 90 degrees from prevailing winds under high winds to reduce stresses on internal components and to avoid over-speed conditions. If a grid failure were to occur in conjunction with an extreme wind event—which is a likely scenario—the yaw control system will become inactive. The loss of yaw control could increase the likelihood of damage/failure in the case of an extreme wind event.

The rotor portion of the wind turbine consists of the turbine blades, the hub at which the roots of the blades are connected, and individual blade pitching systems, if present in the particular design. The wind turbine blades experience the most complex, dynamic loading of the entire wind turbine system. In addition to experiencing rapid changes in wind direction and speed as well as wind shear, turbine blades may be susceptible to icing conditions, lightning, severe weather conditions, and debris impact. The structure of the blade is typically made up of an ‘internal beam’ which may be jointed in the case of blade pitching designs. The internal beam is designed such that it withstands the major portion of the dynamic loading (bending and torsion) of the blade. The materials employed in its manufacture vary widely depending upon size and manufacturer. Some of the largest blades consist of steel spars with composite outer sections and aeroshells. Some blades consist primarily of

composite materials. Regardless of design, the composite portions of blades are subjected to harsh environments of wind, salt spray, and constant ultraviolet exposure that can degrade the strength, creep resistance, toughness, and adhesive properties of the composite material that may ultimately lead to failure of the turbine blade.

ECONOMY OF OFFSHORE WIND

From an economic standpoint, wind energy is a sensible energy source as the primary source of such power generation results from a non-expendable natural resource. Wind does not suffer from erratic commodity prices unlike every other source of energy with the exception of solar energy. For this reason alone, continued exploration into the development of more efficient and resilient wind turbines is important as the need for energy continues to rise as the population of the world grows. Significant investment is required for any power generation project. Its selection is based upon net power generation as a function of cost. Expansion of wind as a major source of energy necessitates a continued drive toward reduction of cost. For wind, these costs include initial construction expenses, regular and unscheduled maintenance and repairs, as well as decommissioning at the end of the design life. The two components that experience the greatest dynamic loads are also the two most expensive components, i.e., the gearbox and turbine blades; they account for about 13% and 16%, respectively, of initial costs. A couple of cost factors for offshore wind farms that should not be overlooked are hose related to ‘grid connection’ and ‘feed-in rates’ since distances from land to these offshore facilities can be great.

Maintenance can be divided into two subsets, preventative and corrective. Preventative maintenance is composed of calendar-based, regular interval maintenance as well as condition-based maintenance that is a function of the state of a component at specific points in time. Corrective maintenance consists of planned and unplanned maintenance. Planned maintenance deals with maintenance as a result of an observed condition while unplanned maintenance deals with unexpected failures.

The availability of power from an offshore wind farm is a complicated issue of conflicting parameters. On one hand, a location with high constant wind energy density is desired for greatest consistent net energy production. However, a site with high wind energy density will also likely experience greater sea states and wind gusts. These conditions will require robust designs capable of withstanding high loads which can lead to increasing design, construction, and installation costs. Such conditions can also complicate maintenance procedures which will likely increase in frequency. As an alternative, additional wind data for offshore locations could be collected to determine the most ideal location for a wind farm (a location with sufficiently high consistent wind energy density without excessively severe sea states or gusts). The determination of such a perfect location would likely take a great deal of time and, thus, increase initial design costs. Also, a search for this perfect location could reduce the number of available wind farm locations to a degree at which point

the overall power goals for offshore wind may not be achieved. Furthermore, the likelihood of the perfect location coinciding with major traffic lanes, endangered wildlife habitats, or points of recreational/visual interest could increase as well. It seems that a delicate balance of low cost, robustness, high efficiency, low maintenance, and versatility must be achieved in order for offshore wind to become a viable option for energy production.

FAILURE MODES OF WIND TURBINES

The components of a wind turbine including the blades, tower, foundation, and mechanical elements can exhibit various structural failure modes. These can include fatigue of blades or foundation components, local buckling in the tower assembly, and foundation failure such as sliding or anchorage failure. However, failures are not just structural. Other failure modes include material failure, electrical failure, mechanical failure, output inaccuracy, and electrical insulation failure. These conditions can reduce energy output and render a project uneconomical. Typical root causes of failure include mechanical overload, vibration fatigue, and corrosion.

Failures that have been observed in the past and up to the present day suggest that the working environment for a wind turbine is very complex and not completely understood yet. Or, at the very least, it has not been fully accounted for in the design and manufacture of the units themselves. The various systems within a turbine are interconnected. If a sub-system or a component within a system fails to perform properly (e.g., due to excessive blade flexure), it may lead to catastrophic failure of the entire wind turbine. The environment (and the resulting load spectra) in which each wind farm operates is undeniably site-specific. Therefore, it may be necessary to modify the design of each turbine individually thus incurring additional design and manufacturing costs that would not be required if one robust design could meet the demands of most situations.

For large-scale offshore wind farms to become a reality in the United States, these hurdles faced by existing wind farms must be overcome. Cost-effective electricity will require efficiently designed, inexpensive, robust structures requiring minimal maintenance and downtime.

STATISTICAL RELIABILITY OF WIND FARM TOTAL NET ANNUAL OUTPUT

An offshore wind farm is a complex system with many inter-related variables which makes reliability evaluations difficult. There have been several reliability studies of specific limit states such as tower bending or foundation failure. Since cost is always critical for new energy-producing plants, cost-benefit studies have also been undertaken to investigate their economic viability. Ultimately, regardless of the factors chosen to determine the performance of a wind turbine or an entire offshore wind farm, this is a complex system of dependent variables. Generalized means of

defining and evaluating relevant parameters may be the only way to critique performance and compare potential wind farm locations versus other means of power generation. The parameters chosen for comparison depend upon the goal of the particular study. The study may be focused on structural behavior, maintenance activity, output power, cost of net power generation, or a combination of these. It may also be concerned with the survivability of a single component or group of components with respect to different design/build schemes and particular siting factors.

Given the high variability of wind and the dependence on other factors that affect overall net power generation over specified periods of time, developing a means of assessing the reliability of power output from a statistical standpoint could prove beneficial. Output power is dependent upon air density, area swept by the turbine blades, wind velocity, and the power coefficient (related to Betz Law). Other factors that may be affected by the inflow wind include power generation losses (the difference between gross and net power output), availability of the wind turbine to produce power due to planned or unplanned maintenance, frequency of occurrence of storms that force the entire wind farm to cease operation or stagnant conditions in which power generation is not feasible, as well as aerodynamic effects caused by the geometry of the wind farm itself (referred to as wake effects). Selection of a location for a wind farm is not arbitrary. Detailed studies of the wind are typically performed to determine not only the feasibility of a wind farm, but the ideal design of the turbines as well as the geometric layout of the farm itself.

Internal losses of a wind turbine may be a function of the rotational speed of the turbine blades. Such losses might result from friction in components including bearing, gears, and rotating portions of the generator. Other internal losses may be independent of rotational speed and might occur in stationary portions of the generator and subsystems of the wind turbine that utilize output power of the turbine to function. Availability of the turbine associated with planned and unplanned maintenance and repair is somewhat predictable. Planned maintenance is scheduled ahead of time with fairly certain downtime; unplanned events are not predictable. However, for a given design, historical maintenance records can be used to predict an approximate percentage of downtime for a given year. Severe storm and stagnation periods typically follow weather patterns that repeat on a fairly predictable basis at least from the standpoint of predicting approximate yearly downtime as a result of such events. Finally, a factor that may pose a lot of uncertainty is the wake effect. Many times, wind turbines are situated such that they are staggered with respect to prevailing winds. However, significant winds can occur outside of the prevailing direction. It is likely impossible to totally negate the effect of the wake. Continued research into this phenomenon with respect to its effects on wind turbines, both structurally and on power output, will assist in predicting power output and downtime. It may be reasonable to assume that a wake will affect power output (in a nonlinear fashion) from the leading row of turbines to the trailing rows.

Gross output power for a single wind turbine as a function of air density (ρ), rotor sweep diameter (d), hub-height air velocity or wind speed (v), and power coefficient (c_p), is as follows:

$$\dot{W}_{gross} = \frac{\pi}{8}\rho d^2 v^3 c_p \tag{1}$$

Taking into account losses (l_i) that are dependent upon rotational speed and those that are independent of rotational speed (L_i), turbine availability due to planned and unplanned maintenance (a_i), wake effect (ω_i), severe storm and stagnation period (z), and the layout of the farm into rows (r) and columns (n), the net power generation for a wind farm can be expressed as follows:

$$\dot{W}_{net} = zn \cdot \sum_{i=1}^{r} a_i \omega_i \left[l_i \dot{W}_{gross} - L_i \right] \tag{2}$$

The hub-height wind speed is typically assumed to follow a Weibull distribution curve. The equation describing the Weibull probability density function (pdf) is the following:

$$f(v) = \frac{k}{\lambda}\left(\frac{v}{\lambda}\right)^{k-1} \cdot e^{-\left(\frac{v}{\lambda}\right)^k} \tag{3}$$

The actual net work or energy output for a power generation system is the area under a curve of instantaneous net power as a function of time. Using the pdf for the hub-height wind speed, the gross output can be expressed as follows:

$$W_{gross} = \dot{W}_{gross} \cdot \Delta t \tag{4}$$

where $\Delta t = f(v)dv \cdot (1\ year)$ for an entire year of net generation.

Combining the previously defined equations for $\dot{W}_{net}$, $f(v)$, and W_{gross} (i.e., Eqs. 2, 3, and 4), an expression for net output can be found as follows:

$$W_{net} = \frac{\pi}{8} k \left(\frac{1}{\lambda}\right)^k \rho d^2 zn(1\ year) \cdot \sum_{i=1}^{r} a_i \omega_i \int_{v_{cut-in}}^{v_{cut-out}} \left(l_i v^3 c_p - L_i'\right) v^{k-1} e^{\left(\frac{v}{\lambda}\right)^k} dv \tag{5}$$

where $L_i' = \frac{8}{\pi} \frac{L_i}{\rho d^2}$

The goal of the statistical analysis is to determine the probability that certain specified event(s) will occur. In this case, the objective is to estimate the probability that the actual annual net output will meet the design value (W_{design}). Thus, the resulting reliability function is as follows:

$$\frac{\pi}{8} k \left(\frac{1}{\lambda}\right)^k \rho d^2 zn(1\ year) \cdot \sum_{i=1}^{r} a_i \omega_i \int_{v_{cut-in}}^{v_{cut-out}} \left(l_i v^3 c_p - L_i'\right) v^{k-1} e^{\left(\frac{v}{\lambda}\right)^k} dv - W_{des} \tag{6}$$

This function is made up of two parts, the resistance (capacity) and the load (demand). The annual output energy capacity of the wind turbine is the first term in Eq. (6) while the power demand is the second term, W_{design}. All the random variables that appear in Eq. (6) can be transformed into standard normal random variables using either their probability distributions or their first two marginal statistical moments and correlation coefficients, if applicable for correlated variables. Using the Hasofer-Lind First-Order Reliability Method (FORM) algorithm (Melchers, 1999; Nowak and Collins, 2000), a reliability index (or performance indicator) associated with Eq. (6) can be evaluated. This can be used as a relative means to assess the power generation performance of a wind farm.

CONCLUSION

A general reliability function describing the probability of net available energy meeting a prescribed design value was developed. Thorough examination and determination of second-order statistics (mean, standard deviation, and correlation coefficients) for each random variable in the function will allow for estimates of the probability that specific wind farm schemes composed of particular wind turbine designs can meet imposed demands. This measure of probability should prove to be a better means of characterization of wind farm output compared to the customary use of rated power in conjunction with a fixed reduction factor. The proposed probability method takes into account all variations that are present in the entire energy generation process for a wind farm and ultimately leads to estimates of the

likelihood of meeting the proposed value (W_{design}) set by the developer of the wind farm.

Future efforts may include examination of existing wind farms and turbine designs to estimate desired statistics for the variables defined herein. These statistical values can be used in turn to obtain statistical estimates of net wind farm output. Subsequently, a probability distribution function of output values can be generated and compared against actual output values of a wind farm over several periods of time as a means of verification and validation of this concept.

ABSTRACT

As an important clean and renewable energy, tidal energy is attracting more and more attention, and various plan and projects are being made worldwide to generate power. First, this paper discusses the current status of tidal power generation, and then describes Marine Hydrokinetic (MHK) energy turbines and related facilities. Then, the paper proposes performance indicators of the power generation systems in aspects of their power output estimate and reliability.

INTRODUCTION

According to a recent survey, the global energy consumption in 2007 is 11103 million tons of oil equivalence, and this consumption consists of 35.6% oil, 23.8% natural gas, 28.6% coal, 5.6% nuclear power, and 6.4% hydroelectricity, with 88% of it coming from fossil fuels (IEA, 2007; Rourke et al., 2010). The heavy dependence on fossil energy now results in an unprecedented consequence that challenges the whole world; at the current rate of exploitation, this type of energy is expected to be exhausted in a near future. Even more, burning of fossil fuels produces CO_2 and has led to the greenhouse effect, which results in global warming and climate change (US NREL, 2005).

In recent years, more and more attention has been shifted to clean and renewable energy, and various plans and pilot projects have been developed to move away from using fossil fuels as the primary source of energy generation. Tidal energy is a clean and renewable energy, and it is able to provide a significant amount of energy. A study completed in 1999 by the Marine Oversight Committee of the British House of Commons concluded: “if 1/10 of 1% of the energy in the world’s oceans could be converted into electricity; it would supply the world energy demand five times over.”

At present about 5% of the UK's electricity comes from renewable energy resources. With a plan to produce 20% of its total energy from renewable resources by 2020, which corresponds to about 35% of its electricity demand, the UK is exploring to increase generation of renewable energy from tidal sources (DTI, 2003; Xia et al., 2010). The Korean government plans to increase investment on alternative energy sources in the country's energy spending from current 1.4 percent to 5 percent by 2011 (Lee and Yoo, 2009). New Jersey State has set goals to achieve 20% renewable energy generation by 2020 and considers tidal energy as an important part of it. It is estimated that if only 1% of the New Jersey shoreline is utilized for tidal energy production, it could contribute an estimated 500 MW or more power based on presently available technology during the next 2-3 years, while adding over $1 Billion to the New Jersey economy in the next decade (NJDOT 2010). The first tidal energy site in New Jersey received its Waterfront Development Permit from the NJ Department of Environmental Protection (NJDEP) on January 14, 2010.

Tidal energy consists of potential and kinetic components. Accordingly tidal power facilities are categorized into two types: tidal barrages and tidal current turbines, which use the potential and kinetic energy of the tides, respectively (Lemonis & Cutler, 2004). A tidal barrage is typically a dam, built across a bay or estuary that experiences a tidal range in excess of 5 m, and electricity generation from it employs the same principles as hydroelectric generation, except that tidal currents flow in both directions (IET, 2007). Tidal barrage is the main form in tidal energy generation at the early stage in its development. Currently, there are four such power plants in operation in the world. The four plants are La Rance, France, built in 1960's, Jangxia Creek, east China sea, constructed about the same time, Kislaya Guba power facility, Russia, also built in 1960, and Annapolistidal generation, Canada, finished in 1980's. Technology of electricity generation using tidal barrages has become mature and reliable. However, in consideration of cost and environmental impact, it is now a trend to utilize Marine Hydrokinetic (MHK) energy and tidal current turbines in tidal power generation. Currently the technology of MHK energy power generation is still in its infancy, and various problems are involved and need investigation. Reviews for tidal power generation can be found in Khan et al., (2009) and Rourke et al. (2010).

This paper deals with MHK energy generation and facilities and discusses related performance indicators.

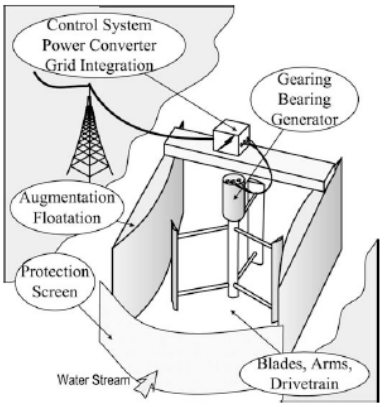
MHK ENERGY, TURBINES, AND SUPPOERTING STRUCTURES

Marine Hydrokinetic (MHK) energy comes various motions of coastal ocean waters. MHK energy of a current can be evaluated using the per square meter transient kinetic energy flux F as follows (e.g., Carballo, 2009):

$$F = \frac{1}{2}\rho V^3 \tag{1}$$

where ρ is the density of water and V is the transient depth-averaged velocity. With the seawater density of 1030 kg/m^3, it is known from this formula that the kinetic energy flux is about 515 W/m^2 at V=1 m/s and 4120W/m^2 at V=2 m/s. This indicates that water current contains a large amount of energy that increases rapidly with its velocity.

In power generation using MHK energy, the energy flux will be transformed into electricity by current power generation systems (Fig. 1). A simple current power generation system consists of four parts: 1) a turbine, 2) a gear box, 3) an electricity generator, and 4) a supporting system. Parts 1), 2), and 3) of the system are mounted to the supporting structure 4). Flowing water turns the turbine by propelling its blades, the gear box transfers the rotation of the turbine into motion of the generator, and the generator transforms the energy of its mechanical motion into electricity, which is transmitted to land through cables.



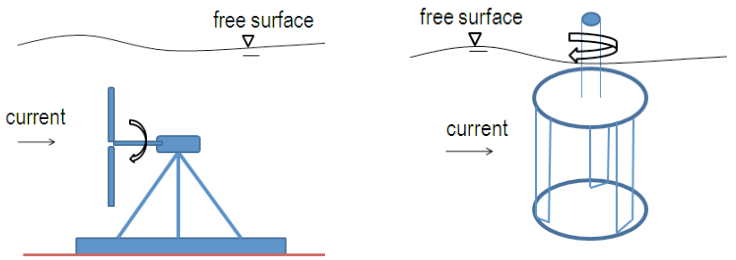


Figure 1. Schematic representation of power generation using MHK energy (from Khan et al., 2009).

(a) (b)

Figure 2. Categories of MHK energy turbines. a) Horizontal axis turbines. b) Vertical axis turbines.

Turbines using MHK energy fall primarily into two categories: vertical and horizontal axis turbines (Khan et al., 2009), as illustrated in Fig. 2. Horizontal axis turbines are common in tidal energy converters and are very similar to modern day

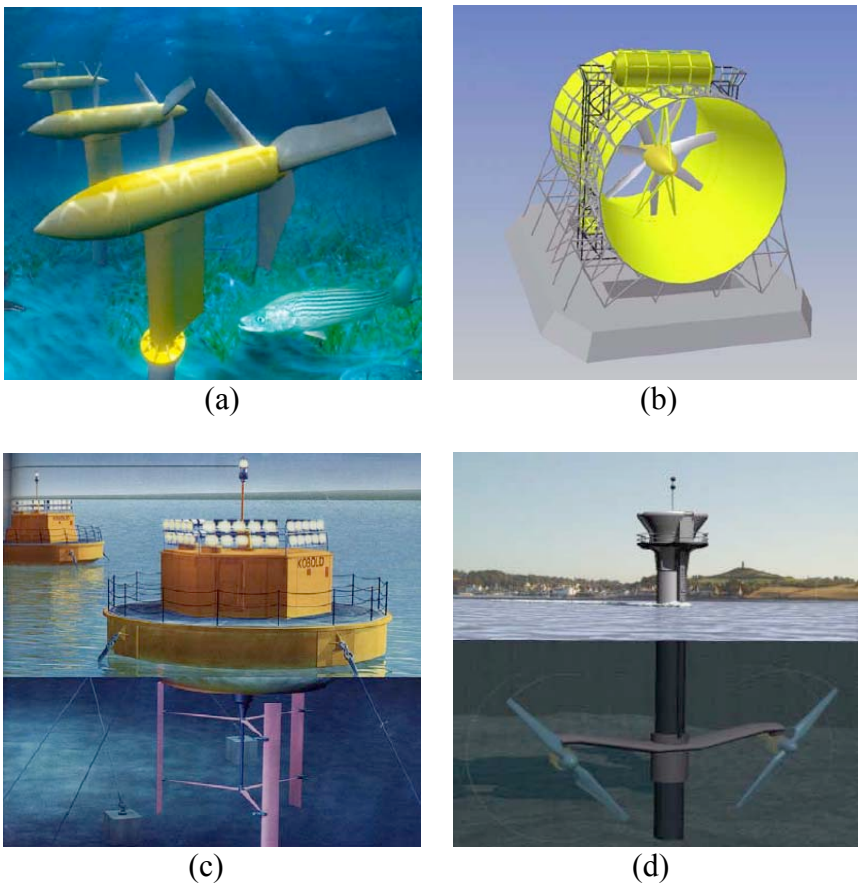

Figure 3. Examples of tidal current turbines (from Bedard, 2005; Rourke et al., 2010). (a) Free flow turbine. (b) Lunar energy tidal turbine. (c) Kobold turbine. (d) Marine current turbine.

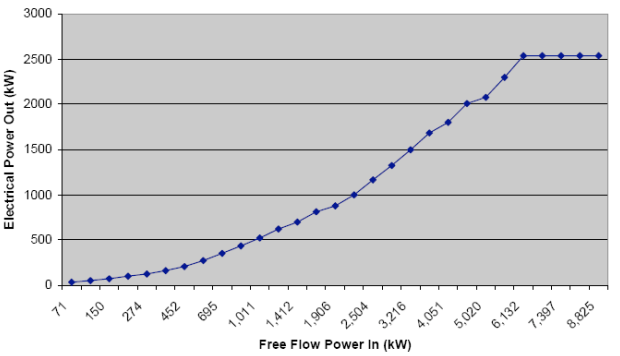

Figure 4. Power curve of Marine current turbine (from Bedard, 2005).

wind turbines from concept and design point of view. MHK turbines can be either mounted on the structures at seabed or floating structures floating in water. The floating structures are usually moored to the seafloor using chains or wires. Fig. 3 presents examples of several actually designed MHK turbines. Various investigations have been made to characterize the efficiency of the turbines (e.g., Bedard, 2005), and Fig. 4 presents the efficiency for one of such MHK energy turbines.

From Eq. (1) it is known that kinetic energy flux from a fluid flow is proportional to the cube of the stream velocity of the flow. Therefore, in order to increase the available MHK energy flux, it is crucial to obtain a large flow velocity. For this purpose, augmentation channels are proposed for MHK turbines (Setoguchi et al., 2004; Ponta and Jacovkis 2008). Fig. 5 presents an augmentation channel supporting a floating water current turbine. A simple channel may consist of a single nozzle or cylinder or straight path. In a hybrid design, all the three options may be incorporated in one unit. A survey shows that around one-third of the horizontal axis turbines are considered for such arrangements, and almost half of vertical turbines are planned with some form of augmentation (Khan et al., 2009).

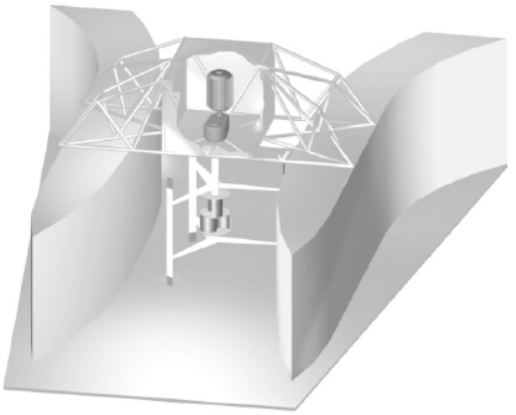

Figure 5. A designed and tested argumentation channel for a floating MHK turbine (from Ponta and Jacovkis, 2008).

PERFORMANCE INDICTORS

It requires a significant amount of historical data and effort to develop a realistic velocity process for a geographic site. Consider a site with an annual tide current velocity history as shown in Fig. 6. Frequently, for a tide power generation device, there is a cut in and cut out velocity. The device stops working at a current velocity lower than the cut in velocity or higher than the cut out velocity. The output power P of such device can be expressed as follows:

$$P = \begin{cases} \frac{\eta}{8}\pi\rho V^3 D^2, & V_{ci} \le |V| \le V_{co} \\ 0, & otherwise, \end{cases}, \tag{2}$$

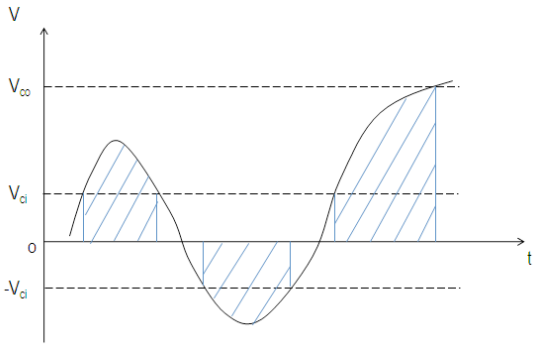

Figure 6. Current velocity history. The shadow area indicates MHK energy available for a turbine to generate power.

where D is the diameter of the blades η is the efficiency coefficient of the turbine, and V_{ci} and V_{co} are respectively the cut in and cut out velocity. The annual average output of the device $\overline{P}$ reads as

$$\overline{P} = \frac{\eta\pi\rho D^2}{2T}\int_0^T |\hat{V}|^3 \, dt, \tag{3a}$$

$$\hat{V} = \begin{cases} V, & V_{ci} \le |V| \le V_{co} \\ 0, & otherwise, \end{cases} \tag{3b}$$

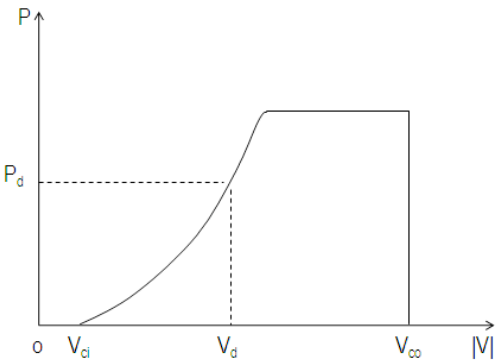

Figure 7. Power curve of MHK energy generation system. P_d is the designed minimum power output of the system, and V_d is the corresponding current velocity.

where T is one year duration or 3.1536×10^7 s. In view of the cut in and cut out velocity and other specifications, the power curve of a MHK energy generation system can be modeled as that shown in Fig. 7 (Bedard, 2005; Karki et al, 2006).

Suppose the velocity of a selected site at a time follows a probability distribution function f as shown in Fig. 8. Unlike wind power generation (Karki et al., 2006), two directions rather than one direction of flow are considered. At a given time at this site, the probability that a current is available for a MHK energy generation system to produce designed power output P_d will be

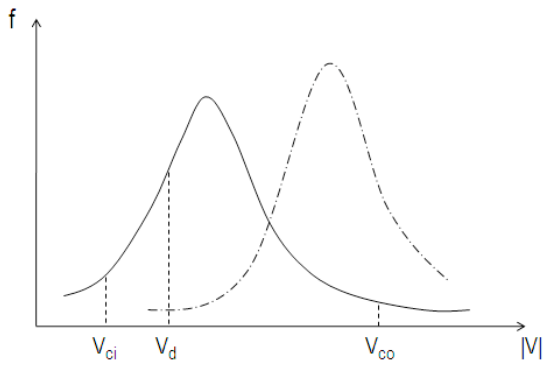

Figure 8. Probability distribution function of current velocity.

$$p_c = p(V_d \le |V| \le V_{co}) = \int_{V_{ci}}^{V_d} f d|V|, \tag{4}$$

and the probability that the system cannot generate the designed power output will be

$$p_{nc} = p(|V| < V_d \cup |V| > V_{co}) = 1 - p(V_d \le |V| \le V_{co}). \tag{5}$$

Let the probability that the turbine, the gear box, the generator, and the supporting structure of a MHK energy generation system be at working states be p_t, p_b, p_g, and p_s, respectively. Since all of these components are subject to impact of water and air flows, the probability if they are at working states will be related to the categories of hurricane classes. Hurricanes are classified into five categories as shown in Table 1, and the observations of damages on structures due to them have been found (ORACLE ThinkQuest, 2011).

Let index i denote the categories of hurricane 0, 1, 2, 3, 4, and 5, and the probability of occurrence of them are p_h^i. Assume the probability that the turbine, gear box, the generator, and the supporting system are working under the condition of hurricane p_h^i is respectively p_t^i, p_b^i, p_g^i, and p_s^i. Then, according to the theorem of total

probability, the probability for the turbine at working condition is (Ang and Tang, 2007)

Table 1 Hurricane category and its wind speed, storm surge height, and air pressure (from ORACLE ThinkQuest, 2011).

Category	Wind Speed	Surge Height	Central Pressure
0 – No hurricanes	<74 mph	<4 feet	> 28.94 in
1 - Minimal	74 - 95 mph	4- 5 feet	>28.94 in
2 - Moderate	96 - 110 mph	6 - 8 feet	28.50 - 28.91 in
3 - Extensive	111 - 130 mph	9 - 12 feet	27.91 - 28.47 in
4 - Extreme	131 - 155 mph	13 - 18 feet	27.17 - 27.88 in
5 - Catastrophic	>155 mph	>18 feet	< 27.17 in

$$p_t = \sum_{i=0}^{5} p_t^i \cdot p_h^i , \quad p_b = \sum_{i=0}^{5} p_b^i \cdot p_h^i , \quad p_g = \sum_{i=0}^{5} p_g^i \cdot p_h^i , \quad p_s = \sum_{i=0}^{5} p_s^i \cdot p_h^i . \tag{6}$$

Then, the probability for a single MHK energy generation system to output designed power at the given time will be

$$p_o = p(P > P_d) = p_d \cdot p_t \cdot p_b \cdot p_g \cdot p_s . \tag{7}$$

In Eqs. (6) and (7), the probability p_d, p_h^i, p_t^i, p_b^i, p_g^i, and p_s^i will be evaluated on the basis of information on manufacture, constructions, weather and current conditions at the sites.

Suppose that there are N MHK energy generation devices at a tide site and each of them is independent of each other, then the number of the devices that are producing the minimum required power output follows the binomial distribution (Ang and Tang, 2007). The probability of at least M ($M \leq N$) of them work at a given time is

$$p_N = \sum_{n=M}^{N} \binom{N}{n} p_o^{\,n} (1 - p_o)^{N-n} . \tag{8}$$

Eqs. (2) and (3) are performance indictors on power output of MHK energy generation systems, and Eqs. (7) and (8) are those on reliability of them.

CONCLUDING REMARKS

Tidal energy is now becoming a significant energy source for our society, and power generation using MHK energy has become a trend in its research and development. Although many technologies in hydro and wind power generation are potentially available for tidal power generation, many new problems are involved and investigations on new technologies are necessary. For instance, a crucial issue will be the estimate of reliability of tidal power systems including their individual components under conditions of normal tides as well as hurricanes at different categories, that is, the probability that involves in Eq. (7). How to make a robust electricity generators and circuits immersed in water? How to construct supporting system that can survive huge repeated hydrodynamic impact including that in thunderstorms and last long time? In addition, the impact of tidal energy generation on environments and ecological systems will be another crucial issue in its commercialization.

ABSTRACT

Transmission tower networks, consisting of lattice support towers and conductor cables, play an important role in the infrastructure system of many countries throughout the world. Lattice support towers are typically comprised of two different components: the vertical tower body and the horizontal conductor support cross-arms. Much research has been directed towards the evaluation of aerodynamic coefficients of the compact lattice form typical of the vertical tower body sections of transmission towers, which now can often be calculated (based on solidity ratio) to an acceptable accuracy. However, the horizontal lattice form of the conductor support cross-arms have not been studied in depth. In this paper, results from wind tunnel tests on a typical conductor support cross-arm are used to show that the aerodynamics of these types of horizontal lattice sections are not as easily predicted as those for vertical lattice sections. The results from the wind tunnel tests are compared to the values calculated through the use of *ASCE Manual No. 74: Guidelines for Electrical Transmission Line Structural Loading*, and reasons for these discrepancies are discussed. This comparison is used to illustrate two examples where *Manual No. 74* may or may not provide a conservative design estimate for tower and line loading at skewed wind directions, depending on the relative contributions of the cross-arm and tower body sections to the total wind loads. This is attributed to the underestimation of the wind loads on the cross-arms at skewed wind directions. Examples are used to show that the ratio of cross-arm area to total structure area is important for the consideration of the design wind direction. In light of the emphasis on efficiency in the world of transmission tower design, recommendations towards an improved evaluation of cross-arm force coefficients are provided.

INTRODUCTION

Power distribution companies across the globe rely on transmission networks comprised of lattice towers and conductor cables in order to transmit and distribute electricity. Many of these networks exist across the United States and are highly visible; it is rare to drive for much longer than half an hour without spotting such a system. In order to compile and disseminate a combination of research, accepted

practice, and general knowledge on the subject of transmission lines, the American Society of Civil Engineers (ASCE) maintains the *ASCE Manuals and Reports on Engineering Practice No. 74: Guidelines for Electrical Transmission Line Structural Loading* (for brevity, herein referred to as Manual No. 74), which is currently in its 3rd edition (ASCE, 2010). While Manual No. 74 itself is not an official code, the provisions and methodology for the calculation of structural loading are compatible with *ASCE-7 Minimum Design Loads for Buildings and Other Structures* (ASCE, 2010b). Some of the important facets of transmission tower and line design that Manual No. 74 addresses are: advice on weather related loads (including ice accretion); information on design loads for various failure mechanisms; and suggestions of force coefficients for 3-D lattice frames and conductor cables.

In order to facilitate discussion of the various wind loads on the tower-line system this paper adopts the terminology used in Manual No. 74, for which a diagram is shown in Figure 1. As in Manual No. 74, a longitudinal force is any force which acts parallel to the conductor cables, while a transverse force is any force which acts perpendicular to the conductor cables. For skewed winds ($0° < \Psi < 180°$), both a longitudinal and transverse force will exist for the tower, while only a transverse force exists for the conductors (assuming a line angle of 0°).

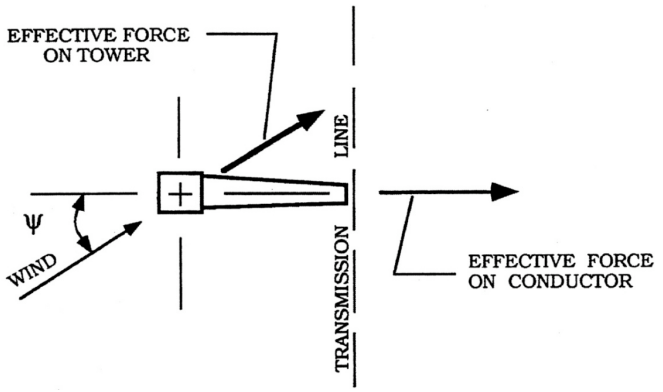

Figure 1. Sign convention in ASCE Manual No. 74 (ASCE, 2010)

For the calculation of the longitudinal and transverse forces on the tower due to wind loading, basic geometric and aerodynamic information must be known about the tower. This information includes the force coefficients of the longitudinal and transverse faces, C_{fl} and C_{ft}, and the solid areas of the longitudinal and transverse faces, A_{ml} and A_{mt}. The force coefficients are calculated based on solidity ratio, which is the ratio of solid area to total enclosed area; this relationship is tabulated in Manual No. 74. The evaluation and use of force coefficients is developed further in the following section. In addition to the aerodynamic and geometric information, the calculation of the forces includes the design wind speed, V, and the yaw angle of the wind, Ψ, as well as additional constants accounting for topographic effects, unit conversion and exposure.

The focus of the remainder of this paper is on the evaluation of the aerodynamic force coefficients, specifically for cross-arm geometries, and how wind tunnel experiments recently performed at the Boundary Layer Wind Tunnel

Laboratory resulted in aerodynamic behaviour which differs significantly from that proposed by Manual No. 74. The intent of the paper is to identify cases where cross-arm geometry may result in wind loads not adequately specified in Manual No. 74.

FORCE COEFFICIENT DEVELOPMENT

Early investigations into the force coefficients of lattice sections were primarily directed at assessing the wind loads on bridge trusses and girders (e.g., Biggs, 1954; Pagon, 1958). At the time of these experiments, it was generally accepted that a relationship existed between the drag coefficient and the solidity ratio, and the results in these studies supported that notion. Although the conclusions drawn from experiments directed at the above trusses answered questions regarding the force coefficients for 2-dimensional (2-D) lattice frames, they were not applicable to 3-D lattice frames. This is due to the presence of shielding (sometimes called interference), which is the effect of members on the leeward face of the frame being shielded from the wind flow by those on the windward face. This effect led to significant differences between the 2-D results mentioned above and realistic wind loads on 3-D trusses or frames, and was the focus of investigation in numerous studies (e.g., Jacobs, 1978; Georgiou and Vickery, 1979; Whitbread, 1979; Kopp et al., 2010). The effects of turbulence intensity has been investigated in many studies as well (e.g., Sykes, 1991; Carril Jr. et al, 2003; Mara, 2007), all which suggest that the level of turbulence intensity is negligible over the range explored in the experiments for the calculation of mean aerodynamic coefficients.

A relationship between force coefficient and solidity ratio is presented in Manual No. 74 (ASCE, 2010), which follows closely with that given by Bayar (1986) resulting from wind tunnel experiments on 3-D lattice frames. Each of these relationships are plotted in Figure 2. The experimental drag coefficients developed from the wind tunnel tests on the cross-arm section (Mara, 2007) described in the following sections are also plotted for yaw angles 0° and 90°.

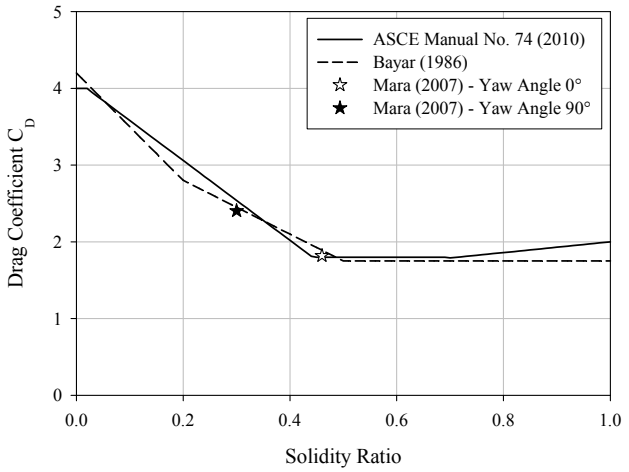

Figure 2. Manual No. 74 and experimental drag coefficients vs. solidity ratio

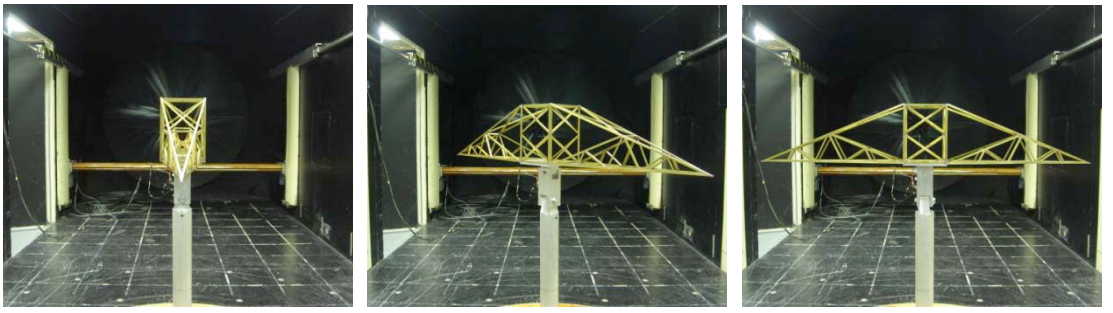
As shown in Figure 2, it can be seen that the provisions in Manual No. 74 (ASCE, 2010) provide excellent estimates of the force (drag) coefficient at each of these 'normal' yaw angles (0° and 90°). However, in the case of cross-arm type sections of towers, the evaluation of the drag coefficient at skewed yaw angles is cumbersome, primarily due to the calculation of the projected and total enclosed areas. Manual No. 74 circumvents this problem by considering only the solidities and areas of each face and applying a wind pressure which reduces at skewed angles. This is a convenient method, as the calculation of projected area at skewed wind directions is an extremely tedious task due the geometry of lattices sections. This calculation is further complicated if it is being carried out for a section similar to that of a cross-arm, which is comprised of many members which are not at right angles to one another. Thus, the evaluation and interpretation of the conventional drag coefficient becomes confusing as the value of projected area may change considerably over a change in yaw angle of 10°. The amount of projected area is also highly dependent on individual member design.

While the force coefficient provisions in Manual No. 74 provide good estimates at 'normal' wind directions, the prototype parameters required to use the provisions are complicated to assess, as described in the above paragraph. In addition, the force coefficient data are only provided for 3-D frames which are square or triangular in plan, a category into which a cross-arm certainly does not fall. Thus, the following questions pertaining to cross-arm aerodynamics are raised, of which the answers are obtained through experimental investigation:



- How applicable are the force coefficients provided in Manual No. 74 at describing the aerodynamics of unique sections such as cross-arms?
- If a discrepancy does exist, are the provisions conservative?
- What will be the effect on the total structure if the wind loading contribution from the cross-arm increases?

Due to the paucity of investigations into the aerodynamic force coefficients of transmission tower cross-arm sections, a reduced-scale wind tunnel testing programme was conceived which would provide estimates of the aerodynamic force coefficients of the cross-arm section for a full range of wind directions. The results from this series of wind tunnel tests, as well as the applicability to design considerations for transmission tower structures, are described in the remainder of this paper.

WIND TUNNEL EXPERIMENT

In order to evaluate the aerodynamics of a realistic cross-arm design, the wind tunnel tests were carried out on a model based on the cross-arm of a Manitoba Hydro Type A HVDC guyed transmission tower. The cross-arm was modelled at a scale of 1:10 and was constructed from angled brass sections; all members were soldered and rigid. The model was then mounted on a strut in order to elevate the model outside of the boundary layer, and measurements of the mean drag forces on the cross-arm were carried out for wind directions at 10° intervals. The wind load accumulated on the strut alone was treated as a tare subtraction from the overall measurement of base

forces. Measurements were averaged over a sampling time of 90 seconds, and the experiments exhibited a repeatability within 1%. All tests were carried out under steady-state flow conditions at a wind speed of 7.6 m/s and a longitudinal turbulence intensity of approximately 7%, which are consistent with testing parameters used in past experiments (e.g., Sykes, 1981; Bayar, 1986; Carril Jr. et al, 2003). Hotwire measurements were used to measure profiles of the speed and turbulence intensity at various positions across the test section, and no abnormalities in flow conditions existed over the area of the model. All wind tunnel tests were conducted in Tunnel I at the Boundary Layer Wind Tunnel Laboratory at the University of Western Ontario and are described in detail by Mara (2007). The cross-arm model is shown mounted in the wind tunnel in Figure 3 at a) a yaw angle of 0°; b) a yaw angle of 45°; and c) a yaw angle of 90°.

a) b) c)

Figure 3. Cross-arm model shown in wind tunnel at a) 0°, b) 45° and c) 90°

The overall drag force on the model was measured using a robust balance located at the base of the strut, which was necessary to support the weight of the model. The measurement of the overall drag force can be decomposed into its vector components, which correspond to the longitudinal and transverse forces that the presence of the cross-arm would add to the tower-line system. The experimental results are presented in terms of $C_D A_p$, which is obtained by rearranging the basic drag force equation

$$F_D = \frac{1}{2}\rho V^2 C_D A_p \tag{1}$$

where F_D is the measured drag force, ρ is air density, V is the mean wind speed used in the experiment, C_D is the drag coefficient of the section, and A_p is the amount of projected member area. This approach is analogous to the effective projected area (EPA) approach to wind design used in ANSI/TIA 222-G (ANSI, 2006), and facilitates the comparison of different yaw angles as the change in area is inherently included in the comparative values of $C_D A_p$. It also provides an accessible comparison to the provisions in Manual No. 74, which are carried out later in the paper.

The experimental values are plotted in terms of $C_D A_p$ at each yaw angle for the overall drag force, the longitudinal force, and the transverse force in Figure 4. It should be noted the that overall force is not simply the sum of the forces in the longitudinal and transverse directions, rather it is the vector sum. It is interesting to

see that the experimental data shows a maximum transverse force occurring at 40°, although due to the resolution of the yaw increments the true maximum may occur at +/- 5° from this angle.

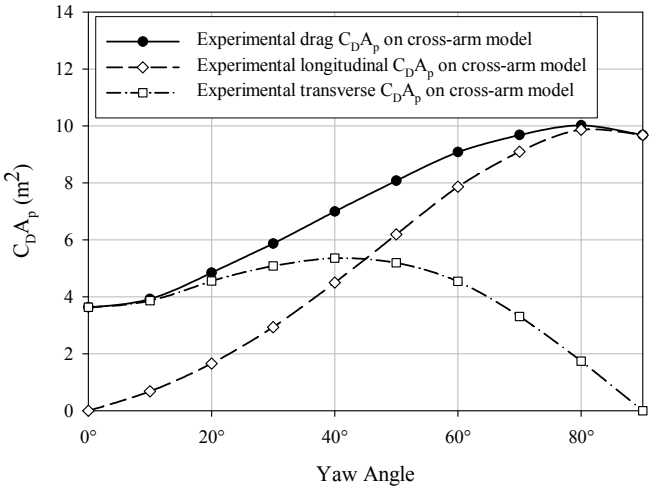


Figure 4. Experimental C_DA_p on cross-arm model

COMPARISON OF EXPERIMENTAL DATA TO ASCE MANUAL NO. 74

ASCE Manual No. 74 approaches the calculation of longitudinal and transverse forces on a transmission tower structure in an orthogonal fashion. In other words, for skewed wind directions the methodology assumes that there are components of the resultant wind which pass through the longitudinal face-plane and transverse face-plane of the structure, which result in longitudinal and transverse forces on the tower-line system. The equations taken from Manual No. 74 are shown in Equations (2) and (3), in which F_l and F_t are the longitudinal and transverse forces, respectively, and where Ψ is the yaw angle measured clockwise from the transverse axis of the tower. That is, when $\Psi = 0°$, the transverse wind load is theoretically at a maximum and the longitudinal wind load is 0. This results in a large transverse force, as the conductors accumulate the greatest amount of wind loading at this orientation, and is often viewed as a design case. Due to this fact, the comparison between Manual No. 74 and experimental data is focussed on forces in the transverse direction. The remainder of the terms are constants accounting for various features (e.g., exposure, wind speed) and correspond to full scale conditions. Thus, they are not discussed in any of the comparisons made.

$$F_l = \gamma_w Q K_z V^2 G_t \sin\Psi \, C_{fl} A_{ml} \tag{2}$$

$$F_t = \gamma_w Q K_z V^2 G_t \cos\Psi \, C_{ft} A_{mt} \tag{3}$$

In order to compare experimental values to those calculated using Manual No. 74, the terms which are not constants were extracted from (3). Thus, the transverse C_DA_p measured in the wind tunnel tests can be compared to the term ($\cos\Psi \, C_{ft} A_{mt}$),

in which C_{ft} and A_{mt} correspond to the cross-arm geometry. These data are plotted in Figure 5, and it is shown that the yaw angle which results in the maximum force differs significantly between the experimental results and that predicted by Manual No. 74. It is noteworthy to mention that the previous edition of Manual No. 74 (ASCE, 1991) included an additional equation for the calculation of the resultant force on tower components, which is based on an IEC standard (IEC, 1988). Equation (4) shows the transverse component of this resultant force, the calculation of which uses characteristics of both the transverse and longitudinal faces. In this case, the term $\{(1 + 0.2sin^2(2\Psi))(A_{mt}C_{ft}cos^2\Psi + A_{ml}C_{fl}sin^2\Psi)(\cos\Psi)\}$ can be considered analogous to $C_D A_p$. It can be seen that the relationship in (4) provides a much better description of the transverse force on the structure, however it is acknowledged that results have been compared for a single cross-arm design only. While the magnitude difference is likely due to complex member aerodynamics, the shape of the curve is likely to be similar for cross-arm type frames.

$$F_t = \gamma_w Q K_z V^2 G_t (1 + 0.2sin^2(2\Psi))(A_{mt}C_{ft}cos^2\Psi + A_{ml}C_{fl}sin^2\Psi)(\cos\Psi) \quad (4)$$

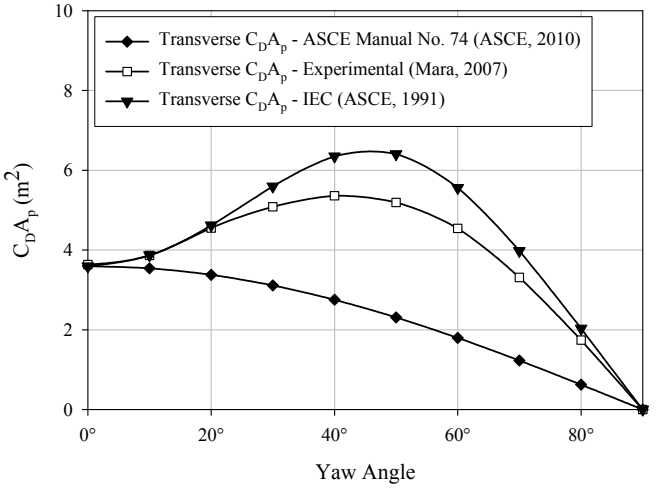

Figure 5. Manual No. 74 vs. experimental transverse $C_D A_p$ on cross-arm section

In Figure 6 an 'overage factor' is introduced, which describes how much greater the transverse wind load on the cross-arm is when calculated using the wind tunnel data than that calculated using Manual No. 74. The overage factor is based on the data presented in Figure 5, and will be used in combination with Manual No. 74 calculations in the following section. It should also be noted that no overage factor is calculated for a yaw angle of 90°, as no transverse force theoretically exists for this wind direction.

IMPLICATIONS ON OVERALL TOWER WIND LOADING

When considering the design case for part of a transmission tower network, it is important to address every part of the system which accumulates wind load. While the results presented in the previous section discussed the wind load on the cross-arm

only, the following sections apply those results and put them into context of an entire tower structure in order to assess the importance of the load contributions from the cross-arm. As shown in Figure 5, the complicated geometry of the cross-arm section will result in a transverse force greater than that calculated using Manual No. 74. It is worth mentioning that due to the fact that the cross-arm features are often located near the top of the tower, they will experience a greater wind load than most of the tower body section. This also plays a role in the ratio of loading, and is accounted for in the current results, but is beyond the scope of discussion in this paper.

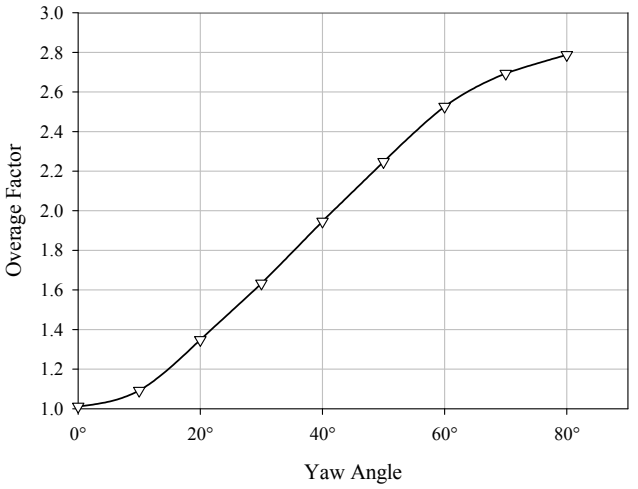

Figure 6. Overage factor for transverse $C_D A_p$ with yaw angle

In order to assess the importance of the increased wind forces on the cross-arm to the wind loading on the entire tower, the design of the full Manitoba Hydro Type A guyed tower (the same tower design on which the cross-arm is based) was considered. The geometry was used with the methodology in Manual No. 74 to calculate the expected transverse forces on the entire tower, which are shown in Figure 7a. The forces are shown in kips in order to maintain consistent units with Manual No. 74. Figures 7a and 7b include 4 tower configurations: no cross-arm (this is theoretical, and provides a base for comparison); a single cross-arm (which corresponds to the design of the Manitoba Hydro tower); 2 cross-arms; and 3 cross-arms. A range of yaw angles from 0° to 50° was selected for the plots in order to focus on the differences at the most important wind directions for the transverse force. It is shown that although the transverse force increases over low yaw angles, each curve exhibits a similar shape, which illustrates the additive behaviour of Manual No. 74.

Figure 7b shows the expected wind loads based on the aerodynamic behaviour obtained from the wind tunnel tests. Here the contribution of the cross-arm section is determined from the Manual No. 74 calculation augmented by the overage factors shown in Figure 6. The difference in the form of the curves when compared to Figure 7a illustrates the importance of the cross-arm wind loads in the overall tower loads, particularly for cases where the tower has more than one cross-arm.

Figure 8 shows the ratio of the expected transverse force to the original transverse force calculated using Manual No. 74. While Figure 8a plots the entire range of yaw angles, Figure 8b is provided in order to observe the ratios at the low end of the range of yaw angles. It is worth mentioning that although the ratios seem high at large yaw angles, these forces are not as important in the calculation of the transverse force on the structure due to the skewed direction of the wind.

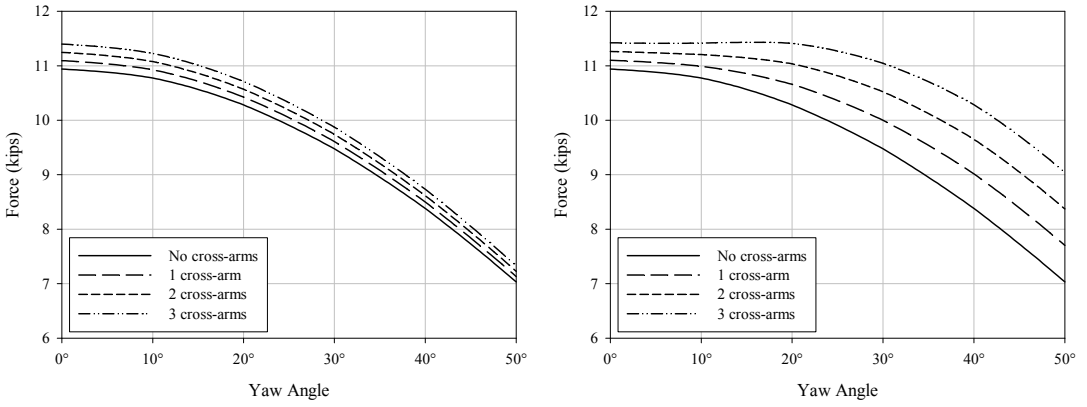

Figure 7. Transverse force on tower for a) Manual No. 74 and b) augmented with wind tunnel data for cross-arm aerodynamics

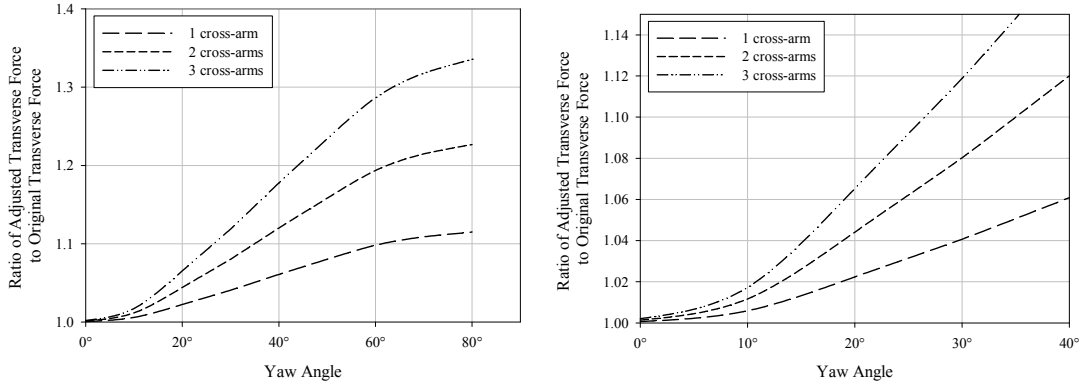

Figure 8. Effect of using wind tunnel test data in transverse force calculation

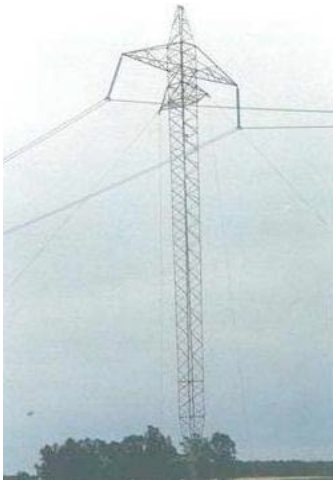
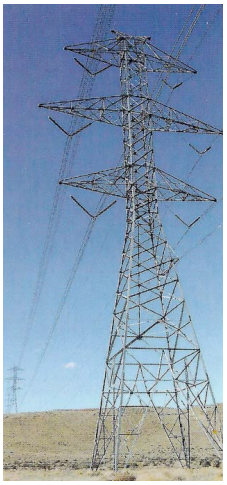


In addition to the wind forces on the tower structure, the wind forces on the conductors contribute a significant amount to wind load on the tower-line system. The wind force on the conductor (or ground wire) is calculated per Equation (5), where F is the transverse force on the wire. It is worth noting that the wind forces on the wires resolve to transverse forces only, with the exception of cases where a line angle exists between towers (see ASCE (2010) for further discussion).

$$F = \gamma_w Q K_z K_{zt} V^2 G_w \cos^2 \Psi \, C_f A \tag{5}$$



The addition of the wind loads on the lines will also reduce the importance of the increases in loading from the cross-arm on the overall wind loading of the structure. Of importance is the fact that the wind loads on the conductors reduce with yaw angle proportional to $\cos^2 \Psi$, while the wind loads on the structure only reduce with yaw angle proportional to $\cos \Psi$. Examination of various design cases is ongoing, with the outcome expected to provide a quantitative range of the reduction. While worth mentioning, the work in this paper is focused on the tower loads only.

INFLUENCE OF UNIQUE TOWER DESIGN

There are many conditions which contribute to the style and design of transmission tower used in particular situation. These include the transmission capacity of the network, available surrounding land and topographic features, to name a few. These factors often result in a wide variety of transmission tower designs used in practice, which are tailored to the exact demands of the loading situation at hand. For example, towers may be self-supported or supported by guy wires. The example design used in this paper to develop the methodology was a guyed tower (see Figure 9a), and was characterized by a relatively small ratio of cross-arm area to total area as it had a single, small cross-arm. Shorter, bulkier self-supported towers (see Figure 9b) are also common, and possess much higher cross-arm area to total area ratios. While the effects of the approach taken in this paper has not been applied to this type of tower, it is expected that the increases observed in the transverse force at skewed wind directions would be more severe.

CONCLUSIONS AND RECOMMENDATIONS

The third edition of *ASCE Manual No. 74: Guidelines for Electrical Transmission Line Structural Loading* is an important contribution to the field of transmission tower design. The work carried out in this paper combines the findings

from a series of wind tunnel tests with the Manual No. 74 approach for the calculation of transverse wind forces on a lattice transmission tower. A comparison of the aerodynamic behaviour of the cross-arm was carried out between the Manual No. 74 calculation and the wind tunnel tests over a range of yaw angles, and it was found that the maximum force on the cross-arm occurs at a yaw angle of approximately 40°, rather than the yaw angle of 0° suggested by Manual No. 74. The IEC method (IEC, 1988) of calculating resultant force (Equation 4) was also compared to the experimental work, and was shown to provide a better relationship of transverse force with yaw angle for the cross-arm in question. The impact of the increased wind forces on the cross-arm component were considered in the calculation of the transverse wind force on the entire structure, and it was found that the impact is not significant for a small ratio of cross-arm member area to total area. However, the impact increases as this ratio grows, and for some towers may result in a design case which does not correspond a yaw angle of 0° (pure transverse loading). Winds occurring at this direction are assumed by Manual No. 74 to be the governing case. Work is currently being carried out to quantify this effect, and will hopefully result in a set of generic specifications which would assist in identifying if a particular structure is susceptible to the mentioned increases in transverse wind load.

With regards to force coefficients, the conclusion can be drawn that the orthogonal method used for the calculation of the longitudinal and transverse forces as specified in Manual No. 74 are likely appropriate for typical vertical portions of lattice transmission towers, but may underestimate the wind loads on cross-arm portions at skewed wind directions. This is attributed to the complex geometry of the cross-arm section, which results aerodynamic and geometric parameters varying significantly with yaw angle. While the method in Manual No. 74 for the calculation of longitudinal and transverse forces is convenient (as only the wind pressure changes with yaw angle), the approach fails to properly account for accumulated wind load on cross-arm type sections due to complicated aerodynamic features. The IEC method suggested in previous editions of Manual No. 74 appears to capture the correct shape of increased loading due to skewed winds for the cross-arm, although it is slightly conservative in magnitude. Wind tunnel testing is likely the most accessible method to study these features, and therefore further investigation into the aerodynamic behaviour at skewed winds for sections which are characterized by unbalanced aspect ratios (e.g., cross-arm, bridge) is recommended. When approaching the wind load calculations for sections such as these, current provisions for typical 3-D lattice frames appear to be inadequate.

ACKNOWLEDGEMENTS

The authors would like to thank Manitoba Hydro, the Natural Sciences and Engineering Research Council of Canada (NSERC), CEA Technologies Inc. (CEATI), and the Institute for Catastrophic Loss Reduction (ICLR) for providing financial support towards the wind tunnel testing component of this work.

NEW APPROACHES IN FIXING TECHNOLOGY: APPROVALS FOLLOW DESIGN GUIDES, SHOWN BY EXAMPLE OF ANCHOR CHANNELS

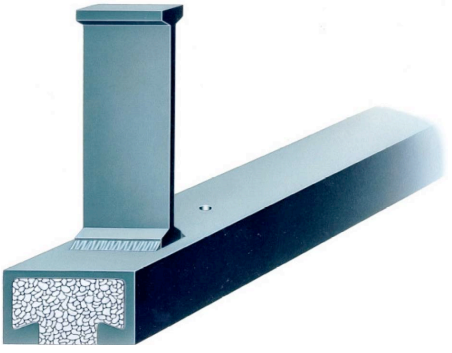
Matthias Roik[1]

[1]Halfen GmbH, Department Research and Development, Liebigstrasse 14, D-40764 Langenfeld; Germany; PH +49 (0)2173-970-485; email:matthias.roik@halfen.de

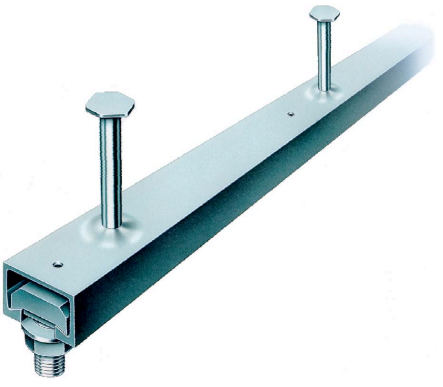
ABSTRACT

Connections between steel and concrete were not yet covered by codes until 2009.
A European Technical Specification was published in 06/2009 with the aim to provide design rules for anchorages to concrete. This work of the European committee CEN TC 250, published as prCENTS 1992-4, led to a European Technical Approval (ETA) for anchor channels.
Following the technical approach, a *fib* design guide was developed. This design guide will be published approx. in 2010 and gives design rules for several fixing methods such as dowels, headed studs and also anchor channels. This *fib* design guide will present the basis for a future international approval for anchor channels. This approval will be issued approximately in 2010/2011.

In the present state of the art, technical approvals basing on test results only confirm a defined amount of applications with definite boundary conditions. A building product (here: a fixing construction) can only be used in accordance to these regulations. Diverging from the boundary conditions of the technical approval means using a non licensed product e.g. to infringe the approval.
With a design guide which describes the general application of a product, a universal calculation becomes possible without constraints towards boundary conditions.
A technical approval then "only" proves the applicability of the design rule and the suitability of the product to this documented state of technique.
It should be a clear aim of the holders of approvals to support the efforts obtaining design guides and standards to document the technical state of the art which then can be incorporated into technical approvals.



This paper gives an overview of these new methods of calculating the resistance of fixing constructions, in this case: anchor channels. The practicality of these formulas on the products is stated by an adequate approval. The design rules are explained and the experimental results are illustrated.



INTRODUCTION

The design of fixing constructions was not yet covered by codes. All results concerning the resistance of a fixing were gained by tests, which had to be provided by the supplier.
The preliminary release of the technical specification prCEN/TS 1992-4 (CEN, 2009) enables the calculation of a fixing construction's resistance. In this technical specification fixings with headed fasteners, post installed fasteners as mechanical and chemical systems, and anchor channels are covered.
In the following, the technical regulations for anchor channels are introduced and their contents are compared. The focus lies on the possibility of calculating all significant parameters which influence the load bearing of an anchor channel to gain a flexible and variable fixing method to concrete constructions which guarantees the required safety and reliability.

ANCHOR CHANNELS AND THEIR APPLICATION

Cast-in channels consist of a C-profile with at least two anchors attached to the back of the profile. Corrosion protection is achieved by galvanization or the use of stainless steel.

Figures 1 and 2: anchor channels with welded I-anchor and with riveted round anchor

The channels are equipped with anchors either made of a cut I-profile, fig. 1, or round anchors, shown in fig. 2. The round anchors are riveted or welded to the back of the channel. I-anchors can be welded on in longitudinal or transversal direction.
Before casting the concrete, the channels are fixed onto the formwork. After curing of the concrete and striking the formwork, the foam filling inside the channel is removed and the channel is ready for installation of the fixtures. Hammerhead or hookhead bolts with associated nuts and washers are supplied for the fixing of any structural element.
Using anchor channels, a flexible and multi-functional fixing method is accomplished.
In the following, the development of the design methods is shown.

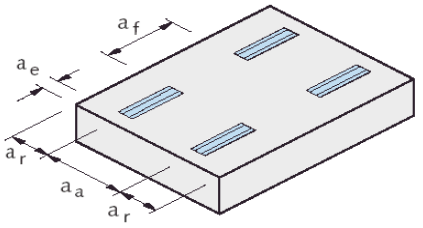
In the wake of this approvals became more and more specific permitting a growing number of applications.

REGULATIONS

Anchor channels were not produced and planned according to harmonised standards. Due to this, a technical approval is to be achieved, in which the design resistances and the boundary conditions for the use of such building products are defined.

GERMAN NATIONAL APPROVAL

The national approval for anchor channels valid for Germany is based on test results only. The first examinations of the load bearing behaviour of anchor channels which led to the technical approval started in 1965. Large series of tests were performed. Not only was the selection of different types of anchor channels examined but also a large variety of applications. All tests were performed on channels cast into concrete with precisely specified geometrical boundary conditions. Edge distances as well as member thicknesses were defined as minimum values, see fig. 3.



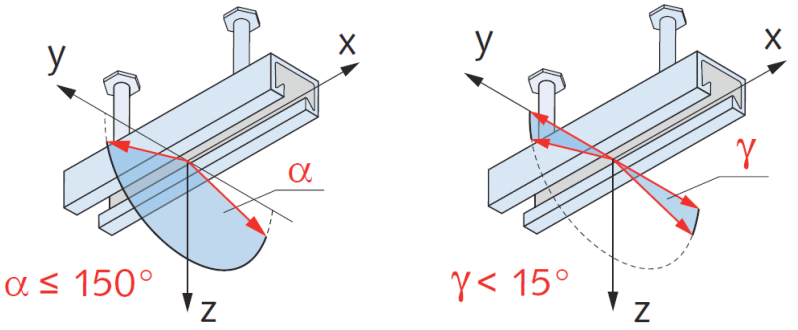


Figure 3: Definition of geometrical boundary conditions

The large variety of load directions and load application made it difficult to find an universal model to describe the bearing behaviour of anchor channels. As an easy to handle method to regard the direction of the applied load two areas of load direction were defined. Loads were differentiated between tension and shear loads. The range of shear was defined from 90° to 75°, relating to the axis of the bolts, see fig. 5. The rest of the load range was considered as tension, figure 4. Both load ranges were tested under different boundary conditions such as varying concrete strength or varying geometries i.e. edge distances, member thicknesses etc.

Figures 4 and 5: Load range Tension" and load range "Shear"

The achieved loads were statistically evaluated and - after taking into account the adequate global safety factor – given in the technical approval (DIBt, 1976) as a table for maximum permissible load.

As a consequence only the considered geometrical combinations could be fixed in the German national approval. As no statements are made regarding the general bearing behaviour, this approval cannot give values for applications where those boundary conditions are not maintained. Diverging from these boundary conditions means to infringe this technical approval.

TECHNICAL PROGRESS

In the last decades, the technical basis for the design of fixing constructions was developed. Based on test results, universally valid equations were derived to describe the bearing behaviour.
Especially the research work on concrete cone failure led to a universally valid calculation method which could be adapted to manifold applications. By these approaches the geometrical conditions, the material properties and the individual bearing behaviour of diverse fixing can be considered in the calculation of the resistance.
The sum of these approaches are published by the European Committee for Standardisation, CEN, in a technical specification.
Up to now this specification has the status of a preliminary standard and is incorporated in the Eurocode series as prCEN/TS 1992-4 (CEN, 2009). It is also published in Germany as DINspec 1021 (DIN, 2009).
This technical specification (TS) contains chapters for general applications, headed fasteners, post installed fasteners as mechanical and chemical systems and for anchor channels.

Failure modes. For a universally valid calculation method, the knowledge about all possible failure modes is required.
Subdivided into tension and shear as well as into steel and concrete failure modes, figures 6 to 7 show the observed failure modes.

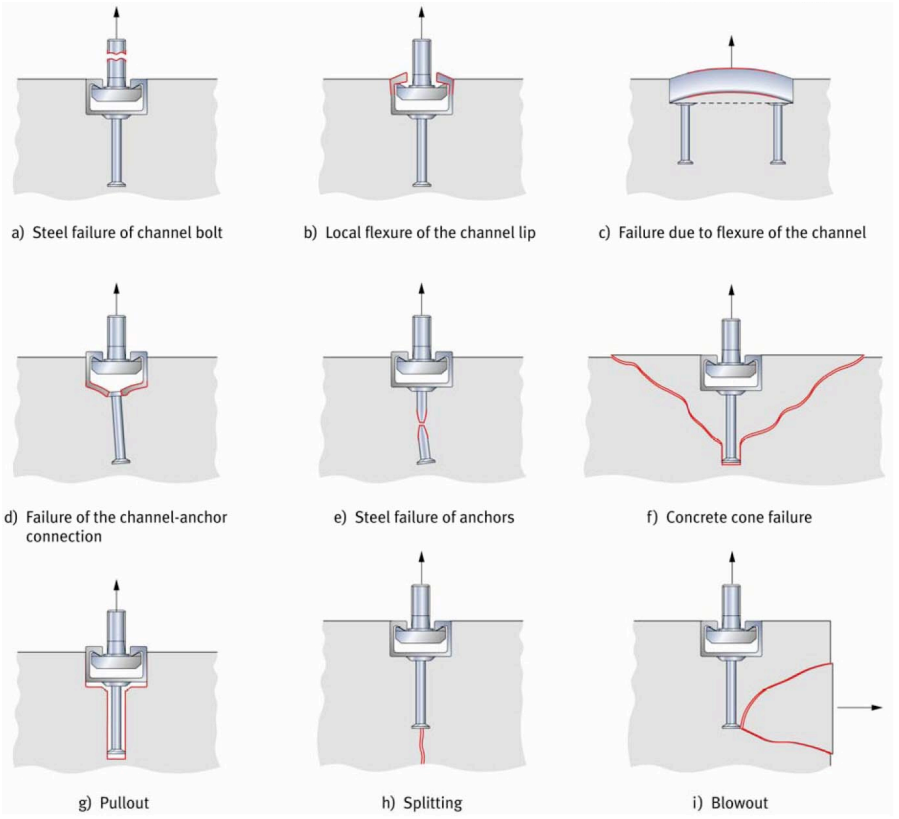

Figure 6: Failure modes of anchor channels due to tension load

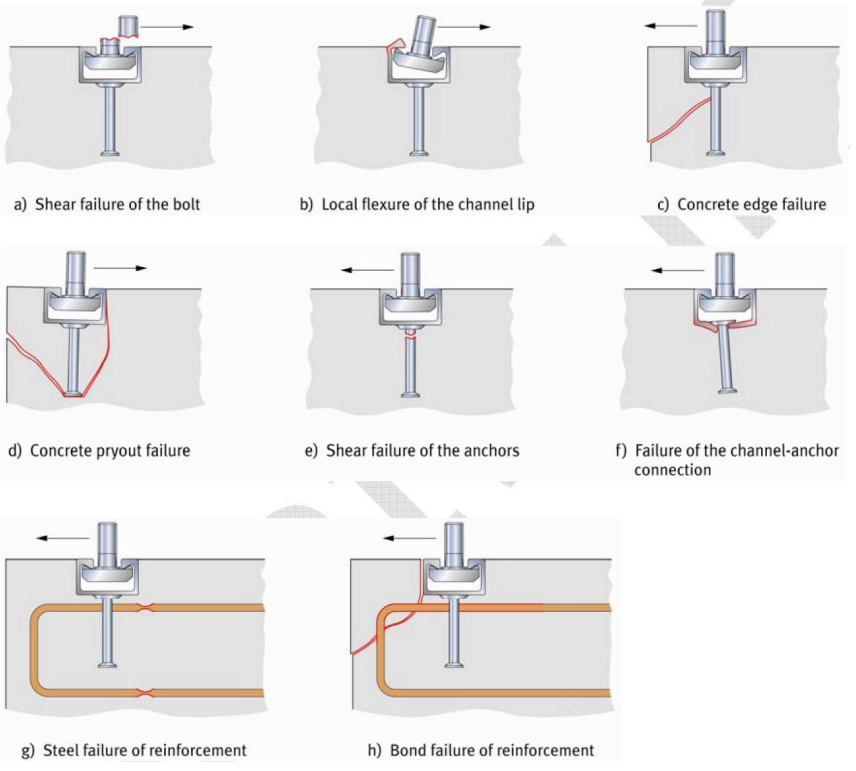

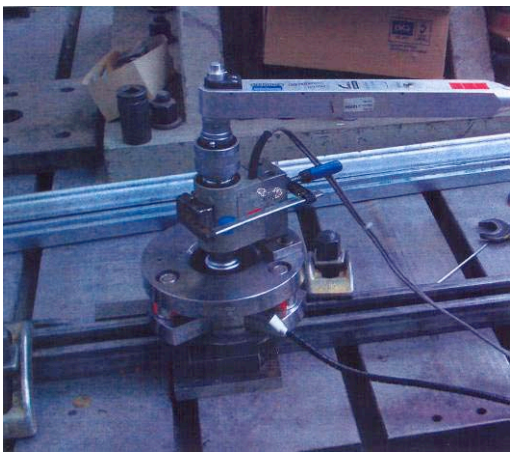

Figure 7: Failure modes of anchor channels due to shear load

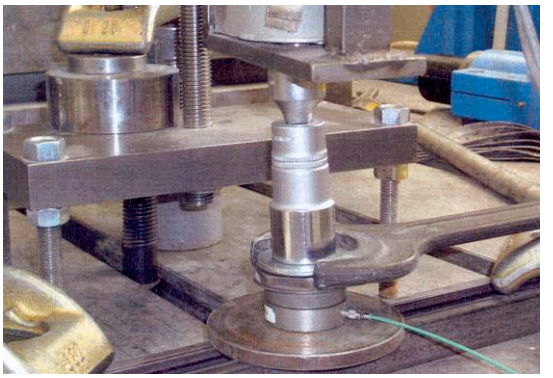
Each failure mode was observed and evaluated individually. An enormous effort of experimental work was provided to figure out the decisive parameters which influence the bearing behaviour.
In the following figures some test setups and failure modes are shown. The pictures are taken from variouss tests, arranged

Steel failure. The steel failure modes due to tension and shear have to be examined to determine the characteristic resistance of the bolt, the channel profile and the anchor. In various installation tests, tensile as well as shear tests and pull out tests, the failure modes were examined. Exemplary see fig. 8 and 9 which show the test setup for installation tests.



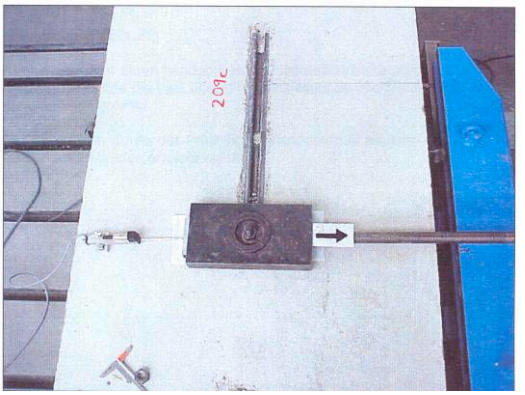


Fig 8 and 9: Test setups for evaluating tension forces due to installation

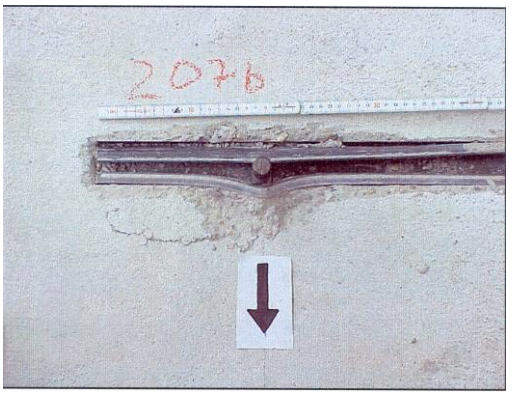
Concrete failure. Some test setups and results are shown in the following figures, fig. 10 to 13. The possible failure modes e.g. concrete cone breakout, blow out, pry out or edge failure had to be investigated by taking into account the specific characteristics of the fixture, here: anchor channel.
It is assumed, that the channel profile distributes attached loads into the anchors which introduce the loads into the concrete.



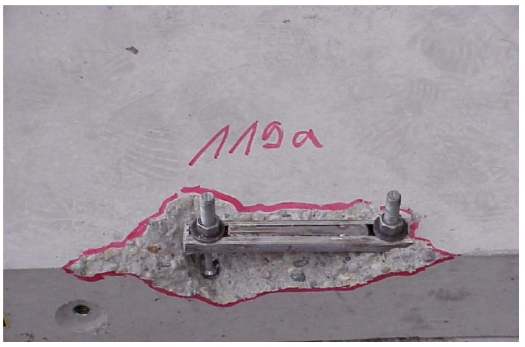


Fig 10 and 11: Test setup and failure mode for shear failure without edge influence

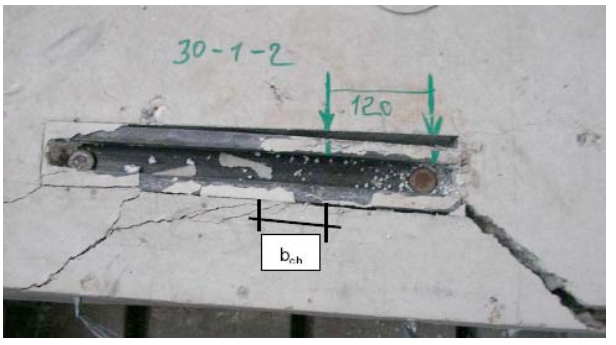

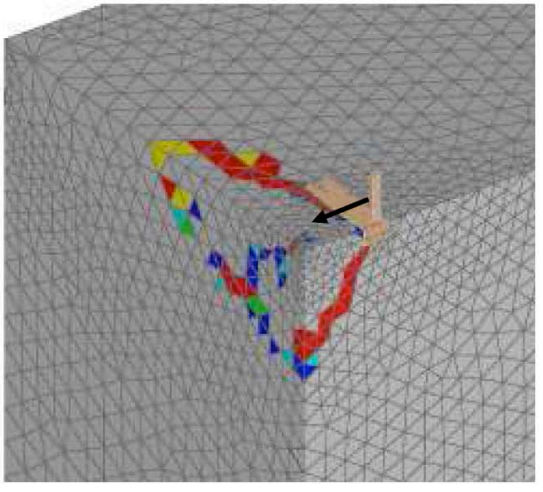

Fig. 12 and 13: Concrete breakout failure due to tension and shear for channels close to an edge

Additionally, results from numerical investigations were taken into account to interpret basic effects of the bearing behaviour.

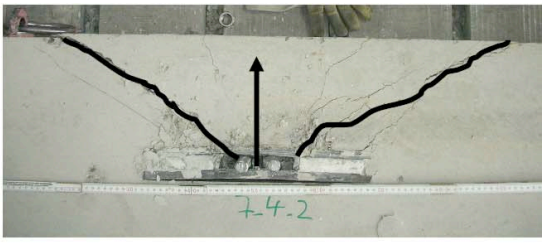

Fig. 14 and 15: Numerical Investigation and comparison to test results (Schmid, 2010)

Alternatively to specific tests, some basic parameters were adopted from similar bearing constructions, mostly from headed studs. For example the concrete breakout failure mode is equivalent for anchor channels and for headed studs. The basic resistance can be calculated by the CC-method with supplemental consideration of the channel profile which crosses the concrete breakout cone: The channel might disrupt the flow of the stress in the concrete and introduce splitting forces by reducing the deformation due to creep and shrinkage. In this case, an additional factor is introduced which takes this effect into account:

$$N_{u,c}^{0} = N_{u,c}^{0}(headed\ stud) \cdot \alpha_{ch,N} = 15{,}5 \cdot h_{ef}^{1,5} \cdot f_{cc}^{0,5} \cdot \alpha_{ch,N}$$

with :

$$\alpha_{ch,N} = (h_{ef}\ /180)^{0,15} \leq 1{,}0$$

The factor $\alpha_{ch,N}$ is derived from additional tests.

This example shows how universally valid parameters can be adjusted by specific factors.

For each possible failure mode, a numerical verification is required. It must be stated that the design action does not exceed the design value of the resistance:
$E_d \leq R_d$

The adequate resistance has to be specified for the product. Some resistances may be calculated, some have to be evaluated by tests. It is task of the applicant for a technical approval to attest the necessary resistances of his product e.g. fixing construction.

Safety concept. The design resistances according to the above mentioned failure modes are calculated basing on the European system for partial safety factors.
The partial safety factors from EN 1990 apply (CEN, 2002).

$$\mathrm{E_d} = \sum \gamma_{\mathrm{G}} \cdot \mathrm{G_k} + \gamma_{\mathrm{Q,1}} \cdot \mathrm{Q_{k,1}} + \sum_{\mathrm{i>1}} \gamma_{\mathrm{Q,i}} \cdot \psi_{\mathrm{0,i}} \cdot \mathrm{Q_{k,i}}$$

γ_{G} = partial safety factor for permanent actions (γ_{G}=1,35)
γ_{Q} = partial safety factor for variable actions (γ_{Q}=1,5)
$\mathrm{G_k}$ = characteristic value of the permanent actions
$\mathrm{Q_{k,1}}$ = characteristic value of the largest variable action
$\mathrm{Q_{k,i}}$ = characteristic value for further variable actions
ψ_0 = combination factor for variable actions

EUROPEAN APPROVAL

Approval concept. An official guidance document is required to obtain an European Approval (ETA). For product groups, a so called ETAG - European Technical Approval Guideline - is to be developed by a European Approval Body.
For single building products, such as anchor channels, a leaner guideline, the CUAP - Common Understanding of Assessment Procedure -, is sufficient. This guidance document which specifies the required testing procedures was published in 2004 (DIBt, 2004).
A final report – the Evaluation Report – states the adduced test results and the properties of the product.
These documents - the documentation of the Technical Design Rules, the Approval Guideline and the Evaluation Report - lead to a European Technical Approval which is issued by the European Organisation for Technical Approvals, EOTA.
This ETA is valid in all European EOTA-member states, which are up to now 27 European states.
It is valid for 5 years and enables the owner to "CE-mark" the approved products.

Up to now, two German manufacturers have received an ETA for anchor channels (EOTA, 2009-1) and (EOTA, 2009-2).

INTERNATIONAL APPROVAL

Approval concept. The concept for applying for an International Approval is similar to the before described European concept.
The International Codes, or I-Codes, are published by the International Code Council and fifty states and the District of Columbia have adopted the I-Codes at the state or jurisdictional level.
For fixing constructions and here for anchor channels the concerning technical regulation can be found in the *fib* design guide for Anchorages to Concrete, which has reached the final draft status and is to be published in 2011 (fib, 2010).
This design guide covers fixing constructions by various dowel systems, headed anchors, post installed reinforcing bars and anchor channels.

Based on this regulation, the so called Acceptance Criteria are developed by the ICC-ES (International Code Council – Evaluation Service). These Acceptance Criteria define the required properties the product should provide. Also the testing procedure and the evaluation method are determined.

Fig 16 shows the complete test program. The program is composed to verify the resistances according to the before mentioned failure modes.

TABLE 4.1 -- TEST PROGRAM FOR ANCHOR CHANNELS FOR USE IN UNCRACKED AND CRACKED CONCRETE

Test no.	Test ref.	Test description	f_c	Δw	Minimum No. of tests	Channel	Anchor	Material	Channel bolt	
									d_s	strength
[-]	Section in Annex A	[-]	psi [N/mm²]	inch [mm]	[-]	[-]	[-]	[-]	inch [mm]	[-]
Steel failure under tension load										
1	7.3	channel / anchor	-	-	5[1]	all	all	all	max	max
2	7.3	bending of channel lips, pull-out of channel bolt	-	-	5[1]	all	all	all	see Section 7.3.2	
3	7.3	screw head	-	-	5	see Section 7.3.2	-	all	see Section 7.3.2	
4	7.4	bending strength of the channel[2]	low	0						
		$s=s_{max}$, inch [mm]			5	all	max	all	max	max
		$s<s_{max}$, inch [mm][3]			5	all	max	all	max	max
5	7.5	torque tests[4]	-	-	5	all	max	all	all	all
Concrete failure under tension load										
6	7.6	splitting failure due to installation[5] $c_a = c_{a,min}$ $s=s_{min}$, $h=h_{min}$	low	0	5	all	see Section 7.6.2			
7	7.7	Splitting failure under load $c_{a1} = c_{a2} = c_{cr,sp}$; $s_{cr,sp}$	low	0	4	all	see Section 7.7.2		max	max
Steel failure under shear load										
8	7.8	failure of anchor, failure of connection between anchor and channel, local rupture of channel lips[6],	low	0	5[1]	all	see Section 7.8.2	all	max	max
9	7.9	Interaction for combined tension and shear loads[7]	low	0	5[1]	See Section 7.9.2				
Concrete failure under shear load										
10	7.10	Concrete edge failure[8] $c_a = c_{a,min}$, $= s = s_{max}$	low	0	5	see Section 7.10.2			max	max
Seismic tests										
11	7.11	Seismic tension	low	0,5	5	all	all	all	see Section 7.11.2	
12	7.12	Seismic shear	low	0,5	5	all	all	all	see Section 7.12.2	

[1]If the coefficient of variation of the failure loads is $V \leq 5$ percent, the number of tests can be reduced to $n = 3$.

[2]Tests are only necessary if restraint of channels embedded in concrete shall be taken into account ($\alpha_r > 4$).

[3]The tests shall only be performed if the conditions in Section 7.4.2.1 of this annex apply.

Fig 16: Test program for anchor channels (ICC-ES, 2010)

The test program assures the determination of each characteristic resistance which is needed for each specific verification.
All test results will be gathered in an evaluation report that states the specific value for each resistance that is needed.

It becomes possible to verify the resistance of a fixture with anchor channels according to the fib design guide.

CONCLUSION

The technical progress especially on the field o anchorages to concrete improved enormously in the last decade. The number of publications grew continuously so that a verified scientific basement could be gained.
A large amount of research work was incorporated into norms and regulations. Provided by institutes and manufacturers a profound technical background and knowledge could get gathered and compressed into technical papers such as design guides and regulations. These technical specifications enables the user to provide a "realistic" design of a fixing construction, as the influencing parameters such as various boundary conditions - concrete strength, edge distance, member thickness, anchor distances and interaction tension /shear – are considered.
Applications basing on these regulations, such as European Technical Approvals (ETA) or ICC Approvals therefore represent technically the "state of the art". It should be a clear aim of the holders of approvals to support the efforts obtaining design guides and standards to document the technical state of the art which then can be incorporated into technical approvals.

Design of Sports Lighting Support Structures – Will Your Structures Perform to Expectation?

Brian R. Reese, P.E., C.W.I, M.ASCE[1]

[1] Vice President Northeast Region, ReliaPOLE Inspection Services Co., 22955 Tomball Parkway, Suite 24, Tomball, TX 77375; Chairman TIA TR-14.7 Engineering Subcommittee; PH (281) 259-7000; FAX (281) 754-4166; email: breese@polesafety.com

ABSTRACT

For many years, tubular steel poles have been utilized in various industries. A popular support structure for the sports lighting industry due to their strength, reliability, and ease of installation, the steel pole has served the industry well. The industry has steel pole installations that have been in service upward of fifty years. However, in recent years, there have been numerous failures of sports lighting structures. While manufacturing, installation, and maintenance issues have contributed to these failures, design issues have also contributed. Careful attention to the design requirements for these structures will prolong their lifespan and ensure public safety.

As with any steel support structure, consistent application of a design standard is critical. Historically, the sports lighting industry has not utilized a consistent standard for the design of its support structures. Some pole structures are purchased to meet a recognized structural code with appropriate load and strength safety factors and others are sold as general "commercial" design. Design issues include improper factors of safety, inadequate base plate design, insufficient anchor bolts, improper application of wind and wind coefficients, undersized welds, improper material specifications, and ignoring fatigue issues. Standardizing the design process will improve the safety of these structures and reduce confusion during the procurement process.

This article will present current methods used to design sports lighting structures to the AASHTO *Standard Specifications for Structural Supports for Highway Signs, Luminaries, and Traffic Signals*, 5th Edition, 2009. The document is specifically for pole structures, specifies factor of safety, addresses fatigue issues, and addresses wind induced vibration issues.

INTRODUCTION

Tubular steel poles are a popular support structure in many industries. Poles have been utilized as support structures in the sports lighting, utility, transportation, and communications industries for many decades. Combining a long history of reliable performance, competitive pricing, and ease of use and installation, steel poles are the sports lighting industry's preferred support structure and have performed admirably at some of America's most popular sporting venues. A typical installation of sports lighting poles can be seen in Figure 1 below. However, in recent years, there have been numerous failures of sports lighting structures across the country. In some cases, the property damage has been significant. As with America's other aging infrastructure, the cost of ignoring this issue can be significant to public safety and welfare. While manufacturing, installation, and maintenance issues have contributed to these failures, design issues have also played a role. Careful attention to the design requirements for sports lighting pole structures will prolong their lifespan and ensure public safety.

Figure 1. Typical sports lighting pole installation

STEEL POLES

Steel poles in the sports lighting industry can be anchor based, direct burial, or stub based. AASHTO *Standard Specifications for Structural Supports for Highway Signs, Luminaires, and Traffic Signals*, Fifth Edition, 2009, defines a pole as a vertical

support that is long, relatively slender, and generally rounded or multisided (Specifications, 2009). Anchor based poles are supported with anchor bolts embedded into a concrete foundation. Direct burial structures are embedded into the soil. Stub based poles are flanged to a pipe section that is also directly embedded into the soil. Typically galvanized and in some cases weathering steel, steel poles are pressed in polygonal shapes or comprised of round cross sections. Polygonal pole shells are longseamed (vertical weld along pole axis joining pole half-shells) via submerged arc welding (SAW) techniques and round tapered poles are longseamed via SAW or electric resistance welding (ERW) methods. In most cases for structural efficiency, the structures taper over their height to a smaller tip diameter at the top. Steel sports lighting poles are typically fabricated with high strength steel plate and range in height from 55 ft to 150 ft. The structures can be designed to support as little as four lighting fixtures or as many as dozens of fixtures. A standard sport lighting pole and its components can be seen in Figure 2 below.

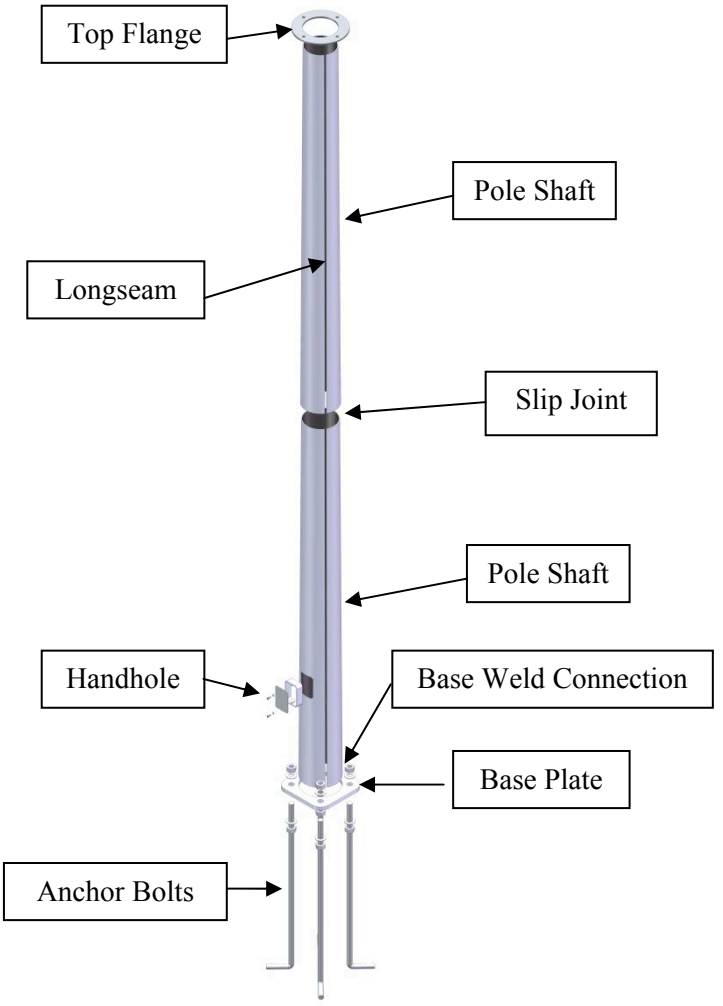

Figure 2. Sports lighting pole structure components

Pole collapses in the sports lighting industry, while an infrequent occurrence, have increased in occurrence and have made news in recent years. With their proximity to areas where the public gathers for sporting events, there is a significant potential for loss of life and injury. Collapses of sports lighting poles are shown in Figure 3.

Figure 3. Sports lighting pole collapses

LACK OF DESIGN CONSISTENCY

Historically, the sports lighting industry has not utilized a consistent standard for the design of its support structures. There has been significant latitude on design techniques for sports lighting poles causing confusion with owners, designers, and those procuring light support structures. Typically, the supporting pole structures are packaged with the light fixtures and provided as a component of the lighting system by the supplier. Unlike other industries where the support structures are purchased by a knowledgeable owner directly from the pole manufacturer, owners of sports lighting poles are typically not active in the specifications development or procurement process and are downstream in the supply chain. As a result, owners have had very little input into the specifications and design processes for their sports lighting pole structures.

Some pole structures today are purchased to meet a recognized structural code with appropriate load and strength safety factors and others are sold as general "commercial" design. Design issues include improper factors of safety, inadequate base plate design, insufficient anchor bolts, improper application of wind and wind coefficients, undersized welds, improper material specifications, and ignoring fatigue issues. These issues have resulted in drastic differences in pole structure design and quality depending on the supplier. As with any steel support structure, consistent application of a design standard is critical. Standardizing the design process will

improve the safety of these structures, reduce confusion during the procurement process, and ensure the longevity of the structure.

AASHTO STANDARD SPECIFICATIONS

AASHTO's *Standard Specifications for Structural Supports for Highway Signs, Luminaires, and Traffic Signals*, Fifth Edition, (Specifications, 2009) are applicable to the structural design of supports for highway signs, luminaires, and traffic signals. The document is intended to serve as a standard and guide for the design, fabrication, and erection of these types of structures. As the only available standard to address the design of luminaire support structures, the Specifications should be utilized for the design of sports lighting poles. The Specifications state in Article 1.4.2 that structural supports for luminaires include typical lighting poles, pole top-mounted luminaire poles, and high-level poles (Specifications, 2009). Commentary C1.4.2 further defines high-level lighting poles as structures normally in heights from 55 ft (17 m) to 150 ft (46 m) or more, usually supporting four (4) to twelve (12) luminaires and used to illuminate large areas (Specifications, 2009). This definition clearly covers the application of sports lighting pole structures.

The Specifications were the result of National Cooperative Highway Research Program Project (NCHRP) 17-10 and the corresponding NCHRP Report 411 (1998) and replace the previous 2001 version of the AASHTO Standard Specifications (2001). Note that the Specifications are only the minimum requirements necessary to provide for public safety. The owner in conjunction with the designer may require the pole design be greater than the minimum requirements as established in the Specifications.

POLE LOADING

Section 3 of the Specifications specifies the minimum requirements for loads and forces, the limits of their application, and load combinations that are used for the design of lighting pole structures. Criteria for dead load, live load, ice load, and wind load is addressed.

Dead load - consists of the weight of the pole, lights, support baskets or arms, and any other appurtenances. Temporary loads applied during maintenance should also be considered (Article 3.5, Specifications 2009).

Live load – consists of a single load of 500 lb (2200 N) distributed over 2 ft (0.6 m) transversely to the member used for design of members for walkways and platforms. This load represents the weight of a person and equipment during servicing of the structure and is only applied to members of walkways and service platforms (Article 3.6, Specifications 2009).

Ice load – consists of a load of 3.0 psf (145 Pa) applied around the surfaces of the pole and luminaires. The map in Figure 4 below from the Specifications shows where ice loading should be considered in the United States (Figure 3-1, Specifications, 2009). The loading is based on a 0.60 in (15 mm) radial thickness of ice at a unit weight of 60 pcf (960 kg/m^3) applied uniformly over the exposed surface (Article 3.7 and Commentary C3.7, Specifications, 2009).

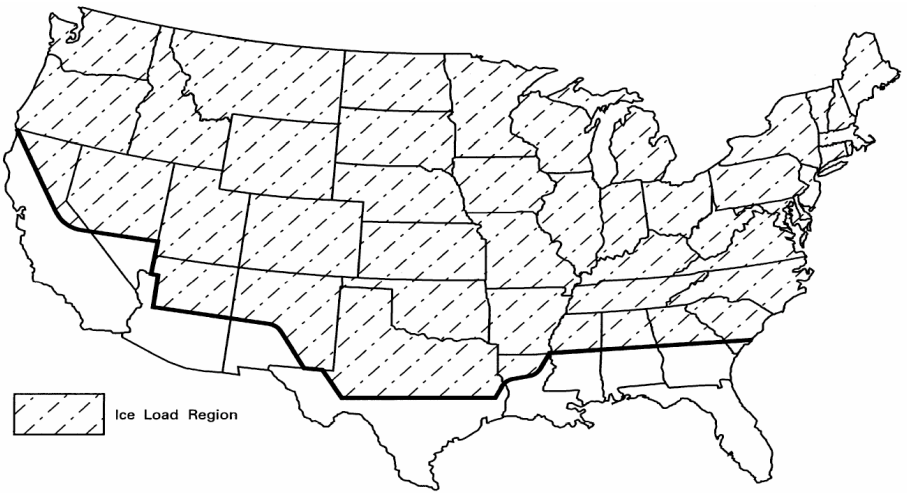

Figure 4. Ice Load Map (Figure 3-1 from *Standard Specifications for Structural Supports for Highway Signs, Luminaires, and Traffic Signals*, 2009, by the American Association of State Highway and Transportation Officials, Washington D.C. Used by permission.)

Wind load – the pressure of the wind acting horizontally on the pole, lights, support baskets or arms, and any other appurtenances corresponding to the appropriate 50-yr mean recurrence interval basic wind speed and the appropriate wind importance factor, I_r (Article 3.8, Specifications, 2009). Wind load is defined in terms of 3-s gust wind speeds instead of the fastest-mile wind speed utilized in the previous version of the Specifications (2001). A 3-s gust wind speed is defined as the average wind speed measured over an interval of three (3) seconds. The country map of 3-s wind speeds is included below in Figure 5 with permission of ASCE.

The design wind pressure calculation is based on fundamental fluid-flow theory and formulations presented in ASCE 7-95, *Minimum Design Loads for Buildings and Other Structures* (1995), and is computed as follows:

$$P_z = 0.00256\, K_z\, G\, V^2\, I_r\, C_d \quad \text{(psf)} \qquad \text{(Equation 3-1, Specifications, 2009)}$$

$$P_z = 0.613\, K_z\, G\, V^2\, I_r\, C_d \quad \text{(Pa)} \qquad \text{(Equation 3-1, Specifications, 2009)}$$

The height and exposure factor, K_z, is related to height and is determined from Table 3-5 in the Specifications or calculated by equation C3-1. The gust effect factor, G, is a minimum of 1.14. Previous versions of the Specifications addressed wind sensitivity by incorporating an increased gust coefficient of 1.3. This gust coefficient corresponded to a gust effect factor of 1.69 = (1.3)(1.3) for use with fastest-mile wind speeds. The fastest-mile gust coefficient of 1.3 is converted to a 3-s gust coefficient by multiplying the gust coefficient of 1.3 by the ratio of the fastest-mile wind speed to the 3-s gust wind speed. The corresponding gust effect factor, G, is then found by squaring the 3-s gust coefficient (Commentary C3.8.5, Specifications 2009). The basic wind speed, V, is determined from the ASCE wind map in Figure 5 below (Figures 3.2 a and b, ASCE 7-05) associated with a height of 33 ft (10 m) for open terrain and associated with a 50-yr mean recurrence interval (annual probability of two percent that the wind speeds will be met or exceeded). The wind importance factor, I_r is determined from Table 3-2 in the Specifications and is selected based on the specified design life of the structure. For a 50-yr recurrence interval, I_r is 1.00.

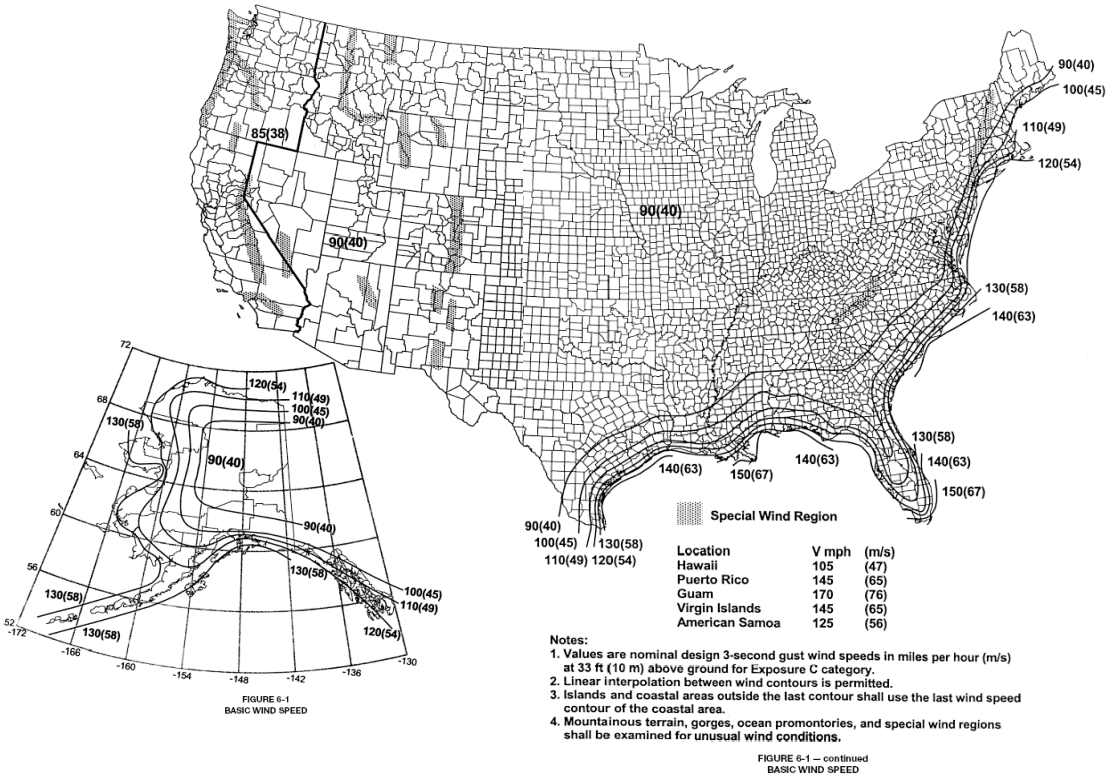

Figure 5. Basic Wind Speed Map in mph (m/s) - Figure 3-2 from ASCE 7-05
(with permission from ASCE)

The wind drag coefficient, C_d, is determined from Table 3-6 of the Specifications. For a pole structure, C_d will depend on the number of flats (shape) of the pole, the ratio of corner radius to radius of inscribed circle, and the wind speed. For attachments such as luminaires, the drag coefficient is typically provided by the light fixture supplier in terms of effective projected area (EPA), which is the drag coefficient multiplied by the projected area. If the EPA is provided, the drag coefficient is taken as 1.0.

Group loading combinations are addressed specifically in Article 3.4 of the Specifications. Each individual load is to be combined into group load combinations as shown in Table 1 below (Table 3-1, Specifications, 2009). Each part of the structure shall be designed for the combination producing the maximum load effect using allowable stresses increased as indicated for the group load.

Group Load	Load Combination	Percentage of Allowable Stress[a]
I	*DL*	100
II	*DL* + *W*	133
III	*DL* + *Ice* + ½(*W*)[b]	133
IV	Fatigue	[c]

[a] Percentages of allowable stress are applicable for the allowable stress design method. No load reduction factors shall be applied in conjunction with these increased allowable stresses.

[b] *W* shall be computed based on the wind pressure. A minimum value of 1200 Pa (25 psf) shall be used for *W* in Group III.

[c] See Section 11 for fatigue loads and stress range limits.

[d] See Article 3.6 regarding application of live load.

Table 1. Group Load Combinations (Table 3-1 from *Standard Specifications for Structural Supports for Highway Signs, Luminaires, and Traffic Signals*, 2009, by the American Association of State Highway and Transportation Officials, Washington D.C. Used by permission.)

POLE DESIGN

Section 4 of the Specifications describes methods of analysis for the structural design of poles. Although the engineering community has been trending to Load and Resistance Factor Design, (LRFD, AISC 1994), the Specifications follow an allowable stress design, (ASD, AISC 1989) approach for design. ASD is based on elastic stress calculations where the strength of the member is divided by a factor of

safety. The allowable stress value is compared to actual calculated stresses in the member and structure. For pole structures, Article 4.8 of the Specifications require second-order effects be accounted for in the design. Secondary bending moments caused by the axial load should be accounted for by an approximate simplified method in Article 4.8.1 or a more exact method where the member is analyzed considering the actual deflected shape of the structure in Article 4.8.2 (Specifications, 2009).

Section 5 specifies design provisions for steel poles. Article 5.5 addresses local buckling and the classification of steel sections as compact, non-compact, or slender element sections. For a section to qualify as compact or non-compact, the width-thickness ratios of compression elements must not exceed the applicable corresponding values given in Table 5-1 of the Specifications. For design, Table 5-3 provides the allowable bending stress, F_b, for tubular members. Pole structures subjected to axial compression, bending moment, shear, and torsion should satisfy the following requirement from Article 5.12.1:

$$\frac{f_a}{0.6F_y} + \frac{f_b}{C_A F_b} + (f_v / F_v)^2 \leq 1.0 \qquad \text{(Equation 5-16, Specifications, 2009)}$$

Equation 5-16 may be increased by 1/3 for load combination Groups II and III involving wind. C_A is calculated in accordance with Article 4.8.1 to estimate second-order effects or is 1.0 if the more exact method of 4.8.2 is utilized (Specifications, 2009).

Per Article 5.14 of the Specifications, the minimum thickness of material used for main supporting members shall be 3/16 in (4.76 mm). Telescoping slip joint field splices should be detailed such that the minimum length shall be 1.5 times the inside diameter of the female pole section. All welding design should be per the latest edition of the American Welding Society *Structural Welding Code D1.1* (2010). Article 5.15 states that full-penetration groove welds shall be used for pole and arms sections joined by circumferential welds. Longitudinal seam welds for pole and arms sections shall have 60% minimum penetration expect within 6 in (150 mm) of circumferential welds where the weld shall be full-penetration and in slip joint areas where it shall be full-penetration the length of the slip joint plus 6 in (150 mm).

BASE PLATE AND ANCHOR BOLT DESIGN

The Specifications state in Article 5.14.2 that the pole base plate thickness should be considered in the design of the structure and that the thickness of unstiffened base plates should be equal to or greater than the nominal diameter of the connection bolt. In steel poles, the flexibility of this joint can greatly contribute to the reduced fatigue strength of this connection. While the Specifications do not provide detailed

guidance on base plate design techniques, it is recommended that careful consideration be given to the design of the pole base plate connection so that premature failure of this joint due to design, fatigue, or manufacturing issues does not occur. The pole shaft to base plate weld connection should be a full-penetration groove weld (CJP) or socket-type joint with two fillet welds per Article 5.15.3 as shown below in cutaway Figures 6 and 7. The CJP connection base plate is butted against the pole shaft and consists of a groove weld with 100% complete weld penetration and reinforcing fillet weld. The socket connection base plate sleeves over the pole wall and is welded with double fillet welds. For base plate materials per Article 5.4, all steels greater than 1/2 in (13 mm) in thickness that are main carrying load members shall meet the current Charpy V-Notch impact requirements in AASHTO *Standard Specifications for Highway Bridges*, 17th Edition (2002).

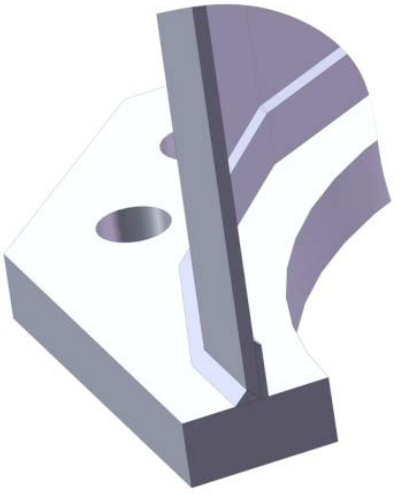

Figure 6. Pole base complete penetration groove weld joint (CJP)

Figure 7. Pole base socket weld joint

Article 5.17 addresses anchor bolt connections and provides minimum requirements for the design of steel anchor bolts used to transmit loads in the critical connection from the pole to the foundation. The Specifications require cast-in-place anchor bolts be used conforming to the requirements of ASTM F1554 (2007) or hooked smooth bars with a yield strength not exceeding 55 ksi (380 MPa). Headed anchor bolts are preferred to reduce the possibility of pull-out. To reduce susceptibility to corrosion and fatigue, for a design life of 50 years, a minimum of six (6) anchor bolts should be considered at the base plate connection (C5.17.3, Specifications, 2009). This is not widely practiced by designers and pole manufacturers in the industry today. For a

single anchor bolt subjected to combined tension and shear, the following equation shall be satisfied:

$$(f_v / F_v)^2 + (f_t / F_T)^2 \leq 1.0 \qquad \text{(Equation 5-24, Specifications, 2009)}$$

For a single anchor bolt subjected to combined compression and shear, the following equation shall be satisfied:

$$(f_v / F_v)^2 + (f_c / F_C)^2 \leq 1.0 \qquad \text{(Equation 5-25, Specifications, 2009)}$$

Equations 5-24 and 5-25 may be increased by 1/3 for load combination Groups II and III. If the clear distance between the bottom of the bottom leveling nut and the top of concrete is less than the nominal anchor bolt diameter, bending in the anchor bolt from shear forces or torsion may be ignored. If the clear distance exceeds one bolt diameter, bending of the anchor shall be considered per Article 5.17.4.3 (Specifications, 2009).

SERVICEABILITY REQUIREMENTS

Horizontal deflection limits for poles are defined in Section 10, specifically Article 10.4.2 in the Specifications. According to the Commentary in C10.4, deflection limits serve two purposes: 1) Provide for an aesthetically pleasing structure under dead load; and 2) Provide adequate structural stiffness that will result in acceptable serviceability performance (Specifications, 2009). Limits for Group I load combinations (dead load only) include a deflection limit of 2.5% of the structure height and 0.35 in/ft (30 mm/m) slope. For pole structures under Group II load combination (dead load and wind load), deflection should be limited to 15% of the structure height. The 15% deflection limitation for Group II load combination is not a serviceability requirement, but it constitutes a safeguard against the design of highly flexible structures. While serviceability may be more critical for certain types of traffic structures than sports lighting poles, the owner and designer should understand the ramifications of overly flexible structures and the resulting fatigue consequences.

FATIGUE

Fatigue is damage resulting in fracture caused by stress fluctuations due to cyclic loading. The fatigue and premature failure of structures has cost lives and industry billions of dollars. Specifically for pole structures, fatigue can be very detrimental to the long term performance of the structure and can risk public safety. Sports lighting poles are exposed to several wind phenomena that can produce cyclic loads. The resulting vibrations can be significant and can shorten the lifespan of the pole. A pole structure is especially susceptible to vortex shedding and natural wind gusts; the amplitude of vibration and resulting stress ranges are increased by the low levels of

stiffness and damping possessed by a flexible pole structure (C11.7, Specifications, 2009). As tall, slender, cantilevered structures with no base connection redundancy, this phenomenon should be acknowledged by owners and considered carefully by the sports lighting pole designer.

Section 11 of the Specifications requires fatigue design for high-level, high-mast lighting structures. To avoid large-amplitude vibrations and to preclude the development of fatigue cracks at the base connection of a pole structure, sports lighting poles should be designed to resist limit state equivalent static wind loads acting separately per Article 11.7. These loads should be used to calculate nominal stress ranges near the fatigue-sensitive base connection of the pole and deflections for service limits described in Article 11.8. Stresses due to these loads on all components of the pole should be limited to satisfy the requirements of their respective detail categories within the constant-amplitude fatigue limits (CAFL) provided in Article 11.9 (Specifications, 2009). The basis of the pole fatigue design provisions in the Specifications is the National Cooperative Highway Research Program Project Report 412 (1998).

Fatigue importance factors are introduced in Article 11.6 of the Specifications to adjust the level of structural reliability of a pole structure. The fatigue importance factor, I_F, accounts for risk of hazard and should be applied to the limit state wind load effects specified in Article 11.7. The Commentary of the Specifications in C11.6 recommends this value be determined by the owner. In the case of sports lighting structures, the owner should be generally aware of these provisions and determine this in conjunction with the advice of the pole designer. The Commentary in C11.6 also states that high-mast structures (without mitigation devices) in excess of 100 ft may be classified as Fatigue Category 1. Typically, sports lighting poles present a high hazard in the event of failure and as a result should be designed to resist wind loading and vibration phenomena. Based on Section 11.0 and Table 11-1 in the Specifications, the fatigue importance factor, $I_{F,}$ is 1.0 for cantilevered lighting pole structures for both vortex shedding and natural wind gusts (Specifications, 2009). The importance categories and fatigue importance factors in the Specifications are from NCHRP Reports 469 (2002) and 494 (2003).

VORTEX SHEDDING

The shedding of vortices on alternate sides of a pole exposed to wind may result in oscillations in a plane normal to the direction of wind flow as shown below in Figure 8. This phenomenon is commonly seen with tubular steel poles.

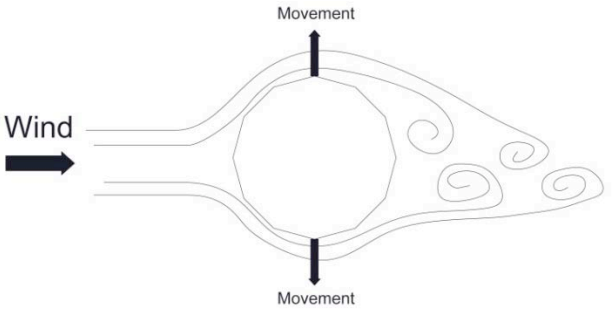

Figure 8. Vortex shedding phenomenon

NCHRP Report 469 (2002) shows that poles with tapers exceeding 0.14 in/ft (0.0117 m/m) can experience vortex shedding. A taper of 0.14 in/ft (0.0117 m/m) is very common for a sports lighting pole. According to the Commentary in C11.7.2 of the Specifications, tapered poles can experience vortex shedding in second or third mode vibrations which can lead to fatigue problems. Per Article 11.7.2, high-level, high-mast lighting structures should be designed to resist vortex shedding-induced loads for critical wind velocities less than approximately 45 mph (20 m/s). The critical wind velocity, V_c, in mph at which vortex shedding lock-in can occur may be calculated by the Strouhal relationship as follows for circular sections:

$V_c = 0.68\,(f_n\, d / S_n)$ (mph) $V_c = f_n\, d / S_n$ (m/s) (Eq. 11-2, Specifications, 2009)

For multisided sections:

$V_c = 0.68\,(f_n\, b / S_n)$ (mph) $V_c = f_n\, b / S_n$ (m/s) (Eq. 11-3, Specifications, 2009)

where f_n is the natural frequency of the structure in cycles per second; d and b are the diameter and flat-to-flat width of the pole shaft for circular or multi-sided sections (ft, m), respectively; and S_n is the Strouhal number (0.18 for circular sections or 0.15 for polygonal sections). For tapered poles, d and b are the average diameter and width (Specifications, 2009).

Article 11.7.2 designates the equivalent static pressure range to be used for the design of vortex shedding-induced loads for poles as follows:

$P_{VS} = (0.00256\, V_C^2\, C_d\, I_F)/2\beta$ (psf) (Equation 11-4, Specifications, 2009)

$P_{VS} = (0.613\, V_C^2\, C_d\, I_F)/2\beta$ (Pa) (Equation 11-4, Specifications, 2009)

where V_c is mph (m/s); C_d is the drag coefficient as specified in Section 3 which is based on the critical wind velocity V_c; and β is the damping ratio, which may be

estimated as 0.005. The equivalent static pressure, P_{vs}, is to be applied transversely (horizontal direction) to pole structures (Specifications, 2009).

NATURAL WIND GUST

Natural wind gusts are basic wind phenomena that are variable in velocity and direction and can induce vibrations in pole structures. This is also a fairly common phenomenon with pole structures. Per Article 11.7.3, steel poles should be designed to resist an equivalent static natural wind gust pressure range of:

$$P_{NW} = 5.2\ C_d\ I_F \quad \text{(psf)} \qquad \text{(Equation 11-5, Specifications, 2009)}$$

$$P_{NW} = 250\ C_d\ I_F \quad \text{(Pa)} \qquad \text{(Equation 11-5, Specifications, 2009)}$$

where C_d is the appropriate drag coefficient based on the yearly mean wind velocity of 11.2 mph (5 m/s) specified in Section 3 of the Specifications. The natural wind gust pressure range should be applied in the horizontal direction to all exposed areas and should consider the application of gusts for any direction of wind. The Specifications allow the owner to modify the natural wind gust pressure if there are more detailed wind records available.

FATIGUE RESISTANCE

Constant-amplitude fatigue limits (CAFL) are the nominal stress ranges below which a particular fatigue detail can withstand an infinite number of repetitions without fatigue failure. Typical fatigue sensitive connections in steel poles are the base plate to shaft weld connection and the slip joint previously shown in Figures 6, 7, and 2, respectively. Fatigue details and corresponding stress categories are specified in Table 11-2 and illustrated in Figure 11-1 of the Specifications for use by the designer. Allowable CAFL's are specified in the Specifications Article 11.9, Table 11-3 (Specifications, 2009). For steel pole base connections (Figures 6 and 7), the Stress Category and corresponding CAFL is as follows:

CJP groove weld ➡ *Stress Category E'* ➡ *CAFL = 2.6 ksi (18 MPa)*

Socket weld ➡ *Stress Category E'* ➡ *CAFL = 2.6 ksi (18 MPa)*

Table 11-2 of the Specifications, footnote j, states that fillet welds for socket connections shall be unequal leg welds, with the long leg of the fillet weld along the column. The termination of the longer weld leg should contact the pole shaft's surface at approximately a 30° angle.

For pole slip joints (Figure 2), where the telescoping overlap is greater than or equal to 1.5 diameters, the Stress Category and corresponding CAFL is as follows:

Slip joint ➡ *Stress Category B* ➡ *CAFL = 16 ksi (110 MPa)*

Note that the wind loads from Article 11.7 should be utilized to compute the fatigue stress range.

CONCLUSION

Active involvement of the owner, communication with the pole designer, and professional responsibility is crucial to the accurate structural design of steel poles for sports lighting applications. Standardizing the design process will improve the safety of these structures and reduce confusion during the procurement process. The owner should ensure the following:

1. Hire an experienced professional engineer (P.E.) to develop the technical specification for the procurement process for the pole structures
2. Require the poles be designed to AASHTO *Standard Specifications for Structural Supports for Highway Signs, Luminaries, and Traffic Signals*, 5th Edition, 2009 (Specifications, 2009)
3. If the poles are being procured packaged with the lights and electrical components, know who is fabricating the pole structures
4. Require a P.E. certification of pole and foundation designs provided prior to shipping and installation of the structures
5. Have a third party review the pole and foundation designs
6. Maintain all project records including specifications, site specific soils information, P.E. documentation, and the pole fabricator's drawings

The AASHTO *Standard Specifications for Structural Supports for Highway Signs, Luminaries, and Traffic Signals* (Specifications, 2009) discussed in this paper is specifically for pole structures and specifies factor of safety, addresses fatigue issues, addresses wind induced vibration issues, and other design requirements. With longevity and proven performance in the traffic industry, the owner who specifies this document as a design standard will have sports lighting pole structures that will perform satisfactorily and safely for many years.

ABSTRACT

This paper presents the results of a preliminary numerical investigation into the interaction between precast concrete cladding systems and moment resisting frames. Macro-scale models of cladding systems are implemented in existing lumped plasticity models for moment resisting frames. Different failure mechanisms and various configurations are considered in order to show the effect of the entire cladding system upon a structure's seismic behavior. Several parameters are varied in order to establish their associated influence on the overall structural response. Results show that it is clearly more advantageous to have a failure mechanism governed by the connection than one governed by either the panel or the frame.

An experimental program is now underway building on what has been learnt from the parametric investigation. The authors intend to continue the research to successively develop improved or innovative low-damage cladding-moment resisting frame systems. They also aim to produce simple design tools that provide easy inclusion of the seismic effects of cladding-frame interaction.

INTRODUCTION

The response of non-structural components can significantly affect the functionality of a building after an earthquake, even when the structural members are left undamaged. The poor performance of non-structural components or secondary structural elements in past earthquakes has led to buildings being left unoccupied, resulting in substantial economic losses due to business interruption. Furthermore, damage to non-structural components, such as that shown in Figure 1, can pose a serious risk to the safety of people inside and outside the building (Charleson, 2008). Recent earthquakes in L'Aquila, Italy (6 April 2009), Concepcion, Chile (27 February 2010) and Darfield, New Zealand (4 September 2010) have further highlighted the severe impact that damage to non-structural elements can have upon the overall recovery effort.

In order to develop and propose practical and efficient solutions that reduce the risk of damage to non-structural components it is necessary to understand how they interact with a structure. In addition, determining which parameters most influence this interaction is essential so that all possible damage and/or failure mechanisms are identified.

This paper presents the preliminary results of a numerical study on the interaction between a precast concrete cladding panel attached to a reinforced concrete moment resisting frame. This is achieved using static push-over and cyclic push-pull analyses of a lumped plasticity model representing an interior single-storey, single bay of a multi-storey building. In order to understand the different possible damage and failure mechanisms several parameters of the systems are varied. The results also confirmed the sensitivity of the systems' behavior to such changes.

Figure 1: Example of cladding failures

BACKGROUND

Precast concrete panels are widely used around the world as an exterior cladding for multi-storey buildings. Such cladding can be considered as non load bearing wall systems which are designed primarily to transfer their self-weight and out-of-plane (wind and earthquake) lateral loads to the supporting building structure. The contribution of the cladding system to the lateral stiffness of the building is often ignored in the structural design. However, experimental investigations on newly designed buildings have shown that claddings can contribute significantly to the lateral stiffness of the structure and that the panels can be subjected to significant in-plane forces (Goodno et al., 1988) which might cause unexpected structural failure. In order to avoid this unintended interaction, it is possible to isolate cladding panels, as shown by research using autoclaved lightweight aerated concrete (ALC) panels. ALC panels can be connected using sliding and rotating connections, as shown in Figure 2, such that they contribute very little to the stiffness and strength of the overall structure, even under a very large inter-storey drifts of 0.04 radians (Okazaki et al., 2007).

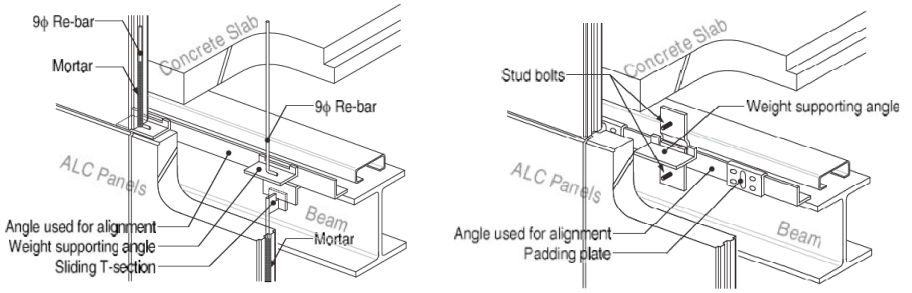

Figure 2: Sliding panel (left) and rotating panel (right), (Okazaki et al., 2007)

Complete isolation with the structural system does however mean that the cladding is simply a dead weight. Consequently, investigations have been carried out into ways in which the structure can profit from having cladding panels attached. If the additional stiffness and strength that cladding panels provide is utilized during design then a savings up to 25% in the volume of steel used in the structure can be achieved (De Matteis, 2005).

Cladding panels can also be used to provide passive control for the seismic behavior of buildings with the use of energy dissipative connections. Results show that energy dissipative cladding connections like that shown in Figure 3 could provide the total hysteretic energy required of the structural system (Pinelli et al., 1995).

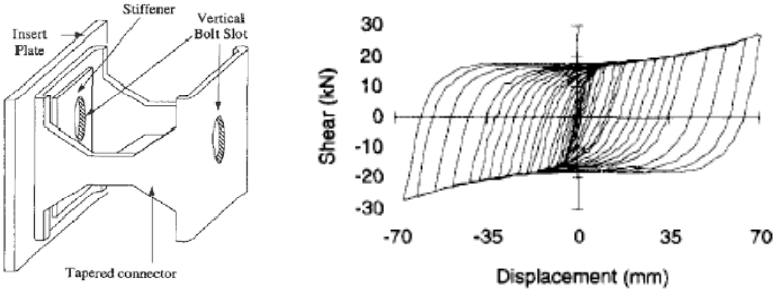

Figure 3: Advanced energy dissipating connection (left) and hysteretic loop (right), (Pinelli et al., 1995)

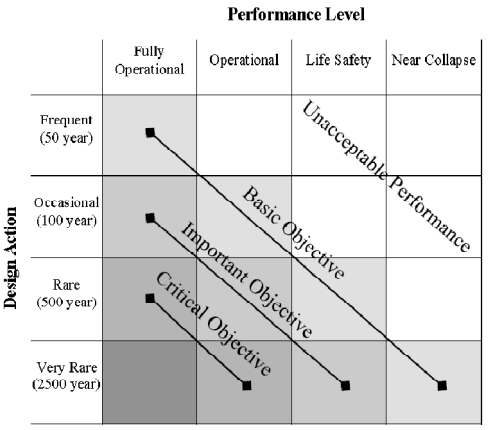
The main emphasis of research on cladding systems to date is on detailed research into isolated façade technology. This therefore leaves open the question of whether benefits found can be applied should some parameter be slightly different. This paper aims to help in providing a way to broaden the results of such research so it can be applied to a range of similar façade technology.



PERFORMANCE-BASED DESIGN and FAILURE MECHANISMS

Design for seismic resistance has been undergoing a critical reappraisal in recent years, with the emphasis changing from ‘strength’ to ‘performance’. For most of the past 80 years (the period over which specific design calculations for seismic resistance have been required by codes) strength and performance have been considered to be synonymous (Priestley, 2000). However now, performance based engineering has become a standard norm for research, development and practice of earthquake engineering, particularly after the 1994 Northridge and 1995 Kobe earthquakes (Okazaki et al., 2007). The primary function of performance-based seismic design is the ability to achieve, through analytical tools, a building design that will reliably perform in a prescribed manner under one or more seismic hazard conditions. The performance,

or condition of the building as a whole, is typically expressed through qualitative terms, intended to be meaningful to the general public. These terms use general terminology and concepts describing the status of the facility (i.e. Fully Operational, Operational, Life Safety and Near Collapse) but should also be associated and linked to appropriate technically-sound engineering terms and parameters. These performance-based design criteria are applicable to both structural and non-structural elements. Table 1 provides descriptions of the damage associated with three performance levels for two façade elements.

Table 1: Suggested performance levels (FEMA 356, 2000) and seismic design performance matrix (SEAOC Vision 2000 Committee, 1995)

	PERFORMANCE LEVEL		
Element	**Collapse Prevention**	**Life Safety**	**Immediate Occupancy**
Precast Concrete Panels	Some connection failure but no elements dislodged.	Local crushing, spalling at connections, but no gross failure.	Minor working at connections, crack width <1.5mm
Cladding	Severe damage to connections and cladding. Many panels loosened.	Severe distortion in connections. Distributed cracking, bending, crushing and spalling of claddings	Connections yield; minor cracks (<1.5 mm width) or bending in cladding.

Seismic Performance and Failure Mechanisms for Façade Systems

In assessing the overall performance of a building, traditional design methods tend to consider the structural and the non-structural systems separately. When the behavior of the bare structure is affected by the interaction with the façade, e.g. additional stiffening and hysteretic damping, then it becomes more appropriate to assess the performance of the combined system rather than the systems separately. Both of these approaches are depicted below in Figure 4 using a simplified chain diagram.

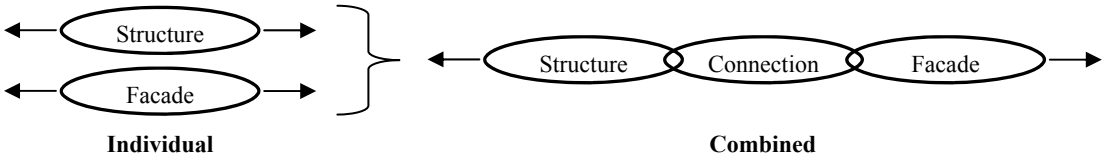


Figure 4: Simplified diagram for structure-façade system of a building

When a combined system approach is taken, capacity design principles can be used to define a number of different scenarios of failure, as depicted in Figure 6. Assuming that the cladding system is comprised of a structural frame member, a connector body and cladding panel, linked together with strong and stiff attachments, as shown in Figure 5, then the problem can be simplified in order to determine where failure is most likely to occur. An advanced performance-based design would thus target the most desirable hierarchy of strength and sequence of events of the overall system.

If the in-plane strength of the cladding panel is greater than that of the connector body, then the connector body (weakest link of the chain) is expected to govern the

overall cladding failure mechanism. Conversely, if the connector body is stronger than the panel, then failure is governed by the panel strength which becomes this time the weakest link of the chain. For the above two scenarios it is assumed that the attachment of the connector body is stronger than both the cladding and the connector body itself. Despite the simplicity of these design principles, errors have been made in the past where the attachment ends up being the weakest link in the system. When the attachment governs the failure then the risk of falling panels is very high. From herein the connector body is referred to as the 'connection'.

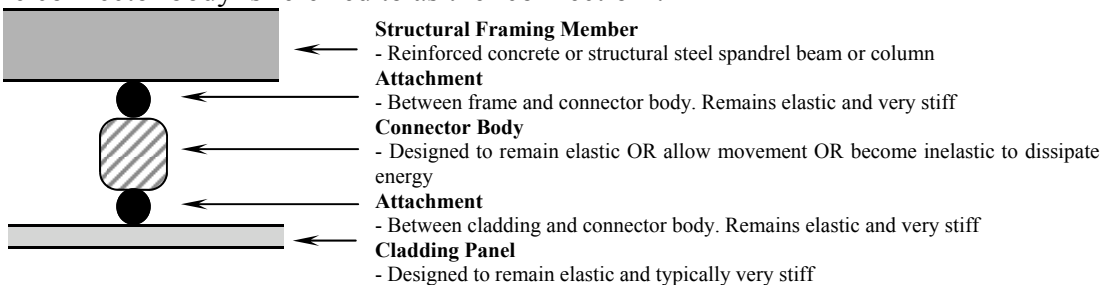

Figure 5: Structure – cladding system (Cohen, 1993)

There is also the highly undesirable case where the panel, connector and attachments are stronger than the frame member and failure occurs in structural members due to local interaction. This scenario is only possible if concrete panels might be adopted and designed with the intention to behave as a structural wall.

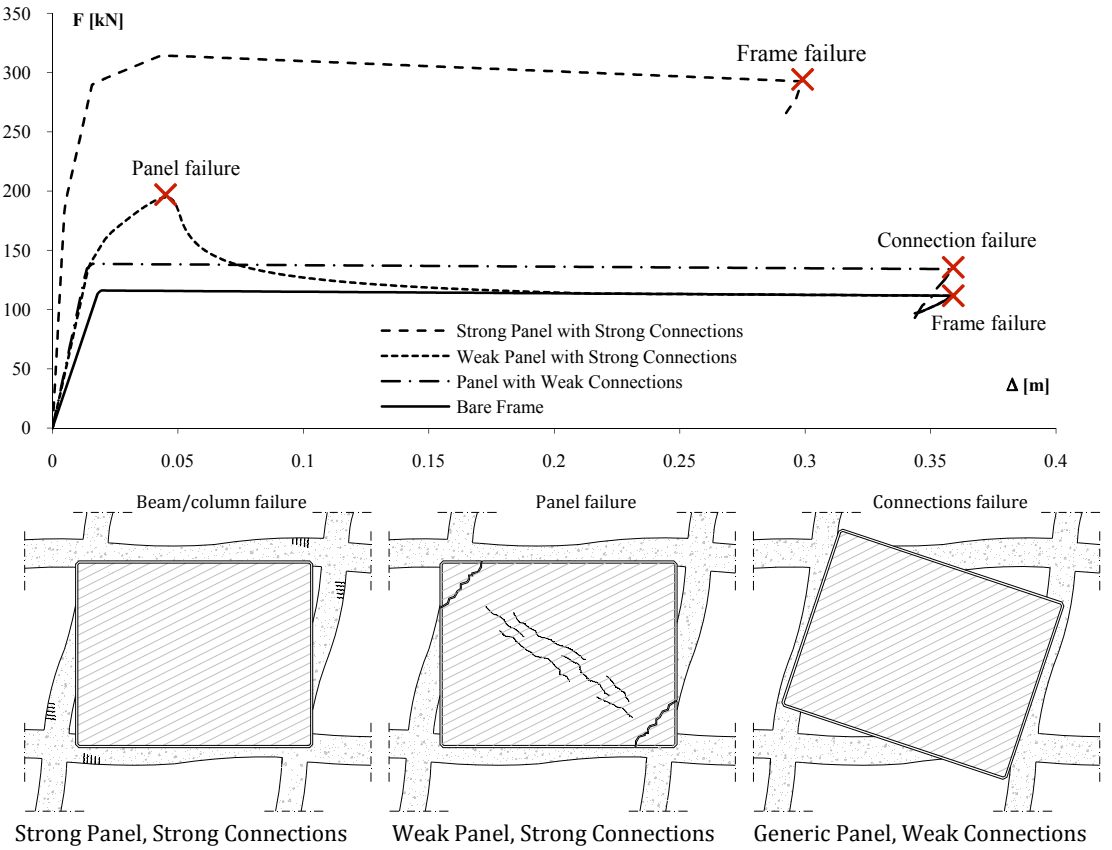

Figure 6: Different failure mechanisms and push-over behaviour of precast panels attached to a frame system

NUMERICAL INVESTIGATION

The numerical investigation has been considered using a monolithic single bay, singly storey reinforced concrete frame with the presence of a single precast concrete cladding panel. The setup is based on a corresponding experimental program that is currently undergoing considering cladding typologies and various cladding panel/connection configurations. The frame is designed in accordance with capacity design principles and the cladding system is designed considering the drift limits at Serviceability Limit State (SLS) and at Ultimate Limit State (ULS).

The numerical investigation only considers a single panel and all openings in the panels are herein neglected. The model has been implemented using the program RUAUMOKO (Carr, 2004), based on a lumped plasticity model, with the beams and columns represented by elastic elements with inelastic behavior concentrated in plastic hinge regions (Giberson model) and defined by the moment curvature hysteresis rule 'Modified Takeda' (Otani, 1974).

The cladding panel is connected either vertically on the beams or horizontally on the columns. The behavior of the connections is based on experimental testing of several connections used to support precast concrete cladding (McMullin et al., 2004). The panel and connections are modeled with appropriate hysteretic rules which vary case by case. The aim of the numerical investigation is to carry out a sensitivity analysis of the parameters which affect the behavior of the facade-structure system. This will be achieved through a parametric analysis. At the same time, different failure mechanisms of the facade-structure system will be explored.

The investigation is separated into two parts, distinguished by failure mechanism. The first part covers the cases where failure of the cladding connections governs the behavior of the system. The second section covers the cases where the failure of the cladding panel or the frame governs.

Part 1: Connection Governing Model

The connection governing model has been designed such that yielding of the cladding connection occurs prior to yielding of either the cladding panel or the frame. The connection yield displacement was based on a drift chosen between the range of SLS and ULS. For this example the value used for the yielding drift is 0.3%. Considering commercial connections available, the strength and stiffness of the connections was chosen to satisfy this predetermined limit.

The panel element has four connections; two bearing connections and two tie-back connections. The bearing connections are located on the lower half of the panel and are intended to transfer the self weight of the panel to the structure. The tie-back connections are located on the top half and are intended to deform under in-plane loading whilst providing out-of-plane support. Each connection is modeled by a spring member with horizontal and vertical stiffness. For the bearing connections, the connector elements in both horizontal and vertical directions are assumed to be very stiff and very strong. The tie-back connections have lower stiffness and yield strength so these govern the force that the cladding can carry. The model and force displacement behavior are shown in Figure 7.

The tie-back connections are modeled with an elasto-plastic hysteresis rule or bi-linear with slackness (representing a slotted connection, which is typically used to also accommodate thermal variations). The use of a perfectly plastic model with no strain hardening is a simplification that is judged reasonable based on the behavior of experimental cladding connector testing (McMullin et al., 2004).

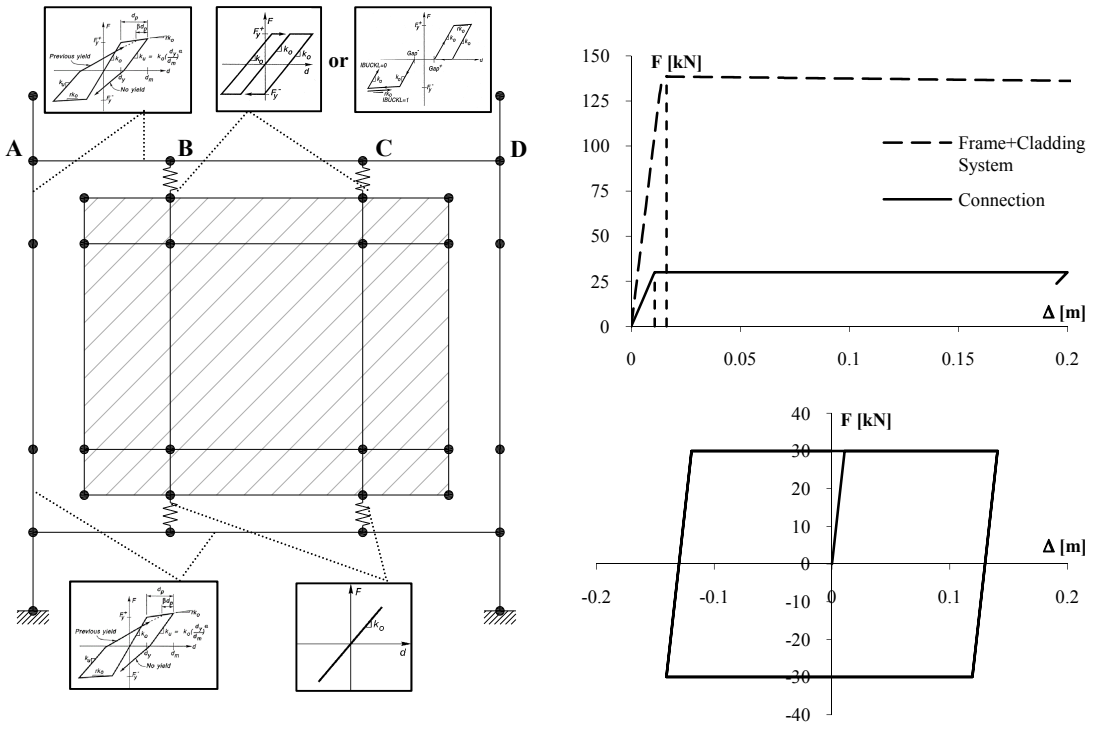

Figure 7: Connection governing model with force displacement behavior

Since the tie-back connections are significantly weaker and less stiff than the bearing connections, the bearing connections are modeled as elastic. The tie-back connections can also not carry sufficient force for the panel to ever yield, thus the panel is assumed to remain elastic and is represented by an elastic 'quadrilateral' element, as shown in Figure 7 (left), which does not consider post-yielding effects.

Part 2: Panel/Frame Governing Model

If the cladding connection is assumed to be strong, then the failure mechanism is not governed by the connection but rather by either the panel or the frame. When this is the case it is essential that the panel is modeled with an appropriate non-linear behavior. Diagonal springs representing the compressive struts are herein used as typically done for infill panels. The model and force displacement behavior is shown in Figure 7.

The hysteretic behavior of the diagonal struts is modeled using the Crisafulli hysteresis rule, extensively validated to model stiffness and strength degradation in masonry infill panels (Crisafulli, 1997). The implementation of this rule requires several parameters which are based largely on experimental data. The most critical parameter dictating the behavior of the strut is the compressive strength. This does not represent the standard compressive stress of the concrete but rather of the strut. Hence it should take into account the inclination of the strut and expected mode of failure (Crisafulli, 1997). Accordingly, without experimental data to verify the accuracy for a panel of the particular geometry and reinforcement used, the accuracy of this parameter is, at this stage, likely to be limited. However, it has been assumed that panel failure consists of crushing of the concrete where the strut bottlenecks into where the panel connection is located and values have been used that correspond to such behavior (Brown et al., 2006). Even so, the compressive strength is varied as part of the investigation in order to appreciate the different behavior expected of different strength panels. The model does not take into account possible shear failure mechanism in the joint induced by the panel.

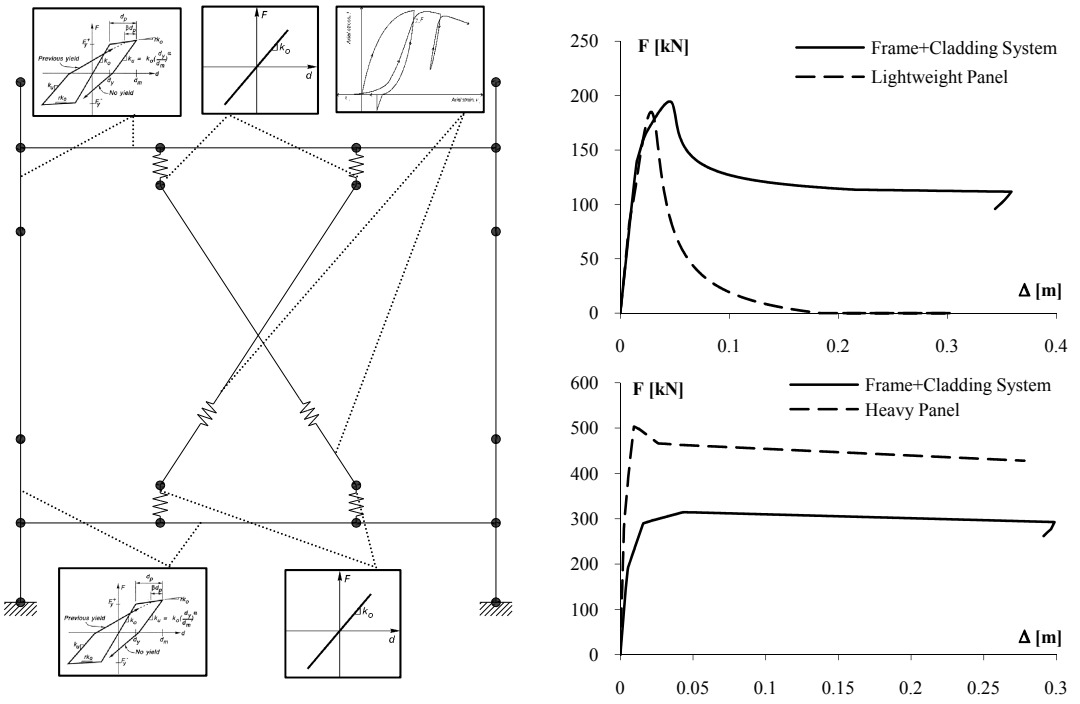

Figure 8: Panel/frame governing model with force-displacement behavior

PARAMETRIC ANALYSIS

In order to understand the effect that various parameters have upon the behavior and performance of cladding panels under in-plane seismic loading, a multi-parametric analysis has been conducted. The parameters to be varied are based primarily on modifications to typical commercial connections. The analyses consist of push-over and push-pull displacement controlled tests where a monotonic displacement is applied at the top of the column. The push-over analyses aim to reveal the yielding and failure characteristics of both individual components and of the system as a whole. The push-pull analyses are performed at repeating cycles of 4% drift in order to provide additional information on the hysteretic behavior.

As mentioned in the previous section, the parametric analysis is separated into two groups; those cases where the connection failure governs the interaction between the panel and the frame and the cases where either failure of the panel or frame governs. This means that not all variables are considered in each part of the analyses but only those that are deemed appropriate, e.g. modifying the panel strength is not seen as important when the connection failure governs. Furthermore, modularity of cladding, i.e. panels' configuration, is not considered for sake of brevity.

The following parameters are to be varied:

- Frame height to span ratio (1:1, 1:1.5, 1:2)
- Connection configuration (beam vs. column)
- Connection behavior (fixed vs. slotted)
- Panel type (and strength)

Part 1: Connection Governing Analyses

The fixed variables for these analyses are the panel type and bearing connection behavior. The panel type is a concrete panel that covers the entire frame bay and is reinforced with steel mesh. Both the panel and the bearing connections are assumed to be stiff and elastic.

Results

Shown in Figure 9 are force-displacement plots of the push-over and push-pull analysis results. These particular plots are for a frame ratio of 1:1 with fixed beam connections. The general shape of these plots is similar for all analyses where connection failure governs. The frames base shear and deflection at yield for all of the analyses conducted can be seen in Table 2 in order to compare the results.

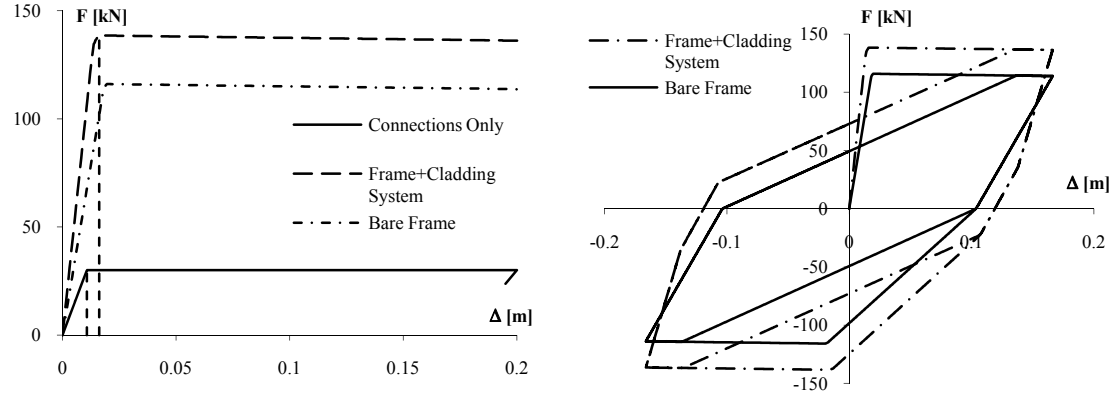

Figure 9: Force-displacement analyses for connection governing cases

Table 2: Parametric results for push-over analyses of connection governing cases

			Beam Connections		Column Connection	
	Frame Ratio	Bare Frame	Fixed	Slotted	Fixed	Slotted
Base Shear at Yield	1:1	115.8 kN	129.3 kN (+11.7%)	129.2 kN (+11.6%)	138.3 kN (+19.4%)	138.3 kN (+19.4%)
	1:1.5	115.8 kN	129.4 kN (+11.7%)	129.3 kN (+11.7%)	138.4 kN (+19.5%)	138.3 kN (+19.4%)
	1:2	115.8 kN	129.4 kN (+11.7%)	129.4 kN (+11.7%)	138.4 kN (+19.5%)	138.4 kN (+19.5%)
Frame Deflection at Yield	1:1	0.020 m	0.021 m (+5.0%)	0.033 m (+65.0%)	0.016 m (-20.0%)	0.020 m (+0.0%)
	1:1.5	0.025 m	0.024 m (-4.0%)	0.033 m (+32.0%)	0.017 m (-32.0%)	0.020 m (-20.0%)
	1:2	0.030 m	0.029 m (-3.4%)	0.033 m (+10.0%)	0.019 m (-36.6%)	0.020 m (-33.0%)

The changing level of damping of the system as well as individual elements is shown in Figure 10 for increasing levels of ductility. The four lines show the damping of the bare frame, the frame-cladding system and the contribution from each component to the system.

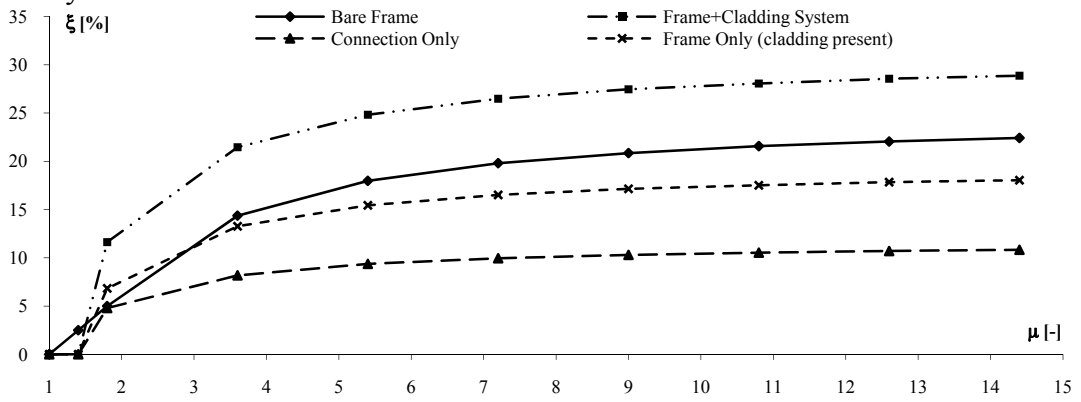

Figure 10: Damping vs. ductility for connection governing cases

Member demand envelopes along one of the beams are shown for a frame ratio of 1:1 with fixed beam connections. Again, the general shape of these plots is similar for all analyses where connection failure governs; so the full results have been tabulated in Table 3 for comparison purposes. The values in the table represent the largest moment and shear force in the beam or column at the cladding panel connection.

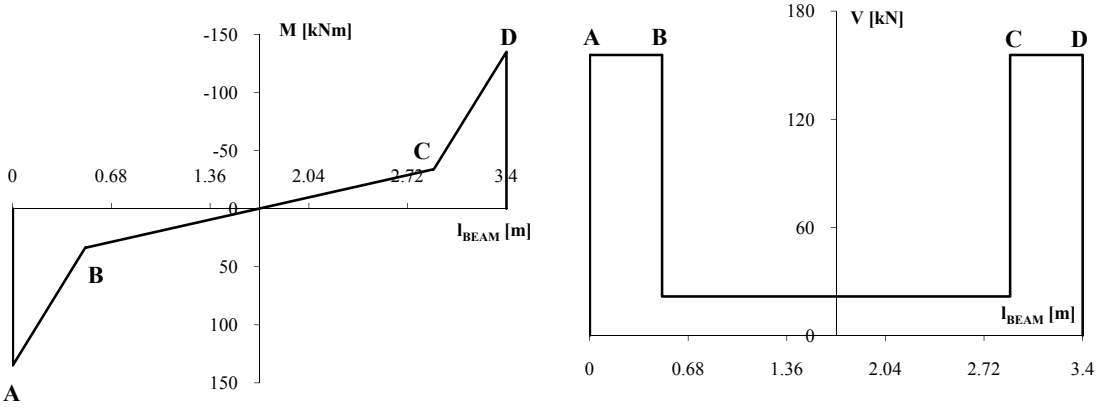

Figure 11: Moment/shear envelope for connection governing cases (refer to Figure 7 (left), where B and C are locations of panel connections)

Table 3: Full results for moment/shear envelope

Beam Connection	Bare Frame		Fixed		Slotted	
Frame Ratio	M	V	M	V	M	V
1:1	85.2 kNm	71.0 kN	-69.5 %	-69.4 %	-68.8 %	-68.7 %
1:1.5	102.4 kNm	46.5 kN	-70.9 %	-70.8 %	-70.6 %	-70.5 %
1:2	110.8 kNm	34.5 kN	-71.8 %	-71.6 %	-71.7 %	-71.6 %
Column Connection	Bare Frame		Fixed		Slotted	
Frame Ratio	M	V	M	V	M	V
1:1	58.8 kNm	57.9 kN	-13.1 %	-13.3 %	-6.0 %	-6.6 %
1:1.5	58.7 kNm	57.9 kN	-14.7 %	-14.2 %	-9.4 %	-9.5 %
1:2	58.5 kNm	57.9 kN	-15.0 %	-14.2 %	-12.1 %	-12.3 %

Part 2: Panel/Frame Governing Analyses

For these analyses the connections are assumed to be infinitely stiff and to remain elastic. This assumption is valid for cladding panels of low strength, however, for higher strength panels, the force transmitted through the connections becomes very large and as such would be unrealistic if a typical cladding connection is used. This case would be applicable to a panel that is fixed in place with grouted connections or intended to behave similarly to a shear wall. The connection configuration is varied in the same way as part 1. The panel strength is varied from a low strength, typical of aerated concrete, up to a high concrete strength (from 4 MPa to 30 MPa). The 'medium' strength panel represents the failure transition point from panel failure to frame failure. The frame's height to span ratio is kept fixed.

Results

Shown in Figure 12 are force-displacement plots of the push-over and push-pull analysis results. These particular plots are for a frame ratio of 1:1 with fixed beam connections. The general shape of these plots is similar for all analyses where panel/frame failure governs. The frames base shear and deflection at yield for all of the analyses can be seen in Table 4 in order to compare the results and failure mechanism.

The push-over plot in Figure 12 (left) shows the different behavior of the three different panel strengths particularly the change in failure mechanism. The low strength panel fails before the frame so the overall resistance provided by the system returns to that provided by the frame alone. The theoretical medium strength panel shows the same behavior as the high strength panel up to yielding. If the panel is weaker than this failure transition strength then it exhibits the same behavior as the low strength panel, decaying back to the frame strength. However, if the panel is stronger it results in the beam yielding in flexure at the connection point and eventually leads to failure of the beam at this point.

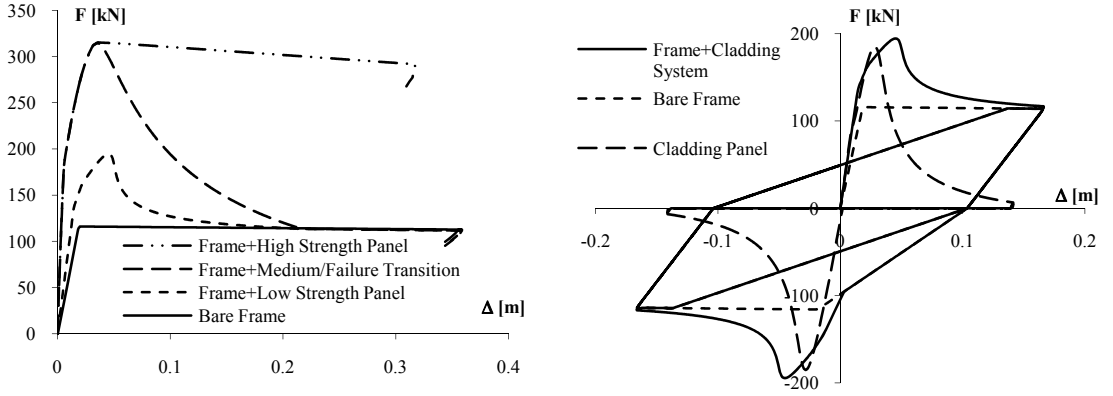

Figure 12: Force-displacement analyses for panel/frame governing cases

The push-pull analyses can only be conducted for cases where the frame does not fail, i.e. panel failure. As shown in Figure 12 (right) after one cycle in either direction, once the compressive strut representing the panel is effectively destroyed then the behavior returns to that of the bare frame.

When the panel is attached to the column the failure mechanism was found to always be in the panel however this result is not very realistic because of the large shear forces in the column. Since the model herein adopted does not take into account shear failure in the structural elements this failure mechanism is likely being missed.

Table 4: Parametric results for push-over analyses of panel/frame governing cases

		Bare Frame	Low strength	Medium strength Failure transition	High strength
Fixed beam connections	Base shear at yield	116.1 kN	194.6 kN (+67.6%)	314.8 kN (+171.1%)	314.8 kN (+171.1%)
	Frame deflection at yield	0.020 m	0.045 m (+128.3%)	0.036 m (+83.0%)	0.044 m (+127.4%)
	Failure mechanism	STRUCTURE	PANEL	PANEL/STRUCTURE	STRUCTURE
Fixed column connections	Base shear at yield	116.1 kN	186.5 kN (+60.6%)	300.2 kN (+158.6%)	662.2 kN (+470.4%)
	Frame deflection at yield	0.020 m	0.024 m (+20.0%)	0.045 m (+132.0%)	0.062 m (+216.8)%
	Failure mechanism	STRUCTURE	PANEL	PANEL	PANEL

CONCLUSIONS

The results show that there is an increase in strength of at least 10-20% for all systems when the influence of cladding panels is taken into account. This contribution is greater when panels are attached to the columns rather than to the beams because the beams deflect more and activate the connections later. There is also an increase in hysteretic damping for all systems. Frame height to span ratio does not affect the yield force of the system greatly however, increasing it does allow for a higher

deflection/drift of the system at yield. When both panel and connections are strong the capacity of the system is increased but the ductility is decreased. The model limits the additional hysteretic damping provided by the panel crushing to one cycle, when in reality the panel would still be dissipative, but this dissipation is not reliable.

It is apparent that it is more advantageous to have and thus design for a connection governed failure mechanism than a failure mechanism which is governed by either the panel or the frame. Connection governed failure allows greater damping, strength and stiffness over many cycles. However this assumes that the tie-back connections are designed to accommodate a large level of ductility. Also in terms of the cost and ease of repairs; the substitution of failed connections is seen to be more favorable than having to replace entire damaged panels.

To improve the analyses, the consideration of shear failure in the beams, columns and beam-column joint is vital. It is also worth considering other typologies of connections with different behavior, e.g. non-ductile.

ABSTRACT

Over the past two decades fatigue failure of cantilevered highway sign and traffic signal structures are increasingly being reported around the United States, primarily due to wind induced oscillations. For aesthetic reasons many of these structures are built with multisided tubular sections with sharp corners. Fatigue performance of fillet-welded tube-to-end plate connections in multi-sided sign/signal structures were evaluated by laboratory testing and parametric finite element analyses (FEA). Seven full size galvanized sign/signal structure specimens having eight sided cross section were fatigue tested under constant amplitude loading simulating wind induced aero-elastic galloping oscillation. Fatigue cracking in multi-sided sections mostly initiate at the bend corners of tube-to-end plate welded connection, and may appear early in service. Flexibility of the end plate, the number of sides, and the corner bend radius are the important parameters that affect fatigue resistance of multi-sided tubular structures. The existing specification does not address the effects of the connection geometry on their fatigue design. The experimental and analytical studies established the fatigue design provisions of tube-to-end plate connections in multi-sided sign and signal structures.

INTRODUCTION

Background. Over the past two decades, fatigue cracking in cantilever sign, luminaire, and traffic signal structures are increasingly being reported around the United States. These structures, built with thin-walled hollow shapes of circular or multisided cross section, are extremely flexible with a typical fundamental natural frequency on the order of 1.0 Hz and damping usually less than 1% of critical. As a result, they are often subjected to large amplitude and long duration vibrations owing to wind induced aero-elastic effects such as galloping and vortex shedding, in addition to aerodynamic vibrations due to natural gusts and truck induced gusts, which impart fatigue damage to the various welded connections in these structures.

Fatigue cracking in these structures has mostly occurred at the tube-to-end plate connections at the mast-arm and pole bases. The primary load carrying mechanism in these thin tubular structures is through in-plane membrane stresses. At the tube-to-end plate connection, the membrane stress is augmented by large out-of-plane bending stress through the thickness of the tube that arises to maintain compatibility of deformations between the tube and the end plate. This geometric stress coupled with conditions inherent to a welded connection (Roy et al. 2008), and precipitates fatigue cracking at the weld toe on the tube wall.

For aesthetic and fabrication reasons the sign and traffic signal structures are often built with multisided tubular sections with sharp corners. The fatigue resistance of these connections is further affected by the geometric stress concentration at the bend corners. Fatigue cracking may appear early in service at the bend corner. The multi-sided tube-to-end plate connections mostly employ a socket connection, where the tube is inserted into a matching through-thickness hole in the end plate, and a fillet weld is deposited around the perimeter between the tube wall and the end plate.

Previous research and specification. The only previous research on multi-sided specimens was conducted at the University of Minnesota (UM) (Ocel et al. 2006) on twenty full size sign and traffic signal structures specimens having eight sided cross section. In sixteen specimens comprising pole and mast-arm assembly, eight poles employed socket connections having 8 mm ($^5/_{16}$ in) thick tubes and 32 mm ($1^1/_4$ in) thick end plates. The outer flat-to-flat distance of the sections in poles and mast-arms were 328 mm (12.9 in) and 272 mm (10.7 in), respectively. Remaining four specimens only consisted poles with outer flat-to-flat distance of 328 mm (12.9 in) and 64 mm ($2^1/_2$ in) thick end plate. Two of these specimens had 8 mm ($^5/_{16}$ in) thick tubes, and the other two had 5 mm ($^3/_{16}$ in) thick tubes. A bend radius of 22 mm ($^7/_8$ in) was specified for all specimens. Static tests on these specimens showed presence of higher stress concentration at the weld toe in bend corners compared to the weld toe on the flat side. The cracking at the tube-to-end plate connection was found at the toe or the root of fillet-welds initiating at the bends. The weld toe cracking of tube-to-end plate connections with 32 mm ($1^1/_4$ in) end plate exhibited a fatigue resistance much less than AASHTO fatigue Category E′, which is defined as the fatigue resistance of this detail in the existing AASHTO specifications. The specimens with thicker end plate exhibited a fatigue resistance between Category E′ and D.

Ocel (2006) also conducted parametric studies involving the geometric parameters of a tube-to-end plate connection in multisided section such as, number of sides, corner bend radius, tube diameter (outer flat-to-flat distance), tube thickness, end plate thickness and number of anchor bolts. These studies indicated that the geometric stress concentration increased with fewer anchor bolts, sharper bends, and proximity of a bend to an anchor bolt. Although the experimental results provided valuable insight into the behavior of the multisided sections, their use for designing the structures is limited. Use of thin end plates and discrete fasteners are the primary reasons for increased geometric stresses and poor fatigue performance of tube-to-end plate connections. As the test results showed, using a thicker end plate is the most cost-effective means of improving fatigue resistance of these connections (Roy et al. 2008). Moreover, in view of the uncertainty in defining the accurate wind load

spectra for designing these structures, and the possibility that these structures may experience more than 100 million cycles of wind induced oscillations in their design life time of 25 years, infinite life design of the structures is rational and mandatory. The UM study, however, did not investigate the infinite life fatigue performance of multi-sided tube-to-end plate connections.

The fatigue design guidelines in the existing *AASHTO Standard Specification for Structural Supports for Highway Signs, Luminaries, and Traffic Signals,* were developed based on limited fatigue test results of socket connections in round tubes and anchor rods, and were extrapolated from the provisions for: the attachment details in the AASHTO LRFD Bridge Design Specifications; the tubular structure details in AWS D1.1; and similar structural details in the Eurocode. These provisions do not consider the out-of-plane deformation associated with the connection geometry and do not make any distinction in fatigue performance of welded connections having round and multi-sided sections.

Current study. To address the deficiencies of the existing specification, fatigue performance of multi-sided tube-to-end plate welded connection was evaluated under the National Cooperative Highway Research Program (NCHRP) Project 10-70: Cost Effective Connection Details for Highway Sign, Luminaire and Traffic Signal Structures, at the ATLSS Engineering Research Center, Lehigh University. Fatigue performance of the subject structures was evaluated in full scale specimens in both finite and infinite life regimes. The effects of multi-sided section geometry on fatigue performance of subject structures were also evaluated by parametric finite element analyses (FEA).

EXPERIMENTAL STUDIES

Specimen design. When the testing under NCHRP Project 10-70 was initiated, the only fatigue test data available for multi-sided signal and pole structures were conducted at the University of Minnesota (UM) (Ocel et al. 2006). A full scale specimen, identified as Type VII, representing a multi-sided sign and traffic signal structure was designed to provide bases for comparison with the previous test results, as well as with the structures having circular cross sections that were tested under this project. An eight sided cross section was decided similar to the UM study, but with a bend radius of 25 mm (1 in). The bend radius of UM study was 22 mm ($^{7}/_{8}$ in). The bend radius was increased as it was realized that a radius as sharp as the previous test specimens will cause severe stress concentration and poor fatigue performance. The bend radius of 25 mm (1 in) was chosen somewhat arbitrarily such that it was not too large compared to the previous test specimens to confound the effects of all the geometric changes on the fatigue test results, and also to satisfy the limitations of available tooling with most fabricators.

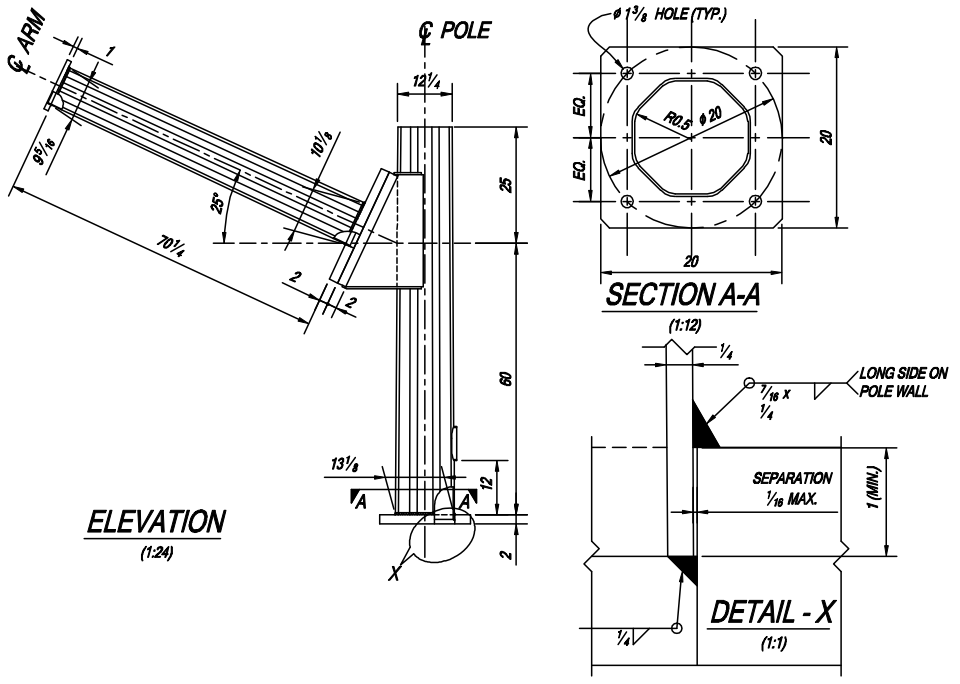

Figure 1. Details of Specimen (units in inches, 1 inch=25.4 mm)

Seven Type VII specimens were fatigue tested. These specimens employed fillet-welded tube-to-end plate connections in the pole and the mast-arm. The outer flat-to-flat dimensions of the poles and the mast-arms were respectively 330 mm (13 in) and 254 mm (10 in). An end plate of 51 mm (2 in) thickness was also provided at the pole and mast-arm bases. Although a bend radius of 25 mm (1 in) was specified, the as-received specimens had a bend radius of about 13 mm (0.5 in). The details of this specimen are shown in Figure 1.

Prior to testing, a three dimensional (3D) finite element analysis (FEA) of the specimen was conducted. The FE model was developed as the specimen was designed and included all the features of the as-built specimen. The FEA results, in terms of maximum principal stress contour, are shown in Figure 2 demonstrating the behavior of the multi-sided tube-to-end plate connections in the mast-arm and the pole. A sharp stress concentration is noted at the weld toes on the tube in bend corner. The cut-away view also shows the reverse bending at the welded connection. The predicted finite life for both mast-arm and pole was determined based on the local stress approach for tubular joints suggested in the *Det Norske Veritas (DNV) Recommended Practice DNV-RP-C203: Fatigue Design of Offshore Steel Structures*. The constant amplitude fatigue threshold (CAFT) was estimated by the notch stress based analytical approach implemented by Roy and Fisher (2005), which was determined for the mast-arm as 20 MPa (2.9 ksi).

Figure 2. Result of sub-model analysis of specimen Type VII

Fatigue test results. Fatigue testing of the specimens was conducted under constant amplitude sinusoidal fatigue loading. Minimum stress and stress range were the two design stress variables considered for the fatigue tests. The specimens were tested under a high level of minimum stress, representing the dead load effects from the overhanging weights of the signs and signal attachments. The applied nominal minimum tensile stress was 105 MPa (15.3 ksi) at the weld toe on the tube in the middle of flat side of the mast-arm tube-to-end plate connection.

Three specimens were fatigue tested to determine the finite life fatigue performance in this specimen. The remaining four specimens were fatigue tested to determine CAFT of the tube-to-end plate connection.

Specimens VII-1, VII-2 and VII-3 were tested at 83 MPa (12 ksi) nominal stress range at the section of mast-arm tube-to-end plate weld toe and experienced fatigue cracking in the mast-arm tube-to-end plate weld toe. Specimens VII-4 and VII-5 were tested under a nominal stress range of 31 MPa (4.5 ksi), the CAFT of AASHTO Category E, at the tube-to-end plate fillet-weld toe on the tube at the mast-arm base and experienced fatigue cracking in the mast-arm. In view of the result of VII-4 and VII-5, it was decided to fatigue test specimens VII-6 and VII-7 at a nominal stress range of 18 MPa (2.6 ksi), corresponding to the CAFT of AASHTO Category E′, at the tube-to-end plate weld toe on the tube at the mast-arm base. In VII-7, a small crack was detected at one of the outermost bend corners on the tension face at a very early age of 70,000 cycles. However, this crack did not demonstrate any significant growth since. Fatigue testing of specimens VII-6 and VII-7 was run-out at the stress range corresponding to the CAFT of Category E′. The testing stress range was raised to the stress range corresponding to the CAFT of Category E which is 31 MPa (4.5 ksi). Testing of specimen VII-6 was again run-out, without further fatigue cracking from the other welded details. Specimen VII-7, however, experienced fatigue cracking in the mast-arm. Specimen VII-6 experienced fatigue cracking in the

mast-arm when re-tested at an elevated stress range of 48 MPa (7.0 ksi) at the tube-to-end plate fillet-weld toe on the tube at the mast-arm base.

All Type VII specimens developed fatigue cracking in the mast-arm at the tube-to-end plate fillet-weld toe on the tube at the mast-arm base (Figure 3). These cracks initiated at the at the bend corners on the tension face at an early age due to high stress concentration, precipitated by sharp bend radius (~13 mm (0.5 in)) and were detected very early into the fatigue tests. The cracks then progressed through the thickness and grew as a through thickness crack on two fronts. Specimens VII-1, VII-2 and VII-3 also experienced similar fatigue crack growth at the tube-to-end plate fillet-weld at the pole base. The stress range at the pole base was 46 MPa (6.6 ksi), which corresponds to the stress range of 83 MPa (12 ksi) at mast-arm.

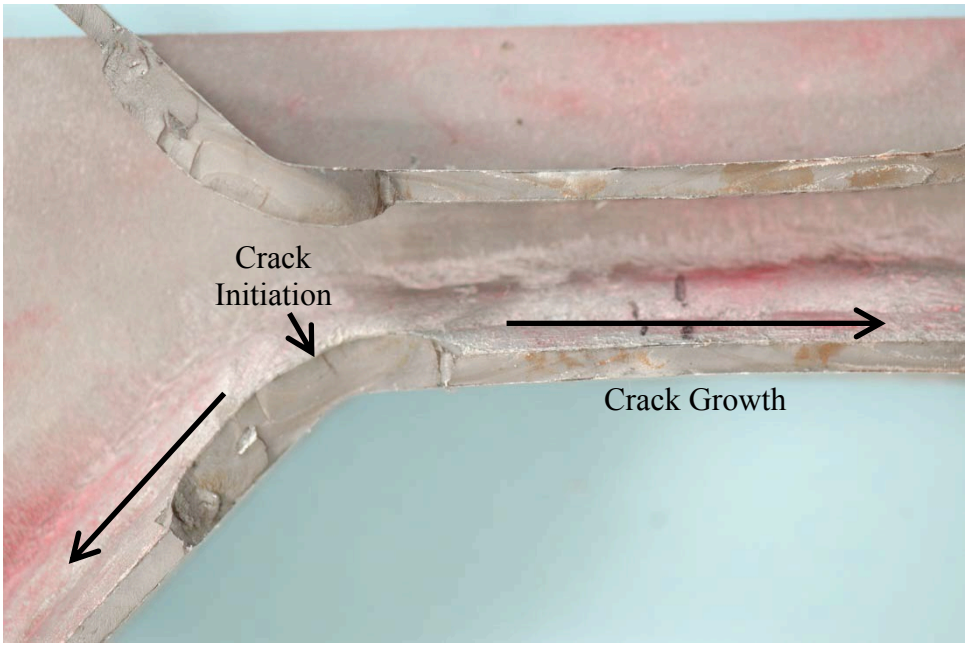

Figure 3. Facture surface of specimen VII-1 mast-arm

After failure of mast-arms in specimens VII-4, VII-5, VII-6, and VII-7, fatigue testing of the poles in these specimens were continued with a special replacement mast-arm. The pole base in specimen VII-6 and VII-7 was tested at a nominal stress range of 10 MPa (1.4 ksi), which corresponds to a nominal stress range of 18 MPa (2.6 ksi) at the mast-arm tube-to-end plate weld toe section. The specimens did not develop a crack at the stress range until the stress cycle reached to 20×10^6 cycles. The pole base specimens VII-4, VII-5, VII-6, and VII-7 were tested at a nominal stress range of 18 MPa (2.6 ksi), which corresponded to a nominal stress range of 31 MPa (4.5 ksi) at the mast-arm base. The specimens also did not crack at the stress range. The specimens VII-6 and VII-7 re-tested at an elevated stress range of 27 MPa (3.9 ksi), which corresponds to a nominal stress range of 48 MPa (7.0 ksi) in the mast-arm, at the pole base. The fatigue crack initiated at the pole base in specimen VII-6, but the test was terminated after 15.4×10^6 cycles due to the fatigue cracking at the handhole. The fatigue crack also initiated at the pole base in specimen

VII-7 and failed at the stress range. The poles in specimens VII-4 and VII-5 were re-tested at an elevated nominal stress range of 31 MPa (4.5 ksi), corresponding to the CAFT of AASHTO Category E. In specimen VII-4, test terminated after 1.2×10^6 cycles due to the fatigue cracking at handhole. The pole base of specimen VII-5 developed a fatigue crack at the tube-to-end plate weld toe on the tube.

DISCUSSION OF FATIGUE TEST RESULTS

Presentation of results. The S-N plot of the fatigue test results of specimen Type VII having multi-sided cross section are shown in Figure 4, along with the fatigue design curves from the AASHTO LRFD Bridge Design Specification. The fatigue test results are plotted against the corresponding nominal stresses, which were computed based on the section properties at the cracked section. The plotted fatigue lives correspond to a crack length of half the tube diameter (outer flat-to-flat distance) at the critical section – 127 mm (5 in) for mast-arm and 165 mm (6 ½ in) for pole – which were defined as a fatigue failure criteria.

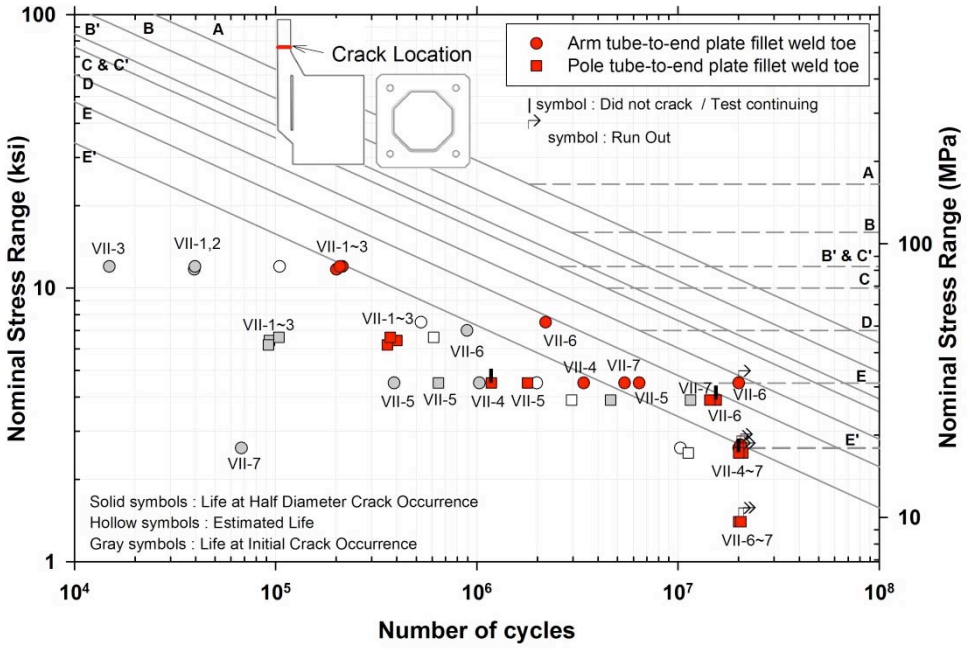

Figure 4. Fatigue test results for specimen Type VII

Evaluation of fatigue performance. The fillet-welded tube-to-end plate connections in the mast-arms demonstrated a fatigue resistance of AASHTO Category E′ corresponding to a crack length of 127 mm (5 in). These cracks initiated at the outermost bend corner on the tension face and were detected very early into the fatigue tests. Once the cracks developed out of the corner bends into the flat face, the crack propagation rate reduced.

The fillet welded tube-to-end plate connections in poles also exhibited early cracking at the outermost bend corners on the tension face and demonstrated similar crack propagation behavior. Due to higher geometric stress concentration in the pole

compared to the mast-arm, these details demonstrated a fatigue resistance less than Category E′ corresponding to a crack length of 165 mm (6 ½ in).

None of the type VII specimens developed fatigue cracks when tested at or below a stress range of 18 MPa (2.6 ksi), the CAFT of AASHTO fatigue Category E′. It appears that the CAFT of the multi-side tube-to-end plate fillet-welded connection for this specimen geometry is 18 MPa (2.6 ksi). The analytically predicted CAFT for this detail was 20 MPa (2.9 ksi).

PARAMETRIC EVALUATION OF MULTI-SIDED TUBE-TO-END PLATE CONNECTIONS

Behavior of multi-sided tube-to-end plate connections. As discussed earlier, fatigue cracking at the tube-to-end plate connections precipitate due to the out-of-plane bending stress in the tube wall that develop to maintain compatibility between the tube and the plate, irrespective of the tube cross section. To determine the reasons for high stress concentration at the bend corners of multi-sided tubes, FE models for round and multi-sided tube-to-end plate connection were analyzed. The diameter (outer flat-to-flat distance in multi-sided sections) and the thickness of tubes were 254 mm (10 in) and 5 mm (0.179 in) respectively. The end plates were 51 mm (2 in) thick and fastened with four bolts on a bolt circle of 584 mm (23 in). The normal stresses in the longitudinal (meridional) direction and the deflection in the radial direction as obtained from FEA are compared between an eight-sided and a round tube around the perimeter at the tube-to-end plate fillet-welded connection (Figure 5). Both tubes were analyzed for identical condition. The longitudinal stresses were obtained at the section $0.1\sqrt{(rt)}$ ahead of the weld toe on the tension side, where r and t are respectively the radius and thickness of the tubular member (DNV 2005). The stress profiles show that higher stress occurred at the bend corner of multi-sided tube compared to the stress in the round tube at the same circumferential position. The stress in the multi-sided tube then decreased compared to the stress in the round tube, as the circumferential position moved towards the center of flat side. The behavior could be interpreted as the bend corner behaving as a stiffener to the flat face. Since this stiffening effect would disappear as the multi-sided section approaches round, it is obvious that the stiffening effect and the resulting stress concentration are functions of the cross-sectional geometry of multi-sided tube.

Overview of parametric studies. The effect of geometric parameters of a multi-sided section on the fatigue performance of a tube-to-end plate connection was evaluated parametrically based on elastic FEA of 3D models. The models for parametric studies consisted of a tube and an end plate with fillet-welded connection. The maximum stress at the section $0.1\sqrt{(rt)}$ ahead of the weld toe on the tube wall was considered as a fatigue critical stress, and was used as the basis for comparison. The geometric parameters considered for the study was the tube diameter (outer flat-to-flat distance), the tube thickness, the bend radius, and the number of sides. Total 102 FE models were analyzed considering different combinations of the geometric parameters. The outer flat-to-flat distance and the thickness of a tube were varied from 254 mm (10 in) to 610 mm (24 in) and 5 mm (0.179 in) to 13 mm (0.5 in), respectively. The thickness of the end plate was kept constant at 51 mm (2 in). The

number of sides was varied from 8 to 20, and bend radius was varied from 13 mm (0.5 in) to 152 mm (6 in). All models were analyzed such as to produce the same nominal stress at the critical section. The FEA were conducted using the commercially available software ABAQUS (Dassault Systèmes. 2010). Twenty node iso-parametric quadratic elements with reduced integration (C3D20R) were used.

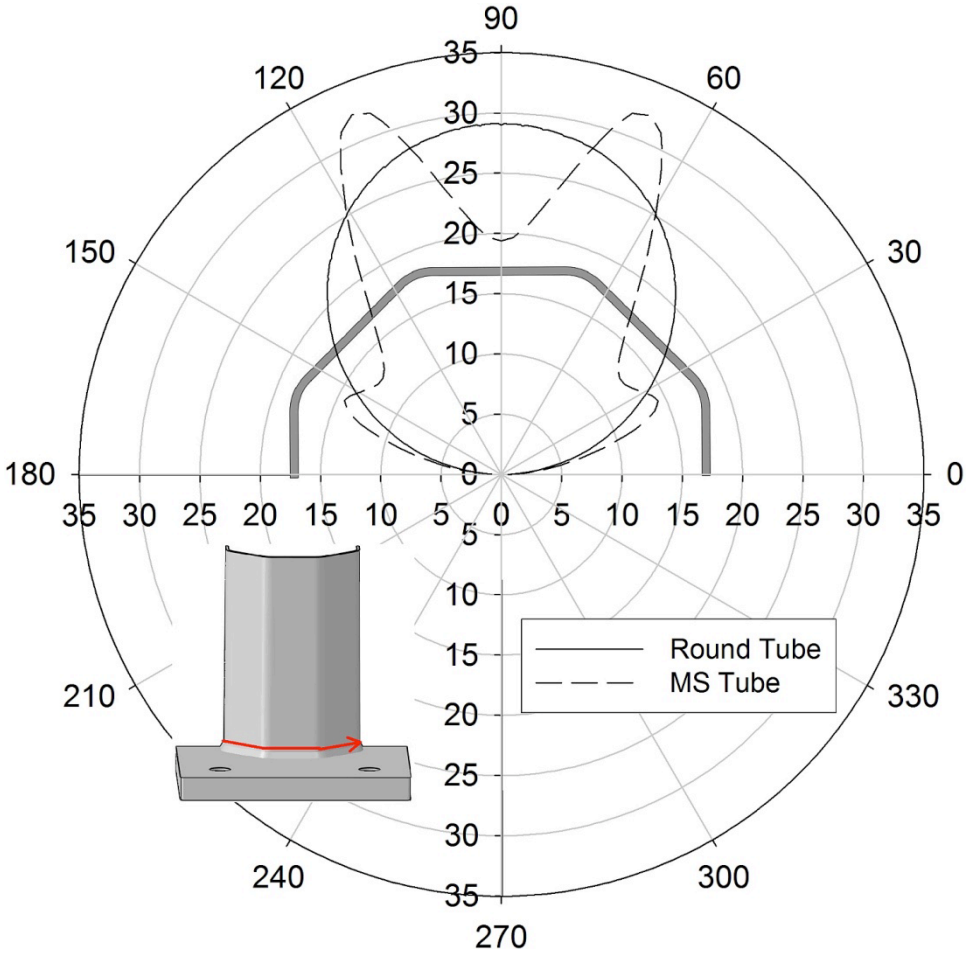

Figure 5. Comparison of longitudinal stress distribution between round and multi-sided tube-to-end plate connections

Discussion of findings. The parametric study results of the multi-sided tube-to-end plate fillet-welded connection are presented in Figure 6 (*a*) and (*b*), as an example. The effects of bend radius and number of sides on the stress concentration are presented as ratio of stress concentrations in a multi-sided tube and a round tube having the same cross-sectional dimensions. The results show that the stress concentration ratios decrease as bend radius and number of sides increase, and stress concentrations approach to that of round tube-to-end plate connections.

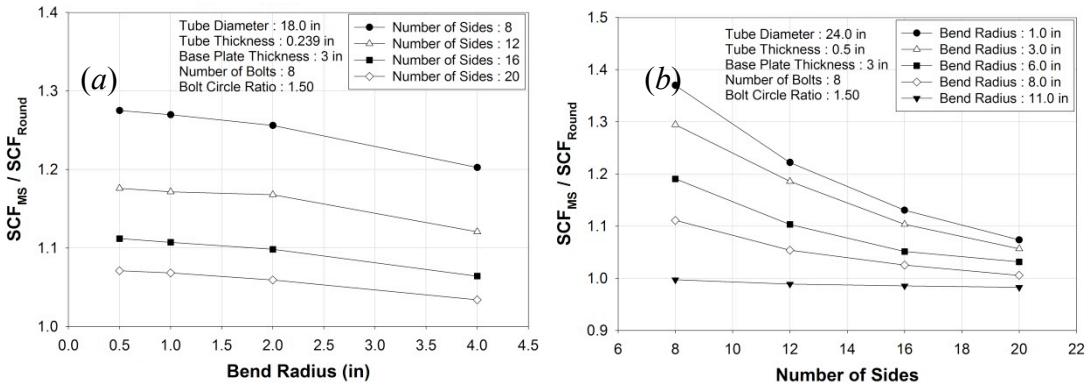

Figure 6. Typical parametric study results : (*a*) effect of bend radius; (*b*) effect of number of sides

To define the combined effect of bend radius and number of sides, a "roundness" factor was defined that quantifies the closeness of a multi-sided section to a round section.

$$\text{Roundness} = \frac{\cos(\frac{\pi}{N_S})}{1-\frac{r_b}{R_i}\left[1-\cos(\frac{\pi}{N_S})\right]}$$

The definition consists of three factors — the inside bend radius (r_b), the radius of inside inscribed circle (R_i), and the number of sides (N_S). The factor was determined by dividing the distance from the center of tube to the inside face of bend corner with the inscribed radius of inside face of multi-sided tube section. The factor can vary from 0.5 to 1.0, where 0.5 indicates three-sided tube with zero bend radius and 1.0 is represents a perfectly round tube. For a given number of sides, the length of flat face will reduce with increasing bend radius, and the shape will approach to that of a round tube. On the other hand, with increasing number of sides the shape of a multi-sided tube will approach to round tube, even with a sharp bend radius. Fouad et al. (1999) proposed a "roundness" factor, defined as the ratio of the inside bend radius to the inscribed radius of the multi-sided tube, which varied from 0 to 1, where 0 denoted the perfectly sharp corner and 1 denoted the perfectly round tube. However, this definition did not include the effect of number of sides, one of the primary and independent geometric parameter, and as such was incomplete. For a eight sided tube, the roundness factor as obtained from the above equation is greater than 0.923, which is the value of roundness for zero bend radius.

Figure 7 shows the variation in ratio of stress concentrations with respect to the roundness. The stress concentration ratios decreased with higher roundness and approached 1.0 for a perfectly round section. However, the ratios are clearly grouped by different outer flat-to-flat distance of a tube, and a small variation caused by variation in tube thickness is evident within each group. It is apparent that the stress concentration ratio is a function of the tube flat-to-flat distance, and the variation with respect to roundness factor for each tube flat-to-flat distance exhibits similar trend. The results also demonstrated that for a tube with a larger flat-to-flat distance, the

roundness should be increased to reduce stress concentration. This can be achieved by increasing number of sides and/or increasing bend radius.

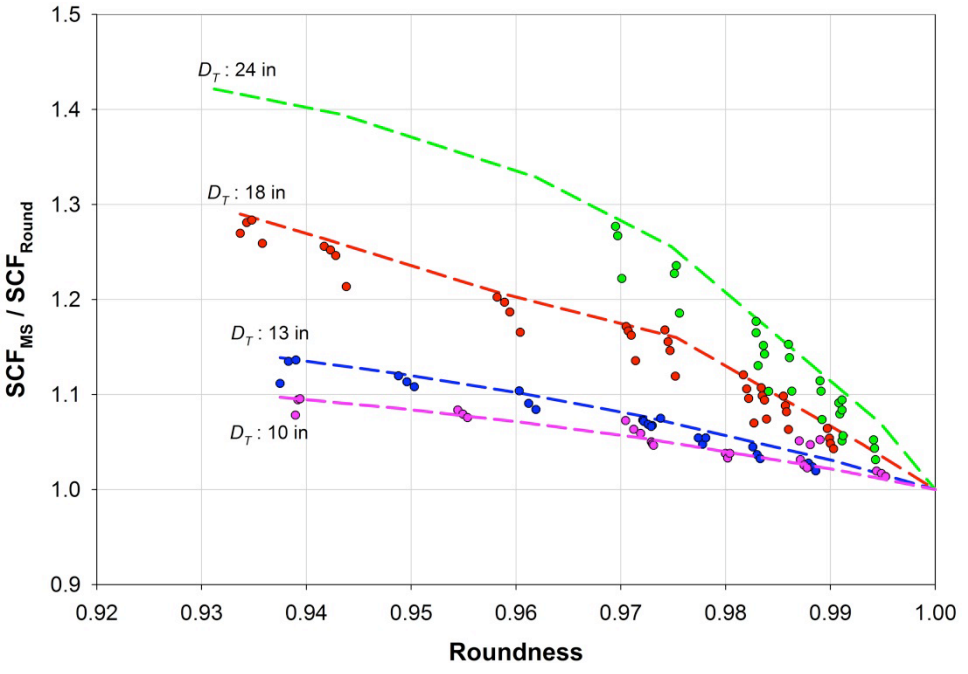

Figure 7. Parametric study results: stress concentration ratio verse roundness

CONCLUSIONS

The experimental studies established the fatigue resistance of multi-sided tube-to-end plate fillet-welded connections, against fatigue cracking at fillet-weld toe on the tube, as AASHTO Category E′ both in the finite and infinite life regimes. Fatigue cracking in multisided tube-to-transverse plate connections initiated at the bend corners and progressed towards the flat face in between the corners. Experimental and analytical research showed existence of high stress concentration at the bend corners, which caused crack initiation very early during the fatigue tests in eight sided tubes with sharper bend radius. The local stress and notch stress approach provided reasonable lower bound estimates of fatigue performance in finite life and infinite life regimes respectively. The parametric studies demonstrated that compared to a round tube of similar size, welded connections in multi-sided tubes with lower roundness exhibited significantly less fatigue resistance. Increasing number of sides and/or increasing the internal bend radius can improve fatigue performance of multisided sections. The fatigue design provision in the current AASHTO specification should be revised to reflect the effects of connection geometry on their fatigue resistance.

ABSTRACT

The current practices used in blast design for reinforced masonry are largely based on single-degree-of-freedom analyses. These analyses use a resistance function, i.e., a load-deflection response, to define the behavior of the structural system (in this case, a wall). This paper presents an improved method for determining the resistance function for reinforced masonry walls. The new approach is capable of more accurately capturing the true behavior of a reinforced masonry wall loaded out-of-plane. The improved method is compared to current blast design practices and test data.

INTRODUCTION

Reinforced masonry (RM) is commonly used for exterior wall applications when the walls must be designed to resist an external explosive load. For infill applications, RM walls are typically non-loadbearing since the vertical loads are carried by a steel or reinforced concrete frame. RM is very effective at resisting both accidental explosions and intentional terrorist attacks. This is mostly due to the fact that when RM is fully grouted, it has a significant amount of mass that supplies an inertial resistance force. However, designers can only rely on this inertial resistance if the wall is adequately reinforced to allow it to sustain very large strains and deflections.

Typical blast design for RM uses the single-degree-of-freedom (SDOF) approach, which usually relies on a bilinear, linear-elastic-perfectly-plastic resistance function. Some references on blast design ignore the guidance provided by ACI 530/530.1 (ACI Committee 530 2008) and simply use the procedures for reinforced concrete to develop the resistance function. Most blast design standards, such as the Unified Facilities Criteria (UFC) 3-340-02 (Department of Defense 2008), are being updated to adopt the RM design procedures outlined by ACI 530/530.1. However, the resistance function will still be bilinear, and therefore, cannot properly describe the deflection at which cracking of the masonry or yielding of the reinforcement occurs.

Also, because it is assumed to behave plastically under large deflection, the design procedure does not account for any additional resistance due to strain hardening nor does it identify the deflection at which the ultimate capacity is reached. This paper describes the development of a resistance function for RM that includes these regions of behavior and also predicts the ultimate allowable deflection. The resistance function is based on empirical constitutive properties for the masonry and the steel reinforcement. The empirical relations are used in a user-developed numerical routine to calculate the complete nonlinear moment-curvature relation for an RM section. The moment-curvature relation is then used to calculate a nonlinear resistance function using a numerical implementation of the moment-area method. The resulting resistance function is compared to that obtained using the bilinear approach.

APPROACH

Previously, Browning et al. (submitted 2010) analyzed the flexural response of an RM wall using a numerical implementation of the moment-area method (Gere and Timoshenko 1997). The procedure used a piecewise-linear moment-curvature definition to calculate the resistance function, i.e., the load-deflection response, of the wall. The results of the analysis from Browning et al. showed that this approach was conservative in terms of both ultimate capacity and allowable deflection. This procedure also provided a more robust and fundamental definition of resistance because it explicitly defined the load-deflection values at which cracking, reinforcement yielding, and masonry crushing occurred; this is in direct contrast to the current approach taken by UFC 3-340-02, which cannot correctly identify any of these values.

The approach taken here was to build on the previous work by Browning et al. and to incorporate more robust constitutive properties for the masonry and reinforcing steel. The properties of reinforcing steel have been understood for quite some time, and equations defining the complete stress-strain response for reinforcing bars can be found in various textbooks. Accurate definitions of the complete stress-strain response for concrete masonry are less abundant, but a thorough search provided a set of equations that appear to perform quite well. By implementing these constitutive definitions into the procedure for calculating the resistance function, a more accurate definition of strength and ductility should be obtained.

CONSTITUTIVE PROPERTIES FOR STEEL

In constructing the algorithm to calculate the moment-curvature response, two options were used for defining the constitutive properties for the steel reinforcement. The first option uses a generic set of equations taken from Naaman (2004), a textbook on prestressed concrete design. The second option allows the user to define an engineering stress-strain curve for the steel.

Naaman's constitutive definition for the steel separates the stress-strain curve into three segments: a linear-elastic segment up to yield, a yield plateau up to strain hardening, and a strain hardening segment up to failure. The three segments are defined as follows.

$$\sigma_s = E_s \varepsilon_s \qquad \text{for} \quad 0 \le \varepsilon_s \le \varepsilon_y \tag{1}$$

$$\sigma_s = f_y \qquad \text{for} \quad \varepsilon_y \le \varepsilon_s \le \varepsilon_{sh} \tag{2}$$

$$\sigma_s = f_y + E_{sh}\left(\varepsilon_s - \varepsilon_{sh}\right)\left\{1 - \frac{E_{sh}\left(\varepsilon_s - \varepsilon_{sh}\right)}{4\left(f_{su} - f_y\right)}\right\} \qquad \text{for} \quad \varepsilon_{sh} < \varepsilon_s \tag{3}$$

where σ_s and ε_s are the stress and strain in the steel, E_s is the modulus of elasticity, f_y is the yield stress, ε_{sh} is the strain at the onset of strain hardening, E_{sh} is the modulus at the onset of strain hardening, f_{su} is the ultimate stress achieved during strain hardening, and ε_{su} is the strain corresponding to f_{su}. Using the regression equations from Naaman's textbook to calculate the undefined parameters, the resulting stress-strain definition for a Grade 60 reinforcing bar is shown in Figure 1. Also shown in Figure 1 is the stress-strain data from Browning et al. for an ASTM A 615 Grade 60 steel. The yield stress for the tested material is approximately 33% higher than that used for design; but, if the modulus of toughness is calculated by integrating these curves with respect to strain, then the strain-energy density is found to only differ by 1.5%. The strain-energy density values were compared at a strain value of 10.5%, which was the ultimate strain of the test specimen. This shows that the prediction provides a reasonable and conservative estimate for many applications. However, using a lower yield stress is not necessarily conservative in situations where reaction forces are being calculated for the purpose of designing connections. Therefore, the designer must ensure that the constitutive properties are appropriate for the problem at hand.

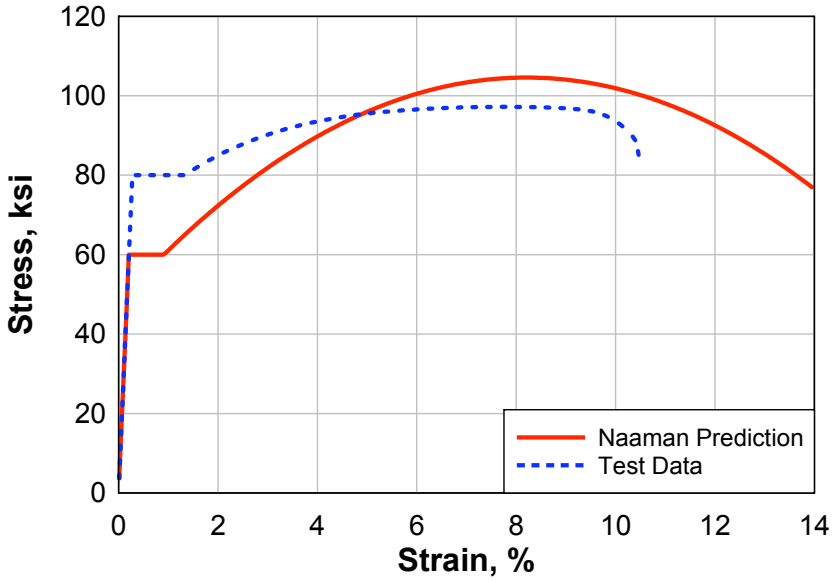

Figure 1. Predicted stress-strain curve for Grade 60 reinforcing bar.

CONSTITUTIVE PROPERTIES FOR MASONRY

The constitutive properties for masonry were taken from a paper by Hart et al. (1989). This work was conducted to complement the work done by the Technical Coordinating Committee for Masonry Research (TCCMAR) U.S.-Japan Coordinated Program for Masonry Research. Hart et al. developed two analytical models for defining the stress-strain behavior of confined and unconfined concrete masonry. The first model was known as the Acceptable Fit model, and the second was known as the Best Fit model. The Acceptable Fit model was intended to be very simple and user-friendly for designers. The Best Fit model was intended to provide a more accurate definition of the behavior at the cost of more complexity. Because this effort is focused on implementing the equations into an automated software program, the more robust Best Fit model was used.

The Best Fit model separates the stress-strain response of concrete masonry into two regions: the rising branch and the falling branch, as shown in Figure 2. The rising branch is described by a second-degree polynomial of the form

$$\sigma_m = A\varepsilon_m^{\,2} + B\varepsilon_m \tag{4}$$

where σ_m is the stress in the masonry, ε_m is the strain in the masonry, and A and B are shape parameters.

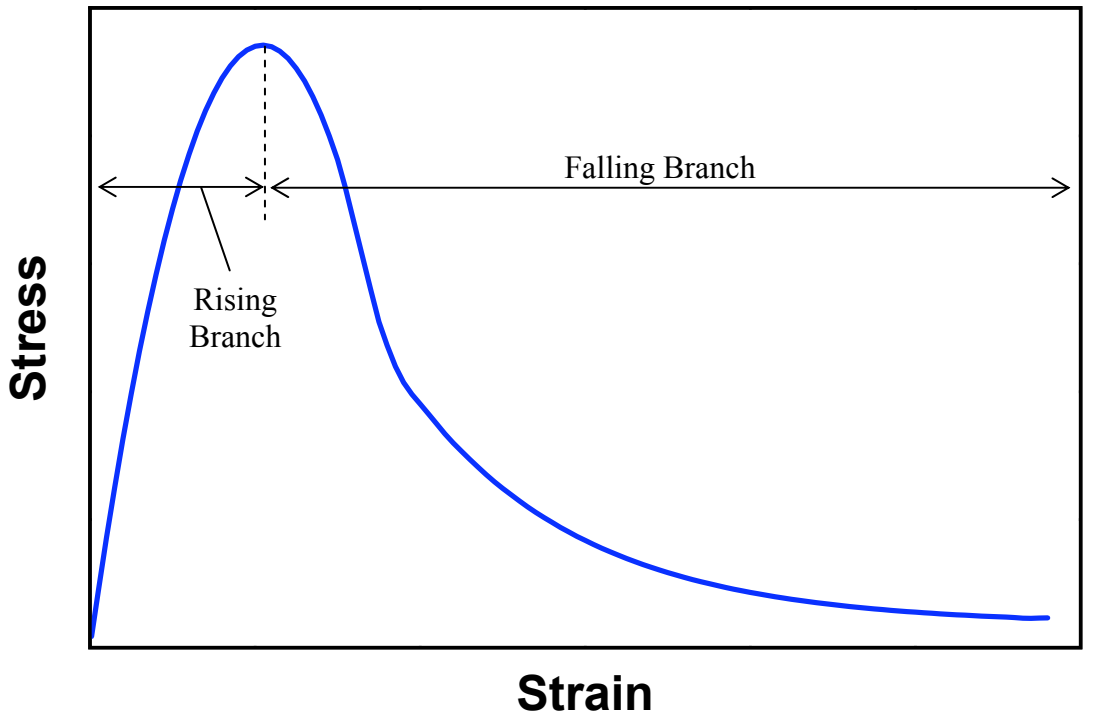

Figure 2. Typical stress-strain behavior of concrete masonry.

Hart et al. show that the rising branch equation can be written in terms of one shape parameter and two material parameters by defining a new parameter C as A/f'_m, where f'_m is the unconfined compressive strength of the masonry, and by applying the boundary condition $\sigma_m = f'_m$ at $\varepsilon_m = \varepsilon_u$, where ε_u is the strain at ultimate strength. This allows Eq. (4) to be rewritten as

$$\sigma_m = f'_m \left\{ C\varepsilon_m{}^2 + \left[\left(1/\varepsilon_u \right) - C\varepsilon_u \right] \varepsilon_m \right\} \tag{5}$$

The falling branch is defined by an exponential function of the form

$$\sigma_m = B + Ce^{(-E\varepsilon_m)} \tag{6}$$

Hart et al. rewrote Eq. (6) by applying the same boundary condition as before and by defining a new parameter D as B/f'_m. The new form of the equation then becomes

$$\sigma_m = f'_m \left\{ D + [1 - D] e^{(-E(\varepsilon_m - \varepsilon_u))} \right\} \tag{7}$$

This allows the full range of behavior to be defined by three shape parameters (C, D, and E) and two material parameters (f'_m and ε_u). Hart et al. then fit the curves to experimental data to obtain the shape parameters. For this effort, Hart et al.'s shape parameters were used, but in practice, the parameters could be recalculated if more precise experimental data were available.

CALCULATION OF MOMENT-CURVATURE RESPONSE

A complete explanation of the classical approach for calculating a moment-curvature response for RM is provided by Browning et al. (submitted 2010). The classical approach provides a simple piecewise-linear plot such as that shown in Figure 3. This approach can be used to develop a nonlinear resistance function, but it does not account for strain hardening of the steel or the nonlinear behavior of the masonry. Therefore, a more robust method is needed.

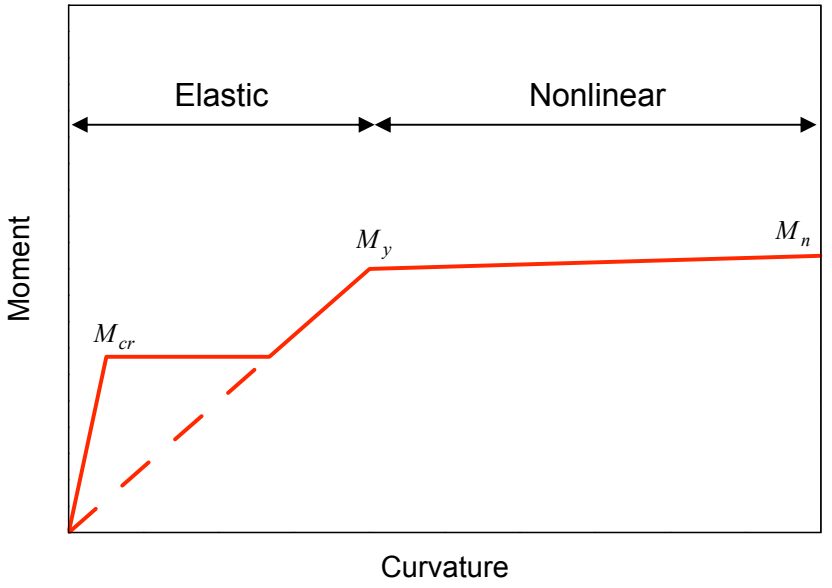

Figure 3. Piecewise-linear moment-curvature definition for reinforced masonry.

The method used to calculate the moment-curvature response is sometimes referred to as a fiber analysis or a sectional analysis. This procedure discretizes the cross section of the wall or beam in question into a large number of layers, or fibers, that can be analyzed individually. A strain profile is then applied, which is assumed to remain linear throughout the entire response. From the strain profile, the strain is known in each fiber; then, the stress can be calculated using the appropriate constitutive relations. Once the stress in each fiber is known, the forces in each fiber can be used to calculate the bending moment on the section. The curvature is calculated based on the current value of the strain. This gives a moment-curvature point, and then a new strain profile is applied to obtain another point. This process is repeated until a limiting factor, such as ultimate stress or strain, is reached. The accuracy of this process depends on the number of fibers. Therefore, it is not a practical option for hand calculations but is easily handled by the computational power offered by a normal desktop computer.

The moment-curvature definition was developed using input data from Browning et al. The input data was taken from what was referred to as the static calibrated prediction. The input parameters for calculating the moment-curvature response, as well as the resistance function, are summarized in Table 1. The stress-strain curve for the steel was taken from the test data shown in Figure 1. The resulting moment-curvature response is shown in Figure 4 along with the piecewise-linear approach previously used by Browning et al. Note that the response is essentially the same while the curvature is small, which is only natural since the simplified methods are most accurate for small strains.

Table 1. Parameters for moment-curvature and resistance function calculation.

Material Property	Definition	Input Value
f'_m, psi (kPa)	Unconfined compressive strength of masonry	4,670 (32,199)
f_r, psi (kPa)	Modulus of rupture of masonry	163 (1124)
ε_{mu}, in./in. (cm/cm)	Maximum usable compressive strain of masonry	0.0025 (0.0025)
f_y, ksi (MPa)	Yield stress of reinforcement	80 (552)
E_s, ksi (MPa)	Modulus of elasticity of reinforcement	29,000 (199,948)
b, in. (cm)	Width of cross section	144 (366)
h, in. (cm)	Thickness of cross section	7.625 (19.37)
d, in. (cm)	Depth of reinforcement	3.8125 (9.68)
A_s, in.^{2} (cm^2)	Area of reinforcement	1.24 (8.00)
L, in. (cm)	Clear span	112 (284)

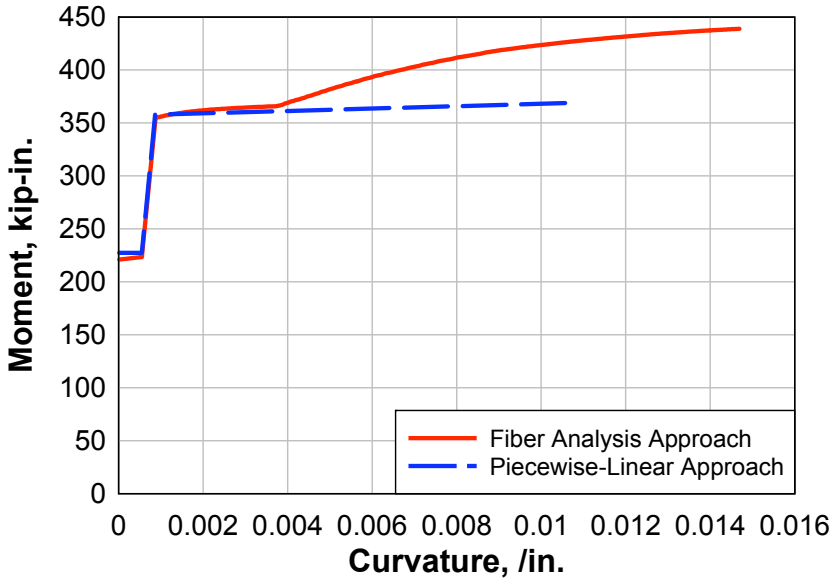

Figure 4. Moment-curvature plots.

CALCULATION OF THE RESISTANCE FUNCTION

The resistance function is simply a plot of load vs. deflection for a given structural element. In the case of a simply supported masonry wall, the deflection of interest is at midspan. In the past, Biggs (1964) showed a simple way to determine the linear-elastic-perfectly-plastic resistance function using a few fundamental equations. More recently, Browning et al. showed that an arbitrary nonlinear resistance function can be easily produced using a numerical implementation of the moment-area method. This method is currently applied only to a simply supported beam/wall, but the method is applicable to any set of boundary conditions.

The resistance function developed by the method described here is shown in Figure 5 along with that corresponding to the piecewise-linear approach. Also shown is the resistance function currently used by UFC 3-340-02 (Department of Defense 2008), which superseded the tri-service manual TM 5-1300 (U.S. Army et al. 1990). Lastly, the test data used by Browning et al. is also shown in Figure 5. These test data are more thoroughly described in the Air Force Research Laboratory report by Salim et al. (pending publication 2011). All of these cases represent the same wall loaded at a quasi-static rate; dynamic increase factors were therefore not included in the resistance function calculations.

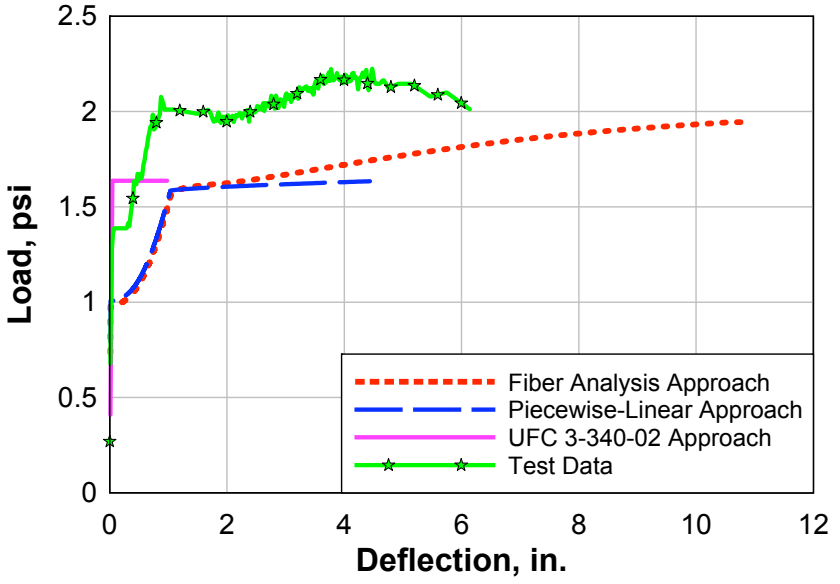

Figure 5. Resistance function plots.

Figure 5 shows that the UFC 3-340-02 approach is conservative in terms of ultimate deflection but does not correctly depict the overall behavior. For a case where deflections were required to be kept very small, it is conceivable that the UFC approach could become non-conservative if the cracking strength of the wall was significantly lower than expected. For this reason, it is proposed that a more robust definition of resistance should be used so that the actual behavior of the wall is adequately simulated.

Figure 5 also shows that there is a significant difference between the ultimate deflections predicted by the piecewise-linear method and the fiber analysis. This difference is simply due to the fact that the fiber analysis allowed the calculation to be carried out to a larger ultimate strain in the masonry. Therefore, this approach may raise more questions than answers, such as: which one is correct? This question is not an easy one to answer and is often problem dependent. However, one observation is that at deflections on the order of 6 in. (which is where the test specimen failed), the moments caused by P-delta effects from self-weight become quite significant. Further study is needed to determine if this is true, but the hypothesis is that the fiber analysis is more correct. However, the fiber analysis needs to be modified to account for P-delta effects when the resistance function is calculated. This would reduce the failure deflection, which would likely correlate better with test results.

SUMMARY AND CONCLUSIONS

A more robust method for defining the flexural resistance of RM walls was presented. The method makes use of more advanced constitutive properties than are historically used for SDOF analyses for blast resistant design. The advanced constitutive properties were used to develop a nonlinear moment-curvature definition using a fiber analysis. A numerical implementation of the moment-area method was then used to convert the moment-curvature response into a resistance function.

This method was compared to a previous approach taken by Browning et al. that made use of a simple piecewise-linear moment-curvature definition. The two approaches match well during small to medium deflections. However, there are significant differences in the ultimate deflection and noticeable difference in ultimate capacity. The reason for these differences is due to the ultimate strain used in the calculation, but the most appropriate method for calculating ultimate deflection is still being studied. It is hypothesized that P-delta effects must be included to accurately predict the failure deflection and capacity.

This method and the previous method by Browning et al. were also compared to the linear-elastic-perfectly-plastic approach taken by UFC 3-340-02. The UFC approach did not capture the true behavior of the wall, i.e., it cannot define the point at which cracking of the masonry or yielding of the reinforcement occurs. It was also shown that it could be non-conservative in special cases where deflections are critical.

Abstract

The U.S. Army Engineer Research and Development Center (ERDC) is currently conducting material research on advanced cementitious composites with randomly distributed fiber reinforcement. The successes of the research are well documented, and unconfined compressive strengths on the order of 200 MPa are not uncommon. However, as with most cementitious materials, these materials exhibit a brittle tensile failure response. To improve the material's response to blast and ballistic loads, the tensile capacity must first be quantified and subsequently enhanced. This paper presents findings of three laboratory experimental series conducted to characterize, quantify, and enhance the tensile failure response of a new rapid-set, field-curable geopolymer concrete that offers distinct advantages over other cementitious composites.

Individual fiber, single fiber pull-out, and direct uniaxial tension experiments were conducted for a geopolymer concrete capable of achieving 44 MPa in 24 hours, and 62 MPa in 28 days in ambient temperatures with no additional curing requirements. Three fiber types were examined at various embedment lengths in the matrix. Load versus displacement curves are presented for each type of fiber, as well as the mechanical properties of the fiber itself. Direct tension samples were cast with each type of fiber at 2% by volume in the matrix and tested in a direct uniaxial experiment. The corresponding load versus displacement responses are presented and discussed. Key steps are identified for ongoing research to optimize the fiber matrix interaction, thus maximizing ductility for enhanced material response to tensile forces.

Introduction

A mission of the Geotechnical and Structures Laboratory of the ERDC is to provide innovative engineering and scientific solutions to protect the U.S. warfighter and

critical facilities. Recent shifts toward nontraditional threats and tactics from terrorists have presented new challenges to providing force protection for U.S. troops in foreign theaters of operation. In typical operations, a significant threat to the U.S. warfighter was direct and indirect fire weapons such as mortars, artillery, shoulder-fired rockets, suicide bombings, and small-arms fire. Physical protection for the warfighter was traditionally provided by hardened structures, large soil-filled revetment walls or concrete barriers or, simply put, mass.

Although a proven protective solution, the typical approach is often not practical or desirable, as it requires significant time, manpower, equipment, and other valuable resources. Furthermore, constructing massive concrete structures with limited, or at best, poor quality, in situ construction materials often results in having to transport better quality raw material from neighboring countries or from the United States. This presents many logistical challenges and is often not cost effective. Additionally, U.S. troops operating in close-engagement conditions such as contingency outposts and outside-the-wire construction or repair operations are often left vulnerable to terrorist attacks. In this typical scenario, the warfighter may occupy an area for very short periods of time—typically hours or days, rather than months or years—until the task is completed. Hardened structures and massive walls or barriers are not practical for such conditions.

Given this, recent Army research programs are focused on developing high performance concrete (HPC) mixtures and lightweight, rapidly deployable protective structures. A goal of the research thrust is to develop protective options that depend more on system ductility or enhanced material properties to provide protection from blast and weapon fragmentation, rather than mass alone (O'Neil et al. 2004). Examples of such research programs include the "Modular Protective System for Future Force Assets" (MPS) and "Defeat of Emerging Adaptive Threats" (DEFEAT). For the MPS program, a primary objective was to develop a lightweight structure that could be rapidly constructed and positioned without heavy equipment or significant manpower while providing the required level of protection from specific threats (Nelson et al. 2008). The lightweight structure was clad with multiple layers of thin HPC panels that were prefabricated at a U.S. manufacturing facility and shipped into theater. The panels were developed to provide protection from blast and weapon fragmentation at a considerably reduced thickness than that required by a more traditional concrete mixture, thus reducing mass. Full-scale field experiments validated the prototype and showed initial success of the approach. To build on this success, a component of the DEFEAT program investigated further development of a similar HPC mixture, as well as a more thorough multiscale material property characterization effort to better understand and improve similar cementitious composites. This paper

will present the initial results from unique laboratory experiments conducted on a specific cementitious composite that offers distinctive benefits, different from current HPC mixes. The cementitious composite discussed in this paper may serve as a material option for providing physical protection to the U.S. warfighter.

High Performance Concrete

The term "HPC" typically refers to a concrete that satisfies certain criteria that conventional concrete cannot. Examples of such criteria may be strength, durability, toughness, increased structural capacity, or even resistance to environmental influences (Zia et al. 1997). With respect to force protection, a HPC is typically distinguished as a concrete mixture with a very small maximum particle size, randomly distributed short fiber reinforcement, and high compressive strength.

Researchers focused on attaining high compressive strength as the criterion for achieving improved ballistic resistance. Some studies (Borvik et al. 2007) reported that an increase in compressive strength may result in improved ballistic resistance; however, it was often noted that an increase in compressive strength did not necessarily produce a comparable increase in such resistance. For example, one penetration study (Borvik et al. 2007) with a conical-nose projectile against a 100-mm-thick concrete slab showed that increasing the compressive strength from 41.4 MPa to 116.7 MPa resulted in only a 20% increase in ballistic limit. Similarly, increasing the compressive strength of a second concrete mixture from 84.4 MPa to 196.6 MPa also increased the ballistic limit by the same 20%. The ballistic limit is defined as the average of the fastest impact velocity without producing perforation and the slowest impact velocity producing complete perforation. Thus, a higher ballistic limit is advantageous and beneficial in mitigating weapon fragmentation. Other studies showed that the benefits might be less than 20% (Hanchak et al. 1992).

Pursuing a higher ballistic limit, ERDC researchers demonstrated substantial progress in producing a HPC that has a compressive strength in excess of 200 MPa. For this specific mixture, the high compressive strength was achieved by dense particle packing, a very low water-to-cement ratio, high-range water-reducing admixtures, and specific curing conditions at elevated temperatures (O'Neil 2008). A typical curing regimen would include 7 days at 22°C and 100% humidity, followed by submersion in a water bath at 85°C for 4 days and then drying in an oven at 85°C for 2 days (Williams et al. 2009). Though these techniques successfully achieved a very high compressive strength, data showed that the HPC tends to be quite brittle and has very limited tensile capacity. While conventional concrete has a tensile capacity that is normally 10% to 15% of the compressive strength, the specific HPC developed at

ERDC has a tensile capacity that is approximately 4% to 5% of the compressive strength (Williams et al. 2009). Current ERDC research programs are investigating and improving this aspect of the HPC mixture (Li et al. 2010).

Ductility is another important material property for protection against forces caused by blast and impact effects. In general, an increase in material ductility increases material toughness, or energy dissipation potential. This is an important attribute for a material resisting severe loading, such as blast load. In a high compressive strength HPC with a brittle matrix, ductility is achieved through an optimized selection of fiber reinforcement. It should be noted that randomly distributed short fibers are the preferred method for HPC reinforcement because conventional continuous reinforcement is not practical for thin panels, especially for applications stated in the preceding section. Since the brittle matrix has very low tensile strength, appropriate fibers must be selected to successfully bridge the crack openings. If this process is properly engineered and optimized, additional energy is consumed as the fiber partially pulls out of the matrix before arresting the crack, causing another crack to repeat the process. In order for this progressive cracking condition to exist, a balanced design between the fiber, matrix and interface is required. This quantitative link between material properties and material microstructures (i.e., fiber, matrix, and interface) is termed "micromechanics" (Li 1992). Researchers at the University of Michigan successfully developed and implemented this approach.

The purpose of the research discussed herein was to investigate and enhance an alternative high-early-strength cementitious material offering a simplified mixing and curing procedure capable of being produced by a soldier in the field. Such a material would retain some of the benefits of a high compressive strength HPC, while offering a more versatile casting and curing process achievable in an austere environment. To better understand the inherent material properties and enhanced ductility, laboratory experiments were developed to apply the micromechanics approach toward optimal material performance. Relevant mechanical properties were obtained for three fibers, as well as their bonding properties with the matrix. Finally, direct uniaxial tension tests were developed and conducted to quantify the tensile properties of the matrix with and without coarse aggregate, and the matrix reinforced with these three fiber types.

Description of Material

Matrix

The primary focus was on a geopolymer cement as a HPC material option for use by the U.S. warfighter. The term "geopolymer" was coined by Davidovits to describe materials stemming from his research on inorganic polymers; it refers to a broad class of synthetic alkali aluminosilicate materials (Davidovits 1991, Tempest et al. 2009). Specifically, when an aluminosilicate powder reacts with a highly alkaline silicate or hydroxide solution, a synthetic alkali aluminosilicate, or "geopolymer," is formed. Depending on its constituent raw materials, a geopolymer can possess many desirable properties, such as high compressive strength, high early strength, fire resistance, low thermal conductivity, and fast or slow setting characteristics. Therefore, the key to realizing the desirable material properties hinges strongly on the source of the aluminosilicate and the activating agent (Duxson et al. 2007).

Fly ash is an example of an aluminosilicate powder that may be used to produce a geopolymer cement. This is an industrial waste product that is generated from burning pulverized coal in power stations. Most engineers are familiar with fly ash as a mineral admixture in portland cement concrete. However, because of aluminosilicate content and easy availability, the material has generated research interest as a component for geopolymer cements. Whether low calcium (Class F) or high calcium (Class C), most fly ashes generated from modern furnaces contain 50% to 85% aluminosilicate glass (Hewlett 1998, Mehta and Monteiro 2006). The benefits of using an industrial waste product that "poses a major solid waste disposal problem in the United States and Canada" (Helmuth 1987) to produce geopolymer cements to protect the U.S. warfighter, as an alternative to portland cement produced by an industry identified as "one of the most important users of carbon-based fuels as a source of heat energy," are obvious (Hewlett 1998).

For producing this type of geopolymer cement, a Class C fly ash was combined with an alkali metal salt of citric acid. No hydraulic or portland cement was used in the mix. A chemical retarder and a superplasticizer were added to slow the reaction and to improve workability, respectively. All components of the resulting cementitious product can be premixed and stored with a 3-year shelf life, requiring only the addition of water to initiate the reaction when desired. This geopolymer cement is capable of achieving 44 MPa in 24 hours, 55 MPa in 7 days, and 62 MPa in 28 days in ambient temperatures ranging from 12^{o} to 44^{o}C. These rapid strength gains in ambient temperatures are an advantage not typical among other HPC mixes.

Aggregate

A crushed limestone aggregate with maximum particle size of 6.35 mm was included in the geopolymer cement. The grain-size distribution of the aggregate is shown in Figure 1. Coarse aggregates are typically not used in HPC mixtures. The bond between the paste and aggregate is a source of weakness that can be detrimental to the HPC. Aggregate mineralogy and surface texture affect the bond between the paste and aggregate, and studies showed that surface texture may also affect the modulus of elasticity. Moreover, surface texture and surface area per unit volume of the aggregate can affect tensile strength (Zia et al. 1997). Another study showed that aggregate mineralogy significantly influenced compressive strength and elastic moduli for concretes with strengths ranging from 85 MPa to 105 MPa. However, of the aggregates investigated, crushed limestone produced the best results. Although aggregates may have deleterious effects on HPC material response to an applied load, they offer significant benefits to the mixture, such as improved workability, dimensional stability, and significant cost savings (Mehta and Monteiro 2006). Therefore, to observe the influence of the aggregate on material response to unconfined compression, direct uniaxial tension, and packing density, samples were also cast with 74% of the aggregates removed, leaving only aggregates smaller than 1.2 mm (passing No. 16 sieve) in the mixture. This grain size distribution will be referred to as “Gradation B.”

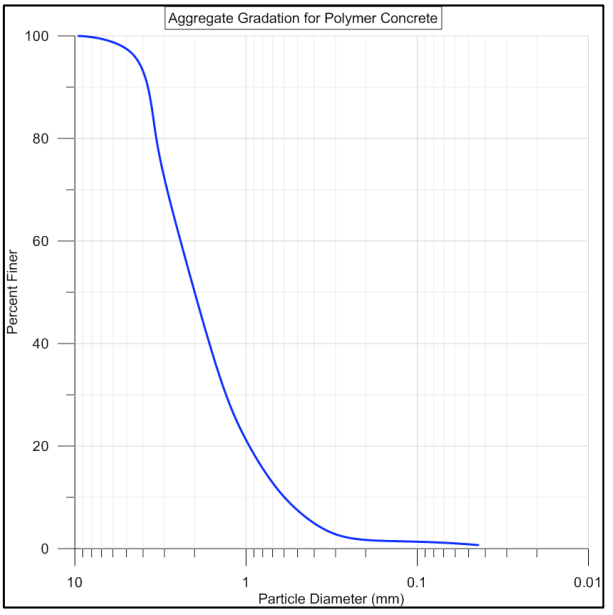

Figure 1. Grain-size distribution of aggregate used in the geopolymer concrete.

Fibers

Several fibers were evaluated for use in the geopolymer concrete. The initial findings are presented for three of the fibers that were tested: a crimped steel fiber (STC), a crimped monofilament polypropylene fiber (PPC), and a bundled monofilament polypropylene fiber (PPH) (all shown in Figure 2). The STC fiber is a continuously deformed low-carbon steel fiber approximately 38 mm long. The PPC is a continuously deformed polypropylene fiber 49 mm long. The PPH fiber is approximately 41 mm long, consisting of several monofilament polypropylene fibers bundled by two larger diameter helical monofilament fibers. A literature review on the use of various fiber reinforced cements (FRC) suggested that 2% by volume is the upper limit of fiber volume content for mixing without special processing techniques or additional admixtures to improve workability and dispersion. This limit was adequately confirmed after several unsuccessful attempts to exceed this limit in the laboratory, regardless of the fiber type used in the batch.

According to Li (1997), FRCs can be considered under three groups based on their fiber volume content. Low fiber volume contents (<1%) are typically used only for plastic shrinkage crack control with very little strength enhancement. Medium fiber volume contents (1%–2%) are often used to supplement main reinforcing steel and offer good workability for use as a cast-in-place or precast FRC without special processing requirements. High fiber volume content (>2%) can offer exceptional mechanical properties such as improved fracture toughness and enhanced ductility, and some may demonstrate strain hardening. However, to ensure proper dispersion, high fiber volume content FRCs are burdened by inordinate processing requirements, thus limiting their use in the field. Therefore, obtaining the benefits of a high volume fiber content FRC with a fiber content not exceeding 2% would, by definition, categorize the material as a HPC. Furthermore, since the stated purpose of this research was to investigate, and potentially enhance, geopolymer concrete as a field-cast and cured HPC for use by a soldier, maintaining a simple mixing and casting process with common tools is considered to be of paramount importance.

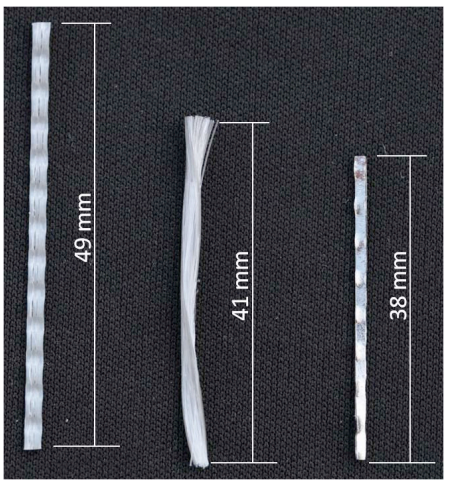

Figure 2. PPC (left), PPH (middle), and STC (right) fibers.

Casting

All samples cast for the experiments described below follow the same mixing and curing procedures. The dry ingredients, consisting of fly ash, activator, chemical retarder, superplasticizer, and aggregate, were stirred to ensure a thorough mixing of the components. Water was added to the components and stirred for 3 minutes, 30 seconds with a common hand-held 12.7-mm drill with a paddle bit. The mixture was then cast into the appropriate mold and vibrated on a platform for 2 minutes and then cured at ambient temperatures. If fibers were included in the mixture, the same procedure was used, but fibers were introduced into the mixture after 2 minutes of mixing. The yield of a typical batch was approximately 1.2×10^{-2} m^3. For samples cast without aggregates larger than 1.2 mm, the only adjustment was a slight reduction in the amount of water to maintain consistency of the mixture and to account for water absorbed by the aggregate. When the aggregate was removed from the mixture, the yield was approximately 7.6×10^{-3} m^3. Figure 3 shows an example of a small batch being mixed in a 20-liter bucket. For larger batches, a mortar mixer was used.

Figure 3. Mixing a small batch of the geopolymer concrete.

Description of Experiments

Three sets of experiments were conducted to quantify tensile properties of the fiber, matrix, and interfacial bond. First, individual fiber tests were conducted to establish the tensile strength of an individual fiber under a displacement-controlled quasi-static load. Secondly, for fiber pull-out tests, single fibers were embedded in the matrix at different embedment lengths and angles of inclination to the direction of the applied load. The single fiber pull-out experiments were conducted to establish the load versus displacement relationship and to determine the pull-out response to a quasi-static load. The third experimental set was designed to capture the response of a fiber reinforced coupon subjected to a quasi-static direct uniaxial tensile load. Each experimental setup is described below.

Individual Fiber

Figure 4 shows the individual fiber experiment. Testing was conducted on an Instron Electropuls universal testing machine (UTM) with a 2-KN load cell. A closed-loop setup with a displacement rate control of 2.54 mm per minute was provided by a built-in linear variable displacement transducer (LVDT). For the PPH fiber, the sample ends were set in resin and cured for 24 hours. This prevented slippage between the fiber and the grips and ensured that all of the bundled fibers were engaged, thus identifying the load capacity of the fiber independent of the bond. However, the STC fiber was gripped directly, as was the PPC fiber. This was justified by the location and mode of failure observed in the fibers.

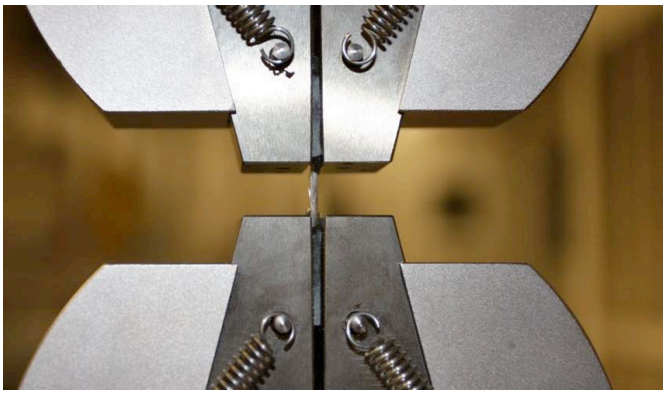

Figure 4. Testing a PPH fiber.

Single Fiber Pull-Out

A single fiber pull-out experiment was conducted to determine the bond capacity between the matrix and the fibers. These tests were also conducted on the Instron

Electropuls UTM with a 2-KN load cell and a displacement rate control of 0.254 mm per minute. When the total displacement had reached 5.08 mm, the rate was increased to 2.54 mm per minute. The rate was increased to significantly reduce the amount of time required for each test and was not expected to influence the load displacement relationship. Various lengths of PPH, PPC, and STC fibers were embedded in the matrix. Single fiber pull-out tests were conducted for each fiber with various embedment lengths. Figure 5 shows the specially designed mold (to position the fiber at the desired angle and embedment depth) and a sample being tested in the single fiber pull-out experiment.

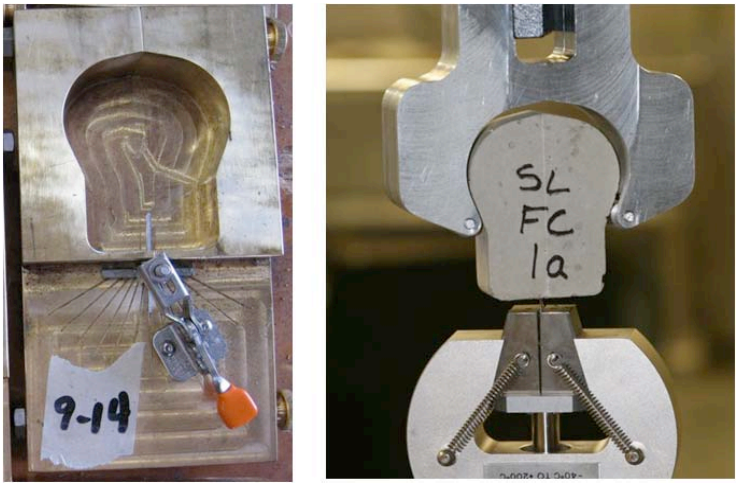

Figure 5. Fiber ready for casting and sample tested in single fiber pull-out experiment.

Direct Uniaxial Tension

In the literature, there appears to be no consensus on the recommend procedure for testing concrete in direct uniaxial tension. Some researchers have attempted a uniform sample geometry with various epoxy bonded end designs to transfer the load to the sample through the grips of the UTM. However, this approach requires tedious sample preparation and allows the potential for slippage due to inadequate strength of epoxy. More importantly, this method tends to induce significant clamping forces on the sample area held within the grips of the testing equipment. An alternative approach is to use a variation in sample geometry near the ends to enable load transfer through friction. With this approach, stress concentrations are developed at any abrupt change in sample geometry. However, the sample geometry can be designed to minimize this effect. The Japan Society of Civil Engineers has adopted a recommended procedure for testing HPC under direct uniaxial tension employing this method (Yokota et al. 2007). This procedure formed the impetus for conducting the direct tension experiments on the geopolymer concrete specimens. The sample geom-

etry used in the study is shown in Figure 6. Tests were conducted on an MTS 810 testing machine with a 98-KN load cell. The loading machine head was monitored with a built-in LVDT to maintain a displacement rate of 0.5 mm per minute throughout testing. Head displacement was recorded in addition to measurements obtained using two external LVDTs. The external LVDTs were Honeywell Model S5 with a ±5-mm stroke and were mounted on the sides of the sample slightly above the tapered region. The sample rate for the exterior LVDTs was 20 Hz, or one sample every 0.05 second.

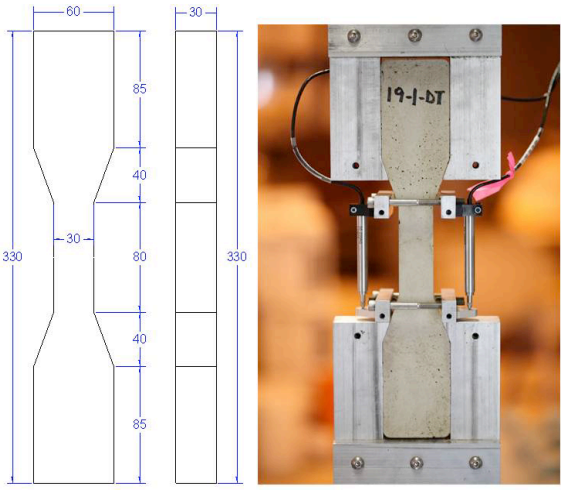

Figure 6. Direct tension dimensions and test configuration.

Results

Figure 7 shows the results of the individual fiber and the single fiber pull-out experiments for a given embedment of L/4 for each fiber where L is the fiber length. In this figure, a dashed line represents the load-displacement relationship for the individual fiber alone. In other words, a dashed line is a fiber's response to a load that is independent of bond; therefore, these results are from the individual fiber (IF) tests. Similarly, a solid line represents the load-displacement plot, or slip capacity, of a single fiber when 25% of the fiber length (L/4) was embedded in the matrix representing the results from the single fiber pull-out (SFPO) test. Since the length, surface area, and surface geometry were different for all three fibers, maintaining an L/4 embedment allows for a relative comparison of the effectiveness of these variables and their contribution to the energy dissipated when the fiber pulls out of the matrix.

In Figure 7, no IF result is shown for the STC fiber. This lack of data resulted from the combined effect of surface geometry and mechanical properties of the low carbon steel in the STC fiber leading to a bond capacity far exceeding the fiber's tensile load capacity. Essentially, the fiber failed in tension prior to bond failure for any fiber embedment length exceeding 6 mm, or L/6, when the load was applied along the axis

of the fiber. As the angle between the direction of the applied load and fiber axis was increased to a maximum of 45 degrees, a combination of fiber yielding and matrix spalling was observed, but the bond never failed. Recalling that more energy is dissipated by fiber pulling out of the matrix than fiber yielding, the above behavior is not a desirable scenario for composite material ductility.

Other notable aspects of the results shown in Figure 7 are the ratio between peak load of the IF curve and SFPO curve for each fiber type, as well as the area under the curve, or total work expended in pulling out each fiber. It is not the value of the peak load that is important; rather, the relative contribution of the two values for a particular fiber indicates the energy dissipation potential in the pull-out test. For example, the ratio of peak loads for the PPH fiber is approximately 3.0, whereas the PPC fiber has a ratio of approximately 2.0. On the other hand, the STC fiber has a ratio of 1.0. Clearly, a higher value of this ratio would indicate better potential for bond failure at a given embedment length, rather than fiber failure. Similar data were generated for different embedment lengths and angles, but only the results for the L/4 embedment at 0 degrees are shown here. These plots provide insight to the potential material ductility manifested in the direct uniaxial tension test for different fiber parameters but with a constant percent volume in the matrix.

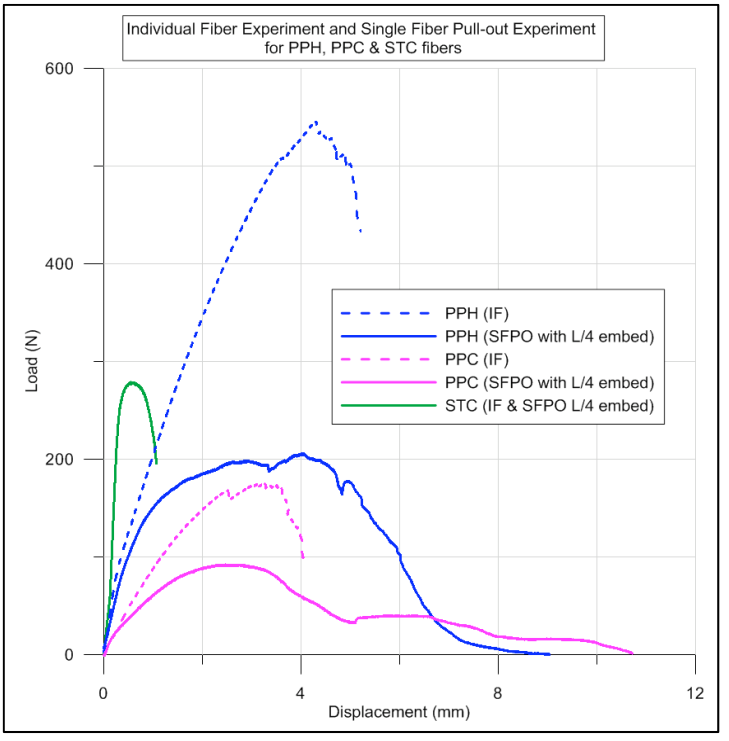

Figure 7. Results of the individual fiber and single fiber pull-out experiments for all three fibers.

Figure 8 shows two typical examples of cross sections of direct tension samples cast with the aggregate gradations shown in Figure 1. Several tests were conducted on these direct tension samples; however, the results are inconclusive because the external LVDTs indicated that the applied load to the samples cast with aggregate gradation B was eccentric. This eccentricity led to a lower initial cracking tensile load in the direct uniaxial tension test, which is inconsistent with an increase in compressive strength for the batch. Therefore, these tests will be repeated in the near future. However, the photos in Figure 8 are useful to observe typical aggregate volume and distribution as well as voids generated during the casting process.

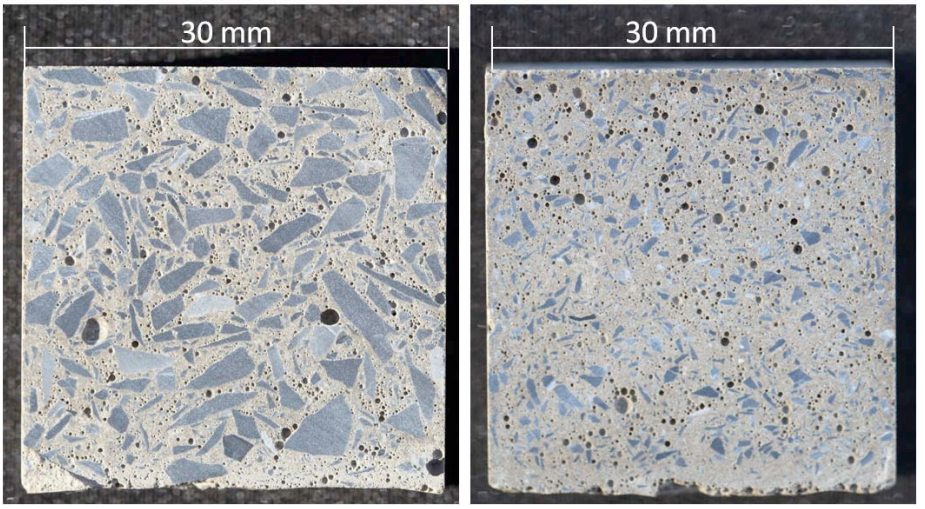

Figure 8. Typical aggregate gradation (left), Gradation "B"- maximum particle larger than 1.2 mm removed (right).

Results from the direct uniaxial tension experiments are shown in Figure 9. During the casting process, a minimum of three cylinders were cast for each batch of geopolymer concrete. These 4-in.-diameter by 8-in.-high cylinders were tested according to American Society for Testing and Materials (ASTM) C39 (2005) to monitor compressive strength of the mixture at the same time the direct tension samples were tested.

Table 1 shows values for the compressive strengths along with key values taken from all direct tension tests. Data shown in the table were obtained from a minimum number of four direct tension samples for each fiber type with the exception of the PPC fiber. For the PPC fiber, data were obtained from only three samples. As seen from the data, this batch encountered some inconsistencies with a very low compressive strength and, as a result, a low initial tensile cracking load of the matrix was obtained. This was most likely due to an error during mixing of the particular batch. This fact should be kept in mind when comparing results for the PPC fiber with

the PPH fiber. Additional testing with the PPC fiber is needed for more conclusive data. As anticipated, the direct tension samples cast with the STC fibers experienced less ductility and toughness than the samples cast with the PPH and PPC fibers. To verify adequate fiber distribution, several direct tension samples cast with the STC fiber were cut through the cross section. Examples of these photos are shown in Figure 10.

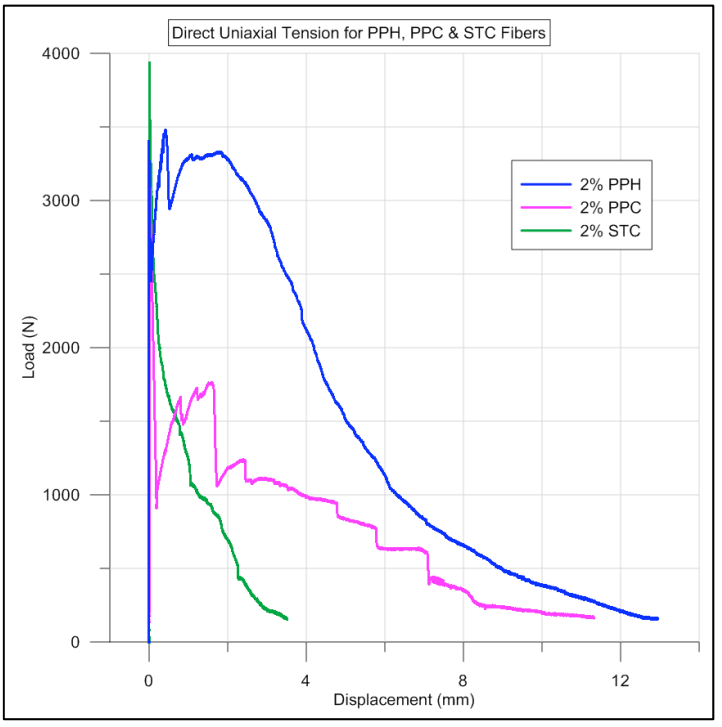

Figure 9. Direct uniaxial tension test results for all three fiber reinforcements at 2% by volume in the mixture.

Table 1. Results from the direct uniaxial tension experiments.

Sample	Wt. avg. (gm)	P_M avg. (N)	P_M std. dev. (N)	P_F avg. (N)	P_F std. dev. (N)	F'c avg. (MPa)	F'c std. dev. (MPa)
PPH	0.045	3588	180	3277	228	50.4	2.4
PPC	0.027	1987	1028	1505	495	30.0	4.9
STC	0.154	4273	471	-	-	46.9	2.7
NF_A	n/a	3114	222	n/a	n/a	49.1	2.9
NF_B	n/a	-	-	n/a	n/a	60.1	2.9

Table notes:
Wt. avg. – average weight of a single fiber
P_M avg – average load (N) at first cracking of the matrix
P_M std – standard deviation of P_M
P_F avg – average maximum load (N) carried by 2% fiber volume after initial crack

P_F std – standard deviation of P_F
F'c avg – average compressive strength (MPa) for a given batch
F'c std – standard deviation of F'c
NF_A – samples cast with no fibers with aggregate gradation A
NF_B – samples cast with no fibers with aggregate gradation B

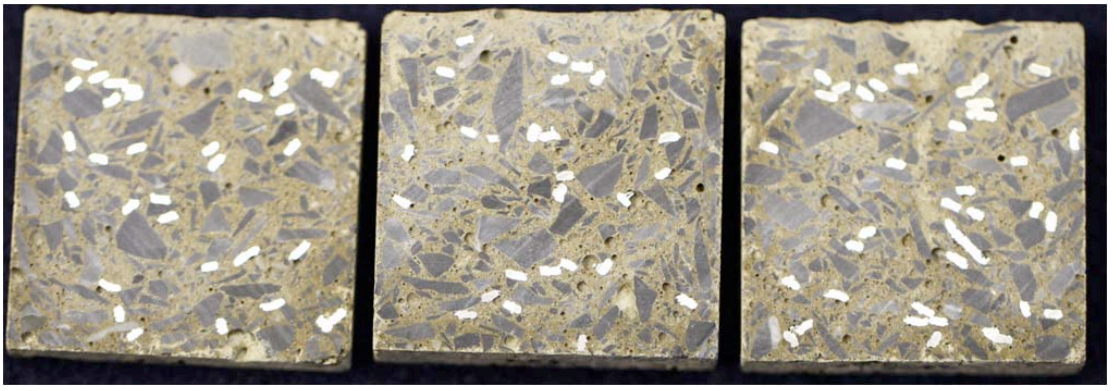

Figure 10. Cross sections taken from direct tension samples cast with the STC fiber.

Conclusions

The geopolymer concrete achieved early high compressive strengths without the aid of special curing environments or techniques. Mixing and casting was a very simple procedure that was accomplished with common tools. Incorporating aggregates improved workability and significantly increased the yield. Additional testing is required to fully understand the impact of the aggregate on the mechanical properties of the geopolymer concrete. The STC fiber had a very strong mechanical bond with the matrix, but low yield and ultimate strengths; as a result, the fiber did not pull out of the matrix. This resulted in low ductility and toughness for samples cast with the STC fiber and tested in the direct uniaxial tension experiment. The PPH and PPC fibers did not break, but were pulled out of the matrix in the single fiber pull-out experiment. This resulted in an increase in toughness and ductility of the direct tension samples compared with the STC fiber samples. Some of the direct tension samples cast with the PPH fiber experienced work-hardening after initial cracking of the matrix. Fracture toughness of the matrix should be determined experimentally, and further improvement of the geopolymer cement could result in additional work-hardening.

This paper represents initial findings of ongoing research on a geopolymer concrete. All three types of experiments were conducted with quasi-static loads. Though these experiments serve as an indicator of material performance under quasi-static tensile loads, response to dynamic loads may be entirely different. Bond between the matrix

and the PPH and PPC fibers demonstrated sensitivity to the loading rate when the quasi-static load rate was increased by a factor of 10 in the single fiber pull-out experiment. This is evidence that further testing is required.

The Evaluation of Pre-stressed Pre-cast Panels Subjected to Blast

A. Billek[1] and S. Marjanishvili[2]

[1]Hinman Consulting Engineers, One Bush Street, Suite 510, San Francisco, CA 94104; PH (415) 621-4423; email: abillek@hce.com; [2]email: shalva@hce.com

Abstract

In this paper we present a comparative study of precast prestressed concrete façade panel analysis using single degree of freedom (SDOF) and finite element methodologies. LS-Dyna was used to develop the finite element formulation. The goal of the study is to identify simple, easy and economical analytical procedure to determine the reaction loads for the precast panels. This study was motivated by a real project, with the requirements dictated by UFC 4-010-01 *DoD Minimum Antiterrorism Standards for Buildings*. The reaction forces obtained from the two analysis methods are juxtaposed and the differences are discussed. This paper presents a summary of our findings, conclusions and recommendations.

Introduction

The following paper presents a case study of the evaluation of architectural precast prestressed concrete façade wall panels subjected to blast as designed for a three-story military office building. The goal of the study is to identify simple, easy and economical analytical procedure to determine the reaction loads for detailed connection design using different analysis methods. In this study we have compared the results of single degree of freedom analysis with the results obtained using nonlinear finite element methodology. Our study is based on a real project which was completed in 2010. This paper summarizes our findings and conclusions. The goal of the design project was to analyze and design the precast façade panels for a Low Level of Protection to comply with the UFC 4-010-01 requirements. Each precast panel, measuring approximately 50ft by 10ft, is comprised of both prestressed and non-prestressed concrete regions and blast resistant glazing. Our study assumed all panel designs were complete to conventional and extreme loadings (including air-blast)were complete and focuses on the differences in the reaction forces between the two methods of analysis. Figure 1 below shows a plan and elevation view of the building with the location of the elevation circled on plan and the typical panel shaded.

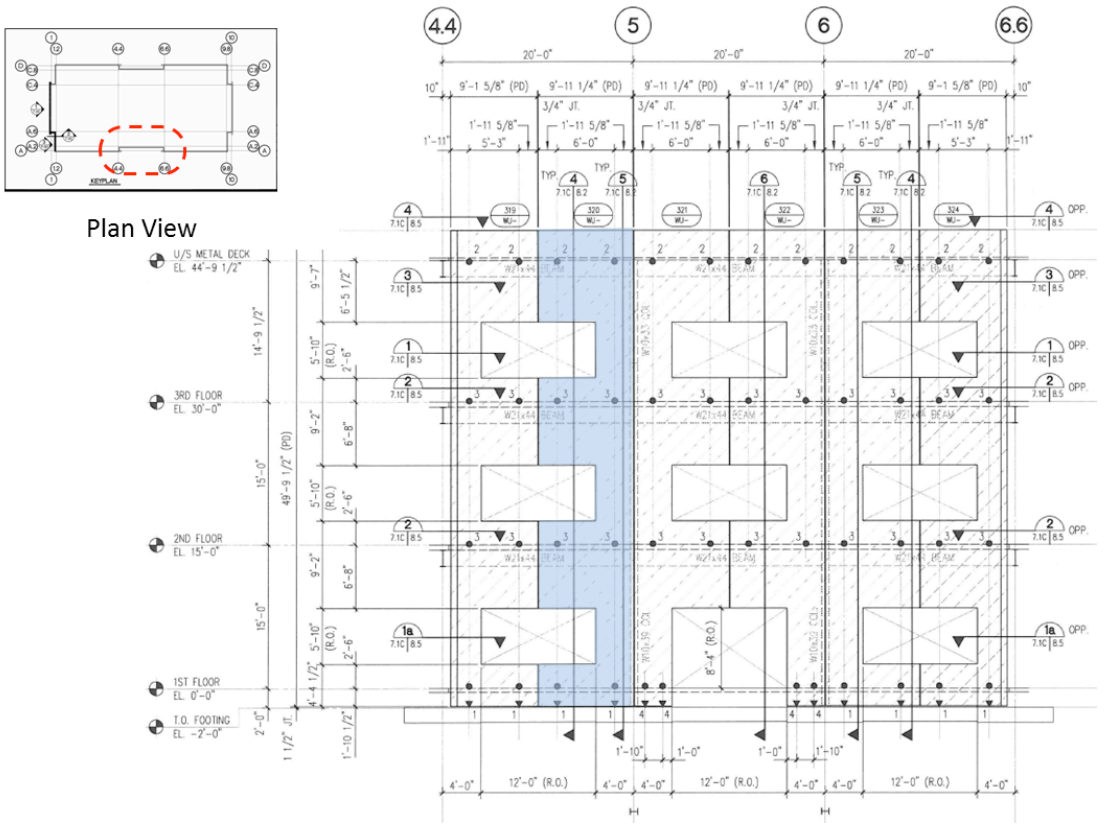

Figure 1 – Plan and Elevation View of Precast Prestressed Concrete Façade Panels

Overview of Study

The precast wall panels analyzed in this paper make up the façade of a three-story mixed-use military office building. The building, rectangular in plan, is three stories tall and clad with full-height precast prestressed concrete façade panels with fenestrations. Each panel, ranging in width from 9 to 13ft, is supported by eight lateral support points, two at each floor level. The gravity load was resisted by bearing at the ground level. The clear story height was 15ft with the exception of the roof slab which sloped for drainage. Without considering the specific connection details, there were three distinct panel types; panels without windows, panels with windows centered within the width and panels with windows adjacent to one edge of the panel

Although multiple panel types with different geometry and connection details were present, this paper will focus on what we consider to be the most complex panel type on the facade, the E-type panel, as shown in Figure 2 below. The E-type panel is primarily comprised of three different structural sections; prestressed reinforced concrete section along the height of the panel, mild reinforced concrete section between window fenestrations and blast resistant glazing at each story. The prestressed reinforced concrete section is composed of both (5) 1/2" oversized 270k prestressing strands and welded wire fabric (WWF) mild reinforcement both placed

at the mid-depth of the panel. The window spandrels account for the non-prestressed section of the façade and are reinforced with WWF at mid-depth. Between both reinforcement schemes, WWF is present at every cross-section along the panel height which provides continuous reinforcement throughout the panel. Lastly, the panel design assumes that all fenestrations will be fitted with blast resistant glazing capable of resisting the blast load without failure. The overall section depth for the panel is 8" but a ¾" reveal exists both vertically and horizontally such that the structural section depth was considered to be 7-¼".

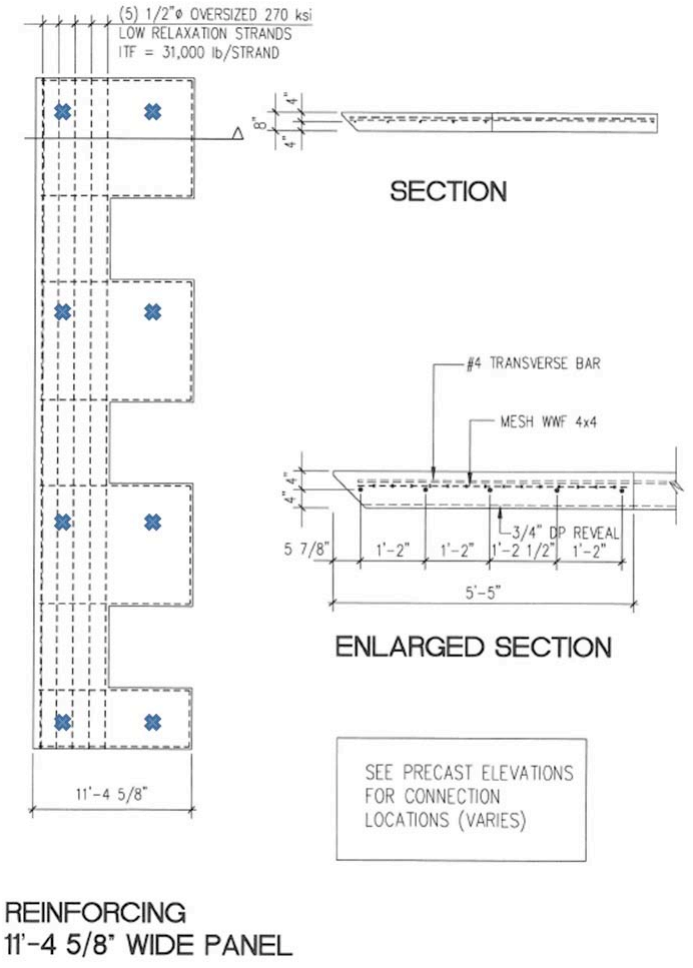

Figure 2 – Typical Prestressed Precast E-Type Panels

Because the building meets the required standoffs as stated by the UFC, there are two basic design threats to consider. The UFC requires that inhabited buildings which meet all conventional standoffs be designed for a W1 threat at a standoff of no greater than 148ft and a W2 threat no greater than 82ft. Based on threat and standoff location alone, it is not possible to predict which scenario will govern the design. We have completed analyses for both threats.

Approach

Based on the geometric complexity of the prestressed panels, our main concern was to determine an analysis procedure that would address both the material properties of prestressed concrete and the geometry of the façade panels. As we proceeded through the study, we experimented with multiple analysis methods to evaluate the performance of the panels. This case study will contrast the results obtained from the following two analyses:

- Single Degree of Freedom Analysis (SDOF)
- Finite Element Analysis using LS-DYNA

SDOF Analysis

The first analysis we used to develop the response quantities of interest was an SDOF system model. SDOF modeling is the most typical analysis methodology used in industry as it's the simplest solution technique available to obtain the nonlinear response of a dynamically loaded element. For single span elements and geometrically simple components, the SDOF solution can provide accurate results without requiring far reaching assumptions. However when using a SDOF procedure to model a complex component such as our façade panel, we will need to verify that our analysis assumptions develop a model which reflects the actual structure as closely as possible.

The continuous façade panel was divided into three independent SDOF models. Each model was assigned end restraints which matched the curvature of the deflected shape under a uniform lateral load. Therefore, the SDOF model corresponding to the first and third stories was analyzed as fix-pin and the second story façade model was analyzed as fix-fix. Solutions for these three systems can be obtained independently using the SDOF procedure (as highlighted by Biggs) and the overall results for the whole panel can be determined post-analysis. To determine the reaction forces, we can sum up the end forces from the three SDOF models and obtain the support reactions. Figure 3 below shows how a typical façade panel is divided into three SDOF analysis models.

In order to create any SDOF model, a load resistance path must be determined and quantified. Although our façade panel may seem to have one primary load path apparent, there are many different ways our support reactions can be loaded. Our SDOF model assumes the primary lateral load path between supports will be the continuous prestressed section which extends the full height of the panel (See Figure 2). Additional structural concrete present at the window spandrels is not account for in the SDOF resistance function but it is considered as additional mass in the system.

In order to determine the stiffness of the prestressed section, we followed the equations for prestressed concrete given by UFC 3-340-02, *Structures to Resist the Effects of Accidental Explosions*. Our SDOF model considered both the prestress and mild steel within the section when computing the moment capacity. Our resistance

function assumes elastic-perfectly plastic behavior at yield. Dynamic increase factors were considered for materials when appropriate to account for the increased strength due to high strain rate loading. For prestressing steel, a dynamic increase factor of 1 was used since prestressed steel is not expected to increase in strength at high strain rates.

We have used a number of different assumptions in order to model prestressed panels using the SDOF methodology. Without comparative analysis, it is difficult to determine how our assumptions will affect our response quantities of interest. It is important to remember that the SDOF method has reduced our complex load path, continuous beam structure into three simple, independent SDOF models. We will compare our SDOF analysis with the FEA methodology to determine the validity of our assumptions.

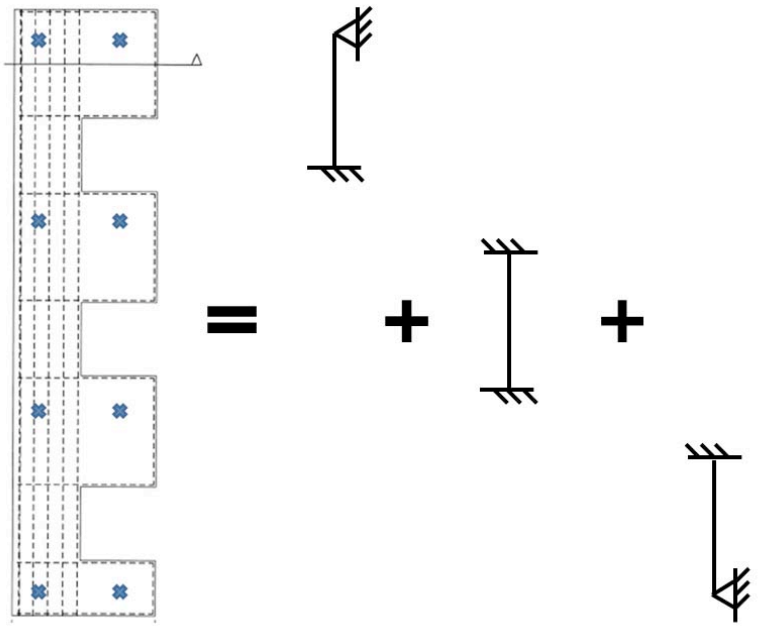

Figure 3 – SDOF System Model

SDOF Results

Figure 4 below shows the displacement time history response of each SDOF model and the reaction forces at each slab level. The reaction forces drawn on the façade panel are the total force to be resisted at the support level based on the aggregate reaction forces from the three independent SDOF models. Because the SDOF methodology lumped all the resistance to a single load path and assumed single end supports, it is unclear how to distribute the reaction loads to supports at the same slab level. A simple distribution of the reaction forces at particular slab level would be to

assume that each support takes half of the load. Depending on the level of accuracy required, this approach may be acceptable however it is clear from the geometry of the panel and the relative stiffness of all the structural elements present that the true force distribution is quite complex.

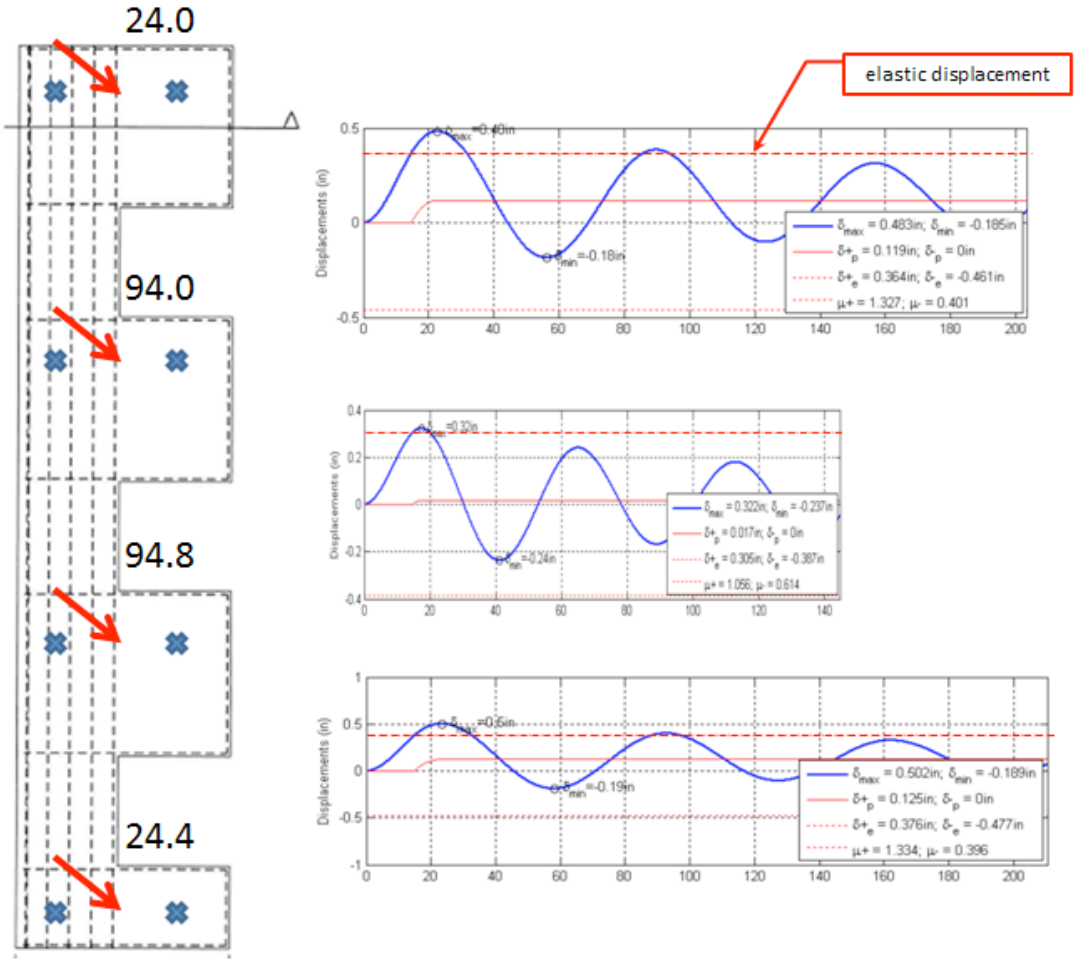

Figure 4 – SDOF Reaction Forces (units = kips)

Considering the displacement time history response plot for each SDOF model (see Figure 4), we can see that each model has yielded because the maximum displacement exceeds the elastic displacement, as indicated by the thick dotted lines on each

plot. The yielding of each SDOF model is significant to the development of the reaction forces. Because our SDOF model assumes elastic perfectly plastic behavior, yielding implies that the peak reaction forces are no longer governed by the dynamic response of the system but rather the equivalent static capacity. Therefore, although the reaction loads presented in Figure 4 were computed using a dynamic solution methodology, the same results could have been obtained by computing a static plastic hinge capacity calculation and accepting the maximum reaction.

Finite Element Analysis

To capture the effects of the precast panel geometry, we have developed a finite element model of the panel. A computer program, LS-DYNA was used to analyze the precast panel in question. Below is a list of our assumptions.

The façade was modeled using Belytschko-Tsay shell elements. Shell elements were assigned material type 103P, mat_anisotropic_plastic, and were used to model the concrete as elastic perfectly plastic. All plasticity parameters were based on the moment capacity equations of TM5-1300 (UFC 3-340-02) regarding prestressed concrete materials. By using this material type, our model is based on a "smeared" plasticity approach where the effort was made to capture the global nonlinear behavior of the section. To compute the yield stress for the material model, the moment capacity developed using UFC 3-340-02 was divided by the gross plastic modulus of the section.

Both the continuous prestressed concrete section and the non-prestressed concrete window spandrels were developed with different material properties using the same plasticity material. Nodes between both prestressed and non-prestressed sections were constrained with respect to displacement and rotation such that shear and moment forces can transfer through the panel.

Because the windows are expected to resist the blast loads without failure and are expected to distribute all blast loads over the entire duration, all window glazing was modeled as material type 101, mat_elastic, the elastic material type. Window glazing was connected to the façade panels at the window corners such that the nodal displacements were constrained and shear forces were transferred but relative rotation between the two materials was not captured.

LS-Dyna Results

Figure 5 below shows the peak reaction forces for our finite element analysis. The eight graphs plotted to the right of the façade model represent the reaction force time history at the eight lateral support points of the panel. The peak inbound reaction force is noted in black.

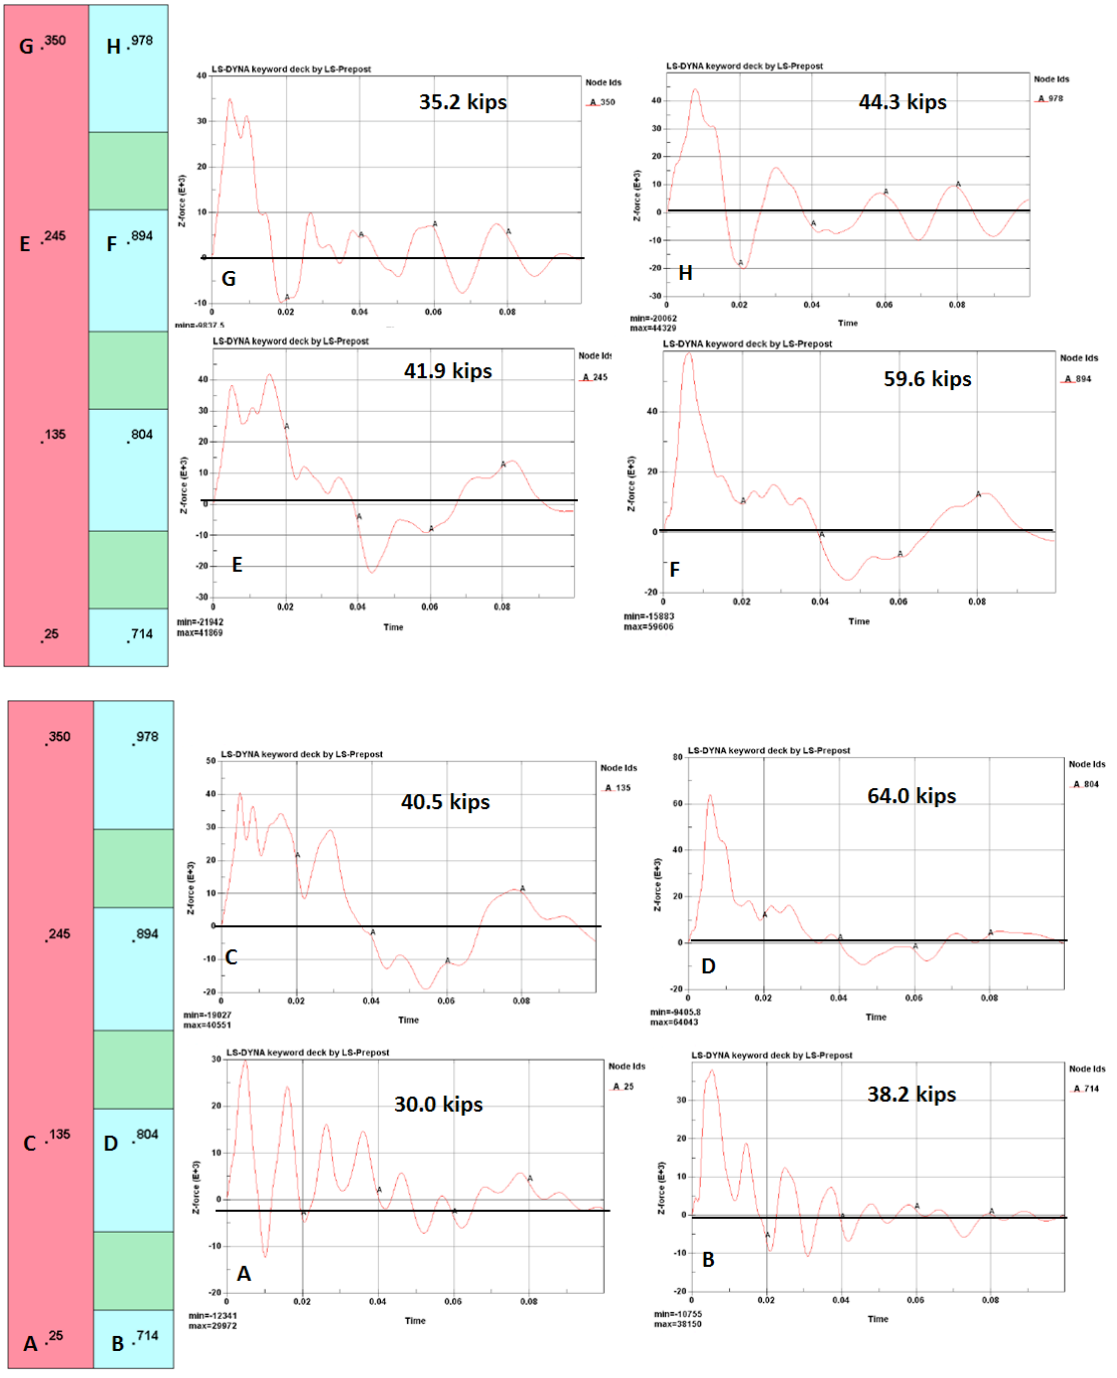

Figure 5 – LS-DYNA Reaction Force Time Histories.
Peak inbound reaction forces are noted.

Comparison of Analysis Results

Figure 6 below shows the reaction forces computed for both the SDOF and FEA methodology.

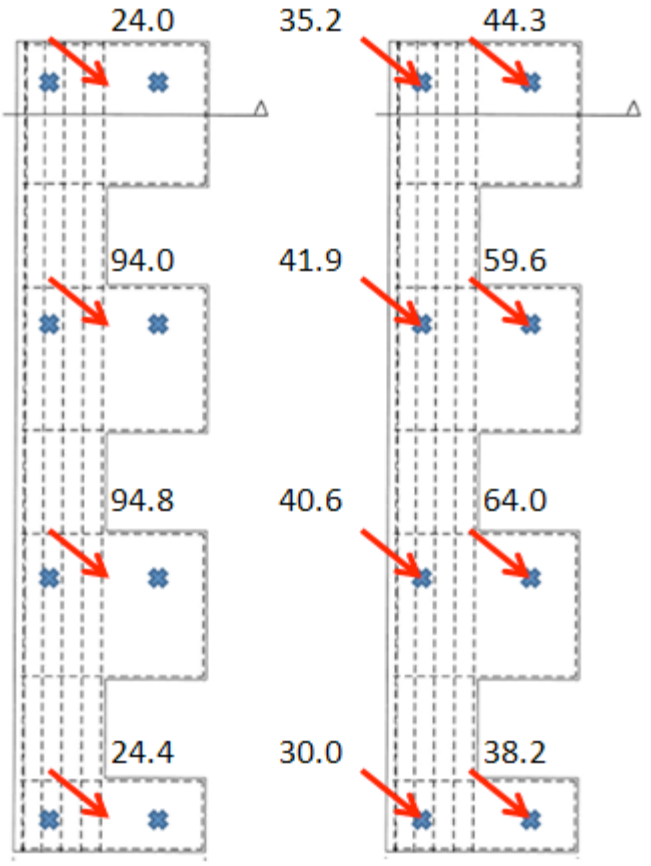

Figure 6 – SDOF (left) vs. FEA (left) peak inbound reaction forces (units = kips)

Side by Side comparison of the reaction forces developed using the SDOF method and the FEA method show that the reaction forces under FEA were larger than the SDOF results. Our results also show that FEA reaction forces were different for reaction connections at the same support level. Most interestingly, the FEA model shows that the inbound forces on the right side of the panel (where the fenestrations are) have the highest reaction forces, which are higher than the reaction forces for the left side prestress supports at the same level.

Conclusion

In this study we have used two methods of analysis for evaluation of the precast panels. The first analysis method used an SDOF system model which divided the façade panel into three SDOF models and aggregated the results to determine the

reaction forces. The SDOF analysis resulted in an equivalent static approximation of the support reaction forces that provided the total load at each slab level but not the distribution of force between individual supports. Our second analysis developed a FE model to verify and possibly improve our SDOF analysis results by accounting for the geometric complexities of the panel. Contrary to our original thought that SDOF analysis would yield conservative reactions, the FE model resulted in higher reaction forces by developing multiple horizontal and vertical load paths. These load paths are apparent in our results because the difference in magnitude of the reaction forces is considerable for each analysis methodology.

One possible explanation for the difference in the support reactions is due to the number of load paths available. The reactions developed using the SDOF model were based on the prestressed section properties assuming no other alternate load path was developed. In contrast, the FE analysis developed different reaction forces by allowing load carrying mechanisms to form organically thereby assuming no particular load path. Another explanation for the higher reaction forces can be attributed to the interaction effects between the different parts of the panel with various resistance and relative stiffness (see Figure 3), which are captured by the FE analysis but missed in SDOF.

Recommendations

Based on the limited study we have conducted during this project, the following recommendations are made:

1. Peak dynamic forces from FE analysis are larger than SDOF reactions. To obtain maximum reaction forces for panels with complex geometry, FE analysis of façade panels should be completed.
2. Peak dynamic forces in FE analysis are present for a short period of time and it may be overly conservative to design connections assuming peak reaction forces are static.
3. Currently there is no definitive approach to connection design to the effects of highly impulsive loading. Therefore a series of physical testing should be conducted to gain essential knowledge about connection behavior for very short duration loads.

ABSTRACT

This paper presents the results of testing and analytical developments sponsored by the U.S. Department of State to provide recommendations for support connection design of through-edge bolted laminated glass. Design equations are presented that capture the capacity of the through-bolted laminate material in reaction to in-plane membrane induced loading. A simple analytical treatment of edge-clamping and tear-out resistance forces is presented. Specific recommendations for bolt pre-load and gasket characteristics are presented. Test data are presented to support the validity of the calculations and recommendations. The various tests were executed by the Force Protection Branch of the Air Force Research Laboratory (AFRL) at Tyndall Air Force Base, Florida and Southern Research Institute in Birmingham, Alabama.

INTRODUCTION

The current research is a continuation of efforts to support developments of the U.S. Department of State focused on new and innovative ways to retrofit facilities for improved safety against physical threats resulting from blast, ballistic, and forced-entry attacks. Considerable effort has been directed toward evaluation and design recommendations for connecting laminated glass to framing members in window and curtain wall retrofit systems. Global failure of laminated glass subjected to high-energy, short-duration blast loading most often results from glass edge support failure. Edge support failure results from displacement induced loss of glass edge bite or insufficient in-plane membrane resistance at the glass-frame interface. The primary

objective of the present investigation is to develop detailed guidelines for the evaluation and design of through-bolted, edge supported laminated glass. Edge confirmations are sought that will fully utilize the strength and ductility of laminates in the post-cracked-glass phase of blast shock wave resistance. Simply said, the goal is that the connection not be the weak link in the global laminated glass response. This research involves static, high strain rate, and high load rate testing to support the development and validation of design equations and guidelines.

BACKGROUND

The current investigation as described in Duke et al. (2009) focuses on window retrofit systems wherein laminated glass is connected to framing systems using through-bolted edge connections. The retrofit systems currently under investigation may be subjected to extreme blast loading. Many of the systems are designed with allowance for very large displacements and rotations. Movement of the support and framing systems allows and sometimes induces glass edge conditions that are well outside the realm of classical blast window design. While the glass displacements and edge deformations are extremely high, the glass edge must be supported in a way such that the glass panels are restrained against free flight into the building. An example of one of the retrofit concepts is shown in Browning et al. (2009). The through-bolted connection shown in Figure 1 is a concept being pursued for supporting the laminated glass edge. A typical connection is made up of gasket material with pressure bars that press the gasket material against the glass. The bolts are preloaded against the pressure bar, causing gasket compression. The primary technical goal of the current investigation is to provide a connection design that will support the full capacity of the laminated glass panel. An architectural concern is the width of the connection and the associated interference with visual sight lines.

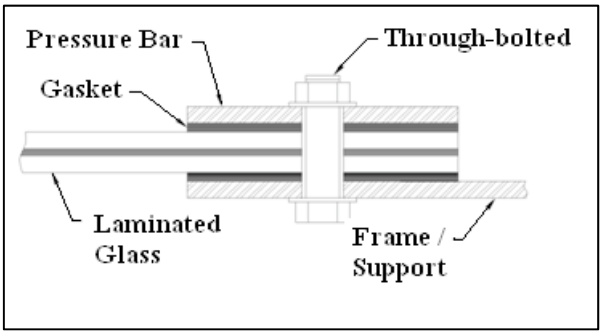

Figure 1. Typical through-bolted edge connection.

Glass panel and support frame displacements and deformations combine to yield both in-plane and bending loads along the edges of the laminated glass. As the edge of the glass is recessed between the support and the pressure bar (Figure 1), the impact of the through-holes on bending capacity of the glass edge at the connection is assumed to be small. However, the presence of holes at the through-bolted connection results in classical bolted connection tensile stress risers at and between the holes

when the laminated glass is subjected to in-plane loading. The stress risers can reduce the capacity of the connection to the point that full in-plane capacity of the laminate is not developed. Thus, while global evaluation of the glass is outside of the scope of the current investigation, the connection may become the weak link in the global response of the laminated glass.

Blast load induced glass panel and support displacements typically result in cracking throughout the glass layers early in the response of the system. The post-crack response of the laminated glass is primarily characterized by the laminate material with glass fragments remaining attached. A common assumption is that the post-crack behavior is dominated by laminate material acting as a membrane with the glass providing mass only. In terms of in-plane loading this may be a valid assumption. However, the post-cracked bending resistance of laminated glass is likely very different than that of a simple membrane. The membrane assumption is integral to one aspect of the current research in that it matches the effort to understand the capacity of the edge support relative to in-plane membrane loading. Thus, the current research is focused on characterizing the in-plane capacity of through-bolted edge supported laminated glass panels.

The discussion that follows summarizes previous results, reports new findings and describes planned efforts.

SUMMARY OF PREVIOUS RESULTS

Duke et al. (2009) presented test results aimed at characterizing the in-plane pull-out capacity of a common laminate material. The test setup is shown in Figure 2. Tests were conducted with variations in bolt spacing and edge distances. Failures at or between the bolts were observed that match classical bolted connection results for in-plane tensile loading. Shown in Figure 3 from left to right are classic V-notch failure, pure shear/pull-out, and hole-to-hole net area tension failure.

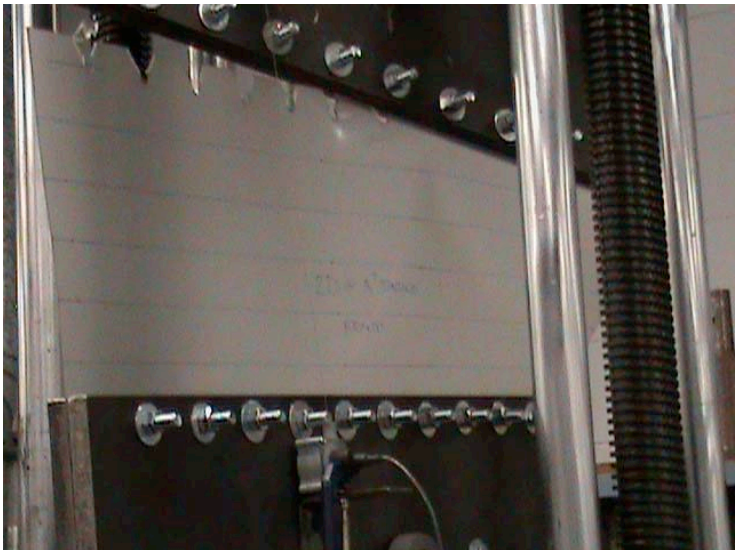

Figure 2. Static component level testing of laminate.

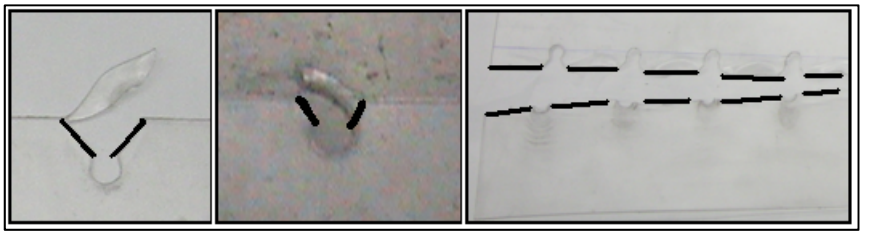

Figure 3. Laminate edge failure mechanisms.

Simple equations based on classical mechanics were developed to predict the edge capacity of the laminate material. Figure 4 shows the key geometric parameters used to evaluate the edge capacity. As seen above, failure is either V-notch / tear-out at the bolts or net area tension failure between the bolts. The V-notch / tear-out resistance is predicted by Equation 1

$$R_n = \frac{2\left(e - \frac{d}{4}\right)tF_u Tan\theta}{s} \qquad \text{Eq. 1}$$

where Rn has units of force per unit length, t is the laminate thickness, Fu is the ultimate tensile strength of the laminate, and s is the center-to-center bolt spacing dimension. The bolt-to-bolt net area tension failure capacity is calculated from

$$R_n = \frac{(s-d)tF_u}{s} \qquad \text{Eq. 2}$$

The (s - d) term in Equation 2 is the net distance between the bolt holes. The minimum value from Equations 1 and 2 is taken as the capacity of the laminate.

Test results confirm that the capacity prediction shown above provides reasonable and conservative values for the edge capacity of the laminate material. Additional tests have been performed that were aimed at capturing other key aspects of through-edge bolted connections. Specifically, a series of drop hammer tests was conducted where various make-ups of laminated glass panels were supported by a rigid frame and subjected to impact loading. The results supported the predictions represented by Equations 1 and 2 above. There were also clear indications that a more fundamental understanding of the connection characteristics would serve to clarify interpretation of the drop hammer results. Thus, a series of tests described below was executed.

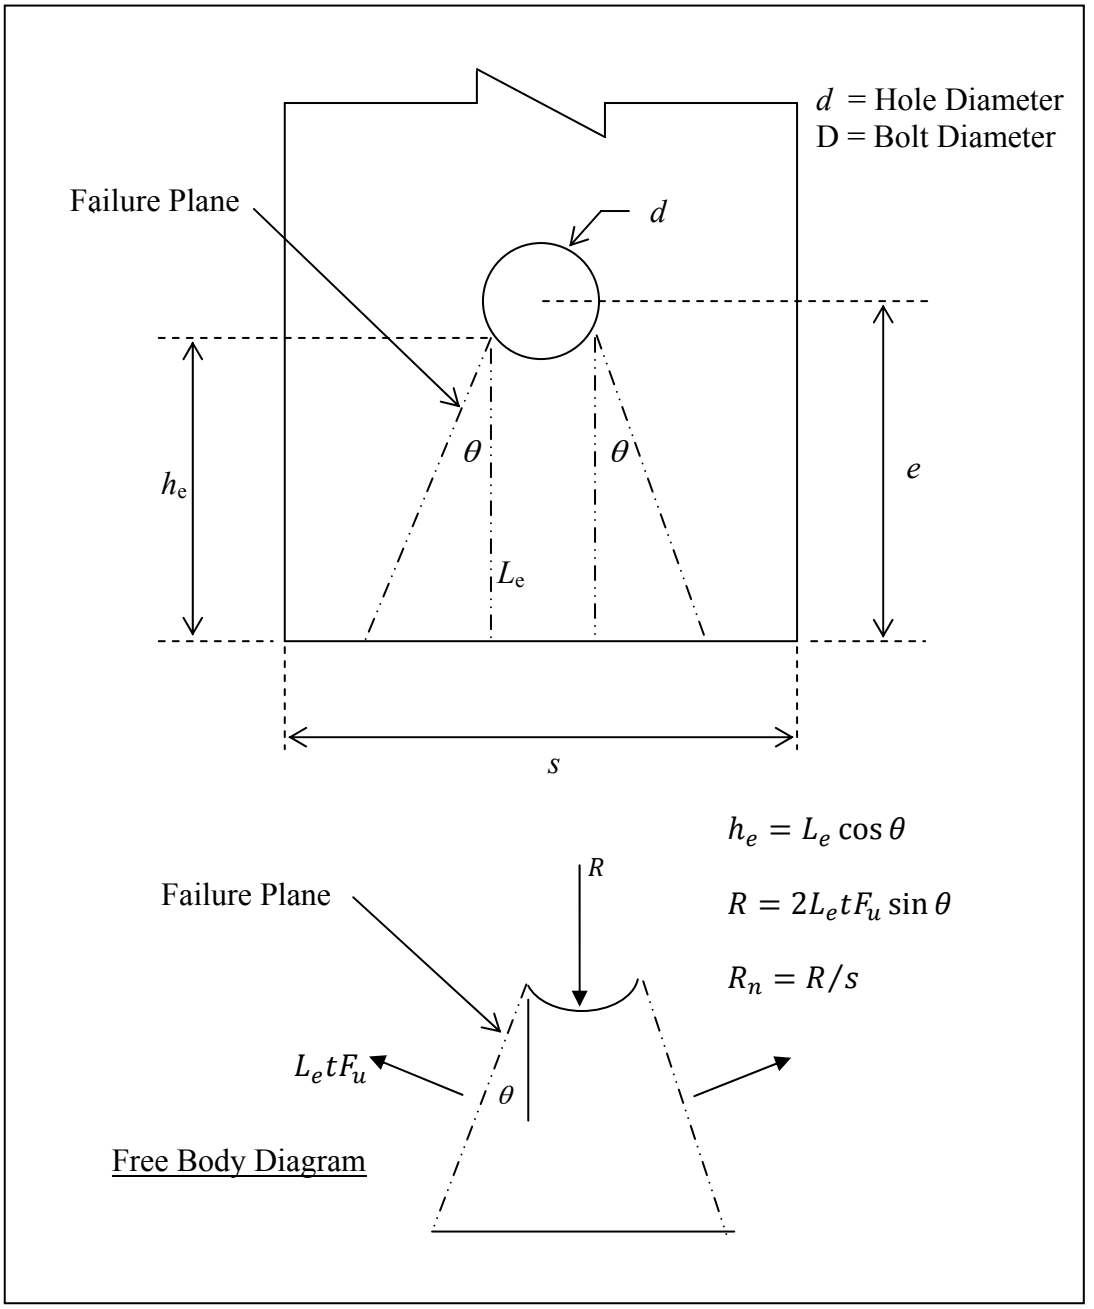

Figure 4. Classical solution parameters.

PULL-OUT TESTS

In-plane pull-out resistance for the inner layer (laminate) of through-edge bolted laminated glass is presented above. Further testing was conducted at AFRL to help clarify some of the results from previous tests. While a fundamental part of edge pull-out resistance is characterized by the laminate capacity, other factors contribute to edge capacity. Those factors include shear forces between the glass and the gaskets in the form of either simple friction or cracked glass "digging" into the gasket material. The shear forces between the gasket and cracked glass is considered as an effective friction. A second factor relates to the added strength resulting from glass remaining attached to the laminate in a post-cracked configuration. The test setup in Figure 5 was designed to help capture the effects of some of the factors described above. In the test setup laminated glass is held between fixture plates and gaskets with through-bolts. For the current set of tests the bolt spacing and edge distance were held constant. Load cells were used in some of the tests to capture bolt pre-tension so that bolt preload and bolt torque could be correlated. Very large edge distances were used at the upper edge of the glass specimens so that edge failure would be predictably seen at the bottom edge. As part of the core investigation, the bolted connection at the bottom has either through-holes in the laminated glass panel or the glass panel was slotted from the center of the bolt hole locations to the bottom glass edge as shown in Figure 6.

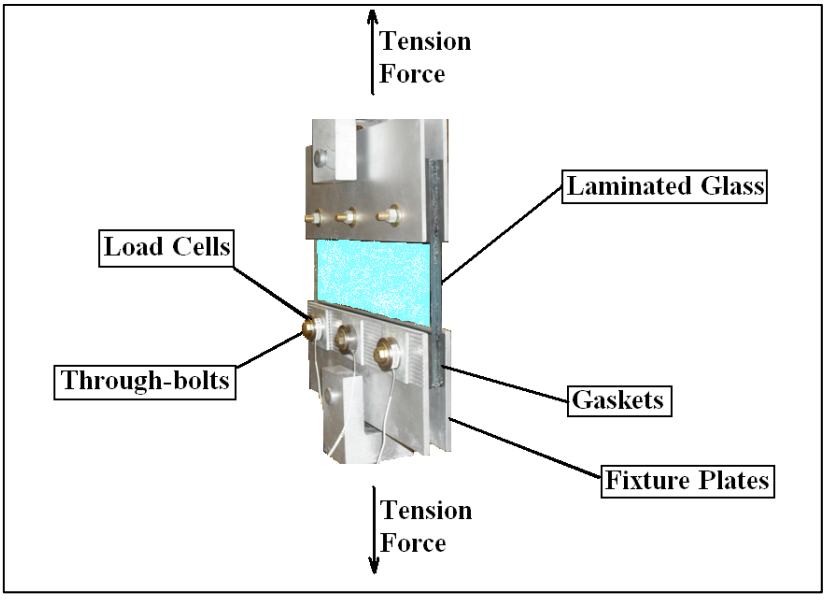

Figure 5. Pull test setup.

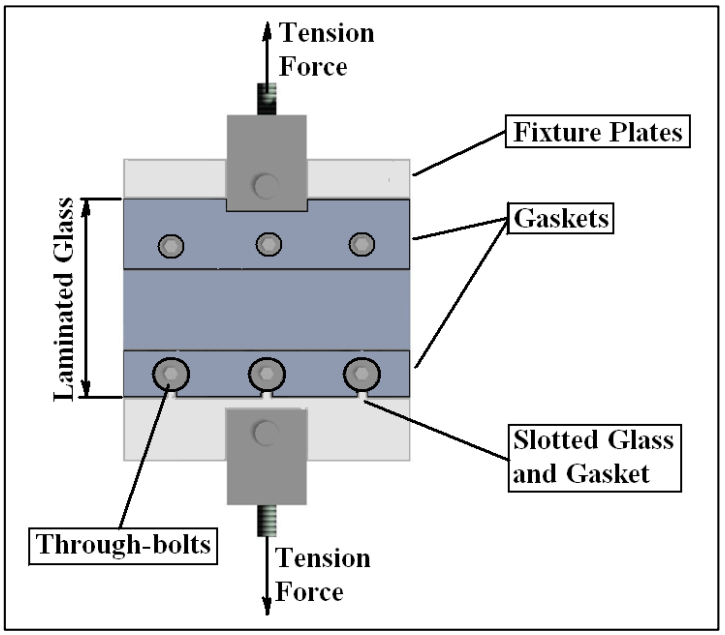

Figure 6. Slotted glass setup.

Bolt preload.

A practical issue associated with bolted connections where tension preload is important is how to assure that the bolts are installed with the proper range of preload. In classical structural applications various methods are available to control preload including the turn-of-the nut method and load indicator washers. In the window and glass curtain wall industry bolt torque measurement is often the preferred method. All of the methods have advantages and disadvantages under the best of conditions. In the current research where gasket material and laminated glass are in the stack of bolted layers, there are additional concerns over proper bolt preload. In an effort to quantify bolt preloads in this context, bolt tension forces were measured using load cells. Corresponding bolt torques were also measured. Figure 7 shows a plot of preload versus torque. A semi-empirical formula that is widely used to estimate bolt torque versus preload is $T=0.2FD$ where T (in-lb) is torque, F (lbf) is preload bolt tension and D (in) is the bolt diameter. The data in Figure 7 provides reasonable correlation with the classical formula and thereby supports the notion of using the formula to estimate compressive forces in the gasket.

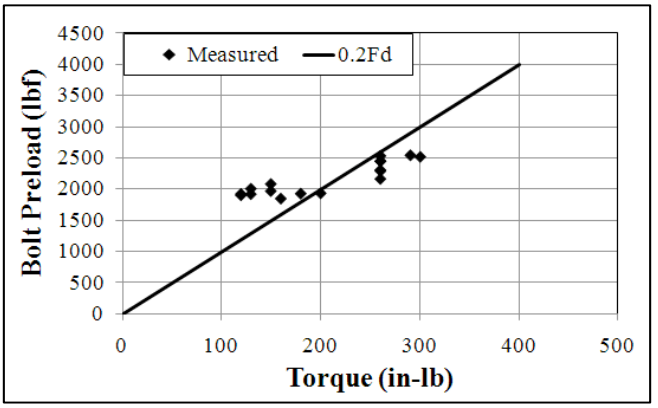

Figure 7. Bolt preload versus torque.

Effective friction.

More testing is planned to characterize the segmented strengthening effect of fragments of glass remaining attached to the laminate in a post-cracked configuration. However, the primary focus of this discussion relates to the effective friction associated with the interaction between the glass and the gasket material. As indicated above several test specimens were used that have slotted holes at the edge. The goal for this portion of the test was to quantify the effective friction versus clamping force (bolt preload) for smooth and cracked glass. The slots allow pullout without engagement between the bolts and the inside edge of the bolt holes. That is, the goal is to obtain friction only with the understanding that the structural capacity of the laminate inner layer is quantified using Equations 1 and 2 above.

Pull-out tests were conducted using the setup shown in Figures 5 and 6 above. Table 1 lists the geometrical characteristics of the specimens. The bolts at the bottom (slotted) edge were pre-loaded using torque values (or in some cases load-cell measurements in conjunction with torque values as in Figure 7 above). The pull-out tension force was measured for each specimen. Table 2 summarizes those results for the slotted specimens. Note that in all but one case the glass layers cracked early in the loading. This is likely due to the bolts bearing on inside edge of the holes near the top edge of the glass. In the one case where the glass did not crack, the effective friction force corresponds to the case of smooth glass on gasket material. Using the classical preload estimate from 0.2FD the effective preload force is calculated to be 4200 lbf. Given two surfaces of contact, the effective coulomb friction value is 0.3. While one data point should not be considered statistically defensible, it is worth noting that 0.3 is considerably lower than values in the literature for similar materials.

Figure 8 provides a plot of the pull-out force versus the average bolt torque. A plot of effective friction versus gasket compression force (bolt pre-load) would yield a plot with a similar shape. An immediate point to take from the shape of the curve is the fact that the linear curve fit does not pass through zero force at zero torque. The fact that at least some preload is present and the glass is cracked combine to yield a

gasket to cracked glass interface that is far different than that of simple coulomb friction. The digging in effect clearly contributes to the complexity of the problem of predicting edge capacity. Observations made during the test indicate that the cracked glass does not simply slide on the gasket. There is actually surface shaving and cutting of the gasket by the glass at the crack locations. It is suggested that in the presence of gasket compression forces, the cracked glass edges function much like teeth that dig into the gasket.

A second point to take from Figure 8 is that an increase in torque correlates to an increase in pull-out force, there is not a one-to-one relationship. Approximately 80 percent of the maximum pullout resistance was developed with 500 in-lb torque as compared with 1500 in-lb. In addition, there is concern over the sensitivity of laminated glass to cracking during the installation and bolt pre-loading process. These points suggest that there is a practical limit to value of increasing torque to increase pullout resistance.

Laminated glass make-up	0.25 in. Heat Strengthened 0.18 in DuPont SentryGard 0.25 in. Heat Strengthened
Overall dimensions	18 in. wide, ~12 in. high
Bolt size	0.5 in.
Bolt spacing	6.0 in.
Edge distance	1.5 in. (3d)
Gasket material	EPDM, Durometer 60, Shore A
Gasket width	3.0 in.

Table 1. Specimen characteristics.

Example.

Practical application of the results from Figure 8 involves obtaining an effective friction value based on torque. Bolt pre-load values may be summed to obtain to gasket compression force. The effective friction value is used with the pullout force to obtain an effective coefficient of friction. In an effort to generalize the results, it may be useful to convert the forces to forces per unit area. An example corresponding to an average bolt torque of 600 in-lb from Figure 8 is summarized in Table 3 below. For the example in Table 3 the shear force per area is calculated to be 78.1 psi. The range of values for all the cracked slotted glass is 52.1 to 97.6 psi.

Bolt Torque1	Bolt Torque2	Bolt Torque3	Average Torque (in-lb)	Pull-out (lbf)	Glass not cracked
180	120	120	140	2572	X
130	130	200	153	5542	
160	150	150	153	6202	
260	260	260	260	8777	
260	260	260	260	7399	
300	290	260	283	7944	
192	192	312	232	8143	
240	348	360	316	6203	
240	396	432	356	5332

1390	1494	1330	1405	10580	
1440	1480	1546	1489	9970	
1480	1480	1480	1480	8755	

Table 2. Pull-out force versus torque.

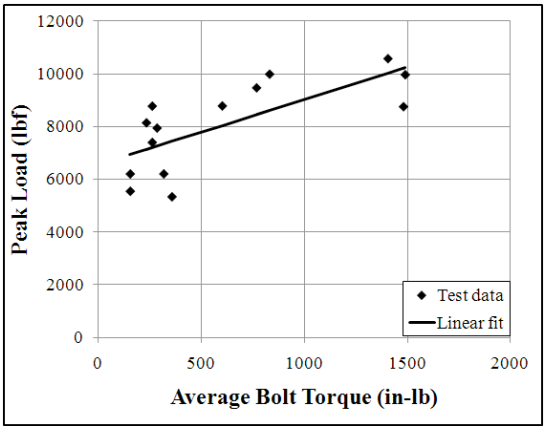

Figure 8. Pull-out force versus torque - slotted edge.

Torque (in-lb)	600
Pull-out force (lbf)	8000
Bolt pre-load (lbf from 0.2Fd)	6000
Gasket compression force (lbf)	18000
Effective friction coefficient	.222
Net gasket area (in^2)	51.2
Shear force per area (psi)	78.1
Compression force per area (psi)	352

Table 3. Pull-out force versus torque.

Application of the values in the previous paragraph along with the predictions from Equations 1 and 2 results in an estimate of edge capacity based on in-plane resistance of the laminate plus effective friction associated with cracked glass interaction with compressed gasket material. Using the test specimen bolt hole size, bolt spacing and edge distance as an example, the edge capacity calculated from Equations 1 and 2 yields a laminate edge capacity of 150 lb/in (Fu = 4000 psi, θ = 25º, d = 0.625 in). Using the values from Table 3 the effective friction force is 444 lb/in. The sum capacity is 594 lb/in. A basic goal of the current development is that the edge pull-out capacity be large enough to develop the full strength of the inner layer acting as a membrane. For this example the membrane strength is calculated as 720 lb/in. The 594 lb/in value obtained here falls short of the membrane strength of the laminate by 17.5 percent.

OBSERVATIONS AND RECOMMENDATIONS

Note that while the capacity obtained in the example above falls short of the goal capacity, there are some additional points that should be highlighted.

1. The pull-out resistance obtained here is under ideal in-plane loading. In reality, while the edge loading may be dominated by pull-out, there is generally a component of bending or shear at the edge of the glass near the support. The localized interaction between the glass and gasket material and the associated digging in effect is very likely more severe than indicated by the pull-out test results presented above. Moving forward, the results of this investigation will be used along with the drop hammer test data referred to above to help quantify the full effect of connection racking, and high strain rate effects.
2. Until further test results are obtained and reduced it is suggested that the results from Equations 1 and 2 are suitable for use with a simple adjustment for strain rate effects.
3. Given specific cases involving materials and conditions listed above, the data in Figure 8 is suitable for use in design conditions.
4. Application of the test results presented above to other glass types must be executed with caution. Heat strengthened glass crack patterns are typically

random in shape but somewhat uniformly distributed and spaced at less than one inch apart. The crack patterns for annealed glass are such that there may be relatively large areas of un-cracked glass. The possible absence of cracks at the gasket interface could reduce the digging in effect thus minimizing the effective friction. Alternatively, fully tempered glass most often exhibits crack spacing that is smaller than heat strengthened glass of the same thickness. Given that point, the effective friction is anticipated to be higher for fully tempered glass.

5. Pressure between cracked glass and the gasket material induces a digging in effect. Bolt pre-load is used to compress the gasket material. There is concern over relaxation (compression set) of the gasket material that may serve to diminish the pressure with time. Investigation and / or testing to clarify this issue should follow.

SUMMARY AND CONCLUSIONS

Results of various analytical and experimental efforts have been presented that address pull-out resistance of through-edge bolted laminated glass. Specific design recommendations have been provided along with suggestions for further testing

ABSTRACT

The Federal government mandates blast protection for all of its facilities, which can be particularly challenging for existing buildings, especially those of historic interest. The blast protection of historic façades is one of the most challenging aspects since historic window structures offer little blast resistance and it is critical to preserve the existing aesthetic. As a solution to this issue, Hinman Consulting Engineers, Inc. (Hinman) investigated the potential application of a window cable catchment system as a means of cost-effective blast protection.

This paper discusses the unique design features and analytical modeling of the cable system on exterior windows to resist potential external blast threats. The cable catchment system consists of steel cables installed behind glass panes and anchored into the structural system above and below each window. A three-dimensional finite element (FE) model was developed to investigate the performance of the window catchment system. This analytical model was then validated by the results of shock tube tests sponsored by the General Services Administration (GSA). Finally, the key parameters of interest in the performance of different cable system configurations including the interaction between cables and glass panels, details of the system configuration, and the reliability of the system are outlined. The results of this study show that the cable systems demonstrate considerable potential to provide efficient blast protection for existing window systems.

INTRODUCTION

Windows are an important aesthetic consideration for historic buildings and their blast mitigation presents both challenges and the opportunity to apply innovative mitigation technologies. Other than providing sufficient blast protection, low cost and feasibility are the other major objectives of the blast engineer in the design of mitigating solutions. However, in addition to historic and blast considerations, there are often other design objectives that must be integrated in to the design solution, for example, energy performance, daylighting, and window operability. These are project specific and provide additional challenges for developing an appropriate mitigation system.

WINDOW MITIGATION OPTIONS FOR BLAST PROTECTION

In general, window replacement and window retaining/retrofit are the two major mitigation approaches for upgrading existing historical windows to provide the required blast protection level. *Window replacement* requires the replacement of the entire window system, which may have a significant impact on the appearance and authenticity of the historic building. The argument for replacing existing windows is usually based on the energy efficiency and replacement of deteriorating window materials. However, replacement of the entire window of a historic building may not be cost effective due to historic replication workmanship requirements and the likely requirement for supporting structure strengthening. Accordingly, this mitigation approach is generally not a desirable upgrade option for historic buildings.

Applicable *window retaining and retrofit* approaches may consist of the following: (1) Application of anti-shatter security films, (2) Secondary interior window installment, (3) Glazing replacement, and (4) Catchment or debris mitigating systems.

(1) Application of anti-shatter security film is one of the most common methods of upgrading existing windows for blast mitigation. The easiest and fastest way of applying anti-shatter film is to use day-light film, which bonds directly to the glass without any attachment to the mullions or window frame. Wet-glazed film or high-strength anchored film are other means of anti-shatter film applications; wet-glazed film requires removal of the pane from its frame for installation (resulting in more labor cost); anchored film can be problematic with operable windows and transfers load in to the framing elements, which will likely necessitate strengthening of the supporting frame. While anti-shatter film does hold glass fragments together, it also fails as a single pane, which could result in more serious occupant injuries (Bogosian and Avanessian, 2002).

(2) Providing a secondary interior window (*i.e.,* storm window) behind the existing is another common retrofit option for historic windows, because it does not require strengthening of existing mullions and window frame. However, most systems are not operable, which limits natural ventilation opportunities and can lead to maintenance issues. In addition, a secondary window will impart significant anchorage forces on the existing supporting structure, which will need to be evaluated. This system will provide a higher level of protection than window film only and is relatively easy to install, however the upfront cost is likely to be higher. In addition, the interior aesthetic will be significantly affected by this addition.

(3) Replacement of the existing glazing is another retrofit solution when the mullions, window frame, and structural members have adequate capacity to resist the loads transferred from the new glass. For historic windows, this option is usually not preferable as a standalone solution due to its high installment and labor cost and lack of measurements for the load bearing capacity of existing window elements at in-situ conditions.

(4) Catchment or debris-mitigating systems consist of the application of advanced systems such as blast curtains, shades, blinds, and cable catchment systems. Blast curtains, shades, and blinds sufficiently increase the blast protection level when they are used in conjunction with anti-shatter film application or laminated glass replacement. One serious shortcoming of these upgrade solutions is that they are intended to remain secured or shut at all times to be effective, limiting access to the operable windows. Additionally, they may significantly impact the aesthetics and reduce the energy efficiency of the building by degrading the amount of light that can pass through the window. Another solution, the installment of cable catchment systems behind the existing windows in conjunction with window film or glass replacement, catches and limits glass debris from entering protected areas. In combination with energy absorbing spring anchorage systems they can limit the load transferred in to the existing structure and are easy to install and cost efficient. They also allow access to open windows and are relatively unobtrusive from an aesthetic perspective.

The cable catchment system is discussed in detail in the following sections with its recent application to two historic building modernization projects. Additional information on the other window retrofit options is provided in Lin *et al*. (2004), GSA's Technical Preservation Guideline on Upgrading Historic Building Windows (Alderson, 2009).

DESCRIPTION OF CABLE CATCHMENT SYSTEMS

The presented cable catchment system was developed by Glasslock Inc. and is composed of three major components: (1) High-strength cables, (2) Aluminum track; and (3) Patented spring system and is shown in Figure 1. Rather than strengthening the façade, this system is expected to provide the level of protection required for the building by capturing the glass (which is preferably filmed or laminated) exiting the window frame during a blast event, while at the same time maintaining the historic sashes, keeping the window operable, and minimizing reaction forces on the existing structure. Because of their ease of installation and low maintenance requirements, these systems are cost-effective systems to achieve blast protection in renovation projects with budget restrictions, the desire for operable windows, and the concern of historic preservation.

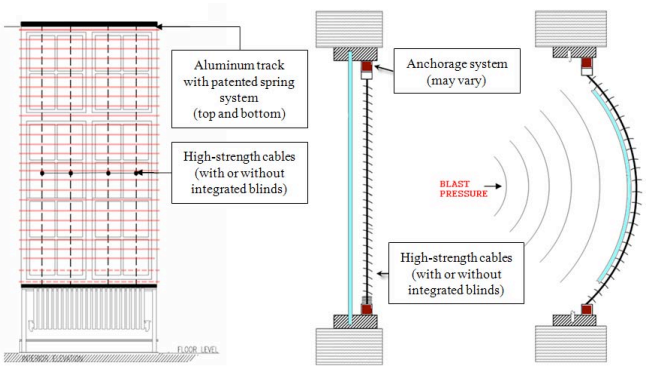

Figure 1. Illustration of Cable Catchment System

PROJECT APPLICATIONS

The cable catchment system has been used on several commercial buildings and the blast protection it provides has been recognized for large pane systems (Crawford, Lan et al., 2006). Hinman has investigated the application of this system on a couple of recent Federal historic renovation projects.

The presented renovation projects, *Project 1* and *Project 2*, involve the retrofit of existing operable wood frame windows to meet a medium level of protection under a 4 psi and 28 psi-ms blast load as defined in the *ISC Security Design Criteria for New Federal Office Buildings and Major Modernization Projects* (ISC, 2004). The following criteria contributed to the decision to opt for a cable catchment solution:

(1) Operability: Having minimum number of cables for the ease of window operation by the building occupants

(2) Blast protection and energy requirements: Meeting the intended blast design criteria and energy efficiency performance requirements

(3) Budget restrictions: Avoiding labor intensive installment and anchorage details

(4) Minimize aesthetic impact and retain historic character

For *Project 1,* it was decided to retain the existing window frames, sashes, and muntins but to upgrade the existing glass to a 1/4-inch laminated glass with 0.030-inch PVB (Polyvinyl butyral) interlayer that is more durable and provides more energy efficiency than the existing 1/4-inch monolithic glass. Although replacement of glass costs more than the secure daylight film application, laminated glass does not need maintenance, so there are minimal life-cycle costs compared to a daylight film application. *Project 2*, has a target for lead Platinum, so the glass needed to be upgraded to an IGU to meet for energy performance requirements. Due to deterioration of the existing sash and the fact that the sash needs to be re-profiled to accommodate an IGU, it was more cost effective to replace the existing sash and glass together. To keep the IGU thickness to a minimum, the preferred glass layup was 1/8-inch tempered glass pane, ¼-inch air gap, and a ¼-inch laminated glass with 30-mil PVB interlayer, however, a thicker glass layup comprising double ¼-inch laminated glass panes (with 30-mil PVB interlayer) separated with 1/4-inch air gap was also considered as a replacement option due to concerns regarding the unpredictable nature of the tempered glass fragmentation.

As the cable catchment system is a newly-developed system and its design depends on the project specific conditions, a blast design approach, analytical procedures, as well as physical testing program had to be developed to validate its performance for their proposed applications.

First, Hinman developed numerical models using the nonlinear dynamic simulation software LS-DYNA version 971 (Livermore Software Technology Corporation, 2007) to simulate the behavior of the cable catchment systems. Next, a series of shock-tube explosive tests of the cable catchment system were conducted at the testing facility of Baker Engineering and Risk Consultants, Inc. in San Antonio, Texas. The objective of the testing program was to validate the performance of the system to meet the design requirements defined in "*ISC Security Design Criteria for*

New Federal Office Buildings and Major Modernization Projects" (ISC, 2004). These tests consisted of several full-scale window system configurations with or without integrated blinds. Following the tests, the FE models were refined and validated using the physical explosive test data.

PRELIMINARY FINITE ELEMENT ANALYSIS

Details of FE Model

To investigate the feasibility of the proposed cable catchment system manufactured by Glasslock Inc. for the selected two renovation projects, *Project 1* and *Project 2*, preliminary FE analysis was performed. The finite element model consisted of the glass, cables, and springs. The wooden window frame and sashes were not included in the model as the mechanical behavior and failure mode of wood are strongly dependent on the wood material properties, aging conditions, and moisture content, which are difficult to model accurately with FE analysis. Since it was expected that the wood frame and putty would be weaker than the glass and would not restrain the glass in reality, it was predicted that excluding it from the model would not affect the results. Aluminum channels housing the springs at the head and sill were also not included in the model, therefore, any energy absorption through plastic deformation was neglected for a conservative approach. Additionally, the spring ends were modeled with fixed connections to the supporting structure, assuming that the connections would have higher capacity than the catchment system.

The initial FE models developed based on the GlassLock catchment system proposed for the glazing blast retrofit of *Project 1* and *Project 2* are shown in Figure 2 and Figure 3 and in Figure 4 and Figure 5, respectively. Window glazing layups and vision openings of each glass lite are summarized in Table 2 and Table 3. Due to aesthetic and operability considerations for *Project 1*, only one cable per pane was desired even though this was unlikely to be effective. It was anticipated that non-uniform blast loading and aerodynamic effects would cause the glass panes to rotate around the cables in reality. Due to energy and historic considerations for *Project 2*, an IGU unit was desired with a tempered outer layer, so there were concerns regarding the tempered fragments entering the protected space. However, tempered glass (*i.e.,* outer pane of the IGU) was not included in the FE models, since tempered glass fragmentation could not be captured in the FE analysis.

In LS-DYNA, MAT_LAMINATED_GLASS (Material#32) was employed to model laminated glass with a PVB interlayer. This material model allows different material properties for the glass and PVB materials. When the force in the glass layer reaches the yield limit, the glass fails and the PVB remains as the element contacting the cable and resisting the blast load. The cables (7x19 pre-formed stainless steel aircraft cable with a reported 1760 lbs breaking strength) were modeled with MAT_PLASTIC_KINEMATIC (Material#3). This material model includes the yielding and plastic hardening of cable elements. MAT_SPRING_ELASTIC (Material#S1) was employed to model the springs, which remain elastic throughout the simulation. For accurate analysis, mesh studies involving shell and beam elements were performed through uniform mesh refinement. A robust and computationally

efficient automated contact algorithm between the cables and the glazing was also included in the model. The material properties used for the components of the cable catchment system are listed in Table 3. Detailed information about the material models used can be found in the LS-DYNA Keyword User's Manual (Livermore Software Technology Corporation, 2007).

Results of Preliminary Finite Element Analysis for Project 1:

Results from the preliminary FE parametric studies showed that 1/4-inch laminated annealed glass with 0.030-inch PVB retrofitted with single 1/8-inch stainless steel cables was predicted to perform to a GSA Condition 3b for 4 psi and 28 psi-ms dynamic blast loading. The maximum predicted tension reached by the cable was 1724 lbs, which is less than the reported capacity of 1760 lbs. The maximum inward cable deflection was predicted to be 31 inches. Given the desire and space for only a single cable per pane and the concern that uneven loading or aerodynamic instability effects would have on the pane angle, simulations that considered the angle of impact effects were performed for the system. These simulations showed that the cables were not capable of catching the 1-degree rotated glass panels that were propelled inwards by the blast load, because the panes rotated around and slipped through the cables. It was, therefore, predicted that integrated blast blinds would be required for the window retrofit of *Project 1*.

Results of Preliminary Finite Element Analysis for Project 2:

The preliminary FE analysis showed that the following systems were predicted to perform to a GSA Condition 3b for 4 psi and 28 psi-ms dynamic blast loading: (1) System with double ¼" laminated glass and three cables across each pane, and (2) System with tempered IGU and three cables across each pane (assuming tempered glass was contained). FE simulations of these two systems indicated that the maximum tension force reached by the cable was within the axial force capacity of the cable. For both of the systems, the maximum inward cable deflection was predicted to be less than 25 inches. The system with double laminated glass predicted a lower tensile cable force than the tempered IGU which was attributed to the increased period of the system due to the additional mass of the glass. The FE simulations demonstrated that the inner glass pane of the tempered IGU was not significantly wrapping around the cables, which was expected to result in small openings for the fragments of the outer tempered glass pane to enter inward and land on the floor. Therefore, physical testing

of the system with tempered IGU was required due to its unpredictable fragmentation progress and cable response. Based on the promising results of the double laminated glass and three cables across each pane, additional FE simulations were run for a two cable system as a backup and it was predicted that that the cable forces were slightly exceeding the allowable limits. These results indicated that a double laminated glass layup with three cables would be required for the window retrofit of *Project 2*.

FULL-SCALE TESTING PROGRAM

There were three primary objectives of the testing program as follows:

(1) Evaluate the performance of the cable catchment system (whether they meet the GSA Performance Condition 3b for a 4 psi and 28 psi-ms blast load)

(2) Establish the failure limit-states for the system

(3) Validate the FE model against the test data for system performance

Hinman developed the test plans for each project based on the results of the preliminary FE analysis to achieve the above objectives. For each project, the testing program consisted of eight-shock tube tests that were conducted in accordance with the "*Standard Test Method of Windows and Glazing Systems Subject to Dynamic Overpressure Loadings*" dated January 1, 2003 (U.S. General Service Administration, 2003).

The window system specimen that represents the typical triple-hung wood-framed operable historic windows of *Project 1* and the typical double-hung poplar wood-framed operable historic windows of *Project 2* are shown in Figure 6 and Figure 7, respectively. For each project, eight identical specimens were built and during each test, one specimen was mounted in an enclosed steel reaction structure with the cable catchment system configuration to be tested. For *Project 1*, the preferred system with one cable per pane was tested first and then the backup systems with blinds followed, whereas for *Project 2,* the preferred tempered system with three-cables was tested first and then the double laminated systems followed.

It is important to note that since it was not possible to place a load cell on the cable, dynamic load cells were located on the anchorage bolts used to attach the aluminum track of the cable catchment system to the steel reaction frame as shown in Figure 8. This was to provide data on the reaction forces to be resisted by the anchor bolts.

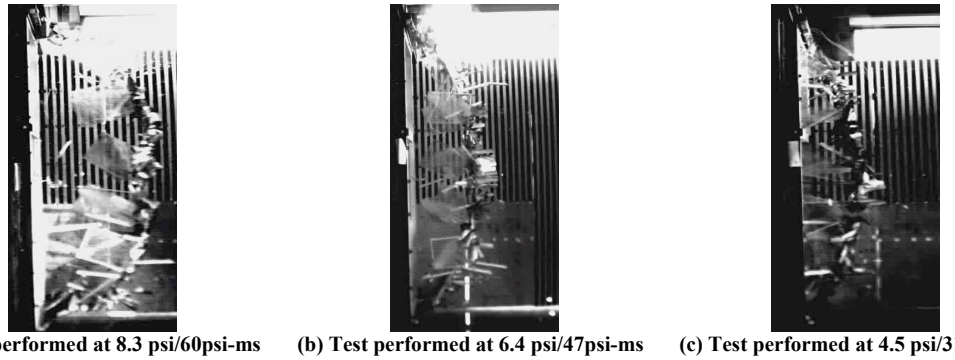
Figure 8. Load Cell Locations

Major Findings for Project 1



The wood sashes remained in place during the tests, but both the glass and small muntins exited the frame, as expected. It was noted that there was significant rotation of the panes due to less stiffness in the center of the sash compared with the edge, which resulted in the panes rotating rather than wrapping around the cables. The single cable per pane cable catchment system without blinds subjected to 4 psi and 28 psi-ms blast load did not meet the GSA Condition 3b requirement due to significant wood debris from the wooden muntins. Since the cable catchment system alone was not effective for this application, blast blinds were introduced into the system. The addition of blinds met the performance requirements, mitigating most of the wood and

glass debris from the window, although some small wood debris exited the system, but the velocity and mass would be unlikely to cause significant injuries.

The introduction of blinds would make it more difficult to open the windows; therefore, tests were performed raising the blinds to a third of the way up and only 8 inches up, respectively, to allow the building occupants direct access to open the windows. The former did not meet the performance criterion due to both glass and wood debris escaping the system. The latter constrained the glass, but small fragments of wood debris were in evidence on the witness panel. However, these were very small pieces with little mass. Video snap-shots showing the maximum inward displacement of cables for selected tests that were performed in an attempt to determine the failure load of the system are included in Figure 10. Based on these tests, the failure load was estimated to be around 7 psi and 50 psi-ms.

(c) Test performed at 4.5 psi/31psi-ms 30" max. inward cable displacement

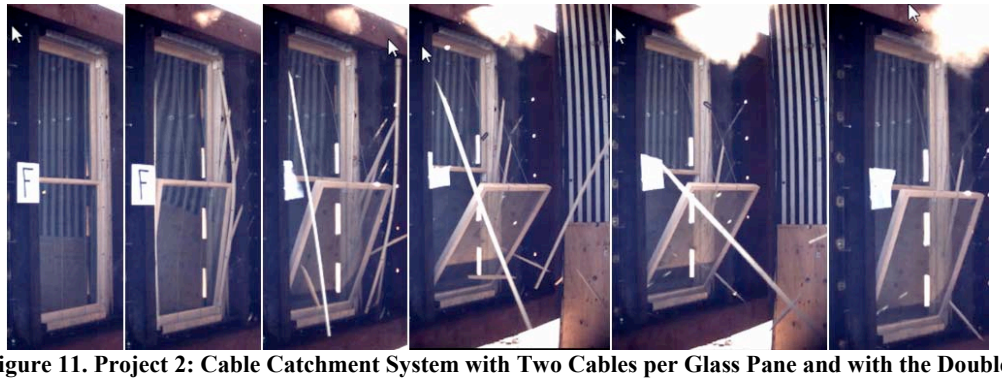
Figure 10. Side View Shots from Tests of Project 1

Major Findings for Project 2

During all tests for *Project 2*, the top edge of the bottom sash with glass and stops exited the frame, but the top sash remained in place. This illustrated that the wooden frame and glass had significant resistance to the blast load and glass did not exit the sash, as had been anticipated.

The response of the window system consisting of two cables per glass pane with the double laminated glass layup is shown in Figure 11. Video snap-shots showing the maximum inward displacement of cables for these tests are also included in Figure 12. Overall, the test results of *Project 2* showed that there were two major sources of

debris: (1) Wood debris from the wood window frame, window stops, and sashes entering into the protected area, and (2) Glass debris from the tempered outer glass pane, escaping from the cable catchment system and perforating the witness panel. At the design blast loads, the top window sash remained in the frame and was not propelled into the protected area, but the sash stops spalled and made it to the witness panel, causing some wood debris. Given that only one pane exited the window frame, the cable catchment system did not have to restrain the entire window system; however, in reality, in-situ conditions could cause the existing system to be weaker and then the cable system would see more load. Consequently, the preferred solution was the double laminated IGU and it was suggested to maintain three cables per pane, which was later verified using the validated FE analysis as documented in the section below.



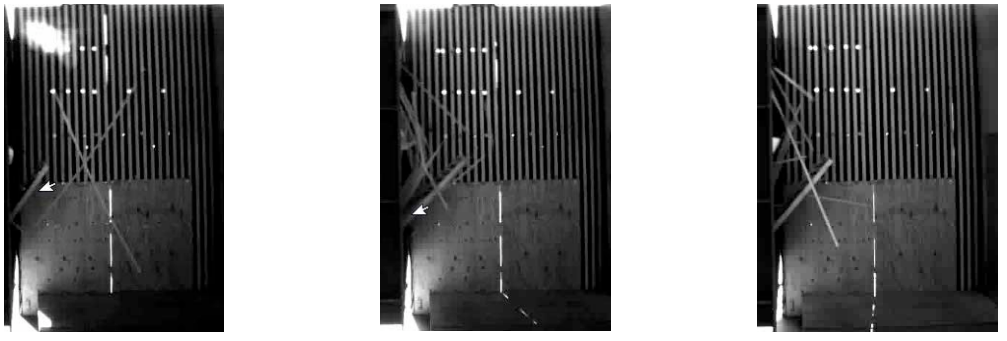


Figure 11. Project 2: Cable Catchment System with Two Cables per Glass Pane and with the Double Laminated Glass Layup (4.1 psi & 30 psi-ms)

(a) Test performed at 4.1 psi/30 psi-ms 20" max. inward cable displacement

(b) Test performed at 9.3 psi/62 psi-ms

(c) Test performed at 6.4 psi/49 psi-ms 16" max. inward cable displacement

Figure 12. Side View Shots from Tests of Project 2

VALIDATION AND EVALUATION OF TEST RESULTS

Following the tests, the FE models were calibrated to match the observed test results by varying the following items:

Glass: For *Project 1*, the physical tests confirmed that the individual panes exhibited several degrees of rotation before hitting the cables due to the discrepancy in stiffness between the center and edges of the window frame. This initial rotation was incorporated in to the FE model. The physical tests of the double-hung window of *Project 2* showed that the top sash remained in the window frame and did not engage

with the cable. Therefore, for validation purposes, the top glass pane was removed from the FE model.

Blinds: For *Project 1*, the physical tests confirmed that aluminum blinds would be required in addition to the single cable per pane. Therefore, 2-inch wide aluminum (6063-T6) blast blinds were included in the FE model using material model MAT_PLASTIC_KINEMATIC (Material#3). This material model includes yielding and plastic hardening, with limited energy absorption capacity through plastic deformation.

Sash weight: For *Project 2*, the preliminary FE model only included glass weight. However, tests showed that glass panes remained in the wood sashes. Therefore, the measured weight of the tested sashes was incorporated in to the modified FE model to account for this additional mass. Nodes of the glass edges were coupled with *CONSTRAINED_NODAL_RIGID_BODY in the FE model to account for the pane sashes that kept the inner and outer panes of the IGU together during the test.

Aerodynamic resistance: Gravity and damping were included in the FE model to account for aerodynamic drag forces that were experienced during the physical testing. Damping was adjusted to 1% and applied to the cables, glass, and blinds.

The FE model of *Project 1* was modified based on the collected data from the three tests for the integrated blind cable system with two cables per pane. The first two tests provided information on the cable yielding and failure limit states as they determined the performance of the system subject to high blast loads (*i.e.,* test performed at 8.3psi & 59psi-ms and test performed at 6.4psi & 47psi-ms). The third test performed at 4.5 psi/31 psi-ms was selected for validation purposes as it determined the performance of cable catchment system for the required blast design criteria.

For *Project 2*, the FE model was refined with the available data from the tests of the double laminated window system with two cables per pane. The main objective of the validation study was to reproduce the overall physical response of the system observed during the two tests (*i.e.,* test performed at 6.4 psi & 49 psi-ms and test performed at 9.3 psi & 62 psi-ms), in which the system was subjected to high blast loads and cable failure was observed. Next, the performance of the cable catchment system was determined when subjected to the explosive load (*i.e.,* 4 psi and 28 psi-ms) in Test F, with the assumption that the bottom sash would fully engage with the cable catchment assembly. Finally, the analysis was re-run assuming both sashes disengaged to conservatively account for potentially weaker windows.

Results of Finite Element Analysis

The refined FE simulations of the window system in *Project 1* and *Project 2* captured at different time states during the non-linear dynamic analysis are illustrated in Figure 13 and Figure 14, respectively. Results of FE simulations for *Project 1* shown in Figure 15 and Figure 17, indicate that all cable forces were within the allowable limits with a maximum cable force of 1390 lbs (Figure 15a) with a maximum inward cable displacement of 26.5 inches (Figure 15b). Additionally, FE simulation results for *Project 2* showed that all cable forces were within the allowable limits with the maximum cable force and the maximum inward displacement of 1445 lbs (Figure 16a

and Figure 18) and 22 inches (Figure 16b), respectively. Additional FE analysis, where the pressure impulse combinations were iterated to find the failure load of the systems in Project 1 (integrated blind cable system with single cable per pane) and in Project 2 (double laminated system with two cables per pane with the assumption that only the bottom sash disengage) also confirmed the results observed during the physical tests. These results predicted that cable catchment systems fail at approximately 7 psi and 50 psi-ms and 5.5 psi and 38.5 psi-ms, for *Project 1* and *Project 2*, respectively.

The FE analysis that explored the performance of the two-cable system for *Project* 2 when both the top and bottom sashes exit the frame to provide a conservative prediction in the event of a weaker existing window system, indicated that the cable force exceeds the allowable limits with a maximum value of 1930 lbs and therefore 3 cables per pane were recommended.

Comparisons between actual test results and the FE analysis predictions for *Project 1* and *Project 2* are summarized in Table 4 and Table 5, respectively. Given the modeling difficulties, such as the geometric imperfections, unknown initial positions, and boundary conditions, the differences in results for the FE simulations compared to actual collected data appear to be relatively insignificant and to err towards conservatism for the response of the cable by predicting larger cable forces. Overall, the results of the FE simulations showed good correlation with the physical tests, even though the wood component was not included in the analysis.

1-Exceeding breakage limit of the cable
2-Not available from sidewall video due to failure of cables
3-Readings from load cells located on the anchor bolts (not reflecting the exact cable load)
4-Full engagement to cable from bottom sash

CONCLUSIONS AND RECOMMENDATIONS

In this paper, the application of cable catchment systems to historic windows as a blast mitigation option was reviewed based on the results of both physical tests and FE simulations and the following was observed:

(1) For large pane windows with a minimum of two cables, the cable catchment system alone is effective at mitigating glass debris from entering the protected space and provides access to open windows and minimal aesthetic impact.

(2) For large windows with small panes and muntins (*Project 1*), significant wood debris from the muntins is to be expected, therefore blast blinds in conjunction with the cable catchment system are recommended to reduce this hazard. It is possible to allow the blinds to be raised slightly to allow access to open windows, but the height depends on the pane size and configuration.

(3) For single glazed systems either laminated glass or filmed glass is recommended in conjunction with the cable catchment system. Where IGUs are required for energy reasons, a double laminated IGU is recommended to reduce potential glass debris from the exterior pane.

(4) The performance of the cable catchment system showed high dependency on the historic window details, such as window stops, locks, and putty conditions. Physical test results indicated that glass panes cannot be released from the wood frame and fully engage with the cable catchment system when they are externally glazed windows with a window stop inside. Therefore, for historic window upgrades, it is important to carefully assess the existing conditions and detailing of the existing windows. The most favorable preconditions consist of interior putty and no interior window stops.

Overall, test results showed that the cable catchment system performed well and provided a promising blast mitigation solution while preserving the historic nature of the building and meeting window operability and low maintenance needs.

In addition, Hinman developed FE models of project-specific cable catchment systems and validated the accuracy of the simulation model against test data. In general, FE analysis was shown to be a cost-effective means of predicting the overall system response, especially when wood fragments are less of a concern. Considering the budget and time constraints of renovation projects, and the limited feasibility of repeated testing and instrumentation capabilities, validated FE models in combination with the measured data from complementary physical tests showed the potential to offer options for reducing the need of configuration-specific physical tests. The validation of FE analysis performed will serve as a base for future studies and provide a computational platform for the optimization of catchment system configurations prior to prototype production and the investigation of new retrofit strategies.

ACKNOWLEDGMENTS

The work presented in this paper was supported by the U.S. General Service Administration (GSA). The tests discussed were conducted by Baker Engineering and Risk Consultants, Inc. in San Antonia, Texas. The authors wish to thank Mr. Willie Hirano of GSA and Mr. Brian Frest of GlassLock, Inc. for their review and guidance during the program, as well as in the course of the preparation of this paper.

ABSTRACT

The application of blast resistant design principles has become more prevalent for buildings due to risk of accidental industrial explosions and terrorist attack. This has precipitated to more attention to exterior doors subjected to blast loadings, including the publication of ASTM F2247-043 "Standard Test Method for Metal Doors Used in Blast Resistant Applications (Equivalent Static Load Method)". However, the evaluation of doors subject to blast loadings lags significantly compared to the documented analytical tools and methodologies for other structural components, as well as windows. This paper lists and compares several techniques for evaluating doors subject to blast loadings, including testing and analytical approaches.

A recent research program has generated static and dynamic shock tube test results for various low-range hollow metal door types. The static data was used to develop single-degree-of-freedom models which were used to predict the door response for several dynamic tests. The comparison of the analytical predictions and test data provides a basis to adjust the dynamic model to better predict the response of the subject door. The results of the effort may allow blast designers to utilize existing static data for commercial doors to develop reasonable dynamic models for blast evaluations.

INTRODUCTION

Over the last two decades, buildings are more apt to include blast design to limit damage from either accidental explosions or terrorist bomb attacks. The response of doors to blast loads has received less attention than other building components, simply because they have been typically addressed by the architects since historically are not part of the primary resisting structural system and do not represent a major percentage of the building exterior such as glazing and other cladding systems. However, as blast resistant building design became more common, the response of blast doors has become a higher priority because doors do exist in every building and they represent the means of ingress and egress to the building for occupants and rescuers. Deaths resulting from failed doors from accidental explosions have also been documented. The early lack of focus on doors in the blast resistant design of buildings has led to a situation where well documented methodologies for predicting the response of doors to blast loads lags behind methodologies for other building components. In fact, most available blast related data for doors is limited to doors specifically designed for blast resistance by a handful of specialized door manufacturers. Therefore, research in this area was deemed necessary.

This paper provides background on available blast response data on doors, discusses various methods of evaluating doors for applied blast loads, and summarizes a recently completed research project aimed at developing a methodology more accurately predict the response of doors to applied blast loads. The research effort was performed by Baker Engineering and Risk Consultants, Inc. (BakerRisk) under a contract with the National Institute of Building Sciences and under the direction and funding by the US Army Corps of Engineers, Protective Design Center. The research effort was focused on determining the effectiveness of using load-deflection data from uniform static tests of doors as input into single-degree-of-freedom (SDOF) analysis models for the prediction of door response. The research program also focused on doors likely to be used in government buildings that were not specifically designed for blast resistance.

EVALUATION METHODOLOGIES FOR DOOR RESPONSE TO BLAST LOADS

The common methodologies used to evaluate doors for response to blast loads includes a full spectrum of analytical and testing methodologies similar that of other building components. The difference is that lack of research in this area and the nature of door construction provide for a higher level of uncertainty in analytical prediction of door response compared to other building components that have been studied in numerous previous research programs.

Analytical Methodologies

Doors have been evaluated for response to blast loads by the more common approaches used for other building components, including static equivalent design, SDOF, multiple-degree-of-freedom (MDOF), and finite element analysis (FEA) modeling techniques. Each of these methods are reasonable means of analysis, but the complexity of door construction, door panel support conditions, and interaction of the door panel and door frame require the analyst to make various structural interaction and response limit assumptions that can affect the model results significantly.

The static equivalent method is a convenient analytical tool for determining if a building component meets a given response criteria for a given blast load. Comparisons of the component's natural period of vibration to the load duration allows determination of a dynamic load factor for a given response limit. The static capacity of the component is then compared to the equivalent static load based on the dynamic load factor and peak blast pressure. Determination of the natural period and load capacity of door panels can be a complex task if done by analytical means, as hollow-metal doors may exhibit partial composite action between its member make-ups and support conditions lead to complex two-way plate responses. It is also difficult to take into account potential support movement with regards to the door frame in the static equivalent load analysis. In addition, door rebound response can only be considered in an uncoupled evaluation with an assumed rebound load.

SDOF and MDOF methods of analysis are possibly better means of determining response of structural components as they can predict both inbound and rebound response of the component. MDOF methods can also account for interaction between various components. However, like the static equivalent approach, the SDOF and MDOF methods depend on the definition of the resistance and deflection characteristics of the component being analyzed.

FEA analysis of doors may provide the best method of predicting response of doors to blast loads assuming a pure first principal analytical approach, but this depends on the complexity of material and geometric modeling and the accuracy of the contact algorithms between the door hardware, panel and frame. A FEA model that clearly defines all individual parts of the door, each spot weld, door hardware, and possible bonding to filler materials should predict response well if the contact is also modeled well. However, it is not always practical to build such a detailed model for each hollow metal door product.

Test Methodologies

Testing of doors in support of blast resistant applications can be provided by several means. Static and dynamic uniform pressure tests can be performed to validate analytical model assumptions for all analytical approaches. Dynamic testing can be used to prove performance of a door design for a specific blast loading. Note that in all testing, tests may be valid only for the support conditions used in the tests. Because doors may be installed in a variety of wall types, the stiffness of the door frame or connections to the building and the level of support provided can vary significantly depending on details.

Static testing of doors can provide good load-deflection data for use in analytical models, but cannot be used singularly to prove performance of a door for a specified blast load. With that said, doors must be tested in both the seated and unseated direction to determine response data for each direction, including when concerned with blast loading in one direction but with defined rebound requirements. In summary, static testing alone cannot be used to support door response to blast loadings. Another limitation of static data is that the data will not provide indications of dynamic strength increases that are typically observed for dynamically loaded members.

Dynamic testing of doors can provide proof of performance for a given door design and installation at a specified load on its own. However, a single dynamic door test cannot be used to prove performance when variables exist between test conditions and installation conditions

without some form of analytical proof that the variability does not affect door response. Therefore, it is inefficient to use dynamic testing alone to prove door response to a range of blast loads or a multitude of installation conditions.

Combined Analytical and Testing Methodologies

Using test data to validate analytical models is a very effective means to gain confidence in an analytical model that can be used for multiple door installation conditions. Static and dynamic test data can be used to validate analytical models. The more structural response information gathered in the test the better support provided for assumptions made in the models. However, even a simple static load test with no more than a "passed" response characterization can be used to support assumptions.

Static testing can be used to determine the load-deflection characteristics of a door, which provides all the data necessary to confidently use the static equivalent load analysis methodology. ASTM F 2247-03[1] provides direct guidance in testing of doors to gather the necessary door response information to determine a static equivalent load and provides the necessary analytical equations and information to do so.

Typically, validation of dynamic analytical models (SDOF, MDOF, and FEA models) is performed by comparing model predictions to observed responses in dynamic tests. In this manner, the model is assumed to be properly accounting for the most important response mechanisms in the components being evaluated. By testing numerous doors to various loading conditions to vary observed responses and to account for different natural period-to-load-duration ratios, the models can be validated for use for a large range of blast loads, or door response levels.

RESEARCH PROGRAM

The research program discussed in this paper specifically focuses on the use of static testing to develop load deflection curves that can be converted to SDOF properties for a door. The program also included dynamic testing to provide a means of validating the SDOF models developed and to determine if adjustment of the data from static testing was warranted to account for dynamic strength increases. This combination of static testing and dynamic testing is intended to determine if using SDOF models created using load-deflection information from static testing is an acceptable door evaluation methodology.

The research program included a literature search to gather information on commercially available doors, including design details, existing static test data and existing dynamic test data. After evaluation of the gathered information, a test plan was developed that included static and

[1] ASTM F2247 – 04, *Standard Test Method for Metal Doors Used in Blast Resistant Applications (Equivalent Static Load Method)*, 2004.

dynamic testing of selected doors. The static test data was used to create analytical models and the dynamic test data was used for comparison to analytical model predictions.

Literature Survey

The literature survey gathered publically available data on hollow metal doors available from a variety of manufacturers. The data collected included typical door details and static test data, as well as additional references for the evaluation of doors for applied static loads.

Door detail information included details of the door panel internal components, door frame details, and door frame anchorage details from several door manufacturers. Comparison of these details indicated that doors from different manufacturers use different details for doors having the same general description. These differences may significantly affect performance of the doors in their analysis. For example, there can be differences in stiffener section properties, door skin connection details, and locations of reinforcement. Figure 1 through Figure 4 show typical construction of doors from four door vendors.

Figure 5 shows a comparison of the reinforcement present in the door lock insertion areas for some typical doors. Note that while some degree of reinforcement is present in all the systems, the reinforcement approach used is often times different depending on manufacturer and model, and may result in different localized stiffness characteristics during their deflection.

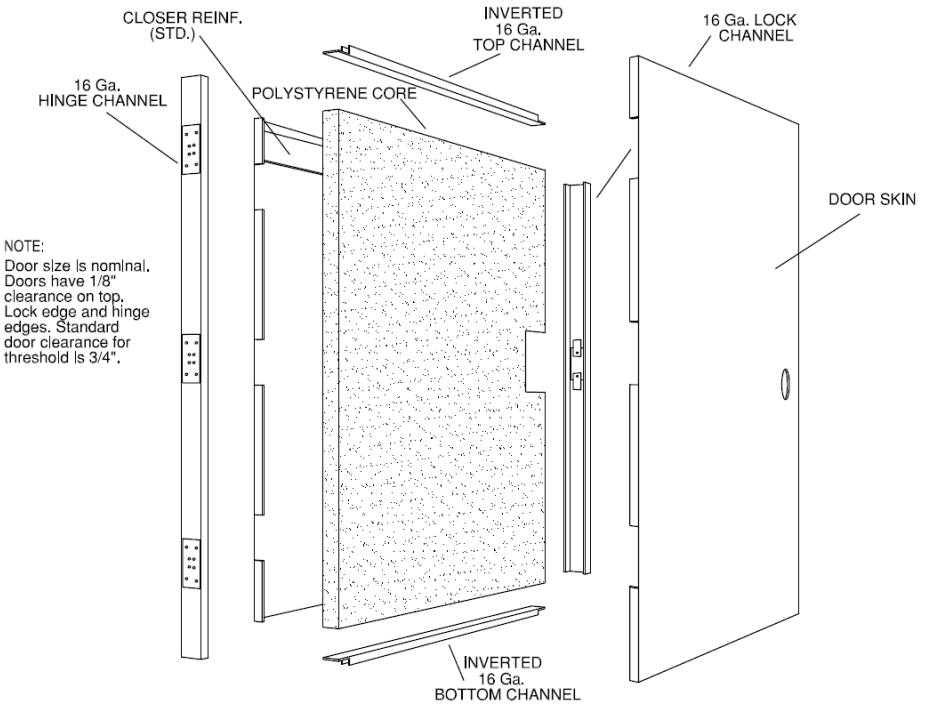

Figure 4. Deansteel Standard Door Construction

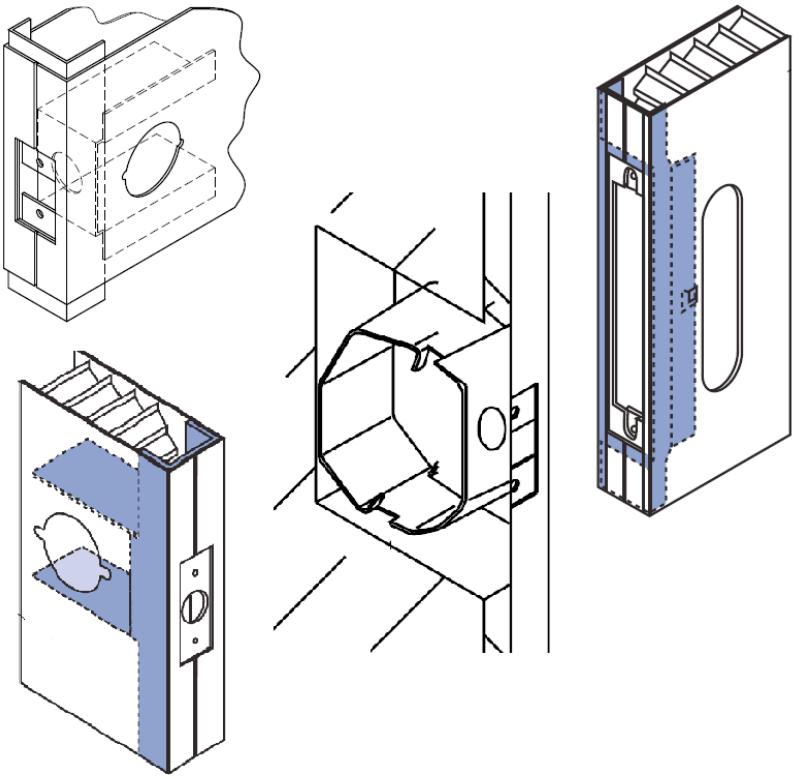

Figure 5. Comparison of Door Latch Reinforcement Systems (Clockwise from left: Deansteel, Republic Cylindrical, Ceco, Republic Mortise)

Most manufacturers provide some static capacity information for their doors, typically a design pressure rating. These ratings vary from manufacturer to manufacturer for similar door types as would be expected to the variability in internal reinforcement observed in the door details. Examples hurricane pressure ratings for selected doors are provided in Table 1 and Table 2.

[1]KD: Knock-Down frame provided in three pieces for field assembly. Weld: One piece factory-welded frame.

Static data from tests that include load-deflection information was very limited in the public domain. In fact, the only data from ASTM F2247 found was for doors specifically designed for blast resistance and thus not applicable to the study. Significantly more manufacturer test data is available in the public domain provided in accordance with ASTM E-330, which is a standard used to determine structural performance by using a uniform static air pressure differential across the panel. This method is primarily intended to simulate positive and negative pressures sustained by structural components under wind loading, the results of which are not directly applicable to blast resistance. However, the results of such testing do provide a range of static test loads to which the tested doors in this study should be subjected.

Additional static test results of doors found in open literature follow other test standards and guidelines, or follow very generic test descriptions. For example, some data is available for door systems tested under FEMA 361 criteria, which specifies the design of safe rooms to resist wind loads.[2] This set of criteria borrows heavily from ICC-500[3] and ASCE 7-05[4]. Other test results are simply presented as load-deflection measurements, with no duration or load cycle information given. Figure 6 shows an example of such results, defined simply as a "surface load

test." These results may not be comparable to results from the above testing standards or ASTM testing specifications such as F2247 or E330.

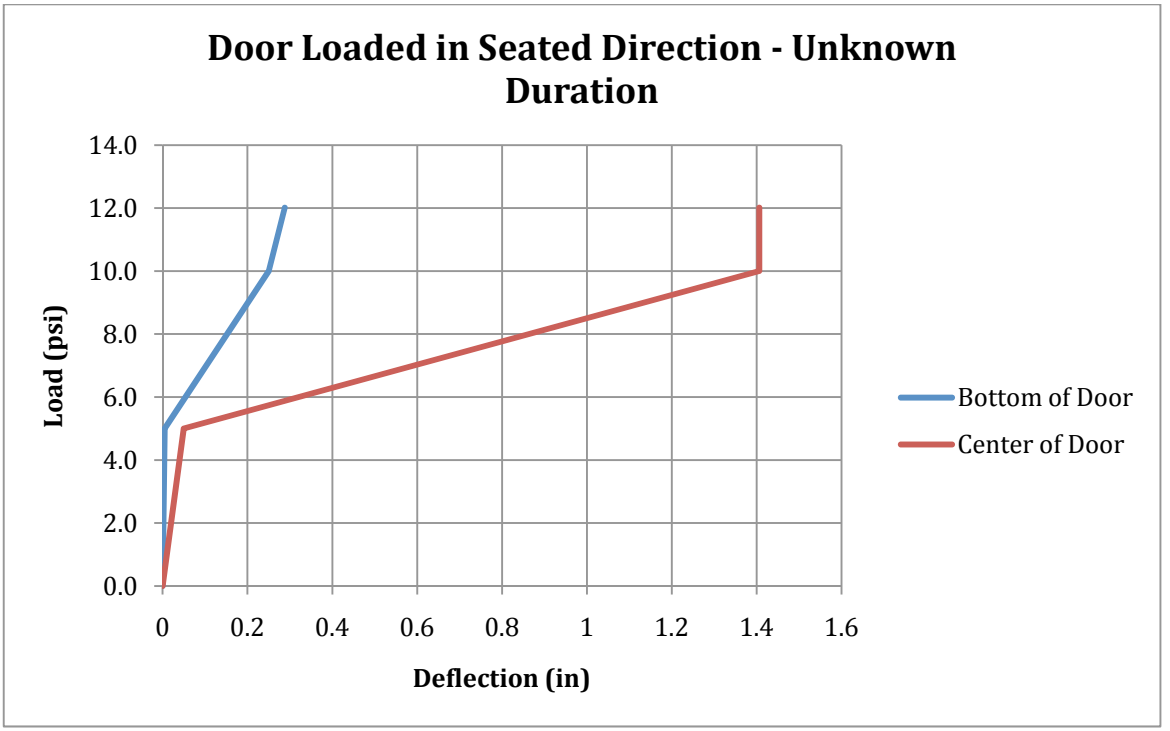

Figure 6. Composite Steel-Polystyrene Core Door Static Test Results

Dynamic test data available in open literature was also very limited. The only data available for non-blast resistant doors was available previous research performed by BakerRisk (formerly, Wilfred Baker Engineering).[5,6,7]. This data was limited to 18ga and 20 ga. hollow metal doors test to low pressure long duration blast loads, which was not directly related to the door types and blast loads of interest for this study. However, the data was useful in aiding in the selection of door for use in the test program. A summary plot of the prior BakerRisk door test information is provided in Figure 7. Note that the test was performed prior to the writing of ASTM F 2247 and used slightly different door response criteria. The door responses were correlated to ASTM F 2247 response level descriptions for presentation of the data in Figure **7**.

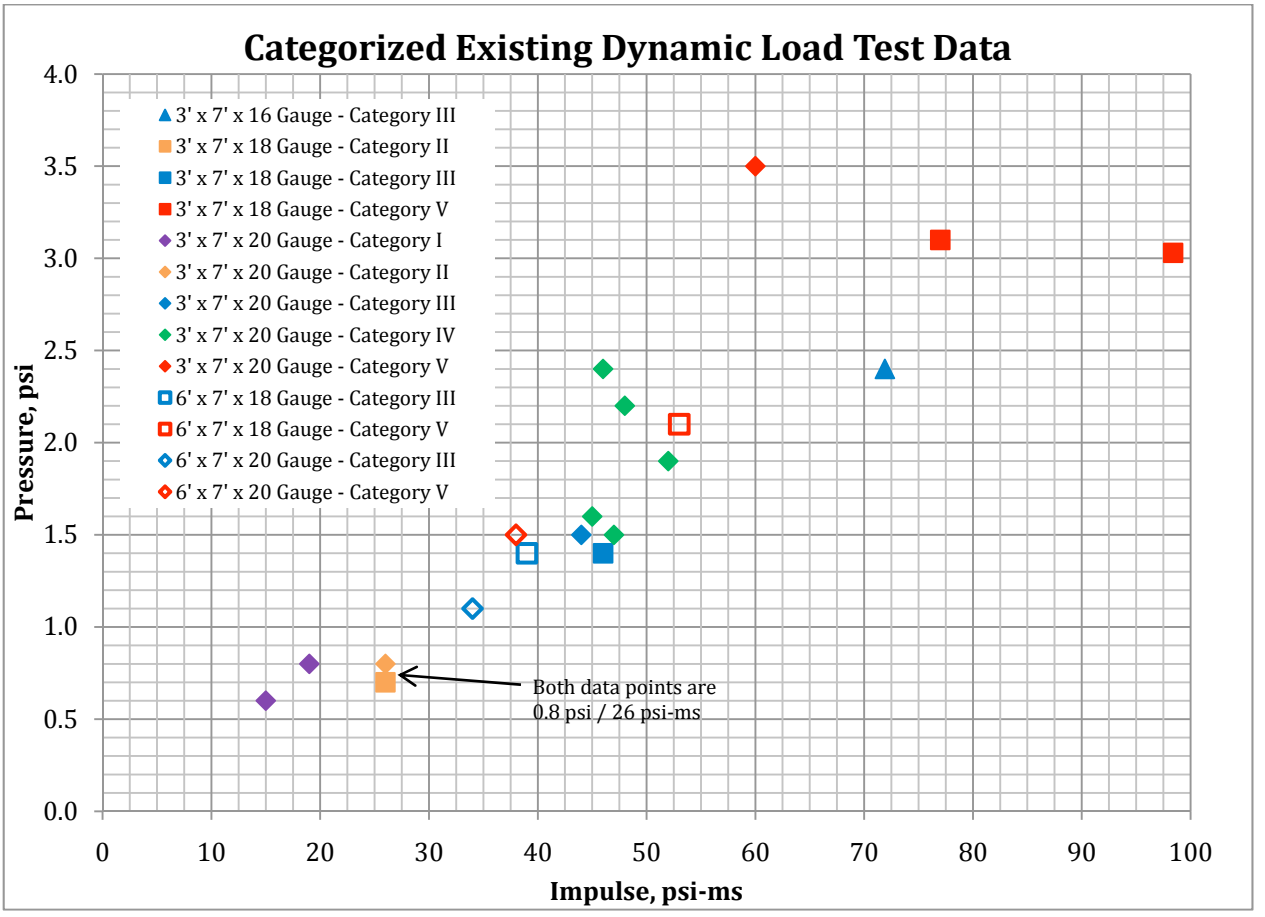

Figure 7 – Categorized Existing Dynamic Load Test Data

TEST PLAN AND PROCEDURES

A test plan was developed to provide a data set to evaluate the use of resistance functions obtained from static tests on doors to predict the dynamic response of those doors using SDOF analysis. The information obtained from the literature search was used to focus the test plan on the testing of doors suitable for use in government facilities for the protection against the minimum blast loads specified for antiterrorism protection. The test plan consists of the test approach and subsequent validation of the static test method according to dynamic shock tube testing. Door configurations for the initial testing were selected in coordination with the PDC. The initial proposed test matrix is defined and discussion related to the door configurations is included.

The static and dynamic test apparatus, data collection, and documentation are described, as well as response characterization for both static and dynamic test results. Frame configuration is addressed, along with the feasibility of numerical methods for use in the development of resistance-deflection functions for doors.

Test Approach

BakerRisk developed a progressive test approach in conjunction with the PDC, in which three series of tests were performed and the results of each test series were used to determine the tests conducted in subsequent test series. Additionally, test loads for the dynamic tests were developed from static tests performed in accordance with a modified approach to Procedure B outlined in ASTM F2247 as well as the commonly specified dynamic design loads for antiterrorism projects.

In contrast with the procedure outlined in the ASTM test specification, the BakerRisk test method does not predefine the maximum static test load for each specimen. Each specimen was tested to its ultimate (failure) resistance. As the original Procedure B calls for no less than four approximately equal increments of load application based on a pre-determined maximum test load, the increments used were calculated according to the postulated capacity of the door, which were based on the door's static load rating and existing test data.

Upon completion of the static test and development of the resistance-deflection curve based on the empirical data for each specimen, the natural period of the primary mode of response for each door was calculated according to the procedure outlined in the Annex of ASTM F2247. This approach provides all necessary data available from the ASTM test approach for determining static equivalent loads for given blast threats. The resistance-deflection curve was used in an SDOF model to prepare P-I (pressure-impulse) diagrams for the doors for each of the defined response categories. The design response limits used to develop the P-I curves are based on observed deflections in the static tests that relate to elastic limit, loss of support at the door frame stop, the deflection just prior to complete loss of support by the frame or other failure event, and latch failure in the unseating direction. These P-I curves were used to determine dynamic test loads expected to cause a specific door response for use in the latter stages of the test program.

Based on the existing data, blast loading interests of the PDC, and knowledge of doors typically used in government buildings a test matrix was developed. This test matrix along with the selected test approach provided resistance deflection relationships for two types of doors from the static tests. The dynamic tests provided a data set for validating SDOF model predictions using the resistance-deflection curves from the static tests. Additionally, they could serve to validate the basis and rationale of the equivalent load determination method outlined in the Annex of ASTM F2247.

Test Matrix

The door test matrix is provided in Table 3. Again, the matrix was conducted in three phases, with each phase of matrix development defining eight tests in the matrix. The conclusions of all completed tasks were considered in development of the subsequent tests.

The doors selected for use in the test program were a 16 ga. polystyrene core door and a 14 ga. vertically stiffened door. These doors were selected in a concerted effort with the PDC, with consideration of commonality, variation in fabrication details, and feasibility of the doors providing the blast resistance required for antiterrorism protection. The 16 ga. polystyrene core door represents a readily available standard door and the 14 ga. vertically stiffened door represents the most robust of typical conventional metal doors on the market. Note that although the 14 ga. door is a standard design for most manufacturers, it is considered a special order door.

The doors identified for use in the project were purchased from Deansteel Manufacturing, Inc. in San Antonio, Texas. Deansteel manufactures a full line of conventional steel doors, marine fire doors and several blast rated doors. Their conventional doors are of similar design and value to other door manufacturers identified in the literature search effort.

The 16 ga. polystyrene core doors are fabricated from galvanized materials and include reinforcements for door closers, and are prepared for 4 ½-inch hinges and mortise locks. The doors are provided in 5 ¾ inch deep cold-rolled 16 ga. door frames. The frames are welded at the head-to-jamb interface and prepared for bolt-in installation with four 3/8-inch diameter bolts. Door hardware includes PBB, Inc. standard weight 4 ½-inch ball bearing (BB) non-removable pin (NRP) hinges and Dorma Grade 1 mortise locksets (ML9956LTM) with lever handles.

The 14 ga. vertically stiffened doors are stiffened with cold-rolled steel hat members and includes reinforcements for door closers and are prepared for 4 ½-inch hinges and a mortise lock. The doors are provided in 14 ga frames identical in detail to the 16 ga. frame for the polystyrene doors, and have identical hinges and locksets.

Table 3. Test Matrix

Test No.	Method	Door Panel Type	Load
1	Static, Seated	16 ga. with Polystyrene Core	Increasing load to failure of door
2	Static, Unseated	16 ga. with Polystyrene Core	
3	Static, Seated	14 ga. Vertically Stiffened	
4	Static, Unseated	14 ga. Vertically Stiffened	
5	Dynamic	16 ga. with Polystyrene Core	5.8 psi, 31 psi-msec
6	Dynamic	16 ga. with Polystyrene Core	4.8 psi, 41 psi-msec
7	Dynamic	14 ga. Vertically Stiffened	5.8 psi, 31 psi-msec
8	Dynamic	14 ga. Vertically Stiffened	4.8 psi, 41 psi-msec
9	Static, Seated	16 ga. with Polystyrene Core, Mounted in Wood Studs	Increasing load to failure of door
10	Static, Seated	16 ga. with Polystyrene Core, Stiffened Frame	
11	Static, Seated	14 ga. Vertically Stiffened, Stiffened Frame	
12	Static, Seated	14 ga. Vertically Stiffened, Mounted in Wood Stud	
13	Dynamic	14 ga. Vertically Stiffened, Mounted in Wood Stud	4.8 psi, 41 psi-msec
14	Dynamic	16 ga. with Polystyrene Core Mounted in Wood Studs	4.8 psi, 41 psi-msec
15	Dynamic	16 ga. with Polystyrene Core, Stiffened Frame	4.8 psi, 41 psi-msec
16	Dynamic	14 ga. Vertically Stiffened, Stiffened Frame	4.8 psi, 41 psi-msec
17	Dynamic	16 ga. with Polystyrene Core	12.6 psi, 78 psi-msec
18	Dynamic	16 ga. with Polystyrene Core	
19	Dynamic	16 ga. with Polystyrene Core	
20	Dynamic	14 ga. Vertically Stiffened	12.6 psi, 78 psi-msec

22	Dynamic	14 ga. Vertically Stiffened	
23	Dynamic	16 ga. with Polystyrene Core, Mounted in Wood Studs	5.8 psi, 31 psi-msec
24	Dynamic	14 ga. Vertically Stiffened, Mounted in Wood Studs	5.8 psi, 31 psi-msec

Static Testing Apparatus

The static tests were performed in a test apparatus similar to the required fixture outlined in ASTM F2247. Figure 8, adopted from the ASTM document, show horizontal and vertical section views of the membrane system used to apply a uniform static load on the test specimen, for seated direction tests. The BakerRisk static test apparatus uses modular bladders within a rigid box in place of the sealed box and membrane shown in the ASTM apparatus. The bladders are designed to take the shape of the confined space within the apparatus with the test specimen forming one side of the space. The apparatus uses the same support fixture for doors that are dynamically tested in the BakerRisk shock tube. The use of the same reaction structure provides very consistent installation and support of specimens between the two test methods. A photograph of the static test apparatus with the bladders inflated against a clear test sample is provided in Figure 9.

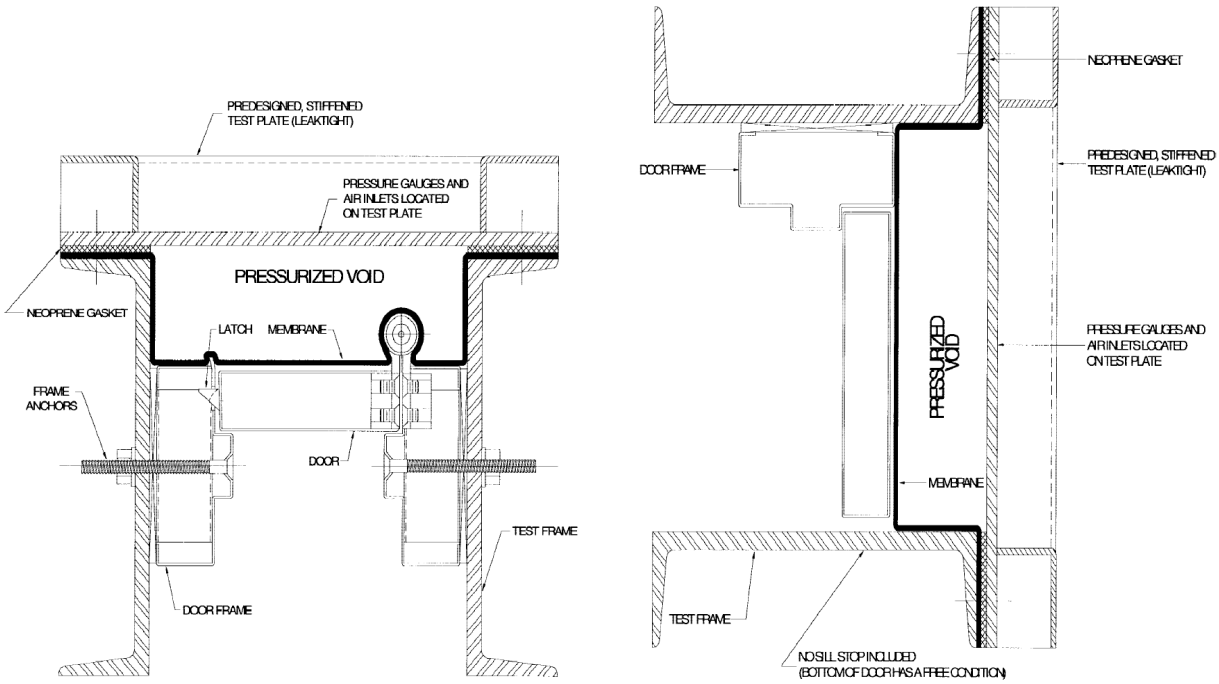

Figure 8 – Section Views, Seated Load Case

Figure 9. Photograph of the BakerRisk Static Test Apparatus

Dynamic Testing Apparatus

All dynamic tests in this test program were performed in the BakerRisk shock tube. Although the BakerRisk shock tube is capable of testing up to a 10-foot by 10-foot square test specimen, the 8-foot by 8-foot section was used in its normal configuration for the dynamic tests. A photograph of the BakerRisk shock tube is shown in Figure 10. For this test program, the target end of the shock tube was fitted with a test frame with a variable sized door opening.

Figure 10. BakerRisk Shock Tube

Instrumentation, Data Collection, and Test Documentation

Each dynamic test was instrumented with three airblast pressure transducers measuring the blast load applied to the test specimen and one airblast pressure transducer measuring pressure that may be present on the back side of the test specimen. All data from the blast transducers were electronically recorded at a sampling rate of 500 kHz or faster. These data were plotted as pressure-time histories and included in the test report.

High-speed video was used to record the response of the door system from two view angles oblique to the blast direction. A digital video camera was used to record each test, in addition to the high-speed video cameras. The digital video camera was also used to record the post-test state of the each test specimen, and to document the location of any debris generated during the test.

For both static and dynamic tests, still photography was used to document the test in both pre-test and post-test states.

The pressure and deflection measurements for each static test were documented for use in the test report in accordance with Section 13 of ASTM F2247.

Response Characterization Improvements

For informational purposes, although ASTM F2247 defines four categories of door blast response, there exists slightly modified performance categories defined by the BakerRisk Petroleum and Chemical Processing Industry Technology Cooperative (PCPITC), now the Explosion Research Cooperative (ERC). These ERC categories consist of expanded definitions of the four ASTM categories, and will be included in the future draft of a new standard test method for blast resistant doors being developed by ASTM subcommittee F12.10. The categories for response characterization are shown in Table 4.

Table 4. Expanded Performance Categories

Response	Description
Category I: No Damage	The door panel and all other components of the door must remain in the elastic response range. Analytical design limits for this response category are a ductility ratio of 1. Additionally, the analysis must include an evaluation that demonstrates that all parts of the door can support the door panel to its maximum capacity.
Category II: Limited Damage	The door panel may experience limited plastic deformation, but must be shown to remain in the frame in both the inbound blast direction and in rebound. All hardware must be evaluated and proven capable of supporting the door panel to its ultimate capacity. An evaluation of door shortening must be performed to ensure that shortening of the door panel due to deflection does not cause loss of bearing on the doorstop or pullout of the lock bolt from the frame. The design limit on the door panel is 5 degrees of support rotation. The panel shortening evaluation includes effects of doorpost deformation, if applicable, and rounded corners of bent plate frames and door skins. The total loss of panel/stop or latch bolt/plate engagement is limited to one-half of that provided under normal installation tolerances.
Category III: Non-Catastrophic Failure	The door panel must remain in the frame and remain a barrier to prevent blast load propagation through the door opening. The door panel may be severely deformed and may be inoperable. The design limit on the door panel is 8 degrees of support rotation. An evaluation related to loss of support due to door panel and post deformation must show that the total loss of engagement is less than the engagement provided, minus the dimensions of any corner radii.
Category IV: Failure without Debris Hazard	The door panel may be severely deformed, with openings between the panel and door frame allowed, but the door panel must remain affixed to the door frame. This level of response is difficult to predict analytically, due to the many influencing factors of response once a door panel deflects to the point where bearing supports or latch bolt engagement is lost. Also, simple analytical methods such as single-degree-of-freedom models assuming elastic/perfectly-plastic response do not predict large deformation well. Testing is the best methodology to predict this level of response.

These performance categories were used for both static and dynamic tests. Note that a category is not included to characterize blow-out failure. For this test program, characterization of this type of failure is not necessary, as door panel response occurring after total separation from the frame falls above the ultimate resistance of a door system.

Both inbound and rebound response of the door systems are considered by default in the dynamic tests. In the static tests, considerations were made for both inbound and rebound response by the testing of the door specimens in both the seated and unseated directions, respectively.

Frame Connection Configurations

Frame connections, such as the attachment of the door frame to the test fixture, followed normal installation details as close as possible to be representative of those normally employed for

anchorage to steel substrates. The effects of minor differences in shimming for rough openings in door frame openings in typical construction practices are not expected to play a significant role in the applicability of the test results to real-world blast response of the door systems, if proper manufacturer connection specifications are adhered to in construction.

Deviation from ASTM F2247-03 Test Specification Methodology

A deviation was made from Procedure B of the ASTM specification regarding the static testing in this program. The maximum static test load was not predefined. The load increments were calculated according to a postulated capacity of the doors for selection of incremental load steps, but ultimately the doors were tested to failure. During setup and testing two other deviations from the ASTM recommended approach were made. These are described in the following paragraphs.

A deviation from the ASTM suggested approach was made with regard to the suggested data instrumentation locations for the door specimens in both the seated and unseated directions. The locations of the BakerRisk test apparatus deflection instrumentation are shown in Figure 11, superimposed on the ASTM suggested locations. These measurement location adjustments were made based upon previous observations of door deformation under blast loading. The resistance-deflection curves created in this study use the deflection gathered at mid-span of the door panel, rather than at the bottom edge. Test observations indicate that the panel jamb may lose frame engagement, prior to development of full panel resistance. This point is best for predicting door performance, as the door panel behaves as a two-way plate with maximum deflection at the mid-point, except in the vertically stiffened case where the point of maximum deflection shifts to the bottom of the panel after it is pushed past the frame stop and the resistance continues to be provided by load transfer through the stiffeners.

The ASTM approach requires checking for door operability after each load step. BakerRisk did not perform these checks. The purpose of these static checks was to determine the ultimate load capacity of the doors. If a door operability check resulted in a non-operable result, such that a door latch opens but would not re-latch, the test could not continue and the ultimate resistance could not be determined. Therefore, BakerRisk did not operate the latches once a test was started.

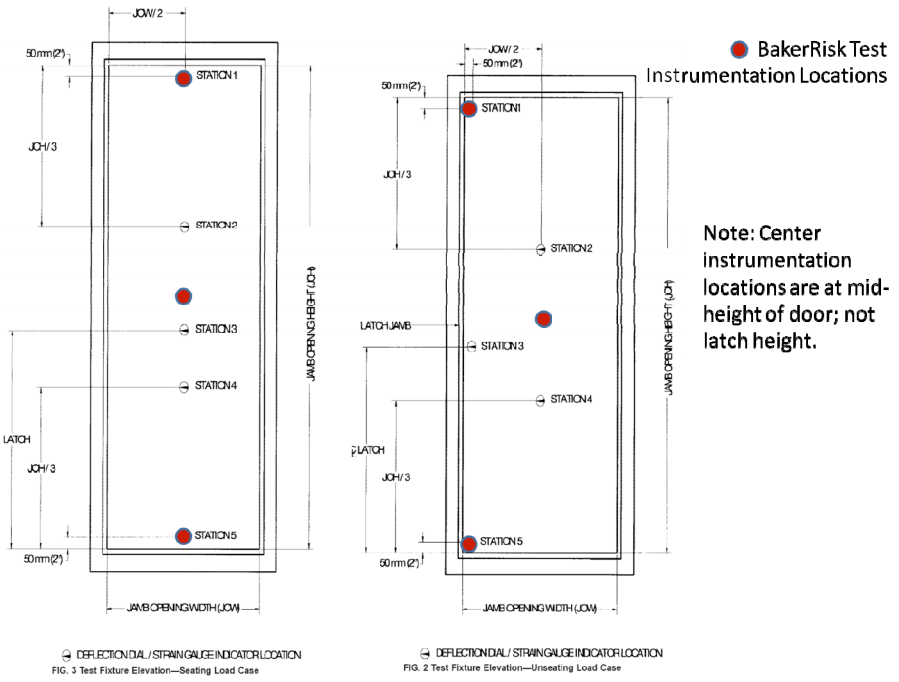

Figure 11. BakerRisk Test Instrumentation Locations: Seated (Left) and Unseated (Right)

TEST RESULTS

The results of all three tests are reported in the following sections grouped by each test series. Conclusions drawn from each test series that were used in the development of the follow-on test series are discussed with the results. Sub-sets of data are grouped in the analysis section based on door type for side by side comparisons.

Static Test Results

The all static tests were conducted in the BakerRisk static test apparatus. Results of each test are summarized in Table 5. For door type and installation details, see the test matrix in Table 3. Sample recorded data and resulting resistance deflection curves for sample seated and unseated static tests are provided in Figure 12 and Figure 13. Post-test photographs for these same tests are provided in Figure 14 and Figure 15.

Table 5. ASTM F2247-03 Damage Category Ratings – Static Testing

Test Number	Load Increment	Increment Load (psi)	Category[1]
1	1	0.4	I
	2	0.8	II
	3	1.2	II / III
	4	1.6	III
	Failure	3.5	IV
2	1	0.3	I
	2	0.6	II
	3	0.9	II / III
	Failure	1.2	IV
3	1	1.0	II
	2	2.0	III
	Failure	2.8	IV
4	1	0.3	II
	2	0.6	II / III
	3	0.9	II / III
	4	1.2	III
	Failure	1.5	IV
9	1	0.7	II
	2	1.4	II
	3	2.1	II
	Failure	2.4	IV
10	1	0.8	II
	2	1.6	II
	3	2.4	II/III
	4	3.2	II/III
	5	4.1	III
	Failure	5.2	IV
11	1	0.7	II
	2	1.4	II
	3	2.1	II/III
	4	2.8	II/III
	5	3.5	II/III
	6	4.2	III
	7[3]	5.0	III
	Failure	5.6	IV
12	1	0.8	II
	2	1.6	II
	3[3]	2.4	II
	Failure	3.3	IV

[1]Differentiation between ASTM F2247 Categories II and III based upon door operability was not made; testing door operability between load cycles is not practical. Distinctions between Categories II and III are made based upon visual observation of damage during testing.

Dynamic Test Results

Dynamic tests were conducted using the BakerRisk Shock Tube. All tests of doors were performed in the seated direction. The dynamic test loads used in each test were selected based on the test matrix prepared for the test program. The ASTM F2247-03 damage category rating results for each dynamic test is shown in Table 6. Note that a shock tube misfire occurred during Test 6. A subsequent test, Test 6A, was performed on the same specimen. Sample post-test photographs are provided in Figure 16 through Figure 19.

Table 6 – ASTM F2247-03 Damage Category Ratings – Dynamic Testing

Test Number	Load (psi / psi-ms)	Door Panel Type	Category[1]
5	6.3 / 34	16 ga. with Polystyrene Core	II
6	3.6 / 33	16 ga. with Polystyrene Core	II
6A	4.4 / 39	16 ga. with Polystyrene Core	III
7	6.2 / 30	14 ga. Vertically Stiffened	I
8	5.2 / 41	14 ga. Vertically Stiffened	I
13	4.8 / 41	14 ga. Vertically Stiffened - Wood	V
14	4.9 / 38	16 ga. Polystyrene Core - Wood	V
15	4.9 / 39	16 ga. Polystyrene Core – Stiffened Frame	III[2]
16	4.9 / 38	14 ga. Vertically Stiffened – Stiffened Frame	III[2]
17	12.0 / 77	16 ga. with Polystyrene Core	V
18	9.1 / 58	16 ga. with Polystyrene Core	III

POST-TEST ANALYSIS

Using the resistance-deflection curves obtained from the static tests of the first series, SDOF and two degree of freedom (2DOF) models were created. The PDC tool SBEDS was used for SDOF modeling, while the BakerRisk proprietary ISADS tool was used to model both the frame and panel components as a 2DOF system. The second degree of freedom in the analysis was developed by loading a static finite element frame model with a unit load and obtaining the peak elastic deflection. The displacement criterion used was a frame sway limit of H/50.

While the displacement-time history phasing of door opening during rebound matched closely for most tests, it did not match for Test 6A, for which the frame may have been slightly deformed from the earlier misfire in Test 6. Models were executed with both the measured applied loads from the tests (Table 7) and equivalent right-triangular loads (Table 8) and the results are similar.

Table 7 SDOF and 2DOF Preliminary Modeling Results Summary (Measured Loads)

Door Type	Load (psi / psi-ms)	Component	Analysis Type	Tool	Inbound defl. (in)	Rebound defl. (in)	Ductility
16GA Unstiffened (Test 5)	6.3 / 34	Door Panel	SDOF	SBEDS	2.86	N/A	1.43
		Door Panel	2DOF	ISADS	2.00	N/A	1.09

RECOMMENDED ANALYTICAL MODELING METHODOLOGY

The paramount goal of this study was to establish a methodology to utilize static test data gathered in accordance with ASTM F2247-03 for the development of SDOF resistance functions for hollow metal doors. This section presents analytical pressure-impulse (P-i) diagrams created from SDOF analysis using the ASTM F2247-03 static resistance functions obtained from this program. The diagrams presented provide conservative estimates of damage level, based on the available test data. Recommendations for use and applicability of static door test data for assessment of dynamic response are given.

SDOF Parameters

Using the load-mass factors for a 3-sided simply supported 2-way plate, SDOF models can be created for doors with both unstiffened and vertically stiffened panels. The resistance-deflection curves obtained in this program were curve-fit for use in the SBEDS software for inbound and rebound response.

Care must be taken to examine the response output for post-yield response in rebound so that subsequent response is disregarded. For example, Figure 20 shows a sample SBEDS input page representing a model of the 16GA door in Test 5 of this program. Note that the maximum ductility ratio computed by the SBEDS input sheet is shown for the rebound phase, which is technically incorrect. The peak positive displacement is 2.2 inches, which is approximately 10% over yield, representing a ductility ratio of 1.1. Examining the SDOF response output shown in Figure 21, the door reached rebound yield deflection (-1.5 inches) at 31 ms, which occurs earlier in time than the peak rebound response shown in the model.

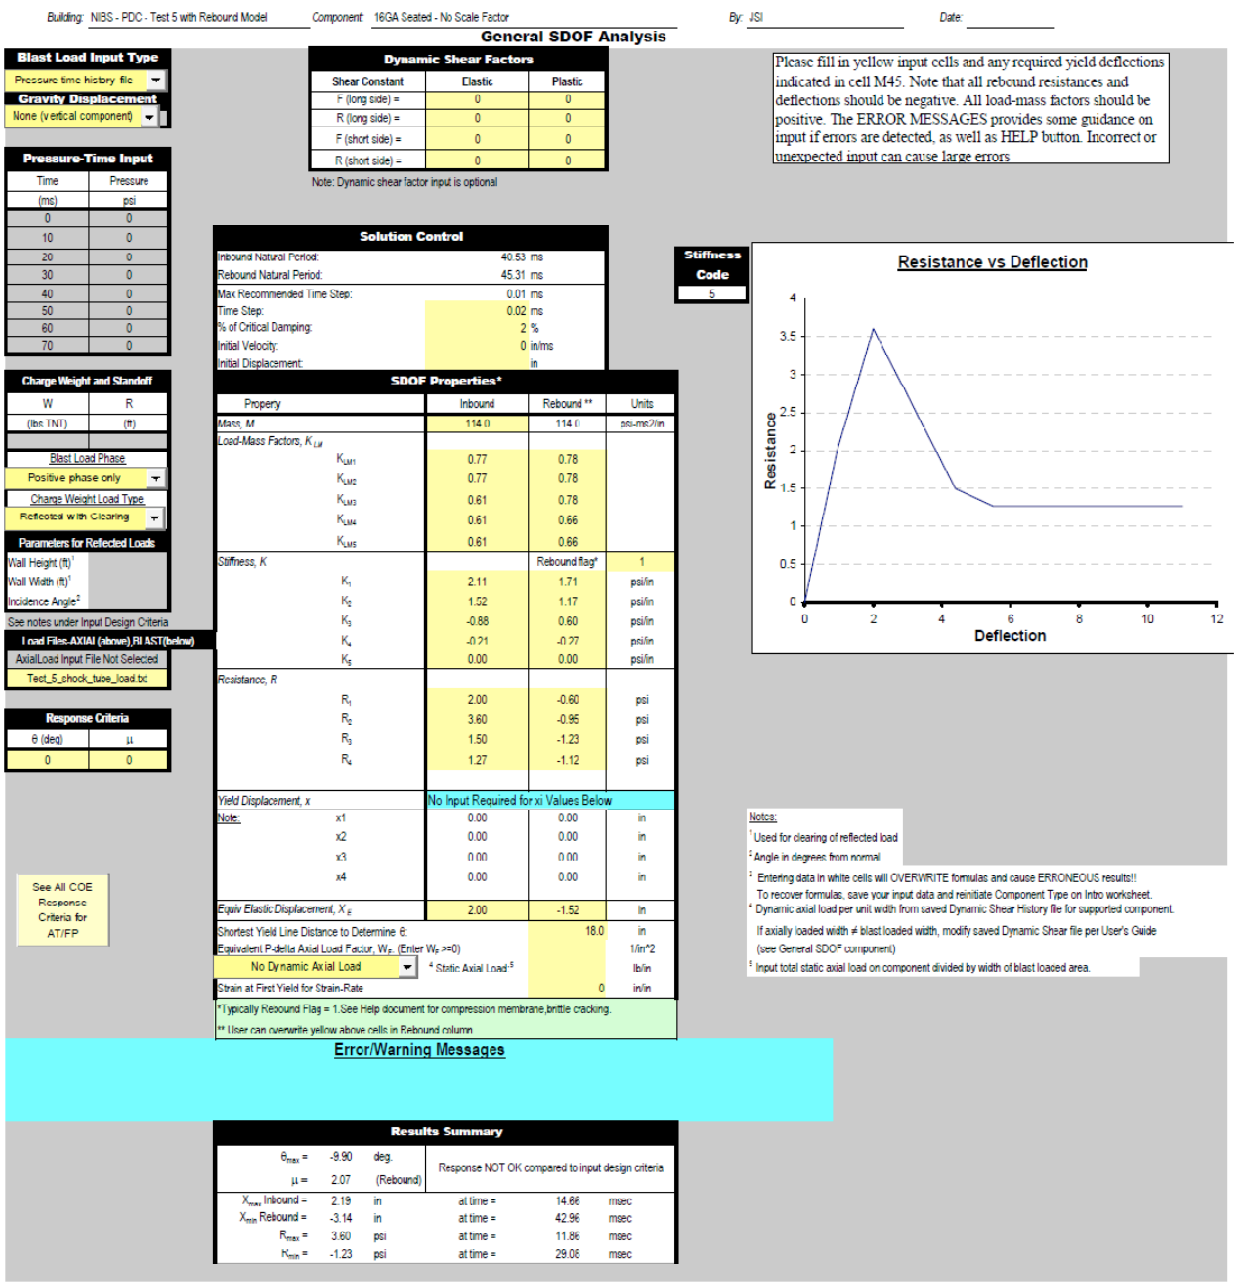

Figure 20. SBEDS Input Sheet (Test 5)

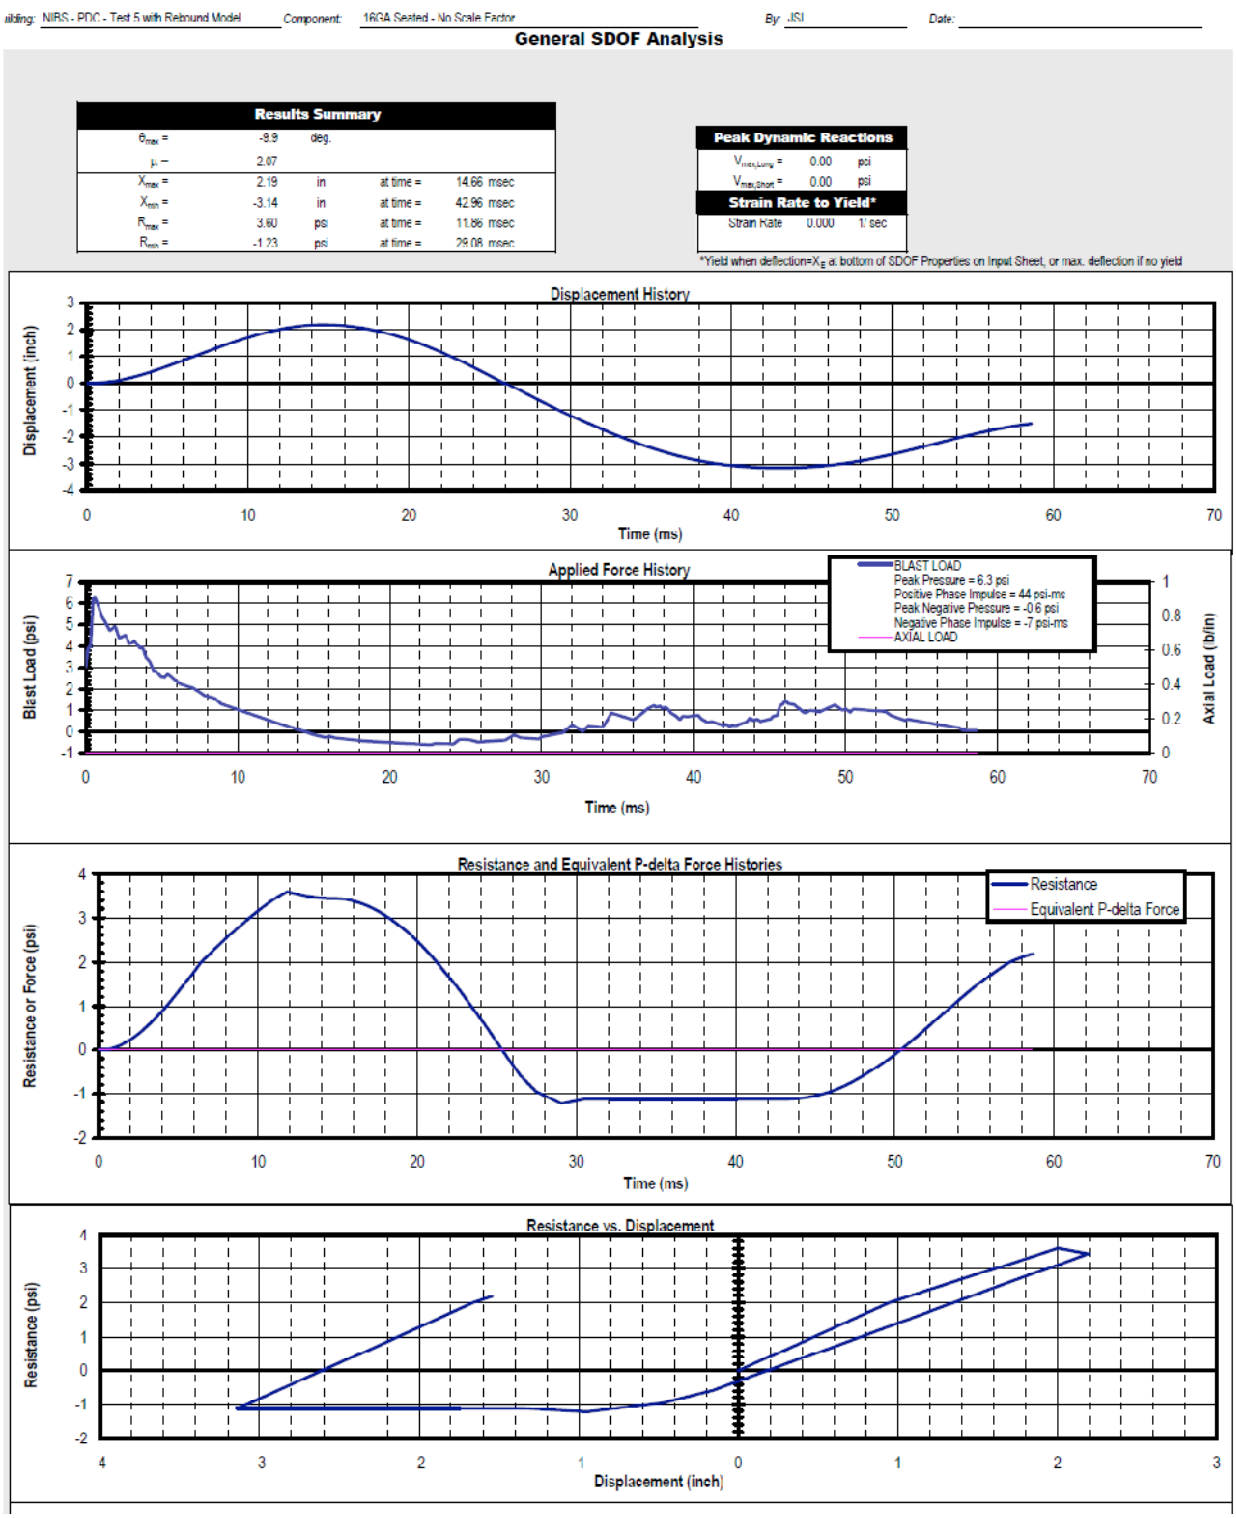

Figure 21. SBEDS Output Sheet (Test 5)

16GA Doors with Polystyrene Cores

The static resistance deflection curves obtained from the first test series were used to model the dynamic behavior of the 16GA polystyrene core doors using SDOF methods. A comparison of these analytical results with the test data is shown in Table 9.

Table 9 – 16GA Polystyrene Core Door Test and Analytical Data Comparison

Test	Observed Panel Response		Calculated Panel Response	
	Qualitative	Measured	Ductility	Time to Peak
5	Rebounded open at 36ms	None	1.1	Rebounded open at 31ms
6	Rebounded open at 30ms	None	1.0	Rebounded open at 33ms
6A[1]	Panel pushed past stop at 24ms	N/A	1.2	Pushed past stop at 49ms
17	Door panel and frame detached from test fixture; panel pushed past stop at 10ms	N/A	7.0	Pushed past stop at 7ms
18	Panel pushed past stop at 6ms, rebounded, then opened	5/8" Perm. at Midspan	3.1	Pushed past stop at 8ms
19	Panel lodged in frame; first peak of bottom of panel response at 32ms, second at 66ms	3.25" Perm. At Midspan	3.9	First and second peak at 32ms and 66ms[2]

[1]Test 6A was a retest due to a shock-tube misfire in Test 6. As a result, the frame had already undergone slight permanent deformation, which provided a stiffer support for Test 6A. This phenomenon is reflection in both the experimental and analytical results.

[2]The peak response of the bottom of the door panel and the mid-height, mid-span of the door panel may not be necessarily in phase.

The analytical results, using the static resistance deflection curves, agree very closely with the observed experimental results without the use of any increase factors applied to obtain the dynamic response. P-i diagrams representing the ASTM F2247-03 static door damage categories are shown in Figure **22**. These diagrams are based on the analytical models. Test data points from this program are plotted on the diagram independently.

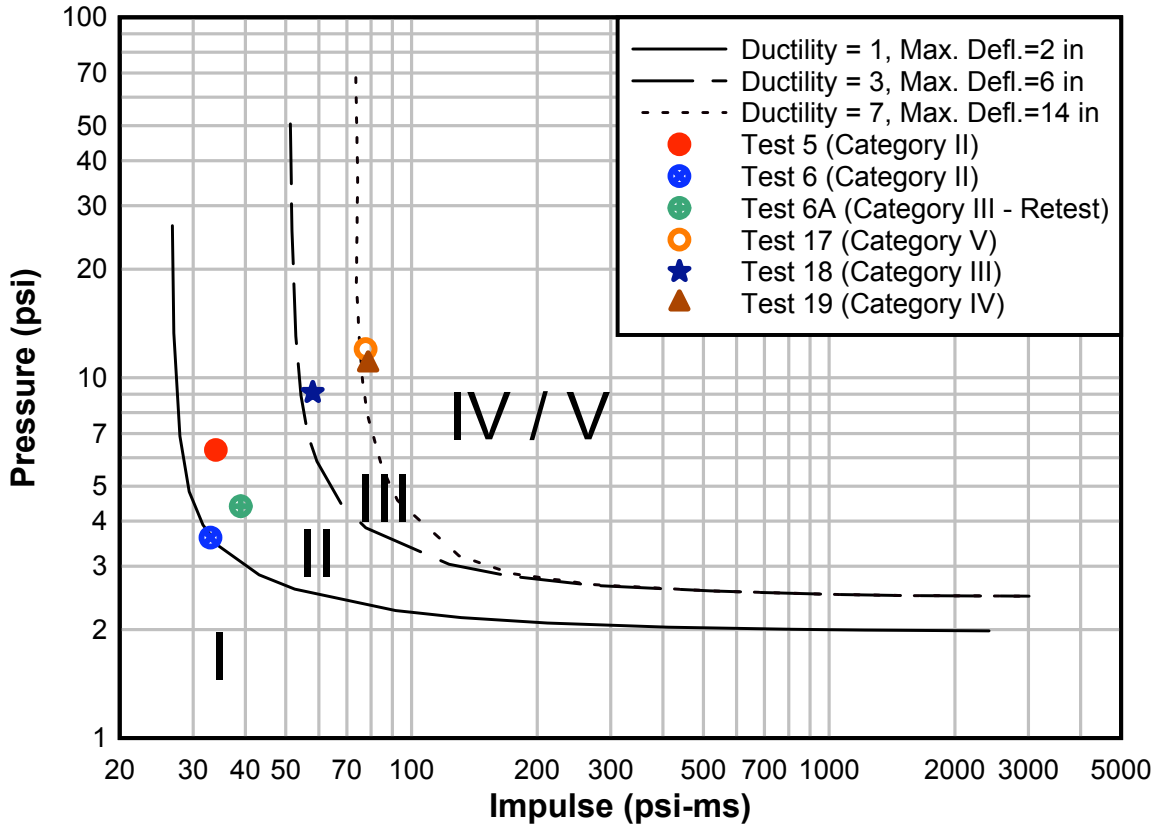

Figure 22 – 16GA Polystyrene Core Door Damage Levels

14GA Doors with Vertically Stiffened Panels

The static resistance deflection curves obtained from the first test series were used to model the dynamic behavior of the 14GA doors with vertically stiffened panels using SDOF methods. Again, the analytical results agree very closely with observed experimental results. While inbound response agrees well, the SDOF models tend to under predict the rebound response. A comparison of these analytical results with the test data is shown in Table 10.

Again, the analytical models were used to create P-i diagrams of the ASTM F2247-03 damage levels, as shown in Figure 23. Test data from this program is overlaid on the chart. The data point representing Test 22 appears in the Category III region, while observed test results dictate a Category II (permanently deformed but operable) rating. Note that the door frame flexed significantly in this test, thus reducing the likelihood of latch damage and further door panel damage.

Table 10. 14GA Vertically Stiffened Panel Door Test and Analytical Data Comparison

Test	Observed Panel Response		Calculated Panel Response	
	Qualitative	Measured	Ductility	Time to Peak
7	Rebounded open at 40ms	1/4" Perm. at Midspan	1.2	Did not rebound open, but peak rebound occurred at 40ms
8	Rebounded open at 40ms	1/2" Perm. at Midspan	2.0	Did not rebound open, but peak rebound occurred at 53ms
20	Panel pushed past stop at 20ms and two frame bolts failed in shear	3.8125” Perm. At Midspan	5.4	Pushed past stop at 22ms
21	Panel pushed through frame at 14ms, five frame bolts failed in shear, and the door frame partially came out of the test fixture	N/A	7.1	Pushed past stop at 18ms
22	Panel stayed closed, exhibited permanent deformation, and frame flexed significantly	5/8" Perm. at Midspan	4.0	Stayed closed

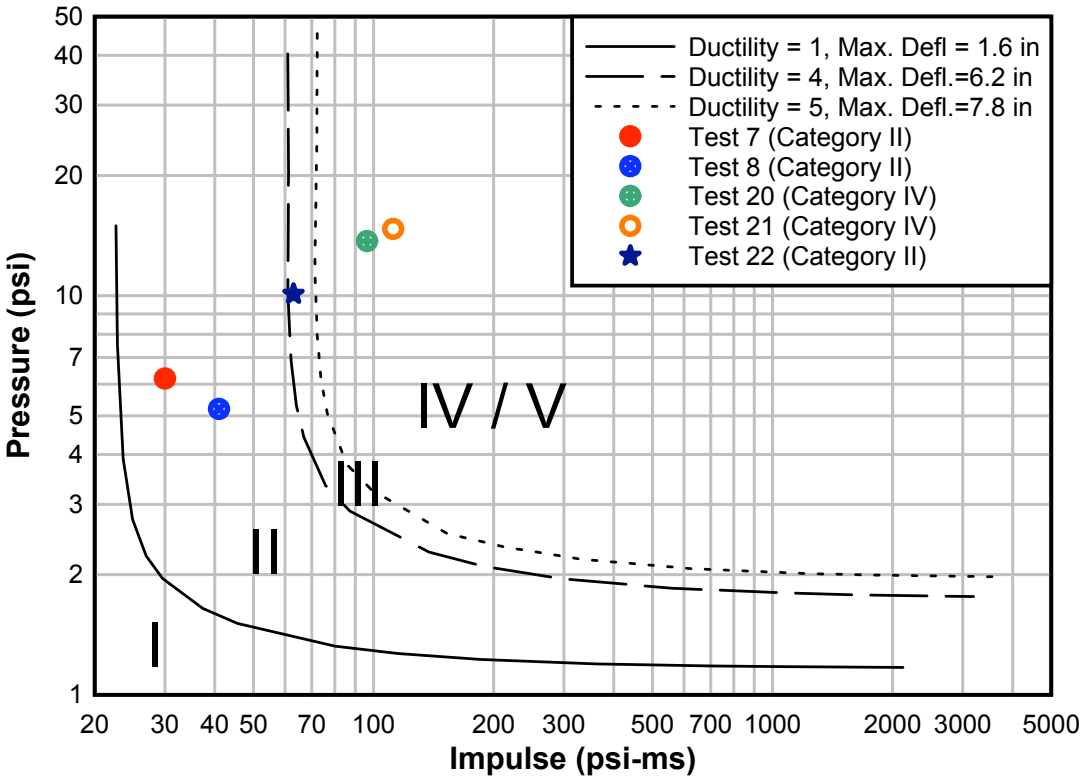

Figure 23. 14GA Vertically Stiffened Panel Door Damage Levels

Rigid Door Frames

Two dynamic tests were conducted with stiffened door frames, representing frames made rigid by grouting during construction (Tests 15 and 16). Although rigid door frames may increase door panel resistance, they decrease the chance of operability, post-blast. The permanent deformation of the door panels was decreased by 88% for the 16GA doors and by 40% for the 14GA doors when using rigid frames. However, both doors rebounded open and were rendered inoperable by latch failure. In door tests without rigid frames, the frame twist and flex, allowing door latches to often disengage with minimal or no damage. Due to the rigidity of the door frames in Tests 15 and 16, the latches failed when the door panels rebounded.

For the reasons above, and with the absence of further dynamic test data for rigid frame doors, shifting of the damage level P-i diagrams to represent increased door panel resistance when using rigid frames is not recommended. The two rigid frame test data points will currently fall within the Category II region of the respective charts, although their responses can be technically characterized as Category III due to latch damage during rebound response resulting in inoperability. Operability is the only parameter which defines the threshold between these two categories, and these categories are intended for use in categorizing static tests which do not subject doors to rebound. The Category III response in these two tests characterized by rebound latch damage is not equivalent to Category III response observed in a case where inoperability is the result of inbound latch damage and door panel push-through. Therefore, it is determined that the use of these diagrams for rigid door frame systems is conservative.

Applicability of ASTM F2247-03 Static Test Data to Dynamic Results

It is evident that the static resistance-deflection functions obtained in this test program provide relatively accurate SDOF models for dynamic behavior of hollow metal door systems. It is logical to assume that FEA models can be validated to produce similar static test results and then used for dynamic analysis. However, there are several aspects of the ASTM standard which this study deems unnecessary for the applicability of static test results to dynamic models.

The ASTM standard calls for subdividing the test load into segmented peaks, and maintaining these peak pressures for a period of no less than three minutes, while unloading the specimen completely to measure permanent deformation after each loading period. However, without a check for operability after each loading period, the permanent deformation data is of no use for damage categorization. Checking and observing for operability may compromise the test results by disturbing a deformed and latched specimen. Furthermore, loading the specimen in segments is unnecessary, as the speed in which the load is applied, even if done in a continuously increasing trend to failure, is still much too slow to induce any possible dynamic effects. Lastly, the repeated cyclic loading may induce failure of internal welds or other structural failure which may not occur at the same deflection during continuously increasing load or dynamic load. It is for these reasons that BakerRisk recommends a continuously increasing load to failure.

Other Concerns

Throughout the test program, the results indicated that variables in frame stiffness and anchorage can play a major role in the response of the doors both under static and dynamic loading. Therefore it is important to consider these door support details when evaluating doors.

ASCE 7-10 Changes to Flood Load Provisions

William L. Coulbourne, P.E. M.ASCE

Director, Wind and Flood Hazard Mitigation, Applied Technology Council, 19266 Coastal Highway, Unit 4, #19, Rehoboth Beach, DE, 703-850-2891 (cell), 302-227-7652 (fax), email: bcoulbourne@atcouncil.org

ABSTRACT

The flood loads that are covered in Chapter 5 of ASCE 7-10 have not changed in any substantive way since ASCE 7-05. The same flood forces are discussed with formulas exactly as they were in ASCE 7-05. The issue for the designer using the flood standard is in trying to understand the unknowns inherent in the formulas so they can make good decisions about how to apply the formulas to real problems.

The paper will describe the issues that designers must consider for each of the flood forces delineated in ASCE 7-10 and where continued work needs to be done to improve the understanding we have about the magnitudes of flood loads. The paper will also offer guidance on the magnitude of the load factors used in strength and allowable stress design situations.

INTRODUCTION

The ASCE 7 flood load provisions we use today have not changed significantly since the ASCE7-02 version. Nevertheless, it appears that many designers are not familiar with the provisions and how they should be applied. The results of the last several coastal flood events suggests we continue to ignore or improperly apply flood forces to building designs, again especially at the coastlines, and the results of significant damage somewhat support that conclusion.

There are many unknowns about flood conditions and forces. For example, as a profession we know little about the magnitude and direction of flood velocity during a design event, especially at coastal locations. Also, while some work has been done on determining floodborne debris forces, we still have low confidence in our method for calculating these forces.

CURRENT ASCE 7-05 FLOOD LOAD REQUIREMENTS

Hydrostatic loads

Hydrostatic loads are caused by standing water and include horizontal loads such as those against a basement wall or vertical loads on immersed objects (buoyancy). The application of hydrostatic loads has not changed over many years since fluid mechanics principles were developed.

The formula for lateral hydrostatic force (lb/ft) is:

$f = 1/2\gamma d^2$ where γ is the unit weight of water (lb/ft^3) and d is the depth (ft) of standing water (or stillwater if coastal wave conditions exist). Figure 1 illustrates the concept of hydrostatic loads and uses d_s as the depth of stillwater. The force is applied normal to the surface at a point 2/3 below the water surface. The unit weight of water can vary from 62.4 lb/ft^3 for fresh water to 64.0 lb/ft^3 for salt water.

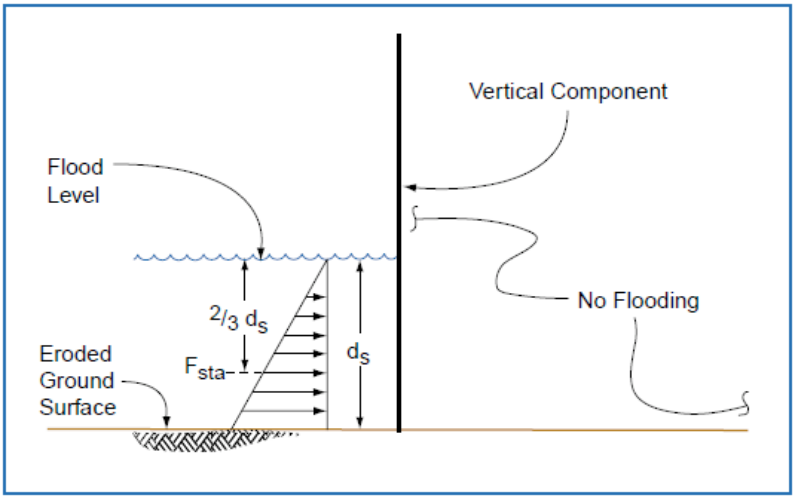

Figure 1. Hydrostatic load diagram

The nuance related to hydrostatic forces for flooded buildings is that there is a floodplain requirement that building foundations in floodplain locations have flood vents in the walls to reduce unbalanced hydrostatic pressure. So while the principles of water pressure against vertical or horizontal surfaces still applies, the application of these loads has been purposely modified by requiring flood openings in walls. An issue that arises frequently is one where standing water will be on both sides of a wall but will be at unequal depths, thus presenting an unbalanced hydrostatic force.

Hydrostatic loads can also act vertically, primarily as buoyancy loads. These loads must be counterbalanced by either the weight of the object or by some attachment of the object to a counterbalancing weight such as a concrete foundation. The formula for buoyancy forces is:

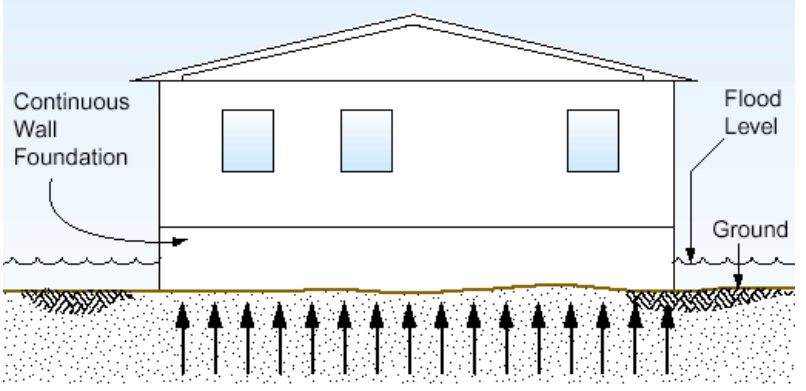

Figure 2. Buoyancy under building

$F = \gamma * volumedisplaced$ where γ is the unit weight of water and the volume displaced is the volume of building, tank, or pool that displaces the water. Figure 2 illustrates the concept of buoyancy. Objects submerged under water also weigh less than they would if not submerged -- by the buoyancy force F (weight of the displaced water) as written above.

Hydrodynamic loads

Hydrodynamic loads are those caused by moving water. The primary flood parameter needed to determine these loads is the velocity of the moving water. In riverine flood conditions where flow is confined to a streambed or channel, our ability to calculate velocity is determined by the relationship between quantity of flow (cfs) and area (sf) of a cross-section used to carry the flow, and the results are frequently provided in a Flood Insurance Study (FIS).

The actual hydrodynamic force depends on the shape of the object water is flowing around. This shape is defined by a drag coefficient. Drag coefficients are provided in fluid mechanics texts or in the Coastal Construction Manual (CCM). The Commentary in ASCE 7-10 suggests using a drag coefficient C_d = 1.25 unless better information is available. The C_d factor usually only varies between 1.0 and 2.0 in any case.

Section 5.4.3 of ASCE 7-10 states that hydrodynamic loads should be calculated by basic principles of fluid mechanics. However, the Standard does allow hydrodynamic loads to be converted to equivalent hydrostatic loads in cases where velocities are less than 10 fps.

The Commentary provides guidance for estimating lower and upper velocity bounds for coastal areas. In coastal areas, velocities are much less certain so the depth of water is used either as a proxy (in areas that are some distance from the flood source) ($V = d \div s$) or to help determine velocity using the wave celerity (in areas that are closer to the flood source) ($V = \sqrt{gd}$).

The result for hydrodynamic force using either the equivalent head method or the equation below is fundamentally the same. If the flow was 8 fps and the water depth was 5 ft, the hydrodynamic force calculated by converting the velocity flow into head and treating it as a hydrostatic force is 387.58 lb/ft. The formula for hydrodynamic force when the velocity is greater than 10 fps is:

$f_{dyn} = 1/2 C_d \rho V^2 d$ where C_d is the drag coefficient, ρ is the mass density of water, V is the velocity and d_s is the depth of water. The unit hydrodynamic force for the example above using this formula is 388 lb/ft (nearly identical to the previous answer). The force f is assumed to act at mid-depth of the water.

Wave loads

Wave loads presented in ASCE 7-10 have formulas to determine loads for both piles and solid walls. The magnitude of the loads is primarily a function of the square of the wave height (which is assumed equal to a depth-limited value of 0.78 x d_s). The formula for breaking wave forces on a pile is:

$F_{brkp} = 1/2\gamma C_d D H_b^2$ where C_d is the drag coefficient for the pile, D is the pile diameter in feet, and H_b is the breaking wave height. C_d is 1.75 for round piles and 2.25 for square piles. F_{brkp} acts at the stillwater elevation.

Wave loads on solid walls is provided for two cases: one case where the water is on one side of the wall only and one case where water is on both sides of the wall by using wall openings to equalize the hydrostatic pressure. The formula accounts for both hydrostatic and dynamic pressures and is shown here as Figure 3 (Figure 5.4-1 in ASCE 7-10). The formula for the condition of water on one side of a wall is:

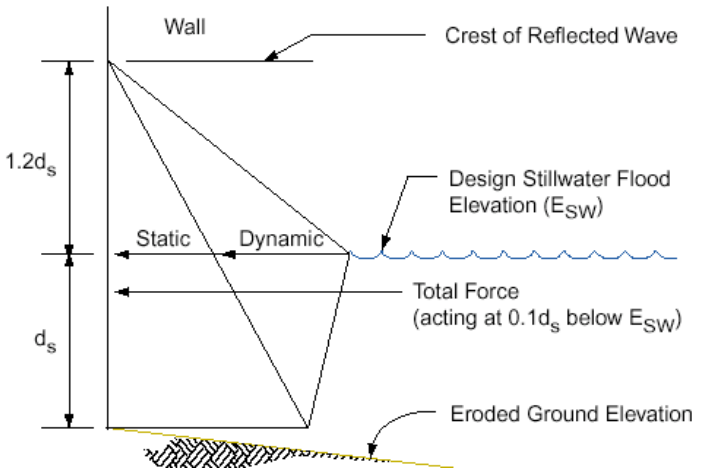

Figure 3. Pressure distribution for wave loads on wall

$F = 1.1 C_p \gamma d^2 + 2.4 \gamma d^2$ where C_p is a dynamic pressure coefficient that is based on the risk category for the structure and d is the stillwater depth. The force F is a unit force per length of wall and acts at the stillwater elevation.

Wave loads on walls where there is water on both sides is determined by the formula:

$F = 1.1 C_p \gamma d^2 + 1.9 \gamma d^2$

The formulas assume that the waves are normal to the walls. If the waves break on the walls at an angle, the forces are reduced by the square of the sin of the incident angle calculated by: $F_{oi} = F \sin^2 \alpha$ where ά is the incident angle and F is the normal force on the wall as determined from above for water on one side or both sides of the wall.

Debris impact loads

Debris impact loads are caused by objects propelled by the water into the structure. These loads are difficult to quantify, and the damage is difficult to predict. ASCE 7-10 has limited information in the body of the standard; most useful information is in the commentary where there is no requirement for users to comply with the design suggestions and no requirement for the Authority Having Jurisdiction to mandate the calculation procedure.

Significant laboratory work has been done in recent years attempting to improve the approach to determining debris loads. It is reasonable to assume that debris striking a structure is a dynamic impulse and is affected by the stiffness of the structure, the material properties of the structure, the velocity of the debris, and the orientation of

the structure component being struck with the debris. In the commentary, the formula for determining the debris force is:

$$F_i = \pi W V C_i C_o C_D C_B R_{\max} / 2g\Delta t$$

This formula requires a substantial amount of designer understanding of the flood debris damage mechanism in order to make accurate assumptions regarding the many coefficients in this formula. There is substantial explanation of the parameters in the ASCE 7-10 Chapter 5 Commentary.

There have been significant variations on how to handle debris impact loads in several documents published by FEMA. The method suggested in the 2000 version of the CCM had contact time of debris with the structure in tenths of seconds. Note in the formula above, that the magnitude of Δt will significantly influence the result given it is in the denominator. FEMA P646 *Guidelines for Design of Structures for Vertical Evacuation from Tsunamis* devotes an appendix to the discussion of impact loads and concludes that an equation that is in the form of constant-stiffness has greater reliability and less variability than an equation that uses Δt. However, one form can be converted to the other, and designers may choose the form to use, depending on whether they have better knowledge regarding impact duration or structure stiffness.

Flood Load Combinations

Chapter 2 in ASCE 7-10 includes flood loads (F_a) as one of the loads that combine with wind and is included for either riverine or coastal flooding conditions. The ASCE 7-10 Commentary for Chapter 2 describes how the load factors were developed but it does not describe what how individual flood loads [hydrostatic (F_{sta}), hydrodynamic (F_{dyn}), breaking waves on piles (F_{brkp}), and debris impact (F_i)] should be combined to yield F_a – the maximum of all flood loads that are applicable or some combination of flood loads that do or can occur simultaneously.

The only reference that discusses the combination of flood loads to use for F_a is the CCM (FEMA 55). In the 2000 version, the guidance for flooding in V Zones was to use the largest of breaking wave loads or hydrodynamic loads and then add debris impact loads to a critical structural element (such as a corner pile or column) and the sum of the largest loads should be used in global overturning or sliding investigations as F_a.

This guidance has still caused confusion so it is being modified again in the new edition of CCM, and may be included in the ASCE 7-15 revision for flood loads. The revised guidance will be published in an upcoming revision to the CCM and will suggest that F_a for global forces be the largest of F_{brkp} or F_{dyn} on the front row of piles + F_{dyn} for all the other piles, and for forces on any one pile, F_a should be the sum of the largest of F_{brkp} or F_{dyn} + F_i. One of the appropriate flood load combinations will be F_a and then must be multiplied by a load factor for use in the appropriate load combination cases.

FLOOD LOAD UNKNOWNS

One of the reasons why the flood load factors used in the load combinations are so large is the uncertainty inherent in flood design. The issues that are important to determining flood load magnitudes yet for which we know little include:

- Velocity: wave celerity is used as the way to determine wave and water velocity yet there is little known research in this area and values for velocity have low confidence
- Wave heights: the assumption in coastal flooding is that waves are depth limited, thus the water depth determines the wave height. The breaker index used to relate wave height to stillwater depth (0.78) is conservative, and lower values may be justified in some cases. Small changes in depth caused by erosion can then change the depth, thus increasing the waves, and this process is constantly changing over the life of a storm.
- Debris impact: the resulting impact to the structure when debris strikes is based on mathematical simulation and testing of debris but in water conditions different than actual wave conditions.

These unknowns – velocity, wave heights and debris impacts are those physical phenomena that largely determine the magnitude of our flood forces and thus the robustness of our flood design and because we know so little about them, a load factor of 2.0 (for strength design) is applied to these loads, increasing the magnitude and the robustness even more.

CCM REVISIONS

Four significant changes will be occurring in the 2011 CCM update:

1. Hydrodynamic load calculations will be made simpler by using just one equation for those loads irrespective of the velocity of the water. This will eliminate some confusion about how to treat these loads while not changing the magnitudes of the results.
2. Debris impact load calculations will also be revised. The current equation shown above for debris loads and that is provided in the ASCE 7-10 Commentary will be changed to:
   $F_i = WVC_D C_B C_{str}$ where C_{str} is a structure coefficient that accounts for structure responses based on construction materials, the suggested time of impact of the debris is 0.03 seconds and default values for other coefficients provided in ASCE 7-10 will be used. The value of C_{str} varies: 0.2 for timber piles or masonry columns, 0.4 for concrete piles or concrete or steel moment-resisting frames, and 0.8 for reinforced concrete walls.

   A comparison of results using the two debris load methods in this paper show that for a timber pile building, with a 1000 lb object as debris, with velocity of 5 fps based on water depth of 5 ft and blockage and importance coefficients of

1.0, F_i using the current formula in ASCE 7-10 equals 1041 lb. F_i using the revised CCM formula equals 1000 lb.

3. Flood load combinations that are required to develop Fa used in the load combinations of ASCE 7-10 Chapter 2 will be made much clearer. This discussion will still not be part of the standard; it will require consideration for the next revision of ASCE 7.

4. An additional flood load will be discussed for the first time in the CCM and this load occurs when the building frame is lower than the top of breaking waves. The load is called wave slam and is important to understand when analyzing damage to buildings. The form of the equation is similar to hydrodynamic loads where a wave slam coefficient is used instead of a drag coefficient.

CONCLUSIONS

The flood damage that has been caused to buildings after the severe flood events of the last 10 years has created an important and urgent need to do a more thorough analysis of flood loads and their effects on buildings in an effort to reduce flood-related losses.

Several aspects of flood design as currently provided in ASCE 7-10 will be changing in the current update of FEMA's CCM due to be published in 2011. Revisions to ASCE 7 flood provisions, likely similar to those in CCM, will be the first significant changes since 2002.

ABSTRACT

The new edition of ASCE 7, ASCE 7-10 *Minimum Design Loads for Buildings and Other Structures*, contains new, revised and updated provisions for dead and live loads to be used for structural design since the previous edition, ASCE 7-05, was published five years before. The provisions of this Standard, adopted by reference by building codes across the nation, impact the structural design of nearly every building in the country, and are used by all who are responsible for these designs.

New material has been introduced which provide for the live load requirements for structures not previously covered in prior editions, specifically for helipads and screen enclosures.

Revisions to the live load requirements for balconies and decks, roofs, and vehicle barrier systems have been made which better define the nature of live loads acting on these particular occupancy areas or structural elements.

There has also been a revision to the live load reduction provisions for structural members in one- and two-family dwellings supporting more than one floor load.

The rationale for the new live load provisions and for the substantial technical revisions to previous live load requirements are presented, relating the discussions and comments by committee members during the five-year balloting period since the previous Standard was published in 2005, and incorporating guidance from the Commentary to the Standard where this helps to clarify some of the new or revised loading requirements.

NEW LIVE LOAD PROVISIONS

Helipad. Load requirements for helipads, defined as structural surfaces that are used for landing, taking off, taxiing, and parking of helicopters, are introduced into the ASCE 7 Standard for the first time. In building codes and other references, different terminology may be used when describing helipads, e.g., heliports, helistops, but the distinctions between these are not relevant to the structural loading issue addressed in the Standard.

The uniform load requirement of 60 psf (2.87 kN/m^2) is a minimum to ensure a degree of substantial construction, but may be lowered to 40 psf (1.92 kN/m^2) where the design basis helicopter has a maximum take-off weight of 3,000 lbs (13.35

kN) or less. The uniform load requirement may not be reduced based on influence area loaded.

Concentrated loads, intended to cover the primary helicopter load and which shall not be concurrent with the uniform load, must also be investigated in the event they produce a greater load effect on the structural members under consideration. Two single concentrated loads (representing the helicopter's two main landing gear, whether skid type or wheeled type, intending to account for an impact factor for a hard landing with many kinds of landing gear), 8 ft (2.44 m) apart shall be applied on the landing area, each having a magnitude of 0.75 times the maximum take-off weight of the helicopter. These loads shall be applied over an area of 8 in. by 8 in. (200 mm by 200 mm).

A single concentrated load of 3,000 lbs (13.35 kN), intended to cover maintenance activities similar to the jack load for a parking garage, shall be applied over an area of 4.5 in. by 4.5 in. (114 mm by 114 mm).

The designer should always consider the geometry of the design basis helicopter and be aware that some helicopter configurations, particularly those with rigid landing gear, could result in substantially higher impact factors that should be considered.

Screen Enclosure. Load requirements for screen enclosures, defined as buildings or parts thereof, in whole or in part self-supporting, having walls and roofs of insect or sun screening using fiberglass, aluminum, plastic, or similar lightweight netting material, which enclose an occupancy or use such as outdoor swimming pools, patios or decks, and horticultural and agricultural production facilities, are introduced into the ASCE 7 Standard for the first time.

The uniform load requirement of 5 psf (0.24 kN/m^2) is applied to the roof frame members only, not the screen, and is nonreducible.

A concentrated load of 200 lbs (0.89 kN) is applied to the supporting roof frame members only. This load provides for miscellaneous loads (such as flower pots or similar items) which may be suspended from the frame members.

REVISED LIVE LOAD PROVISIONS

Balconies and Decks. Previous editions of the Standard prescribed the following uniform live loads:

- Balconies not exceeding 100 ft^2 (9.30m^2) on one- and two-family residences . . . . . 60 psf (2.87 kN/m^2)
- Exterior balconies . . . . . 100 psf (4.79 kN/m^2)
- Patio and roof decks. . . . . same as the area served or the type of occupancy accommodated

ASCE 7-10 revises these uniform live loads to:

- Balconies and decks . . . . . 1.5 times the live load for the occupancy served, but need not exceed 100 psf (4.79 kN/m^2)

There was considerable discussion by committee members for the proposal submitted to revise these live loads which were based on a perceived illogical

distinction between deck and exterior balcony live loads. ASCE 7-05 defined an exterior balcony as *an exterior floor projecting from and supported by a structure without additional independent supports*, and defined a deck as *an exterior floor supported on at least two opposing sides by an adjacent structure and/or posts, piers, or other independent supports*.

A view was put forth that there was no engineering justification for having different live loads for different support conditions, if the use is the same. Either the loads are there, or they aren't, and changing how the element is supported doesn't change the loads. If it was felt that cantilevers or prop cantilevers are less redundant than supported structures and, thus, should have a higher live load requirement, then the solution should be dealt with on the resistance side by increasing the factor of safety rather than by increasing the live load.

Accepting the premise that the loads should not differ based on the structural support conditions, the committee considered the question of the appropriate live load. ASCE 7-05 stipulated uniform live loads ranging from 50 psf (2.40 kN/m^2) for decks serving offices to 100 psf (4.79 kN/m^2) for decks serving public rooms and corridors in hotel/multifamily houses and for exterior balconies.

Establishing the live load to be 1.5 times the occupancy served, but not to exceed 100 psf (4.79 kN/m^2) results in the following examples of revised balcony and deck design loads for various defined occupancies:

Occupancy or Use Served (psf/kN/m^2)	Design Live Load (psf/kN/m^2)
Dining rooms and restaurants (100/4.79)	100/4.79
Office buildings, offices (50/2.40)	75/3.59
Residential, one- and two-family (40/1.92)	60/2.87
Residential, private rooms/corridors (40/1.92)	60/2.87
Residential, public rooms/corridors (100/4.79)	100/4.79

Balconies and decks are generally found contiguous to defined occupancy areas which have defined live loads which, in turn, tend to create balcony and deck areas having similar occupancy or use, but which have generally recognized distinctly different loading characteristics. A number of committee member comments raised the issue of balconies and decks being subjected to concentrated live loads from people congregating along the edges of these areas (e.g., for viewing vantage points), and this loading condition is acknowledged by the increase of the live load for the occupancy served, up to the point of satisfying the loading requirement for most assembly occupancies. The addition of a line load along the edge of all balconies and decks to address the concern of balcony and deck occupants tending to congregate at an edge was judged to be slanted to provide extra insurance for balconies and decks which are cantilevered from their support, and this view was rejected based on the concept that loads are not a function of the structural support conditions.

Vehicle Barrier Systems. The point of application of the stipulated horizontal load of 6,000 lb (26.70 kN), applied to a system of components placed near open sides or walls of garage floors or ramps which act as restraints for vehicles, was changed from 1 ft 6 in. (460 mm) above the floor or ramp surface to between 1 ft 6 in. (460 mm) and 2 ft 3 in. (686 mm).

The impetus for this change was the latest vehicle sales data which showed that approximately 50% of the vehicles sold in 2006 were light trucks, vans or SUV's which had front bumper heights well in excess of the 1 ft 6 in. (460 mm) application height above the pavement that previous editions of the Standard required. The revised upper limit of 2 ft 3 in. (686 mm) covers 96% of these vehicles, with the remaining 4% of vehicles having front bumper heights only 2 in. (51 mm) higher.

A direct reference to the AASHTO *LRFD Bridge Design Specifications* has been added for the design of vehicle barrier systems in garages accommodating trucks and buses.

Reduction in Live Loads. The existing criteria for reducing live loads for members supporting two or more floors permitted a reduced live load provided the influence area for such members, $K_{LL}A_T$, was 400 ft^2 (37.16 m^2) or more, and limited the reduction to $L \geq 0.40L_0$, where:

L = reduced design live load per ft^2 (m^2) of area supported by the member
L_0 = unreduced design live load per ft^2 (m^2) of area supported by the member
K_{LL} = live load element factor
A_T = tributary area in ft^2 (m^2)

There was a proposal submitted to modify the live load reduction permitted for such members, requesting an exception to the criteria and offering an alternate formula for this exception:

> EXCEPTION: For structural members in one- and two-family dwellings supporting more than one floor load, the following live load reduction shall be permitted as an alternate to Eq. 4.7-1:
>
> $$L = 0.7 \times (L_{o1} + L_{o2} + \ldots)$$
>
> L_{o1}, L_{o2}, . . . are the unreduced floor live loads applicable to each of multiple supported story levels regardless of tributary area. The reduced floor live load effect, L, shall not be less than that produced by the effect of the largest unreduced floor live load on a given story level acting alone.

This proposal intended to provide a means of accounting for multi-story live load coincidence effects independent from tributary area effects. The concern was felt important for typical light frame dwelling design because tributary areas of individual repetitive members are small (typically much less than 200 ft^2), yet the effects of floor live load coincidence over multiple stories are valid from a probabilistic standpoint irrespective of cumulative floor area served.

The justification for the proposal was based on a study from *Residential Building Loads: Review and Roadmap for Future Progress* which called attention to the fact that live load reductions in ASCE 7 are limited to influence areas greater than 400 ft^2, yet in the design of residential construction, influence areas for individual repetitive framing elements (i.e., studs and joists) are narrow, long, and commonly less than the 400 ft^2 influence area limitation in ASCE 7, even for multi-story loading conditions. In such cases, live load area reductions of ASCE 7 do not apply even though a multi-story live load coincidence effect may be present for influence areas of less than 400 ft^2.

Recent findings indicate that, depending on the level of correlation between live load processes on different stories, the accumulative multi-story nominal design live load may be reduced by a factor of 0.4 to 1.0.

A view was expressed that differences in level of multi-story live load temporal correlation may be dependent on the nature of the residential occupancy. For typical single-family detached dwellings and townhouses of multiple stories, upper stories are often used as sleeping areas whereas the lower story level is used for day-time activity and gathering purposes.

Based on this information, a live load reduction factor of 0.7 was proposed for the alternative live load reduction formula.

Live Load Reduction Restriction. In ASCE 7-05, live load reductions were not permitted for certain categories of occupancies:

4.8.2 Heavy Live Loads. Live loads that exceed 100 lb/ft^2 (4.79 kN/m^2) shall not be reduced.

4.8.4 Special Occupancies. Live loads of 100 lb/ft^2 (4.79 kN/m^2) or less shall not be reduced in public assembly occupancies.

ASCE 7-10 has editorially revised the text (for Section 4.8.4 only) so that these requirements now read:

4.7.3 Heavy Live Loads

Live loads that exceed 100 lb/ft^2 (4.79 kN/m^2) shall not be reduced.

4.7.5 Assembly Uses

Live loads shall not be reduced in assembly areas.

To clarify these restrictions, a footnote "a" was added to some of the listed occupancies in Table 4-1:

[a]Live load reduction for this use is not permitted by Section 4.7 unless specific exceptions apply.

This has not changed any technical requirements from previous editions of ASCE 7, but was added to simplify those occupancies or uses in Table 4-1 which are not allowed to have their live loads reduced. Footnote "a" flags these occupancies where live loads shall not be reduced, even though some of the occupancies may have live loads less than or equal to 100 lbs/ft^2 (4.79kN/m^2) since they are considered to be assembly areas.

Marquees. The occupancy or use defined as "Marquees" has been listed in the Standard extending back to 1945. The term has not been defined in ASCE 7, but has been defined in building codes as a roofed structure that projects into a public right-of-way.

The committee judged that the relationship between a structure and a right-of-way does not control loads that are applied to a structure, and that a marquee should therefore be designed with loads appropriate for a roofed structure. If the arrangement of the structure is such that it would invite additional occupant loading

(e.g., there is a window or door access that might invite loading by spectators of a parade), then balcony loading should be considered for the design.

Based on this view, the occupancy or use defined as "Marquee" was removed from Table 4-1 in the ASCE 7-10 Standard, and its removal is noted and documented in the Commentary.

Roofs. ASCE 7-05 listed an occupancy or use for "Roofs used for promenade purposes" stipulating a loading of 60 psf (2.87kN/m^2). The term "promenade" was considered to be an archaic term not used elsewhere in the Standard or in building codes. "Promenade purposes" is essentially an assembly use and is more clearly identified as such.

Accordingly, Table 4-1 in the ASCE 7-10 Standard no longer lists "Roofs used for promenade purposes" and provides an occupancy or use for "Roofs used for assembly purposes" with an associated uniform live load stipulated to be the same as the occupancy served.

The occupancy or use defined in ASCE 7-05 as "Roofs used for roof gardens or assembly purposes" has been revised to read "Roofs used for roof gardens" with the associated live load remaining unchanged.

Elevators. Elevator impact loads in the ASCE 7-10 Standard have been changed from a direct 100% impact factor to a reference to ASME A17.1. The provisions in ASME A17.1 include the 100% impact factor, along with deflection limits on the applicable elements.

There were some sentiments (one comment being that "going back and forth between standards is driving the designers nuts") against removing the explicit 100% impact provision and instead incorporating the structural requirements for elevators contained in ASME A17.1 directly into ASCE 7-10. However, the committee felt that the requirements in ASME A17.1 were more complex than a mere increase of 100% in elevator loads for impact and that all elements of the structure that are designed to support elevator loads are required by ASME A17.1 to be designed for increased loads. Furthermore, there are limitations on allowable stresses for allowable stress design (and, by implication, increases in load factors for strength design) to be considered. Replicating the requirements of ASME A17.1 for structural design in ASCE 7-10 would necessitate a large amount of text that could be subject to misinterpretation, and that ASME A17.1 should be consulted directly for these requirements.

ERRATA FOR CHAPTER 3, TABLE 3.2-1

In ASCE 7-10, Chapter 3, Dead Loads, Soil Loads, and Hydrostatic Pressure the text and technical provisions remain unchanged from the previous edition. However, in the printing of the new Standard errors to the footnotes in Table 3.2-1 have occurred.

At the bottom of the Table, the footnote designated as "c" should be corrected to read "b"; the footnote designated as "d" should be corrected to read "c"; and the footnote designated as "b" should be corrected to read "d".

CONCLUSIONS

Changing society needs has had an impact on altering live load requirements for buildings. Some occupancies and uses now present did not exist in the past or were not previously recognized.

Helicopters atop buildings, screen enclosures for outdoor living and working areas, increased and changing uses of balconies and decks, new information concerning live load reduction requirements – these have caused engineers to examine and alter the live loads resulting from these activities, and to revise the ASCE 7 Standard accordingly.

The importance of the ASCE 7 Standard cannot be overemphasized. As a document written in mandatory language and produced under consensus procedures, it has been adopted by reference by the nation's building codes. To this end, there is an ongoing effort by the ASCE committee members to continually review the loading requirements of the Standard, revising existing requirements where research has indicated the necessity for doing so, and incorporating new requirements as our understanding of structural loadings and material behavior increases.

Structural failures, while rare, provide engineers with important information concerning the nature of building loads and their application to structures and, coupled with ongoing structural research and changing society needs, dictates continual change to the loading requirements contained in the ASCE 7 Standard.

It is anticipated that the next edition of the Standard will continue the trend of providing vital new and revised information to the nation's structural engineering community.

Load Combination Requirements in ASCE Standard 7-10: New Developments

Therese P. McAllister,[1] M. ASCE
Bruce R. Ellingwood,[2] Dist. M. ASCE

Abstract

The fundamental load combination requirements for strength design (or load and resistance factor design) appearing in Section 2.3 of *ASCE Standard 7-10* incorporate major revisions, among them the treatment of self-straining actions, fluid and soil loads, load combinations for extraordinary events, and probability-based load requirements for non-specified loads. The last item is based on suggested reliability levels for the new performance-based design procedures in the Section 1.3.1 Commentary. The Commentary to Section 2 of *ASCE Standard 7-10* presents the technical basis for these changes. Since the basis of the traditional allowable stress design combinations was purely judgmental, the ASD combinations in Section 2.4 have been brought into alignment with the strength combinations in Section 2.3, which have a rational reliability basis.

Introduction

The fundamental load combination requirements for strength design (or load and resistance factor design) appearing in Section 2.3 of *ASCE Standard 7-10* were first implemented in 1982 (Galambos et al., 1982; Ellingwood et al., 1982). These load combinations were developed using modern probabilistic models of structural loads and load combinations, statistical data on load intensities, and structural reliability analysis. They utilize a "principal action – companion action" format, which is based on the notion that the maximum combined load (or load effect) during a service period (commonly taken as 50 years) occurs when one time-varying load attains its maximum value while the remaining time-varying loads are at their frequent (or arbitrary-point-in-time) values. Research has demonstrated conclusively that this model best represents how time-varying loads found in other sections of *ASCE 7* combine on structural members, components and systems (Turkstra and Madsen, 1980).

The new load combination requirements for strength design in *ASCE Standard 7-10* incorporate a number of significant revisions. The self straining force, T, fluid load, F, and soil (lateral earth pressure) load, H, are no longer shown in the basic combinations. The reliability analysis leading to *ASCE 7-05*, Section 2.3.2, was supported by an extensive statistical database on dead, live, snow, wind and earthquake loads. However, the self-straining force, fluid load, and soil load do *not* have the same statistical support as the primary loads. Over the years, they were added to the combinations primarily on the basis of judgment, in order to be responsive to users of *ASCE Standard 7* and the other design documents that refer to *ASCE Standard 7*. The treatment of these loads now is addressed separately in

[1] Research Structural Engineer, Building and Fire Research Laboratory, National Institute of Standards and Technology, Gaithersburg, MD 20899 (therese.mcallister@nist.gov)
[2] The Raymond Allen Jones Chair in Civil Engineering, School of Civil and Environmental Engineering, Georgia Institute of Technology, Atlanta, GA 30332 (ellingwood@gatech.edu)

text following the basic combinations to remain responsive to the needs of the design community and, at the same time, to distinguish load combinations technically supported by engineering principles and observed data from those based on judgment. The wind load factors were revised to accommodate the changes in the wind load criteria. The load combinations for extraordinary events, which formerly appeared in a Commentary section, now appear in the *Standard*, where they serve as a point of reference for codes, standards and guidelines for design against disproportionate collapse, fire and other extreme events. In anticipation of the demands for "beyond-code" design from performance-based engineering and to accommodate design of structural systems for loads that are not included in *ASCE Standard 7*, a new standardized method for calculating load and resistance factors has been provided, along with an extended commentary on its proper application. The load 0.6D in the ASD combinations for counteracting loads now is permitted to be increased to 0.9D in certain instances. Since the basis of the traditional allowable stress design combinations was purely judgmental, the ASD combinations in Section 2.4 have been brought into alignment with the strength combinations, which have a rational reliability basis. Additional guidance on the use of LRFD and ASD methods for structural design is provided in the Commentary. Finally, the Commentary to Section 2 of *ASCE Standard 7-10* has been extensively revised to explain the technical basis for these changes.

The following sections describe the basis for these changes in more detail.

Self-Straining Force

The self-straining force, T, was removed from the basic combinations in Sections 2.3.2 and 2.4.1 and now is treated in Sections 2.3.5 and 2.4.4, respectively, with an extended commentary. The self-straining force covers temperature effects, creep, shrinkage, differential settlement and similar effects. The presence of T in the basic combinations was problematic because its effect depends on the material of construction and conditions of constraint. This load situation is more a potential issue for concrete/masonry than it is for steel. Cracking may relieve the stress in concrete/masonry structures; however, it may be detrimental to the performance and serviceability of structures, such as tanks and containment structures.

Self-straining actions should be calculated based on a realistic assessment of the most probable values rather than the upper bound values. The most probable value is the value that can be expected at any "arbitrary point-in-time".

When self straining loads are combined with dead loads as the principal action, a load factor of 1.2 may be used. However, when self straining loads are considered as a companion load, the load factor may be reduced to no less than 1.0, if it is unlikely that the principal and companion loads will attain their maximum values at the same time.

If only limited data are available to define the magnitude and frequency distribution of the self-straining load, then its value must be estimated carefully. Estimating the uncertainty in the self straining load may be complicated by variability in material stiffness of a member or structure under consideration.

Fluid Loads

Fluid load, *F*, defines structural actions in structural supports, framework, or foundations of a storage tank, vessel, or similar container due to stored liquid products. The fluid load of a product in a storage tank shares characteristics of both dead and live loads. It is similar to a dead load in that its self-weight and hydrostatic loads have a maximum calculated value, and that the magnitude of the actual load may have a relatively small dispersion. However, the fluid load is not permanent. Emptying and filling causes fluctuating forces in the structure, the maximum load may be exceeded by overfilling, and densities of stored products in a specific tank may vary.

The fluid load, F, was removed in the basic load combinations. There are no statistical data on fluid loads that can be used to address its treatment in load combination analysis or to support a particular value of load factor. However, when fluid loads are considered in design, they are included with the same load factor as dead load D in combinations 1 through 5, when additive to other loads, and in combination 7 when it provides resistance to uplift forces. To make it clear that the fluid weight in a tank can be used to resist uplift, F was added to load combination 7 where it will be treated as dead load only when F counteracts earthquake load, E. The mass of the fluid also is included in the inertial effect due to E (see 15.4.3) and the base shear calculations for tanks (15.7). Note that the fluid mass effects on stabilization depend on the degree to which the tank is filled. F is not included in combination 6 because the wind load can be present, whether the tank is full or empty, so the governing load case in combination 6 is when F is zero.

Loads due to Lateral Earth Pressure, Ground Water Pressure and Bulk Materials

Loads due to lateral earth pressure, ground water pressure and pressure of bulk materials, H, were removed from the basic load combinations. Similar to fluid loads, there are no statistical data on H. However, where they are present, they are included in the load combinations as follows:

1. where the effect of H adds to the primary variable load effect, include H with a load factor of 1.6;
2. where the effect of H resists the primary variable load effect, include H with a load factor of 0.9 where the soil load is permanent or a load factor of 0 for all other conditions.

Uncertainties in lateral forces from bulk materials, included in *H*, are higher than those in fluids, particularly when dynamic effects are introduced as the bulk material is set in motion by filling or emptying operations. Accordingly, the load factor for such loads is set equal to 1.6.

Where H acts as a resistance, a factor of 0.9 is suggested if the passive resistance is computed with a conservative bias. The intent is that soil resistance be computed for a deformation limit appropriate for the structure being designed, not at the ultimate passive resistance. Thus an at-rest lateral pressure, as defined in

the technical literature, would be sufficiently conservative. Higher resistances than at-rest lateral pressure are possible, given appropriate soil conditions. Fully passive resistance seldom would be appropriate because the necessary deformations in the soil would cause the structure to be compromised. Furthermore, there is great uncertainty in the nominal value of passive resistance, which would also argue for a lower factor on H.

Load Factors on Wind Loads

ASCE Standard 7-10 contains new wind speed maps in Chapter 26. The wind loads, W, for ordinary buildings and other structures in the previous edition of ASCE Standard 7 were based on mapped 3-s gust wind speeds with a 50-year mean recurrence interval (MRI) [the MRIs were 100 years for critical facilities.] and the load factor applied to the nominal wind load was 1.6. The wind climatology in interior and in hurricane-prone coastal areas of the United States is different, and using the 50-yr MRI as a basis led to differences in facility risk in those areas. ASCE Standard 7-10 now maps the "design-basis" wind speed directly (MRI of 700 years for ordinary buildings; 1700 years for critical facilities), and applies a load factor of 1.0 to the resulting wind load. This approach ensures that the risk is essentially uniform and better aligns the manner in which ASCE 7 treats the wind and earthquake hazards. At the same time, the wind load factor in Section 2.3 was reduced from 1.6 to 1.0 in combinations where it was the principal load to maintain the reliability of the load combinations.

Counteracting Loads in ASD

Beginning with the 1998 edition of ASCE Standard 7, the load factor on the nominal dead load in ASD combinations (7) and (8), which govern counteracting loads, was reduced to 0.6 to achieve consistency between ASD and LRFD. This factored load, 0.6D, has been viewed as problematic and has drawn criticism from segments of the structural engineering community. Ellingwood and Li (2009) have confirmed that this reduction was warranted and necessitated by the large variability in W and E; failure to reduce the gravity load for design (i.e., not using 0.6 D) may lead to inadequate safety in many counteracting load situations. However, in the design of certain non-building structures, foundations and in special reinforced masonry shear walls, adjustments to ASD combinations (6) and (7) may be justified on other grounds. These adjustments are reflected in the Exceptions to the ASD combinations in Section 2.4.1.

The first of these situations is defined by Exception 2 of Section 2.4.1 for non-building industrial facilities, which permits the wind load factor in the counteracting load combination to be modified for foundation design of non-building structures. When wind forces act on a structure, the structural action causing uplift at the structure-foundation interface is less than would be computed from the peak lateral force, due to area-averaging. Accordingly, the wind effects can be reduced when checking global stability and bearing or uplift at the soil-foundation interface. Accordingly, for situations where a foundation element exceeds 1000 ft^2 (93 m^2), on either a vertical or a horizontal plane, W can be replaced with 0.9W in combination (7), excluding anchorage of the structure to the foundation. Exception (2) applies to the design of the foundation and to self-anchored ground-supported tanks. For different reasons, a similar approach is

already provided for seismic actions by ASCE 7-05 Section 12.13.4 and in Section 12.4.2.2, exception 2.

The second of these situations is defined by Exception 3 for Special Reinforced Masonry Walls. This Exception is based upon three factors, all of which yield a conservative design for overturning resistance under the seismic load combination:

1. The basic allowable stress for reinforcing steel is 40% of the specified yield, f_y;
2. The minimum reinforcement required in the vertical direction provides protection against the circumstance where the dead and seismic loads result in a very small demand for tension reinforcement; and
3. The maximum reinforcement limit prevents compression failure under overturning.

Of these three, the low allowable stress in the reinforcing steel is the most significant. Exception 3 will be reconsidered if the allowable stress in tension reinforcement in the standard for design of masonry structures is increased above $0.4f_y$.

Load Combinations for Extraordinary Events

Section 2.5, Load Combinations for Extraordinary Events, provides load combinations for low-probability events such as fire, explosions and vehicular impact. Since the 1995 edition of ASCE Standard 7, Commentary C2.5 has provided a set of load combinations that were derived using a probabilistic basis similar to that used to develop the load combination requirements for ordinary loads in Section 2.3 (Ellingwood and Leyendecker, 1978; Ellingwood and Dusenberry, 2005). In recent years, social and political events have led to an increasing desire on the part of architects and structural engineers, project developers and regulatory authorities to enhance design and construction practices for certain buildings by providing additional structural robustness and to lessen the likelihood of disproportionate collapse if an extreme event were to occur. Several Federal, state and local agencies have adopted policies that require new buildings and structures to be constructed with such enhancements of structural robustness [GSA 2003, DOD 2009]. Concurrently, advances in structural engineering for fire conditions (e.g., AISC 2005 Specification, Appendix 4) raise the prospect that new structural design requirements for fire safety will supplement the existing deemed-to-satisfy provisions in the next several years. To meet these needs, the load combinations for extraordinary events, which formerly appeared in the Commentary, were moved up to Section 2.5 Standard, where they now serve as a point of reference for codes, standards and guidelines for design against disproportionate collapse, fire and other extreme events.

Performance-Based Engineering

Engineers may wish to develop load criteria for strength design that are consistent with the requirements in *ASCE Standard 7* for situations that are not covered explicitly in the *Standard*. They also may wish to consider loading criteria for

special situations, as required by the client in performance-based engineering (PBE) applications, in accordance with Section 1.3.1.3. In addition, groups writing standards and specifications for strength design of structural systems and elements may wish to develop resistance factors that, when used with the load requirements in the *Standard*, permit a stipulated reliability to be achieved. Such load criteria must be developed using a standardized procedure to ensure that the resulting factored design loads/load combinations will lead to target reliabilities (or levels of performance) that can be benchmarked against the common load criteria in Section 2.3.2 and in existing standards and specifications governing strength design for common construction materials. Section 2.3.6 permits, for the first time, the engineer to develop load combinations for strength design through a standardized method that is consistent with the methodology used to develop the basic combinations that appear in Section 2.3.2.

Use of LRFD and ASD Methods

Section 2.1 requires the engineer to use either ASD or LRFD exclusively when designing a structure. This requirement dates back to the introduction of the load combinations for strength design (LRFD) in the 1982 edition of the Standard. The General Commentary in C2.1 notes that an indiscriminate mix of the LRFD and ASD methods is not permitted in structural design, as such an approach may lead to unpredictable structural system performance. The reliability analyses and code calibrations leading to the LRFD load combinations were based on member limit states rather than system limit states.

However, designers of cold-formed steel and open web steel joists often design (or specify) these products using ASD and, at the same time, design the structural steel in the rest of the building or other structure using LRFD. The AISC *Code of Standard Practice* states that cold-formed products and steel joists are not considered to be structural steel. Foundations are also commonly designed using ASD, while strength design is used for the remainder of the structure. Using different design standards in these situations has not been shown to be a problem. Thus, Section 2.1 is intended to permit current industry practice while, at the same time, not permitting LRFD and ASD to be mixed indiscriminately in the design of a structural frame.

Summary

The load combination requirements for strength design in *ASCE Standard 7-10* incorporate a number of major revisions. Changes to the ASD requirements were made for consistency with the probability-based strength design requirements:

- Self-straining force, T, was removed from the basic combinations and now is treated in a separate section, with an extended commentary.

- Wind load factors were revised to accommodate the changes in the wind speed map in Section 26.

- The load 0.6D in the ASD combinations for counteracting loads may be increased to 0.9D in design of certain non-building structures and special reinforced masonry shear walls;

- Load combinations for extraordinary events, formerly in a Commentary section, were moved up to the Standard, as a point of reference for codes, standards and guidelines for design against disproportionate collapse, fire and other extreme events.

- A standardized method for calculating load and resistance factors has been provided, along with an extended commentary on the application of this method.

Introduction of Performance Criteria into Chapter 1 of ASCE 7-10

Ronald O. Hamburger, SE, SECB[1]

ABSTRACT

Since its inception, the purpose of the ASCE 7 standard has been to set minimum design loads for buildings and other structures, such that they would provide safe and reliable service. It has never been intended to comprise a complete design standard, deferring for the most part to other industry standards for requirements for determination of strength and detailing. Because reliable seismic performance is as much dependent on structural detailing as it is strength and stiffness, the seismic chapters have also included detailing requirements as a condition of loading determination. The 2010 revisions to Chapter 1 of the standard take a major step towards conversion of the document into a comprehensive design standard with the introduction of a performance-based design alternative. The Performance-based design process is one of setting performance criteria then evaluating the ability of a design, either through testing, simulation or a combination of these, to meet these criteria. As such, design loading, in the conventional sense is not used, but rather design scenarios, which include consideration of inherently uncertain loading events and equally uncertain structural response, must be evaluated. Initially, the performance-based option is likely to see most application in seismic and force-protection design, where it already experiences wide use. However, as engineers become more familiar with this approach and the freedom it provides, it will likely see wider use with satisfaction of performance criteria being the primary objective of design.

INTRODUCTION

U.S. building codes first developed in the late 19th and early 20th century as a means of avoiding large scale life and property loss in urban conflagrations, earthquakes and other disasters. These early codes were developed on an experience-basis, by documenting and codifying procedures and methods that had been observed over time to provide acceptable performance, while prohibiting designs and procedures observed to perform unacceptably. The developers of these early codes recognized that if the codes only permitted design and construction practices validated by past successful experience, there would be no way to permit the use of new design and construction methods and provide for an ability for practice to evolve and modernize. Therefore, since their inception, U.S. building codes have included so-called "alternative means" clauses that specifically permit the use of design and construction methods not specifically prescribed by the code, provided that the proponent for the alternative method could demonstrate to the building official's satisfaction, that the alternative approach would provide equivalent durability, serviceability and protection of the public safety. Since durability, serviceability and protection of the public safety are measures of performance, the use of alternative means eventually came to be known as performance-based design.

In recent years, performance-based design approaches have become increasingly popular and have been used not only to introduce new design methods and construction procedures, but also

[1] Senior Principal, Simpson Gumpertz & Heger Inc. The Landmark @ 1 Market, Suite 600, San Francisco, CA 94105, rohamburger@sgh.com

as a means of designing building types and occupancies not previously considered by the code, designing buildings capable of superior performance, reducing project construction costs, or providing other building attributes not achievable by strict conformance to the code. Performance-based design approaches have seen extensive use in seismic engineering, fire engineering and force-protection engineering.

Present-day approaches to performance-based engineering evolved in the 1990s with the development of the ATC-40 (ATC, 1996) seismic evaluation and retrofit methodology and the FEMA-273/274 *Guidelines and Commentary for Seismic Rehabilitation of Buildings* (ATC, 1997), now revised and standardized as the ASCE 41.06 (SEI, 2006). These procedures form the basis not only for performance-based seismic design but also design to protect against blast and progressive collapse. Figure 1, adopted from the FEMA P-58 (ATC, 2011) report presents the basic performance-based design process. As shown in the figure, the basic steps include 1) confirmation with all parties that the approach is acceptable, 2) selecting the performance project performance objectives, 3) developing an initial design, 4) assessing the design's performance capability, 5) comparing the design's performance capability against the objectives set in the second step, and 6) revision of the design and re-evaluation of its performance capability until the design is demonstrated capable of meeting the performance objectives agreed to by the building official.

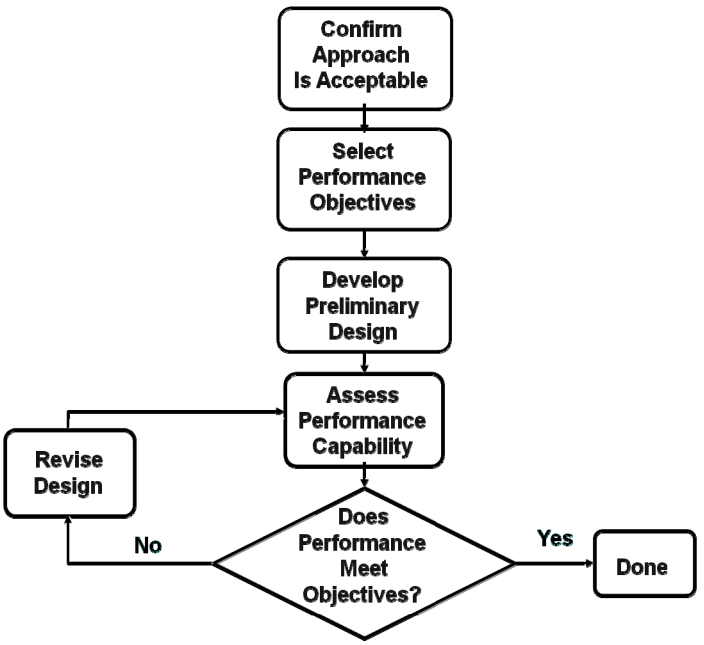

Figure 1 – Performance-based Design Process

For the first time, the 2010 edition of the ASCE 7 loading standard (SEI, 2010) addresses this design process. Chapter 1 of the standard specifies the acceptable procedures to assess a design's performance, and demonstrate that it meets acceptable criteria, while commentary to Chapter 1 describes the performance objectives inherent in buildings conforming to different occupancy categories, renamed in the 2011 edition of the standard as Risk Categories.

PERFORMANCE OBJECTIVES

Performance objectives are quantitative statements of the desired behavior for a design, given that it is subjected to a particular design scenario or event. Classical structural design methods are based on achievement of two performance objectives: 1) a service level state, and 2) a strength level state. Service level behavior is typically expected to preclude damage that would result in strength loss or require repair, while maintaining deflections and vibration at levels that do not impair the structure's use. The strength level state is specified as a means of protecting against structural failure. Service level behavior is expected to be achieved under the routine "point in time" loads that structures will experience on a routine basis throughout their lifetimes. Strength level behavior is targeted to assure that structures have a suitably low probability of incurring loading that would exceed their capacity and trigger failure. Early Allowable Stress Design procedures sought to meet these performance objectives, by requiring design of structures to provide acceptable control of deflections under code-specified loads (the Service level state) and to provide a suitable margin against failure (the Strength level state) through specification of allowable stresses that incorporated a suitable factor of safety. Later, when Load and Resistance Factor design methods were developed, researchers set specific notional reliability targets, or acceptable probabilities of failure, and using statistical methods, developed load and resistance factors to account for the uncertainty inherent in load and strength prediction and to achieve the desired reliability.

For the Service level state, the standard continues to rely on the time-honored methods first introduced with Allowable Stress design procedures. However, for the first time, Commentary to Chapter 1 of ASCE 7-10 sets forward in one location, the strength-level reliability criteria that underpin the Load and Resistance Factor Design method. In parallel with this introduction, Commentary to Chapter 2 of the standard set forth the procedures for development of load and resistance factors to achieve these reliabilities, given quantification of loading and resistance variability in the form of dispersions.

The standard differentiates between reliabilities sought for seismic loading and other sources of loading, such as that from the structure's self weight, occupant (live) loading, snow, wind and thermal effects. Table C1.3.1a of the standard, reproduced below as Table 1 below, specifies desired reliability as a function of the risk associated with failure. Risk of failure is measured in two ways: 1) by a structure's occupancy, and the number of persons that would be put at jeopardy should failure occur; and, 2) by the nature of the failure mode. Three failure mode natures are recognized: 1) gradual and non-progressive; 2) gradual but progressive; and, 3) sudden and progressive. Failures of the first type occur slowly, and are foreshadowed by evidence including visible deformation and cracking that provide warning that failure is impending. Also, such failures tend to be localized and do not result in spread of failure to adjacent elements. The second type of failure occur slowly, as do the first type, but can lead to progression of failure, with more global structural consequences. The third type, are failures that are sudden, and therefore do not provide evidential warnings of their occurrence, and which also progress to more global failures. Progressively more reliable performance (lower probability of failure) is required for each of these various failure types.

Table 1 – Acceptable Reliability for Loading Other than Seismic

	Risk Category			
Basis	**I**	**II**	**III**	**IV**
Failure that is not sudden and does not lead to wide-spread progression of damage	$P_F = 1.25 \times 10^{-4}$/yr $\beta = 2.5$	$P_F = 3.0 \times 10^{-5}$/yr $\beta = 3.0$	$P_F = 1.25 \times 10^{-5}$/yr $\beta = 3.25$	$P_F = 5.0 \times 10^{-6}$/yr $\beta = 3.5$
Failure that is either sudden or leads to wide-spread progression of damage	$P_F = 3.0 \times 10^{-5}$/yr\ $\beta = 3.0$	$P_F = 5.0 \times 10^{-6}$/yr $\beta = 3.5$	$P_F = 2.0 \times 10^{-6}$/yr $\beta = 3.75$	$P_F = 7.0 \times 10^{-7}$/yr $\beta = 4.0$
Failure that is sudden and results in wide spread progression of damage	$P_F = 5.0 \times 10^{-6}$/yr $\beta = 3.5$	$P_F = 7.0 \times 10^{-7}$/yr $\beta = 4.0$	$P_F = 2.5 \times 10^{-7}$/yr $\beta = 4.25$	$P_F = 1.0 \times 10^{-7}$/yr $\beta = 4.5$

The reliability indices are provided for a 50-year service period, while the probabilities of

The Risk Categories referenced in Table 1 (C1.3.1a of ASCE 7-10) serve the same role as the Occupancy Categories contained in earlier editions of the standard. The Committee felt that the term Risk Category more appropriately recognized their role in the design process, i.e., to adjust design conservatism based on the acceptable risk of failure, as reflected in Table C1.3.1a, rather than just the functional use of the structure, as implied by the term Occupancy. In parallel with this change in terminology, the standard deleted the lists of building occupancy types associated with each Risk Category, and instead, defined the categories in broad terms. Risk Category I now includes structures that are typically not habited and whose failure poses little risk to human life. Risk Category II, III and IV structures are habited by progressively greater numbers of persons, or have other attributes, e.g. containment of hazardous materials, or provision of essential service, that could affect the lives of many persons. Commentary to Chapter 1 suggests that Risk Category should be selected based on the number of persons placed at risk, should the structure fail, as represented in Figure C1.1, reproduced as Figure 2, below. Recognizing that these concepts may be uncomfortable to some engineers and building officials, the standard requires that Risk Category not be assigned at a lower value than the corresponding Occupancy Category, specified by the building code.

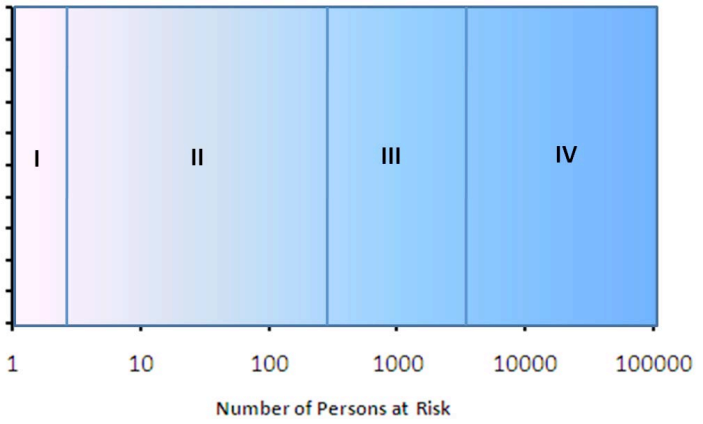

Figure 2 – Risk Category and Persons Placed at Risk (ASCE 7-10, Figure C1.1)

In Table 1 (Table C1.3.1a), the P_F value for each Risk Category and failure mode type is the acceptable annual frequency of failure for a single member or connection, under the specified loading. The term β in the table is the so-called reliability index, which is the number of standard deviations below the mean probable value at which design capacity is set to achieve these annual failure frequencies. The reliability indices are used in the calculation of resistance factors contained in the materials industry design standards, as explained in companion commentary in Chapter 2.

Historically, the profession has accepted much higher risk of seismic-initiated failure than it has for other load types. This is a function of the infrequency of severe seismic events, the severity of the loading when it occurs, the high uncertainty associated with prediction of that loading and the economic impracticality of designing to achieve reliability levels comparable with those that underpin design procedures for other load types. The reliability criteria adopted by the standard for seismic loading are based on those contained in FEMA P-750 (BSSC, 2009). Table C1.3.1b of the standard, reproduced as Table 2 below states these criteria.

Table 2 – Acceptable Earthquake Reliability

Occupancy Category I and II	
Total or partial structural collapse	10% conditioned on the occurrence of Maximum Considered Earthquake shaking
Failure that could result in endangerment of individual lives	25% conditioned on the occurrence of Maximum Considered effects
Occupancy Category III	
Total or partial structural collapse	6% conditioned on the occurrence of Maximum Considered Earthquake shaking
Failure that could result in endangerment of individual lives	15% conditioned on the occurrence of Maximum Considered Earthquake shaking
Occupancy Category IV	
Total or partial structural collapse	3% conditioned on the occurrence of Maximum Considered Earthquake shaking
Failure that could result in endangerment of individual lives	10% conditioned on the occurrence of Maximum Considered Earthquake shaking

For seismic loading, the table distinguishes between failures that could result in endangerment of individual lives, such as failure of anchorage for an architectural element or mechanical equipment item, as opposed to partial or total structural collapse which would place many lives in jeopardy. In all cases, seismic reliability is conditioned on the occurrence of Maximum Considered Earthquake shaking as depicted on national seismic design maps maintained by the United States Geologic Survey. For most regions of the United States, Maximum Considered Earthquake shaking has an annual frequency of exceedance of approximately 4×10^{-4}, adjusted so that the annual probability of partial or total collapse for appropriately configured, ordinary occupancy structures (Risk Category II) does not exceed 2×10^{-4}. This can also be stated as a 1% risk of collapse or partial collapse in 50 years, which as can be seen in comparison with the values in Table 1, is several orders of magnitude higher risk

of failure than is accepted for other load conditions. In regions of high seismic activity, within a few kilometers of major active faults, such as portions of California, the acceptable risk is set higher, with Maximum Considered Earthquake shaking specified based on deterministic events that have return periods of hundreds, as opposed to thousands of years.

PERFORMANCE ASSESSMENT

The standard sets three means of demonstrating that a design is capable of meeting the prescribed performance objectives. Two of these are satisfaction of the prescriptive provisions contained in the standard and the building code. These procedures are now respectively called the Allowable Stress Design Procedures and the Strength Design Procedures. Both procedures are "deemed to comply" means, in that the engineer using these procedures never actually evaluates the design's performance capability, but instead, demonstrates that the design conforms to prescriptive criteria that are deemed capable of providing the desired performance. Using the Allowable Stress Design Procedures, engineers use the load intensities for dead, live and environmental loads specified in later chapters of the standard, combine them in accordance with the Allowable Stress Load Combinations of Section 2.4 of the Standard and assure that the design complies with the appropriate strength and detailing criteria of referenced national design standards. Under the Strength Procedures, engineers use the same load intensities, but combine them using the Strength Load Combinations of Section 2.3 and again assure that their design provide adequate strength and meet the detailing criteria of the referenced national design standards. In addition, using either the Allowable Stress or Strength procedures, engineers must assure that their designs comply with the Serviceability criteria of Section 1.3.2 of the standard.

The third, Performance-based Procedure is specified by Section 1.3.1 which requires demonstration by analysis, or by a combination of analysis and testing, that structures are capable of providing reliability equivalent to that anticipated of structures designed using the Strength Procedures, and described in the section on Performance Objectives, above. Although rigorous methods of structural reliability analysis could be used to satisfy the requirements of this Section, few practicing engineers today have the knowledge and training to employ such methods, and therefore, it is unlikely that such methods will be frequently used. Instead, it is more likely that two other approaches will be adopted. One of these involves the use of Load and Resistance Factor Methods, but in which the engineer develops custom resistance factors based on the unique characteristics of their structural system and the inherent uncertainties. Commentary to Chapter 2 of the standard provides guidance on the implementation of this technique.

The second approach, and the one most likely to be used in the immediate future involves definition of conservative deterministic design scenarios and performing simulations (analyses) of the structure's response to these scenarios to demonstrate conformance with the intended performance. For seismic design, this approach involves selection of suites of ground motion records that represent the Maximum Considered Earthquake shaking intensity, then performing nonlinear response history analysis of the structure to predict its response and qualitatively, a suitable low probability of collapse or partial collapse. For wind design, the scenario event would consist of flashover fires with appropriate estimates of fuel and air flow. For wind design, the scenario events would consist of suitable wind storm simulations.

The standard requires that analytical models used to predict performance be benchmarked against suitable test data. Where national standards specify appropriate test procedures, such as those indicated by AISC 341 (AISC, 2010) for testing of steel moment connections, those must be used. Based on requirements contained in AISI S100-07 (AISI, 2007), analytical modeling parameters and acceptance criteria for simulations must be based on at least three tests. Where the coefficient of variation for parameters obtained from the tests exceeds 15%, additional tests must be performed until either the coefficient of variation is 15% or less, or at least 6 tests have been performed.

The testing and analytical procedures used in performance-based approaches are sophisticated and few building departments have personnel with suitable training to perform meaningful review of the designs and supporting data. Therefore, the standard requires that designs justified by performance-based procedures be subjected to rigorous peer review of the assumptions, underlying test and analytical data, reliability calculations and detailing. Peer review must be performed by knowledgeable engineers and researchers with appropriate experience and knowledge of the structural systems and materials. Peer reviewers must present certification to the building official that they have performed the review and that they concur with its performance capability.

CONCLUSION

The inclusion of performance-based design procedures in the 2010 edition of ASCE 7-10 is an important step in the evolution of the standard. Though a long history of acceptance of performance-based designs by building officials exists, neither the building codes nor their referenced standards have ever attempted to quantify the required performance characteristics for structures nor the procedures used to demonstrate compliance. The ASCE 7-10 standard does both, for the first time publishing quantitative reliability standards that designs should be capable of meeting, and also indicating acceptable procedure for demonstrating compliance.

Much additional work needs to be done in future editions of the standard to improve and enhance these new procedures. In particular, the performance criteria specified in Tables 1 and 2 above focuses on 1) protection of life safety, and 2) structural performance. However, structural design is intended to protect more than life safety, including continued function and operability of some structures, and minimization of repair and replacement costs to acceptable levels. Performance criteria for these other considerations are still needed and should be considered in the development of future editions of the Standard. In addition, the ASCE-7 standard also addresses design of cladding and nonstructural components to resist structural loading. The performance criteria of Tables 1 and 2 should be expanded to better address these building components.

Performance-based design has already become a popular approach for the seismic design of tall and important structures worldwide, as well as design to resist terrorist attach and unanticipated events. In New Zealand and Australia, performance-based design is also commonly used to justify fire/life safety design features of buildings. The introduction of performance-based design procedures into ASCE 7-10 should facilitate the further development of this approach in the U.S. and its spread to a broader range of structure types and design considerations.

ABSTRACT

ASCE 7-10 "Minimum Design Loads for Buildings and Other Structures" contains several changes regarding wind loads. The major editorial change is a complete reorganization to a multiple-chapter format as done previously for seismic loads with the objective being to make the provisions easier to follow. Technical changes include the introduction of new wind speed maps to be used with a 1.0 load factor for LRFD and a 0.6 load factor for ASD, the reintroduction of Exposure D for water surfaces in hurricane-prone regions, and revised wind-borne debris regions. A new simplified procedure for buildings up to 160 ft has been added based on the provisions for buildings of all heights.

INTRODUCTION

The major changes to the wind load provisions of ASCE 7 introduced in ASCE 7-10 are:

- Reorganization of wind load provisions
- Wind speed maps
- Re-introduction of Exposure D in hurricane-prone regions
- Wind-borne debris region
- Simplified procedure for buildings ≤ 160 ft

This paper presents a general background on the basis for these changes. Thirty other changes related to wind loads were included in ASCE 7-10. The majority of these changes were editorial but some did include technical changes. These include:

- Minimum wind loads
- Improved exposure and roughness examples
- Revisions to low-rise "envelope" method
- Rooftop equipment

REORGANIZATION OF WIND LOAD PROVISIONS

The wind load provisions of Chapter 6 in ASCE 7 have been reorganized into 6 new Chapters. In recent years, there has been much discussion about the layout and presentation of the wind load provisions in ASCE 7. While, ASCE 7-98 did make some improvements to the format (introduction of the 3 Methods), much of the important information was buried deep within the paragraph numbering. In addition, Method 2 Analytical Procedure actually contained several analytical methods embedded within the section (e.g., Buildings of All Heights and Low-rise Buildings). While the provisions were technically correct and properly numbered, understanding and applying the appropriate wind loads could be somewhat cumbersome.

The primary goals of the reorganization effort were to keep the section numbering smaller and to locate major subject areas as distinct chapters. Additionally, it was desired to order the wind provisions in a logical sequence for the general structural design community. Accomplishing these goals led to the creation of 6 distinct chapters and the relocation of the provisions into their most logical new chapter. For example, the provisions for determining MWFRS loads are in separate chapters from Components and Cladding. Additionally, the different methods for determining MWFRS loads are located in the 3 separate chapters – Chapter 27 Directional Procedure (formerly buildings of all heights in Method 2); Chapter 28 Envelope Procedure (formerly low-rise buildings in Method 2); and Chapter 29 Other Structures and Building Appurtenances (formerly embedded in Method 2).

Each chapter was again subdivided into “parts” where deemed appropriate for clarity. For example in Chapter 28 the analytical method for determining wind loads for low-rise buildings is identified as Part 1 and the simplified method for determining wind loads for low-rise buildings is identified as Part 2. Similar subdivisions occur in Chapters 27 and 30.

To ease the transition to the new format and to facilitate improved awareness of the provisions applicable to the various methods, each chapter and parts contain tables that specifically identify and outline the steps and provisions applicable for that respective chapter or part. Table 27.2-1 shown below is an example of one of the outlines presented for Part 1 in Chapter 27.

Table 27.2-1
Steps to Determine MWFRS Wind Loads
Enclosed, Partially Enclosed and Open Buildings of All Heights

Step 1: Determine risk category of building or other structure, see Table 1.4-1
Step 2: Determine the basic wind speed, V, for the applicable risk category, see Figure 26.5-1A, B or C
Step 3: Determine wind load parameters:
- Wind directionality factor, K_d, see Section 26.6 and Table 26.6-1
- Exposure category, see Section 26.7
- Topographic factor, K_{zt}, see Section 26.8 and Table 26.8-1
- Gust Effect Factor, G, see Section 26.9
- Enclosure classification, see Section 26.10
- Internal pressure coefficient, GC_{pi}, see Section 26.11 and Table 26.11-1

Step 4: Determine velocity pressure exposure coefficient, K_z or K_h, see Table 27.3-1
Step 5: Determine velocity pressure q_z or q_h Eq. 27.3-1
Step 6: Determine external pressure coefficient, C_p or C_N
- Fig. 27.4-1 for walls and flat, gable, hip, monoslope or mansard roofs
- Fig. 27.4-2 for domed roofs
- Fig. 27.4-3 for arched roofs
- Fig. 27.4-4 for monoslope roof, open building
- Fig. 27.4-5 for pitched roof, open building
- Fig. 27.4-6 for troughed roof, open building
- Fig. 27.4-7 for along-ridge/valley wind load case for monoslope, pitched or troughed roof, open building

Step 7: Calculate wind pressure, p, on each building surface
- Eq. 27.4-1 for rigid buildings
- Eq. 27.4-2 for flexible buildings
- Eq. 27.4-3 for open buildings

Additionally, a table was added to the commentary that provides a cross-reference of all sections, figures, and tables between ASCE 7-05 and ASCE 7-10. Sections applicable to ASCE 7-05 are shown in the left column in numerical sequence so that users familiar the ASCE 7-05 may easily locate the applicable sections in ASCE 7-10.

WIND SPEED MAPS

Multiple Maps. The decision to move to multiple ultimate, limit state, or strength design wind speed maps to be used in conjunction with a wind load factor of 1.0 for LRFD instead of using a single map coupled with an importance factor and a wind load factor of 1.6 was made because:

- An ultimate or strength based map brings the wind design approach more in line with that used for seismic design in that they both essentially eliminate the use of a 1.0 load factor for strength design.
- The multiple map approach eliminates the inconsistencies in the use of the importance factor that strictly varies with location and between the hurricane and non-hurricane regions.

- The new maps establish uniformity in the return period for the design basis winds, and they more clearly convey that information
- The new maps, by providing the design speeds directly, more clearly inform owners and their consultants about the storm intensities for which their designs are performed.

The hurricane importance factor specified in ANSI A58.1 1982 and ASCE 7-93 was eliminated from the 1995 Edition of ASCE 7 by incorporating it into the wind speed contours. Consequently, at no time since the introduction of ASCE 7-95 have the wind speed contours in the hurricane prone region been representative of a 50 year return period wind speed, although most users erroneously thought this was the case. In the development of the wind speed map used in ASCE 7-98 the Wind Load Task Committee (WLTC) re-visited the hurricane importance factor inherent in the Standard since 1982 primarily because it was recognized that the importance factor varied with location along the coast and using a constant value of 1.05 was not appropriate. This spatially varying factor was incorporated into the map by dividing the 500 year wind speeds by the square root of the load factor, which at the time was expected to be 1.5, not the value of 1.6 that was finally recommended by the load factor committee.

In ASCE 7-10, the approach taken to determine the return periods associated with different occupancy category importance factors began with the premise that the nominal wind load, computed using the methods given in ASCE 7-05, when multiplied by the wind load factor, represents a limit state or strength load. Furthermore, it was assumed that the variability of the wind speed dominates the calculation of the wind load factor. This is an approximation, and depends on the uncertainty in the various components of the wind loading chain (Davenport, 1983). The wind speed uncertainty is combined with uncertainties in pressure coefficient, exposure factor, gust factor and modeling errors. Since these errors combine as sums of squares, and because the uncertainty effect of the wind speed is doubled as it appears in the wind load equation as a pressure, the net result is the wind speed uncertainty contributes in the range of 70% to 80% of the total uncertainty. Regardless of the exact contribution of the wind speed uncertainty to the total uncertainty, the return period for the ultimate, or strength, design point for ASCE 7-10 was determined using the approximation where all the uncertainty was treated through the wind speed variability. Using this approach, the limit state wind load, W_T, is given as:

$$W_T = C_F V_{50}^2 W_{LF} I_v \quad (1)$$

where C_F is a component/structure specific coefficient that includes the effects building height, geometry, terrain, etc. V_{50} is the 50 year return period wind speed, W_{LF} is the wind load factor, and I_v is the occupancy importance factor applied to the wind load. In order to estimate the magnitude of I_H, the committee required that the annual probability of exceeding the limit state wind load in hurricane and non-

hurricane regions be the same. Recalling that the nominal design wind speed in the non-hurricane regions of the United States is associated a 50 year return period, the WLTC sought to determine the return period associated with the wind speed producing the limit state load in a non-hurricane region. As defined in ASCE 7-95 through the present, in the non-hurricane regions of the United States, the ratio of the wind speed for any return period, T, to the 50 year return period wind speed is:

$$V_T / V_{50} = [0.36 + 0.1\ln(12T)] \tag{2}$$

where V_T is wind speed associated with the strength load condition having an annual exceedance probability of $1/T$. This strength load, W_T, for an occupancy Category II structure (I_v=*1*.0) occurs when:

$$W_T = C_F V_T^2 = C_F V_{50}^2 W_{LF} \tag{3}$$

Consequently from (2) and (3), V_T / V_{50} can be represented as an algebraic function in the form:

$$V_T / V_{50} = [0.36 + 0.1\ln(12T)] = \sqrt{W_{LF}} \tag{4}$$

From (4), the return period T associated with the limit state wind speed in non-hurricane regions is for Occupancy Category II structures is:

$$T = 0.00228\exp(10\sqrt{W_{LF}}) \tag{5}$$

Using the wind load factor of 1.6 as is currently specified in ASCE 7-05, from (5) we get T = 709 years~700 years for Occupancy Category II structures. In the case of Occupancy Category I and Occupancy Categories III and IV, W_{LF} in (3), (4) and (5) is replaced with $W_{LF}\, I_v$, yielding return periods of 294 years (rounded to 300) for Occupancy Category I and 1700 years for Occupancy Categories III and IV. The return periods of 294 and 1700 years were computed with the more accurate definition of importance factor obtained from the square of (3) with T= 25 years for Occupancy Category I and 100 years for Occupancy Category III and IV, rather than using the rounded values given in ASCE 7-05 which yield return periods of 309 years and 1780 years. In ASD the wind speed from any of the three maps are used in conjunction with a WLF of 0.6, which is the rounded result of an ASD WLF that is equal to $1/\sqrt{1.6} = 0.623$.

Hurricane Simulation Model Updates. The design wind speeds given in ANSI A58.1 1982 and all versions of ASCE since that time have been comprised of a combination of hurricane and non-hurricane winds. The non-hurricane wind speeds are the same as those that have been in ASCE 7 since 1995 (adjusted to different return periods). The hurricane winds which are derived from a simulation model

differ due to updates in the hurricane modeling. The hurricane wind speeds were developed using the hurricane hazard model described in Vickery et al. (2009b). These hurricane wind speeds are combined with the statistical model for non-hurricane wind speeds given in Peterka and Shahid (1998) to develop maps that consider both hurricane and non-hurricane winds.

The major differences between the simulation models described Vickery et al. (2000a,b) (used to define the design wind speeds in ASCE 7-98 through ASCE 7-05) to those in the current model (Vickery et al., 2009b) are:

- A new intensity model includes ocean mixing to limit hurricane
- A new statistical model for Holland B parameter
- A new filling (storm weakening after landfall) model
- A new wind field model

In addition to changes to the simulation model itself, the new maps were developed using a 100,000 year simulation vs. a 20,000 year simulation for the old map. The maps were developed using predicted wind speeds at 2851 points vs. the 208 points used to develop the old map, resulting in a much more precise representation of the change in contours as one moves inland away from the coast.

The *primary* reason for the reduction in wind speeds produced by the 2009 model compared to those obtained using the previous model is through the modeling of the Holland *B* parameter. The details of Holland *B* parameter are discussed in Holland (1980) as well as Vickery et al. (2010), among others. Figure xx1 shows the impact of changes in *B* on the radial variation of the wind speeds and pressures for a hurricane with constant values of central pressure, radius to maximum wind speed (*RMW*) and translation speed.

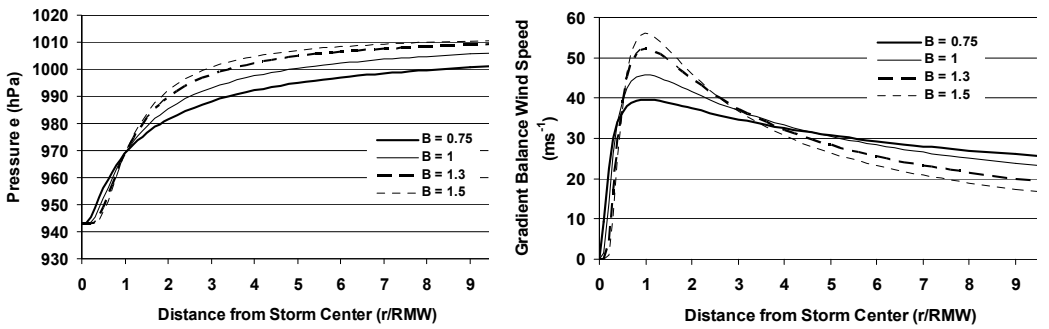

Figure 1 Effect of B on azimuthally averaged radial profiles of wind speed and pressure

Figure 1 shows that as *B* increases, the radial variation of both wind speed and pressure increases, and the maximum wind speed increase. It can be shown that in a stationary hurricane the maximum gradient level wind speed, V_{Gmax}, in a hurricane is proportional to the square root of *B* in the form $V_{G\max} \propto \sqrt{B\Delta p}$ where Δp is the

difference between the low pressure at the center of the hurricane and the high pressure well away from the storm center. With all else equal, in a stationary hurricane, a 10% decrease in either B or Δp corresponds to a 5% decrease in the maximum wind speed in the hurricane, indicating that both variables are important.

As discussed in Vickery and Wadhera (2008), B has statistically significant correlations with RMW (increasing as RMW decreases), latitude (decreasing as latitude increases) and sea surface temperature (SST) (decreasing with decreasing SST). In an attempt to incorporate a relationship between latitude, SST, RMW and B using a single parameter, B over open water, is modeled as:

$$B = 1.7642 - 1.2098\sqrt{A} + \varepsilon \; ; \qquad r^2=0.345,\ \sigma_B = 0.226 \qquad (6)$$

where A is a non-dimensional parameter that incorporates SST, RMW and latitude. In (6) the numerator of A is a function RMW and latitude and the denominator is a function of central pressure and SST. The two most important parameters controlling the behavior of B in (6) are RMW and latitude.

The model for B used in Vickery et al. (2000b) is:

$$B = 1.38 + 0.00184\Delta p - 0.00309\,RMW + \varepsilon \; ; \qquad r^2=0.026,\ \sigma_B = 0.381 \qquad (7)$$

Note that in (7) there is no dependence on latitude and that the r^2 value is much lower and the error term is much higher than in (6). The reduction in r^2 and the associated decrease in the error term, σ_B, plays an important role in the reduction of wind speeds associated with rarer events, as these events are driven by the tails of the input distributions rather than the means.

Whereas Figure 1 shows the importance of B from the viewpoint of a single storm, Figure 2 shows the effect of the new statistical model for B on predicted wind speeds though comparisons of predicted hurricane gust wind speeds at Wilmington, NC and Miami, FL. In the Wilmington case, the use of the new model for B reduces the 100 year return period gust wind speed by 9.4%, and in the Miami case a 6.8% reduction occurs. For a 700 year return period, the reductions are 10.9% and 9.3% for Wilmington and Miami respectively.

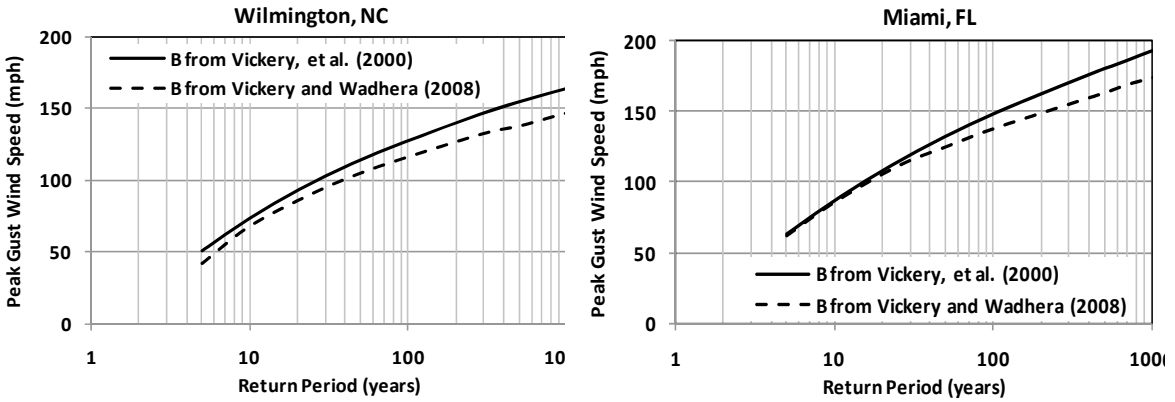

Figure 2. Effect of Holland B modeling on predicted wind speeds

RE-INTRODUCTION OF EXPOSURE D IN HURRICANE PRONE AREAS

One of the more significant differences between the hurricane wind field models used in Vickery et al. (2000a) and Vickery et al. (2009) is in the modeling of the sea surface drag coefficient, C_d. In Vickery et al. (2009) the hurricane wind field model uses a representation of C_d, which reaches a maximum value at mean wind speeds of around 20 m/sec. This treatment of the C_d varies markedly from that used in Vickery et al. (2000a), where C_d increases monotonically with wind speed without limit. The change in the modeling of the C_d is due to the work described in Powell et al. (2003) which indicates that C_d does not continue to increase with increasing wind speed, but reaches a maximum or limiting value. A limiting value of C_d contradicts the findings given in the earlier works of both Powell (1980) and Garrett (1977), but has been supported by other research since 2003. The hurricane wind field model used to develop the ASCE 7-10 wind speeds models the limiting C_d through the use of an upper bound on C_d that varies with distance from the center of the hurricane

Figure 3 presents the water-land gust wind speed ratios derived from the Vickery, et al. (2008) model (near the *RMW*), the ratios derived from the Vickery et al. (2000a) model (also near the *RMW*), and those implied in ASCE 7. The wind speed ratio is defined as the marine gust wind speed divided by the open terrain (defined as z_o=0.03m) gust wind speed. In ASCE 7 this ratio is equal to $\sqrt{K_z}$ evaluated in Exposure D at z=10 m. As indicated in Figure 3, the ratios produced by the new wind model are approximately consistent with the Exposure D ratio. Using model for C_d that does not have a limiting value the wind speed ratio approaches that of Exposure C in ASCE 7 as the wind speed increases, and thus for simplicity Exposure D was eliminated from the hurricane prone coastline in the 1998 Edition of ASCE 7.

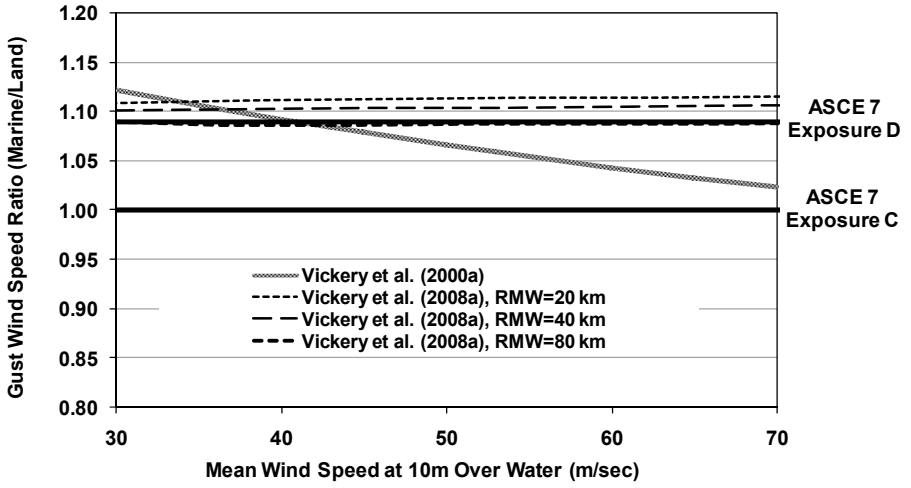

Figure 3. Gust wind speed ratio (Gust wind speed on land divided by gust wind speed over water). A gust wind speed ratio of 1 indicates no reduction in wind speed as wind moves from sea to land (i.e. marine roughness is the same as open terrain).

WIND-BORNE DEBRIS REGIONS

The primary changes to the wind-borne debris provisions in ASCE 7 are to accomplish relative coordination with the new ultimate wind speed maps that are now basis for determining design wind speeds. The language that triggers the Wind-borne Debris Region (WBDR) has been relocated to Section 26.10.3.1. The language is still similar but includes a couple of key changes. The appropriate map for the category of building under consideration is to be used for determining the application of the WBDR requirements. For Risk Category II buildings and Risk Category III buildings except health care facilities, the WBDR triggers are to be based on the wind speed map for Risk Category II buildings, Figure 26.5.1A. For Risk Category IV buildings and Risk Category III health care facilities, the WBDR triggers are to be based on the wind speed map for Category III and IV buildings, figure 26.5.1B. Using the Risk Category III and IV wind speed map does substantially increase the WBDR for these buildings and structures as compared with the provisions of ASCE 7-05 except around Jacksonville, Florida and the "big bend" region of Florida. Using the appropriate risk based map for the appropriate Risk Category provides a means for achieving a more risk consistent approach for defining WBDR, particularly with regards to life safety. The types of buildings and structures included in Risk Category III suggest that life safety is most important for health care facilities. Therefore, the expanded WBDR in Figure 26.5.1B applies to Risk Category III health care facilities.

For Risk Category II buildings, there is a notable change in the geographic area that is now designated as a WBDR. The WBDR contained in the previous editions of ASCE 7 (1998, 2002, and 2005) were based on judgment and essentially applied the region in a strip of the coast along most of the Gulf of Mexico and

Atlantic coast regions where the risk of a direct strike of a Category 3 or larger hurricane was high. The new criteria continue that judgment based definition by including the coastal areas that are approximately consistent with those given in prior editions of ASCE 7 for Risk Category II. A straight translation of the 110 and 120 mph wind speeds from ASCE 7-05 to the 700 year return period maps in ASCE 7-10 would yield triggers of 140 mph and 150 mph respectively. This would have eliminated the WBDR along most the Texas coast and substantially reduce the region in other areas that are considered to be in a WBDR in ASCE 7-05. This is due to the changes in the hurricane simulation model that reduces the magnitude of wind speeds for long return periods. However, while the applicability of the WBDR has essentially been shifted by 10 mph, the applicable region for Risk Category II and Risk Category III buildings excluding health care facilities has be substantially narrowed and eliminated in some places as compared to the regions applicable in ASCE 7-05 and prior editions. Significant reductions in the WBDR occur around Jacksonville, Florida, the Florida panhandle, and along the coast of North Carolina.

SIMPLIFIED PROCEDURE FOR BUILDINGS ≤ 160 FT

New to ASCE 7-10 is a simplified approach for determining design wind pressures applicable to buildings with a mean roof height $h \leq 160$ ft. Design pressures for both roof and wall surfaces are determined directly from a set of tables. The method is based on the same principles that form the basis of the Directional Procedure defined in Chapter 27 Part1 for the MWFRS and Chapter 30 Part 3 for CC.

MWFRS – Chapter 27 Part 2. The method for MWFRS covers two classes of buildings that are a function of building height. In addition to the normal limitations listed in Chapter 27 Section 27.1.2 regarding a regular building and absence of unusual dynamic characteristics, the requirements for each class are stipulated below:

Class 1 Buildings:

1. Enclosed simple diaphragm building (as defined in Section 26.2)
2. $h \leq 60$ ft.
3. $0.2 \leq L/B \leq 5.0$
4. $K_{zt} = 1.0$ with exceptions as defined in Section 27.5.2

Class 2 Buildings:

1. Enclosed simple diaphragm building (as defined in Section 26.2)
2. $60\ ft < h \leq 160$ ft.
3. $0.2 \leq L/B \leq 5.0$
4. $K_{zt} = 1.0$ with exceptions as defined in Section 27.5.2
5. The fundamental natural frequency shall not be less than $75/h$ where h is in feet.

The procedure can be applied for buildings with either rigid or flexible diaphragms as discussed in Section 27.5.4. Net wind pressures for wall and roof surfaces are determined from Tables 27.6-1 and Table 27.6-2 respectively. Tables are presented for all exposures, B, C and D and for wind speeds varying from 110 MPH to 200 MPH. A procedure is also specified for determining pressures for roof parapets (see Figure 27.6-2) and roof overhangs (see Figure 27.6-3). Loads from the tables are applied to the walls and roof simultaneously. The step by step procedure is defined at the front of Chapter 27 Part 2 Table 27.5-1.

An excerpt from Table 27.6-1 for walls is shown below. An excerpt from Table 27.6-2 for roofs is also shown. For roofs, the procedure covers flat, gable, hip, monoslope and mansard roofs as referenced in Table 27.6-2.

For wall pressures determined from Table 27.6-1, two pressures are tabulated for each building height and wind speed. The uppermost row in the table defines p_h which is the roof pressure at the top of the building. The lower row (shown shaded) defines p_0 which is the pressure at the base of the building. A linear variation of pressure between the two is to be used in design as shown at the front of Table 27.6-1. This linear variation has been developed to produce essentially the same story shears and overturning moments as the "exact" values from Part 1 of Chapter 27. It is to be noted that the procedure includes the calculation of the Gust Effect Factor based on conservative assumptions for building frequency and damping. Further details on the derivation of tabulated pressure values can be found in the commentary to ASCE 7-10.

C&C – Chapter 30 Part 4. The method for CC covers both wall and roof surfaces. Roof and wall pressures for flat, gable, mansard, hip and monoslope roof buildings are covered Table 30.7-2. Tabulated pressures are shown for five zones that include all wall and roof surfaces as shown in the figures in Table 30.7-2. The step by step procedure is defined at the front of Chapter 30 Part 4 in Table 30.7-1.

Table 30.7-2 shows pressure for Exposure C only. However, pressures for all exposures can be determined by applying the Exposure Adjustment Factor shown in a graph within the table. Tabulated values are shown for an effective wind area of 10 sf but reduction factors are shown in graphs part of the table for other effective wind areas. The various factors are applied to the tabulated pressures according to Equation 30.7-1. A procedure is also specified for determining pressures on parapets (refer to Figure 30.7-1) and overhangs (refer to Figure 30.7-2). An excerpt to Table 30.7-2 is shown below.

OTHER CHANGES

Minimum wind loads. Minimum wind load pressure was increased from 10 psf to 16 psf to account for the change in load factors.

Improved exposure and roughness examples. New figures were added to the commentary to provide examples on how to determine exposure conditions for different roughness conditions around the building

.

Revisions to low-rise "envelope" method. The figure for determining MWFRS exterior pressure coefficients, GC_{pf}, for low-rise buildings was revised to be consistent with that used in ASCE 7-98.

Provisions for roof-top equipment. Provisions have been added to quantify both lateral and vertical wind loads on rooftop equipment.

CONCLUSION

This paper provides a general overview of the major changes to the ASCE 7 wind load provisions in ASCE 7-10. The reorganization and change in the return period of the wind speed maps has made the overall format of the wind load provisions similar to that of the ASCE 7 seismic provisions. Additional information on changes can be found in the ASCE 7-10 Commentary.

OVERVIEW OF UFC 3-340-02, STRUCTURES TO RESIST THE EFFECTS OF ACCIDENTAL EXPLOSIONS

Author: Patrick F. Acosta, PE, US Army Engineering and Support Center, Huntsville; ATTN: CEHNC-ED-CS-S (Acosta); PO Box 1600; Huntsville, AL 35807-4301; phone 256-895-1661; fax 256-895-1602; e-mail: Patrick.F.Acosta@usace.army.mil.

Abstract

UFC 3-340-02, "Structures to Resist the Effects of Accidental Explosions," was recently approved by the Services. Publication of UFC 3-340-02 represents the culmination of a 5-year, Department of Defense Explosives Safety Board (DDESB) effort to update DoD's mandatory blast design requirements for explosives safety applications, as provided in Army TM 5-1300/NAVFAC P-397/AFR 88-22 (TM 5-1300), revision 1, November 1990. As an unlimited distribution document approved for public release, TM 5-1300 has long provided both government and private sector engineers with an invaluable source of blast effects and loading data and with step-by-step procedures for blast analysis and design. UFC 3-340-02 continues this tradition, using straightforward guidance and examples to illustrate and explain protective construction design requirements.

While based upon TM 5-1300, UFC 3-340-02 incorporates several beneficial changes to the manual's reinforced concrete design requirements. This presentation provides an overview of the more significant of these changes. Anticipated, future revisions and additions to other chapters also are presented and discussed.

UFC 3-340-02 may be downloaded from the Whole Building Design Guide website. For users who have the DPLOT computer program, readable versions of some manual figures also are available through this website. In 2003, the Department of Defense Explosives Safety Board (DDESB) established a Technical Working Group to revise the tri-service blast design manual, "Structures to Resist the Effects of Accidental Explosions," Army Technical Manual 5-1300/NAVFAC P-397/AFR 88-22. As an unlimited distribution document approved for public release, TM 5-1300 provides both government and private sector engineers with an invaluable source of blast effects and loading data and with step-by-step procedures for blast analysis and design.

This paper provides a status update of TWG activities and plans for future work. Emphasis will be given to revisions to chapter 4, "Reinforced Concrete Design." Anticipated revisions and additions to other manual chapters also will be presented and discussed.

Introduction

When US Army Technical Manual 5-1300/NAVFAC P-397/AFR 88-22, "Structures to Resist the Effects of Accidental Explosions" (TM 5-1300) was first published in 1969, it provided

engineers with groundbreaking, quantitative procedures for analyzing and designing structures to withstand non-nuclear blast effects (Department of the Army, 1969) [1]. Based upon the results of numerous explosive test programs and accident investigations, the manual included detailed design procedures and step-by-step design examples to illustrate their application. Since reinforced concrete performs particularly well under intense, short duration blast pressures, the manual emphasized the design of reinforced concrete structural elements.

DDESB in 2001 solicited input from a broad range of TM 5-1300 users on recommended changes, corrections, and additions to the manual. APT Research, Inc., Huntsville, AL, consolidated the resulting comments in a summary report (APT Research, 2002) [3]. In October 2002, Naval Facilities Engineering Service Center (NFESC) submitted supplementary comments (NFESC, 2002) [4].

A wide range of input was received. The blast design community strongly recommended the update of the manual, both to remove outdated criteria and to incorporate research conducted since publication of revision 1. In addition, TM 5-1300 users requested the addition of new guidance on various topics such as the retrofit of existing structures, constructability, and the applicability of computer codes in blast resistant design.

Based upon these comments, DDESB established the Technical Working Group to Update Army Technical Manual 5-1300/NAVFAC P-397/AFR 88-22 (TWG) in March 2003. The TWG provides direction to the revision effort and makes technical decisions related to the manual's content. The TWG charter specifically limits the scope to incorporation of existing procedures and products; no new research will be funded. Mr. Bill Zehrt, DDESB, serves as TWG chair.

At the June 2003 organizational meeting, TWG members reviewed recent advances in blast resistant design meriting inclusion in Revision 2. A wide range of areas were considered including blast load prediction and modeling, analytical methods, design procedures, retrofit of existing structures, and innovative blast resistant materials. Per the TWG charter, discussions centered on items that were sufficiently developed to allow their incorporation without additional research.

In addition, the TWG-funded studies to evaluate reinforced concrete research and test data published since the development of revision 1. When warranted, draft revisions to chapter 4 requirements were prepared for TWG consideration.

At the June 2006 TWG meeting, USAESCH was tasked with developing a draft final interim UFC that incorporates both the foregoing changes and other updates approved at the meeting, including the revision of outdated references in chapter 4 to satisfy current code requirements (ACI, 1983) [6] and (ACI, 2008) [7]. Draft final revisions to the manual then were developed and disseminated, first through 2006 DoD Explosives Safety Seminar papers (Woodson and Zehrt, 2006) [8] and (Zehrt, Woodson and Beck, 2006) [9], next through draft final mark-ups to TWG members. Since that time, TWG comments have been resolved and incorporated in chapter 4.

Chapter 4 Revision Highlights

Due to the extent of chapter 4 revisions, it is not feasible to discuss each change in this paper. Instead, we will illustrate the scope of the changes by providing portions of the pending revision 2 guidance in four manual sections: Section 4-13.2. Dynamic Increase Factor; Section 4-22. Design of Non-Laced Reinforced Slabs – Introduction; Section 4-55. Prediction of Concrete Spalling; and Section 4-66.3.1. Single Leg Stirrups.

4-13.2. Dynamic Increase Factor

The dynamic increase factor, DIF, is equal to the ratio of the dynamic stress to the static stress, e.g., f_{dy}/f_y, f_{du}/f_u and f'_{dc}/f'_c. The DIF depends upon the rate of strain of the element, increasing as the strain rate increases. The design curves for the DIF for the unconfined compressive strength of concrete are given in Figure 4-9 for $2{,}500 < f'_c < 5{,}000$ psi and in Figures 4-9a and 4-9b for $f'_c = 6{,}000$ psi. Test values for the DIF in tension (before cracking) also are given on Figures 4-9a and 4-9b. The DIF design curves for the yield and ultimate stresses of ASTM A 615 Grade 40, Grade 60 and Grade 75 reinforcing steel are given in Figure 4-10. Grade 40 steel is not permitted in new protective construction. Thus, Grade 40 data are provided for comparative purposes and for use in evaluating existing construction. The curves were derived from test data having a maximum strain rate of 300 in./in./sec. for concrete and 100 in./in./sec. for steel. Values taken from these design curves are conservative estimates of DIF and safe for design purposes.

Section 4-22. Design of Non-Laced Reinforced Slabs - Introduction

Conventional reinforced concrete elements are for the purpose of this manual, members without lacing. These non-laced elements make up the bulk of protective concrete construction. They are generally used to withstand the blast and fragment effects associated with the far design range but may also be designed to resist the effects associated with the close-in design range. Non-laced elements may be designed to attain small or large deflections depending upon the protection requirements of the acceptor system.

A non-laced element designed for far range effects may attain deflections corresponding to support rotations up to 2 degrees under flexural action. Single leg stirrups are not required to attain this deflection. However, shear reinforcement is required if the shear capacity of the concrete is not sufficient to develop the ultimate flexural strength.

Type A, Type B, or Type C single leg stirrups, as defined in section 4-66.3, must be provided when a non-laced element is designed to resist close-in effects. The shear reinforcement must be provided to prevent local punching shear failure. When the explosive charge is located at scaled distances less than 1.0, Type C single leg stirrups or lacing must be employed. For scaled

distances greater than 1.0 but less than 3.0, single leg stirrups must be provided, while for scaled distances greater than 3.0, shear reinforcement should be used only if required by analysis.

Type A stirrups may be used only if concrete spalling is prevented and the scaled distance is greater than 1.0. If these requirements are satisfied, a slab with Type A stirrups may attain deflections corresponding to support rotations up to 2 degrees under flexural action.

A slab with Type B or Type C stirrups may attain deflections corresponding to support rotations of up to 12 degrees. While Type B stirrups may be used only if the scaled distance is greater than 1.0, Type C stirrups are allowed as long as the minimum separation distance requirements of section 2-14.2.1 are satisfied. It should be emphasized that the Section 2-14.2.1 separation distances are the minimum clear distance from the surface of the charge to the surface of the element. The normal scaled distances R_A (center of charge to surface of barrier) corresponding to these minimum clear separation distances are equal to approximately 0.25 ft/lb$^{1/3}$.

A type I and II cross-section provides the ultimate moment capacity and mass to resist motion for elements designed for 2 and 6 degrees support rotation, respectively. If spalling occurs then a type III cross-section would be available. In addition, a non-laced element designed for small deflections in the close-in design range is not reusable and, therefore, cannot sustain multiple incidents.

A non-laced reinforced element may be designed to attain large deflections, that is, deflections corresponding to incipient failure. These increased deflections are possible only if the element has sufficient lateral restraint to develop in-plane forces. The element may be designed for both the close-in end far design range. A type III cross-section provides the ultimate moment capacity and mass to resist motion.

4-55. Prediction of Concrete Spalling

As previously explained, direct spalling is due to a compression wave traveling through a concrete element, reaching the back face and being reflected as a tension wave. Spalling occurs when the tension is greater than the tensile strength of the concrete.

Many spall tests have been conducted on the configuration shown in Figure 4-65, where a cylindrical charge, cased or bare, is oriented side-on at a stand-off distance from a wall slab and oriented end-on in contact with the ground. Tested variations to this configuration include non-cylindrical charge shapes, charges off the ground, and charges in contact with the slab. Test data for all of these cases have been compiled and analyzed and are plotted in Figure 4-65a. The test data in this figure are reported in terms of the observed severity of spall, i.e., as either no spall, spall (no breach), or breach. Threshold spall and breach curves are plotted as approximate upper bounds to the spall and breach data points, respectively and may be used in design. The spall threshold curve is given by Equation 4-178:

$$\frac{h}{R} = \frac{1}{a + b\Psi^{2.5} + c\Psi^{0.5}} \qquad 4\text{-}178$$

where: h = concrete thickness (ft.)
R = Range from slab face to charge center of gravity (ft.)
a = -0.02511
b = 0.01004
c = 0.13613
Ψ = spall parameter (equations 4-180a and 4-180b)

The breach threshold curve is given by Equation 4-179:

$$\frac{h}{R} = \frac{1}{a + b\Psi + c\Psi^2} \qquad 4\text{-}179$$

where: h = concrete thickness (ft.)
R = range from slab face to charge center of gravity (ft.)
a = 0.028205
b = 0.144308
c = 0.049265
Ψ = spall parameter (Equations 4-180a and 4-180b)

The spall parameter for noncontact charges is given by Equation 4-180a:

$$\Psi = R^{0.926} f'_c{}^{0.266} W_{adj}{}^{-0.353} \left(\frac{W_{adj}}{W_{adj} + W_c} \right)^{0.333} \qquad 4\text{-}180a$$

Equation 4-180b gives the spall parameter for contact charges:

$$\Psi = 0.527 R^{0.972} f'_c{}^{0.308} W_{adj}{}^{-0.341} \qquad 4\text{-}180b$$

where: Ψ = spall parameter
R = range from slab face to center of charge (ft.)
f'_c = concrete compressive strength (psi)
W_{adj} = adjusted charge weight (lb)
W_c = steel casing weight (lb)

The spall parameter equations have limits of $0.5 \leq \Psi \leq 14$. The adjusted charge weight, W_{adj}, is the weight of a hemispherical surface charge that applies an equal explosive impulse at the target to that of the actual charge (see Figure 4-65) and is given by Equation 4-181a:

$$W_{adj} = B_f C_f W \qquad 4\text{-}181a$$

where: W_{adj} = adjusted charge weight (lb)
B_f = burst configuration factor = 1.0 for surface bursts, 0.5 for free air bursts
W = equivalent TNT charge weight (lb)
C_f = cylindrical charge factor given by equations 4-181b and 4-181c:

$$C_f = 1 + 2\left(\frac{LD}{\pi(3LD^2/16)^{0.667}} - 1\right)\left(1 - \frac{R}{2W^{0.333}}\right); \text{L > D and R/W}^{0.333} < 2.0 \qquad \text{4-181b}$$

$C_f = 1.0$; all other cases 4-181c

where: L = charge length [ft]
D = charge diameter [ft]
R = range from slab face to charge center of gravity [ft]
W = equivalent TNT charge mass [lb]

The burst configuration factor, B_f, is used to correct to a surface burst condition, such as the ground in Figure 4-65. The charge shape factor, C_f, is used to correct to a hemispherical charge geometry in the case of close-in cylindrical charges oriented side-on to the slab. These corrections are applicable to both standoff and contact charges. It should be considered in design that when the munition position is variable, a contact burst may not be worst-case. The spall effect for cased charges can be greatest at a small standoff, particularly for heavy casings.

The test data range listed in Table 4-15a for each parameter shows that the data spans a wide range of subscale and full-scale tests. Although subscale tests predominate in the data base, the applicability of Figure 4-65a to large full-scale weapons is enhanced by the fact that concrete strain rate effects are accounted for in the Ψ term.

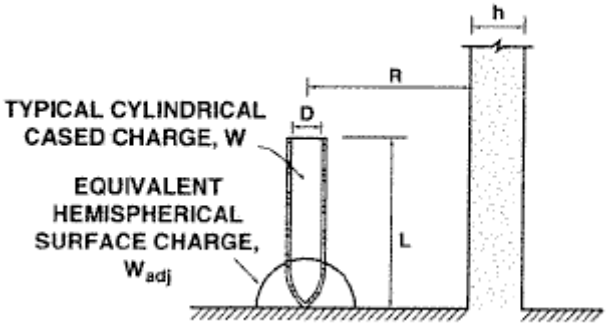

Figure 4-65 Typical geometry for spall predictions

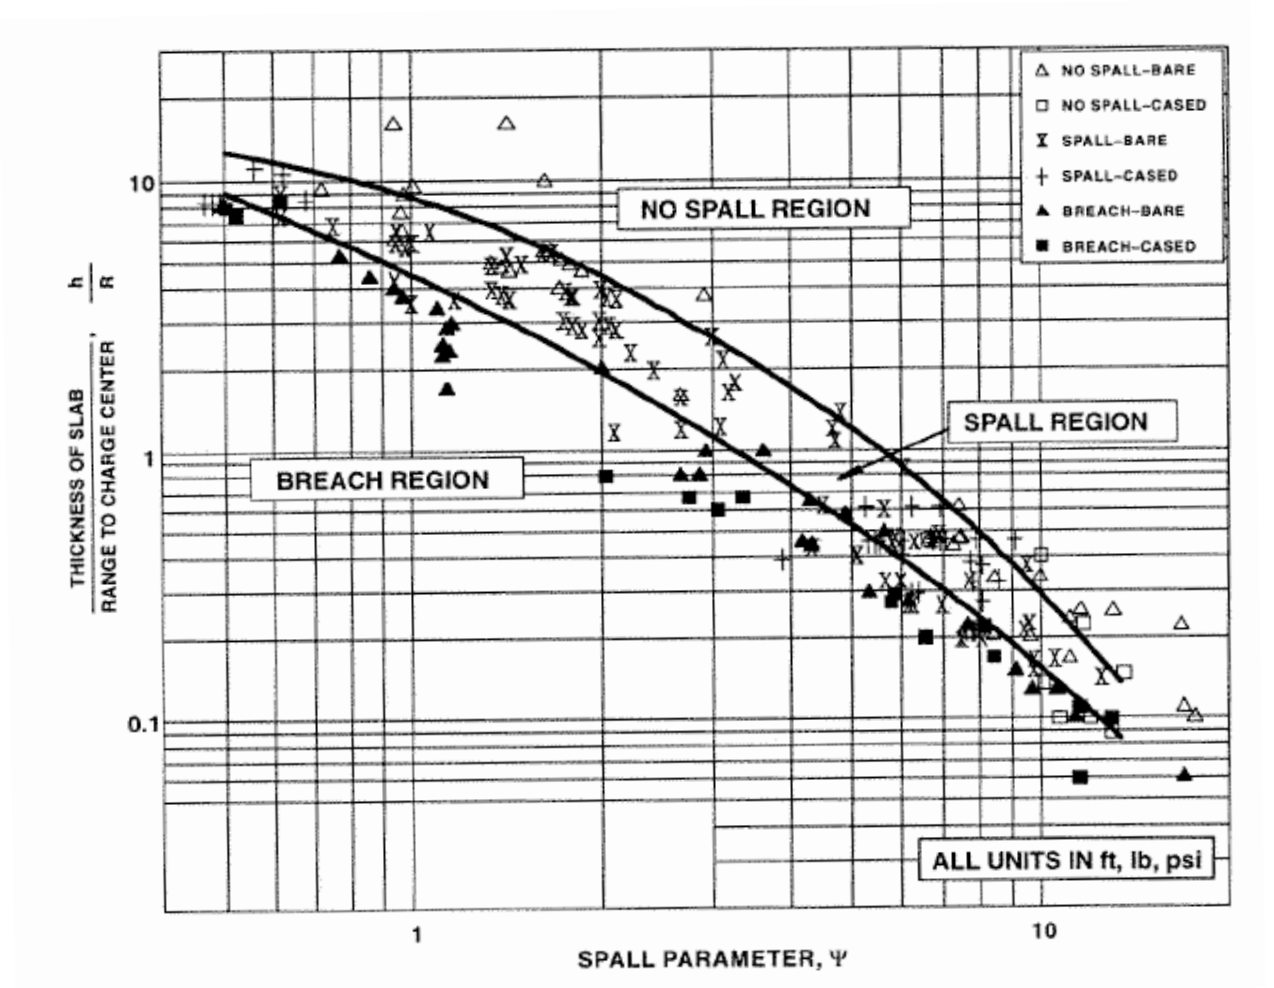

Figure 4-65a Threshold spall and breach curves for slabs subject to high-explosive bursts in air (standoff and contact charges, cased and bare)

Table 4-15a Parametric ranges for spall prediction

Parameter	Max.	Min.	Avg.

Reinf. Ratio, ρ	0.025	0.0005	0.0054	

[1] Per section 4-32, the minimum allowable design value for $R/W^{1/3}$ is approximately 0.25 $ft/lb^{1/3}$.

4-66.3. Elements Reinforced with Single Leg Stirrups

4-66.3.1. Single Leg Stirrups

A single leg stirrup consists of a straight bar with a hook at each end. Minimum bar bend requirements for single leg stirrups depend upon both the design support rotation and the scaled distance of the charge from the element, as follows:

1. Type A – Single leg stirrup with a 90-degree hook on one end and a 135-degree hook on the other end. Type A stirrups may be used only if the scaled distance from the center of the charge to the element is greater than 1.0 $ft/lb^{1/3}$, the design support rotation is 2-degrees or less, and concrete spalling is prevented in accordance with section 4-55. Placement requirements for Type A stirrups are summarized in Figure 4-101. For elements designed for blast loading on one-face only, the 90-degree leg shall be placed on the blast face. For elements designed for blast loading on either face, the 90-degree leg shall be alternated between each face.

2. Type B – Single leg stirrup with 135-degree hooks on both ends. Type B stirrups may be used only if the scaled distance from the center of the charge to the element is greater than 1.0 $ft/lb^{1/3}$. Type B stirrups are acceptable for all protection categories and thus, may be used for design support rotations up to 12-degrees.

3. Type C – Single leg stirrup with 180-degree hooks on each end. Type C stirrups may be used for all charge separation distances allowed by this manual. Type C stirrups also are acceptable for all protection categories and thus, may be used for design support rotations up to 12-degrees.

Hooks shall conform to the ACI 318 Building Code. At any particular section of an element, the longitudinal flexural reinforcement is placed to the interior of the transverse reinforcement and the stirrups are bent around the transverse reinforcement (Fig. 4-101).

The required quantity of single leg stirrups is calculated in the same manner as lacing. It is a function of the element's flexural capacity while the size of rebar used is a function of the required area and spacing of the stirrups. The maximum and minimum size of stirrup bars are No. 8 and No. 3, respectively, while the spacing between stirrups is limited to a maximum of d/2 or $d_c/2$ for type I and type II or III cross-sections, respectively.

The preferable placement of single-leg stirrups is at every flexural bar intersection. However, the transverse flexural reinforcement does not have to be tied at every intersection with a longitudinal bar. A grid system may be established whereby alternate bar intersections in one or both directions are tied within a distance not greater than 2 feet. The choice of the three possible schemes depends upon the quantity of flexural reinforcement, the spacing of the flexural bars and the thickness of the concrete element. For thick, lightly reinforced elements, stirrups may be furnished at alternate bar intersections, whereas for thin and/or heavily reinforced elements, stirrups will be required at every bar intersection. For those sites where large stirrups are required at every flexural bar intersection, the bar size used may be reduced by furnishing two stirrups at each flexural bar intersection. In this situation, a stirrup is provided at each side of longitudinal bar.

Single leg stirrups must be distributed throughout an element. Unlike shear reinforcement in conventionally loaded elements, the stirrups cannot be reduced in regions of low shear stress. The size of the stirrups is determined for the high stress areas and, because of the non-uniformity of the blast loads associated with close-in detonations, this size stirrup is placed across the span length to distribute the loads. For two-way elements, diagonal tension stresses must he resisted in two directions. The size of stirrup determined for each direction is placed to the same extent as the lacing shown in Figure 4-92. However, the distribution does not apply for cantilever elements since they are one-way elements requiring only one stirrup size which is uniformly distributed throughout.

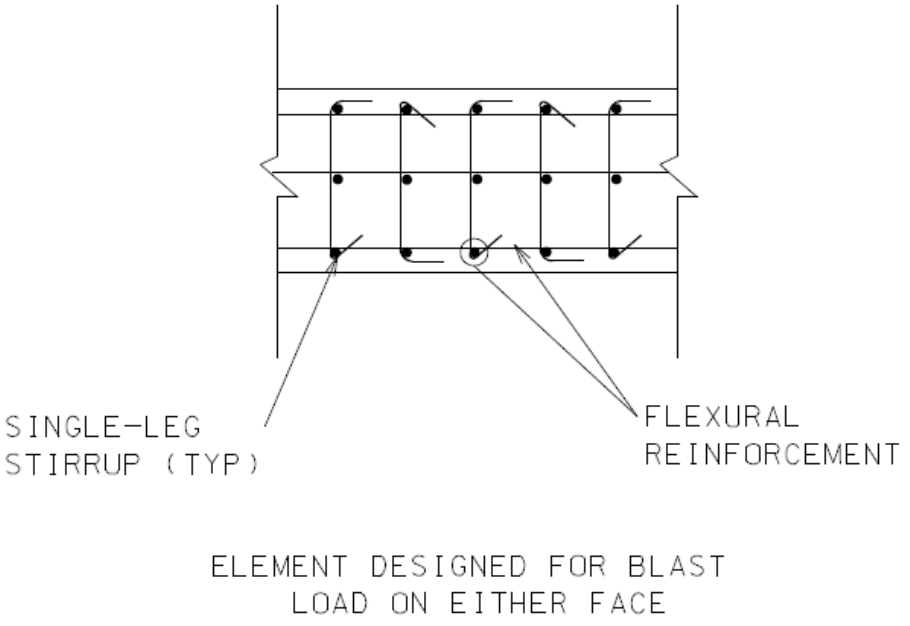

Figure 4-101 Placement requirements for Type A single-leg stirrups.

Future Work

Future TM 5-1300 TWG tasks will focus on two areas. First, we will continue to update and expand the content of TM 5-1300. We anticipate that this work will include the revision of the gas pressure calculation procedure for partial containment cells (Bogosian & Zehrt, 1998) [10], (Tancreto & Zehrt, 1998) [11] and (Hager, Doolittle and Needham, 2006) [12]; the update and expansion of structural steel and masonry design guidance; and the addition of new guidance on innovative materials and retrofit of existing structures. Second, we will support both JUM development and the corresponding revision of TM 5-1300 to provide guidance specific to explosives safety applications.

Conclusions and Recommendations

Since its initial publication in 1969, Army TM 5-1300/NAVFAC P-397/AFR 88-22 (TM 5-1300, 1969) [1] has provided uniquely practical and intuitively straightforward procedures for analyzing and designing blast resistant structures. With its unlimited distribution, TM 5-1300 is the blast design manual of choice of both government explosives safety experts and private A-E firms throughout the world.

The September 11, 2001 terrorist attacks on the United States underscore the need for up-to-date, blast design guidance. To obtain maximum benefit from recent research advances, pertinent data must be disseminated quickly to the blast design community in an open distribution document. Whenever possible, guidance should be written so it can be understood and applied by a veteran structural designer with little or no blast experience.

Although the interim TM 5-1300 UFC chapter 4 revision will provide updated guidance in several key areas, additional revisions and supplementary coverage of new, innovative systems and materials are sorely needed. Future TWG work will concentrate on developing and disseminating this guidance, either in a future TM 5-1300 revision or in the proposed Joint Use Manual for the explosives safety, hardened structures, and AT/FP communities.

ABSTRACT

This paper presents a brief overview of historical and current practices for the design of windows and glass curtain walls subjected to short-duration, high-energy loading from blast shock waves. General discussion is provided that describes typical treatment of force-displacement relationships, boundary conditions, pre- and post-cracked behavior of laminated glass, and failure criterion. Various practical examples from design projects are presented that demonstrate limitations or misapplications of methods that are often used in blast engineering. Developments from parallel research are cited to highlight some of the current deficiencies.

CLASSICAL METHODS

High-energy load events associated with accidental and intentional explosions present serious threats to the physical safety of building occupants in countless private, commercial, and government facilities around the world. In particular, there continue to be very real threats of terrorist attacks against U.S. assets globally. The threats often take the form of high-energy, short-duration blast-induced forces applied to the exterior of buildings. As part of the façade of a building, windows and glass curtain walls most often serve as weak points in the protection of personnel against explosion events. Failure of windows often results in physical harm or death of occupants. "In the 1996 Khobar Towers Bombing for example, approximately 80 – 90% of injuries were caused by flying glass." (HazL, 2004).

Major testing, research, and development efforts over decades have focused on design of windows to protect against blast loading. Several references offer insight into many of the technical aspects of window design including ASCE (1999), GANA (2010), HazL (2004) and WINGARD (2005). As is typical of structural applications, the design process involves load prediction, physical model definition,

mathematical solution, response evaluation, failure criteria assessment, and design of support system.

In the context of this paper, reference to classical methods may include classical analytical developments and empirical methods where physical test data or finite element analysis results are used to characterize various aspects of the problem. The discussion that follows highlights selected topics related to classical approaches to the evaluation of windows and glass curtain walls for blast application. An exhaustive treatment of the issue is well beyond the scope of this paper.

Load prediction.

Blast loads are obtained from information regarding explosive charge type, mass, and position relative to the impacted structure. Predictive methods typically result in pressure versus time load curves similar to those shown in Figure 1. The curved line is the result of an exponential-form curve fit of experimental data which is rooted in developments by Friedlander (1946). As represented by the curve, the pressure wave typically exhibits a very short (almost instantaneous) rise time to a peak pressure. The pressure is initially positive against exposed surfaces (positive phase) followed by a negative pressure pulling away from the surface (negative phase). The peak positive pressure is typically several times larger than the largest negative pressure. Accordingly, the pressure wave may often be idealized by a simple linear load curve as shown in Figure 1. The linear curve is in the shape of triangular pulse with a zero rise time. The area under the triangular pulse is typically set equal to the area under the positive phase portion of the Friedlander curve. Both forms are often used in blast engineering with the linear shape being particularly suited for the application of classical methods (Biggs, 1964).

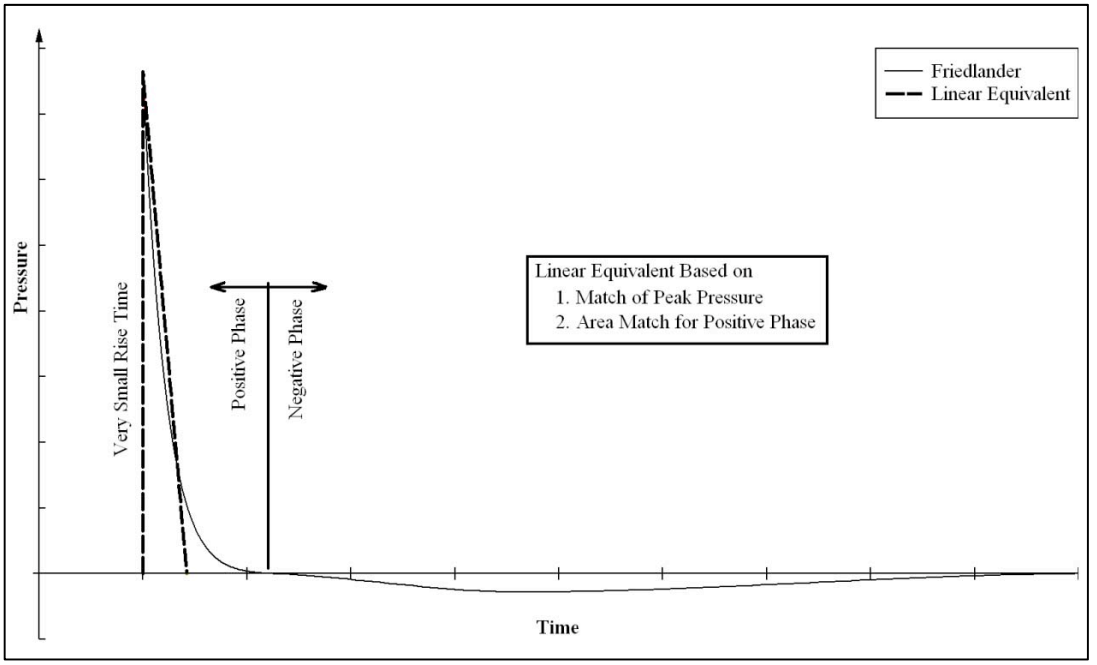

Figure 1. Pressure versus time curve.

Physical model definition.

Characteristics that are considered in historical and current modeling tools include the following.

1. Glass Characteristics. The response of glass is generally treated as linearly elastic up to a stress level corresponding to brittle cracking. Glass cracking varies in stress and crack pattern depending on glass type (annealed, heat strengthened, tempered, etc.). Glass generally exhibits a relatively large range of maximum stress versus probability of failure. Low failure probabilities are typically used in the selection of glass while higher glass failure probabilities (yielding higher reaction predictions) are used in the design of the glass support framing.

2. Glass Makeup. Glass "make-up" is used to describe the combination of glass and other components that serve as the "glass" portion of a window. The glass make-ups vary depending on specific application and performance requirements. Glass make-ups can include combinations of monolithic glass plates, intermediate air spaces, laminated glass panels, shatter resistant films, and ballistic resistant layers. Laminate inner layers, shatter resistant films, and ballistic layers are typically modeled as linearly elastic or linearly elastic perfectly plastic materials. Air spaces are often treated as gaps with closed volumes of air. The closed volume of air effectively serves as a nonlinear spring between inner and outer panes of glass.

3. Boundary Conditions. Figure 2 depicts the two classes of boundary conditions that are most often used in current practice. In the pre-cracked configuration, the edge is held against translation normal to the plane of the glass. Thus, the glass edge is allowed to translate toward the support edge. This assumption is consistent with that included in Moore (1980), which serves as a key reference in much of the mathematical modeling of the glass. The post-cracked stage of the glass response (non-monolithic) is assumed to be dominated by membrane action of inner layers or films. The post-crack membrane edge condition has the glass edge restrained against movement toward the support edge. The implied assumption is that in-plane reactive forces develop between the laminate or film and the supporting frame through some form of friction, bonding, or mechanical attachment.

   The supports are assumed to be dynamically rigid as related to glass response calculations. Limits on support displacement and rotation are typically imposed with an aim toward maintaining a safe overlap between the edge of the glass and the edge of the support (glass bite).

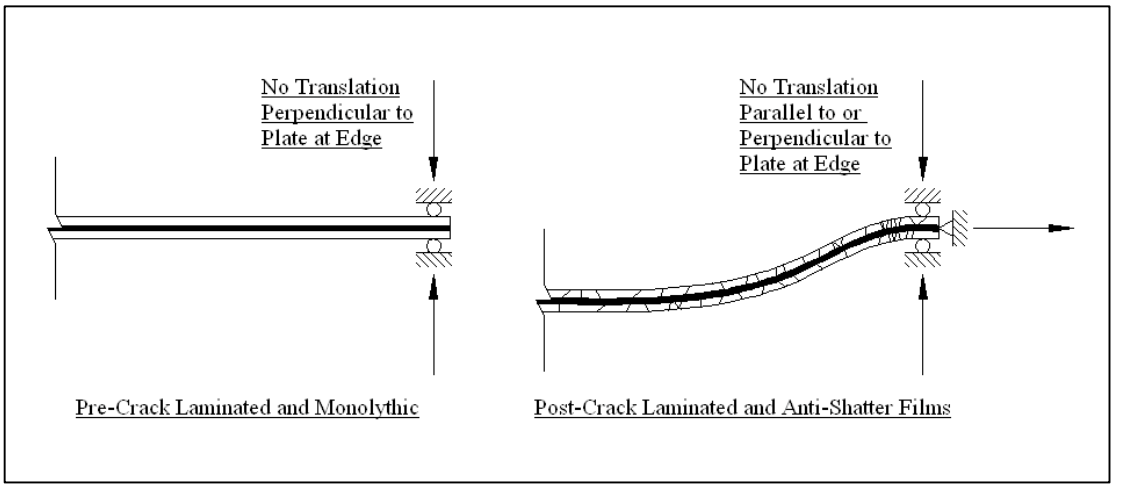

Figure 2. Glass edge boundary conditions.

4. Force – Displacement Relationships. In the context of classical blast engineering applications, resistance functions are developed to represent the response of structural components to load. Figure 3 shows various resistance functions for a simple laminated glass make-up. As seen in Figure 3, the HazL Analytical curve and the WINGARD Default curve yield very similar results. The most pronounced differences lie in the following:

    a. Probability of glass failure and associated glass cracking stress.
    b. Single-step glass cracking versus two-step glass cracking.
    c. Prediction of yield stress in the laminate.

    Various other issues may influence the shape of the resistance function including limitations on maximum glass deflection plus stress or strain limits for laminates, films, and ballistic materials.

    Referring again to Figure 3, the HazL Empirical curve shows significantly higher resistance capacity in the post-crack phase of the response compared with the analytical model results. This observation matches results from research related to edge capacity of through-bolted glass (Duke et al., 2009). It is proposed that the increase in resistance is associated with the post-crack interaction between the glass and the laminate. In the analytical model results presented in Figure 3, the post-cracked glass is assumed to contribute mass with no stiffness to the laminate membrane. In reality, the post-crack piecewise continuous attachment of glass fragments to the laminate interlayer provides increased bending and in-plane stiffnesses that are not accounted for in the current classical analytical models.

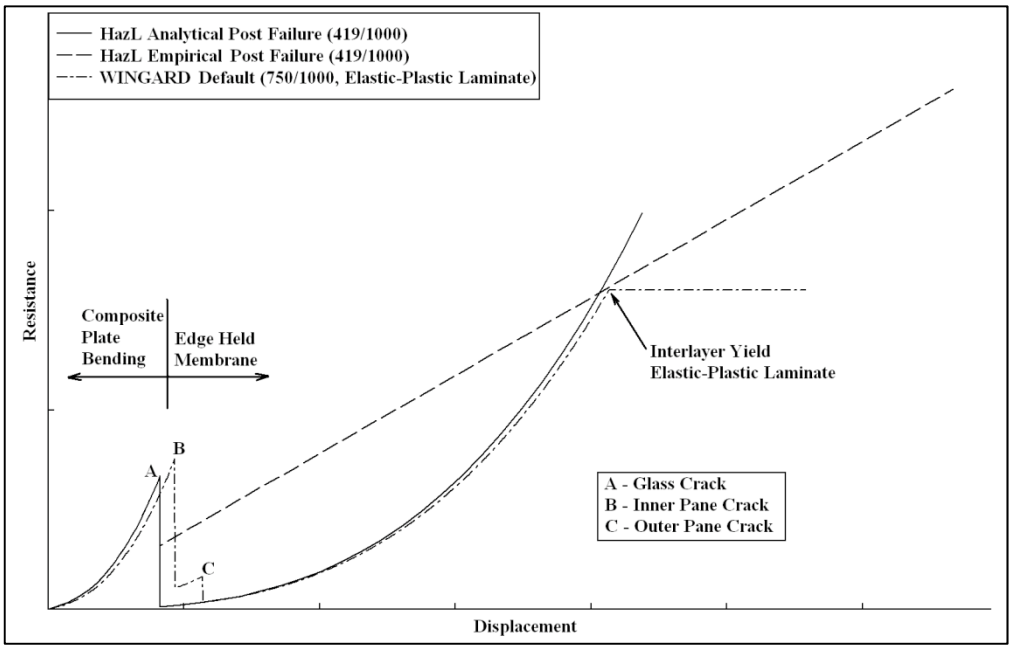

Figure 3. Glass resistance function.

Mathematical solution.

In general, load applications similar to Figure 1 along with force-displacement relationships similar to Figure 3 combine to yield nonlinear transient dynamic problems. In the simplest form, the problem may be treated using a classical equivalent static load method. In most cases, however, the dynamic nature of the problem mandates application of single-degree-of-freedom (SDOF) numerical solution techniques similar to those discussed by Biggs (1964). The solutions typically yield a displacement as the primary result with stresses and reactions as secondary. If predicted glass deflections indicate separation of the pane from the support, projectile dynamics calculations are typically performed to predict the flight paths of fragments.

Response evaluation.

1. Displacements. The displacement prediction resulting from the mathematical solution represents the maximum displacement in the glass panes (at the center of the panel). Assuring that the glass remains attached to the frame is most often essential to a suitable design. In addition to stress and strain evaluations for the various layers of the glass make-up, the bite is evaluated relative to the displaced shape of the glass. A common practice for bite evaluation is represented in Figure 4. The primary concern is that the edge of the glass remains engaged with the support. As the glass deflects, the glass edge moves toward the edge of the support, and the bite dimension decreases. For small glass displacements, the bite reduction is small. However, many blast window designs exhibit very large displacements where the bite can be

compromised. As indicated in Figure 4, the overall glass length is assumed to be unchanged (no in-plane membrane strain).

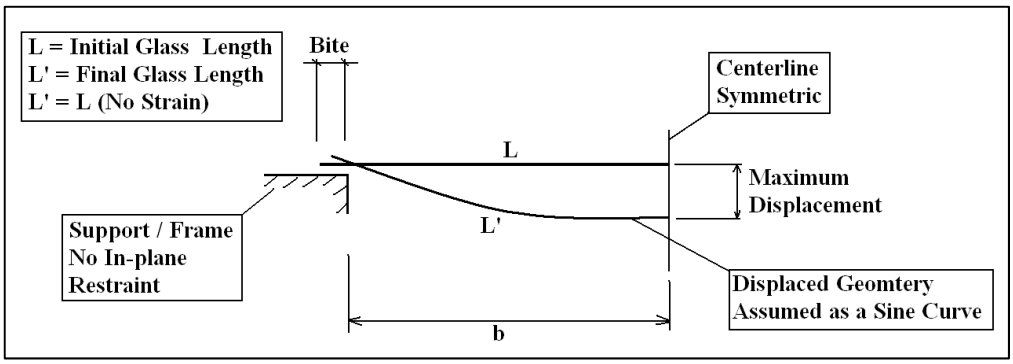

Figure 4. Bite evaluation.

2. Stresses and Strains. Pre-crack stresses are often evaluated using methods similar to Moore (1980) wherein laminated panes are treated as monolithic glass. A lamination factor is often used to account for the lower stiffness of laminated glass. Post-crack stresses are obtained from classical membrane developments where the edge is assumed to be pinned but held against in-plane translation (true pin – not a roller).

3. Reactions. Edge reactions are determined by using simple equations from dynamics and/or force displacement relationships. Given that SDOF models are typically used, the edge shear reactions are represented by a total force as a function of time. The total force is typically distributed around the glass edges using results from small displacement plate theory, which is historically considered accurate for displacements up to approximately one-half the plate thickness. Note that in the context of blast window design, the displacements are most often much higher than one-half the plate thickness. In-plane reactions may be obtained from the post-cracked membrane model described above. Note that boundary conditions integral to the pre-cracked plate model do not include allowance for in-plane reactions at the supported edge.

Failure criteria.

Various limits are imposed that influence component level responses including glass stress and glass deflection. Either may be used to trigger glass cracking. Limits on predicted laminate and film membrane strains are also imposed that prevent. The limits which are based on a percentage of strain to material failure typically represent very large global strains that may be unrealistic when evaluated in light of the post-cracked glass behavior discussed below. Global failure of a glass pane results from either failure of all layers in a pane or loss of bite at the edge of the glass. The actual definition of failure associated with the response of windows to blast loading most often falls into the following categories.

1. No glass breakage predicted. Glass remains attached to the frame.

2. Glass cracks but remains attached to the frame. A limited number of glass shards may travel some distance into the building.

3. Global failure. Glass panes separate from the frame and travel into the building. Categories are defined that effectively scale the violence with which the glass travels into the building (GANA, 2010).

4. Window travelling away from the building. The window separating from the frame and falling away from the building may occur due to some combination of timing of the negative phase, dynamic rebound of window, and weaker restraint at the support in the outward direction.

Design of support system.

Predicted dynamic reactions are typically reported in terms of force versus time. The dynamic reaction curves are most often used as input for the evaluation of connections and framing members. In the case of reactive (flexible) support systems, dynamic methods similar to those indicated above for the glass are used to predict dynamic responses. An embedded assumption is that the support response and the glass response are dynamically uncoupled. Limits on frame deflections are typically imposed that serve to support many assumptions made in the window analysis developments. Note that blast events most often result in high strain-rate responses of structural components. Accordingly, some increased effective strength is often allowed for selected materials.

FINITE ELEMENT METHODS

The finite element method has been a viable tool for decades in structural engineering and, specifically, nonlinear transient dynamic applications. Proper application of the methods to windows and curtain wall systems requires the following:

1. Understanding the physical characteristics of the actual structures.
2. Understanding the nature of blast load events and the general response of structural components.
3. Understanding nonlinear dynamic applications of the principles from engineering mechanics.
4. Understanding finite element methods in the context of nonlinear transient applications.

Viable finite element solutions to blast window and curtain wall applications fit into two major categories. First are high fidelity models that require large amounts of memory, large computers, and/or excessive computational time. Modeling and post-processing requirements may be unwieldy. The glass make-up may, for example, be modeled using several layers of solid elements that by their nature drive

up the model size. This class of solution is particularly useful for research and development efforts but is simply not practical for production design applications.

The second category of models compares with those used by Browning et al. (2009) and Duke (2005). Beam, shell, contact, weld, and solid elements are used to capture the essence of the physical characteristics of the structure. This type of model is suitable for practical design applications in that they execute quickly on a personal computer. Most of the key aspects of the system response may be captured including glass response, edge loading, component stresses, dynamic reactions, and displacement of reactive supports. This class of finite element model has repeatedly been shown to provide reasonable predictions of blast response and can be particularly useful in guiding the development, design, and evaluation process. As with the high-fidelity models, this type of model can be very useful in support of research and development efforts related to dynamic response of structures.

A primary limitation of plate-element-level finite element models for windows and curtain walls relates to the element formulations available for laminated glass. As an example, LS-DYNA (2006) has a laminated glass model that includes polymer layers and glass layers. As the predicted glass stresses exceed an input failure stress, the glass stiffness is removed from the element. In effect, the post-cracked stiffness of the laminated glass is primarily that of the internal polymer layer acting as a membrane. This characteristic matches a basic assumption included in the classical approach discussed above. As indicated above, the reality is that the post-cracked behavior of laminated glass panes is most often much different from that of a simple membrane.

A second concern regarding plate-element-level models relates to the experience and technical knowledge of the analyst. In general terms, blast engineering requires specialized abilities and experience for proper application of any of the available tools (SDOF, experimental, empirical and finite element). However, issues related to model design including selection of element type, element formulations, material models, mesh refinement and integration schemes cause yet another level of technical requirements for proper use of plate-element-level finite element models.

TECHNICAL CHALLENGES

As suggested by the discussion above, there are several areas where it is challenging to execute technically sound investigations using the current methods. As an example, Figure 5 shows representative cross sections for glass to mullion attachment for a curtain wall design at a government office building in the United States. The aluminum extrusions serve as the frame members for the glass. In the context of the actual project, some of the extrusions are primary and span floor to floor vertically. Other frame members are secondary and span between the primary verticals. In the case shown, the glass make-up includes a laminated inner pane with a monolithic outer pane separated by a closed air space. The inner pane is attached to the frame at the inside edge with structural silicone. The outer edge is covered by a non-structural snap cover. Screw chases are included in the extruded shapes to provide for mullion to mullion connection, typically using shear blocks.

Eccentric loading.

Note that while the middle image in Figure 5 amplifies the possibility of eccentric loading on the mullions, reality may be much worse. As an example, glass may only be on one side of the frame member. The glass span dimensions and resulting edge loadings are most often different on either side of the frame. The fact that the structural silicone attachment is at the inside edge only results in eccentric resistance to in-plane forces in the glass. The eccentric loading conditions cause torsional rotation of the mullions and edge bending of the glass that is often not considered using classical methods. Both responses may contribute to additional glass stresses and possible compromise of bite retention.

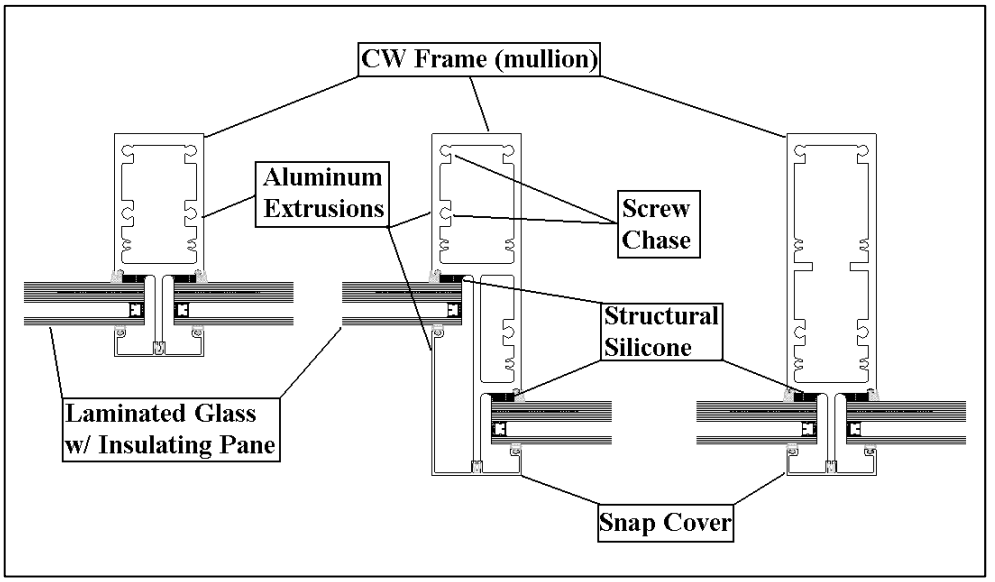

Figure 5. Curtain wall frame.

Reactive structures.

Reactive structures are structures that exhibit significant displacements during a load event. The reactive nature of the mullions is a consideration. As the mullions undergo translations and torsional rotations, the actual reactions at the edge of the glass may be significantly reduced. The effectively softer supports likely improve the performance of the glass in reference to the rigid support assumption integral to the classical methods. Considerable efficiencies may be gained by taking advantage of energy absorbing characteristics of highly reactive structures. Duke (2005) developed mathematical models of structural connections that allow very large frame movements. The allowance for large frame movements was integral to solving an otherwise very challenging blast design problem.

Another issue related to reactions and reactive structures is in-plane load prediction. Given that the post-cracked membrane model in the classical approach includes a rigid boundary assumption, the in-plane reactions are often over-estimated. This point is supported by finite element calculations and anecdotal evidence from

various curtain wall test results. Direct application of the predicted in-plane reactions to the frame members often results in overly conservative designs for the frame members.

Multiple examples exist where supports and frame members exhibit movements that allow large edge translations and rotations while providing appropriate levels of life safety. In all cases, evaluation of the system requires dynamic modeling where the support system response is included as part of a fully coupled dynamic analysis.

Glass to frame interface.

Figure 5 above shows a structural silicon bond between the inside edge of the glass and the frame. Use of structural silicone, glazing tapes, gaskets with adhesive bonds, through bolted connections, deep rebate at the edge, mechanically attached films, etc. can greatly enhance the capacity of glass in blast events. The classical assumption regarding development of in-plane membrane forces at the supports is based on the notion that the membrane is rigidly held against in-plane translations. The actual connection characteristics may allow responses that are significantly different from the rigidly held assumption.

As an example, structural silicone acts as a relatively soft spring and will allow considerable in-plane movement before failure. The rigidly held assumption often results in in-plane forces that are predicted to fail the silicone. The soft spring action of the silicone serves to relieve some of the in-plane edge loading to the point where the forces in the silicone are acceptable. In parallel to this observation is the reality that the soft silicone may allow larger global deflections and, therefore, more reduction in bite than anticipated.

Another issue relates to glass edge movements allowed in structural silicone connections like in Figure 5 and in dry-glazed configurations similar to Figure 6. Figure 6 represents dry-glazed systems that are widely used in the curtain wall industry. In the case of the single sided structural silicone connection, the softness of the silicone or the possible failure of the silicone associated with shear and uplift allows movement of the glass edge perpendicular to and away from the plane of the support, which is contrary to the boundary condition assumptions in the classical method development (see Figure 2). A similar observation may be made in reference to Figure 6 where the extruded outer bulb gasket is most often chosen to be particularly soft so as to facilitate sealing against air and water leakage. There is concern that the movement indicated above may significantly impact preservation of glass bite and edge reaction distribution. The absence of significant two-sided clamping and associated friction is in conflict with the deeply-rebated-edge assumption integral to the classical post-cracked membrane model.

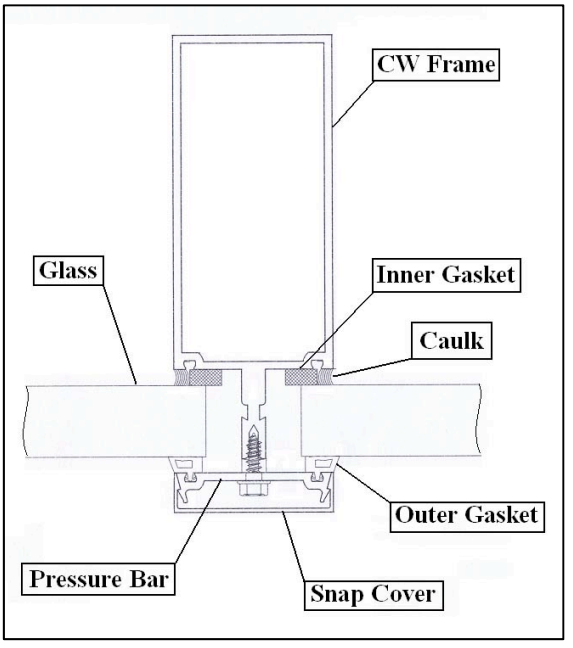

Figure 6. Dry-glazed curtain wall.

Post-cracked behavior of laminate glass.

Considerable evidence indicates that the post-crack behavior of laminated glass is not generally consistent with the pure membrane assumption integral to both classical methods and some finite element approaches. In the post-cracked configuration, large areas of cracked glass remain bonded to the laminate. The result is piecewise continuous stiffening of the laminate by the bonded glass pieces. The stiffening effect may help to explain the higher resistance represented by the empirical data in Figure 3. The stiffening impacts both in-plane and bending characteristics of post-cracked glass.

A second issue relates to treatment of large strains in the laminate material. Inner layer (laminate) materials that are often used in laminated glass make-ups for blast applications exhibit very high post-yield strains before failure (200 – 500 percent). It is common to limit post-crack membrane strains to similar levels. Results of research by Duke et al. (2009) demonstrated that the post-cracked global stains to failure are often much lower than typically assumed.

PRACTICAL CHALLENGE

In practice, window and glass curtain wall designers are faced with the challenge of providing designs that balance life safety and cost effectiveness. It is appropriate that designers provide defensible qualification of the supplied systems. The classical methods discussed above represent decades of testing, development, and evaluation that yield good results within the parameters of the development. Careful review of the discussion above along with more extensive study of the classical methods currently in wide use reveals several limitations or misapplications

of the methods. However, in many cases, the only tools available are the classical methods. Project design review and approval requirements often mandate use of the classical methods. Alternatives include simplified methods that may lead to overdesign and unwarranted cost. Project execution schedules often limit the practicality of testing programs and finite element modeling efforts. Execution of modeling and testing programs to qualify standard designs, particularly as related to windows, is reasonable. However, the glass curtain wall industry offers a much larger challenge in terms of the number of possible configurations. In addition, as new materials or material application concepts are developed, tools are needed that speed the feasibility evaluation process so that the efforts to develop viable designs may be expedited. In summary, the tools currently available for use in a production environment are limited in scope and applicability and thus need extensive enhancement.

MOVING FORWARD

The technical and practical challenges listed above are beyond the capability of current tools. While widely used classical analytical methods have been developed to a significant level of technical sophistication and maturity, they are not suitable to address many of the technical challenges listed above. Empirical methods should continue to be used where test programs and data are available. Test programs should be included in any development to tune modeling assumptions and to provide verification for mathematical models. However, addressing the full spectrum of issues and configurations would require a major test program. The technical flexibility found in finite element modeling techniques is generally suited to address most of the technical challenges. A primary exception relates to material models for post-cracked laminated glass. The greatest downfall in using finite element methods lies in user experience and knowledge requirements and modeling, execution, and post-processing time.

Efforts moving forward should support the primary goals of balancing life safety with cost efficient designs that can be developed within the time constraints of typical design and build projects. New design tools should be developed that are technically well founded and provide practical results both in terms of communication of results and of constructability of the window and curtain wall systems. Tools moving forward should facilitate development of new material applications and design concepts.

The technical and practical challenges warrant a fresh approach to carefully designed engineering level models that merge classical approaches with advanced finite element methods. Practical, productive, and time efficient engineering models have been developed that provide “engineer friendly” user interfaces with classical and finite element calculations executed automatically. The finite element analyses are effectively transparent to the users in that modeling and post-processing are automated within the software system. Many of the key aspects of the design process are rooted in classical methods with the embedded finite element processes focused on analyses that are outside the range of classical methods. As an example, PENCURV+ is a software package that uses the Lagrangian finite element code EPIC

to perform more robust penetration analyses. Information regarding PENCURV+ can be found on the web site for the U.S. Army Corps of Engineers Protective Design Center; PENCURV+ is provided by the U.S. Army Engineer Research and Development Center.

It is proposed that a development similar to that done for PENCURV+ is warranted. The challenges for such a development are in many ways different from those faced by the developers of PENCURV+, but the success of embedding finite element methods into such a program validates the proposed approach. By embedding well designed parametrically driven finite element models within a window and curtain wall evaluation and design program, the result should be a practical tool that can better address the complex technical issues without requiring the user to be a finite element expert.

SUMMARY AND CONCLUSIONS

Selected topics were discussed that address general approaches to window and glass curtain wall design. Key deficiencies in current methods were discussed. A summary of key points includes the following:

- The development and application of classical and empirical methods over a period of decades represents tools and methods that are very effective within the context of assumed geometries and boundary conditions.
- Many applications encountered by practicing designers involve conditions that are outside the boundaries for appropriate application of the current classical and empirical methods.
- The technical depth and breadth of finite element methods offers proper treatment of many of the technical challenges.
- Practical concerns over modeling time, execution, and post-processing most often reduce the effectiveness of finite element methods in their current form.
- A proposed approach is presented that marries classical, empirical, and finite element methods to provide a practical approach to addressing many of the technical challenges.
- In all cases, test programs should be executed that, as a minimum, provide verification data for any models, methods, and analytical tools that are developed.

ACKNOWLEDGEMENT

The authors would like to acknowledge Mr. Steve Lofton. Mr. Lofton was a research structural engineer at the US Army Engineer Research and Development Center in Vicksburg, Mississippi. He dedicated most of his career to the development of blast resistant windows. Mr. Lofton was a key contributor to the vision of this paper but unexpectedly passed away in 2010. The authors dedicate this paper to Mr. Steve Lofton with hopes that it will contribute to continued progress in the field he loved and helped develop.

ABSTRACT

Current United States design provisions for post-installed mechanical anchors are typically tailored toward conventional static and dynamic load regimes, such as seismic and wind loads. In fact, the dynamic behavior of post-installed anchors in reinforced concrete is primarily based on seismic loading effects. Yet, dynamic loads that produce extremely short duration impact, such as air-blast, are not addressed in design criteria, including anchorage to concrete. Usually this is not an issue as most structures are not designed to withstand these forces; however, when blast applications are considered, there is no clear method to determine how these anchors will perform. With little research on the behavior of anchor bolts under impact loads, in comparison to other long term cyclical loadings, properly designing concrete anchorage to meet these demands is difficult.

INTRODUCTION

The International Building Code (IBC) is the design code commonly used for structures in the U.S. In building design of concrete construction, the IBC makes reference to the American Concrete Institute (ACI) 318 manual. ACI 318 provides design procedures and standards for the majority of structural components, including anchorage to concrete. The design of concrete anchorage can actually be very difficult when a blast-resistant design is warranted.

In consideration of air-blast loading effects, structures are designed to withstand a high magnitude, short duration load that linearly decays within milliseconds. Unfortunately, this type of load is not addressed in the design procedures of ACI 318 Appendix D that provides a design methodology for conventional static and dynamic loads. When this approach has been tested on anchors under impact loads, research frequently shows that this method may be overconservative. Therefore, this paper attempts to provide design guidelines for post-installed mechanical anchors that may be utilized in future construction where blast design is required.

IMPACT VS. CONVENTIONAL DYNAMIC LOADS

Impact loads do not behave in the same manner as conventional dynamic loads (i.e., seismic). A typical impact load (Figure 1) initially starts at a high magnitude force or

pressure and linearly decays quickly, on the order of milliseconds. This loading type affects structures locally to the explosive event where large inelastic deformations are expected. Additionally, increase in material strengths are expected due to high loading rates.

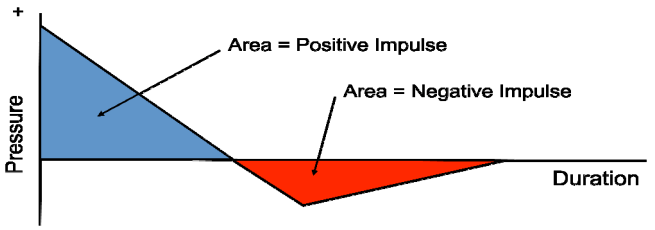

Figure 1. Typical Impact Load Curve

Conversely, conventional dynamic loads (Figure 2) have much longer durations and usually generate less energy demand than impacts. These dynamic loads are cyclic in nature, while impact loads have a positive loading phase in one direction and a negative suction in the other direction. For seismic loads, structures are loaded on a global scale, and rarely affect local components. As this loading is much slower than impacts, there are no increases in material strengths.

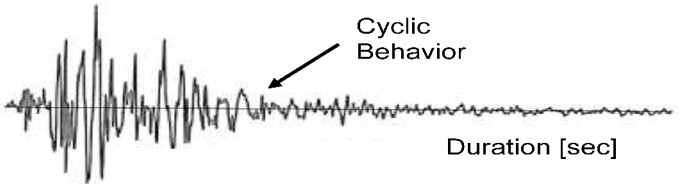

Figure 2. Conventional Dynamic Load (Loma Prieta Time History Adapted from *Chopra 2001*)

ACI 318 APPENDIX D

ACI 318 Appendix D provides a design procedure for structural anchors in concrete that "transmit structural loads related to strength, stability, or life safety" (ACI 318) based on the Concrete Capacity Design (CCD) method (*Fuchs, Eligehausen, Breen 1995*). First introduced in ACI 318-02, it was not implemented until IBC 2003 was released. IBC 2003 required the use of Appendix D if the designer was working with one of the following scenarios: (1) any anchors resisting seismic forces; and (2) post-installed anchors installed in hardened concrete. Dynamic loads that are predominately high cyclic fatigue or impact are outside the scope of Appendix D.

Per Appendix D, anchors are evaluated for failure mechanisms most commonly associated with them under tensile and shear forces. When post-installed anchors are to be used, they must be qualified in accordance with ACI 355.2 (*Qualification of Post-Installed Mechanical Anchors in Concrete and Commentary*). ACI 355.2 presents the methodology to determine the reported post-installed anchor capacities for concrete breakout, pull-out, and shear under both static and seismic loads. The

failure modes designed for in ACI 318 Appendix D are provided below with brief descriptions:

- Tension Failure Modes
  - Steel Rupture: When the external tensile load exceeds the ultimate capacity of the steel, it is expected that the steel will rupture. The maximum capacity of the steel is calculated from the stressed cross-sectional area and the tensile strength of steel.

    This mode of failure is typically a ductile failure mode, where the steel anchor, after it has yielded, is likely to undergo a period of strain hardening and be capable of withstanding further stress and strain.

  - Pull-Out: Pull-out failure is usually associated with expansion anchors. As expansion anchors further expand into the concrete, it creates local deformations in the concrete around the drilled hole, generating a force due to the radial expansion pressure. The failure pull-out load is proportional to the expansion force via the frictional coefficient between the steel and concrete. The pull-out mechanism is at a load level in which the anchor is unable to develop follow-up expansion with a brittle failure occurring.

    This failure mode is considered brittle because once the frictional resistance developed by the concrete and steel is lost, failure immediately occurs.

  - Concrete Cone Breakout: Anchors subjected to conventional loads are likely to fail under concrete cone breakout. This failure mechanism is exhibited when the full tensile capacity of the concrete is exceeded. This mode is characterized by the formation of a 30° to 40° conical fracture to the surface. Edge distance, embedment depth, and concrete compressive strength affect this failure mode.

    Concrete cone breakout is also a brittle failure mode. The failure of the concrete will tend to follow a linear elastic stress-strain curve initially, but as there is no clearly defined yield point of the material, it will fail unexpectedly.

- Shear Failure Modes
  - Steel Failure: This failure mechanism is exhibited when the edge distance and embedment depth of the anchor is sufficient to prevent concrete and pry-out failure. It is indicative of the shear capacity of the steel material. If ductile steel is used, relatively large anchor deformation can be developed.

  - Concrete Edge Failure: Anchors located near a free edge are likely to fail from concrete fracture before the shear capacity of the steel is

reached. The fracture in the concrete originates at the point of bearing and radiates to the free surface. This is another example of a brittle failure mode.

- Pryout Failure: When limited embedment depth is provided, anchors loaded in shear may rotate and produce a pry-out fracture. A pry-out fracture is when the primary fracture surface develops behind the point of load application. Edge distance does not affect this failure mode.

As previously stated, post-installed anchors to be used in hardened concrete are required to follow design protocols established in ACI 318, Appendix D. Post-installed anchors are comprised of both mechanical and adhesive anchors. Since adhesive anchors are excluded from the scope of Appendix D, they have been excluded from this discussion.

Post-installed mechanical anchors typically consist of expansion and undercut anchors. Provided is a brief description of these anchors:

- Expansion Anchors: Expansions anchors can be divided into two groups: (1) torque-controlled; and (2) displacement-controlled.

  Torque-controlled anchors transfer external forces through friction and mechanical interlock to the deformed concrete. When torque is introduced upon installation, it generates a pre-stressing force in the bolt and clamps the item being fastened against the concrete surface. As the anchor is loaded beyond the pre-stressing force, the expansion sleeve further expands generating the necessary additional friction to resist the applied load. Figure 3 shows several examples of torque-controlled expansion anchors, including their load-transfer mechanism.

  Displacement-controlled anchors (Figure 4) are secured through the expansion of the sleeve as controlled by the axial displacement of the plug within the sleeve. These expansion anchors transfer external loads into the base material through friction, and to a lesser degree, mechanical interlock. Additionally, displacement-controlled anchors initially generate a greater expansion force than their torque-controlled counterparts; however, as external load is introduced, subsequent expansion does not increase the resistance force.

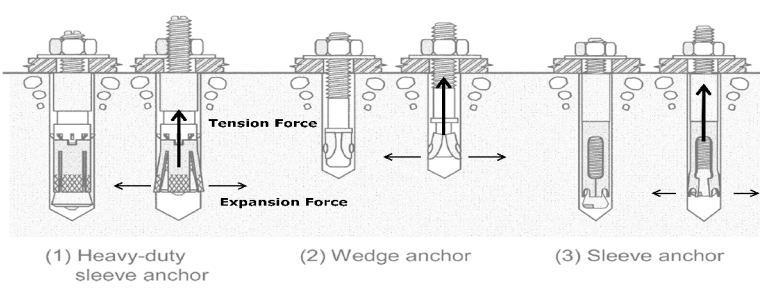

Figure 3. Torque-Controlled Expansion Anchors (Adapted from *ACI 355.2 - 07*)

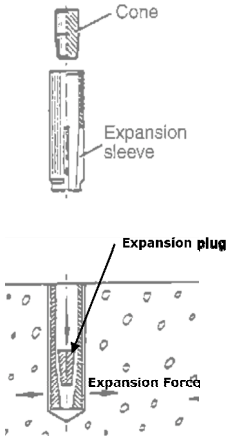

Figure 4. Displacement-Controlled Anchor (Adapted from *Eligehausen, Mallée, Rehm* (1997))

- Undercut Anchors: These anchors transfer external forces by developing a mechanical interlock between the anchor and concrete. Unlike expansion anchors, undercut anchors are installed in a two step process. The first step is to create the undercut in the concrete using an undercutting tool. This process is crucial in developing the maximum capacity of the bolt, as the anchor will bear on the concrete. The second step is to insert the undercut anchor and apply the appropriate torque to develop a bearing pressure that properly clamps the bolt in place, as shown in Figure 5.

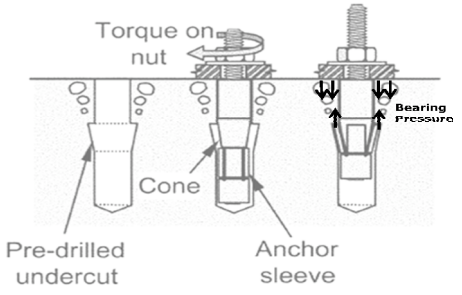

Figure 5. Undercut Anchor (Adapted from *ACI 355.2-07*)

RESEARCH REVIEW

Several studies have been conducted on the tensile and shear capacity of post-installed mechanical anchors under static and seismic loads, but few studies have been done for high strain rate dynamic behavior that are typical of impact loads. Research on this material includes the following: *D. M. Collins, R. E. Klinger, and D. Polyzois* (1989), *Hilti and R.E. Klinger* (1995), *D. Schuler* (1997), *P. Hunziker* (1999), *M. Rodriguez, D. Lotze, J. H. Gross, Y. G. Zhang, R. E. Klinger, and H.I. Graves, III* (2001), *H. Salim, R. Dinan, J. Shull, and P.T. Townsend* (2005), and *G. Mitchell, M. Tolnai, V. Gokani, R. Picon, S. Yang, R.E. Klinger, and E. B. Williamson* (2006).

Collins (1989) and *Rodriguez* (2001) tested anchors with loading rise times of approximately 250 msec. At this loading rate, the load is still relatively slow

compared to impact loads, and anchors behave approximately equivalent as under static conditions. *Hunziker* (1999) tested anchors with load duration rates of roughly 35 msec, and found that torque-controlled expansion and undercut anchors could resist impact loads with torque-controlled expansion anchors resisting more than 4 times the European static capacity. *Salim* (2005) looked at several anchoring systems at various loads. Of these, *Salim* (2005) showed that torque-controlled expansion anchors loaded with relatively short rise times could resist up to 20% more than the U.S. static capacity. Ultimately, all studies showed that displacement-controlled expansion anchors performed unfavorably and should not be considered for applications where impact loads are possible.

Experimental data has shown that as loading rate increases, tensile capacity of expansion anchors and undercut anchors increase also. This increase in capacity is referred to as the Dynamic Increase Factor (DIF). The DIF is equal to the ratio of dynamic stress to static stress of an element, and increases as the strain rate increases. Many Hilti anchors in Europe have been tested under impact loads and allowable shock capacities have been reported, as well as appropriate DIF for expansion and undercut anchors. Assuming that anchors are allowed to undergo plastic deformations and are to be replaced, Hilti states that expansion anchors and undercut anchors can have a DIF of 1.7 and 2.7 respectively, compared to DIBt (Deutsches Institut für Bautechnik)-approved static resistance. Much like the International Code Council (ICC) Evaluation Service in the U.S., the DIBt is the German approval body that evaluates construction products.

ANCHORS SUBJECTED TO IMPACT LOADINGS

The design approach presented attempts to incorporate Appendix D with recommended guidelines derived from research. Further, recommendations are based on the assumption that bolts have manufacturer's minimum embedment depth and edge distances greater than or equal to 150% of the embedment depth. Unless noted, all commentary and design requirements specified in ACI 318 Appendix D are to be used in conjunction with the approach shown.

GENERAL RECOMMENDATIONS

Displacement-controlled expansion anchors are not to be used as testing has shown that these systems do not meet or exceed the static capacity when subjected to an impact load.

In accordance with ACI 318, anchor capacities are lowered and design loads are increased with the use of Strength Reduction Factors, ϕ, and Load Increase Factors, respectively. In doing so, uncertainties in the material and loading are accounted for in the analysis. For blast loading, the resultant force on anchors of a connection is explicitly determined based on the inelastic, non-linear dynamic response of the member being connected to its ultimate flexural capacity. It is therefore

recommended that given the nature of the loading, the Load Increase Factor for blast is assumed equal to 1.0 because it is at an ultimate load level.

Material uncertainties are accounted for inherently in design equations per ACI 318 Appendix D through ψ factors that modify anchor capacities due to anchor location and material properties, etc. Also, the behavior of steel is well documented and easily predictable. Moreover, concrete behaves in a brittle manner under shear and tensile rupture and does not have a well defined yield point.

It is recommended that strength reduction factors are eliminated as this is not a strength design, but rather an ultimate load design. Dynamic increase factors are to be introduced based on material overstrengths and testing results for anchor failure modes due to the nature of this loading type.

DESIGN REQUIREMENTS FOR TENSILE LOADING

ACI 318 Appendix D provides design guidelines to determine the capacity of anchors at failure for steel rupture, concrete pull-out, and concrete cone breakout. Along with recommendations for impact design, Appendix D equations have been provided for comparison.

Steel Rupture: The nominal steel strength of a single anchor or group of anchors is given in ACI 318 Appendix D equation D-3 as $N_{sa} = nA_{se,N}f_{uta}$, where n is the number of anchors in the group, $A_{se,N}$ is the effective cross-sectional area of a single anchor in tension, and f_{uta} shall not be taken greater than the smaller of $1.9\boldsymbol{f_{ya}}$ and 125,000 psi.

Research has shown that anchors subjected to an impact load will have an increase in capacity. As this is a ductile failure mode, it is recommended that deformations enter the plastic region of the steel constitutive model. Therefore, the steel rupture capacity may be multiplied by a DIF.

The recommended DIF is taken from the Hilti European dynamic design manual for anchors. The use of a DIF assumes that the anchor undergoes plastic deformations and will be replaced after an impact event. The steel strength is determined in the same fashion as is given in ACI 318 Appendix D; therefore the following DIF's are to be used:

- Torque-Controlled Expansion Anchors: 1.7
- Undercut Anchors: 2.7

Steel Pull-Out: The nominal pullout strength of a single anchor in tension from Appendix D shall not exceed $N_{pn} = \psi_{c,P}N_p$ where $\psi_{c,P}$ is the modification factor for an anchor located in a region where no cracking is present at service load levels, and N_p is the pullout tensile strength based on the 5 percent fractile of tests evaluated according to ACI 355.2.

Testing has shown that under impact loads, steel pull-out is most common. While pull-out is considered a brittle failure mode, DIF values may still be formulated from the experimental failure impact loads. In comparison with U.S. testing standards, the European Technical Approvals (ETA) provide lower capacities for steel pull-out in cracked concrete. Capacities, not including partial safety factors, conservatively appear to be 65% lower than their U.S. counterparts. For this reason, the recommended values from Hilti of 1.7 and 2.7 for expansion anchors and undercut anchors, respectively, have been factored to reflect this trend.

For pull-out design of anchors, it is recommended to use the prescribed equation in ACI 318 with the inclusion of the following DIF's:

- Torque-Controlled Expansion Anchors: 1.1
- Undercut Anchors: 1.8

Concrete Breakout Strength: The nominal concrete breakout strength of a single anchor or group of anchors in tension from Appendix D is determined from the following equations:

$$N_{cb} = \frac{A_{Nc}}{A_{Nco}} \psi_{ed,N} \psi_{c,N} \psi_{cp,N} N_b \text{ (single anchor)}$$

$$N_{cb} = \frac{A_{Nc}}{A_{Nco}} \psi_{ec,N} \psi_{ed,N} \psi_{c,N} \psi_{cp,N} N_b \text{ (group of anchors)}$$

where A_{nc} is the projected concrete failure area of a single anchor or group of anchors, A_{nco} is the projected concrete failure area of a single anchor with an edge distance equal to or greater than 50% greater than the embedment depth, N_b is the basic concrete breakout strength derived from testing of a single anchor in tension in cracked concrete, and $\psi_{ec,N}$, $\psi_{ed,N}$, $\psi_{c,N}$, $\psi_{cp,N}$ are modification factors as prescribed in ACI 318.

The behavior of anchors under a concrete cone breakout failure mode due to impact loads was not tested. Further, as this is a brittle failure mode, material overstrengths are not expected. Upon further testing, no recommendation can be made for a dynamic increase factor.

Interestingly, the ETA specifies larger anchor spacing and edge distances than the ICC criteria do. At this point, no recommendation is provided for these distances, as well as for this failure mechanism. Further research is required on this topic to provide insight on this matter.

DESIGN REQUIREMENTS FOR SHEAR LOADING

The following section is a recommendation for the design of post-installed mechanical anchors in shear.

Steel Shear Strength: The nominal steel strength of a single anchor or group of anchors is given in ACI 318 Appendix D as $V_{sa} = nA_{se,V} f_{uta}$ where n is the number of

anchors in the group, $A_{se,V}$ is the effective cross-sectional area of a single anchor in shear, and f_{uta} shall not be taken greater than the smaller of $1.9\boldsymbol{f_{ya}}$ and 125,000 psi.

It is recommended that the steel shear capacity use the DIF's proposed for steel rupture. The shear strength for this mode is to be increased by 1.7 or 2.7 for torque-controlled expansion anchors or undercut anchors, respectively.

Concrete Breakout Strength: The nominal concrete breakout strength of a single anchor or group of anchors in tension from Appendix D is determined from the following equations:

$$V_{cb} = \frac{A_{vc}}{A_{vco}} \psi_{ed,V} \psi_{c,V} \psi_{h,V} V_b \text{ (single anchor)}$$

$$V_{cbg} = \frac{A_{vc}}{A_{vco}} \psi_{ec,V} \psi_{ed,V} \psi_{c,V} \psi_{h,V} V_b \text{ (group of anchors)}$$

where A_{vc} is the projected area of the failure surface on the side of the concrete member at its edge, A_{Vco} is the projected area for a single anchor in a deep member with a distance from edges equal or greater 50% greater than the critical edge distance, and $\psi_{ec,V}\psi_{ed,V}\psi_{c,V}\psi_{h,V}$ are modification factors given in ACI 318.

Much like concrete breakout in tension, this is a brittle failure mode and does not warrant increasing the capacity with the use of a DIF.

Steel Pryout: The nominal pryout strength of a single anchor in tension from Appendix D shall not exceed $V_{cp} = k_{cp} N_{cb}$ where k_{cp} is the modification factor for the effect of embedment depth, and N_{cb} is the nominal concrete breakout strength.

No recommendations for DIF are provided for this design as this is a brittle failure mode and research on this topic is sparse.

RECOMMENDATIONS

In the process of developing design guidelines for impact loads on post-installed mechanical anchors, it is apparent that more research is needed on the topic. Furthermore, it appears that the state of practice in Europe on this subject is further ahead than the United States, as testing standards have already been developed in the area. Presented below are items that require more investigation or need to be developed on the topic.

Loading Rate: In the studies reviewed that focused on impact testing of anchors, only few had rise times that were comparable to impact loadings. It is imperative that research be conducted with loads that have time durations with a maximum time of 100 msec to better understand the behavior of post-installed mechanical anchors.

Anchor Properties: Research shows that anchor diameters and embedment depths will have an effect on the anchor's behavior under impact loads. Consequently, the

DIF is expected to not be a single value for just one type of bolt or failure mode. Further investigations could potentially develop trends in capacities and properties, which could be incorporated into future designs.

Anchor Layout: Anchors were tested with large edge distances, which likely led to the dominant failure mode of pull-out. As the anchor edge distance starts decreasing, it is assumed that concrete cone breakout may occur. Testing is needed considering anchors with reduced edge distances. Also, it appears that research did not evaluate the effect impact loads had on anchor groups. Testing of groups of anchors is necessary to fill in the gaps of knowledge on this topic.

Shear Capacity: With little experimental data on the topic, it was very difficult to develop design guidelines for shear. It is predicted that post-installed mechanical anchors, not located near concrete edges, will fail by pryout as anchors will displace horizontally from the initial load and begin to rotate causing this failure mechanism.

Anchor Evaluation Testing: It is important that manufacturers in the United States work with academia and industry to develop testing standards for post-installed mechanical anchors. At a minimum, anchors should be tested to failure to determine prominent failure mechanisms and maximum loads and impulses. This would allow designers to specify anchors that could withstand the energy demands for a given impact.

As an example of a current testing standard for impact, AC Laboratory Spiez Report 9710 (Schuler 1997) provides a testing method to evaluate the pull-out probability and slip behavior in cracked concrete for civil defense installations in Switzerland. Anchors are placed in concrete blocks to manufacturer's standards and loaded twice with impact loads. Slip movements are measured after each load and reported, as well as whether the anchor completely pulled out of the block. These responses are compared to an acceptable pull probability and slip displacement.

CONCLUSION

U.S. design of concrete post-installed mechanical anchors is based on procedures and standards given in ACI 318 Appendix D. For structures that are not subjected to impact forces, the use of Appendix D is appropriate as loads on elements are of a static or conventional dynamic nature. However, Appendix D does not account for impact loads causing a dilemma for designers.

While only a few studies have been done on the topic, design recommendations for impact applications have been provided herein and include:

- Displacement-controlled anchors are not to be used

- Resultant forces on anchors are considered as ultimate loads. For that reason, Strength Reduction Factors are to be eliminated and Load Increase Factors equal 1.0

- Failure loads prescribed in ACI 318 for steel rupture in tension, as well as steel failure in shear may be increased with DIF's specified for torque-controlled expansion anchors and undercut anchors as they are ductile failure modes.

- Failure load prescribed in ACI 318 for pull-out may be increased with DIF's specified for torque-controlled expansion anchors and undercut anchors due to experimental testing

In order for U.S. design to become more efficient and lead the way on this topic, further research is required that would investigate the following: (1) loading rate; (2) anchor properties; (3) anchor layout; and (4) shear capacity. Above all else, it is absolutely necessary that manufacturers work with industry and acadamia to determine a method to qualify post-installed mechanical anchors for impact loads.

Analysis Techniques for Terrorist Risk Assessment and Mitigation of Bridges

A. M. Coughlin[1], P.E., M.ASCE

ABSTRACT

In 2003, the Blue Ribbon Panel on Bridge and Tunnel Security issued its recommendations for risk assessment and mitigation of bridges and tunnels. The report gives general guidelines to help decision makers improve the security of bridges and tunnels. However, the actual implementation can be highly dependent on the methods used to carry out the assessment. Variability in risk assessments may prevent limited funding from going to projects where it is needed most. The factors that determine the relative risk of a bridge include: Occurrence – the likelihood of an event taking place, whether intentional or unintentional; Vulnerability – the consequences of an event; and Importance – the tangible and intangible value of the asset. The product of weighted scores for each of these factors determines the relative level of risk.

A real life example of risk assessment is presented with special attention paid toward the calculation of the weighted score for vulnerability. The threats listed in the Blue Ribbon Panel report were used to determine the consequences of various terrorist tactics of a real-life group of movable bridges over a waterway used for shipping. Potential consequences of attack included damage to bridge, downtime of bridge and waterway, human casualties, and collateral damage to surrounding area. Conventional blast resistant engineering methodology, more commonly used on buildings, was used where applicable and compared to high fidelity modeling. The damage expected on each component in the bridge was used to estimate the vulnerability scores.

The Blue Ribbon Panel report discusses possible mitigation measures and how to prioritize their implementation. Mitigation measures usually focus on reducing either occurrence, though deterrence measures, or vulnerability, through hardening or increasing standoff. Both types of mitigation measures are applied to these real life examples as a model of how bridge owners can most effectively reduce terrorist risk on their assets.

INTRODUCTION AND BACKGROUND

Terrorist actions in recent decades have prompted a global response to mitigate these threats. While terrorist attacks can often be prevented through intelligence, border security, blocking funding sources, and other measures, the last line of defense against terrorist plots on critical targets is physical and operational security. Bridges represent a significant number of attractive targets to terrorists, partly due to their high number of users, importance to local economies, and

relatively easy access to key structural components. In the months following the September 11, 2001 attacks, U.S. officials warned of specific intelligence that high profile bridges in San Francisco were potential next targets. Mitigation efforts were quickly put in place over the next years (San Jose Mercury News 2003). To better allocate terrorist threat mitigation funds, decision makers rely on terrorist risk assessments to identify critical assets, key vulnerabilities, consequences, and countermeasures. Procedures for these assessments have been proposed by SIAC (2002) and others.

In 2003 the Blue Ribbon Panel on Bridge and Tunnel Security issued its recommendations for the protection of U.S. bridges and tunnels (FHWA 2003). Within their seven overarching recommendations were two related to the technical implementation of risk assessment procedures, including:

- *Technical Expertise* – to "engineer" security solutions with the necessary engineering expertise.
- *Research, Development, and Implementation* – To use existing engineering tools and develop new tools to implement consistent standards.

In light of these technical recommendations this paper investigates several established analysis methods and seeks to determine when each method should be used within the time and budgetary constraints of terrorist risk assessments addressing anywhere from several to several hundred bridges at once. As the Blue Ribbon Panel pointed out, the U.S. transportation infrastructure network "is fractionated and regulated by multiple jurisdictions at state, federal, and sometimes local levels" (FHWA 2003). It is clear that a consistent set of threat scenarios and performance objectives should be used by all who are tasked with quantifying the vulnerability on a particular bridge. This paper proposes that a consistent set of analysis *methods* is also critical to terrorist risk assessments that can be useful on a large scale.

TERRORIST RISK ASSESSMENTS

Terrorist risk assessments have been modeled after procedures originally developed for seismic hazard mitigation. They seek to identify assets that have high risk of losses occurring from terrorist attack. It should be noted that terrorist risks are some of the many risks that bridges face and mitigation monies should be allocated considering other natural and manmade hazards.

An important step in a terrorist risk assessment is to identify critical assets. The criticality of these assets is not only due to their critical function, but also to their likelihood of becoming a terrorist target. As Williamson and Winget (2005) point out, terrorist goals vary based on the specific goals of their organization but have most commonly focused on attacks that have high visibility and media coverage, target iconic or critical assets, make political statements or obtain publicity for their cause, cause fear, damage economies, and more. Terrorists would therefore be more likely to target bridges whose destruction would accomplish many of these goals.

Once critical assets have been identified a risk assessment can be conducted, often involving the calculation of risk scores with the following equation (Blue Ribbon Panel 2003):

$$R = \sum (O_i V_i) \times I \quad (1)$$

where

R = Risk score

O = Occurrence: a factor representing the likelihood of a specific terrorist threat

V = Vulnerability: a factor representing the consequences to an asset given a specific threat occurs

I = Importance: a factor representing the socioeconomic value of an asset and its function

i = each threat under consideration

The "occurrence" and "vulnerability" factors are calculated for each specific threat and their product is summed for all threats considered. Potential terrorist threats to bridges include: explosives, ranging from hand-carried explosives to larger explosives delivered by car, truck, or watercraft; cutting devices such as torches, saws, or small explosives; fire which can result in weakening and/or failure of key structural elements; impact by vehicles or watercraft; and, in the case of moveable bridges, sabotage of machinery to disrupt normal operation.

Bridges with a high risk score may be chosen to receive mitigation strategies to reduce risk. Mitigation strategies are prioritized in order of their benefit to cost ratio, where benefit is measured as the reduction in risk score. Mitigation strategies typically seek to deter, deny, detect, and defend, which are explained in Table 1.

Table 1. Examples of Mitigation Strategies

Mitigation Strategy	Goal
Deter	Make target less attractive for potential attacks
Deny	Prevent access to vulnerable locations
Detect	Identify threats and monitor suspicious activity
Defend	Design elements to limit damage from terrorist attacks

Improved response can be considered another mitigation strategy. Well implemented emergency response plans geared toward attending to injured people, providing temporary alternative transportation routes, clearing wreckage, and mobilizing repair crews reduce consequences and should not be overlooked as terrorist risk mitigation strategies.

ANALYSIS TECHNIQUES

The task of conducting terrorist risk assessments for U.S. bridges is often shared between government agencies at the federal, state, and local levels and private consultants experienced bridge design, blast analysis, and physical security. The assessments are often first carried out on a national level to identify critical assets and earmark mitigation funds on a national level. Then, as mitigation funds are made available to bridge owners, more in-depth risk assessments are carried out. The diversity of personnel who may be tasked with a risk assessment will undoubtedly

result in a diversity of methods to conduct the assessments. Assessments to calculate vulnerability may be very detailed, considering many different threats and locations, or very broad, dealing with only specific bridge attributes, such as bridge type, span lengths, number of spans, average daily traffic, etc. This depends on the number of bridges assessed and the time and funding allocated.

Analysis techniques used to calculate vulnerability may include one or more of the following:

- *Visual Observation* – vulnerabilities are identified by an experienced professional and engineering judgment is used to determine likely consequences.
- *Single Degree-of-Freedom (SDOF) Analysis* – individual structural elements are modeled using a lumped mass-spring approximation according to Biggs (1964) often with empirically derived blast pressure-time histories.
- *Finite Element Modeling (FEM)* – multiple response modes are modeled to calculate the response of all or part of the bridge structural system.
- *Coupled Finite Element Modeling* – Computational fluid dynamics (CFD) are used to model the blast wave as it interacts with the structure.

Each method has distinct advantages and disadvantages and all depend, to some extent, on empirical data. As shown in Figure 1, increased accuracy has the tradeoff of taking increased time and cost. In risk assessments of multiple bridges there is rarely time or budget available for finite element modeling. These methods are more often used when a known threat is being considered on a single high profile asset.

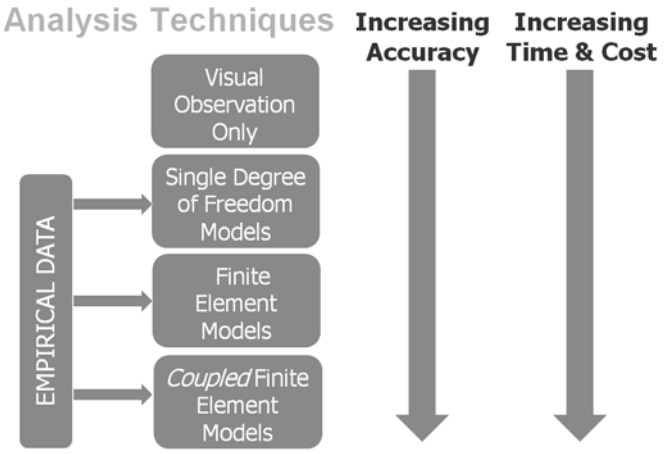

Figure 1. Accuracy, Time, and Cost of Analysis Techniques

SDOF blast analysis has many advantages over simple visual observation without the computational cost of FEM. Commonly used for blast analysis of buildings, SDOF methods are well established and have been validated by an abundance of testing that dates back to the 1940's. Element damage has been separated into superficial, repairable, unrepairable, heavy and blowout based on support rotations and ductilities (UFC 3-040-02 2008). SDOF methods are typically limited to individual elements with standard support conditions where explosive weight and standoff are within the limits of empirical pressure and impulse charts.

Many cases in bridge blast analysis are outside the scope of SDOF methods and require alternative methods.

A useful tool for the analysis of structural elements to blast loads is a Pressure-Impulse (PI) diagram. Calculated with SDOF methods, PI diagrams can be constructed for specific elements with curves predicting the expected damage for blast pressure and impulse combinations. Since a PI diagram is a property of a structure, it can be used to quickly calculate response for many charge weight and standoff distance combinations. An Excel® based tool for construction of PI diagrams is the Component Explosive Damage Assessment Workbook (CEDAW), which is distributed by the U.S. Army Corps of Engineers Protective Design Center (Oswald 2005).

Analytical methods are supplemented by empirical data, especially when close-in blast analysis is required. Localized response becomes more prevalent when scaled distance of an explosive is less than 0.4 $m/kg^{0.33}$ (1 $ft/lb^{0.33}$). Concrete breach prediction curves have been published (UFC 3-340-01 2002), though there is a significant lack of information regarding steel local response. Despite their inherent limitations, breach prediction curves can be used to find crater diameter on a bridge deck or determine the amount of local damage on a concrete pier or abutment. This is especially important since large bridge members, such as primary girders and piers, may not experience flexural or shear failure from a blast but could be severely compromised due to local damage at a critical location. More information about blast effects on bridge piers, including design guidance, is available in *Blast-Resistant Highway Bridges: Design and Detailing Guidelines* (Williamson et al. 2010).

Damage from non-blast threats such as cutting devices, fire, and vehicle impact also have a variety of analysis methods that can be used, though discussion of them is outside the scope of this paper.

POST-EVENT STABILITY ANALYSIS

Progressive collapse analysis following damage to bridge members is important to consider when calculating vulnerability scores for specific terrorist threats. The stability of a bridge following the failure of one or more of its primary members is a function of many things, such as structural redundancy, overstrength of adjacent members, and alternate load paths. Progressive collapse analysis takes the damaged state as initial conditions and finds the structure's ability to transfer forces through alternate load paths. It can be done statically or dynamically with linear or nonlinear member response. The analysis must be repeated for each damage scenario and can be extremely time consuming. In circumstances where full progressive collapse analysis is not feasible, energy balance methods can be used. A conservative assumption , that a structure will collapse once all primary load paths have been removed, can be used to predict progressive collapse if analysis of the structural system is not feasible within the time and budget constraints of a risk assessment.

A measure of a structure's ability to sustain local damage without global collapse is called robustness. Many researchers have embarked on finding methods to quantify robustness. Cavaco et al. proposed a calculation that is applicable to nearly any structure and cause of damage, given as:

$$R_d = \int_{d=0}^{d=1} f(x)dx \tag{2}$$

where R_d is the robustness index (between 0 and 1), d is the amount of damage (0 = no damage, 1 = complete damage), and f is failure (0 = no failure, 1 = total failure). If a small amount of damage, d, results in a large amount of failure, f, the structure will have a very low robustness index. Conversely, if the structure sustains failure at the same rate it sustains damage it will have a higher robustness index (Cavaco et al. 2010). Calculation of robustness index theoretically considers damage resulting from any manmade or natural threat; though in actual practice a finite number of threat scenarios would be considered. Given the number scenarios needed for consideration, simplified methods of analysis are ideally suited for robustness index calculation.

CHOICE OF ANALYSIS TECHNIQUE

Ideally a comprehensive risk assessment of all bridges within a country would be undertaken with a consistent set of analysis methods. However some assessments warrant more in-depth methods and in others it is sufficient to use quicker, simplified methods. Choice of analysis technique for bridge risk assessments depends on:

- Number of bridges in study
- Structural complexity of each bridge
- Type of threats being considered
- Time and budget constraints

When the analysis methods used to calculate vulnerability scores are inconsistent for bridges in the same risk assessment, the results may be skewed and mitigation funds may be withheld from where they are needed most. A case study is used to demonstrate how analysis techniques may be applied to a real-life risk assessment.

CASE STUDY

A group of twelve bridges crossing an inland waterway in a major U.S. city were chosen to receive federal funds to assess the risk of a variety of threats, both natural and manmade. The terrorist risk portion of the assessment was delegated to experts in that field. Details of these bridges are omitted for security reasons. Some of the bridges served critical local and regional transportation routes and heavy economic losses were anticipated if the waterway was blocked. Because of deadlines to use funds the task of calculating the risk scores for the bridges was divided between three consultants, each taking four bridges. This author was tasked with finding the terrorist vulnerability for four moveable bascule bridges serving city streets. The bridges consisted of tapered girders which rotated around a trunnion on each side of the waterway. Steel stringers and girders supported decks of either concrete or open-grate steel. One of the bridges is shown in Figure 2 open with a barge passing beneath it. The threat scenarios considered were taken from the Blue

Ribbon Panel Report (FHWA 2003) and included four sizes of explosives – delivered by hand, passenger car, truck, and barge – and an incendiary threat, not discussed in this paper.

Figure 2. Moveable Bascule Girder Bridge from Case Study

The assessment assumed that each threat was delivered at the location most effective in damaging the bridge threat locations were only considered if they were accessible by the delivery method. For the vulnerability assessment, calculations were done independent of the likelihood of occurrence. It was decided that PI diagrams were an ideal tool because of the ease of analysis for the entire bridge system. Using SDOF methods, PI diagrams were developed for all bridge framing members based on limit states of superficial, repairable, unrepairable, and heavy damage, and blowout taken from U.S. Army Corps of Engineers Protective Design Center, *Single-Degree-of-Freedom Structural Response Limits for Antiterrorism Design* (2008). In some cases the member capacity was reduced based on its connection capacity. The PI diagrams were mapped to their location on the bridge and blast pressures were calculated for the specified location of the threat using a script in Matlab. The bascule girders, typically nonprismatic members, were analyzed using SDOF properties calculated based on first principles (Clough and Penzien 1993). Figure 3 shows the result for an example case and Figure 4 shows a schematic of one of the bascule girders analyzed. The analysis was repeated until the worst case was found for each threat scenario.

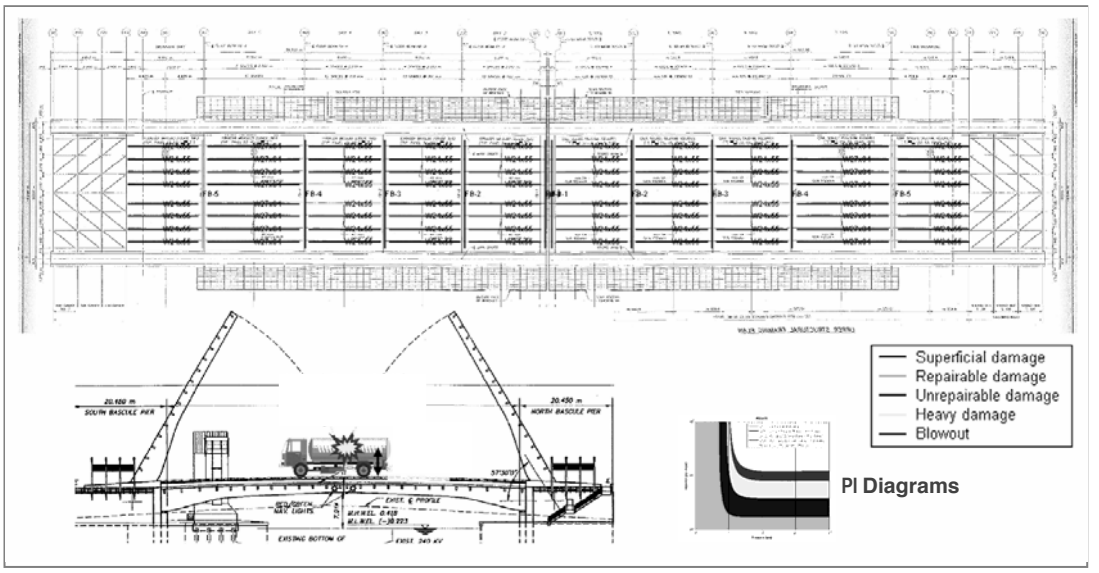

Figure 3. PI Diagram Analysis of Bascule Girder Bridge

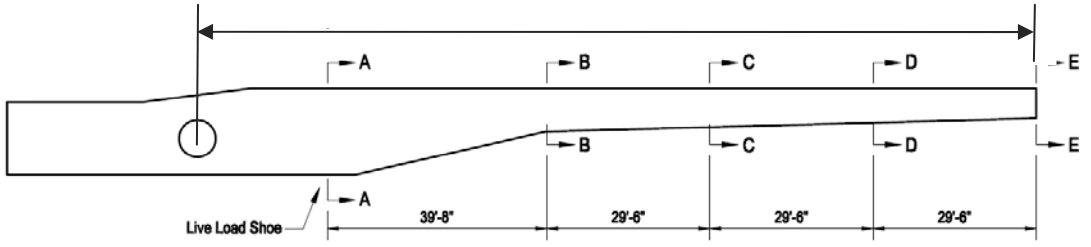

Figure 4. Bascule Girder Schematic

Local effects of blast were found with empirical curves for concrete breach taken from UFC 3-040-1 (2002) and for steel breach taken from FM5-250 (Headquarters Department of the Army 1992). Though these methods may oversimplify a highly variable and complicated phenomenon, they were considered adequate for the scope of the assessment. Based on the damaged condition of the bridge following the blast event, it was assumed that the members experiencing heavy damage and those members supported by them would collapse. Based on the local damage calculated from empirical curves, the residual capacity of the main girders was checked to determine if it could sustain the loads from the AASHTO Extreme Event II load combination, 1.25DC + 0.5LL (Ghosn 2003).

Some aspects of vulnerability, conversely, could be calculated without using analytical methods. If the equipment used to open and close the bridge was disabled, the barge traffic in the waterway would be disrupted. On several bridges, the operating machinery was protected by a concrete wall and on others it was exposed. Without calculation, it was determined that a package sized threat could destroy the operating machinery and disable the bridge until it could be repaired or replaced.

These vulnerability scores were used to calculate risk score for the four bascule bridges and the risk scores were combined with those from the other eight bridges. It was found, however, that the three consultants hired to conduct the risk

assessments used vastly different methods, such that comparison of mitigation options was difficult. Such variance in methods due to lack of guidance from funding agencies may have resulted in mitigation funds going to less critical projects.

SUMMARY OF RECOMMENDATIONS

In some aspects of bridge engineering over-standardization limits engineers from finding creative new solutions to design challenges. In bridge terrorist risk assessments, however, a degree of standardization is necessary so risk scores can be compared and mitigation funds can be properly allocated. The Blue Ribbon Panel made important steps toward standardization of risk assessments (FHWA 2003), but better further guidance is necessary in the areas of:

- Threat definition – Credible threats (both explosive and other threats) for bridges of varying importance should be adopted and provided on an as-needed basis to professionals performing risk assessments. Williamson and Winget have proposed threat definitions that should be considered by federal agencies for standardized risk assessments (2005). Where intelligence suggests a specific threat exists at a certain bridge, that threat should be added those considered.
- Analysis methods – Analysis should be in accordance with blast industry standards – including SDOF analysis, PI diagrams, empirical curves for local damage, etc. More advanced methods should be required in cases outside the scope of these methods.
- Levels of performance – Response of bridges to defined threats should be quantified and benchmark vulnerability scores based on metrics like downtime, repair cost, casualties, and disruption to local economy should be provided.

Many of the above recommendations follow current standards for federal buildings where anti-terrorist design and risk assessment is more established. Though risk assessment and mitigation of bridges can be more complicated than buildings there is no reason similar standards cannot be implemented for transportation assets to protect the nation's critical infrastructure.

ABSTRACT

As an original member of the Blue Ribbon Panel (BRP) that developed the "Recommendations for Bridge and Tunnel Security" published in September 2003 by the Federal Highway Administration and AASHTO the author reviews the use of this and other subsequent homeland security related risk assessment guidelines in practice by sharing observations on how threat and vulnerability assessment (TVA) of existing bridges has evolved and where it may be going. The paper focuses on the original objectives of the BRP recommendations, how they align with the latest National Infrastructure Protection Plans for the Transportation Sector, how well their application has worked in practice, whether they assist DOTs and other agencies in obtaining DHS grant funding for security related projects, their application to rail bridges and tunnels, and why they are an essential part in the decision making process for implementing security improvements and countermeasures for bridges and tunnels. This will be discussed in the context of a case study.

Since the BRP recommendations were issued best practices for TVAs conducted by some state DOTs have given way to simplified decision tables for risk equations and risk values used with electronic spread sheets that can be used to sort security mitigation costs for critical bridges using cost-benefit factors. The prioritized mitigation projects for existing bridges are then included in the rehabilitation project scope for each bridge when they are contracted out based upon the DOT's state-of-good-repair program. Many states, however, have not yet embraced the BRP recommendations based upon the judgment that funds for repairing deficient bridges are their first priority and they will not deal with security related issues until those needs are addressed. Independent of the availability of funds to repair or secure bridges in a given state or agency, there is a need to prioritize the criticality of the bridge and tunnel inventory because whether a bridge fails due to deterioration, an accident, natural hazards, or intentional attack, the owner should know where the first dollar of funding should be spent, be it for repair of deficiencies or for hazard reduction.

BACKGROUND

Blue Ribbon Panel. Following the September 11, 2001 terrorist attacks, the Federal Highway Administration (FHWA) and the American Association of State Highway and Transportation Officials (AASHTO) jointly sponsored a panel of bridge and tunnel experts from professional practice, academia, federal and state agencies, and

toll authorities to assess the vulnerability of bridges and tunnels to the actions of terrorists and other hazards and to develop and recommend strategies and practices to reduce the likelihood of catastrophic structural damage possibly resulting in human casualties, economic losses, and socio-political damage on a national, regional, and local level. The Blue Ribbon Panel on Bridge and Tunnel Security (BRP) published "Recommendations for Bridge and Tunnel Security" in September 2003.

A significant part of the recommendations of the BRP was the use of a risk based approach to guide planning, design, and engineering recommendations to increase security and reduce the vulnerability of bridges and tunnels in a cost effective way. The risk based approach consisted of two tiers, the first being a prioritization of the large number of bridge and tunnel assets by their criticality or importance, and the second being a risk equation similar to ones previously used for natural hazards such as the assessment of seismic risk to bridges and subsequently recommended in FEMA 426 for risk assessment of building facilities.

NIPP. Another major disaster that has influenced the risk assessment of bridges and tunnels was Hurricane Katrina which occurred in August of 2004. After the experiences with emergency response in the aftermath of the event the Department of Homeland Security (DHS), which included FEMA, developed a National Infrastructure Protection Plan (NIPP) that embraced the multi-hazard approach to the planning, risk assessment, emergency preparedness, and mitigation of all hazards to our nation's critical infrastructure, including acts of terrorism. This meant that whether a disaster or extreme event affecting critical infrastructure is caused by a natural event, a manmade accident, or an act of terrorism, the emergency preparedness activities, system resiliency objectives, and recovery operations for critical infrastructure will be similar if not the same. Subsequent to the NIPP being published in 2006, DHS published the Transportation Systems Critical Infrastructure and Key Resources Sector-Specific Plan as input to the National Infrastructure Protection Plan in May 2007. This plan specifically covers the nation's highway infrastructure of which bridges and tunnels are a major subset.

The transportation sector's security goals and objectives are consistent with the goals outlined in the President's National Strategy for Homeland Security and the joint DHS and DOT National Strategy for Transportation Security (NSTS). The three major goals and objectives focus on:

1. Prevent and deter acts of terrorism using or against the transportation system.
2. Enhance resilience of the U.S. transportation system.
3. Improve the cost-effective use of resources for transportation security.

All three on these goals are in harmony with the threat and vulnerability assessment methodology recommended by the BRP. This will be demonstrated further in the body of the text.

TVA METHODOLOGY

Importance of Risk Based Approach. The importance of the TVA methodology cannot be overemphasized. Terrorism and disasters, whether natural or manmade, cannot be treated the way codified engineering design criteria for bridges and tunnels is treated because they represent extreme events of low probability but of high consequence. We could never by any stretch of the imagination afford to protect all of our bridge and tunnel assets to the same level against these extreme events, hence the need for a methodology to allow asset owners, transportation officials, and engineers to selectively identify and evaluate the cost effectiveness of mitigations that are affordable and justified by a rational risk-based procedure.

Basic Risk Equation. The risk equations are adequately covered in the BRP recommendations.

CASE STUDY

Scope. The scope of the case study project was to first provide assistance to the New Jersey Office of Homeland Security and Preparedness Critical Infrastructure Unit (NJ OHS&P) and the New Jersey Department of Transportation (NJDOT) in validating an existing Vulnerability Assessment of Highway Structures and provide a recommended prioritization of bridges and tunnels including freight and passenger rail as well as highway bridge and tunnel assets. This was followed by conducting a threat assessment, a vulnerability assessment, an impact assessment, and a countermeasures needs assessment for the State's top 50 bridge assets. The study was performed by HNTB Corporation with Weidlinger Associates Incorporated.

PRIORITIZATION METHODOLOGY

Tier 1 Prioritization. The original screening conducted by NJDOT followed AASHTO's guide, "A Guide to Highway Vulnerability Assessment for Critical Asset Identification and Protection" (May 2002). The formula prescribed in this guide consists of 14 separate categories in which to rate the facility under evaluation. Each category has a designated point value; some categories have varying values (up to 5 point maximum) while other categories have a maximum value of one. The maximum score for each facility is 43 points. A higher point total implies a facility with a higher vulnerability. It should be noted that the rating system is subjective requiring an expert panel type of decision to establish point values and does not lend itself to prioritizing the thousands of bridges that a typical state DOT has to deal with. A tier 1 methodology that lends itself to sorting by computer spreadsheets is required to meet this need.

Revised Tier 1 Screening Methodology. The revised first tier screening methodology was based upon the following considerations:

1. Reflected the mission of NJ DOT and DHS
2. Reflected a multi-hazard approach

3. Reflected the resiliency of the transportation network
4. Measured cost of the recovery period to the economy by transportation delay
5. Measured impacts to transportation on multi-modal basis

In the process only five of the 14 attributes in the previous tier 1 prioritization methodology aligned with these considerations and were retained. A new metric for the purposes of validating the results produced by the previous screening effort was proposed. Realizing that one of the primary functions of the NJDOT system is to transport people and goods, this new metric serves to quantify the volume of people and goods that are delayed in transport if the given bridge or tunnel is lost or otherwise unavailable for use. In particular, the following four factors are considered important in identifying the most critical bridges:

1. Volume of transport units carried by the bridge each day under full operation.
2. The number of days the bridge would be unavailable for use if it were to be lost in a damaging event of any type.
3. The time delay incurred by each transport unit due to the detour around the closed bridge. This is assumed to be a function of the bridge detour length and the assumed speed that vehicles would use on the detour route.
4. A fourth factor is included to account for the increased importance or criticality of those bridges that serve as designated emergency evacuation routes.

In any state transportation network, the bridges and tunnels are the critical choke points in the system because they cross geographic features that limit other means of access. For the purpose of the screening criteria developed for this project, resiliency is reflected in the availability and length of a viable detour if a bridge or tunnel is knocked out of service by a catastrophic event. The length of detour for each highway bridge is listed in the SI&A database and was used in the calculation of delay due to the need to rely on that detour until the bridge that is lost is restored to service. The assumption made is that the additional detour length traveled will be at a lower than normal speed adding to the delay. This is due to the fact that local roads will likely be used to access the bridge or tunnel detour which may also be of a lower traffic volume capacity than the normal route.

The screening process also included passenger rail and freight rail tunnels and bridges, which required information on passenger or freight volumes be obtained or generated for those assets. In addition, the presence of express buses or HOV lanes are not reflected in the SI&A database for highway bridges and had to be added. In that case, estimates of average daily number of express buses and passengers were added to the volumes for the bridges or tunnels. In the case of detours for passenger rail bridges, it was assumed that passengers will be transported between the train stations at either end of the lost bridge or tunnel by bus. An equivalent detour length was computed adding equivalent time for transfer of passengers to and from a bus.

For freight rail movement of goods, the system is less resilient. If a freight rail bridge is lost for a period of time, it was assumed that the freight trains will have to be detoured to another available freight rail line. Since many old fright rail lines have been abandoned there are relatively few alternative paths left to move rail freight.

If any bridge or tunnel suffers a catastrophic loss, an assumption was made about the length of time it takes to reconstruct the bridge or tunnel. This was based

upon actual data when available for the reconstruction of bridges lost to disasters and assumptions made for repair and recovery of tunnels. This time element for recovery was a major factor in the delay calculation and was a function of the bridges longest span length. This is because construction schedules show that the longer the bridge span the longer it takes to fabricate and erect the bridge.

Another critical factor that tests the resiliency of a transportation network in times of disaster is the ability of the system to evacuate large populations when storms or hurricanes threaten to flood coastal and waterfront communities. Because the designated coastal evacuation routes become critical in such an emergency, the bridges on those routes are even more critical. For this reason the screening criteria applied a factor to increase the criticality of bridges on coastal evacuation routes across the board.

Due to the high volume of bridges and data included in the first phase, the decision was made to base the screening values entirely on available Structural Inventory & Appraisal (SI&A) data provided by NJDOT and other agencies in a spreadsheet format.

New Tier 1 Metric. The formulation of the metric for quantifying the volume of people and goods impacted is as follows:

$$\mathbf{PDTU = [TVTU \times DD \times TDD] \times ER} \qquad \text{(Basic Equation)}$$

Where:

PDTU = Potential delay of transport units (in unit-hours).

TVTU = Total volume of transport units (in units/day, see item 1. above).

DD = Days of downtime when bridge or tunnel is not functional (in days, see item 2. above).

TDD = Time delay due to detour (in hours, see item 3. above).

ER = Importance factor for bridges that are designated evacuation routes. This is a multiplier (1.2 was used) to increase the importance of those facilities that are intended for use during emergencies.

Volume of Transport Units. The Total Volume of Transport Units (TVTU) is a direct manipulation of the SI&A Average Daily Traffic (ADT) data. Since ADT includes truck volume, and Average Daily Truck Traffic (ADTT) is given as a percentage, the percentage of trucks was deducted from the ADT. The following conversions were used to convert various vehicles to Transport Units in this project:

1 automobile (1.2 avg. passengers) = 1 Transport Unit

1 truck = 2 Transport Units

1 railroad passenger = 0.83 Transport Units

1 rail hopper car = 4 trucks = 8 Transport Units

100 Tons (rail freight) = 8 Transport Units

1 cargo container = 1 truck = 2 Transport Units

The numbers and ratios used were determined from a literature search of studies of highway user costs due to construction delays in several states, parameters obtained from the New Jersey DOT Manual of Highway User Costs, and published data from the Iowa Department of Transportation on equivalent units of freight volumes transported by truck, rail, and barge.

Days of Downtime. Based upon an examination of actual bridge collapses and reconstruction periods, and in the absence of such information, the construction schedules for design-build bridge projects, Days of Downtime (DD) was based upon an empirical formula that reflects a best fit to the following data points:

Bridge Constructed (or Reconstructed)	Max Span[1]	Recovery Period
MacArthur Maze Bridge, Oakland, CA	100 ft.	1 month
I 35 Bridge, Minneapolis, MN	500 ft.	13 months
New Tacoma Narrows Bridge, Tacoma, WA	1,500 ft.	42 months

Table 1

The equations[1] for the Maximum Span Length Factor and Days of Down Time (DD) are shown here and plotted in Figure 1:

$$\textbf{Max Span Length Factor (months)} = 7.0E\text{-}6(\text{Max Span})^2 + 0.0168(\text{Max Span})$$

$$\textbf{DD} = 30(\text{Max Span Length Factor})$$

Time Delay Due To Detour. The Time Delay due to Detour (TDD) parameter is the product of two multipliers:

County Multiplier
Detour Multiplier

These two multipliers are based on the location of the bridge that best characterizes the impact of downtime to users. The dimensionless County Multiplier was taken from the Roadway Congestion Index (RCI) from Mobility and the Cost of Congestion in New Jersey – 2003 Update – Appendix II. It adjusts the detour travel time based upon the traffic congestion in each county. The Detour Multiplier is based on the SI&A detour length data divided by a reduced detour speed of travel while traversing the detour to yield the detour travel time.

Evacuation Route. The Evacuation Route (ER) multiplier is an additional weighting that considers the importance of a structure with regards to evacuation routes. This value was not taken from SI&A data, but was determined from county evacuation routes. For any structure found on an evacuation route, a factor of 1.2 was used. For all other structures, the value of the multiplier was taken as 1.0.

Master Ranked List of All State Bridges. The prioritization methodology was used to rank all bridges and tunnels in the state as shown in Figure 2 for state bridge project planning purposes. The information for all 6,600 state bridges was sorted by county and bridge owner and distributed by NJ OHSP to their state wide emergency preparedness task force representatives consisting of county prosecutors and emergency management officers of state transportation agencies who own and operated the assets. A template of the sorted information is shown in Figure 3.

[1] Note: The equations are based upon the NBIS SI&A database which is in units of feet.

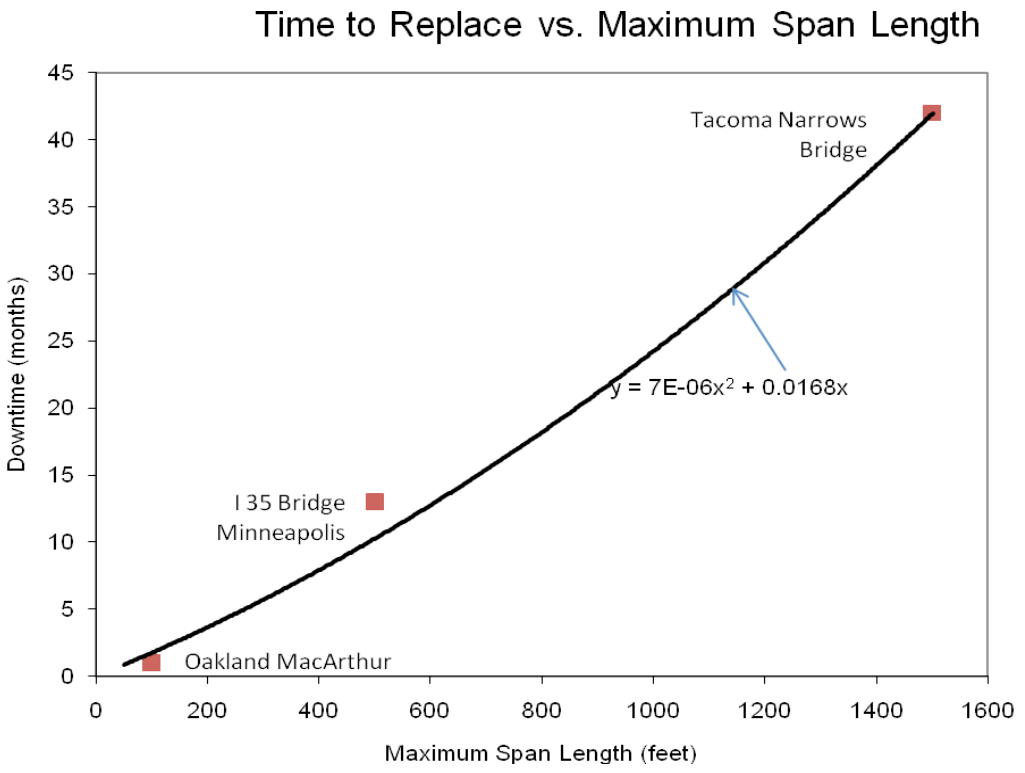

Figure 1

Tier 1 Prioritization Results.

Bridge Characteristics	Percent	Number
State Gov't. Owned Bridges	24%	12 / 50
Evacuation Routes	70%	35 / 50
ADTT exceeding 10,000	34%	17 / 50
ADT exceeding 100,000 (w/o trucks)	38%	19 / 50
12 or more months of recovery time	24%	12 / 50
Passenger Rail Tunnels	10%	5 / 50
Passenger Rail Bridges	8%	4 / 50
Rank of Top 3 Freight Rail Bridges	Ranked 52, 110, 145 (In top 2 percentile of all 6,600 bridges in state)

The information will be used for:

- Use to Determine the criticality of every bridge in the county asset inventory for emergency planning purposes, business continuity planning, and insurance purposes
- Constitutes a "Risk Based" assessment for DHS/TSA federal grant distribution
- Use to develop security/hazard mitigation budget and the order of priority for spending funds
- Use as tool for prioritizing investing of funds for state-of-good-repair for bridges

TVA METHODOLOGY

Sorting Methodology. After identifying the top 50 critical bridges in the NJDOT-owned inventory by the tier 1 prioritization, individual second tier threat and vulnerability assessments (TVAs) were first be conducted on the most critical bridges that represent bridge types or categories. The most critical bridges are those with the highest V values in the R=OVI equation. This means they represent the highest values for expected damage, expected down time, and expected casualties. This is based primarily upon the length of the longest span that could potentially collapse in a hazard or attack, and whether the feature crossed by the bridge is water or land. It is assumed that for the same span length, a bridge constructed over water will be more expensive, will take longer to reconstruct, and will likely have more casualties than a bridge constructed over land. This judgment was validated later since both the longest span over water and longest span over land were selected for an individual TVA. In addition, the types of threats for bridges over land or over water are different in that bridges over land are not exposed to water vessel threats. The database has an additional parameter that reflects the crossing of navigable waterways.

In general the planned methodology for conducting the initial set of representative TVAs was as follows:

1. Sort top 50 bridges by Structure Type
2. Sort by Feature Crossed
3. Conduct one detailed TVA risk analysis per combination (example: Type A over water and Type A over land)
4. Develop Specific Threats
5. Assess Vulnerabilities and Consequences
6. Develop Preliminary Mitigations

Selecting Representative or Key Bridges. After sorting the bridges, map views and satellite photo views from available internet web pages were utilized to examine the representative bridges of each type with the longest spans to confirm their suitability for a detailed TVA. This information was helpful in planning the individual site visits and confirming that existing bridge plans and inspection reports for the structures were consistent.

An individual detailed TVA was conducted for each representative bridge type. This required collection of bridge plans and previous inspection reports. The methodology utilizes the equation R= O x V x I, where the "I" value was based upon the prioritization performed in the step above. The following steps were performed:

1. Perform an on-site assessment of the bridge spans documenting the accessibility, existing level of protective security, and assess target attractiveness and capability of the aggressor. These form the basis of the "O" values.
2. Perform an engineering assessment to determine the impact of each type of threat or hazard to the structures, looking at critical elements that could be attacked. For each type of attack or hazard determine the consequence of that attack (downtime, casualties, and cost to recover the facility after an attack). These will be the basis for the "V" values. The

engineering assessment included an analysis of the structure as detailed below:

a) Perform Blast Analysis using conventional software (Also available through US Army Corps of Engineers Protective Design Center https://pdc.usace.army.mil/ or other source.)

b) Assess structural damage severity from fuel tanker or vessel fire and vehicle or vessel collision if applicable.

c) Perform Progressive Collapse Analysis to assess if damage is local or will lead to collapse.

d) Assess potential for scour or storm surge damage.

3. Adjacent infrastructure that may either increase target attractiveness, or may increase hazards present due to an adjacent independent attack or accident was also assessed and noted. Items of note included the navigable waterway, maritime facilities, ports for large ships, and fuel storage facilities.

4. A pre-mitigation risk assessment was performed to calculate the severity of each potential threat to each critical bridge element (compute sum of R values). The most likely and significant threats were prioritized.

Countermeasure Assessment for Key Bridges. Once the pre-mitigation risks were computed for the bridge facility, effective mitigation measures or countermeasure projects were conceived for each ranked threat starting from the top ranked threat and working downward. The mitigation measures include any measure that reduces one or more of the occurrence or vulnerability attribute values, which are: access for attacks, level of security, attractiveness of target, expected damage, expected downtime, or expected casualties. Capability of the aggressor is not considered because it is usually outside of the control of the facility owner. This can typically only be changed by federal, state, or local law enforcement practices and anti-terror intelligence. Following is a list of categories of countermeasures that are considered:

1. Increase Security Presence (increase security patrols)
2. Establish Secure Perimeter (physical barriers and secure access control)
3. Surveillance, Intrusion Detection & Enforcement
4. Create Standoff Distance (install crash rated barriers, fender systems)
5. Add design Redundancy (modify structure to create additional load paths)
6. Harden/Strengthen Structural Elements (install shields, armor, reinforcing)
7. Develop An Accelerated Response And Recovery Plan (Emergency response plans)

Each mitigation category listed above will either reduce the Occurrence risk values or the Vulnerability risk values. Creating standoff distance actually reduces both since access for attack is reduced, as well as expected damage since the effects of air blast will be lessened, resulting in less damage. The revised risk values were discussed with NJ DOT Officials and law enforcement representatives at a workshop held on March 30, 2007. The values were subsequently modified to reflect the consensus of the workshop attendees.

Construction and Operating Cost Estimating. The following steps were completed to assess the effectiveness and cost-benefit of each mitigation measure:

1. Prepare a conceptual plan or design for the mitigation.
2. Re-analyze the structural effects of the mitigation for standoff, redundancy, and structural hardening mitigations.
3. Estimate the cost (initial and O&M).
4. Re-calculate the mitigated risk value for the threat on the structure.
5. Calculate the reduction in total risk for the entire facility for the mitigation measure.
6. For each mitigation measure, plot reduction in facility risk value (vertical axis) versus cost (horizontal axis). A log-log scale is best. This helps to identify the most effective mitigation measures for the dollars spent on them, for the structure in question. Priority points will plot in upper left quadrant (i.e. highest vertical axis value and lower horizontal axis value).

The last step (6.) above is used to prioritize the mitigation measures to be implemented based upon the available security capital budget and operating budget for each facility and the entire NJDOT program. The plot results for all mitigations for the seven representative bridges are shown in Figure 4.

Extrapolation Methodology for Remaining Top 50 Bridges. Once the seven representative bridges' threat and vulnerability assessments were complete, the results were extrapolated to the remaining 43 bridges of the NJDOT top 50. The seven representative bridges were selected based on two primary characteristics: structure type and feature crossed. Based on these two characteristics, each of the remaining 43 bridges was associated with one of the seven representative bridges.

CONCLUSIONS AND RECOMMENDATIONS

Recommended General Uses for the Assessment Results. The full assessment results, for both representative and extrapolated bridges, will be useful for programming and distributing resources for security projects. For each bridge all of the mitigations, their descriptions, aerial photos, and the cost estimates were formatted in Excel spread sheets and can be sorted by county, by mitigation type, or by cost benefit ratio. By sorting the results in various ways, projects can be developed and grouped by value, by type, or by bridge. While most threat and hazard mitigations will require further design development, the estimate costs can be used to incorporate security improvements in upcoming rehabilitation contracts for critical bridges.

Usefulness of Bridge and Tunnel Prioritization. The ability to prioritize all the bridges and tunnels in the state based upon their criticality to the transportation network is essential for long range transportation planning, for emergency planning purposes, for business continuity planning, and for targeting the most critical assets for state of good repair and bridge rehabilitation funding as well. It also constitutes a "Risk Based" assessment for DHS/TSA federal grant distribution.

State DOTs can utilize Homeland Security funding through Urban Area Security Initiative (UASI) grants and Regional Transit Working Group (RTSWG) grants to

cover their planning costs to conduct both prioritization and threat assessment and mitigation studies so they can develop short term and long term strategies to improve the resiliency of their transportation networks, both for highway and rail systems.

ABSTRACT

In recent times, the use of sandwich panels as sacrificial claddings in the blast/impact protection of structural systems has been the subject of much investigation. Popular sandwich panels systems include core consisting of regular metallic-lattice and metallic-foams. These systems have been proven to be beneficial when used as sacrificial claddings because of their propensity to sustain large deformations and plastic energy dissipation. This allows the panels systems to absorb more energy than a single metallic plate consisting of the same mass. In case of metallic-lattice cores, energy absorption capacity depends on the topological structure and the optimal topology for these cores is not yet established. In this study the effect of topological parameters on the performance of sandwich panel systems with metallic-lattice cores is investigated. Nonlinear finite element analyses of cladding systems with different core topologies are carried out to investigate the effect of core parameters on their performance. The simulation results shows that the performance of the sandwich panel systems is highly influenced the topological parameters.

INTRODUCTION

Sandwich panels (Figure 1) are a popular system that can be used for blast and impact amelioration. In the past, numerous studies have been conducted regarding the use of sandwich panels in blast or impact protection. Many of these studies have focused on investigating different structural topologies that can be implemented within these panels. As a result, a number of different core topologies that can be used in applications are available. Available topologies can be subdivided into three distinct groups: truss, folded plate (corrugated), and honeycomb cores.

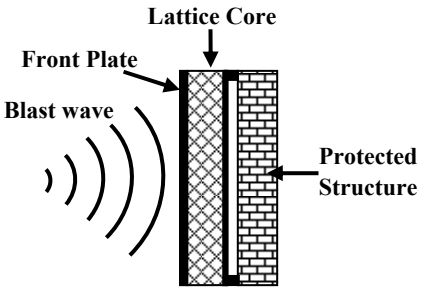

Figure 1. Sandwich Panels for Sacrificial Cladding Systems

Commonly included among the truss topologies are tetrahedral trusses, pyramidal trusses, kagome trusses, octet trusses, and woven trusses. Y-frame, triangular, and diamond shapes generally make up the group of folded plate cores. Finally, the honeycomb cores include square, triangular, and hexagonal honeycomb shapes. Early studies Zhenyu and Hutchinson (2004a) and Zhenyu and Hutchinson (2004b) investigated pyramidal truss, triangular folded plate, and square honeycomb core topologies. These studies investigated the cores behavior under statically applied uniformly distributed pressure, the plastic energy dissipation under quasi-static loading, and the front and back face deflections due to uniform impulse loading. Sandwich panels with triangular folded plate cores and diamond honeycomb cores subjected to different loading directions were investigated by Valdevit et al. (2004). McShane et al. (2007) compared sandwich panels comprised of pyramidal truss and square honeycomb cores subjected to quasi-static and impulsive loading via both experimental testing and finite element simulations. Cote et al. (2006) investigated sandwich panels comprised of triangular folded plate and diamond honeycomb cores for their compressive, transverse shear, and longitudinal shear responses via both experiments and finite element simulations. Vaziri and Hutchinson (2007) investigated air shocks on sandwich panels with square honeycomb and triangular folded plate cores via finite element analyses that subjected the cores to uniform pressure loads and uniform prescribed velocity loads. More recent studies have focused on Y-frame and triangular folded plate core topologies. For instance, Tilbrook et al. (2007) conducted experimental and two-dimensional finite element analyses of the aforementioned topologies. Rubino et al. (2009a) and Rubino et al. (2009b) produced two studies in conjunction with one another to analyze these topologies with experimental and finite element analyses.

The above studies utilized a variety of loading conditions, specimen dimensions, and boundary conditions. Therefore, it is not possible to rationally compare and evaluate the performance of various core topologies. To this end, this study investigates the performance of standardized sandwich panel system with various core topologies using finite element simulations. In particular, the performance of popular core topologies including honeycomb and folded plate cores are compared under the specified blast loading conditions. The effect of front plate thickness, which is considered to be an important topology parameter, on the system performance is evaluated.

FINITE ELEMENT MODELING OF CLADDING SYSTEMS

Three-dimensional finite element simulations of sandwich panels with different core topologies subjected to representative blast loading is conducted using finite element program LS-DYNA (Hallquist 2010). The sandwich panels are modeled using fully integrated Hughes-Liu using shell elements. The shell formulation accounts for finite deformations and 5 mm × 5 mm element sizes are used to account for local strain gradients and to accurately capture the panel response. All elements were initially created with thickness, t = 0.3 mm, however, some of the finite element analyses involved changing component thickness to investigate the

effect of plate thickness on the panel performance. The modeling process including constitutive model selection and the setup of the loading and the boundary conditions are described in the following sections.

MATERIAL PROPERTIES

The material properties used are those corresponding to AISI 304 stainless steel. Steel constitutive behavior is represented by a rate dependent piecewise linear J_2 plasticity material model MAT24 in LS-DYNA. The steel is modeled with the following parameters: relative density, ρ = 7900 kg/m^3; Young's modulus, E = 210 GPa; and yield strength, σ_y = 210 MPa. Strain rates effects are included to accurately capture steel plastic flow under high strain rates. Experimental data from (Rubino et al. 2009a) is used in this investigation. The experimental data includes stress-strain curves for quasi-static strain rate ($\dot{\varepsilon} = 10^{-3}$ s^{-1}) and for several dynamic strain rates ($\dot{\varepsilon} = 1$ s^{-1}, $\dot{\varepsilon} = 10^{2}$ s^{-1}, $\dot{\varepsilon} = 10^{3}$ s^{-1}, and $\dot{\varepsilon} = 10^{4}$ s^{-1}). Figure 2 shows the measured stress-strain data for different strain rates obtained from (Rubino et al. 2009a) and used in this study.

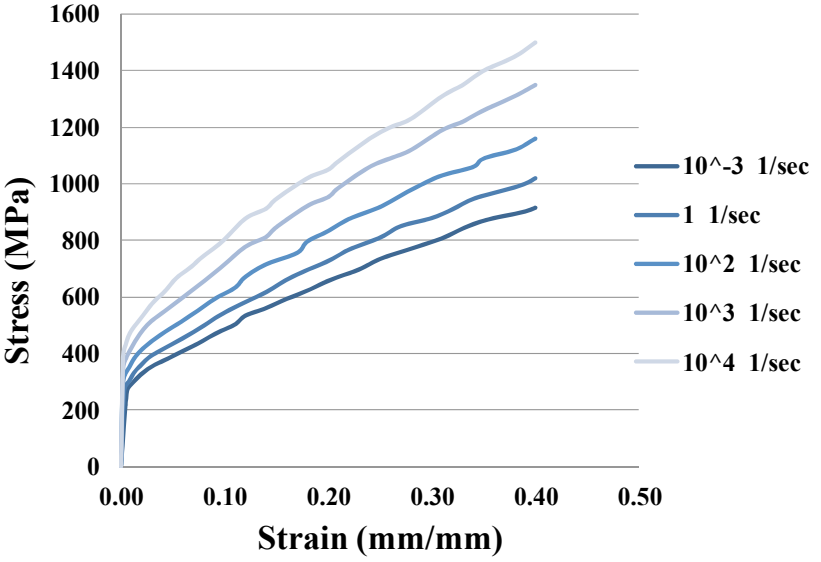

Figure 2. Stress vs. strain for different strain rates (Rubino et al. 2009a)

MODELING OF BLAST LOADING

The panels are subjected to blast loading as described in this section. This loading can be considered as a representation of actual blast loads that can be experienced by these panel systems. In case of blast loading, the pressure that is exerted on a particular point in space from an explosive blast in the air is dependent on the linear distance that the point is from the center of the blast as well as the magnitude of the blast. A popular model for defining blast pressure is given by the modified Friedlander equation (Baker 1973) and is given by Eq. 1:

$$p(t) = p_o + p_{\max}(1 - \frac{t}{t_d})^{-\frac{bt}{t_d}} \qquad (1)$$

where $p(t)$ is the pressure at time t, p_o is the initial air pressure, p_{max} is the peak overpressure from the blast, t_d is the positive pressure phase duration, and b is a parameter to describe the decay of the curve. An idealized plot of the blast pressure vs. time response as modeled by the Friedlander equation is presented in Figure 3.

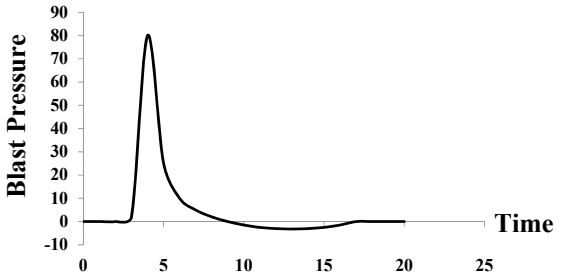

Figure 3. Idealized blast pressure vs. time response of an air blast as modeled by the Friedlander equation

The peak overpressure occurs at the time known as the arrival time, t_a. Additionally, functions that represent the parameters for this pressure vs. time response are typically given in terms of the scaled distance, Z. The scaled distance is the relationship between the distance, d, from the center of a charge of TNT and the mass, W, of the TNT and is given by (2):

$$Z = \frac{d}{\sqrt[3]{W}} \qquad (2)$$

To obtain more realistic blast pressures, Kingery and Bulmash (1984) produced curves of fit to represent the parameters of the pressure vs. time response obtained from experimental data determined on study of blast waves. These curves are deemed appropriate for any scaled distance of less than 40 m/kg$^{1/3}$. The blast pressure vs. time parameters represented by the curves include the scaled time of arrival, peak overpressure, scaled positive phase duration, scaled positive phase impulse, reflected pressure, reflected impulse, and shock front velocity. The data for the curves for these parameters are implemented within the computer model CONWEP, a program utilized by the military in studies of blast impacts on vehicles and structures (Hyde 1988). The CONWEP equations are also available in LS-DYNA, where the user input the coordinates of the blast center and the mass of TNT used to create the blast in order to model the data for the blast wave at any desired point in space.

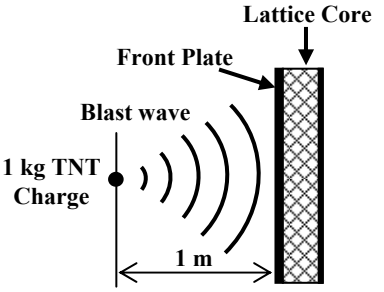

Figure 4. Sandwich Panels - Loading

For this study, the CONWEP blast model in LS-DYNA is used to represent the pressure on the front plate of the sandwich panel created by a blast of size 1 kg of TNT. The front face of the panels is placed at an angle of 90° to the center

of the blast, with the centroid of the face placed at a distance of 1 m away from the center of the blast (Figure 4). Since all sandwich panels modeled have the same front face dimensions, the same loading is applied on each model. This eliminated the effect of various type of dynamic loads utilized in previous studies, and any differences in the responses of the sandwich panels are due to the physical properties of the sandwich panels themselves.

CORE SELECTION

The topological properties of sandwich panel models are selected based on those used in recent studies. In all, six different types of core topologies are modeled, including the three most common types of folded plate topologies as well as the three most common types of honeycomb topologies. The folded plate cores used are the triangular folded plate, the diamond folded plate, and the Y-frame folded plate, while the honeycomb cores used are the square honeycomb, the triangular honeycomb, and the hexagonal honeycomb. Figure 5a shows folded plate core topologies, while Figure 5b shows honeycomb core topologies used in this study.

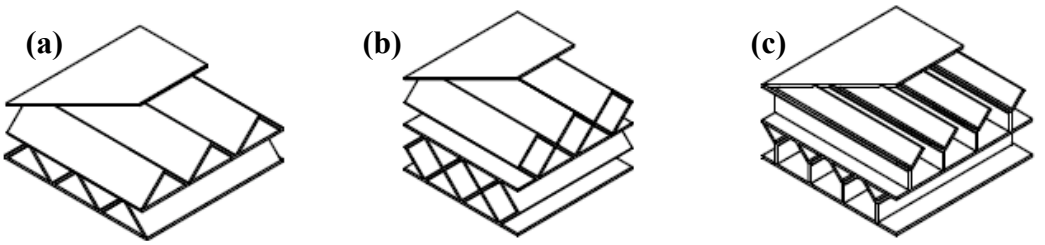

Figure 5a. (a) Triangular folded plate, (b) diamond folded plate, and (c) Y-frame folded plate core topologies used in finite element simulations

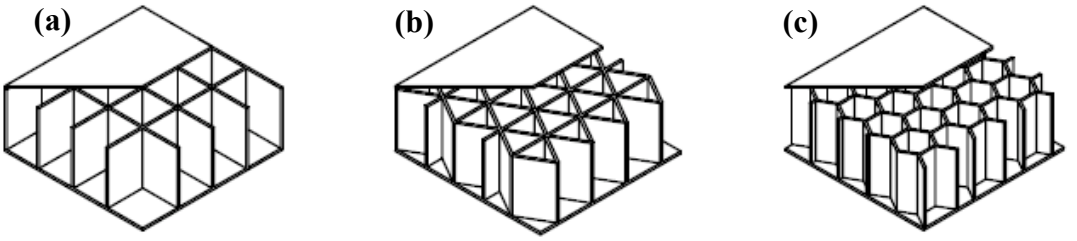

Figure 5b. (a) Square honeycomb, (b) triangular honeycomb, and (c) hexagonal honeycomb core topologies used in finite element simulations

All cores models are designed with a constant area density to ensure that same amount of extra loading per unit area is added to a structure. Furthermore, all cores modeled are .5 m in length and .5 m in width, with varying thickness and varying interior dimensions so as to create cores with constant area densities. Contact and impact between the sandwich panel components is modeling using the CONACT_AUTOMATIC_SINGLE_SURFACE card in LSDYNA.

BOUNDARY CONDITIONS

The manner in which sacrificial claddings can be used in a structure significantly impacts the boundary conditions. For the sake of computation time, the sandwich panels created for finite element analysis represent a 0.5 m by 0.5 m panel section. Actual sacrificial cladding added to a building may be significantly larger in area than this, so this fact is taken into consideration when determining boundary conditions for these models. These claddings can be attached to structures in one of the two ways. In the first scenario, the cladding can be attached by connectors with some clear distance between the face of the structure and the cladding. The second scenario consist of a cladding that it is flush against the face of the structure and thus not allow any clear distance between the two. Both scenarios are considered in this study, and appropriate boundary conditions and performance criteria for these scenarios are selected. In the first scenario, the boundary conditions are chosen to be clamped along the edges of the front and back plates of the sandwich panel and are referred to as the "clamped" boundary condition. For the second scenario, the boundary conditions are chosen to be fixed along the entire back plate and constrained along the edges of the front plate and is referred to as the "fixed" boundary condition.

MODEL LIMITATIONS AND ASSUMPTIONS

Even though the rates effects are accounted for in the constitutive modeling of steel, the actual fracture of the material is not considered. The material model only accounts for the strain dependent plasticity, however, other modes of behavior including brittle fracture is not modeled. Boundary conditions and loading are considered to be representative of that present in real applications.

SIMULATION RESULTS

A series of finite element simulations are conducted with clamped boundary conditions to analyze the effect of varying front plate thickness on a variety of sandwich panels. Core topologies included in these analyses are the triangular folded plate, the diamond folded plate, the Y-frame folded plate, the square honeycomb, the triangular honeycomb, and the hexagonal honeycomb cores. The performance criteria that are investigated include: (a) the front and the back plate deflection, (b) reaction forces at the clamped edges, and (c) the plastic energy dissipation. In addition, finite element simulations on triangular folded plate core topologies with fixed boundary conditions are conducted to investigate the effect of boundary condition.

SANDWICH PANELS - CLAMPED BOUNDARY CONDITIONS

Sandwich panels with different core topologies performed differently for finite element simulations conducted using clamped boundary conditions and varying front plate thickness. For each type of core topology, front plate thicknesses of 0.3 mm, 0.5 mm, 0.8 mm, 1.0 mm, and 1.2 mm are used in the simulations.

Figure 6 shows front plate deformation for all core topologies with varying front plate thickness. For all types of core topologies, the front plate displacements decreased as the front plate thickness increased. However, these displacements decreased at a lesser rate for higher front plate thicknesses. The honeycomb cores experienced less deformation than the folded plate cores, with all of the honeycomb cores performing almost exactly the same. The deformation in the folded plate cores was significantly higher than any of the honeycomb cores, with deformation for certain folded plate cores being in excess of 35 mm greater than any of the honeycomb cores. There were some differences in the front plate deformation for all of the folded plate cores. The Y-frame folded plate cores experienced the least deformation for all front plate thicknesses, while the diamond folded plate core experienced less deformation than the triangular folded plate core for front plate thickness of .3 mm but greater deformation for all over front plate thicknesses.

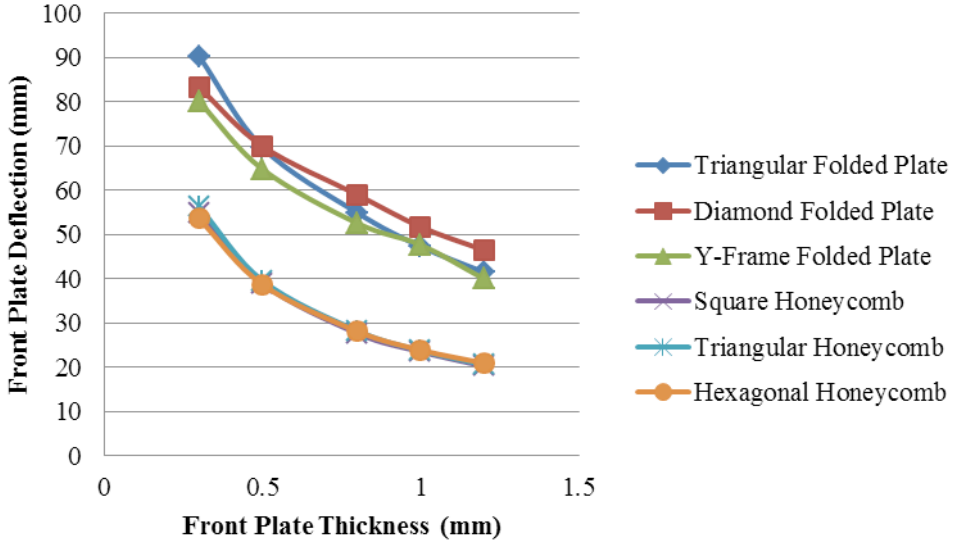

Figure 6. Front Plate Displacement vs. Front Plate Thickness for Sandwich Panels with Clamped Boundary Conditions for Different Core Topologies

Figure 7 summarizes the results of the back plate deformation with varying front plate thickness for all of the cores simulated. The back plate displacements also decreased with increased front plate thickness. However, the honeycomb cores decreased at an almost linear rate while the folded plate cores decreased less and less as the front plate thickness increased. For the honeycomb cores with the smallest front plate thicknesses, the triangular honeycomb core deformed the most and the square honeycomb core deformed the least. For the thicker front plates, the hexagonal honeycomb cores deformed the most and the triangular honeycomb cores deformed the least. The folded plate cores experienced significantly less deformation than the honeycomb cores. For the smallest front plate thickness, the back plate in the diamond folded plate core did deflect almost as much as the honeycomb cores. However, the back plate deformation was almost nonexistent for the diamond and Y-frame folded plate cores with thicker front plates.

Figure 8 shows the variation of the plastic energy dissipation with varying front plate thickness for the honeycomb and the folded plate cores. The plastic energy dissipation decreases with increased front plate thickness, indicating that more blast energy is reflected when a thicker plate is used. The folded plate core topologies all had higher plastic dissipation, with the diamond folded plate cores having the highest amount of dissipation.

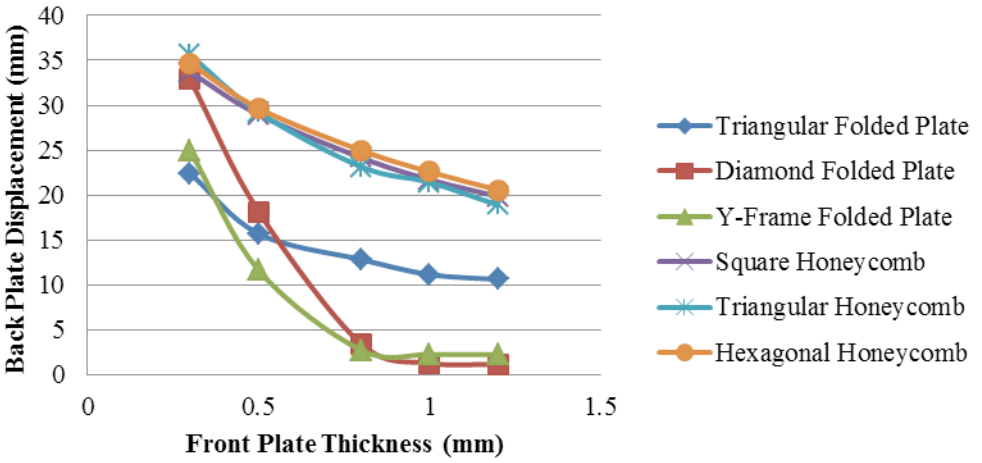

Figure 7. Back plate displacement vs. front plate thickness for sandwich panels with clamped boundary conditions for different core topologies

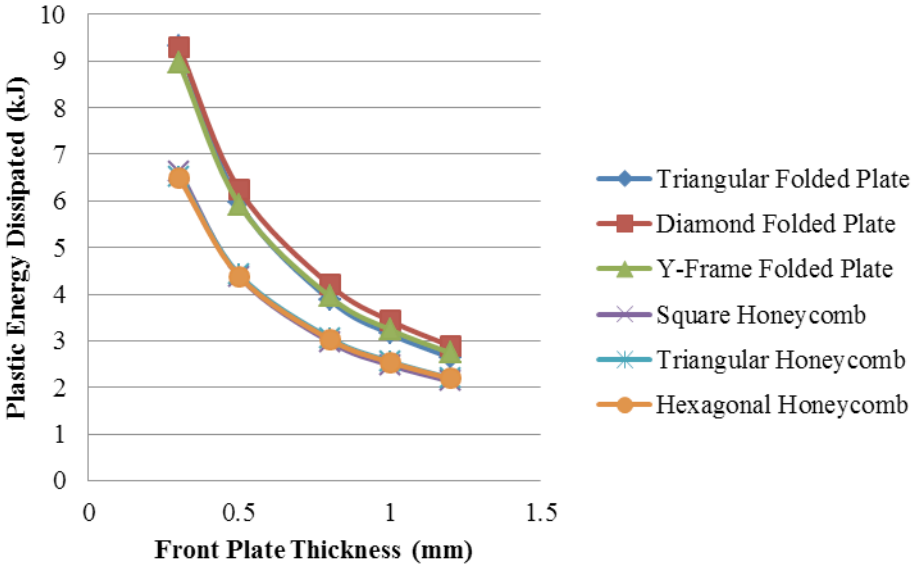

Figure 8. Plastic energy dissipated vs. front plate thickness for sandwich panels with clamped boundary conditions for different core topologies

Figure 9 shows the variation of reaction forces with varying front plate thickness. The maximum reaction forces for the folded plate core topologies gradually decreased linearly with increased front plate thickness, while the maximum

reaction forces for the honeycomb core topologies either remained the same or increased. For the thinnest front plates, the triangular and Y-frame folded plate topologies experienced the highest reaction forces, and, for the thicker front plates, all core topologies experienced a similar amount of reaction force with some variance.

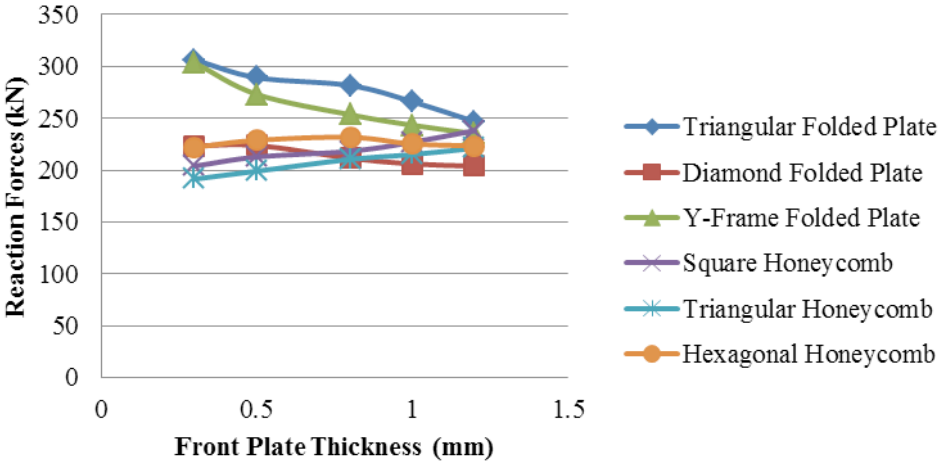

Figure 9. Maximum reaction forces vs. front plate thickness for sandwich panels with clamped boundary conditions for different core topologies

EFFECT OF BOUNDARY CONDITION

Effect of clamped and fixed boundary condition is investigated on the triangular folded plate topology. The clamped boundary condition allowed for the two-way bending of the entire sandwich panel, while the fixed boundary condition allowed the sandwich panel to crush upon itself. With clamped boundary conditions, at large deformations, the areas of the highest strain occurred at the peaks of the two inner-most triangular folded plates that make up the interior core (Figure 10). The magnitude of the strain at a majority of these locations did not exceed the maximum specified plastic strain of 0.4. However, for a front plate thickness of 0.3 mm, the magnitude of the strain did exceed this value immediately next to the clamped edge of the front plate along the triangular folded plate core.

The triangular folded plate core is also simulated with fixed boundary conditions for varying front plate thickness. In this case, at high deformations, the entire sandwich panels crushed. The final deformed shape of the crushed core had very little void space. For increased front plate thickness, the uniform deformation was even more pronounced, and the final deformed shape contains even less void space. Figure 10 shows the final deformed shape of the triangular folded plate core with fixed boundary conditions and front plate thickness of 1.2 mm.

There are several noticeable differences between the boundary conditions. The first difference was the fact that the fixed boundary condition allows for the deformation response of the sandwich panel to be purely the result of the crushing of the core. This was in stark contrast to the clamped boundary condition, which allowed for a significant amount of bending. Additionally, excessive strains were not

generated with the fixed boundary condition. While the clamped boundary condition simulations for triangular folded plate cores had plastic strains that exceeded the limit of 0.4 when the front plate thickness was 0.3 mm and 0.5 mm thick, the fixed boundary condition simulations have strains that did not even come close to approaching this limit.

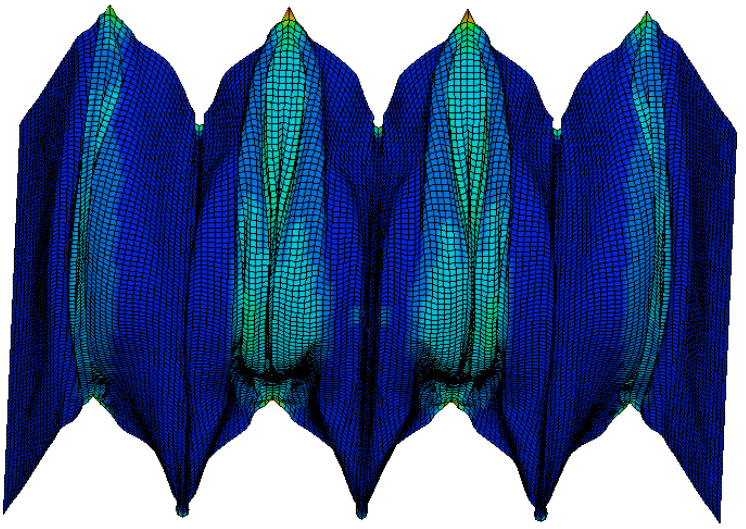

Figure 10. Core deformation of a sandwich panel with a triangular folded plate core and clamped boundary conditions (higher strains are indicated by warmer colors)

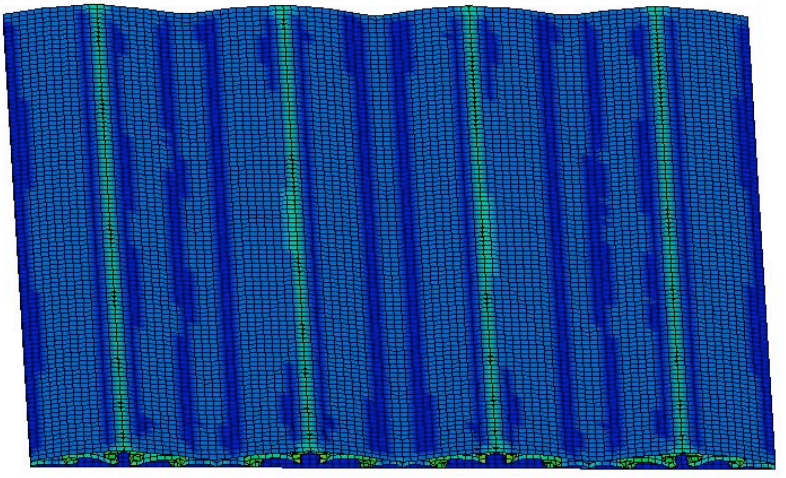

Figure 11: Final deformed shape of a triangular folded plate core sandwich panel with fixed boundary conditions and front plate thickness of 1.2 mm

OBSERVATIONS AND CONCLUSIONS

Following are the important conclusions that can be drawn from the limited simulations carried out under this study:

1. Honeycomb cores have lower front plate displacement because they had many more support locations than the folded plate cores, which increase their stiffness. However, the back plate displacement is large as compared to folded plate cores as the deformation is mode is a bending mode.
2. The folded plate cores, with lower core stiffness, had much greater deformation than the honeycomb cores and deforms in a core crushing mode. However, most of the deformation is concentrated in the cores with reduced back plate displacements as compared to honeycomb cores. As a result, these panels can absorb/dissipate more energy as compared to honeycomb cores.
3. Plastic energy absorption increases with a decrease in front plate thickness for all core topologies considered.

ABSTRACT

There are a few related researches that provide well-defined models to predict the damage size under close-in explosions. This paper presents a prediction of the damage size experienced by reinforced concrete (RC) slabs subjected to close-in detonations using numerical data and a neural network–based model. To train and validate the artificial neural network (ANN), a data base is developed through a series of measurements of the damage diameter (crater/spalling) size induced in reinforced concrete two-way slabs under blast loads. The data was obtained by performing various simulations using the dynamic explicit finite element code LS-DYNA. The principle parameters controlling the breaching size are charge weight, standoff distance, and slab thickness, which were used to develop the ANN training input data set. The trained and validated neural network was used to develop an ANN model capable of predicting the breach size of concrete slabs under close-in detonations.

INTRODUCTION

The damage level in reinforced concrete (RC) slabs is a function of spalling/cratering the slab will suffer under the near-field detonations. The numerical analysis of this study was conducted using the explicit dynamic software LS-DYNA, which can model the blast load propagation towards concrete structures and the slab response to these types of impulsive loads. The blast load definition and properties are introduced in the following section. Also, a review of the up-to-date research regarding reinforced concrete slabs under blast loads is summarized next.

BLAST LOADS

Blast loads are considered one of the extreme loads affecting structures, and even a small amount of blast can produce severe localized damage to the structure skeleton.

In some cases this localized severe damage can potentially progress to global collapse of the entire structure. An explosion starts when a highly explosive material is detonated forming a detonation wave in the material which is pressurized up to 27,580 N/m^2 and temperatures in the range of 4,700° k. This hot gas is expanded, as a rapid release of energy occurs. A shock front moving at supersonic velocity is formed in front of this gas and is called blast wave. This wave propagates outward in all directions from the detonation center. The front of the wave is called the shock front which travels faster than the speed of sound. The pressure of the wave front is called the incident pressure, or overpressure. The flow of the air mass behind the shock results in an outward movement of air and debris which is known as the dynamic pressure. This dynamic pressure depends on the incident pressure, air density, and the explosive material.

BLAST LOADS ON RC SLABS

The study of the structural and material response of RC slabs under blast loads are conducted either by experiments or numerical simulations. However experiments are difficult to be done in full scale and are also costly to perform. In addition to that, the other important factor is the difficulty of measuring the various parameters in the field for close-in detonations where the instrument is often destroyed and the failure process is difficult to document. Therefore, numerical solutions are considered an attractive approach to evaluate reinforced concrete slabs response to explosions.

Cimo (2007) performed background information related to loads caused by blasts and analytical modeling options, as well as a literature review of related research findings. AUTODYN was selected to conduct this modeling. A study to determine the most appropriate constitutive models considering the dynamic material properties was subsequently conducted. This resulted in the selection of four constitutive models for the four materials incorporated in the modeling: air, TNT, concrete, and steel. A mesh sensitivity analysis was also performed to determine the optimum element size to be used, considering the conflicting interests of increased accuracy and decreased processing speed and memory availability with smaller elements. For Cimo's analysis, AUTODYN results were compared against results generated using the semi-empirically based program called ConWep, as well as hand calculations, which also served as a general validation of the accuracy of the program. The results of the constitutive model studies and mesh sensitivity analyses were incorporated in developing a model of a cross-section of a two-lane bridge, where the performance of the cross-section when subjected to a blast below deck was investigated. Within the bridge cross-section investigation, it was determined that the movement of the shock front and its interaction with the structure was greatly influenced by the girder location. Due to the reflected waves generated in confined corners, the pressure in the deck close to the girders was increased and caused this to be the highest area of stress within the deck.

Nago et al. (2007) estimated that blast loading typically produces very high strain rate ranges of 10^2 to 10^4 s^{-1} rather than the ordinary static strain rates of 10^{-6} to 10^{-5} s^{-1}. At high strain rates, the dynamic mechanical properties of the structure may be different from the mechanical properties under static loading. It is reported that the

yield stress of mild steel could be doubled when the strain rate changes from 10^{-3} to 10^{3} s^{-1}.

The effect of explosives on civil bridges was studied by Pelton (1993). It has been suggested that main load carrying members of all bridge structures can be classified into three categories based on the level of damage the bridge might experience and its post-blast load carrying capacity.

Wu et al. (2009) investigated the blast resistance of ultra–high performance fiber reinforced concrete (UHPRC) and FRP-retrofitted concrete slabs against normal concrete slabs as control specimens. The pressure and displacement were recorded at the middle point of the slab and the results were compared with TM5-1300. Wu et al. (2009) added the CFRP to the compression face of the slabs which increased the ductility and the blast resistance as well. The UHPFC samples suffered the least damage between all the specimens.

Mosalam et al. (2001) conducted a computational model using the finite element method to study the nonlinear transient behavior of reinforced concrete slab subjected to blast loading and retrofitted with CFRP composites. The model was used to investigate the effect of loading duration and the effect of the CFRP on the slabs damage accumulations. The study showed that using CFRP prevents the total failure of the slab systems against the cracking and crushing of the as-built slabs. The load carrying capacity of the retrofitted slabs was increased by 200%. Retrofitting the two way slab systems by CFRP limited the spread of yielding in the steel reinforcement.

The basis of a procedure to estimate the explosive charge weight and stand-off distance to impose certain levels of damage on RC structures was conducted by Silva et al. (2009). A series of experiments were also showed to confirm its applicability for assessing the blast resistance capacity of RC slabs. Test results showed that the procedure was accurate in predicting the explosive charge weight and stand-off distance to impose a given damage level on the tested RC slabs. This main conclusion was derived because a reasonable agreement was observed between the damage levels selected for assessment and the damage levels observed during testing.

In the next section, the details of the finite element modeling and the geometry for the studied RC slabs are presented. The material models for concrete and conventional steel are presented.

FINITE ELEMENT MODELING

The numerical simulations were conducted using LS-DYNA 971 (2009) code, which is common finite element analysis software for modeling non-linear mechanics of structures, fluids, and their interaction. LS-DYNA is based on explicit numerical methods, for problems associated with large deformation, and blast load wave propagation. The RC slabs under consideration were designed according to the ultimate strength limit states using the ACI 318-08 building code. The details of the material models and finite element mesh are discussed in the next section.

MODELING GEOMETRY

The slab model represents a two way square slab system of a span of 3.05 m (10ft). The geometric model of the slab system used in these simulations is shown in Fig.1. Concrete was meshed using Lagrangian 8-node solid hexahedron elements with one point of integration and the conventional steel were modeled using the 3-D beam elements. Perfect bond was assumed between concrete and all the embedded steel. With the slab loaded by blast, both the steel and concrete is expected to experience large deformations, causing plastic strains and buckling of the rebars. When widespread element erosion in the model is observed, it was concluded that cracking and spalling of concrete is present. To track the element erosions as the blast event progressed, a damage-based erosion function was implemented to delete the elements which reached a plastic strain of 0.005 for concrete and 0.15 for the steel.

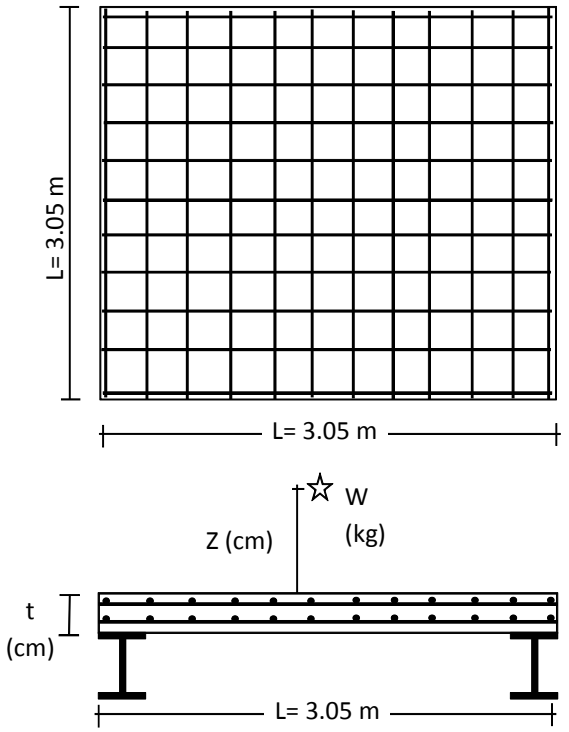

Figure 1. Plan and section elevation of the studied slab.

BLAST LOAD MODELING

In this simulation, the load is imparted on the RC slab by defining the blast function. The load defines an air-blast function for the application of pressure loads due to explosives (LSDYNA, 2009). This option calculates the pressure values when used with the LOAD_SEGMENT command, and these segments normals point toward the charge. The maximum predicted reflected pressure using the procedure in TM5-1300

is compared to the values obtained from LS-DYNA. The calculated pressure from LS-DYNA was measured at the nearest element to the ignition point which is considered as a reflected pressure.

ANN ANALYSIS

Neural networks are computing devices that process information in a manner similar to that of the central nervous system (Flood et al., 1990). In this section, the prediction of the damage size in two way RC slabs subjected to free air blast loads is introduced using an existing ANN code developed by Flood et al. (1994). The prediction for the damage size depends on many parameters, which are discussed in detail later. The study was conducted using the numerical dynamic hydrocode LS-DYNA to develop the training data set. Experimental results were first used to verify the numerical modeling using LS-DYNA first (Ibrahim, 2010, Ibrahim et al., 2011).

The ANN approach is a fast engineering tool that provides a direct mapping of results based on the required inputs. ANN can solve problems from a limited data set to a huge number of variables in an extreme rapid way; capturing nonlinearities in the model with sufficient training data (Flood et al., 1994). Also the ANN is very tolerant to errors in the input data set. The ANN can produce reasonable solutions for problems that have incomplete data set. The ANN consists of three main steps, the input variables, the output variables, and the processing stage. At the same time, the ANN have many shortcomings of its own, most notably, and the results of inexact solutions. Such issues should be solved before the ANN is generalized to every problem (Flood et al., 1994).

The configuration of the ANN consists of parallel processors called neurons or cells, connected to some circuit, the neurons outline is considered individually as trivial functions but in the network itself they can be used to solve very complex problems. These problems varied from the evaluation of production rates in construction process (Karshenain et al., 1992) to the prediction of tower-guy pretension (Issa et al., 1992).

NUMERICAL SIMULATION AND ANN VALIDATION

The goal for this study is to generate an accurate and efficient neural network model which is capable of modifying the limitations of existing methods for predicting the damage size of RC slabs subjected to blast loads. The idea behind using the ANN is that it fits a surface to a set of observations of the performance of the real system. The benefits of using the neural network is it could be trained to find a very good predicted model of damage size.

The three layer feed forward system ANN method was implemented in a RGIN (1992) code with an incremental learning pattern (Flood et al., 1994). The ANN code RGIN represents the data using radial-Gaussian functions. The radial-Gaussian functions represent the hidden neuron part of the feed forward system to calibrate the data points. When a hidden neuron is added to the ANN, a radial-Gaussian automatically added into the system to capture the data point with the

largest error, and then is used to determine the position, amplitude, and spread of the radial-Gaussian function that reduces the residual errors as much as possible.

After the numerical model was set up, the simulations were performed by LS-DYNA. A study was conducted to verify that the data parameters cover a wide range of various damage cases including the spalling, breaching, and no damage cases. The independent variables were the charge weight (kg-TNT), the standoff distance (cm), and the slab thickness (cm). The damage was recorded in terms of three different values; D1, D2, and D3 as described in Figure 2. Some cases exhibited a whole punching failure and others exhibited spalling from one side, while some exhibited spalling and cratering from both sides of the slab. A total of 125 RC slab simulations were performed in this study (Ibrahim et al, 2011).

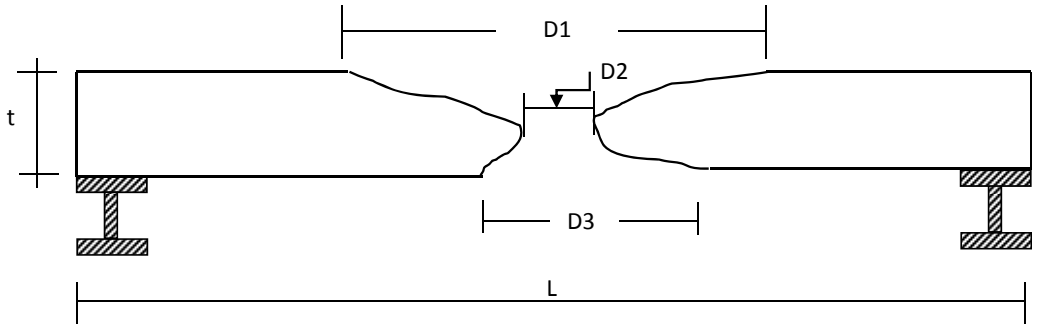

Figure 2. Cross section of slab showing the dependent variables D1, D2, and D3.

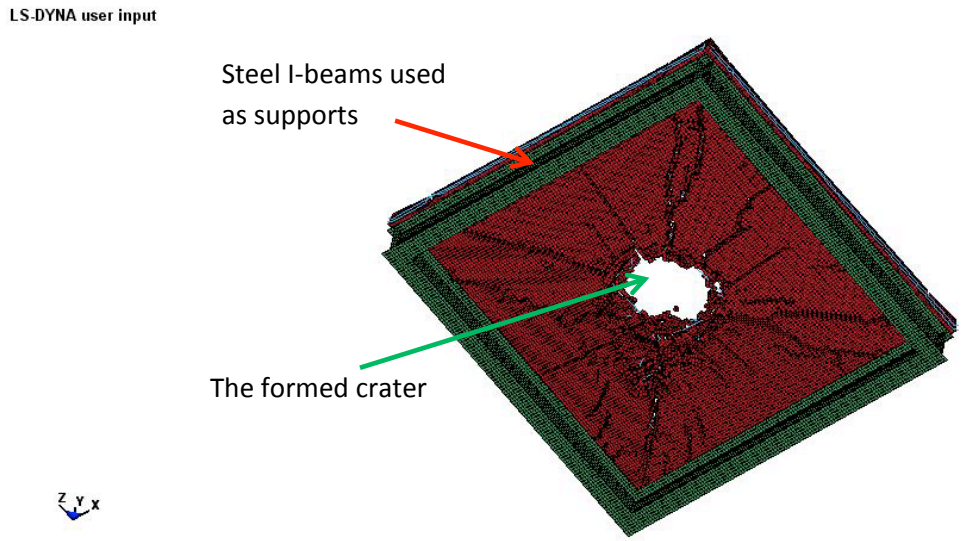

Figure 3. Punching failure mode of one of the tested slabs (bottom view).

The response of one of the slab cases is shown in Fig. 3, which shows the failure as pure shear punching due to the high explosive effect with a small standoff distance. It can be seen that the failure is a typical one as the there is a crater at the middle of the slab and there are many cracks or yield lines expanding towards the corners of the slab.

Figure 4 shows a scatter plot of numerical simulation results for all 125 simulations versus the ANN predicted damage size model for 25 Gaussian points. It is shown in Figure 4 that using 25 Gaussian points does give good results and using the ANN model and the error in the prediction of D1, D2. And D3 was reasonably accepted. The scatter of the ANN and the numerical results were closer to the 45° line when 100 Gaussian points were used to train the neural network. This indicates that the numerical results follow reasonable trends and thus can be fed into the ANN to generate accurate and precise models to predict the damage size for concrete slabs.

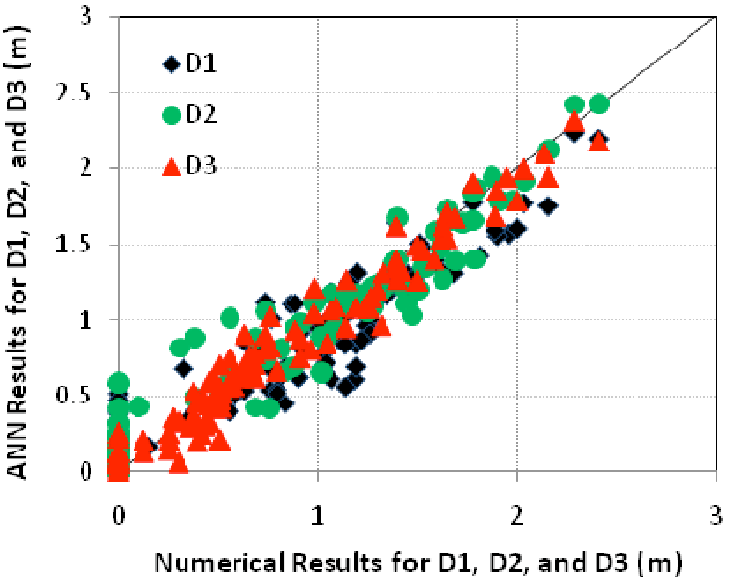

Figure 4. Correlation of ANN and the numerical results for damage size D1, D2, and D3 using 25 Gaussian points.

CONCLUSIONS

The spalling and cratering of reinforced concrete slabs under blast loading was studied in this paper based on a model-based simulation. The two-way reinforced concrete slabs were simulated and verified using the nonlinear explicit dynamic code LS-DYNA. The key parameters of the numerical simulations were the charge weight, the standoff distance, and the slab thickness, which led to 125 simulation experiments. The damage (cratering/spalling) of the concrete slabs were traced and mapped. The study showed that the damage varied between cases with no failure to the formation of large craters. The results of the numerical simulations were fed into a high accuracy Artificial Neural Network (ANN) to predict and estimate the damage size experienced by an RC slab under close-in detonations. A comparison between the ANN results and the numerical simulations were conducted, which showed a good correlation. The damage model can be used to perform post-blast global dynamic response assessment of structural systems resulting from the local damage. Additional research is recommended to include other parameters that could influence the damage size, such as steel reinforcement ratio, concrete compressive strength, etc.

Abstract:

A type of enamel coating that contain hydraulically reactive calcium silicates have been developed to improve the performance and service life of steel used as reinforcement in concrete structures. To demonstrate the effect of enamel coating on the mechanical performance of concrete structures subject to blast loading, two wall barriers with identical dimensions, which were often used to keep the terrorism attack (such as car bomb attack) away from critical buildings, were fabricated and tested in a military base. One of the wall barriers was reinforced with coated rebar and the other with regular rebar. Four equivalent TNT weights, 4 lbs, 10 lbs, 30 lbs and 45 lbs explosive were applied to observe the deformation, cracking and failure mode of the two barrier walls. Generally, the test results indicate that the barrier wall reinforced with enamel coated rebar has much better integrity than that with regular rebar: fewer cracks on the front and back faces of the wall, more stress transferred to the steel rebar, and mitigated catastrophic failure of the wall. The new coating can be of great value in increasing the performance and the service life of defense-critical infrastructure.

1. Introduction

Steel reinforced concrete has been widely used as construction material in buildings and civil infrastructures. The structural condition at the concrete-steel interface is a significant factor in the design and maintenance of constructed facilities. In the past decades, researchers have been seeking effective approaches to enhancing the corrosion resistance of reinforcement and the bond strength between rebar and substrate concrete. To reduce the potential for corrosion in concrete reinforcement, one of the solutions is to coat the concrete with different materials, such as CS compound (Moon et al., 2007), elastomeric surface coatings (Seneviratne et al., 2000) and geopolymer (Zhang et al., 2010) to increase the resistance for chloride penetration, freezing-thawing and carbonation processes.

A direct and practical way to increase the corrosion resistance of steel reinforcement is to coat the steel with corrosion-inhibiting materials: both organic and inorganic. Organic materials include epoxy (Kobayashi and Takewaka, 1984) and modified

resin (Selvaraj et al., 2009) while inorganic materials include galvanizing metal (Kayali and Yeomans, 2000) and phosphate conversion coatings (Jalili et al., 2009). However, studies of evaluating epoxy-coated rebar performance in field conditions by Virginia, Florida, and Oregon Departments of Transportation concluded that epoxy-coated rebar corroded at a faster rate than uncoated rebar due to moisture trapped underneath breached epoxy coatings (Sagues et al., 1994; Brown and Weyers, 2003). The use of epoxy coated rebar requires 20% longer development length because of a reduction in the pullout strength of the rebar in concrete (Kayali and Yeomans, 2000). Kayali and Yeomans (2000) also observed that galvanized steel seemed to have negligible effects on bond strength with concrete. Jalili et al. (2009) concluded that the bond strength between Zn-Ca phosphate coated rebar and concrete is 74% higher than that between uncoated rebar and concrete. In recent years, vitreous enamels have been introduced to increase the corrosion resistance of steel reinforcing bars and their bond strength with concrete (Day et al., 2006; Hackler et al., 2006). They are yet to be systematically characterized for bond and corrosion enhancements in various civil engineering applications.

In this study, pure enamel and enamel mixture with chemically reactive calcium silicate (CS) were applied to improve the bond strength at mortar-steel interfaces. They are characterized with barrier wall subjected to blast loading. The effects of enamel coating on blast resistance performance are studied experimentally. The work presented in this paper constitutes part of a collaborative research program involving comprehensive studies on corrosion resistance, chemical composition optimization, coating process design, and concrete-rebar interface behavior of enamel coatings.

2. Specimen preparation and test setup

2.1. Design and Fabrication

In this study, the military concrete barrier walls used in Iraq were considered as prototype structures to be tested under blast loads. These barriers have been used to protect crucial infrastructure from car-bomb attacks.

Two full-scale barrier walls were tested in this study, each approximately 6 feet tall, 4 feet wide and 6 inches thick. The base of the barrier walls is 4 feet in square and 12 inches thick. Four PVC pipes were embedded in the base of each barrier, which can be used to facilitate the anchoring of the barrier into ground as needed. Each wall is reinforced with #5 vertical reinforcement and #3 transverse stirrups, both at 6 inches spacing. The clear concrete cover on all sides of wall is one inch.

2.2. Material Properties

The materials used in barrier tests include concrete and steel reinforcing bars. The steel bars in one wall were coated by Properma Engineered Coatings, St. Louis, MO, with reactive enamels. Those in the other barrier wall were uncoated for comparison.

At the time of casting each barrier wall, 6 concrete cylinders were cast and used to determine concrete compressive strength. After 28 days of curing, the compressive strength of the concrete is 44 MPa with a standard deviation of 1.38 MPa; the Modulus of Elasticity is 31.5 GPa with a standard deviation of 827 MPa. The yield stress of the rebar is 490 MPa and the ultimate strength is 619MPa. The average strain at yield stress is 0.42%.

2.3. Test plan and procedure

The full-scale barrier specimens were constructed and cured in the laboratory and then transported to the test site at Fort Leonard Wood. Steel formworks were used for the casting of barrier walls and bases. Steel formworks were placed on the plywood that was laid on the Highbay Structures Laboratory floor. The rebar steel cage for the wall base was first made and placed inside the steel formwork. The vertical reinforcement of walls was then inserted into the base steel cage. Standard 90° hooks detailed according to ACI 318-08 (2008) were utilized to provide an appropriate development length for transverse tie bars. All vertical reinforcement was straight and was placed toward the bottom of the wall base with one inch of concrete cover. The base and the wall of each specimen were cast separately at two different times. After three days of base casting, the barrier wall was cast. During the wall casting, six concrete cylinders were also cast for the determination of concrete compressive strengths. After another week, the formworks were disassembled with the finished wall.

A total of 12 multi-purpose strain gauges manufactured by Vishay Company were installed on vertical reinforcing bars as detailed in an inset of Figure 8. Six of them were installed at mid- height and the other six at the very bottom of the wall. At each location (mid-height or bottom), four strain gauges were installed in the front side rebar near explosives and two in the back side rebar away from explosives. They have a grid resistance of 120.0±0.5% Ohms. From two gauges in the front and back rebar, the moment at the location of strain gauges may be evaluated. Additionally, six accelerometers were installed on each barrier wall as indicated in Figure 1 during testing.

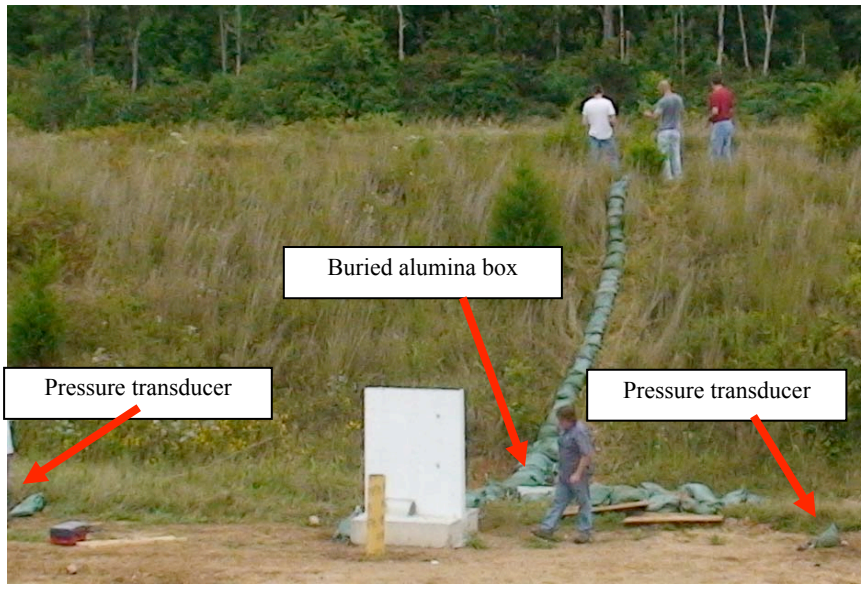

Figure 1 Test site

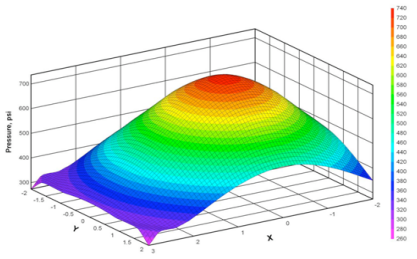
Each wall was installed with two coaxial cable crack sensors that were embedded into the two grooves preset on the near face of the wall (near explosives). Prior to blast, a connection cable was connected to each coaxial cable sensor for reading during and after each explosion. To protect the connector from blast damage, the connection cable was embedded near the top surface of the wall base and covered by a steel angle.

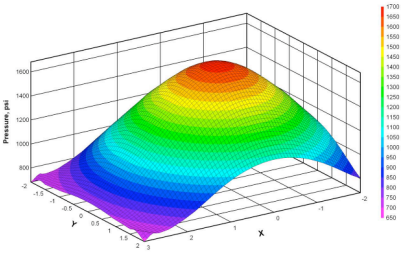
The full-scale barrier walls were tested at FLW. Several data acquisition systems were utilized during each blast test. To acquire strain, pressure and acceleration data, two Synergy data recorders were used. A sampling rate of 20 kHz was used for the Synergy Box data recorders. For the crack sensors, a Digital TDR Oscilloscope was used along with a pulse generator, which is used for dynamic measurements. However, measurements were taken from both sensors during each blast test. A laptop was used to configure and record data from the Synergy Box data recorders.

Explosion creates a very harsh environment for sensors, instruments, and connection wires. For protection purposes, the Digital TDR Oscilloscope and the pulse generator were placed in an alumina box, as shown in Figure 1. The box was situated in a nearby ditch and covered with sandbags. Most part of the connection cable between the Oscilloscope and the cable sensor were buried into the ground and covered with sandbags, as illustrated in Figure 1.



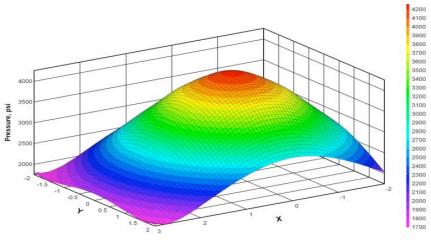
All wires of strain gauges embedded in each wall were led to one side of the wall. To protect them from the effects of blast pressure and its induced debris impact, the strain gauge wirings will then be guided through a steel angle attached to the wall base, and embedded underground together with two strain conditioners.

Coaxial cable sensors were connected to extension cables at the bottom of each wall. For protection purposes, the connectors were covered by steel angles and the extension cables were embedded near top surface of the wall base, which were then covered with sandbags as shown in Figure 1.

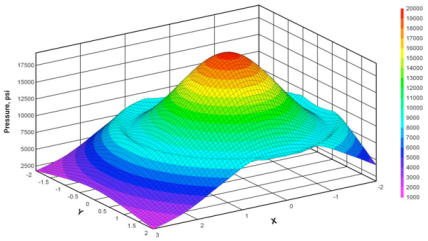


Each wall was tested with 4 lbs, 10 lbs, 30 lbs charge weights with 4ft standoff distance from the center of the wall. After that, all instrumentations were removed and the wall was subjected to one additional charge of 45 lbs placed right above the wall base.

Four different charges were considered for blast testing of each barrier wall. Charge weight is always specified in TNT (Trinitrotoluene) equivalence. The TNT equivalence factor is defined as the ratio of the mass specific energy of the explosive compound to the mass specific energy of TNT (4520 kJ/kg). An alternative approach makes use of two conversion factors, depending on whether the peak overpressure or impulse is to be matched (Mays and Smith, 1995).



The specific charge weights were determined from a simple analysis with the software COMWEP. The pressure distribution each blast causes along the wall is shown in Figure 2. It can be seen from the figure that the pressure reaches its maximum at the center of the wall and decays rapidly away from the wall center. As the charge weight increases from 4 lbs to 45 lbs, the peak pressure at the center of the wall varies from 736 psi to 19,370 psi, which will cause significantly different damages to the wall.



(a) Charge weight: 4 pounds TNT

(b) Charge weight: 10 pounds TNT

(c) Charge weight: 30 pounds TNT

(d) Charge weight: 45 pounds TNT

Figure 2 Pressure distribution: standoff distance of 4 ft

The first charge was made up of 4-pound pentolite cast boosters, resulting in a TNT equivalent charge of 4.4 lbs (with a TNT equivalence of 1.1). For convenience, this event is hereafter referred to as the 4-pound blast. The second charge was made up of 4-pound pentolite cast boosters and a 0.25 lbs pentolite cast booster, resulting in a total TNT equivalent charge weight of 10.2 lbs. This event is hereafter referred to as the 10 lb blast. The third charge was made up of 33-pound ANFO (with a TNT equivalence of 0.83) and 2-pound pentolite cast boosters, resulting in a total TNT equivalent charge weight of 30 lbs. The fourth charge was made up with a TNT equivalence of 45 lbs.

After the completion of each blast, a thorough inspection of each wall was performed. Cracks were marked on the tested wall and their patterns were documented. Any additional visible damage to the wall and its supporting base were also recorded. Based on various measurements, the overall performance of the tested wall can be assessed. It is noted that, due to a measurement limit of 70g, the acceleration data collected during various blasts was distorted and thus not used in the following analysis.

3. Test data and analysis

Two types of spalling can occur in concrete during a blast load — direct spalling and scabbing (TM 5-1300, 1990). Direct spalling of a concrete element is the result of a tension failure of concrete that is caused by the shock pressures of an impinging blast wave as it is being transmitted through the element.

Concrete elements subjected to a close-in blast are generally accelerating before or soon after spalling takes place. This accelerated motion of the element in turn accelerates spalled fragments. The velocities of these fragments can be as high as several hundred feet per second. These fragments can be a real hazard to human occupants, causing casualties in an explosion event.

Scabbing of a concrete element is the result of a tension failure of concrete that is normal to its free surface and is associated with large deflections. In the later stages of the ductile response mode of a reinforced concrete element, extremely large deflections are developed producing large strains in the flexural reinforcement and, consequently severe cracking and/or crushing of the concrete perpendicular to the free surfaces (TM 5-1300, 1990). Since the tension and compression strains are highest at the surface and since the shear reinforcement in the later stages of deflection confines the core concrete, damage to the cover concrete is more severe than damage to the core. After the applied blast load is over, the element is in a stage of deceleration at these large deflections (TM 5-1300, 1990). Therefore, the velocities of scabbed fragments, which are equal to the velocity of the element at θ =

5° (start of scabbing), are lower than the velocities of direct spalling fragments. However, the velocities of scabbed fragments may also be on the order of several hundred feet per second.

3.1. Pressure transducer measurements

Three pressure transducers were placed 18 ft away from the center of the charge and pointed directly at the charge, as illustrated in Figure 1. Although pressure can be measured directly on each wall, pressure transducers mounted on the wall may receive both incipient and reflected shock waves, making post-test data interpretation a challenge. In addition to the high likelihood of being damaged, it would be difficult to keep the transducer mounting apparatus steady during blast tests. As such, the pressure data acquired directly from the wall face may not be credible.

The measured pressure pulses under a 4-, 10-, and 30-pound charge are presented in Figure 3. It can be clearly observed that they are all in single pulse with various intensities and times of arrival. The difference in arrival time is attributed to various sizes of the charges used during tests. The 4-pound TNT equivalent was a cylindrical charge of 8 inches diameter and 10 inches length; 10-pound TNT equivalent was a cubic charge of 12 inches on each side; and the 30-pound TNT equivalent was a rectangular cube with 16 inches long, 12 inches high and 12 inches deep.

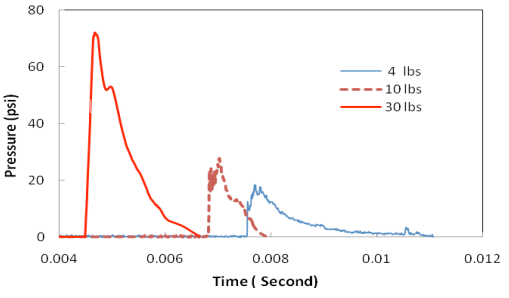


Figure 3 Measured pressures with various charge weights

For comparison with the measured pressure data, the reflected pressure from a spherical free-air burst of a charge of 4, 10, and 30 lbs, placed 4 ft above the ground, was simulated at the locations of two transducers with the A.T. Blast computer software developed by Applied Research Associates, Inc. For realistic simulations, the finite dimension of each charge was taken into account in various simulations. The peak pressure, time of arrival and positive duration of simulated pressure pulses are compared with those in Table 2. Clearly, these parameters are in good agreement.

Since the calculated pressure pulses agree with their corresponding measurements, the pressure pulses and impulses at the face of the wall can be obtained from the A.T. Blast computer software. In various simulations, each wall was considered as a

simply-supported structure. Ammonium nitrate fuel oil (ANFO) of different charge weights was placed 4 feet away from the wall. The pressure pulse and impulse parameters for each of the different charge weights are presented in Table 2.

Table 1 Calculated versus measured pressure pulses at the location of transducers

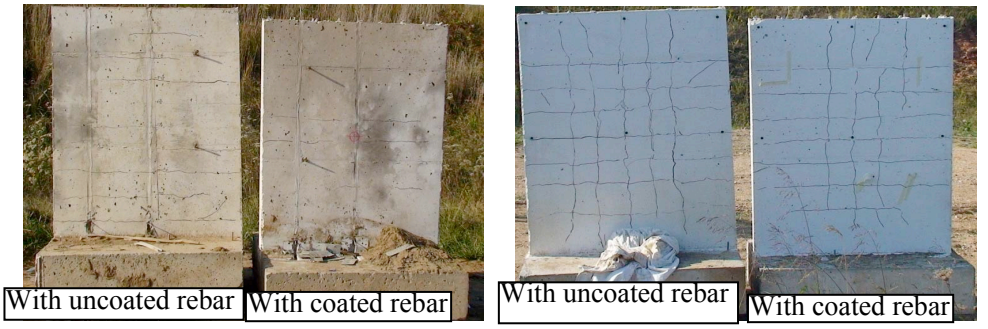
Charge weight (lb)	Calculated pressure pulse		Measured pressure pulse	
	Peak pressure (psi)	Time of arrival (msec)	Peak pressure (psi)	Time of arrival (msec)
4	18.9	9.04	18.1	7.79
10	31.6	7.80	25.0	6.98
30	69.4	5.97	71.6	4.64

3.2. Observations on barrier wall faces after blast tests

To facilitate the understanding of the structural behavior of two barrier walls under blast loading, cracks after each shock were examined carefully. The crack often becomes visible when its width is greater than 0.02 millimeter (7.8×10^{-4} in). Visible cracks were marked with a black marker on the tested walls as shown in Figures 4 and 5 for the walls reinforced with uncoated and enamel coated steel bars, respectively. Note that no concrete spalling was observed on both walls.

(a) 4 lbs charge (b) 10 lbs charge (c) 30 lbs charge

Figure 4 Barrier walls with uncoated rebar after each blast: front face



(a) 4 lbs charge (b) 10 lbs charge (c) 30 lbs charge

Figure 5 Barrier walls with enamel coated rebar after each blast: front face

As indicated in Figures 4 and 5, no cracks were observed on the front face of both walls after the first test with a 4-pound charge weight. After the second test with a 10-pound charge weight, despite several dents on the front face, no cracks were visible. After the third test with a 30-pound charge, visible cracks were clearly observed on the front face. Similarly, no visible cracks were observed on the back face of both walls after the blast test with a 10-pound charge weight. Note that cracks basically follow the pattern of steel reinforcement grids in the walls.

For a better comparison, tested walls are presented side by side in Figure 6. It is clearly observed from the figure that more visible cracks occurred on the front face of the wall reinforced with uncoated rebar. The difference in the extent and pattern of cracks between the two test walls is likely due to the use of enamel coating. As the shock front is engaged with a concrete wall and generates compressive stress on the concrete in contact, the concrete on the front face of the wall and on the shock front is locally subjected to bending as the stiffness of the front reinforcement grid suddenly changes, potentially causing concrete crack. The use of enamel coating on steel reinforcement stimulates a stronger bond between the concrete and steel, and thus a less stiffness change around the shock front. It results in fewer cracks, particularly on the upper portion of the wall. In this case, steel reinforcement is subjected to increased stress as will be discussed later.

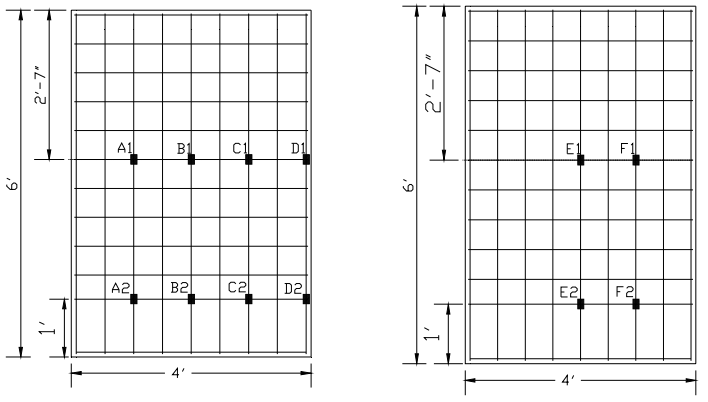
(a)Front faces (b) Back faces

Figure 6 Crack distributions on the faces of barrier walls after three blasts

Figure 6 also indicates that a few more cracks appear to have occurred on the lower portion of each wall. This likely results from the global flexural behavior of a cantilevered wall as the shock wave continues to spread on the front face of the wall.

Similarly, the crack patterns on the back face of the two walls are compared in Figure 6(b). Like the front face, the back face of the wall experienced more visible cracks when the wall is reinforced with uncoated rebar. The difference in the extent and pattern of cracks between the two test walls is likely attributed to the use of enamel coating. With a stronger bond between concrete and enamel-coated rebar, the cracked concrete can still attach to the rebar firmly with no or few longitudinal microcracks developed along the rebar. As such, the locally cracked concrete can work better with the rebar to make the concrete-rebar system stiffer and more difficult to bend as the compressive wave propagates through the reinforcement grid on the back face. This effect is translated into fewer cracks on the back face of the wall.

After the fourth blast test with a 45-pound charge, the barrier wall reinforced with uncoated rebar was completely destroyed as shown in Figure 7(a), leaving the back half of the wall base behind only. The steel cage in the front half of the base was disassembled. The damaged barrier wall reinforced with enamel coated rebar is shown in Figure 7(b). Although the concrete of the wall completely disappeared, the enamel coated rebar on the back side of the wall remained anchored into the base in bent shape. In comparison with Figure 7(a), the remaining rebar in Figure 7(b) implied that the rebar bond with concrete was stronger when coated with enamel coating. Additionally, the rebar cage in the front half of the wall base remained intact with some loose concrete pieces stick to the exposed rebar, indicating strong bond between them as well.



(a) With uncoated rebar (b) With coated rebar

Figure 7 Damaged walls after four blast tests

3.3. Strain gauge data

The 12 strain gauges instrumented on each wall are designated in Figure 8. For the wall reinforced with uncoated rebar, 5 of them were malfunctional due to casting and transportation of the wall and preparation (groove cutting) of the wall test. For the wall reinforced with enamel coated rebar, 4 of them were damaged prior to testing. The strain data taken under a blast load of 4-pound charge are presented in Figure 9 and Figure 10 for the walls reinforced with uncoated and coated rebar, respectively.

(a) Front side (b) Back side

Figure 8 Locations and designations of strain gauges

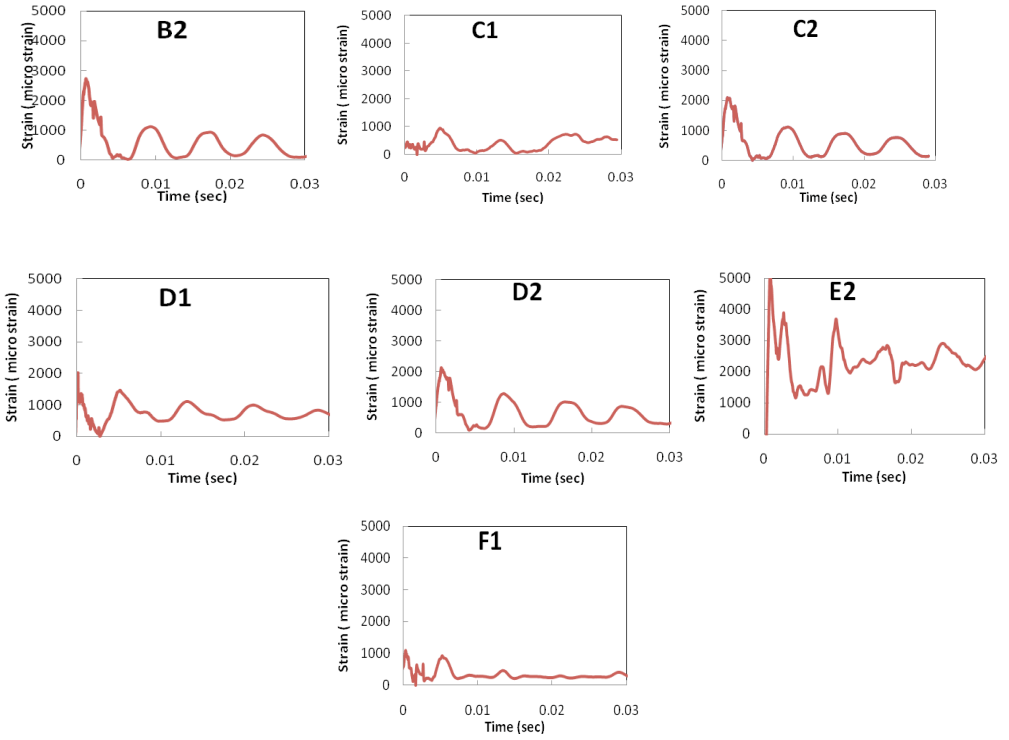


Figure 9 Strain data from the barrier wall with uncoated rebar

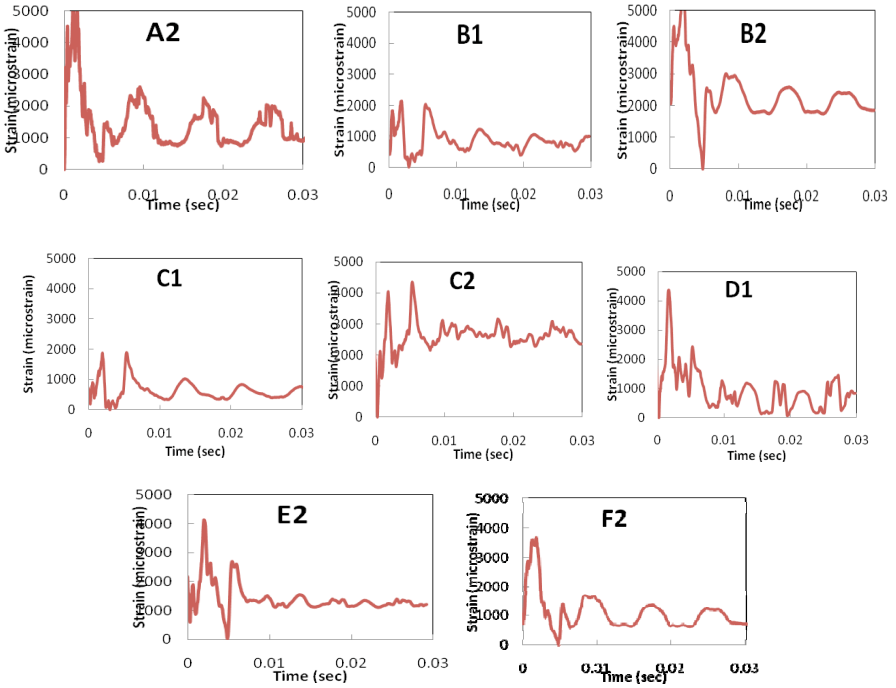

Figure 10 Strain data from the barrier wall with enamel coated rebar

The strain time histories as shown in Figures 9 and 10 are very consistent in terms of locations of peaks. For example, the locations of the first 4 peaks from B2, C2 and D2 are very close. This ensures the reliability of the experimental data. It can also be seen from Figures 10 and 11 that the tensile strains measured from the enamel coated rebar are higher than those from the corresponding uncoated rebar at the middle height of the walls. These results verify the conclusion drawn from the observations on crack patterns that the enamel coated rebar has stronger bond with concrete and, under blast loads, experiences larger strain transferred from concrete.

Consider a barrier wall as a uniform cantilevered beam with consistent mass. The fundamental period of vibration can be estimated to be 0.11 sec, which is over 20 times longer than the positive duration of all blast-induced pressure pulses. Therefore, the propagation of shock waves dominates the deformation and cracking of the barrier wall.

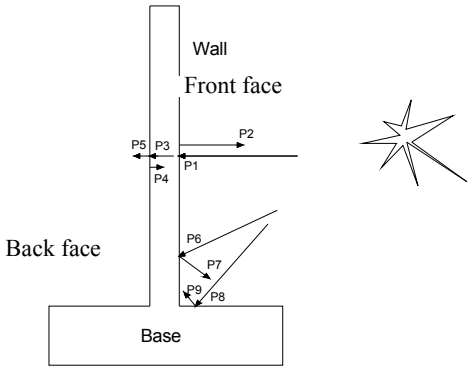

Figure 11 Illustration of pressure wave propagation

Generally, the peak strains at the bottom of the front face (e.g., C2, D2) are larger than that in the mid-height (e.g., C1, D1). Cracks can be found on both front face and back face. This can be illustrated in Figure 12. When the sock is induced from detonation of an adjacent explosive, pressure wave (P1) will reach the front face first, where a reflection wave P2 will be produced. The interaction of left-going wave P1 and right-going wave P2 leads a tension wave on the front face, thus, the front surface may experience a tension stress at some moments and tension cracks will occur there. Besides the reflection wave P2, part of wave P1 will also transmit through the wall, arriving at back face, reflection wave P4 and transmission wave P5 will be produced at the back face. The interaction of waves P3, P4 and P5 will produce tension pressure on the back face. The pressure in the mid-height of the wall is directly caused by pressure P1 and its reflection P2. For the bottom of the wall, in addition to the action of direct wave P6 and its reflection P7, the reflection wave (P9) of the wave P8 on the base will also have vital impact on the bottom part of the wall. The combination of these waves at the bottom may cause much larger deformation at the bottom part of the wall than that in the mid-height. Large cracks were observed at the wall-base corner. This assures that the waves on the base and their reflections have significant effect on the overall behavior of the barriers. More detailed theory about the wave propagation can be found in text books (Paul, 1996).

4. Concluding Remarks

This study has led to the following observations:

- From the typical failure modes of the barrier walls subject to 30 lbs charge, it can be inferred that the enamel coating can enable the adjacent concrete hold the rebar more rightly, inducing less slippage and thus resulting in less cracks on the front face of the wall.

- The results from the strains of steel bar obtained from embedded strain gauges show that the more stress was transferred into the steel rebar with stronger bonding. As a result, larger strains were found in the enamel coated rebar, improving the integrity of the whole structure.
- The failure mode of walls under 45lbs charge clearly indicates the improvement effect of enamel coating on the bonding between steel bars and concrete. This further confirms the conclusions drew from previous report about the mechanical bonding effect on the overall behavior of reinforced structures.
- Future studies shall be directed to investigate a new enamel formulation with improved corrosion resistance, characterize the development length of steel fibers in concrete, and develop the constitutive law of fiber-reinforced concrete in tension and compression.

ABSTRACT

Dynamic modeling and field testing of full-scale window systems using a shock tube are presented in this paper. The modeling includes numerical simulations using LS-DYNA. The dynamic response in terms of the center deflection as well as the dynamic reactions around the window frame is measured and compared to the modeling results. In addition to the positive phase of the blast loading, the response of the window system to negative phase is also investigated. The modeled dynamic deflections and reactions correlated well within the first few peaks of the measured response of the window systems. The results of this study can be used to improve the existing methods for predicting the dynamic response of windows under blast and to provide affordable design recommendations.

INTRODUCTION

Design of civilian structures to resist blast loading has received much attention over the past several years. The behavior of glazing is of particular interest since it is estimated that the majority of injuries from blasts result from airborne glass fragments from glazing (Hinman, 1995). Upon failure due to a blast, sharp fragments of glass can be propelled into a building, resulting in the injury or death of occupants (Norville and Conrath, 2001 and 2006).

In recent years, blast design of window and curtain wall systems made benefit of conventional materials and systems through the use of laminated glass that is properly attached to a window frame and mullion system. To counter the effects of flaws in annealed glass, tempered and/or heat-strengthened glass, which exhibit high compressive residual stresses at the surface of the glass (Amstock, 1997), are often used for blast resistance applications. Laminated glazing is generally fabricated from two or more layers of tempered/heat-strengthened glass with an elastic material between each two layers. Over short durations and at low strains, this interlayer can be treated as a linear elastic material with a Poisson's ratio approaching 0.5 and

stiffness obtained from shear modulus using solid mechanics equations (Wei and Dharani, 2005). The elastic interlayer layer allows the glazing to undergo large deformations, and thus resulting in large dynamic reactions around the edges of the window frame. In addition, insulated laminated architectural glazing systems, which may include an annealed glass layer separated from the laminated glass with an air gap, can provide added blast resistance through the creation of a "sacrificial" layer. These layers are also used to meet other design criteria such as thermal and sound insulations.

The large-deflection response of the glazing system under blast loads generates dynamic reaction parallel and perpendicular to the plane of the glazing. The dynamic reactions are transmitted to the supporting mullion and/or structural frame. This paper present a numerical simulation and field testing program aimed at evaluating the dynamic response of laminated windows, including dynamic reactions, under blast loads as well as comparison of models to measured data for dynamic reactions at the connections.

MODELING

The numerical modeling is performed in this paper using the commercial code LS-DYNA (2009), which is commonly utilized by the blast research community. The glass layers and interlayer polymer are modeled as separate layers within single composite elements using the LS-DYNA material model 32 "MAT-_LAMINATED_GLASS". This material model uses multiple through-thickness integration points to account for multiple layers of glass and polymer within a single shell element, Chung et al. (2010). The glass layers are modeled by isotropic hardening plasticity with failure based on exceeding a specified level of plastic strain. Neither the entire element nor the entire sub-layer is deleted at this specified level of plastic strain but there is a redistribution of internal stress to the remaining glass and polymer sub-layers. This polymer sub-layer material which the glass is bonded is assumed to stretch plastically without failure. Each integration point is flagged with a zero if the layer is glass and with a one if the layer is polymer, LS-DYNA user's manual (2009). The input data for glass layers includes the mass density, Young's modulus, Poisson's ratio, yield stress and plastic strain at failure. The input data for polymer layer includes Young's modulus, Poisson's ratio, yield stress and plastic hardening modulus.

VERIFICATION USING FIELD EXPERIMENTS

Three laminated window systems were tested in the field using a full-scale shock tube (Figure 1). The laminated windows were 1.22 m wide × 1.68 m high. The three windows were made up of 3 layers of glazing and an aluminum frame. Table 1 shows the relevant information of the three windows evaluated in this study, and Figure 2 shows one of the window samples inserted in the test frame before and after test. The measured pressure and impulse are shown in Table 1, and sample gage readings during the shock tube tests of one of the windows is shown in Figure 3.

The pressure-time history recorded from the field experiments was used as the input loading function to the LS-DYNA model, which accounted for all positive and

negative loading phases. The center deflection of the glazing and dynamic reactions transmitted to the aluminum frame are recorded during the experiments and are compared to the numerical modeling results.

The numerical dynamic responses of the windows are compared to field results as shown in Figures 4. The plastic strains contours predicted using the numerical model are compared to glazing failure profile observed in the experiment for window sample #1 as shown in Figure 5. The numerical predictions correlate closely with the field results.

Figure 1. Shock tube.

Table 1. Field Data of Window Systems.

Window Sample #	Laminated Pane Constituents			Measured Average Blast Loading		
	Outer Layer (blast side)	Interlayer	Inner Layer	Pressure (kPa)	Impulse (kPa-msec)	Positive Phase Duration (msec)
1	3.2 mm Annealed	1.0 mm Uvekol-A	3.2 mm Annealed	29	152	30
2	3.2 mm HS*	1.5 mm Uvekol-S	3.2 mm HS*	49	308	59
3	6.4 mm Annealed	1.0 mm Uvekol-A	6.4 mm Annealed	55	306	54

*HS = High Strength

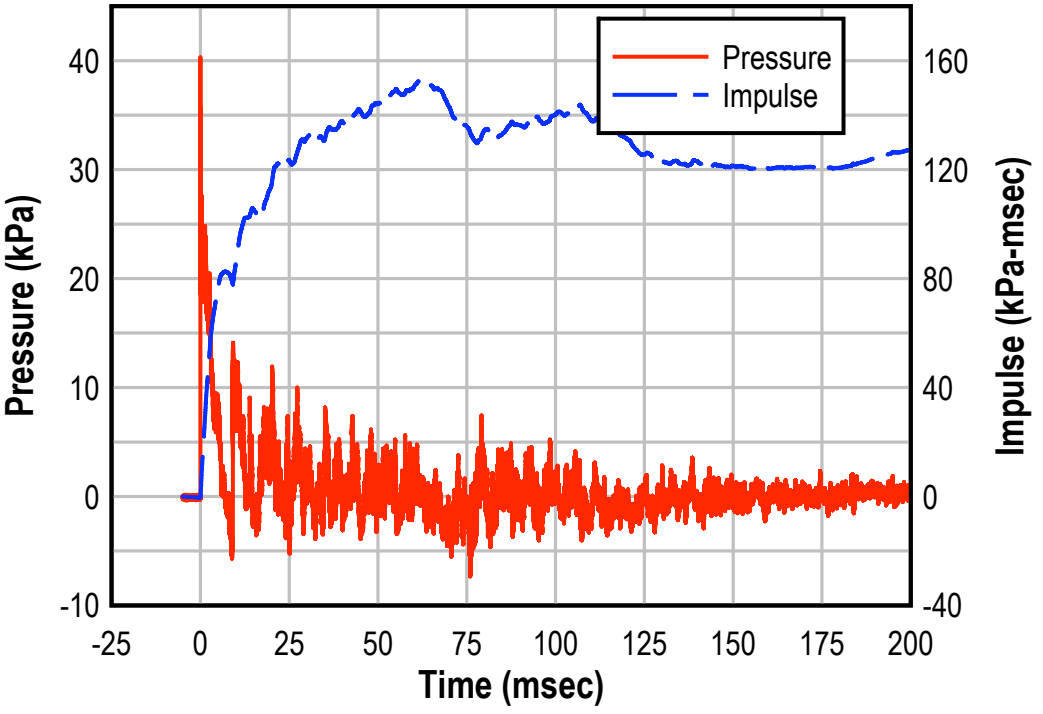

Figure 3. Sample pressure-time history.

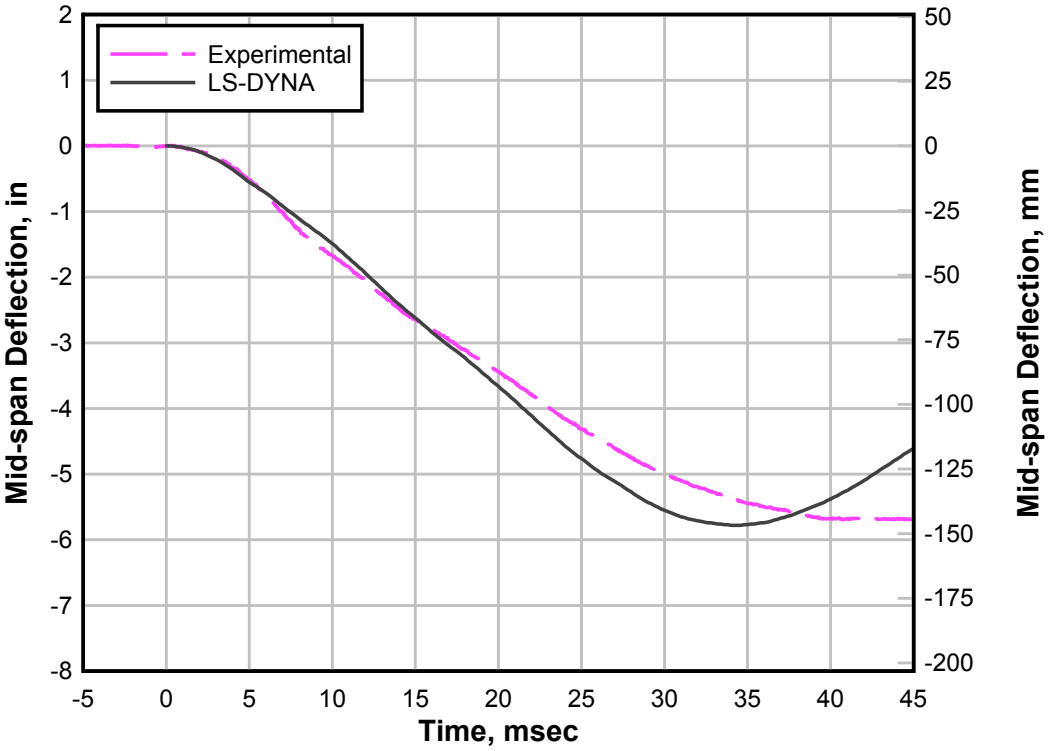

Figure 4. Center deflection comparison for window system #1.

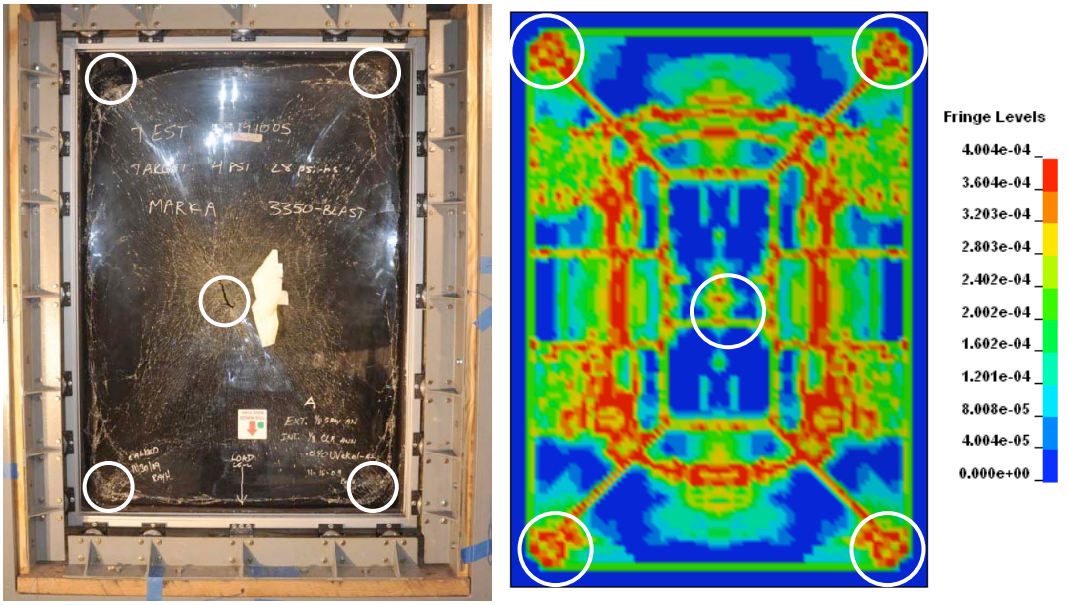

Figure 5. Plastic strains (right) showing predicted failure (left) shown in experiment for window #1.

The dynamic response prediction of window samples 2 and 3, including the dynamic reactions along the aluminum window frames are shown in Figures 6 - 9. The dynamic deflection prediction for window sample 2 matches closely the first two peaks field response, while the results deviate after 40 milliseconds as shown in Figure 6. On the other hand, the dynamic response prediction of window sample 3 matches closely the field response for the first three peaks as shown in Figure 7.

The dynamic reactions for both windows along the vertical (long) edges of the aluminum frames are shown in Figures 8 and 9. The dynamic reactions shown are the ones perpendicular to the plane of the window, i.e., along the blast wave direction. In general, the dynamic reaction predicted by the numerical model matched closely the field dynamic reactions recorded during the blast event. The dynamic reactions for window sample 2 are shown in Figure 8, while the results for window sample 3 are shown in Figure 9. Similar results were also observed for the dynamic reactions along the horizontal (short) edges of the aluminum window frame.

The predicted and measured dynamic reactions can be used to evaluate the existing united facilities criteria (UFC) requirement, which specifies that the loading transmitted to the supporting structure of a laminated window to be eight times the glazing resistance determined by the ASTM standards (ASTM, 2003, 2004, and 2007). Additional numerical modeling and field testing results can be used to develop a probabilistic value for the dynamic reactions experienced by the supporting structure. Alternatively, closed-form solutions of the resistance function of the glazing system can be incorporated into a single degree of freedom (SDOF) dynamic model to calculate analytically the dynamic reactions for a specific window system and blast loading.

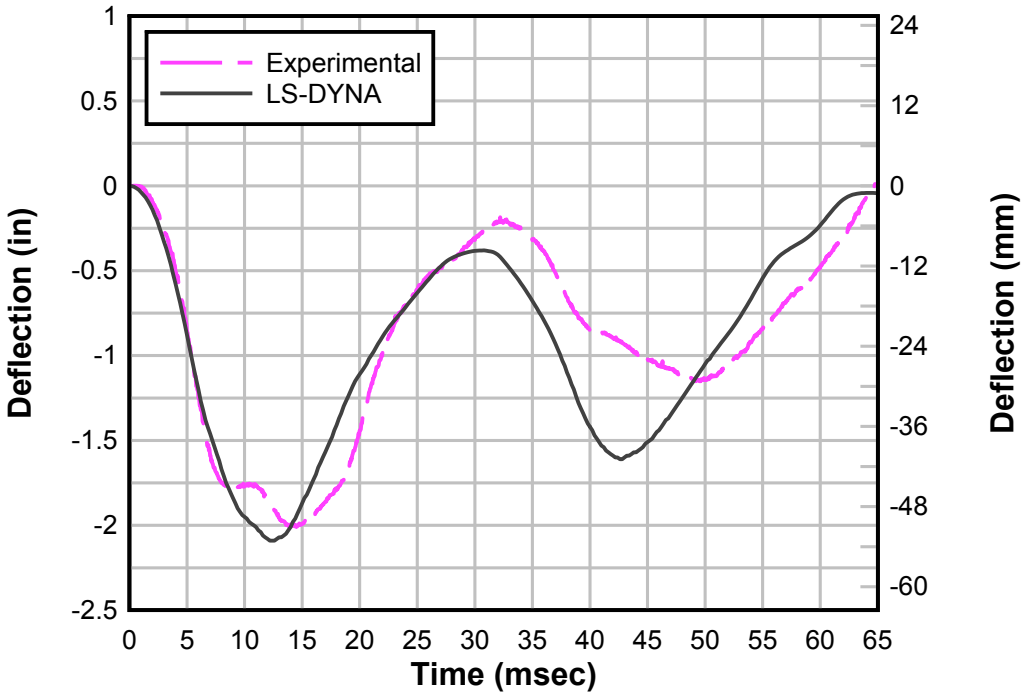

Figure 6. Center deflection comparison for window system #2.

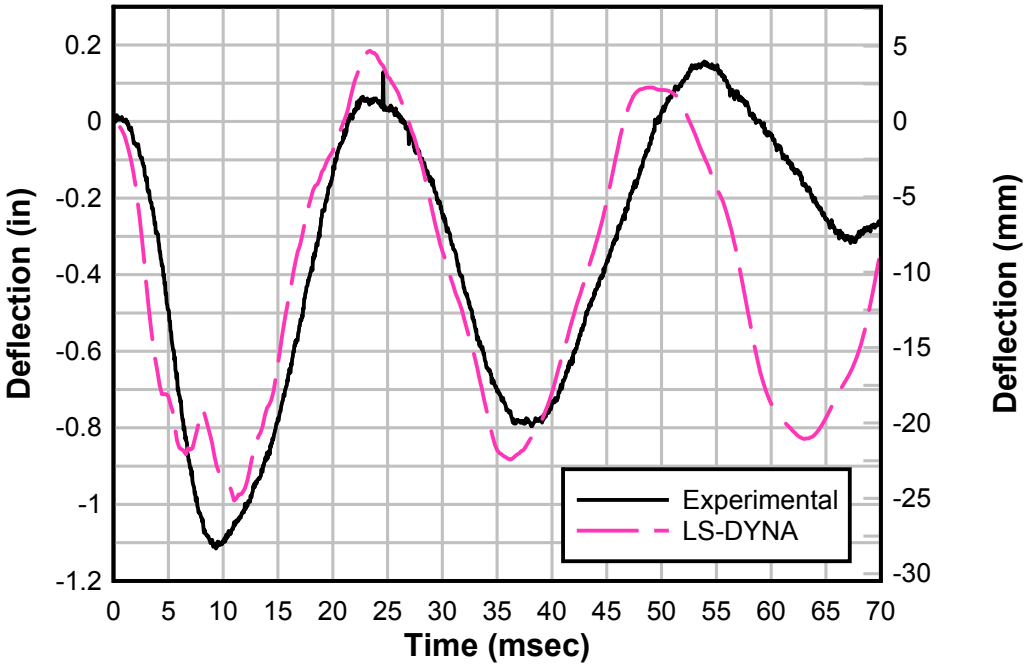

Figure 7. Center deflection comparison for window system #3.

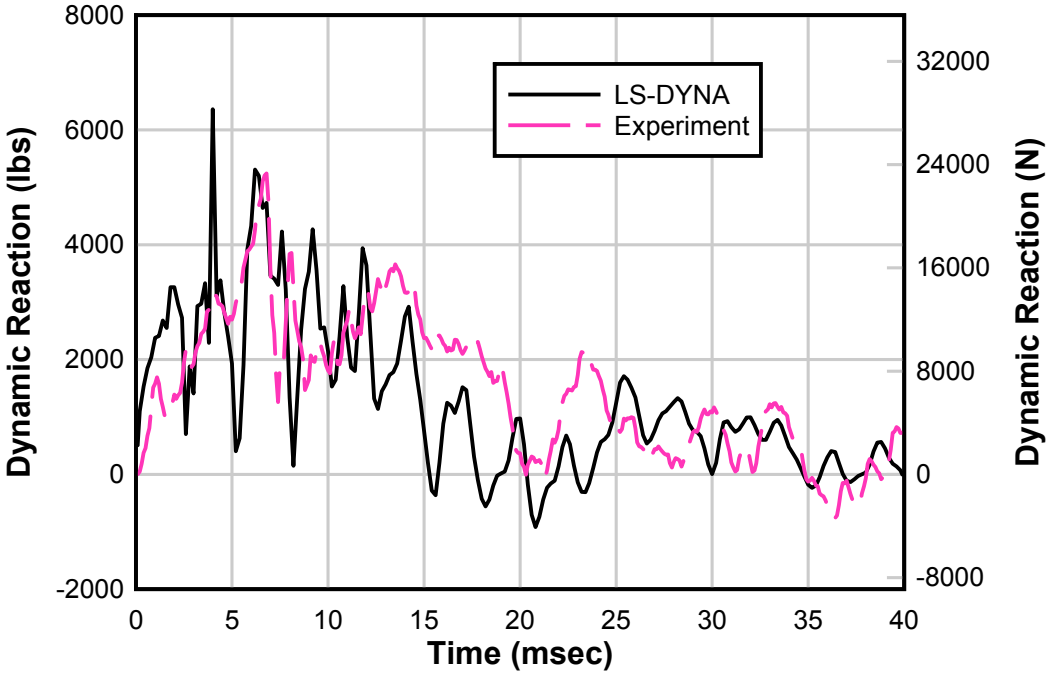

Figure 8. Total dynamic reaction acting on long edge of aluminum frame for window sample #2.

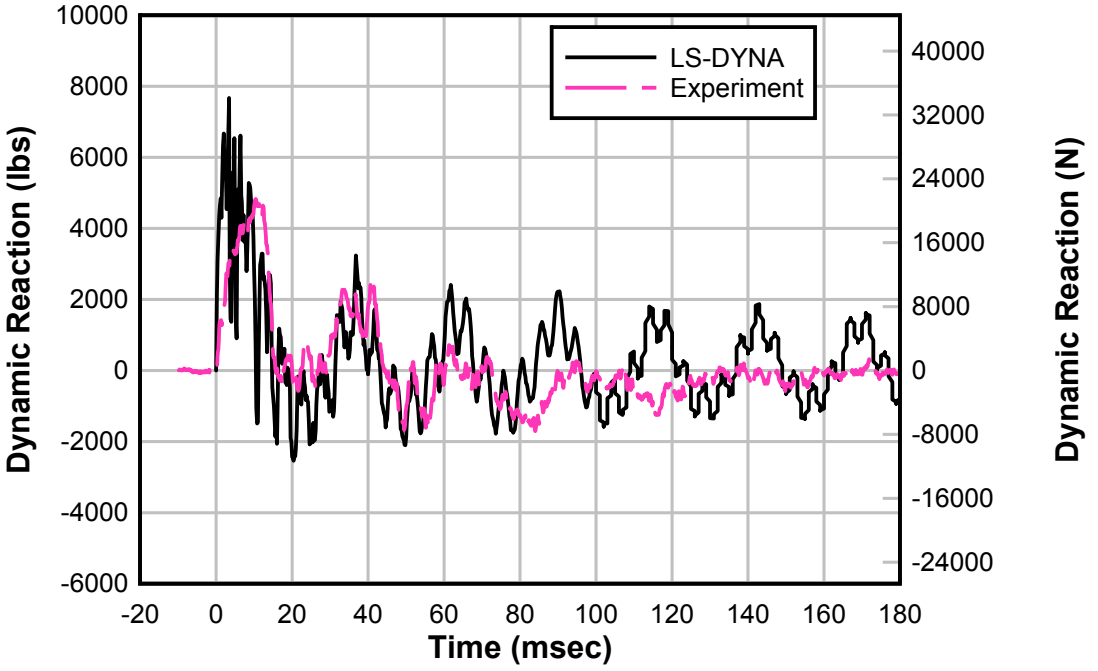

Figure 9. Total dynamic reaction acting on long edge of aluminum frame for window sample #3.

SUMMARY

Numerical modeling was used to predict the dynamic response of the window systems and were verified using field tests under blast loading performed using a full-scale shock tube. The numerical simulations using LSDYNA predicted well the dynamic response and total dynamic reactions. The results of this study can be extended to develop engineering-level analytical models for the design of window systems and their supporting structures. The measured dynamic response from the shock-tube experiment, in terms of the center deflection, compared relatively well with the numerical models developed in this paper for all three windows. In addition, the measured total dynamic reactions perpendicular to the window compared well with the numerical models.

It is recommended that additional numerical modeling supported by field testing be performed to develop a probabilistic factor, similar to the recommended by the UFC for predicting the dynamic reactions for blast design of the supporting system of laminated glazing. Since the static resistance and the mechanical properties of the materials that makeup the window system are the most important inputs to the analytical and numerical models, it is recommended that material, component, and full-scale static testing of various window systems be performed.

Attaching Tower Cranes to Buildings in New York City

Dan Eschenasy, P.E., M.ASCE
Chief Structural Engineer
New York City Buildings Department
deschenasy@buildings.nyc.gov

Abstract.

The paper presents an overview of the issues related to the application of tower crane loads to buildings under construction. Intended for the structural engineers who design these buildings, it provides a primer on the derivation of these loads by the crane installation designers. Based on a review of tower cranes installations designs executed in New York City, the author finds that the attachments at the top of the structure can develop horizontal loads of same order of magnitude as the wind loads used for the base building design. Interaction and responsibility between crane and building engineers is examined. The building designers are better suited to evaluate the effects on the main lateral load resisting system. The crane installation designers need to use more consistency and clarity when presenting the loads for evaluation by the engineers of record.

Introduction. Following two major accidents in New York City, the Buildings Department embarked in a massive revision of its crane approval and inspections processes. The Department has engaged a consortium of engineering companies led by CTL Group, to help in the evaluation of crane procedures as well as of other categories of construction operations where it was experiencing problems (concrete, support of excavation). This process, called High Risk Construction Operations (HRCO) , lasted three years. For the crane section of the project CTL Group selected Crane Tech Solutions (CTS) whose principals Manfred Kohler and Frank Hegan have vast experience in the domain.

Most of the HRCO findings have been made public as the proposed changes in code or operations were discussed with the industry. This author participated in the discussions that CTL and CTS experts had with the New York City engineering consulting industry. The proposal that the structural engineers of record be required to approve the loads imposed on the structure met with significant resistance. Following these discussions and relatively independent of the HRCO effort, the

author examined several crane installation projects focusing on the loads exerted by the tower cranes on the building structure.

At the time the designs under review were prepared, the NYC Building's Crane and Derick approval process required two distinct engineering submittals. The first submittal, required to permit a crane model to operate in the city, includes general structural calculations, description of safety features, etc. Specific calculations are to be submitted for the actual installation at a specific site of any approved model. These designs formed the subject of the author's review. This review focused on methods and engineering responsibility for verifying the capacity of the building to sustain loads induced by the attachment of a tower crane.

Engineers of Record for the Building and for the Crane Installation. The design of the building structure is the responsibility of its structural engineer of record [(B)EOR], who at the time of the design is not aware of the specific methods that will be selected for the erection of the building. The design of the building is based on code prescribed loads and load combinations. These derive their maximums values from the effects of extreme natural events. For the New York City area, most tall building designs are controlled by the wind load.

At some point in the construction management phase, a tower crane solution is selected and an engineer with expertise in tower cranes, designs an installation system. The tower crane installation design includes selection of type of crane, positioning of crane, positioning of the tower attachment, design of tower foundation. This crane installation engineer [(C)EOR], bases the calculations on loads provided by crane manufacturers together with loads specified in building codes or national standards. The load combinations are not always sanctioned by building codes. Crane in service loads loads do not usually account for the possibility of accidents. Excessive loads are avoided by means of mechanical and electrical controls as well as operator training. Human errors play a much larger role in the life of cranes than of buildings'. Human factors are minimized by adherence to the engineer's project specific instructions as well as to the manufacturer's general instructions.

After they reach certain heights, tower cranes cannot stand alone and need to be supported laterally. Such support is most commonly obtained by attaching the tower to the buildings under construction. A collar is set around the tower and tied to the building structure with several steel beams (ties) that are intended to transferonly horizontal loads to the building. The ties need to be positioned in a manner that blocks any horizontal movement of the tower. As the tower advances in height, new collars and ties are installed. The spacing of the collars is limited by the structural characteristics of the tower given the anticipated usage demand and wind speed. The collar also needs to be placed such that it meets a tower horizontal frame. Each new collar addition creates a different structural system, a new loading configuration that needs to be resisted by the building.

The building designed by the (B)EOR under one set of loads is subjected to horizontal loads for which it was not designed. These special new loads are the result of decisions by the (C)EOR whose purpose is to minimize the number of collar (as

the collar installation is a complicated operation). The intensity of these new loads is calculated by the (C)EOR based on manufacturer data and specific local conditions.

Which engineer has the responsibility to verify that the building under construction can safely sustain these loads? Which engineer is in better position to make this evaluation?

General Model of Engineering Responsibility. As a result of various building code provisions a model for engineering responsibility has developed for cases when buildings are subjected to loads for which they were not specifically designed. For example, when the floor of an existing building is subjected to a new set of loads, an engineer representing the tenant introducing these loads needs to verify that these are within the original approved design rating. When the loads exceed this rating, the tenant 's engineer has the obligation to verify that any affected part of the structure can safely sustain the load. Any necessary structural changes to the existing building have to be accepted by the building owner. This owner makes his decision based the advice of his own engineering consultants, usually the engineers of record of the original structure. Discussions between the two sets of engineers ensue.

The building department expects a licensed engineer to demonstrate the adequacy and places entire responsibility on this engineer without regard of who commissioned the evaluation. In fact, this engineer is expected to have performed a due diligence inspection to assess any degradation of the original design condition of the structure.

Crane Loads and the Building Design Process. There are some specific conditions related to supported tower cranes: both sets of engineers work for the same owner, some engineering consultants are covered liability insurance policies that prevent them to perform designs of construction related installations, the officially structural design documents list only the vertical loads related to building occupancy. As the construction is in progress some materials might not have reached their full strength, some installations or connections might not have been completed, results of some inspections might not be available.

There is no dispute as to the responsibility of the (C)EOR to design any local strengthening at and around the attachment points of the crane to the building, but is the (C)EOR in the best position to certify the general capacity of the building to safely resist the crane loads?

Ideally, the crane loads should be specified early so as to be included in the original structural design. This is rarely the case, as final decisions on the erection methods are made at later points. At this point to avoid a costly complete recalculation of the building one tries to first to verify the loads by comparing them to the original design loads.

To perform such lateral load comparison, the (C)EOR can only examine the building’s structural drawings, but these include only the general parameters used in the wind design (exposure, importance factors, etc.). Without collaboration with the

(B)EOR, the (C)EOR has no simple way of knowing what were the actual horizontal loads used in the design of the structure.

Up till recently, in NYC there was only scant collaboration by these two different engineers. The Buildings Department is in the process to require (B)EORs to collaborate in assessments of crane loads effects. Changes in design responsibility will affect also the responsibility for inspection of the execution of the specific construction details present in the crane installation drawings. To be part of the process, engineers involved in high rise design need some basic understanding of crane loads.

Primer on the Derivation of Loads. Structural engineers of tall buildings need to have a basic understanding of the crane effects on buildings. The following paragraphs provide some simplified explanations.

When the crane is not in service (does not lift any load) the weight and resulting moment of the boom is not fully balanced by the moment produced by the counter weight. The resulting unbalanced moment is a dead weight type of load and tends to rotate the tower towards the counterweights. The essential variation in this load would be the result of an improper installation of the counter weights. (Location or actual weight).

When the crane is in operation, the moment produced by the weight of the jib and the weight being lifted might not be entirely balanced by the counterweight moment. The maximum size of this unbalanced moment is determined by the capacity of the crane for a given the type and orientation of the boom. This is a construction live load. One needs to add to this the effect of the slewing moment, an horizontal moment produced by the rotation and braking of the crane. The calculated load could be exceeded by an over loading of the crane combined with a malfunctioning of the embedded safety stops. The specified load might be exceeded during the site load test when this is performed following manufacturer's instruction to use a 10% overload.

Even in the absence of air movement, flexibility due to the unsupported height of the tower or due to the jib configuration can induce second order effects that affect stability of the crane.

Wind effects are a major concern for the stability of cranes. As crane are allowed to lift loads only when winds are below 30 or 35 mph, the pressure at this wind speed and the related effects are added to the “in operation” loads. During operations, the jib might need to take any position so both wind along and perpendicular to the jib need to be considered. The center of application of the wind loads on the jib is determined by its angle to the vertical. The effects of the wind perpendicular to the jib, a larger exposed area, will produce forces and moments in a plane perpendicular to the “in service” overturning moment that acts in plane with the jib.

Effects of stronger winds are combined with effects of “out of service” loads. Crane out of operation are allowed to weathervane so only wind along the jib needs to be considered. Of course for locations where the presence of adjoining structures

(including other cranes) can determine weathervaning. The jib might need to be raised in a certain position to avoid obstructions or weathervaning might not be possible at all. In such cases one needs to consider the position of the resultant of wind forces or even the effect of wind perpendicular to the jib.

In most cases manufacturers recommend removal of some intermediate ties for wind speeds over 65mph (usually the one before last tie). This has the effect of improving the structural behavior of the tower, but also of increasing the load transmitted to the building by the top tie.

It results from that several loading cases are possible.

- Crane without load, no wind included
- Crane at maximum load, no wind included.
- Crane in operation with the wind along and wind across jib.
- Crane out of operation with all braces inplace and wind up to 65 mph. (or at whatever wind speed some ties might have to be removed)
- Crane at maximum wind load with or without any ties removed.

In principle all these load combinations need to be considered for each collar configuration, but some the combinations producing low load demands can be discounted by inspection.

Table 1. Crane and Tie Load Data

Supported Tower Crane -Observations on the current practice in New York City. Several crane installation designs were reviewed Although not random, and

clearly not encompassing all possible cases, the selection provided a good representation of the crane installation design practice as it was evolving under stricter regulation.

All designs required the cranes to be installed outside the main building tower, but in several cases the tower crane was placed inside the low rise podium. The buildings reviewed were relatively symmetric, but their length to width ratios differed significantly. Also, the presence and configuration of setbacks was different for each building. The structural framing systems encountered were steel, concrete and steel frame with concrete shear walls. In one case an existing 16 stories building was altered by the addition of 16 more floors. Here, the tower crane ties were attached directly to the main vertical steel truss core. Data obtained from installation drawings on five of these crane projects is presented in Table 1.

The usual attachment to the structure uses three ties, two of which converge towards to a point in the building's structure. The values P1 represent loads in the first tie and are the loads used for the design of the ties. The values N2 and P2 represent the loads at the point of convergence and do no describe the actual load in the ties. The highest value loads (P1 or the combination of P2 and N2) are used to design the reinforcement at the attachment point. The drawings present separately the In Service and Out of Service loads at each floor. There is no indication as from what particular load combination they were extracted. We found that in fact they are the envelope value of maximum forces. In each of the projects reviewed, the (C)EOR calculated the values P1, P2 and N2 and performed the related calculations related to transfer loads from the collar to the building. The collar loads were sometimes calculated by the (C)EOR and sometimes provided by the crane manufacturer. This resulted in inconsistencies on the wind speed used to evaluate the loads. The manufacturers use full code wind pressures to design the cranes, while the (C)EORs take advantage of the provisions of reduction factors recommended in ASCE 37 *Design Loads on Structures During Construction.* This discrepancy seems justifiable as crane designs need to provide for many years of operation are while the attachment to one particular structure is unlikely to exceed one, two years. The based wind load needs be from NYC Building Code and, as required, it is modified according to applicable provisions from ASCE 7 *Minimum Design Loads for Buildings and other Structures.* At the time when the installation projects were prepared, both ASCE 7 and the NYC Building Code were being modified. This resulted in additional discrepancies.

Structural Capacity of Building and Reinforcement. For all the cases observed, the tie loads at their attachment points exceeded the capacity of the surrounding slab. In addition, these loads overstressed the structural elements in their path towards the main lateral resisting system. All installation projects examined included drawings depicting some local reinforcements. In almost every case, these drawings were prepared by the (C)EOR. The information available on the building structural drawings (slab and beam sizes, type of material, etc) was sufficient to allow a proper verification and design. In some cases, conservative (C)EORs designed the

reinforcement without bothering to verify if the original building structural design was sufficient. The use of the envelope reaction forces (as listed in table) at each tie connection point was adequately conservative. For all practical purposes, we did not see any need to require verification or even acceptance by (B)EOR of the local reinforcement. Coordination was the only potential issue (e.g. to insure that the additional rebars are installed).

All projects reviewed have an engineer's statement certifying the building's main structural system's capacity to carry the tower crane loads. There is no record on how this evaluation was effectuated. When the (B)EORs offered their acceptance, this was based on the loads P1, P2, N2 shown on the crane installation drawings. One can safely assume the (B)EOR has, at a minimum compared these loads to the loads used for the basic structure. In fact, the inspection should compare the resultant of P1, P2 and N2. Admittedly, this combination of envelope values would be over conservative as the actual loads are the loads at the collar and the moments generated by these as they are transferred to the main lateral resisting system.

The (C)EOR knows the loads at the collar, but does not know the loads used for the design of the building. The (C)EOR does not even know if the building was design using wind loads were obtained from wind tunnel studies. Is this acceptance by the (C)EOR, the result of a detailed effort or just based on general considerations?

It is true that for many attached tower cranes operating in New York City, the out of service loads are larger than the in service loads and that this difference is a consequence of the difference between the in and out of service wind speeds. It is also true that the wind load on a tower crane is a fraction of the wind used to design the building. But one does not know in what general situation the preceding considerations can be applied, as buildings and crane configurations, crane payloads and attachments to buildings are extraordinarily diverse.

Maximum Forces Exerted by Crane on Collars (kips)					
PROJECT	1	2	3	4	5
Building Exposure Type by ASCE-7	by manufacturer	by manufacturer	by manufacturer	Exposure A	Exposure B

Collar Level #3 (k)	107	-	135	-	86.5
Collar Level #2 (k)	146	143	135	-	86.3
Collar Level #1 (k)	127	141	139	119.6	80.9
Cummulated Floor Wind Shear at Collar Level					
Floor at Tie #4 (k)	-	-	221	-	84
Floor at Tie #3 (k)	75	-	575	-	200
Floor at Tie #2 (k)	290	344	888	-	309
Floor at Tie #1 (k)	589	591	1326	490	434

Table 2. Forces at Collar vs Wind Design Loads

Simplified Verification. A comparison was performed between the loads at the collar and code imposed wind loads. See Table 2.

The values of the loads at the collar, shown in Table 2, were obtained from the calculation notes submitted to the department. These values underestimate the

crane load on the main lateral resiting system as the effect of the transfer of crane forces to the frame is not accounted for.

The wind shear for the (enclosed) building, cummulated from top down, was evaluated using the base code wind speed and ASCE 7 provisions. The evaluation used architectural renderings of the envelope of each building. The cumulative wind shear was calculated both along and across the building. The tabulated value is the lower of the two. In short, the loads that presumably created the weaker building lateral system were compared to the loads on the collar. Obviously, when the two sets of loads are comparable in intensity, detailed evaluations should follow.

It is evident that the difference is smallest at the top-most collar, although the load at this top collar is not always the smallest. The weakness at this level is due to the fact that the top-most floors are designed for compounded shear values smaller than the lower floor. Even in the few examples shown in Table 2 one can observe the some problems. For building (1), the load at the top collar is higher than the cumulative wind shear. This is due to the fact that the building had a penthouse tower with a smaller footprint. Building (3) is served by two cranes and their added out of service load of 214 kips is within 5% of the wind shear. In fact, the wind affects both the crane and building frame, so one would need to add to the crane loads, the wind effect on the unenclosed building (cummulated from top to that level). This can reach about 20-30% of the enclosed building load. Such addition would make building (5) suspect also.

This simple verification confirms that buildings need an attentive evaluation for horizontal crane loads. The lateral force support systems at the top of buildings are more sensitive and in some cases detailed structural calculations are required as load comparisons cannot suffice. Such calculations are most effective when performed by (B)EORs as they possess complete information on the design capacity.

Other Observations.

Clarification of the responsibility of various engineers needs to reflect the method and stages of erection and field inspection. There are differences between the erection of cast in place concrete and some steel structures where the lateral force resisting system might not always need keep pace with the floor installation. The situation is even more critical for steel buildings with concrete shear walls as the walls are always poured at later stages.

We could not identify tunnel laboratories that have performed tunnel wind tests on cranes. It is not evident that results of such tests will lead to reductions in loads at collars. Similarly, in our discussion with major laboratories, we could not find any example of wind tunnel tests on buildings under construction (unenclosed). Research in this area is necessary.

When loads are provided by manufacturers, they should state explicitly what what terrain condition was considered and if they include the case when the one before last tie is removed.

Experts preparing design standards should examine and specify the load combinations to be used with in service and out of service crane loads. It seems that

there is a high probability that the in service loads are reached during the life of every crane installation.

Conclusions.

Engineering evaluation of capacity of the building to carry crane loads is absolutely necessary. While evaluation of local effects by (C)EORs seems to be standard procedure, evaluation of the lateral structural system seems to use approximations that might not be sufficiently reliable, especially for the levels close to the top of the building. Crane and building engineers need to collaborate in this system evaluation, with (B)EOR taking the lead.

The author thanks David Adler for his contribution in collecting and preparing the data.

Collapse of the I-280 Maumee River Bridge Launching Gantry in Toledo Ohio

Paul E. Kassabian, P.E., M.ASCE[1], Michael McCall, P.E., M.ASCE[2],
Donald O. Dusenberry, P.E., F.ASCE[3], William P. Konicki, P.E., M.ASCE[4]

On 16 February 2004, one of two identical launching gantries used for the parallel construction of the approach viaducts for the I-280 Maumee River Bridge crossing collapsed. The collapse killed four workers and injured four others.

Each launching gantry consisted of two overhead steel trusses and a central lower steel-box-girder underbridge. The trusses spanned between adjacent piers and supported precast concrete segments for post-tensioning. Once a concrete span was post-tensioned, the trusses were moved forward across the newly completed span and the underbridge, which was advanced before the subsequent span. The process was then repeated.

Simpson Gumpertz & Heger Inc. (SGH) was on site after the collapse to observe and record the debris in place and as it was removed. SGH also had access to the second, essentially identical, launching gantry in its position on the approach viaduct.

From review of the two launching gantries and construction records, it was clear that modifications were made to the method and extent of anchoring the gantries to the new bridge.

The results of our analysis indicated that the failure to install prestressed rods at the stools supporting the rear legs of the gantry trusses meant there was insufficient resistance to movement when the underbridge was reversed backwards into a pier.

This paper presents our investigation of possible failure sequences and their correlation to the facts observed on site.

1. INTRODUCTION

On 16 February 2004 at 2:22 p.m., one of two self-launching gantries used to construct the approach viaducts of the I-280 Maumee River Bridge collapsed. The collapse occurred on the south side of the Maumee River during parallel construction

of both the northbound and southbound approach viaducts. The collapsed launching gantry was on the northbound approach viaduct and was referred to as "LG2" for Launching Gantry No. 2. The adjacent launching gantry on the southbound approach was LG1. See Photo 1. The collapse of LG2 killed four construction workers and injured four others.

2. THE PROJECT

2.1 The Bridge and Parties Involved

The I-280 Maumee River Bridge in Toledo, Ohio, is a cable-stayed bridge with two 612.5 ft spans either side of a single concrete pylon located in the middle of the Maumee River. Carrying three lanes of traffic in each direction, the bridge is a fixed high-level continuous passage for Route I-280 that was previously routed across the Craig Memorial Bridge, a bascule bridge that frequently caused traffic delays from regular opening for ship passage (Bonzon, 2008). The bridge was named the "Veterans' Glass City Skyway" to honor military veterans and the region's glass-manufacturing heritage.

The approach viaducts consist of precast post-tensioned concrete segmental box-girder spans initially set into place by the launching gantries using the span-by-span method.

The bridge design was by FIGG of Denver, Colorado. The General Contractor was Fru-Con (the contractor) of Saint Louis, Missouri. The designer and supplier of the launching gantries was Paolo de Nicola (the manufacturer) of Padova, Italy.

2.2 Launching Gantry Layout and Operating Procedure

The manufacturer custom-designed and built the two launching gantries for this project based on designs and sequencing used on other completed bridge projects. Each launching gantry consisted of two overhead steel trusses that supported the precast concrete segments from above. The trusses spanned between rear legs positioned at the end of the previously completed span and front legs that sat on the next pier (called the central pier herein). The rear legs rested on stools that had flat bases and spherical bearings at the top, to accommodate variations in level and beam-like rotations of the rear end of the trusses. The stools were to be anchored to the bridge with four post-tensioned (PT) rods each, to prevent movement. The front legs of the trusses were posts pinned at the top and bottom, thereby offering no resistance to longitudinal forces in the trusses.

A steel box-girder underbridge was positioned over the subsequent span and acted as a temporary bridge to allow the launching gantry to travel forward once post-tensioning of a span was complete. See Figure 1. It was advanced by mechanisms on the trusses that moved the underbridge forward while it was suspended from the cantilevering portion of the trusses. The rear legs of the underbridge rested on the central concrete pier, and were affixed to the forward top face of this pier with horizontal post-tensioned anchor rods that protrude forward. The manufacturer's Safe Operating Procedure stated that the underbridge must be reversed to bring the rear legs into contact with the forward face of the pier, and that the operator needed to move the underbridge slowly and follow signals. Subsequently, spacers were to be inserted between the pier and the underbridge rear bracket.

The forward legs of the underbridge were pinned at the top and bottom, thereby offering no resistance to longitudinal forces in the underbridge.

The seats for the legs of the trusses and the underbridge could be shimmed to achieve leveling of these components.

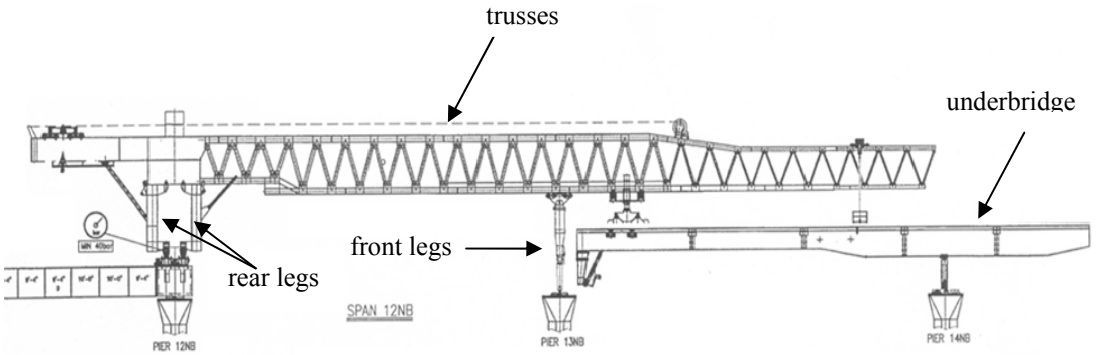

Figure 1. Layout of launching gantry and underbridge before collapse

2.3 Operating Stage at Collapse

By 16 February 2004, the contractor had completed eleven of the thirty spans of the approach viaduct on the south side of the river. Both launching gantries were positioned over the twelfth northbound and southbound spans, between Piers 12 and 13. The underbridge of LG1 was under the main trusses between Piers 12 and 13. The underbridge of LG2 was in the process of being launched to the subsequent span, between Piers 13 and 14.

At the time of collapse, the underbridge had been moved forward into the next span, but was being reversed toward the north side of Pier 13 for attachment to the forward face of that pier.

Photo 2 shows the north side of Pier 13 after the collapse. The horizontal anchor rods and the spacers were already in place. The operator of the underbridge at the time of the collapse stated in an interview that he tried to get the underbridge as tight as possible against the face of the pier to aid with subsequent stressing of the horizontal anchor bolts at the rear of the underbridge.

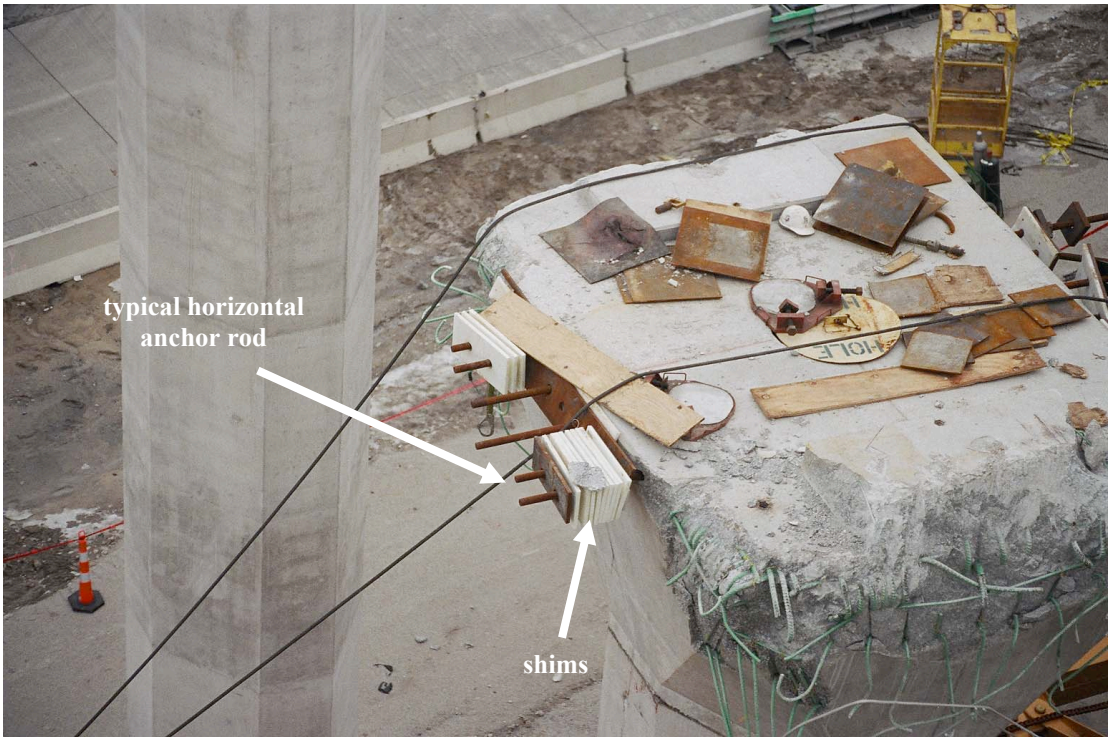

Photo 2. North side of Pier 13NB after the collapse. (North is to the left of the image.)

3. INVESTIGATION

The attorneys for the manufacturer retained SGH to investigate the failure. SGH was on site almost continuously from 23 February to 24 March 2004 while debris was removed. During this time, we monitored activities at the site and in the storage

areas. We observed, photographed, and measured debris in place and as it was removed. SGH was also on site during April and May 2004 for concrete core extractions from a pier and during the download of software and data from the Program Logic Controller (PLC), which was the device that controlled the mechanisms of the trusses and underbridge. SGH analyzed LG2 for its weight, strength, and stability using information based on the manufacturer's Safe Operating Procedure, facts from our site investigations, and operating procedures reportedly used at the time of the accident.

Some information that proved important in our review of failure scenarios is provided below.

3.1 Rear Legs

The manufacturer's Safe Operating Procedure stated the rear legs of each launching gantry must be prestressed to the bridge deck using the four PT rods before launching the underbridge.

From interview reports with the construction workers after the collapse, it seems that the PT rods were not installed before the movement sequence that was underway at the time of the collapse. During our investigation, we verified that the rods were not installed at the stools for the rear legs of LG2. This was based on both the existing condition of LG1, which did not have PT rods (Photo 3), and the rear-leg location for LG2 having (a) not enough holes in the deck to receive the rods and (b) no rods in the inserts and no damaged threads in the inserts (Photo 4).

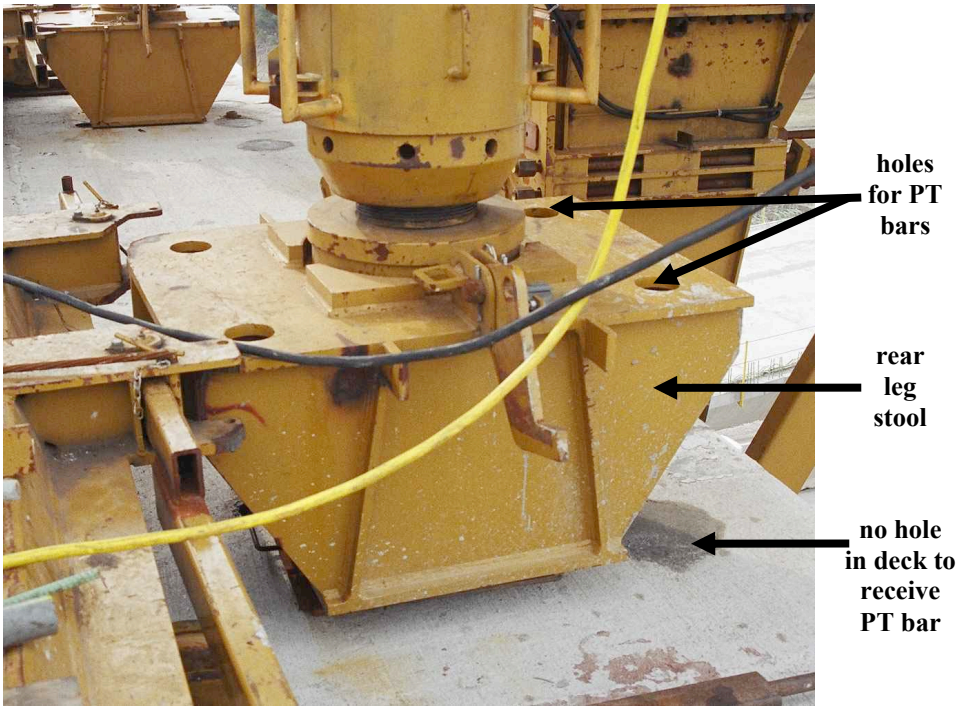

Photo 3. Rear leg supports for LG1.

Photo 4. Rear leg area for LG2. Deck inserts are adjacent to the square shims near the edge of the deck. (North is to the left of the image.)

3.2 Front Legs

The manufacturer's Safe Operating Procedure stated the front legs are to be plumb. We learned that the plumbness of the front legs was being determined primarily by workers using a 4 ft long carpenter's spirit level. From recorded interviews, the accuracy of this plumbness was variously quoted from 1/8 in 4 ft to 4°.

3.3 Plan Curve

To accommodate plan curvature of the bridge, the front legs of the gantry needed to be moved laterally ("sideshifted"). The Safe Operating Procedure stated that a stress-relieving sequence was required at the rear legs after this sideshifting, to relieve the induced horizontal forces at the rear legs of the trusses. The procedure involved the sequential raising and lowering of individual leg components of the four-legged rear-leg structural system. Testimony revealed that this stress-relief procedure did not take place.

3.4 Water in the Underbridge

There were reports that water could collect in the underbridges. We inspected the underbridge of LG1 and observed water trapped between the partial height transverse diaphragms. This water likely leaked in from coped areas in the top flange plate. The water caused staining of the interior plate.

We also noted similar staining from our inspection in the storage yard of the underbridge of the collapsed LG2. See Photo 5. Based on the staining, we believe that the additional weight of water to the underbridge was approximately 0.6% of the total underbridge weight.

Photo 5. Water in the underbridge and staining indicating typical water level.

4. FAILURE SCENARIOS

We reviewed a number of failure scenarios that we developed based on comments from those involved and on our site observations. We correlated our reviews and analyses of these scenarios with our site observations and measurements in developing our final opinions on the most probable cause of the collapse.

4.1 Improper Function of the Controller

Each launching gantry has a PLC that has software to connect the operator's controls to the mechanical system of the gantries. There were reports of programming problems or discrepancies between the PLCs of the two launching gantries. The PLC for LG2 was obtained and the downloaded software was made available for review. No significant difference in the software of the controllers was found.

4.2 Structural Failure

We created an analytical model of the launching gantry to determine forces at various stages of the operation. The analytical load cases for the launching gantry model included the following:

a) The sequence if the manufacturer's Safe Operating Procedure had been followed.

b) The sequence, as described above, that we believe was undertaken by the contractor.

c) The above sequence including the effect of the underbridge possibly positioned at full launch extension with water load.

Five key components of the steel structural system of LG2 were fractured after the collapse. We evaluated the adequacy of each of these under the demands resulting from the load cases listed above. A metallurgist expert also examined the fracture surfaces and found no anomalies that would indicate material weakness or metal fatigue.

In each case, we determined that the steel component should not have yielded or fractured under the operating loads. Further, all applied stresses that we calculated were well below the allowable stresses used in the design of the gantries. Hence, it did not appear that structural failure induced the collapse.

4.3 Overall Structural Instability

The moving components of the gantries – the trusses and the underbridge – were to be sequentially anchored to and released from the bridge structures. They were propelled forward by mechanisms that push or pull against the bridge. At the same time, they rested partially on legs that did not transmit longitudinal forces between the gantry structures and the bridge. Under these circumstances, there existed potential that positioning operations could induce instabilities in the gantry structures.

4.3.1 Underbridge Launch

A witness said he observed the underbridge moving north during the process of the collapse. Gouges, scrapes, and the final resting places of the trusses and the underbridge confirm that the entire gantry structure moved north during collapse.

One scenario we investigated to evaluate the reasons for this movement was the possibility that the underbridge, with added water, when moved to its full extent in the north direction on the cantilever of the trusses, caused overall instability of the structure by lifting the rear legs of the trusses. For this analysis, we reduced the beneficial weight of the gantry (the weight that causes an increased downward reaction at the rear legs) and increased the detrimental weight of the underbridge by 10% (far greater than the additional water weight listed above).

This analysis revealed that the underbridge, at its full extent in the north direction, would not cause uplift at the rear legs.

Marks on the underbridge soffit confirm that the underbridge was not positioned too far forward at the time of the collapse. Scrapes and gouges show that the initial impact location of the underbridge with the concrete pier corresponds to the position to which the underbridge would fall if the rear legs of the underbridge had been positioned at the face of the central pier and both the trusses and the underbridge moved forward together from their pre-collapse location. See Photo 6.

Photo 6. Underbridge soffit with initial impact location visible to the north of the bolted splice with scraping from subsequent sliding down damaged edge of concrete pier. (North is to the left of the image.)

4.4 Horizontal Anchor Rods not Damaged

As seen in Photo 2 above, the horizontal anchor rods on the north side of Pier 13 were not damaged even though reports indicated that the rear legs of the underbridge had been moved rearward over the anchor rods at the start of collapse. We needed to understand how the underbridge could fall away from these anchor rods without damaging them if, indeed, the rear legs of the underbridge were against the spacers at the face of the pier.

During our site visits to the storage yard, we observed that the underbridge rear-leg holes that received the anchor rods had been enlarged by burning away portions of steel plates, apparently to make positioning the underbridge easier. From our site measurements and geometric analysis, we determined that the anchor rods were likely positioned near the center of the opening (shown as a white circle for scale in Photo 7 below). In this position, the rear legs of the underbridge would not have contacted the anchor rods during the collapse if the movement of the underbridge followed that of the trusses from which it was suspended, assuming the trusses first moved principally forward (moving the underbridge off the anchor bolts) and then downward as controlled by the northward tilting of the two-pinned front legs of the trusses.

Photo 7. The rear legs of LG2 underbridge on their side with a close-up showing burnt-out divider plate and a white circle representing the scale of an anchor rod.

4.5 Movement of Rear Legs of Trusses

If the rear-leg assembly of the trusses was not prestressed to the concrete deck in accordance with the manufacturer's Safe Operating Procedure, then there were several sliding and tipping interfaces at which movement could start. In addition, the actual loads on the rear legs were dependent on the following:

1) The existing slope of the deck. This provided lateral force in the south direction at the rear legs.

2) The incline of the front legs. This is unknown but likely was no further than 4° to the vertical based on worker interviews. Northward tilt would provide northerly-acting force on the rear legs.

3) The extent of transverse motion at the front legs. There was some transverse motion induced at the front legs to allow for the plan curvature of the bridge. We calculated the expected amount based on the road geometry and we correlated this estimate with observations of the positioning of the sideshifting mechanism of LG2 after the collapse. Because there was no stress relief at the rear legs (this process requires prestressing of the PT anchor bars), the transverse motion likely imposed longitudinal forces on the rear legs, in the northerly direction on one leg/stool and in the southerly direction on the other.

4) The coefficient of friction between possible slip surfaces. We used a lower, middle, and upper-bound range based on a literature review and correlated these values with site tests of the actual slip surfaces (to account for site grease and dirt, etc.).

5) Location of shims under the legs. It is possible that shims placed eccentrically under the rear legs of the trusses could contribute to tipping or

sliding. Since the actual position of shims could not be determined after the collapse, we reviewed both an offset and a centered position for the shims.

We studied the sensitivity of the stability response to the variables listed above, and found that the incline of the front legs and transverse motion of trusses with respect to the front legs had the greatest effect. We used these variables as the axes of stability charts, and plotted the influence of the other factors. We analyzed the results for tipping and slipping of the various rear-leg-stool interfaces and plotted these as bounding regions.

We determined that with the PT rods for the rear legs missing, the launching gantry could still have been unstable even if normal procedures were followed. However, we also determined that overall instability of unanchored rear-leg stools was effectively ensured if the front legs were out of plumb by 4° or if the underbridge was reversed into the pier with substantial force, thereby inducing a reactive forward force to the rear-leg stools. A sample plot for this latter scenario is provided below.

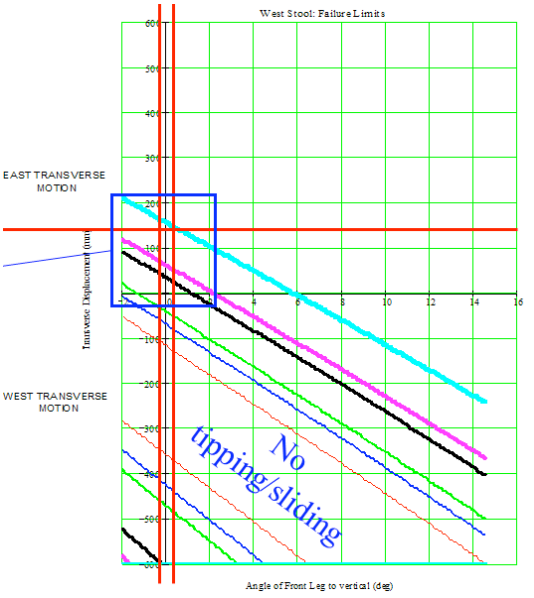

Image 3. Sample plot of bounding zones for west rear leg without prestress and force from reversing underbridge.

In addition, our calculations showed that if the manufacturer's Safe Operating Procedure had been followed completely (i.e., PT bars installed at rear-leg stools, front legs within vertical tolerance, etc.), then the overall gantry would have been stable.

5. CONCLUSION AND DISCUSSION OF LESSONS LEARNED

Most collapse investigations must address potentially-contributing conditions that cannot be determined exactly after the accident. In this case, certain facts were clear from our site observations and others were less certain. However, by bounding the unknown variables, we showed that this collapse occurred principally because the

movement of the underbridge was reversed into the forward face of the central pier while the required anchors for the rear legs of the trusses were missing.

From a construction-safety perspective, probably the most important lesson to be learned from this disaster is that well-developed construction procedures, based on rigorous considerations of structural stability and performance of complex equipment such as large cranes and gantries, should not be violated without careful consideration of the consequences. In this case, it seems that the contractor misunderstood that the PT bars stabilized the entire gantry against unrestrained longitudinal movement, rather than functioning simply as "hold-down" devices. In fact, the PT bars were part of an interrelated, multi-component structural system for operating the gantries in a way required to build a new bridge that had significant horizontal curvature. The sideshifting of the trusses to accommodate this curvature resulted in changes to vertical and horizontal forces in the individual rear legs and stools, and the bridge slope potentially caused longitudinal forces, as did moving and seating the underbridge. These behaviors might not be intuitively apparent without in-depth evaluations. The elimination of these anchors, which were critical to the resistance of longitudinal forces, and the failure to relieve locked-in horizontal forces after sideshifting caused instability due to sliding and overturning of the rear-leg stools when the underbridge was reversed back into the central pier. The movement of the stools inevitably resulted in the global instability and collapse of the entire gantry system, as the two-pinned front legs of the trusses tilted forward.

6. AFTERWORD

Following its investigation, the federal Occupational Safety and Health Administration (OSHA) initially cited the contractor, resulting in a fine of $280,000 (i.e., the maximum fine of $70,000 for each of four cited safety violations related to the failure to anchor the rear-leg stools) (OSHA, 2005). OSHA subsequently reached a settlement with the contractor and released a Safety and Health Information Bulletin highlighting "the hazards associated with deviating from the manufacturers [*sic*] guidelines on the use of overhead launching gantry cranes" (OSHA, 2006).

Following additional operational problems with a modified version of LG1, and at the insistence of the Ohio Department of Transportation, the contractor abandoned the self-launching gantry system and completed the construction of the approach spans using alternate methods. The I-280 Veterans' Glass City Skyway bridge opened to traffic on 24 June 2007, approximately twenty-two months after the original accelerated-construction-completion date.

Vulnerability Assessments of Structural Frames for Critical Facilities

William L. Coulbourne, P.E. M.ASCE

Director, Wind and Flood Hazard Mitigation, Applied Technology Council, 19266 Coastal Highway, Unit 4, #19, Rehoboth Beach, DE 19971, (703) 850-2891, FAX (302) 227-7652, email: bcoulbourne@atcouncil.org

ABSTRACT

There currently is no peer reviewed or broadly accepted protocols for conducting vulnerability assessments on the structural frame of buildings. This lack of protocols and lack of uniformity in vulnerability assessments is particularly important when the building is located in an area that might be subject to a natural hazard event such as a hurricane, a tornado, an earthquake or a flood. The design firm conducting the assessment is required to determine what might constitute a vulnerability based on their knowledge of the building, the hazard, or the owner's stated operational intent during or after any or all of these potential hazards.

The vulnerability of the structural frame of a critical facility (or any other building) depends on:

- Age (which influences the codes and standards that were available at the time of design)
- Quality of design and construction
- Type of construction (wood, concrete, steel, masonry or combinations of these and other materials)
- Risk to the structural frame from events such as an earthquake, a hurricane or a tornado, or from a man-made hazard such as a bomb blast
- Number and extent of past modifications to the building
- Deterioration (corrosion decay, termite damage)

These issues are crucial in understanding how vulnerable any particular building is to an unexpected load (i.e. hurricane or bomb) or to an expected load but one that has not ever occurred or not occurred recently. These issues are very important for the vulnerability assessment team to understand before they can state with some confidence that the building that is being assessed can be expected to perform in some stated manner when future catastrophic events might occur.

This paper will explore what a vulnerability assessment protocol for the structural frame should include, how a standardized protocol would be helpful to both the engineering profession and the building owners, and how such a protocol might reduce potential liability and misunderstandings with owners or future building buyers if a "standardized gage" could be developed that would give an owner a comparative basis for understanding the condition of the subject building vs. the condition of others within the use type (critical facilities) or construction type (wood, concrete, steel, etc.).

THE NEED FOR A STANDARDIZED PROTOCOL

There is currently no standardized method for evaluating existing buildings that are subject to high winds. This lack of a standardized evaluation method requires engineering professionals to create a method for evaluating an existing building each time a building evaluation is needed. When this is done on a project-by-project basis, there is no assurance that the evaluation method will adequately communicate how the building will perform during a high wind event, and there is no consistency between evaluations and approaches.

Most buildings that might be evaluated for performance during a high wind event are likely to be used for health care (such as nursing homes, hospitals, assisted living centers), shelters (for hurricane or tornado evacuations), government (including emergency operations centers, police and fire stations), or large or tall buildings used for hotels or office occupancies that are being sold or converted to different uses. New buildings must be designed to current building codes which for the types of structures mentioned also include being designed for wind loads in accordance with ASCE 7 (with some of these buildings being modeled and tested in a wind tunnel). Existing buildings can be modeled and pressures determined by wind tunnel testing, but in order to determine a building response to the wind, some method of analysis of the existing structure and building envelope still is necessary.

A protocol does exist for conducting evaluations of buildings for seismic hazards (ATC 14, FEMA 310) and this protocol provides the user with a "script" to follow for conducting an evaluation and the owner can be assured that the methodology used for the evaluation has been peer reviewed and tested by experts in the engineering discipline most appropriate for the hazard. This same peer-reviewed methodology needs to be created for high winds.

In many cases, the expected performance of a building in a high wind event is determined by comparing the building construction to the requirements of the current building code. Given the building code defines a minimum set of criteria, this evaluation standard is frequently inadequate to determine more precisely the expected performance of any particular building. Some residential and commercial buildings built prescriptively in accordance with the code might perform closer to expected because there is often little extra load capacity in these types of buildings given their use and the prescriptive nature of the codes. For larger, more structurally robust buildings, the comparison of high wind pressures to the capacity of the building is not a sufficient measure of expected performance. The development of the wind design standard currently in use (ASCE 7 *Minimum Design Loads for buildings and Other Structures*) over the last 15-20 years has seen significant changes occur in the way we determine wind pressures on buildings. These changes have modified our wind design practice substantially and these changes should have improved the performance of our buildings as well.

WHAT SHOULD BE INCLUDED IN AN ASSESSMENT?

Owner Performance Requirements

The starting point for a vulnerability analysis of the structural frame should be the owner's performance expectations. These expectations will vary with defined building use and importance to the community for service during a high wind event. The International Code Council (ICC) has a 2009 Performance Code for Buildings and Facilities with a suggested matrix of damage levels for various performance groups and for a series of event magnitudes (re-created from the 2009 ICC Performance Code as Table 1). The damage levels are defined as mild, moderate, high, and severe and each of these levels is defined in the code. The performance groups are the same as the occupancy groups in ASCE 7 (now called risk groups). The magnitude of the event is defined as small, medium, large and very large and the Mean Recurrence Intervals (MRI) for these various levels for various loads (both ordinary loads such as live and dead loads and extraordinary loads such as explosions or natural hazard loads) is presented in Chapter 5 of the code titled Stability and shown below as Table 2.

Table 1. Expected Performance Levels (per 2009 ICC Performance Code)

		Increasing Level of Performance → Performance Groups			
↓	Event Magnitude	Performance Group I	Performance Group II	Performance Group III	Performance Group IV
	Small	Moderate	Mild	Mild	Mild
	Medium	High	Moderate	Mild	Mild
	Large	Severe	High	Moderate	Mild
	Very Large	Severe	Severe	High	Moderate

Table 2. MRI for Various Event Magnitudes

Event Magnitude	MRI (yrs.) for Environmental Loads of Various Event Magnitudes					
	Flood	Wind	Snow	Earthquake	Ice	Rain
Small	100	50	25	25	25	25
Medium	500	75	30	72	50	50
Large	As determined	100	50	475	100	100
Very large	As determined	125	100	2475	200	100

The robustness of the building design will be largely governed by the types of events that are expected and by the magnitude of the event determined from the MRI. The wind event magnitudes used in the ICC Performance Code are highlighted in Table 2. It should be noted that the very large event of 125 years MRI does not approximate the ultimate wind speeds in ASCE 7-10. The ultimate wind speeds in ASCE 7-10

represent 1700 year MRI for critical facilities and depending on building locations, have a range of speeds from 120 mph to 200 mph. The discrepancy between these event magnitudes must be discussed by the owner and the design team.

Building Performance Expectation

The predicted building performance during a high wind event is a function of:

- Age
- Quality/robustness of design
- Quality of construction
- Building materials
- Building code used for construction
- MRI used for design
- Condition
- Types and/or number of changes to the building over the building life

The expectation of performance for these attributes could be assumed to follow linearly from assumed damage if built today under the current IBC. For any attribute likely to increase performance, an addition would be added to a base score, for any attribute likely to decrease the performance a subtraction would be taken from a base score.

The building age and code used for construction can sometimes be used interchangeably except when no building code has been enforced. Significant building code changes related to wind design occurred approximately in 1960, 1978, 1987, 1995, and 2000 with the initial publication of the International Building Code (IBC). Prior to the 1980s, the model codes used the same uplift pressure throughout the roof area with no uplift pressure increase for perimeters and corners. Uplift pressures on overhangs were not considered by model codes until the 1990s. Building age could be assumed to affect performance approximately the same the building code changes would affect performance. The base building age and building code reference could be taken as the year 2000.

Building materials can be used as a proxy for performance if sufficient detail is included about the many ways various materials perform in high wind events. The materials used in the structural frame listed below are in increasing order of likely damage from a high wind event:

1. reinforced concrete
2. reinforced masonry
3. prestressed or post-tensioned concrete (if tendons fully grouted or attached)
4. precast concrete (if connections to other load path elements are strong)
5. steel moment or braced frame
6. light gage metal frame
7. wood
8. unreinforced masonry

In addition to the primary frame, an important component for wind design is the lateral bracing system and the bracing systems below are in approximate order of increasingly likely damage to the bracing:

1. concrete moment frame
2. steel moment frame
3. reinforced concrete shear walls
4. steel bracing (cross-bracing)
5. wood shear walls
6. unreinforced masonry shear walls (infill walls)

The MRI used in the design is another way to determine robustness. The longer the return period used in design, the better the building is expected to perform under small magnitude, frequent events, and the greater damage is expected from the larger, less frequent event. The difficulty is determining what the design MRI actually is. If new wind speed maps from ASCE 7-10 are used, the MRI will be clear since these maps are based on ultimate speeds and the MRI is noted on the map appropriate to the risk category of the building. For buildings built to other versions of ASCE 7, it is possible to assume an MRI based on the wind speed used and the building type. For buildings designed using building codes prior to the use of the ASCE 7 wind load standard, the conservative approach is to assume a design MRI of 50 years.

The actual condition of the building will have a significant affect on how the building performs in a high wind event. Old, but well maintained buildings with little evidence of material deterioration or corrosion in connections will perform better than a newer building with substantial amounts of deterioration or corrosion in important elements of the building. Condition could be rated on a continuum from poor to excellent as long as descriptions along the continuum were defined. These definitions are shown in Table 3 and might be:

Table 3. Definition of Building Conditions

Building Condition	Definition
Poor	Significant deterioration in materials and/or connections. Stress cracks might be evident in materials.
Fair	Deterioration evident in either materials or connections such that strength is affected. Condition of the building is such that retrofitting is required to recover strength.
Average	Condition represents normal wear and tear on the building materials and connections. Some deterioration and/or corrosion are evident in the structural elements.
Excellent	Materials are practically new in condition with no evidence of deterioration, corrosion, loss of strength or gaps in either the vertical or horizontal load paths.

The type and number of additions or changes that have been made to the building is an indicator of possible discontinuities between structural frames and buildings built to different standards over the years. Although a thorough analysis must be made of the effect of the additions to the overall performance, some aspects of newer additions can be beneficial to performance. For instance, a critical part of an operation may now occupy the addition, so expected performance for that operation is not improved with the addition. The older part of the building now may be considered sacrificial, and while this could affect insurance losses for a building, it might very well improve operational stability during and after a high wind event.

Another important affect on the building performance desired is the difference in building use now compared to the time of original construction. A building built originally for a critical function will more likely have a structural frame designed for more severe loading, especially if built within the last 15-20 years. A building built for a commercial use will not be as likely to be robust enough to resist the higher expected loads for a critical facility and will be more likely to require some level of retrofitting in order to resist the expected loads and meet the expected performance.

The Gap Analysis

A gap analysis must be completed that looks at the differences between the owner's expectations and the expected performance of the building during the wind events defined. Only after this analysis can we make reasonable assumptions about the impact to the owner from the design event. This analysis also may provide the owner with important information about the reality of his expectations if the gaps between required and expected performance is very large and costly to mitigate. This analysis might very well help discover alternatives to mitigation that would positively improve the performance while not completely eliminating damage.

DEVELOPING A COMPARATIVE BASIS

The greatest advantage of having a methodology for evaluating existing buildings for a high wind event is that when all buildings in a portfolio are subjected to the same methodology, the owner will be able to easily determine the relative condition and expected performance of each building compared to the other buildings. This comparative analysis will make it easier to determine which building assets need the most capital improvement funds, which services might need to be relocated to other, better performing buildings, or which services need to either be moved to another site or discontinued as is, since the required performance for that building and those services can not economically be achieved within the configuration of space in the owner's portfolio.

Even with a methodology in place, there must be a way developed to be able to compare properties. For each building, the expected damage level before mitigation would have to be determined. Those damage states would be mild, moderate, high and severe. In order to achieve the required performance level, the extent of building refurbishment must be determined and thus the cost for bringing the building into the

expected range of damage such that the performance level can be achieved. The comparison could thus be developed looking at expected performance, expected damage without mitigation, and the cost to repair to reduce the damage to the level considered acceptable to meet the required performance.

Example

A building built in 1988 is located in Charleston, SC and is to be purchased by the local government as a judicial center. The building is four stories tall, is located in an Exposure B wind environment, the structural frame is steel with an exterior of concrete panels. The roof is flat with a roof deck of reinforced concrete on a metal deck. All windows are vulnerable to windborne debris. The building condition is considered good; there was some roof damage experienced during the 1989 Hurricane Hugo event. The design wind speed for Risk Category III buildings in ASCE 7-10 is 157 mph at a MRI of 1700 years or 114 mph at a MRI of 100 years. The building is shown as Figure 1.

Figure 1. Example Building in SC

The vulnerability assessment would provide a screening mechanism to determine how much further the analysis needed to go before a conclusion could be reached about the possible purchase of this building for its intended use as a judicial center. Each of the screening steps would be assessed against the "norm" where the 2000 IBC is used as the code standard and the construction from 2000 used as the building standard when the construction was specifically for a critical facility.

Table 4. Vulnerability Screening Matrix

Evaluation Metric	Comparison to norm									
1.Design MRI	25	50	75	100	125	500	700	1000	1700	2000
2.Age	1960		1978		1987		1995		2000	
3.Building materials	WD	URM	LGS	STL	PC-PTC		RM		RC	
4.Building code year	1960		1978		1987		1995		2000	
5.Condition	Poor		Fair			Average			Excellent	
6.Number of changes	Many		Some			Few			None	

Table 4 is a possible vulnerability screening matrix for the example building. The elements that apply to this example building are highlighted. The matrix for all six

metrics is in a continuum of "worst to best" along the rows. Since the design considered wind speeds for a 100-year MRI and the building age and building code used in design are more than a decade older than the assumed "norm" of the year 2000, this suggests a steel frame building possibly susceptible to some wind damage. Given the age, the steel frame type and the vulnerability of the building envelope to breakage from windborne debris, this suggests further analysis would be required to sort out the details of possible structural frame failure that could be caused by high winds. It is assumed in this existing building that most if not all of the structural frame is covered over with finish materials and is not accessible for inspection without some level of destructive testing.

There are many aspects to the detailed analysis and any vulnerability assessment protocol must provide some direction on what types of structural details to investigate and what the findings will suggest in terms of likely performance. Those structural details would include but not be limited to:

- roof-to-wall connection strength to determine uplift resistance
- roof deck and roof framing uplift resistance (see Smith 2011 paper on roof covering and assembly vulnerability assessment issues)
- window and door glazing resistance to windborne debris
- exterior wall resistance to both in-plane and out-of-plane bending from wind loads and to windborne debris
- structural frame resistance to lateral loads if exterior walls do not provide this resistance
- stiffness of roof and floor diaphragms

The Gap Analysis

After conducting a screening analysis for building vulnerability to high winds, the owner and the design team need to conduct a "gap analysis" of the desired performance and the likely performance based on the screening and decide the most appropriate next steps.

In the example above, if the performance group is Group III (a critical facility use) and the event magnitude is very large (greater than a 100-year MRI wind event), then the expected damage is **High.** The design team knows that the design event for this type of facility should be the ultimate wind event or the 1700-year MRI event. Given the actual design, the team must evaluate the differences in expected loads/pressures vs. the expected actual resistances in connections, stresses and windborne debris resistance. Using this gap information, the design team then must develop a set of retrofitting strategies that would reduce the vulnerability of the structural frame so that the expected performance level could be achieved when the design event occurred.

BENEFITS OF "STANDARDIZED" APPROACH

Make Building Comparisons Meaningful

A standard approach to the problem of conducting vulnerability assessments on critical facilities is that no matter where the facility is, no matter what the possible hazards are and no matter what the construction type or the condition of the building, design professionals, lenders, insurance agents, and owners would all be able to assess and compare one facility to another when those facilities had been evaluated using the same methodology. The terminology in the reports, the techniques used for assessment, the comparative results of required mitigation and the way the owners articulated performance criteria would all be substantially the same, aiding in a much clearer comparison of various facilities.

Reduce Liability

Using a peer-reviewed methodology for determining high wind vulnerability to critical facilities would potentially reduce the structural engineer's exposure and liability. When the professional uses a methodology they 'made up' based on sound technical information but which together constitutes a procedure that has not been industry tested, the potential liability increases because the procedure has been developed by the lone practitioner.

There is a building inspection methodology adopted by ASTM (ASTM E-2018-08) that provides a standardized basis for conducting building inspections. This ASTM standard does not go very far into how the inspection should be conducted. The stated use of the standard is to obtain a baseline Property Condition Assessment (PCA) using a walk-through survey and reporting on that baseline condition using a report developed by the consultant. A review of architectural or engineering drawings of a building is not a requirement for the consultant under this ASTM standard. The PCA is focused on observable deficiencies and the report is to focus on the deficiency and the recommended remedy. It is generally considered out of scope to prepare calculations to determine a systems adequacy with any specific design requirement.

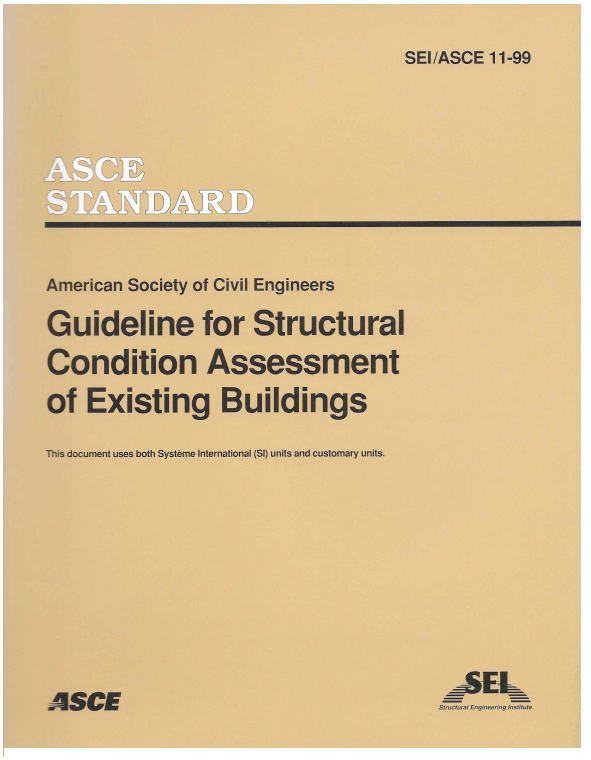

Figure 2. Cover of SEI/ASCE 11-99

SEI/ASCE 11-99 is a Structural Condition Assessment standard supported and published by the Structural

Engineering Institute of ASCE (cover shown as Figure 2). This standard focuses on the structural condition of the building and includes buildings constructed of concrete, steel, masonry and wood or a combination of these materials. The recommended assessment procedure includes a review of the available documentation on the building including drawings and specifications if available, conducting the site inspection, and performing an analysis of the structural elements of the building that compares the expected loads developed if the performance criteria are met with the expected resistance of the structural elements.

Included in the structural analysis is an investigation of the vertical and lateral load paths and the capacity of the elements of those paths to resist the loads expected when the performance level is met. There are preliminary and detailed assessment procedures included but both cover the review of documents, the inspection and the analysis of information – the only difference is in the level of detail required for each assessment step.

There is no specific requirement that the assessment process include the effects of high winds on the building. The procedure for the detailed assessment specifically discusses developing performance criteria that could include drift and deflection limitations which somewhat address issues caused by high winds. The balance of the standard deals with assessment techniques and issues relevant specifically to the various materials that are covered.

Conclusion - Develop an ASCE Standard

This author recommends that ASCE support the development of a standard for the evaluation of critical facilities subject to high winds. The development of such a standard would be viewed by the industry of building assessment professionals as one without bias. It would be a peer reviewed document from the nation's leading experts in various wind engineering issues and building design practices. It would have credibility with courts, insurance and real estate professionals and with the practice of structural engineering.

Wind Vulnerability Assessment of Roof Systems and Rooftop Equipment for Critical Facilities: A Preliminary Protocol for Design Professionals

Thomas L. Smith, AIA, RRC[1]

[1]TLSmith Consulting Inc., 16681 Boswell Road, Rockton, IL 61072; PH (815) 629-2455; email: tlsmith@hughes.net

ABSTRACT

This paper presents a preliminary protocol for assessing the wind vulnerability of roof systems and rooftop equipment on critical facilities. Such facilities include emergency operations centers, fire and police stations, hospitals, jails, nursing homes, power plants, schools, water supply and treatment plants, and other buildings that are essential for the delivery of vital services or protection of a community.

Roof systems and rooftop equipment are key building elements that are frequently damaged during high winds. Leakage from damaged roofs or rooftop equipment has interrupted numerous facility operations, and many critical facilities have been forced to evacuate due to roof leakage. By identifying wind vulnerabilities, mitigation efforts can be undertaken to avoid future damage and disruption of services. The preliminary protocol can be used by design professionals to systematically guide their assessment of these building elements.

INTRODUCTION

A design firm conducting a wind vulnerability assessment on a critical facility is tasked to determine what might constitute a vulnerability based on their knowledge of the building elements, the wind hazard, and the building owner's stated operational intent during and/or after a wind event. However, currently there is no comprehensive peer-reviewed or broadly accepted protocol for conducting such an assessment. Guidance provided by a quality vulnerability assessment protocol would assist design professionals with their assessment work and enhance their understanding of the expected wind and wind-driven rain resistance. Findings from vulnerability assessments can also be used by entities awarding grants for mitigating existing building deficiencies. By better understanding vulnerabilities, the effectiveness of funded mitigation measures can be improved.

If the assessment identifies deficiencies, they can be prioritized and scheduled for remediation. Mitigating deficiencies avoids costly wind damage and interruption of needed services provided by critical facilities. FEMA P-424, 543 and 577 recommend performing a vulnerability assessment on all critical facilities that are older than 5 years. If the facility is located in a hurricane-prone region (as defined in

ASCE 7), the assessment is recommended regardless of building age. These publications note that it is particularly important to perform assessments on facilities located in hurricane-prone and tornado-prone regions.

Mitigation efforts can be very ineffective if they do not address all items that are likely to fail. Therefore, to help ensure that all significant vulnerabilities with respect to wind, wind-borne debris (missiles) and wind-driven rain are identified, the assessment should include the structural system and the entire building envelope. For facilities located in hurricane-prone regions, ramifications of interruption of municipal utilities should also be evaluated. FEMA P-424, 543 and 577 provide a general checklist for performing assessments, and they provide examples of common vulnerabilities. Coulbourne (2011) and Beers (2011) provide further guidance on vulnerability assessments of structural and glazing systems. Development of additional guidance for assessing non-load-bearing walls and wall coverings is needed.

If a building owner has several facilities (such as a school district or large hospital complex), budget constraints may prohibit timely evaluation of all of the facilities. In this case, FEMA P-424 recommends prioritizing facility evaluation, based on the owner's needs and perceived vulnerabilities of the facilities.

Roof systems and rooftop equipment are key building elements that are frequently damaged during high winds (see Figure 1). The wind vulnerability of these elements depends on a variety of factors, including adequacy of their design and installation, and material degradation over time. The following is a preliminary protocol for conducting wind vulnerability assessments of roof systems and rooftop equipment.

Figure 1: The roof membrane on this new police station became detached shortly before the station was to be occupied. The station is located in the Midwest. It was damaged by winds that were well below the design wind speed. A vulnerability assessment has the potential to find problems so that they can be corrected before damage and interruption occurs.

GENERAL

Professional judgment: Accurately assessing the wind resistance of existing roof systems and rooftop equipment is very difficult (in part due to lack of a comprehensive protocol and a severe lack of field test methods). Accordingly, good professional judgment is vital for a quality assessment. The design professional(s) performing the assessment should be experienced with the type of roof system(s) on the building being evaluated.

Building owner's performance expectations: As a starting point for the assessment, a discussion should be held with the building owner to determine their expectations regarding desired building performance. See Coulbourne (2011) for further discussion. As part of the discussion with the owner, also discuss limitations of a vulnerability assessment (see DATA ANALYSIS AND REPORTING).

General guideline: ASCE 30 is a general guideline for assessing the condition of building envelopes. It includes information on professional service agreements, assessment procedures, evaluation of findings, and reporting. It is recommended that the design professional(s) performing the assessment be familiar with this guideline.

Level of assessment: This preliminary protocol identifies two levels of assessment. For some buildings, a Level 1 assessment will be sufficient. For other buildings, both a Level 1 and a Level 2 assessment should be performed. The elements of these two levels of investigation and the need for a Level 2 assessment are as follows:

- **Level 1:** This assessment consists of the following: 1) review of the historical file (i.e., as-built drawings and specifications, submittals, previous leakage and repair reports), 2) discussion with building owner personnel who are familiar with the roof to determine if it is leaking and to obtain historical information that is not in the file, 3) perform a field investigation and 4) provide a report. (Note: Normally a report is prepared prior to beginning a Level 2 assessment. However, an initial verbal report may be given on Level 1 findings. Written findings can subsequently be included in a final report that addresses both Level 1 and 2.

  This assessment should address the general condition of the roof and rooftop equipment (i.e., remaining service life). For guidance in making this assessment, see CIB/RILEM (2003) and Smith (2001). If the roof is leaking, refer to ASTM D 7053 for determining and evaluating the cause of the leakage. If the Level 1 assessment reveals that the roof is at or near the end of its useful service life, it should be scheduled for reroofing. See FEMA P-424, 543 and 577 for reroofing recommendations.

  The Level 1 assessment should also address wind resistance as discussed in the SPECIFIC RECOMMENDATIONS section below.

- **Level 2:** If the Level 1 assessment reveals that the roof has several more years of useful service life, then a Level 2 assessment is recommended for those buildings located where the basic wind speed is greater than 120 miles per hour (mph).[1] However, many of these building owners will be unable to afford a Level 2 assessment. Although all critical facilities are valuable assets, some are more critical than others. For example, a hospital is a more valuable asset than is a clinic. For the very important buildings, funding a Level 2 assessment is prudent because a Level 2 investigation will provide a more accurate vulnerability assessment.

  A Level 2 assessment consists of the following: 1) perform field uplift testing (for those systems where a test method exists), 2) perform destructive observations and 3) provide a report. For those systems that have insulation below the roof covering, a nondestructive evaluation (NDE) to check for moisture is also recommended. In some instances, it is prudent to perform the NDE as part of the Level 1 assessment. For further information about NDE, see Smith (2001). In addition to the techniques discussed in that publication, electronic vector mapping is also available.

  The purpose of the Level 2 assessment is to validate wind-resistance information provided by the as-built drawings and specifications and submittals, or to obtain wind-resistance information when documents are not available.

SPECIFIC RECOMMENDATIONS

The following items are recommended as part of the Level 1 assessment:

- Design uplift pressures: Determine what design uplift pressures the existing roof system was designed for. If this information is not identified on the drawings, specifications, or the submittals, check to see if a roof membrane manufacturer's warranty was issued. If so, check with the warrantor to see if they have this information. If not, find out what building code or standard would have likely been used to determine the original design uplift pressures and then calculate the field, perimeter and corner loads in accordance with that code or standard. Also calculate the design loads based on the current edition of ASCE 7 and compare the original design loads with current loads.[2] (Note: As part of the structural vulnerability assessment, the original and current design loads for the roof deck and deck support framing should also be determined.)

- Roof system uplift resistance: Check the drawings, specifications, submittals or warranty to determine if an uplift resistance rating was specified (e.g., FM 1-60).

[1] The 120-mph basic wind speed is based on ASCE 7-10, Risk Category III and IV buildings. If ASCE 7-05 or an earlier version is used, the equivalent wind speed trigger is 90 mph.
[2] If the building is in a hurricane-prone region, FEMA P424, 543 and 577 recommend using 1.0 for the directionality factor for the roof system.

If so, compare that rating with the rating that would be required based on current design loads. If the original rating is significantly less than what would be currently required, the existing system will need to be enhanced (if possible) or replaced, or the system will present a residual risk of failure. (Note: As part of the structural vulnerability assessment, the resistance of the roof deck and deck support framing should also be determined and compared with current criteria.) Also, if FM *Loss Prevention Data Sheet 1-29* was used to adjust fastener or adhesive ribbon spacings at corners and the perimeter, be aware that prior to the 2006 revision of 1-29, a safety factor of 1.5 was used. In 2006, the safety factor in the corners and perimeter was increased to 2 so that it would match the safety factor of 2 that had been used in the field of the roof.

If the drawings, specifications, or submittals reference a test method, check to see if there have been significant changes to the test method that would negatively affect the uplift test results. For example, if the existing roof system is a mechanically attached single-ply system that was installed around 1990, and the submittals indicate that it had an FM 1-60 rating, then the system was tested on a 5' x 9' apparatus. However in 1993, the test method was revised to require a 12' x 24' apparatus for most mechanically attached single-plies. The apparatus size was changed because it was determined that the smaller frame typically over-estimated the load capacity of the system.

Also check to see if the test method that was originally used is what is currently recommended. For example, metal roof systems can be tested in accordance with UL 580 or ASTM E 1592. ASTM E 1592 is generally recommended because it gives a better representation of the system's uplift resistance. Another example pertains to asphalt shingles, which can be tested in accordance with ASTM D 3161 or by a method referenced in ASTM D 7158. The method referenced in D 7158 is the current state of the practice, and is believed to provide a better representation of shingle wind resistance.

- Nailers and equipment curbs: Check the drawings and specifications to determine if attachment criteria were given for nailers that occur below edge flashings and copings, and for rooftop equipment curbs and stands. If so, determine if the specified attachment is sufficient to resist current uplift loads (and over-turning loads for curbs and stands), using a safety factor of three (as recommended in FEMA P4-24, 543 and 577).[3] (Field assessment of nailers, curbs and stands is addressed in the Level 2 recommendations below.)

- General field assessment: As part of the field investigation, visually observe the roof for signs of distress and detachment, such as tented fasteners and large blisters. Walk the entire perimeter of the roof (make two trips if the width of the perimeter zone exceeds 8'). Also walk the field of the roof at intervals not

[3] Although a safety factor of 2 is typically used for roof systems, a safety factor of 3 is recommended for edge flashings, copings, nailers and curbs because of wind loading uncertainties and the relative importance of these elements and consequences of their failure.

exceeding approximately 20'. With each "footfall," be sensitive to a change in softness of the substrate, which could indicate wet insulation or displaced materials. Also be sensitive to indications of lack of attachment of adhered roof membranes and insulation boards.

- Field assessment of mechanically attached single-ply membranes: Spot check fastener row spacing and spacing of fasteners along the rows. This can be accomplished in a number of ways: 1) by using a magnetic or electronic stud finder, 2) by looking for dust or debris at fastener plate depressions, 3) by feeling or lightly scrubbing the surface of the membrane over the fastener line. Spot checks should be made at each corner,[4] at the perimeter and in the field of the roof. Also spot check for fastener plate bending by feeling the membrane at plate locations. Normally it is sufficient to check plate bending at just the corner areas. Where plate bending checks are made, also carefully observed the membrane in the vicinity of the plate and the nearby seam. Look for fatigue-induced holes, cracks or tears.

  If the deck is steel, check to see if the fastener rows are perpendicular to the deck ribs. If the rows are parallel to the ribs, the decking may be susceptible to blow-off (see FEMA P-424, 543 and 577 for discussion).

- Field assessment of edge flashings and copings: For shop-fabricated units, check to see if the vertical flange is cleated. (For copings, check both vertical flanges.) If the vertical flange is face-fastened, check the fastener type and spacing. If the flange is not adequately face-fastened or if it is not cleated, the edge flashing or coping is quite susceptible to blow-off. Also, grab the bottom of the vertical flange with both hands and try to rotate the flange.[5] On copings, try to rotate both the inner and outer flanges. Perform this rotation test at each side of each corner,[6] and at a few locations along the perimeter. Weak edge flashings and copings will be easily detected by an experienced investigator. However, an edge flashing or coping may be very resistant to rotation and give the impression that it possess adequate wind resistance, when in fact it may not. A field test method (other than hand manipulation) to provide a more definitive evaluation of resistance does not currently exist.

  For pre-engineered edge flashings and copings, check to see if submittal data indicates wind resistance information. (Note: A safety factor of three is recommended for edge flashings and copings). To the extent possible, check to see if the units were installed in accordance with the submittal data. In addition, perform the above rotation tests.

---

[4] If the building has several roofs, it is usually not necessary to check all corners. Also, if the building is outside of hurricane-prone regions, usually it is sufficient to check the corner(s) that faces the prevailing wind direction.

[5] Appropriate safety precautions should be taken when performing rotation tests.

[6] See footnote 4.

For shop-fabricated and pre-engineered edge flashings, check to see if the horizontal flange was placed over the membrane and then stripped-in, rather than placed underneath the membrane. When the horizontal flange is underneath the membrane, it is unable to clamp the edge of the membrane, thereby making the membrane susceptible to lifting and peeling.

- Field assessment of gutters: Visually check the gutter to see if there is a mechanical connection or interlock between the gutter and gutter bracket. If the gutter is not connected or is inadequately connected to the brackets, the gutter is susceptible to blow-off. Also perform rotation tests as described above. For some tests, place a hand on either side of a bracket. For other tests, place both hands mid-way between two brackets. A field test method (other than hand manipulation) to provide a more definitive evaluation of resistance does not currently exist. Also evaluate gutter load path. The uplift and rotational wind load exerted on the gutter will be transferred to the wall, nailers or deck, depending upon the bracket design and attachment. A safety factor of three is recommended for gutters.

- Field assessment of parapet base flashings: For fully adhered base flashings, visually check for detachment. Also check for detachment by spot-slapping with the palm of the hand. For mechanically attached base flashings spot check fastener locations using one of the techniques described above for locating mechanically attached single-ply membrane fasteners. Also, if the base flashing is mechanically attached, but the membrane is fully adhered at the roof, ballooning of the base flashing has high potential to cause lifting and peeling of the roof membrane (as shown in Figure 1). Check to see if the base flashing is applied directly to brick. If so, the base flashing is likely inadequately attached due to the surface irregularity (i.e., lack of planar flatness) that is often associated with the roof-side of brick parapets). Regardless of base flashing type or attachment method, when performing checks, check each corner[7] area and check a few locations along the perimeter.

- Field assessment of ballasted single-plies: If the building is not in a hurricane-prone region and it has a single-ply membrane that is ballasted with aggregate, pavers or cementitious-coated insulation boards, check to see if the system (including parapet height) complies with ANSI/SPRI RP-4.

- Aggregate and lightweight paver surfacing in hurricane-prone regions: If the building has aggregate surfacing, lightweight pavers (i.e. those weighing less than 22 psf), or cementitious-coated insulation boards, FEMA P-424, 543 and 577 recommend replacing the roof system.

- Missile resistance: If the building is located in a hurricane-prone region, check to see if the roof system includes a secondary membrane that will avoid water

[7] ibid

leakage into the building in the event the roof membrane is punctured by missiles. If as-built drawings or submittals are not available, a test cut should be taken to determine roof system composition. Note: If the roof is sprayed polyurethane foam and of the thickness recommended in FEMA P-424, 543 and 577, or the roof is surfaced with concrete pavers weighing a minimum of 22 pounds per square foot (psf), then the foam itself or the pavers should provide adequate protection.

- Field assessment of drainage: If the building is located in a hurricane-prone region and the building has primary through-wall scuppers or roof drains, evaluate the potential for the scuppers or drains to become blocked by leaves, tree limbs and other wind-borne debris. See FEMA P-424 for guidance. Also refer to Sections 8.2 Roof Drainage and 8.3 Design Rain Loads in ASCE 7.

  Check to verify that secondary drainage is provided for all roof areas that have parapets or edge flashings on raised curbs.

- Field assessment of rooftop equipment:

  - Fans, HVAC units, relief air hoods and condensers: Check attachment of the equipment to the curb or stand. FEMA P-424, 543 and 577 provide attachment guidance. Note: Do not assume the dead load of the equipment is sufficient to resist the wind load. If wind resistance is only provided by the equipment dead load, perform wind uplift and over-turning load and resistance calculations to determine if the dead load is sufficient to resist the current wind load. As a qualitative evaluation, push and lift up on equipment. Equipment with weak or no attachment may be detected by an experienced investigator. However, equipment may be very resistant to movement and give the impression that it possess adequate wind resistance, when in fact it may not.

  - Fan cowlings: Where the basic wind speed is greater than 120 mph, check to see if the manufacturer specifically engineered the cowling attachment to resist the current design wind load, or check to see if the cowling has strap or cable tie-downs.

  - Exposed ductwork: Evaluate the wind resistance of the ducts and check to see if the ductwork is mechanically attached to supports that are anchored to the roof deck. Also, as a qualitative evaluation, push and lift up on the ductwork. Ductwork with weak or no attachment may be detected by an experienced investigator. However, ductwork equipment may be very resistant to movement and give the impression that it possess adequate wind resistance, when in fact it may not.

  - Flexible connectors between ducts and fans: Check the connectors for cracks or tears (which can allow water infiltration). If the building is located in a

hurricane-prone region, the flexible connectors may be susceptible to missile damage. See FEMA P-424 for guidance.

- Vibration isolators: If vibration isolators are used to support equipment, check to see if the isolators provide uplift resistance, or check to see if cables or straps are present to provide wind resistance.

- Boiler and exhaust stacks: Check adequacy and tautness of guy-wires. If guy-wires do not exist, check the stack's wind resistance.

- Equipment access panels and doors: Check adequacy of attachment. See FEMA P-424, 543 and 577 for guidance.

- Sheet metal hoods on HVAC units: Check adequacy of attachment. See FEMA P-424 for guidance.

- Natural gas and condensate drain lines: Where the basic wind speed is greater than 120 mph, check adequacy of attachment. See FEMA P-424 for guidance.

- Equipment screens: If screens occur around equipment, check adequacy of attachment.

- Antenna (communication mast): Check mast strength and adequacy of attachment. Also, if satellite dishes are mounted on the mast, try to determine if the mast was designed for the additional wind load that is transferred to the mast. See ANSI/TIA-222-G for guidance.

- Satellite dishes: Check adequacy of attachment. If wind resistance is provided by ballast (e.g., CMU or concrete pavers), perform calculations to verify the ballast is sufficient. In hurricane-prone regions, FEMA P-424, 543 and 577 recommend that dishes be mechanically anchored rather than ballasted.

- Lightning protection system (LPS): Spot check conductor connectors to verify that 1) the prongs engage the conductor, 2) the connectors are still anchored and 3) the connectors are approximately 3' on center. Also spot check the air terminals to verify that they are anchored. Where the roof is more that 100' above grade or if the building is in a hurricane-prone region where the basic wind speed is 135 mph[8] or greater, special attachment is recommended. See FEMA P-424, 543 and 577 for guidance.

The following items are recommended as part of the Level 2 assessment:

[8] The 135 mph basic wind speed is based on ASCE 7-10, Risk Category III and IV buildings. If ASCE 7-05 or an earlier version is used, the equivalent trigger is 100 mph.

- Uplift resistance testing: Field uplift testing in accordance with ASTM E 907 is recommended for built-up, modified bitumen[9] and fully adhered single-ply roof systems. It is recommended that a test be performed at each corner[10] area, at perimeter locations, and at least one test in the field of the roof. Note: This test method is not capable of evaluating the uplift resistance of the roof deck.

- Test cuts at leakage areas: If there has been a history of roof leakage, take 2' x 2' minimum test cuts down to the deck in the leakage area(s) to assess deck integrity. The number of cuts will depend upon several factors, including deck type, leakage history and extent of wet insulation. Where possible, the underside of the deck in the leakage area(s) should also be evaluated. Note: If the roof system is warranted, notify the warrantor before taking the cuts and have the repair performed by a roofing contractor authorized by the warrantor.

- Test cuts to evaluate deck attachment: Except for concrete decks, take 2' x 2' minimum test cuts down to the deck to check deck attachment. It is recommended that a cut be taken at each corner[11] area, at perimeter locations, and at least one cut in the field of the roof. See the note above regarding warrantor notification and repair.

- Destructive observations of nailers: To verify or determine the attachment of nailers that occur below edge flashings or copings, remove lengths of edge flashing or coping (which are typically 8' or 10' long) and membrane material so that the nailer fasteners can be observed. Remove at least two fasteners per length of edge flashing or coping to determine fastener type and length (embedment). It is recommended that one length of edge flashing or coping be removed at each corner[12] area, and at a few locations along the perimeter. See the note above regarding warrantor notification and repair.

- Destructive observation of equipment curbs and stands: To verify or determine the attachment of equipment curbs and stands, remove the base flashing / pitch pocket. See the note above regarding warrantor notification and repair. Note: Destructive observation of curbs or stands is relatively expensive. Considering that curb or stand failure is relatively rare,[13] this effort is typically reserved for those facilities that are particularly important and/or where the basic wind speed is very high.

DATA ANALYSIS AND REPORTING

[9] ASTM E 907 is not suitable for a modified bitumen system mechanically attached just at the seams.
[10] See footnote 4.
[11] Ibid.
[12] Ibid.
[13] Rare failure of curbs and stands may in part be due to weak connections between the equipment and the curb or stand. As more attention is given to attachment of the equipment, curb or stand failure may become more common, and hence suggest the importance of performing destructive observations to determine curb or stand resistance.

After completing a review of the historical file, performing calculations and the field investigation(s), the collected data need to be analyzed in the context of the building owner's expectation regarding desired building performance. Although unlikely, the analysis may reveal that no remedial work is required to meet the desired building performance. The analysis may reveal the need for relatively minor enhancements, or it may reveal the need to reroof. With all three scenarios, there may be acceptable residual risk that is deemed by the building owner to be too expensive to correct.

In reporting the Level 1 and 2 findings and analysis to the building owner, it is important to discuss limitations of the vulnerability assessment (see ASCE 30 for further discussion). As previously noted, a more accurate assessment will be provided by a Level 2 investigation. However, even with a comprehensive Level 2 investigation, the true vulnerability of the roof and rooftop equipment will not be known until actually tested by a real wind event. The assessment limitations are due in part to the severe lack of field test methods, and the fact that field testing and various field checks are performed at discrete locations. These tests and checks provide data on conditions and wind resistance at areas that were tested or checked. However, there is always the potential for an undetected anomaly that can lead to water infiltration. Accordingly, it is prudent for owners of critical facilities to have contingency plans in the event that leakage occurs. For example, if roof leakage begins to occur at a given location in a hospital, a pre-event plan should be available to the staff in that area that directs where their department should be relocated within the facility. A pre-event plan should also be available for evacuating the entire facility.

The report should recommend that the roof and rooftop equipment have a routine visual inspection at least once a year by persons knowledgeable of the type of roof system(s) on the building. FEMA P-424, 543 and 577 also recommend a special inspection following unusually high winds (such as a thunderstorm with wind speeds of 70 mph peak gust or greater).

If the vulnerability assessment reveals the need to reroof or strengthen attachment of rooftop equipment, see the guidance provided in FEMA P-424, 543 and 577 for guidance.

CONCLUSIONS

This paper presents a useful protocol for design professionals. It obviously needs to be expanded to address special considerations and guidance pertaining to a variety of systems, such as asphalt shingles, metal panels, slate, tile, vegetative roofs and photovoltaic panels. Additional specificity is also needed regarding the number of tests and field checks to be taken, and additional specificity is needed for various types of field checking.

There is need for a comprehensive protocol for the vulnerability assessment of the structural system, the entire building envelope and ramifications of interruptions of municipal utilities. This paper along with the papers by Coulbourne (2011) and Beers (2011) lay the foundation for the development of such a protocol.

ABSTRACT

One of the most vulnerable areas for critical facilities in severe windstorms is the exterior building envelope. Loss of roofing, cladding or glazing exposes building occupants to life safety risks and renders facilities inoperable at the time they are most needed. Engineers, Architects and Building Professionals are in need of guidelines for how to assess building envelopes to predict performance during severe windstorms and identify required upgrades.

This paper outlines the necessary steps for assessing severe windstorm threats to cladding and glazing on existing critical facilities. This outline includes developing appropriate design criteria for wind pressure, windborne debris and water infiltration, as the code mandated minimum may not be enough, depending upon the location and use of the facility. A staged analysis approach is presented to allow the user to determine the condition of existing cladding and glazing. An initial assessment would include a review of project documents and a visual survey. Higher level assessments include field testing and destructive analysis.

The included methodology for assessing and analyzing various cladding and glazing systems provides the reader with guidance for make a determination about the resistance of components and overall systems in severe windstorms. The assessment can then be used to identify needed upgrades and plan for safe operations during severe windstorms.

INTRODUCTION

There is a long history of documented failures of cladding and glazing during severe windstorms such as hurricanes and tornadoes. Following Hurricane Alicia in 1982, there was heavy damage to cladding and glazing in high rise buildings in downtown Houston, TX (ASCE 1985). Hurricane Andrew in South Florida in 1992 (ASCE 1993) damaged many exterior facades of commercial buildings, including hospitals and shelters. Tornadoes in Atlanta in 2000 (Dewan) caused glass breakage in high rise buildings downtown. There was extensive glass breakage in some commercial buildings in downtown areas of Miami and Fort Lauderdale following Hurricane Wilma in 2005 (Pasch). Houston had a repeat of glass breakage in downtown high rises during Hurricane Ike in 2006 (Vega), 34 years after the damage from Hurricane Alicia in 1982. Figures 1 and 2 show examples of the damage.

Figure 1. Hurricane Andrew Damage.

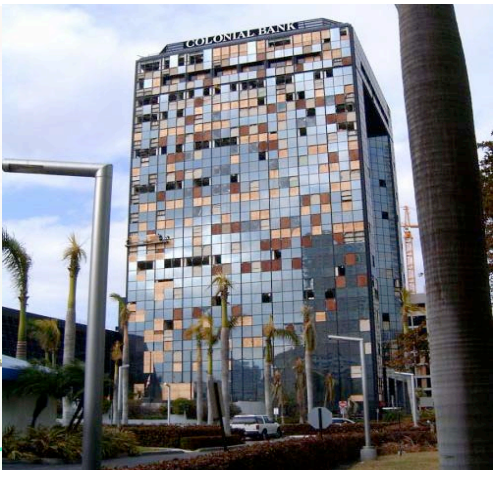

Figure 2. Hurricane Wilma Damage.

Much has been done to improve building façade performance during hurricanes and tornadoes since Hurricanes Alicia and Andrew. Building codes have been improved to design for higher wind loads and to account for windborne debris. In South Florida, buildings constructed after 1995 utilized improved code requirements and have demonstrated improved performance capabilities. Other hurricane prone areas in the United States also have adopted improved standards for wind loads and windborne debris resistance after they were included as part of the International Building Code in 2000.

Many existing critical facilities have upgraded their facades for improved performance in severe wind storms. Mitigation grant funding has provided for hurricane protection of facades at critical facilities including hospitals, shelters, schools, courthouses and public safety facilities. These upgrades typically included

the installation of code compliant storm shutters or replacement of glazing with missile impact resistant systems. Or, as was done at Miami Children's Hospital in 2004 (FEMA), an entire new façade was installed over the existing one.

While the technology exists to improve façade performance during severe windstorms, there is an information void when it comes to determining the ability of existing components to perform during these events. Facility owners need to be able to develop appropriate design criteria for the importance and use of the facility, assess existing facades, predict performance in future wind events, and be able to determine which systems and components need retrofit or replacement.

A staged approach can be used to assess windstorm threats to facades. This includes determining the original design criteria of existing systems, documenting their current condition and performance, and developing appropriate design criteria to utilize in making judgments about their windstorm resistance. After determining the appropriate design criteria, staged levels of assessment can be performed to determine construction types and field conditions, from which a judgment about performance in future windstorms can be developed.

DESIGN CRITERIA

Prior to an assessment, appropriate design criteria must be developed. Sometimes it is provided by the building owner, other times it must be developed by the designer or assessor. Design criteria for building façade assessment includes wind loads, windborne debris resistance and water leakage resistance.

For wind loads and debris resistance, requirements of the local building code in force at the time of the assessment can be used. However, it must be noted that building codes are minimum standards. The stated purpose of building codes "is to establish the minimum requirements to safeguard the public health, safety and general welfare" (Florida Building Code). More often than not, the common practice is to design to meet the code and no effort is made to exceed the code requirements. In addition, some building codes do not have criteria for water leakage resistance.

Critical facilities have uses that differ from structures in the typical building stock. They often need to remain fully functional throughout a severe windstorm event or be ready for use immediately after the storm passes. Some critical facilities, such as hospitals, house critically ill patients during storms. Others, such as shelters and emergency response facilities house people throughout a severe windstorm and must have functioning utilities and infrastructure (Vickery) (Lee) (Emanuel).

For critical facilities, it may be desirous to use design criteria that exceeds minimum building code standards (Beers). The following needs to be considered for enhanced design criteria:

Wind loads: Wind loads are usually developed by following the requirements of ASCE 7, which contains an enhancement factor for "important" facilities. Wind loads in ASCE are based upon wind speed maps and return periods defined as mean recurrence intervals (MRI). ASCE 7 uses a 100-year MRI as a baseline for important buildings, meaning the associated wind loads are based upon the probability of exceeding the wind speed during a 100-year period. Since some severe windstorms can exceed the 100-year MRI, the designer may elect to select a higher MRI, say 300 or 500 years, which would increase the wind loads for the building when using ASCE 7. Although ASCE 7 contains a procedure for determining design wind speeds at a given geographical location for MRI other than 100 years, this procedure does not include consideration of hurricane winds. In hurricane regions a computer modeling technique must be employed to determine wind speeds associated with a specific MRI at a given geographical location.

Another approach is to utilize site specific computer modeling and select a return period that is appropriate for the intended use of the facility (Minor).

Windborne debris design criteria typically uses code mandated missile impacts and cyclic pressure loading or ASTM requirements (ASTM E 1886 and ASTM E 1996). The ASTM standards also have enhanced requirements for important facilities. However, for some sites with a high potential for windborne debris or a use that requires a fail-safe design, higher levels of missile impacts may be appropriate.

For windborne debris, ASTM E1996 provides missile impact requirements for important facilities. However, it may be appropriate to exceed the recommended requirements. A recommendation for higher missile weights and speeds must be developed by the designer as part of the assessment process. The environment around the building must be reviewed to determine the potential for windborne debris in a severe windstorm. Potential debris can be generated from within the building and surrounding site itself, or from adjacent structures, landscaping and site conditions.

The age, condition and construction of adjacent structures must be assessed. If they were not built to newer building codes that include missile impact requirements, the potential for windborne debris is greater. If they contain known

elements of windborne debris, such as gravel or tile roofs, there is high potential for debris. Site conditions, such as vegetation, signage and temporary structures can also be potential debris generators.

It should also be noted that some buildings may be on sites with a low potential for debris, such as campuses of buildings built under recent code requirements, or a high rise structure with no other high rises around it. In those cases, the minimum requirements of the applicable building code may suffice.

Selection of appropriate windborne debris design criteria should be based upon guidance from codes and standards and by considering the site conditions. There often is precedence for what was done with other facilities and standards that can be referenced to determine the appropriate design missile. The pressure cycle portion of the design criteria is directly tied to wind load, so enhanced wind loads are factored in.

Industry standards are used for water leakage design criteria (AAMA/WDMA/CSA). Typically assemblies are tested at 15 to 20 percent of design load using ASTM E 331 for laboratory tests and ASTM E 1105 for field tests. Some projects specify higher loads.

ASSESSMENTS

To evaluate building façade and glazing components resistance to severe windstorms, the assessment team must possess several qualifications. The team must have extensive experience with the systems that are being analyzed including design and testing of such systems. A working knowledge of relevant codes and standards is also required. Assessment teams must also have experience evaluating windstorm damage. Because some parts of the analysis of existing building façade and glazing components will require professional judgment, experience and knowledge is critical for developing conclusions following the assessment.

This paper will present a three stage process for façade and glazing assessments. Level 1 assessment is a non-invasive analysis that includes gathering information about the original design and service history of the building along with a walk around inspection of façade and glazing components. Level 2 assessment builds upon the information developed during Level 1 and may include testing and destructive analysis. Level 3 assessment consists of theoretical calculations utilizing the information collected during earlier assessment stages.

Level 1: This assessment level includes: 1.) review of the original project documents including plans, specifications, shop drawings, calculations and submittals, if available; 2.) review of service and maintenance records; 3.) interviews with onsite building management and users to determine additional information about the service history; 3.) research of weather records to learn about any severe wind storms that the building has already experienced, and 4.) a visual inspection of façade and glazing components.

Level 2: This assessment level adds to the information collected during Level 1 and includes: 1.) selected disassembly of glazing systems; 2.) destructive analysis of cladding systems; 3.) field water infiltration tests, and 4.) analysis of anchors and fasteners.

Level 3: This assessment level takes the information from Levels 1 and 2 and adds theoretical calculations to determine the wind load resistance of glazing and component systems and anchors and compares them to the target design criteria.

Depending upon the building owner's needs and the assessment fee budget, the assessment can be finalized after any stage. If Level 1 is the only stage conducted, useful information will be developed and may be sufficient for an Owner/Operator decision about retrofit or replacement requirements. In addition, it may be appropriate to end the assessment after Level 1 if it is determined that certain materials are not windstorm resistant, rending further analysis useless. Level 2 can be used to develop additional information if Level 1 data does not provide enough information to make decisions. Level 3 takes the information from Levels 1 and 2 and further analyzes it to provide additional information about the existing systems.

LEVEL 1 ASSESSMENT REQUIRMENTS

Level 1 consists of information gathering about the project history and a non-invasive site inspection. The following needs to be considered:

- Review of plans and specifications: If the original plans, specifications and "as built" drawings still exist, valuable information about materials, manufacturers and construction details can be learned. These documents would also contain information about design criteria at the time of construction.
- Review of shop drawings and submittals: Additional information about construction details, materials, warranties and manufacturers can be discovered. Test reports and calculations may contain structural properties needed for a theoretical analysis.

- Review of service history: Seek out any documents that document storm damage, repairs and maintenance of the system.
- Interview building operators and users: Gain insight about problems such as prior storm damage, ongoing water leakage and air infiltration issues.
- Research weather records: Look for a history of the storms that may have affected the property over its service history
- Site inspection: Perform a walk around visual inspection of the exterior façade and glazing. If storm shutters are present they must be also be inspected. For multi-story buildings, it may be necessary to utilize a lift or swing stage to access upper floor areas. Inspect as much as possible, however, it is not necessary to inspect the entire exterior. All unique conditions should be inspected along with typical conditions on each building elevation.

LEVEL 2 ASSESSMENT REQUIREMENTS

Level 2 consists of additional information gathering to build on the data from Level 1. The following actions may be taken:

- Selected disassembly of glazing systems: This step would be required if shop drawings are not available to determine system design and details or to confirm if the field work was done in accordance with the drawings. Measurements can be taken to develop structural properties for theoretical calculations.
- Destructive analysis of cladding systems: If the materials and construction details cannot be determined during Level 1, destructive analysis may be required to determine needed information to make a judgment about the wind resistance of cladding systems.
- Documentation of storm shutters (if present): If there is no information to identify the storm shutter manufacturer, take measurements of sizes and material profiles. Document anchor materials, details and condition.
- Field water infiltration tests: Water leakage performance can be confirmed with the use of field water infiltration tests. Perform tests at areas that exhibit evidence of water damage using ASTM E 1105. The test simulates the conditions of a wind driven rain storm and can recreate leaks that occur during actual storms. Other tests using a water hose or high water pressure are not reliable and should not be used.
- Analysis of Anchors and Fasteners: Destructive analysis and partial disassembly of glazing systems will also allow for inspection of anchors. Determine the materials, details and condition of anchors. Also document the substrate (type and condition) that the anchors are set into.

LEVEL 3 ASSESSMENT REQUIREMENTS

Level 3 consists of a theoretical analysis of the ability of the cladding and glazing to meet the required loads using data developed during Levels 1 and 2. The following analysis is recommended:

- Develop design criteria: As discussed earlier in this paper, develop current design criteria based upon the building owner's requirements, use of the building, codes and standards requirements, anticipated future environmental conditions, and precedence at other similar projects.
- Document or develop structural properties of materials and components including glazing system framing, glass, cladding materials, cladding support systems and anchors. If the manufacturer can be determined, published data may be available. If not, measure and survey materials and develop structural properties as required.
- Calculate load resistance of existing systems: Perform theoretical calculations for cladding and glazing systems to compare their resistance to the desired design criteria.

DATA ANALYSIS

After the staged investigation is complete, the data must be analyzed and a judgment made about the resistance of existing cladding and glazing systems to severe wind storms. The purpose of the analysis is to determine if the existing cladding and glazing systems are resistant to design criteria developed for possible future storm events, including wind loads, windborne debris resistance and water leakage resistance. Development of needed repairs, retrofits and upgrades are beyond the scope of this paper.

The failure criteria for cladding and glazing systems must be developed by the owner and designer. It is not reasonable to expect there would be no damage during a severe windstorm. More reasonable failure criteria would be that the systems would continue to provide shelter from wind and water during and after a storm event, while protecting building occupants and contents. Damage to cladding and glazing systems is acceptable if they provide the needed protection and can be repaired or replaced on a reasonable schedule after the storm event, not under duress.

CLADDING SYSTEMS

Wind loads, windborne debris resistance and water leakage resistance are the factors that must be evaluated in making a judgment about the ability of cladding systems to perform satisfactorily in severe windstorms. The systems must resist wind loads without catastrophic failure. They must stay on the building and be able to survive impacts from windborne debris without failure. They must not allow water entry into the building

Determination of the wind load resistance of cladding systems can be determined from test reports, if they were submitted as part of the construction documents and are still available for review. Wind load resistance can also be determined by consulting with the original manufacturer if they can be identified or reviewing their published literature. Wind load resistance can also be calculated if no other information is available.

In addition to the cladding system, any support structure, such as metal studs must also be analyzed. Anchors, fasteners and anchor assemblies must be analyzed to assure the system will stay on the building in a severe windstorm.

Cladding materials must also be analyzed for their resistance to windborne debris. Resistance to windborne debris can be determined from test reports or manufacturers literature, if available for review. Theoretical calculations cannot be used to determine the resistance of a system or material to windborne debris. In the absence of test data or manufacturers literature, the assessor may be able to compare the materials and construction of cladding systems to similar tested systems and make a judgment about their windborne debris resistance.

Cladding must not allow water entry into the building during a severe windstorm. Site inspections and field water infiltration tests will provide information about the water resistance of cladding systems.

GLAZING SYSTEMS

Glazing systems must also demonstrate resistance to wind loads and windborne debris and water leakage using current design criteria. Evaluations should include the framing, glass and anchors.

Framing should be evaluated to confirm it will resist the specified wind loads. This can be accomplished by referencing the framing manufacturers test reports if they were part of the submittal package or if they are still available from the

manufacturer or evaluation authorities. It can also be accomplished through theoretical calculations.

Glass should be evaluated for wind loads using ASTM E1300. Glass should also be evaluated for resistance to windborne debris. Theoretical analysis cannot be used to evaluate glazing for compliance with ASTM E 1996. Laboratory testing is the only basis for evaluating for compliance

When attempting to predict performance of glass in existing building in severe windstorms, only laminated glass or glazing that meets the desired wind load requirements of the projects and is protected with compliant storm shutters compliant with ASTM E 1996 should be considered for judgment as being compliant. Ordinary window glass types including annealed, heat strengthened or tempered do not pass missile impact testing and can be deemed as not compliant.

Storm shutters complying with ASTM E 1996 used to protect glazing systems that are deemed to meet the desired wind load requirements for the building provide can be deemed to provide adequate protection. This can only be determined with laboratory testing of shutter systems or with test reports evidencing such testing.

CONCLUSION

Development of appropriate design criteria that meets the projected needs of a facility is based upon importance and use, and may exceed minimum building code requirements. Evaluation of existing systems can be a complex process requiring experience, knowledge and professional judgment by the assessor and design professional. While it may be possible to determine a building was constructed to recent hurricane resistant standards, most often that is not the case. Many buildings do not retain records from construction.

Older buildings that predate recent hurricane resistant codes and standards most likely will not be deemed to meet desired design criteria. Simply identifying the glass type in most instances will provide information indicating that the building will not comply. Additional more sophisticated analysis including invasive inspections and field water infiltration tests may identify further areas of concern.

Although it is beyond the scope of this paper, the information developed during an assessment can be used to design upgrades to existing systems for compliance with enhanced design criteria. The enhanced design criteria in

combination with information developed about the structure can also be used to design compliant replacement systems.

In addition to cladding and glazing, vulnerability assessments of critical facilities should include the structure and roof to encompass the structural frame and entire exterior building envelope. This paper in combination with papers by Colbourne (2011) and Smith (2011) can be used for that purpose.

ABSTRACT

This paper proposes an innovative fully probabilistic Performance-Based Hurricane Engineering (PBHE) approach for risk assessment and design of structural systems located in hurricane-prone regions. The methodology is based on the Total Probability Theorem and disaggregates the risk assessment analysis into independent elementary components, namely hazard analysis, structural characterization, interaction analysis, structural analysis, damage analysis, and loss analysis. The proposed PBHE methodology accounts for the multi-hazard nature of hurricane events by including the separate effects of, and the interaction among, hurricane wind, flood, windborne debris, and rainfall hazard. A review of existing models with the ability to describe the different sources of hazard is performed, and a consistent vector of intensity measures for hurricane hazard analysis is proposed. The PBHE approach illustrated in this paper represents a first step toward a rational methodology for risk assessment and design of structures subjected to multi-hazard scenarios.

INTRODUCTION

Performance-Based Engineering (PBE) is a general methodology that (1) defines the performance objectives for structural systems during their design life, (2) provides criteria and methods for verifying the achievement of these performance objectives, and (3) offers appropriate methodologies to improve the design of structural systems. In the last two decades, significant research efforts have been devoted to the development of PBE in earthquake engineering (Ellingwood 2001, Porter 2003), and have led, e.g., to the Pacific Earthquake Engineering Research center (PEER) Performance-Based Earthquake Engineering (PBEE) framework (Porter 2003). Several motivations have generated significant interest in the possible development and extension of PBE to other subfields of civil engineering (Augusti and Ciampoli 2008). In particular, Performance-Based Blast Engineering has received considerable attention in the US after the terrorist attacks of September 11, 2001 (Hamburger and Whittaker 2003). Other PBE

examples are Performance-Based Fire Engineering (Rini and Lamont 2008), Performance-Based Tsunami Engineering (Riggs et al. 2008), and Performance-Based Wind Engineering (PBWE) (Augusti and Ciampoli 2006, Petrini 2009, Ciampoli et al. 2009). PBE has been widely recognized as a rational methodology for assessing and mitigating the risk associated with engineering structures and infrastructures subject to natural and man-made hazard. In earthquake engineering, modern design codes are gradually substituting prescriptive approaches with PBEE procedures for the design of new facilities and the retrofit of existing ones (FEMA 1997, ATC 2005). PBEE has been shown to facilitate design and construction of structural systems based on a realistic and reliable assessment of the risk associated with seismic hazard, leading to a more efficient use of resources for construction, maintenance, and retrofit of structures.

The advantages demonstrated by a PBE approach to civil engineering provide a strong motivation to develop a PBE methodology for structures subjected to hurricanes. The need for assessing and improving the resilience of the built environment subjected to hurricane hazard is widely recognized (NSB 2007). Some initial interest in PBE has been expressed in hurricane engineering (Easley 2003), but a complete and rigorous framework is still needed. The development of a Performance-Based Hurricane Engineering (PBHE) methodology presents several additional challenges when compared to other existing PBE methodologies. In contrast with other natural hazard events, in which a single type of hazard is considered, the landfall of a hurricane involves different hazard sources that interact to generate the risk for a given structure. Therefore, hurricanes can be viewed, and must be analyzed, as "multi-hazard" scenarios.

In this paper, the formal extension of the PBE approach is proposed for a fully probabilistic PBHE methodology. A classification of the uncertainties involved in hurricane hazard analysis is proposed, and analytical models of the relevant environmental phenomena generated by hurricane events are briefly described. The paper concludes with suggestions for possible improvement of the hazard description and for further research regarding PBHE.

PBHE FRAMEWORK

In a probabilistic PBE approach, the structural risk is conventionally measured by the probability of exceeding a specified value of a decision variable (*DV*) corresponding to a target performance. Each *DV* is a measurable attribute of a specific structural performance and can be defined in terms of cost/benefit for the users and/or the society (e.g., loss of human lives, economic losses, exceedance of safety/serviceability limit states). A PBE assessment analysis provides a probabilistic description of an appropriate *DV* for different design choices in order to allow a rational decision among different design options.

In order to outline a procedure for PBE assessment analysis of structures subjected to hurricanes, the assessment analysis can be decomposed into the elementary phases which must be carried out in sequence. Perhaps the most

important expected feature of this procedure is the qualitative independence of each phase from the others (i.e., the choice of certain parameters in a given phase is independent from the parameters adopted in previous phases). A widely accepted approach based on this principle is the one proposed by PEER (Porter 2003) and based on the Total Probability Theorem (TPT).

The probabilistic PBHE framework presented in this paper is based on the TPT, similar to the PEER PBEE and the PBWE frameworks. The structural risk is defined in terms of *DV*s as follows

$$G(DV) = \int\int\int\int\int G(DV|DM)\cdot f(DM|EDP)\cdot f(EDP|IM,IP,SP)\cdot f(IP|IM,SP) \cdot f(IM)\cdot f(SP)\cdot dDM\cdot dEDP\cdot \mathrm{d}IM\cdot \mathrm{d}IP\cdot \mathrm{d}SP \quad (1)$$

in which $G(\cdot)$ = complementary cumulative distribution function, and $G(\cdot|\cdot)$ = conditional complementary cumulative distribution function; $f(\cdot)$ = probability density function, and $f(\cdot|\cdot)$ = conditional probability density function; *DM* = damage measure(s) (i.e., parameters describing the physical damage of the structure); *EDP* = engineering demand parameter(s) (i.e., parameters describing the structural response for the performance evaluation); *IM* = intensity measure(s) (i.e., parameters characterizing the environmental hazard); *SP* = structural parameter(s) (i.e., parameters describing the relevant properties of the structural system and non-environmental actions); and *IP* = interaction parameters (i.e., parameters describing the interaction phenomena between environment and structure). In Eq. (1), *IM* and *SP* are assumed as uncorrelated and independent of *IP*, while *IP* is dependent on both *IM* and *SP*. By means of Eq. (1), the problem of risk assessment is disaggregated into the following tasks (see Figure 1): (1) hazard analysis, (2) structural characterization, (3) interaction analysis, (4) structural analysis, (5) damage analysis, and (6) loss analysis. Detailed explanation of steps (1), (4), (5), and (6) can be found in the PBEE literature (e.g., Porter 2003), while steps (2) and (3) have been introduced in PBWE to rigorously model the effects of interaction between the structural system and the environment on the structural response (e.g., aerodynamic effects, see Petrini 2009).

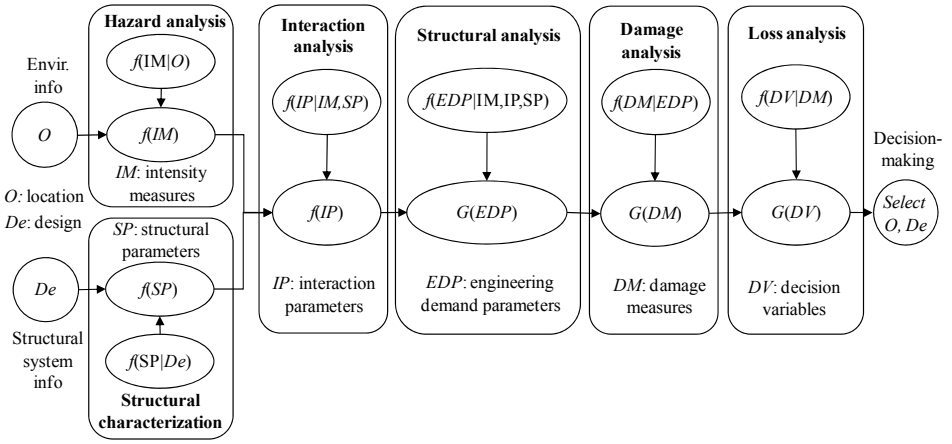

Figure 1. Probabilistic analysis components of the PBHE framework

The remainder of this paper focuses on probabilistic hazard analysis, i.e., on the probabilistic characterization of the *IM*s. This characterization can be done by using the (joint) probability density function *f*(*IM*). The *IM*s are strictly independent on the investigated structure. Thus, the probabilistic information about *IM* should be provided by climatologists, while the engineers have the task of clarifying what information is needed. The proposed point of view is consistent with the state-of-the-art in hurricane hazard and loss modeling, which can be identified with the HAZUS® methodology (FEMA 2007).

CHARACTERIZATION OF UNCERTAINTIES

The PBHE methodology outlined above requires the identification of the uncertainties that characterize the various phases of the assessment analysis. This paper focuses on the hazard for a single structure located in a hurricane-prone region. Three zones can be distinguished (see Figure 2):

- *Environment*, i.e., the space surrounding the structure but sufficiently far from it, where the parameters describing the wind field and other environmental actions (e.g., wind velocity, water level of water bodies surrounding the structure) are not influenced by the presence of the structure itself.
- *Exchange zone*, i.e., the space immediately surrounding the structure, where the structural configuration and the environmental actions are strongly correlated, and the interaction between the structure and the environmental agents, as well as the presence of adjacent structures, cannot be disregarded.
- *Structure*, which includes the original structural system (characterized by a set of uncertain parameters collected in a vector *S*) as well as non-environmental actions and/or elements (characterized by a set of uncertain parameters collected in a vector *A*) that can modify the structure's behavior.

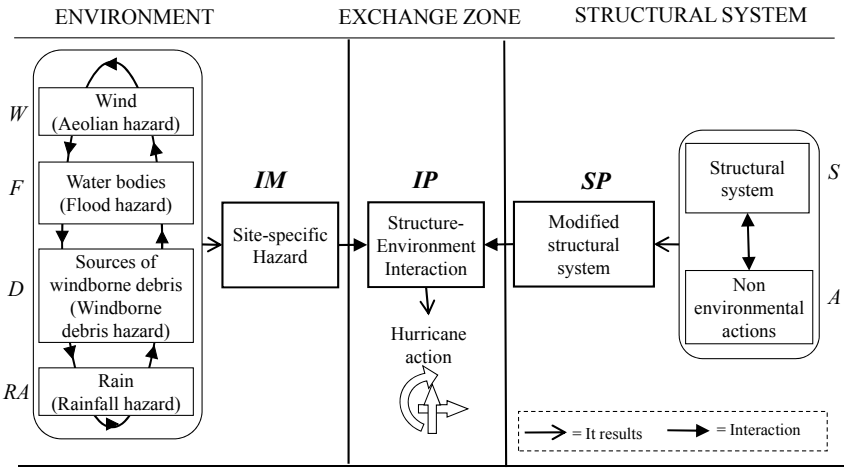

Figure 2. Identification of uncertainties in PBHE

Hereinafter, the uncertain basic parameters of interest describing the environmental actions in the environment zone are collected in the intensity measure vector *IM*; the uncertain basic parameters describing the structural

system and non-environmental actions or devices applied to it are collected in the structural parameter vector *SP*; and the uncertain derived parameters of interest in the exchange zone are collected in the interaction parameter vector *IP* (Figure 2). Examples of *IP*s are aerodynamic and hydrodynamic coefficients, as well as peak factors for stochastic structural response.

Figure 2 shows the different sources of uncertainties corresponding to environment, structure, and exchange zone, and identifies the different hazard sources and their interactions. The environmental hazard due to a hurricane event in a specified geographic region is generated by four main sources of hazard:

- Hurricane strong winds (characterized by the uncertain parameter vector *W*), which can produce wind damage (*aeolian hazard*).
- Water bodies (characterized by the uncertain parameter vector *F*), which can produce flood damage (*flood hazard*).
- Sources of windborne debris (characterized by the uncertain parameter vector *D*), which can produce windborne debris damage (*windborne debris hazard*).
- High rainfall rates (characterized by the uncertain parameter vector *RA*), which can induce flash flooding and direct damage to the interiors of building when the building envelope has been breached (*rainfall hazard*).

In the environment zone, the various sources of hazard usually interact to produce the actual hurricane hazard for a given structure. Typical examples are the interaction between wind and waves in offshore sites and the interaction between storm surge and wind in coastal regions.

A set of uncertain parameters included in vectors *W*, *F*, *D*, and *RA* must be selected in order to describe *IM*. This set must accurately describe all hazard sources and must be as small as possible in order to be both "sufficient" and "efficient" (Luco and Cornell 2007). The same selection operation (from vectors *A* and *S*) is needed to describe *SP*. The PBHE methodology also requires the identification of the vector *IP* of the stochastic parameters governing the interaction between environment and structural system in the exchange zone. The probabilistic description of vectors *IM*, *SP*, and *IP* is needed in order to derive the probabilistic characterization of the hurricane actions on the structural system under study.

INTENSITY MEASURES AND HAZARD ANALYSIS

A selection of the basic parameter vectors *W*, *F*, *D*, and *RA* is needed to generate a comprehensive vector *IM* that can be used for a general hurricane hazard analysis. With regard to the hazard analysis conducted for a specific structure *s* and regarding a specific performance objective *p*, the elements of the general *IM* vector that do not represent a relevant hazard for *s*, and those that have small influence on *p,* can be neglected or treated as deterministic. This selection is performed in order to improve the efficiency of the $IM^{(s,p)}$ (i.e., the vector *IM* specialized for structure *s* and performance *p*) at a negligible loss of sufficiency. For example, the flooding hazard can be neglected in the case of structures that

are located sufficiently far away from water bodies.

The selection of the *IM* parameters strictly depends on the choice of the models used to describe the environmental phenomena related to the various hazards. In general, deterministic models are used, while the key parameters of these models are treated as stochastic variables. In this paper, state-of-the-art models for hurricane-related environmental phenomena are reviewed and the corresponding *IM* components are identified. While the selected *IM* vector depends on the specific models considered, the approach proposed here to identify *IM* is general and can also be applied to different hazard models.

In the following equations, the dependence of a given parameter x from other variables is expressed collecting first the subset of continuous variables independent of the hurricane characteristics, and then the subset of parameters used to characterize the hurricane (i.e., *IM* components). For example, $x = x(\alpha, \beta; \gamma, \delta)$, indicates that x is a function of continuous variables α and β (e.g., distance and time), and of characteristic parameters γ and δ (e.g., hurricane radius of maximum wind and central pressure deficit).

Wind field and aeolian hazard characterization

A model of the wind field associated with a hurricane is needed to characterize the aeolian hazard. In general, two methodologies can be followed to define the hurricane wind field and the corresponding hazard (FEMA 2007):

- The site specific statistics of some fundamental hurricane parameters are obtained and a Monte Carlo approach is used to sample these parameters from the available statistical information. Using these samples, a mathematical representation of the hurricane is adopted and the statistics of parameters needed to describe the hurricane actions are evaluated for the structure of interest at its specific location (Vickery and Twisdale 1995).
- The full track of a hurricane is modeled, from its initiation over the ocean until its final dissipation (Jakobsen and Madsen 2004). Several tracks are statistically simulated. The statistics of the parameters describing the hurricane actions are estimated from the parameters' values in each simulated track for the structure of interest at its specific location.

This study uses the first methodology. The hurricane wind hazard model is subdivided into three components (see Figure 3):

- *Hurricane model*, which provides the wind speed at the gradient height V_G. For a stationary storm, V_G can be obtained as (Vickery et al. 2009)

$$V_G(r;\Delta p_c, RMW, B) = \sqrt{\left(\frac{RMW}{r}\right)^B \cdot B^{-\left(\frac{RMW}{r}\right)^B / \rho_a} + \frac{r^2 \cdot f_c^2}{4}} - \frac{r \cdot f_c}{2} \qquad (2)$$

  in which r = radial distance of the structure to the hurricane storm center, ρ_a = air density, f_c = Coriolis parameter, B = Holland parameter, RMW = radius of maximum wind (defined as the radial distance between the storm center and the maximum wind location), and Δp_c = hurricane central pressure deficit.

- *Boundary layer model*, which provides the mean wind speed U. U can be obtained using one of the existing relations describing its variation inside the atmospheric boundary layer, e.g. (Vickery and Twisdale 1995),

$$U(z,r;\Delta p_c,RMW,B,H^*,z_0)=V_G(r;\Delta p_c,RMW,B)\cdot\left[\frac{ln(z/z_0)}{ln(H^*/z_0)}\right] \quad (3)$$

in which z = height from sea level, z_0 = terrain roughness length, and H^* = atmospheric boundary layer height.

- *Turbulence model*, which provides the gust wind speed V_{gust} for a specified sampling time duration T_0. V_{gust} is commonly expressed as (ESDU 1983)

$$V_{gust}(\tau,z,r;\Delta p_c,RMW,B,H^*,z_0)=U\cdot g(\tau,z,r;U,T_0,u_*) \quad (4)$$

in which τ = averaging time, g = gust factor, and u_* = friction velocity (Vickery et al. 2009).

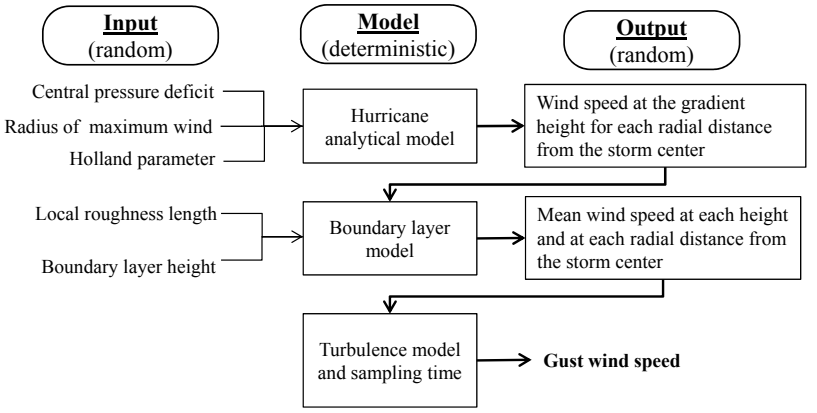

Figure 3. Hurricane wind field characterization and hazard model.

The total hurricane wind speed acting on a structure during a wind gust is equal to the vector sum of V_{gust} given in Eq. (4) and the instantaneous (horizontal) translational speed of the storm V_c. Based on the considered models, the vector W of basic stochastic parameters describing the wind field (Figure 1) becomes

$$W=\left[RMW \quad V_c \quad \Delta p_c \quad B \quad H^* \quad z_0\right]^T \quad (5)$$

where the superscript T denotes the matrix transpose operator.

Flood hazard characterization

The flood hazard due to the presence of water bodies surrounding the considered structure depends on the total water surface elevation with respect to the mean surface, η_{tot}, and on the flooding water velocity, V_{water} (i.e., the value of the component of the water velocity orthogonal to the flooding barriers). These two parameters allow for the computation of the volumetric rate of flow and can be used as synthetic intensity indicators for flood. In this paper, the basic parameters characterizing these indicators are selected as components of the intensity vector F. Three main natural phenomena cause water level increase and contribute to flood hazard: astronomical tide (η_{tide}), waves (η_{wave}), and storm surge

(η_{surge}). The total water surface elevation is the sum of the three contributions at the same instant of time: $\eta_{tot} = \eta_{tide} + \eta_{wave} + \eta_{surge}$. The flooding water velocity V_{water} can be assumed, in first approximation, equal to the highest velocity for each of the three considered phenomena (V_{tide}, V_{wave}, V_{surge} respectively).

The flood hazard due to the astronomical tide can be characterized by the two random variables η_{tide} and V_{tide}, i.e., $F_{tide} = [\eta_{tide} \; V_{tide}]^T$. The individual characterizations of the flood hazard due to waves (parameter vector F_{wave}) and to the storm surge (parameter vector F_{surge}) require more detailed considerations.

The water level, η_{wave}, and the wave celerity, V_{wave}, can be directly related to the water depth, d; the wave height, H; the wave length, L; and the wave period, T. The last three quantities can be obtained by propagating in space and time (Young 1999) the waves corresponding to a wave energy density spectrum (e.g., JONSWAP, Hasselmann et al. 1973) valid for the sea waves as determined by the wind field (i.e., RMW, V_c, Δp_c, and B), as well as by other parameters (Dean and Dalrymple 2004). Due to space constraints, the complete procedure for analysis of flood hazard due to waves is not presented here.

A storm surge is defined as the water surface response to wind-induced surface shear stress and pressure fields (US Army Corps of Engineers 2002). Storm surges can produce considerable short-term increases in water level. Current storm surge models are based on the depth-averaged momentum and continuity equations for steady long waves under the hypothesis of incompressible water (Bode and Hardy 1997). Due to space constraints, the complete procedure for analysis of flood hazard due to storm surge is not presented here.

The vectors F_{wave} and F_{surge} proposed in this paper coincide and are

$$F_{wave} = F_{surge} = \left[RMW \quad V_c \quad \Delta p_c \quad B \quad H^* \quad z_0 \quad d \quad U_{curr} \quad z_b\right]^T \tag{6}$$

in which U_{curr} = current velocity, and z_b = sea bottom friction roughness.

Windborne debris hazard characterization

The main intensity indicators for windborne debris impact hazard are the linear momentum, $M = m_{debris} \cdot u_m$, and the kinetic energy, $E = m_{debris} \cdot u_m^2 / 2$, of the missile at impact, in which m_{debris} = mass of the missile at impact, and u_m = impact velocity of the missile at impact. The proposed procedure for windborne debris hazard analysis is shown in Figure 4. The starting point is the description of the hurricane wind field, which provides some of the input data needed for a debris generation model. The additional data that cannot be derived from the wind field model consists of the density of upwind buildings with respect to the investigated structure, $n_{buildings}$; the properties of the different debris types (m_{debris} = mass of the debris, $C_{D,av}$ = average drag coefficient of the debris, and A_{debris} = reference debris area); and the resistance model for the missile sources. The debris generation model provides the input data for a debris trajectory model (Holmes 2004, Holmes et al. 2006, Baker 2007, Lin et al. 2007). The main goal of a debris trajectory model is the assessment of the wind debris velocity at impact with a

downwind building at a given distance from the debris source. Finally, a debris impact model can be used to determine the probabilistic characterization of impact kinetic energy, impact linear momentum, and number of impacts on the considered structure. The proposed vector D of basic random parameters is

$$D = \left[RMW \quad V_c \quad \Delta p_c \quad B \quad H^* \quad z_0 \quad n_{buildings} \quad C_{D,av} \quad A_{debris} \quad m_{debris} \right]^T \tag{7}$$

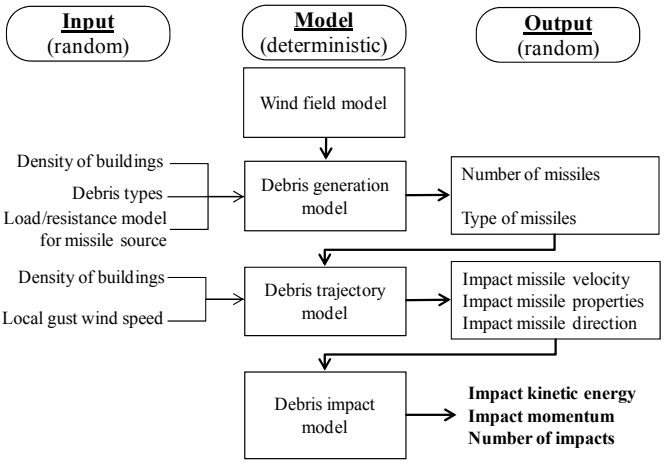

Figure 4. Windborne debris hazard model.

Rainfall hazard characterization

The high rainfall rate associated with hurricane events can induce significant damage to the interior of buildings when the building envelope has been breached (Huang et al. 2001). To the best of the authors' knowledge, no analytical rainfall models are available in the literature heretofore. However, several models based on interpolation of statistical data exist that define the correlation between the rainfall rate and some fundamental hurricane parameters. One of the most widely accepted and used model is the one implemented in HAZUS® (Vickery et al. 2006, FEMA 2007), which is valid for tropical cyclones. The estimates of rainfall rates resulting from this model are successively employed in HAZUS® to estimate the amount of water that enters buildings through broken windows and doors, while these estimates are not used to assess the risk associated with inland flash flooding. Consistent with HAZUS®, this study does not consider inland flash flooding hazard. Due to space constraints, the complete procedure for analysis of rainfall hazard is not presented here. The proposed vector RA of basic random parameters is given by

$$RA = \left[RMW \quad \Delta p_c \quad \mathrm{d}p_c / \mathrm{d}t \right]^T \tag{8}$$

in which $\mathrm{d}p_c/\mathrm{d}t$ = time rate of change in central pressure, and t = time.

PROPOSED INTENSITY MEASURE VECTOR

An analysis of the vectors of basic random parameters describing the different hazard sources associated with a hurricane shows that several parameters are common to different hazards. Therefore, the resulting vector of IM is given by

$$IM = \left[IM_W \quad IM_F \quad IM_D \quad IM_{RA} \right]^T \tag{9}$$

in which

$$\begin{aligned} IM_W &= \left[RMW \quad V_c \quad \Delta p_c \quad B \quad H^* \quad z_0 \right]^T \\ IM_F &= \left[d \quad U_{curr} \quad z_b \quad \eta_{tide} \quad V_{tide} \right]^T \\ IM_D &= \left[n_{buildings} \quad C_{D,av} \quad A_{debris} \quad m_{debris} \right]^T \\ IM_{RA} &= \mathrm{d}p_c / \mathrm{d}t \end{aligned} \tag{10}$$

denote the random parameters needed to describe the hurricane wind hazard, the additional random parameters needed to describe the flood hazard, the additional random parameters needed to describe the windborne debris hazard, and the additional random parameter needed to describe the rainfall hazard, respectively.

CONCLUSION

In this paper, a probabilistic methodology for Performance-Based Hurricane Engineering (PBHE) has been proposed and illustrated. This methodology is based on the Total Probability Theorem and builds on methodologies already developed and used in other civil engineering subfields. The proposed procedure can be used to evaluate the structural risk associated with facilities located in hurricane prone regions. The structural risk is conventionally measured by the probability of exceeding a specified value of a decision variable (*DV*) corresponding to a target performance. Each *DV* is a measurable attribute that represents a specific structural performance and can be defined in terms of the cost and/or benefit for the users and/or the society. The problem of risk assessment is disaggregated into the following basic probabilistic components: (1) hazard analysis, (2) structural characterization, (3) interaction analysis, (4) structural analysis, (5) damage analysis, and (6) loss analysis. This paper presents a review of existing models describing the different sources of hazard associated with a hurricane event. A vector of intensity measures (*IM*) (consistent with the state-of-the-art modeling of hurricane wind, flood, windborne debris, and rainfall hazard) is proposed for hurricane hazard analysis.

This paper presents a general methodology for a performance-oriented design under multi-hazard scenarios, such as the ones determined by hurricanes. The proposed methodology is a first step in this direction with a scope limited to hazard analysis for PBHE. Research is still needed to (1) improve the probabilistic description of the environmental parameters used in hurricane hazard analysis; (2) define sufficient and efficient *IM* vectors for different structures and different geographical regions; (3) develop procedures for interaction analysis, structural analysis, damage analysis, and loss analysis that are appropriate for PBHE; (4) define appropriate performance objectives for hurricane engineering problems; and (5) relate the target performance objectives and the *DV*s obtained using the proposed PBHE methodology with feasible design procedures.

ABSTRACT

The net effect of changes incorporated into *ASCE 7-10 Minimum Design Loads for Buildings and Other Structures* for wind design is often described in broad terms. These include use of uniform recurrence intervals for wind speed contours and removal of conservatism in the hurricane prone region. This paper will explore the net effect of changes on calculated wind pressures for specific locations both within the hurricane prone region and outside of the hurricane prone region. Design velocity pressure calculated using ASCE 7-10 and ASCE 7-05 will be compared and implications on relative vulnerabilities of buildings (between those designed under ASCE 7-05 and ASCE 7-10) will be explored.

INTRODUCTION

Wind design in ASCE 7-10 incorporates several major changes for wind design. Among the changes are new wind speed maps, referred to as ultimate wind speed maps in the 2012 International Building Code (IBC), that vary by risk category and incorporate wind speed contours of uniform recurrence interval throughout all geographic regions including hurricane prone regions of the U.S. In addition, revisions to the definition of Exposure D no longer preclude it from being applicable in hurricane prone regions. Coupled with these changes that affect calculation of the nominal load are revised load factors for wind in ASD and LRFD load combinations.

It is recognized that one outcome of all of the changes includes a reduction in design velocity pressure in some hurricane prone regions. Rather than address the changes in broad terms, this paper evaluates the net effect of all of the above changes for specific sites by comparing the design velocity pressure calculated using provisions of ASCE 7-05 and ASCE 7-10. The purpose of the comparison is two-fold: i) to illustrate where differences in calculations occur, and ii) provide insight into the affect of changes on calculated pressures for specific locations and buildings of varying risk category.

Of particular interest, are the reduced design pressures for Risk Category III and IV buildings given the importance of these buildings to our communities both before and after a major wind event such as a tornado or hurricane. While there is not substantial evidence of failure from high winds using the most recent versions of ASCE 7 or the IBC, there is a concern that reducing design wind pressures will potentially lead to high wind failures that otherwise would not have occurred.

DESIGN VELOCITY PRESSURE

For purposes of comparison, the design velocity pressures calculated herein will represent the factored pressures that would result from use of ASD or LRFD load combinations contained in ASCE 7.

ASCE 7-05 Velocity Pressure

$$q_{z05} = 0.00256 K_z K_{zt} K_d V^2 I \qquad \text{(Eq. 1)}$$

where:

q_{z05} = ASCE 7-05 velocity pressure evaluated at mean roof height (psf)
K_z = velocity pressure exposure coefficient
K_{zt} = topographic factor
K_d = wind directionality factor
V = basic wind speed (mph) from ASCE 7-05 maps
I = Importance factor (1.0 for Category II buildings, 1.15 for Category III and IV buildings)

Design velocity pressure for ASD and LRFD are:

ASD: $(1.0)(q_{z05})$ (Eq. 2)
LRFD: $(1.6)(q_{z05})$ (Eq. 3)

where:

1.0 = ASCE 7-05 ASD load factor for wind
1.6 = ASCE 7-05 LRFD load factor for wind

ASCE 7-10 Velocity Pressure

$$q_{z10} = 0.00256 K_z K_{zt} K_d V^2 \qquad \text{(Eq. 4)}$$

where:

q_{z10} = ASCE 7-10 velocity pressure evaluated at mean roof height (psf)
K_z = velocity pressure exposure coefficient
K_{zt} = topographic factor
K_d = wind directionality factor

V = basic wind speed (mph) from ASCE 7-10 maps referred to as ultimate wind speed maps in 2012 IBC.

Design velocity pressure for ASD and LRFD are:

ASD: $(0.6)(q_{z10})$ (Eq. 5)
LRFD: $(1.0)(q_{z10})$ (Eq.6)

where:

0.6 = ASCE 7-10 ASD load factor for wind
1.0 = ASCE 7-10 LRFD load factor for wind

For comparisons in this paper, values for the topographic factor are taken as 1.0 and the wind directionality factor is taken as 0.85. ASCE 7-10 and ASCE 7-05 equations for calculation of the design velocity pressure have a similar form and are easily compared. The effects of changes to the mapped basic wind speed on design velocity pressure are less obvious. To see effects, the above equations are applied to buildings of different risk category in different locations in the U.S.

BUILDING LOCATIONS AND RISK CATEGORY

Design velocity pressures for specific building locations and within building Risk Category II, III and IV are shown in Table 1. All locations are within the hurricane prone region with the exception of Dallas, TX. Wind speeds shown for each location are determined by interpolation where applicable or taken from Tables C26.5-3 and C26.5-6 from the ASCE 7-10 Commentary.

Table 1. Comparison of design velocity pressures based on ASCE 7-10 and ASCE 7-05 (Exposure C, 33 ft mean roof height)[1]

		ASCE 7-10			ASCE 7-05		
Location	Risk Category	Wind Speed (MPH)	ASD Velocity Pressure (psf)	LRFD Velocity Pressure (psf)	Wind Speed (MPH)	ASD Velocity Pressure (psf)	LRFD Velocity Pressure (psf)
Boston, MA	II	128	21.4	35.7	105	24.0	38.4
Va Beach, VA	II	122	19.4	32.4	114	28.3	45.2
Miami, FL	II	170	37.7	62.9	146	46.4	74.2
Galveston, TX	II	150	29.4	49.0	132	37.9	60.7
Dallas, TX	II	115	17.3	28.8	90	17.6	28.2
Boston, MA	III, IV	140	25.6	42.6	105	27.6	44.1
Va Beach, VA	III, IV	132	22.7	37.9	114	32.5	52.0
Miami, FL	III, IV	181	42.8	71.3	146	53.3	85.3
Galveston, TX	III, IV	160	33.4	55.7	132	43.6	69.8
Dallas, TX	III, IV	120	18.8	31.3	90	20.3	32.4

[1] Exposure C at 33' mean roof height assumed for all calculations, $K_z = 1.0$.

Table 2 provides the same information as Table 1 except design velocity pressure in accordance with ASCE 7-10 assumes Exposure D for sites located in hurricane prone regions. Design velocity pressures for ASCE 7-05 are based on assumed Exposure C because Exposure D is not applicable in hurricane prone regions per ASCE 7-05.

Table 2. Comparison of design velocity pressures based on ASCE 7-10 (Exposure D, 33 ft mean roof height)[1] and ASCE 7-05 (Exposure C, 33 ft mean roof height)[2]

		ASCE 7-10			ASCE 7-05		
Location	Risk Category	Wind Speed (MPH)	ASD Velocity Pressure (psf)	LRFD Velocity Pressure (psf)	Wind Speed (MPH)	ASD Velocity Pressure (psf)	LRFD Velocity Pressure (psf)
Boston, MA	II	128	25.2	42.1	105	24.0	38.4
Va Beach, VA	II	122	22.9	38.2	114	28.3	45.2
Miami, FL	II	170	44.5	74.2	146	46.4	74.2

[1] Exposure D at 33' mean roof height assumed for ASCE 7-10 calculations, $K_z = 1.18$.
[2] Exposure C at 33' mean roof height assumed for ASCE 7-05 calculations, $K_z = 1.0$.

DESIGN PRESSURE DIFFERENCES

From Tables 1 and 2, the ratio of ASD to LRFD is a constant as would be expected based on the applicable equations. A slight reduction in ASD loads relative to LRFD loads results from the load factor differences between ASCE 7-10 and ASCE 7-05 (e.g. ratio of 0.6 versus 0.625). Table 3 compares the relative increase or decrease in design velocity pressures based on location, building risk category, and exposure. Only design velocity pressures for LRFD are shown based on the prior observation that ASD and LRFD velocity pressures vary by a constant value.

Table 3. Comparison of LRFD design velocity pressures based on ASCE 7-10 and ASCE 7-05

		ASDCE 7-10			ASCE 7-05		Ratio	
Location	Risk Category	Wind Speed (MPH)	[A] Exp C Pressure (psf)[1]	[B] Exp D Pressure (psf)[1]	Wind Speed (MPH)	[C] Velocity Pressure (psf)[2]	[A] / [C]	[B] / [C]
Boston, MA	II	128	35.7	42.1	105	38.4	0.93	1.10
Va Beach, VA	II	122	32.4	38.2	114	45.2	0.72	0.84
Miami, FL	II	170	62.9	74.2	146	74.2	0.85	1.00
Galveston, TX	II	150	49.0	57.8	132	60.7	0.81	0.95

Dallas, TX	II	115	28.8	-	90	28.2	1.02	-
Boston, MA	III, IV	140	42.6	50.3	105	44.1	0.97	1.14
Va Beach, VA	III, IV	132	37.9	44.7	114	52.0	0.73	0.86
Miami, FL	III, IV	181	71.3	84.1	146	85.3	0.84	0.99
Galveston, TX	III, IV	160	55.7	65.7	132	69.8	0.80	0.94
Dallas, TX	III, IV	120	31.3	-	90	32.4	0.97	-

[1] Exposure D at 33' mean roof height assumed for ASCE 7-10 calculations, $K_z = 1.18$.
[2] Exposure C at 33' mean roof height assumed for ASCE 7-05 calculations, $K_z = 1.0$.

One of the expected changes in results due to ultimate maps and the reduced load factor was a reduction generally in the design pressures for Exposure C, especially along the Gulf and southern Atlantic coastlines. For Risk Category III and IV buildings the reader will notice that in every location, the pressures using ASCE 7-05 are higher than the pressures using ASCE 7-10 (i.e. ratio less than 1.0). The inland location, Dallas, TX, show only small differences between ASCE 7-10 and ASCE 7-05 for Risk Category II, III and IV buildings.

As noted, one of the expected changes in the use of ultimate maps and Exposure D is that design wind pressures for buildings built where Exposure D is applicable will be very similar to the design pressures used for Exposure C in ASCE 7-05 (see Table 3, column [B]/[C].. However, where the exposures are the same (Exposure C), the elimination of the importance factor coupled with use of uniform return period ultimate maps does not provide equivalent design pressures. For critical facilities, pressures are as much as 27% lower using ASCE 7-10 vs. ASCE 7-05 (see Table 3, column [A]/[C]). The northeast US and inland US locations are closer in comparative wind pressures than many areas of the hurricane coastlines.

RELATIVE SAFETY - ASCE 7-10 VS. ASCE 7-05

In this paper, only wind speed provision comparisons between two versions of the ASCE 7 standard are made. As shown in Table 3, the provisions of ASCE 7-05 were conservative relative to ASCE 7-10. In many areas of the country, new designs that precisely meet ASCE 7-10 wind loads will be designed with lower wind pressures than similar designs that were done in accordance with ASCE 7-05.

The re-introduction of Exposure D in ASCE 7-10 in hurricane prone regions that are on the water or in areas that would be directly impacted by over water flow of high winds was intended to bring the wind pressures in these areas closer to the pressures developed for Exposure C in ASCE 7-05 given the other changes that were made with wind contours and wind speed changes using higher return period maps. The last column in Table 3 illustrates this point. As indicated, for both Risk Categories II and III and IV, the ratio of Exposure D (ASCE 7-10) pressures to Exposure C (ASCE 7-05) pressures is very nearly 1.0 in the five locations considered with the exception of Virginia Beach, VA. While this ratio will vary some along the hurricane prone

coastline, the inland area of the country can be generally represented by results for Dallas, TX (except for Special Wind Regions).

None of the five locations studied have an ASCE 7-10 wind pressure equal to or greater than the pressures developed using ASCE 7-05. In a few cases, the pressures are nearly 30% lower. The pressures for Risk Category II buildings are equally lower using ASCE 7-10.

CONCLUSIONS

Changes in wind design provisions in ASCE 7-10 appear to produce the greatest differences in design velocity pressure when compared to ASCE 7-05 for areas within the hurricane prone regions. In hurricane prone regions where Exposure D is applicable, design velocity pressures in accordance with ASCE 7-10 are both larger (Boston, MA) and smaller (Virginia Beach, VA) than those determined in accordance with ASCE 7-05. For hurricane prone regions where Exposure D is not applicable under ASCE 7-10, design velocity pressures are smaller by as much as 28 percent than those calculated using ASCE 7-05. Differences in changes in design velocity pressures followed the same trends for Risk Category II and Risk Category III and IV buildings.

The actual reduction in design pressures of course is a location specific issue. As seen in the tables in this paper, some hurricane locations indicate significant differences in pressures between the ASCE 7-05 and the ASCE 7-10 standards and other locations indicate very little difference. Design professionals might investigate the differences in design pressures as they prepare a design for an owner, and discuss the differences with the owner in light of the reduction design pressures obtained using the ASCE 7-10 methodology for locations in the hurricane prone region.

Determination of exposure has always been an important issue in determination of wind pressures, but the reduction in design pressures in the hurricane prone region makes the accurate determination of exposures even more important. With the new Exposure D in ASCE 7-10, it becomes even more important for those conducting post event assessments of building performance to accurately identify the exposure category for each building location. Proper assessment of the exposure category is needed to identify the applicable design loads for the specific building location. The demand to capacity ratio associated with the buildings design can then be determined as a possible performance metric when coupled with knowledge of assumptions for design resistance.

ABSTRACT

This paper presents an overview of the damage from the 2010 Chile Earthquake observed by a field reconnaissance team from the Mid-America Earthquake Center. Seismic performances of structures in Santiago, Biobío, and Maule regions in Chile are summarized based on field observations and discussions with researchers and city officials. In addition, post-earthquake analyses of a damaged bridge and a building structure are presented. The analyses are carried out with detailed documentation from the field and the acquired design drawings of the structures. For the building structure, the focus of the analysis is to understand the effect of masonry infill walls on the shear force demand of columns. The analysis results confirm that the infill walls of the building may have caused the damage to columns by increasing the shear force demand. For the bridge structure, the effect of seismic bars on the bridge response is investigated. The seismic bars in the bridge reduce the displacement demand of the superstructure by increasing the energy dissipation capacity of elastomeric bearings.

INTRODUCTION

The Chile Earthquake of February 27, 2010 was the fifth largest earthquake ever recorded in history. The magnitude of the earthquake was 8.8 and it caused damage to at least 370,000 houses and displaced 800,000 people with economic losses of $30 billion (USGS 2010). Despite the large intensity of the earthquake, the number of collapsed structures and the death toll were limited due to the country's modern seismic design code and the strict enforcement of the code. Many researchers from different organizations participated in field investigations after the earthquake to learn how structures designed according to modern seismic code performed in the event of a large earthquake. The research presented in this paper is an overview of the damage observed by a field reconnaissance team from the Mid-America Earthquake (MAE) Center. The regional damage is summarized which includes discussions with

researchers, practitioners, and city officials. In addition, case studies of a damaged building and a bridge are presented to investigate the causes of the damage that were observed in the field. For the case study structures, detailed design drawings were acquired and the damage was documented during the field investigations. For the building structure, the focus of the study is on the effect of masonry infill walls on the seismic demand imposed on the building. For the bridge structure, the effect of seismic bars, which are commonly used in Chile, on the displacement demand of the superstructure is investigated through inelastic time history analyses.

REGIONAL DAMAGE DESCRIPTIONS

Santiago. Santiago is the capital of Chile with a population of 5.2 million. The city is located in Santiago Region, which is one of Chile's 15 administrative divisions. Although the distance from the epicenter of the earthquake to Santiago was 200 miles, the city was close to the rupture area due to the large size of the fault. There were six seismic stations operating in the city during the earthquake event. The peak ground accelerations (PGAs) of the recorded accelerations were in the range of 0.17g to 0.56g for horizontal components and 0.11g to 0.28g for vertical components (Figure 1). Based on 922 responses in community survey system in USGS (Wald and Dewey 2005), the seismic intensity (Modified Mercalli) of the city is determined as VII, which corresponds to very strong shaking and moderate structural damage.

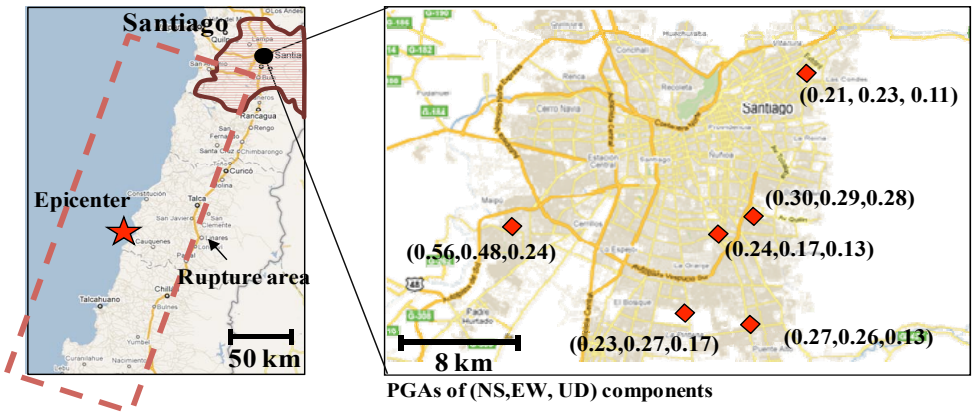

Figure 1. Location of Santiago and recorded PGAs around the city

While most reinforced concrete (RC) buildings in Santiago performed well, suffering only minor damage or even no damage, a limited number of buildings suffered significant damage due to structural deficiencies such as soft stories, horizontal or vertical irregularities, and short-column effects. Several other buildings were damaged due to the failure of bearing walls with proper confinement, as this was not required in the seismic design code. The following is a summary of the observed damage in Santiago.

The building in Figure 2 was used as a hotel. It consists of a tall tower and a low-rise commercial building. The damage shown in the figures are at the connection of the two structures. As it can be observed from the figure, the beams connecting the tall tower and the low-rise building were fractured. It is speculated that the beams were damaged as the tall building vibrated out of phase with the low-rise building,

and that action could have developed large force demand at the connection of the two buildings.

The building in Figure 3 was constructed with load bearing walls covered with masonry cladding. The surface of the bearing walls was chipped such that the cement mortar could develop bond strength between the walls and the masonry cladding. During the earthquake, however, a large portion of the cladding was debonded and fell to the ground, which could have caused injuries or even deaths if people had been near the building at the time of the earthquake. A beam between two vertically slender windows, which separate two large walls, was also damaged. The beam apparently acted as a link (or coupling) beam between the two large walls, and did not have enough shear strength to resist the force demand.

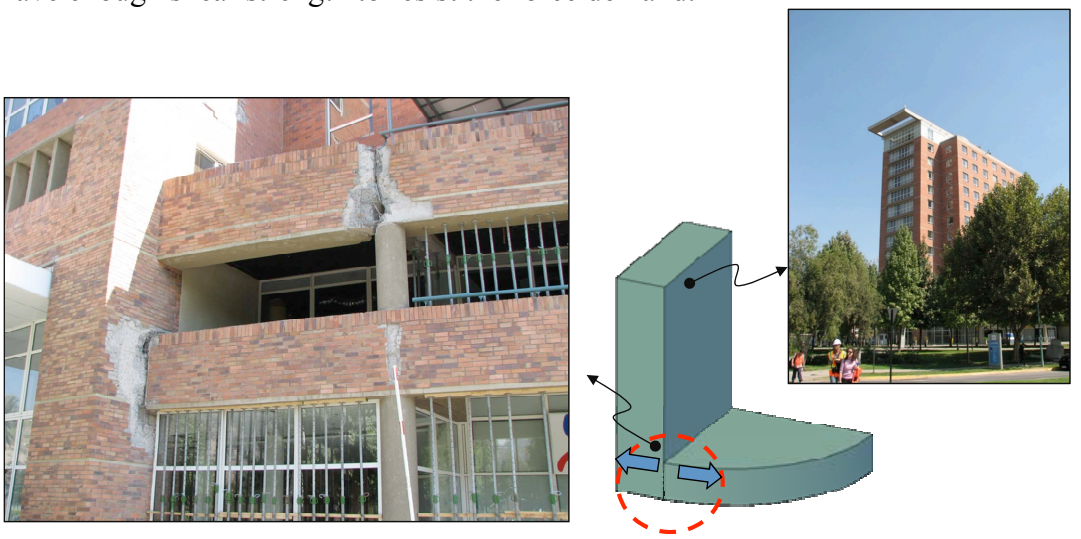

Figure 2. Failure due to vertical irregularity

Figure 3. Collapsed masonry cladding wall and a damaged beam

Biobío Region. The Biobío region is located in the south half of the rupture area as shown in Figure 4. The coseismic slip displacement of Talcahuano and Concepcion area was approximately 3m (Bevis 2010). Main damage to the region was located in the coastal towns of Arauco Province, Talcahuano city, and Dichato town (Figure 4

right). These coastal towns were severely damaged due to tsunami following the earthquake event. The area in Talcahuano Bay inundated with the tsunami is approximately 11km^2 and more than 30,000 people were directly affected by the tsunami (INE 2010).

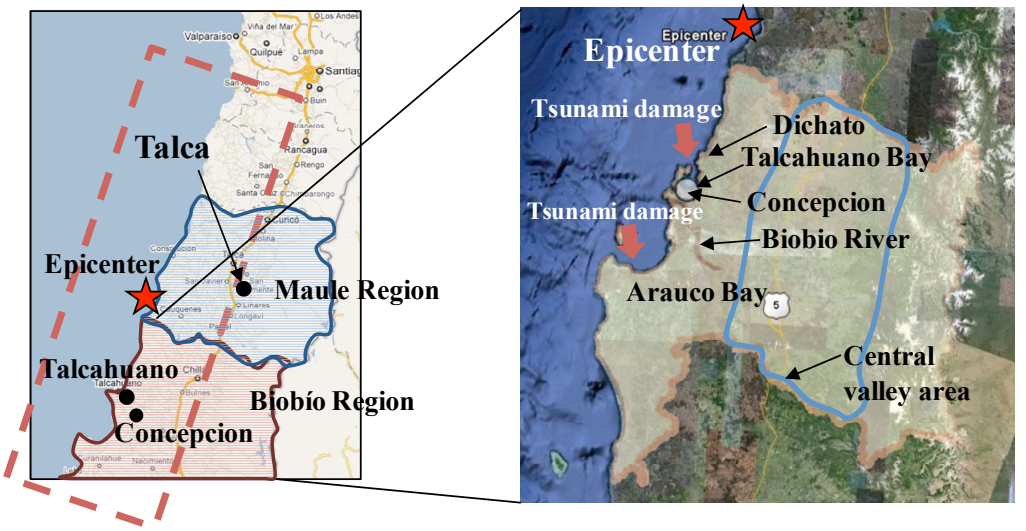

Figure 4. Biobío and Maule Regions (left) and cities in Biobío Region (right)

In Concepcion, several buildings were collapsed and several 15 to 20 story buildings were severely damaged and had to be demolished. Due to the damage to multi-story buildings, several blocks of streets in the downtown of Concepcion were closed at the time of the field investigation. One of the newly constructed buildings was toppled as shown in Figure 5. Interestingly, a nearby building with a similar height remained intact.

Figure 5. Toppled multi-story residential building: Left-illustration of the building before the earthquake, right-toppled building after the earthquake

In the Biobío region, the transportation network suffered only minor damage except a few bridges that were severely damaged or collapsed. Two 2km length bridges collapsed and one 2km length bridge was severely damaged. While the number of failed bridges was small, the failed bridges were the critical links in the regional transportation network, connecting industrial areas to ports. The failure of

these critical bridges resulted in a large economic impact to the area. At the time of the field investigation, around one and a half months after the earthquake event, only 30% of industries were operating in the region due to the difficulty in accessing the facilities in addition to damage to structures and lack of power.

There were failures in critical lifeline networks, such as gas, electricity, water, and waste water. The electricity network was restored most quickly. The gas network was not restored in many areas in the region even after several weeks. As some parts of the network were very old, the vulnerability of the network was high. In general, the central valley area of the Biobío region in Figure 4 was not largely affected by the earthquake except a few of the highway bridges and slopes. The area, however, suffered failures in water irrigation system.

Maule Region. The epicenter of the earthquake was offshore Maule as shown in Figure 4. Talca is the capital of the Maule region with a population of 230,000 and 75,000 houses. The city suffered the largest damage from the earthquake due to its close proximity to the rupture area. In addition, a large portion of buildings in Talca were adobe with negligible seismic resistance. Out of 75,000 houses in Talca, around 15,000 houses were damaged among which around 4,000 were either collapsed or damaged beyond repair. Many of these buildings were 100 to 200 years old. In the historic downtown area, where the majority of buildings were made of adobe, approximately 80% of buildings were damaged and half of the damaged buildings were beyond repair.

There were many new RC or masonry constructions designed according to modern seismic design code. The newly constructed buildings rarely suffered damage. There were only a couple of buildings which had minor architectural damage rather than major structural damage. Timber structures with adobe infill performed relatively well. When interviewed by the field reconnaissance team, the mayor of the city of Talca expressed his concerns that people in the city may rebuild their houses with adobe due to its low construction cost. At the time of the visit, the city did not have a modern design guide for adobe construction.

After the earthquake event, the critical lifeline networks of the city including gas, water, and electricity were damaged. All lifeline networks were recovered in seven to ten days. In the downtown area, recovering from damage took relatively longer as networks were dense in the area. Even though the water network was recovered earlier than the electricity network, due to the lack of electricity, water could not be pumped to higher grounds showing the inter-dependency of the lifeline networks.

Figure 6. Adobe buildings and historic structures

The typical adobe building (left) and the historic structure (right) in Figure 6 exemplify the buildings in downtown area of Talca.

EFFECT ON BRIDGES

Considering the large magnitude and huge rupture area of the earthquake, the damage to bridge structures was not significant. The majority of highways are constructed and maintained by private sectors. These highway networks are as long as 2,200 km in length and have around 2,000 bridges with spans longer than 10 m. Among these bridges, only 1% (8 highway and 12 pedestrian bridges) collapsed due to the earthquake event. Approximately 100 bridges (50 highway and 50 pedestrian) were damaged requiring repairs.

The MAE Center team visited several damaged bridges to understand the failure modes. The most typical bridge damage was due to unseating or displacement of the superstructure, especially for skewed bridges. At one site, it was clearly shown that the bridge designed with a more recent design practice suffered more damage than the bridge constructed with a previous design practice. In the old construction, the integrity of the bridge superstructure was high due to diaphragms connecting the girders. Bridges constructed in recent years often do not have diaphragms. Due to lack of integrity, bridge girders were damaged from the impact of the bridge superstructure to shear keys. In a report from another field investigation team (Yashinsky et al. 2010), it is also stated that the seat-width on bridge bents was not large enough to prevent unseating.

Only a few bridges reportedly had damage at the substructure. It is speculated that as there were not many bridges with integral superstructure-substructure connections, thus the large inertial force from the superstructure was not transferred to the substructure. Instead, the inertial force caused the unseating or large movement of the superstructure, or failure of the shear keys. Most of the investigated bridges had seismic bars, which tied the superstructure to the substructure in order to prevent vertical movement. Based on the design drawings, the seismic bars were embedded such that they can develop enough bond strength. The effect of the seismic bars on the response of the bridge will be discussed later.

CASE STUDIES

After the field investigation, case studies are carried out for one bridge and one building. The main objective of the case studies is to understand the causes of the damage for the building structure and the role of the seismic bars in the bridge structure. Spectrum compatible ground motions are generated using recorded ground motions as seed records. The target response spectra for the sites of the building and the bridge are defined using the attenuation relationships by Zhao et al. (2006) and Campbell and Bozorgnia (2003). For the sake of brevity, only a summary of the observed structural damage, numerical models, and findings from analyses are given in the following. Further details are available in the field investigation report (Elnashai et al. 2010).

Paso Cladio Arrau Bridge

The reference bridge (Paso Cladio Arrau) for this case study has 4-spans and it is 77.5m long. The bridge has three bents each of which consists of 10 piers as shown in Figure 7. As observed in most other bridges in Chile, seismic bars were installed in the bridge. Girders are supported on elastomeric bearings made of neoprene. The bridge has a skew angle of approximately 50 degrees.

The bridge suffered minor damage from the earthquake as shown in Figure 8. The superstructure displaced in the transverse direction, seismic bars yielded and elongated, and the shear keys failed. However, unseating of the superstructure was not observed. Even though the shear keys were damaged, it is speculated that they prevented the unseating of the bridge superstructure. In addition to the shear keys, the seismic bars might have reduced the displacement demands.

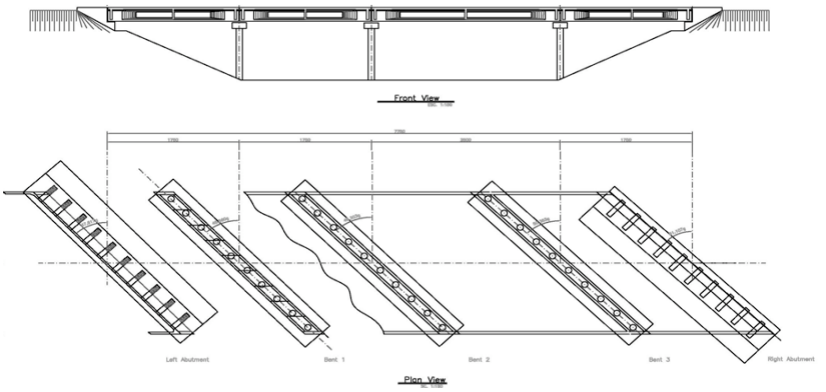

Figure 7. Configuration of bridge bents and abutment

Figure 8. Cracked shear key (left) and yield seismic bars (right)

The 3D model of the bridge was assembled in ZEUS-NL (Elnashai et al., 2010). The stiffness of abutments and hysteretic behavior of the bearings are modeled using lumped springs. The piers, seismic bars, and superstructure are modeled using cubic beam-column elements. Since detailed information on the post-tensioning force of the seismic bars is not available, it is assumed that the seismic bars are post-tensioned up to 30% of the bar's yield stress. The additional normal force to elastomeric bearings due to the post-tensioning is taken into account in the hysteretic behaviour of elastomeric bearings (hysteretic curve in Figure 9). The deck is considered as a rectangular beam having the equivalent section properties of the

girders and the bridge deck. The configuration of the superstructure-substructure connections is illustrated in Figure 9.

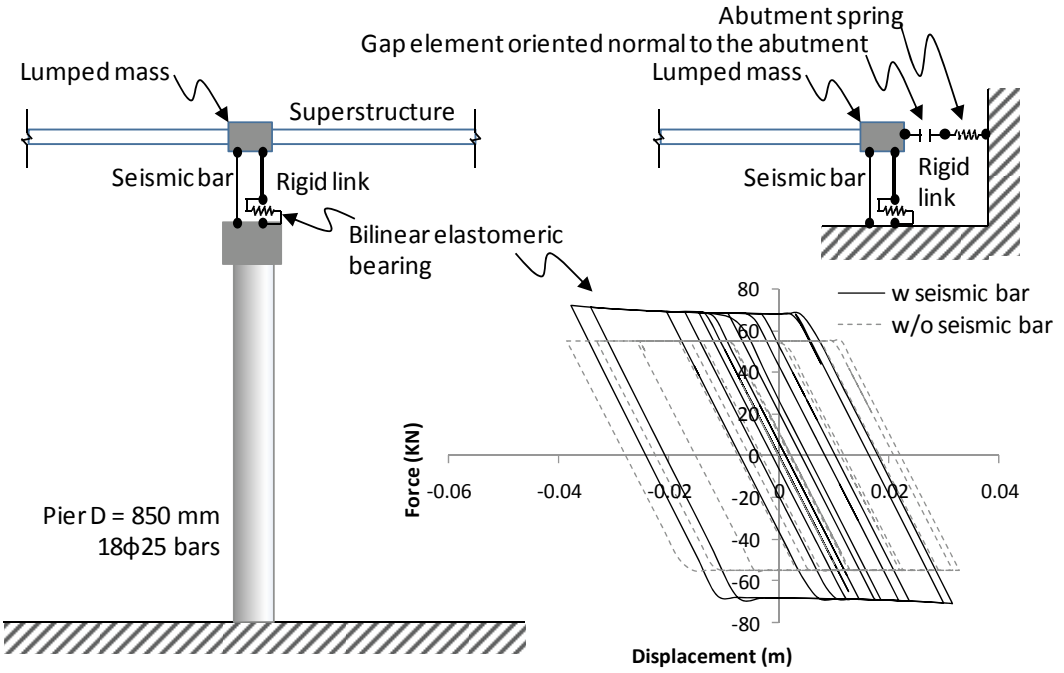

Figure 9. Details of numerical models

Artificially generated ground motions are used for inelastic response history analyses. A total of 18 horizontal components of ground motions are applied in the transverse direction. Two sets of analyses are carried out. In the first set, the seismic bars are included in the numerical model as flexural elements. In addition, the normal force on the elastomeric bearings is increased to take into account the post-tensioning force. It is assumed that the additional normal force on elastomeric bearings due to post-tensioning remains constant throughout the earthquake excitation. For the second set of analyses, all parameters are identical with those in the first set except that the contribution of seismic bars is removed from the model.

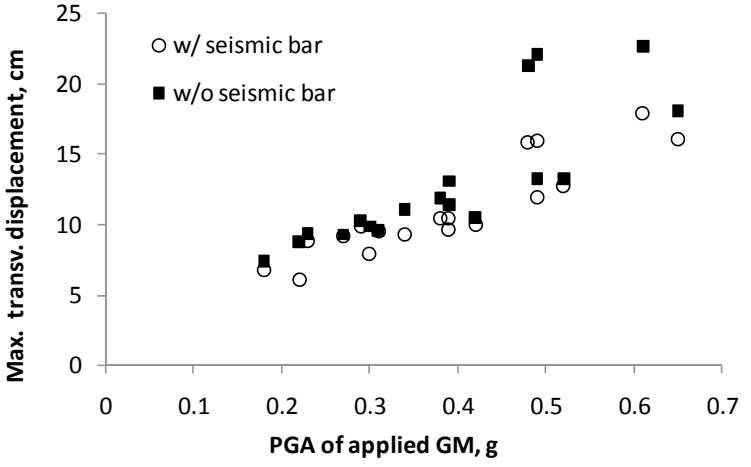

Figure 10. Maximum responses of bridges w/ and w/o seismic bars

Figure 10 compares the maximum transverse displacement for the two analysis cases as a function of PGA of the input ground motion. As it is observed from the figure, the models without seismic bars generally have larger displacement demand, and the same trend is clearly observed as the PGA of the input ground motions increases. This difference is primarily due to increased normal force in elastomeric bearings, which increases the energy dissipation capacity of the bearings.

Odontology Building of the University of Concepcion

This case study aims to explain the observed damage of the Odontology building of the University of Concepcion. The structure was used as the school of dentistry which also included rooms for examination and medical treatment of patients. Due to the requirements of the building occupancy, the reinforced concrete structure has a peculiar configuration. As shown in Figure 11, the structure has 3 regular stories and 3 service stories with approximately half story height that accommodates utility lines. The building has a rectangular shape with 7x5 bays. Structural core-walls are provided at the center of the building to resist the majority of the lateral loads. Except for minor differences in column dimensions of the exterior frames, the structure is symmetrical in both directions. Floors of the building are designed as flat slabs. Masonry infill walls are used at the first floors of the exterior frames. The height of the first story is 3.1 m and the height of the masonry infill walls was measured to be approximately 2.1 m.

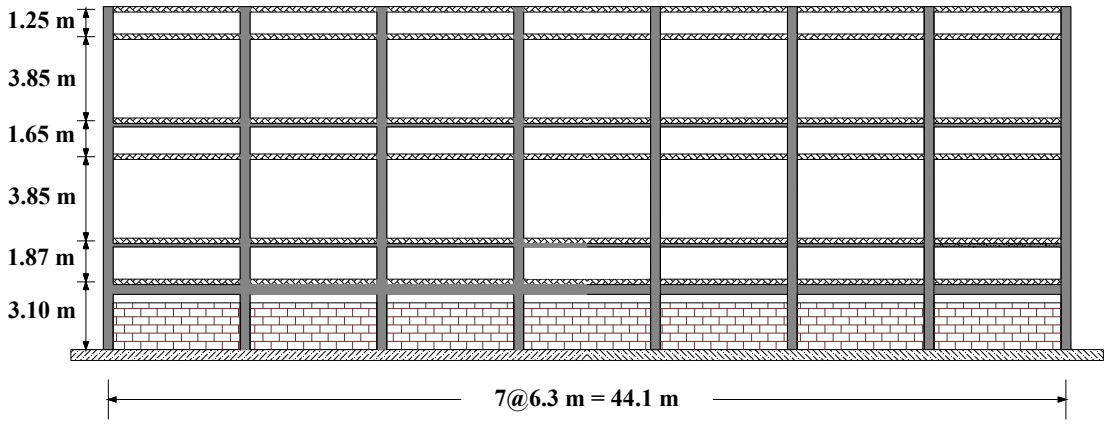

Figure 11. The Odontology building of the University of Concepcion

The earthquake caused interesting damage patterns to the building. The structural damage was confined to columns of the exterior frames. The rest of the observed damage was non-structural: cracking on the partition walls (inside the building) and the diagonal cracks of the masonry infill walls at the exterior frames. The field observations indicated that the combined axial-shear failure at the top of the columns was due to the commonly observed “short-column” effect that results from increased shear demands on a specific portion of the vertical members due to a decrease in the effective length. Some of the damaged columns are shown in Figure

12. In light of the above observations, the 7-bay exterior frame of the building is analyzed to understand the effects of masonry walls on the columns.

Figure 12 Damaged columns of the Odontology building

The fiber-based finite element analysis software ZEUS-NL (Elnashai et al., 2010) is used to model the frame shown in Figure 11. All members except for the masonry infill walls are represented with beam-column elements. The effective flange width of slab is calculated according to ACI 318-08 (ACI 2008). For the flat-slab floors, the portion of the slab that contributes to the frame analysis is determined by using the formulations proposed by Luo and Durrani (1995a, 1995b). The concrete is modeled using the constant confinement model developed by Martinez-Rueda and Elnashai (1997). Steel is modeled with a bilinear elasto-plastic model with kinematic strain hardening. Based on the information on the design drawings, the following material properties are used: a concrete compressive strength of 29.4 MPa, steel yield and ultimate strengths of 411.6 MPa and 617.5 MPa, respectively. In modeling the masonry infill walls, the following assumptions are made: infill walls do not carry any vertical loads and they can be represented with diagonal struts that have horizontal resistance only. The modeling of masonry infill walls follows the approach proposed by Mostafaei and Kabeyasawa (2004). Since the objective of the analysis is to show the effect of masonry infill walls on the response of the structure and observed damage, two building configurations are considered: with and without infill walls. A total of 8 artificially generated ground motions are used for inelastic dynamic time history analysis of the building.

The analysis results indicated that there is a significant reduction in the interstory drift ratio of the first floor, reaching as high as 51%, when the effect of masonry infill walls are considered. In order to explain the shear failures of columns due to the previously described short-column effect, it is required to compute the shear capacity of the columns and compare it against the shear demand imposed during the earthquake. The shear strength of the RC column is calculated according to ACI 318-08 (2008). As an example, the shear capacity and the shear demand on one of the exterior columns is shown in Figure 13. It is observed that the presence of masonry infill walls significantly increase the shear demand on the columns and the shear capacity is exceeded at certain times throughout the analysis.

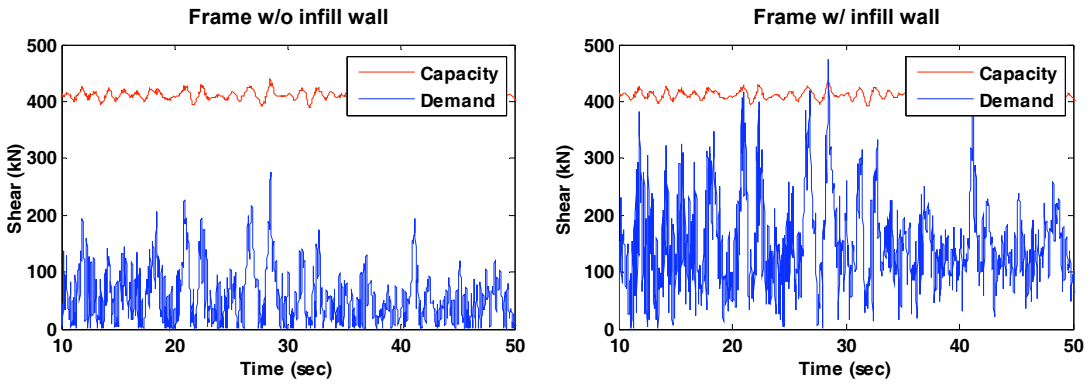

Figure 13 Comparison of shear capacity and demand for column 8

CONCLUSIONS

The seismic performance of structures after the 2010 Chile Earthquake is presented in this paper. Considering the large magnitude of the earthquake, the structures performed very well due to the enforcement of the seismic design code. Some RC buildings in Santiago region were damaged due to insufficient confinement of structural walls. Some others were damaged due to vertical irregularities and/or deficient beam-column connections. In general, damaged buildings were not widely distributed throughout Santiago. In Concepcion, in Biobío region, relatively more buildings were damaged than those in Santiago. It is speculated that it is due to close proximity of the city to the epicenter, or due to local site effects. It was very interesting to observe that a building could collapse while a nearby similar building, supposedly under a similar seismic load, did not suffer major structural damage. It was speculated that the failure of the building was due to a deficiency in the structural system, but more investigation is required to clearly understand the causes of the failure. Talcahuano city in Biobío region suffered significant damage primarily from the tsunami. Most of the damage in Talca in Maule region was due to the failure of adobe structures. Modern buildings in Talca performed very well.

The post-earthquake analysis shows that the seismic bars in bridges may have reduced the displacement demand of bridge superstructures. Since the interaction between seismic bar and elastomeric bearing is not fully considered in the analysis, further study is necessary to generalize this conclusion. The damage to the Odontology building may have resulted from the presence of the masonry infill wall, which can considerably increase the shear force demand imposed on the concrete columns.

ACKNOWLEDGEMENT

The field mission to Chile was sponsored by the Mid-America Earthquake Center, Missouri University of Science and Technology, Georgia Institute of Technology, and National Research Foundation of Korea (KRF-D00644). The MAE Center is an Engineering Research Center funded by the National Science Foundation under cooperative agreement reference EEC 97-01785.

ABSTRACT

Field observations and plausible reasons of damaged bridges are presented and their implications to bridge design are discussed. In general, bridge substructures behaved satisfactorily except that a few columns suffered shear failure. Reinforced concrete shear keys served their design purposes, performing well when they functioned as part of the lateral restraint system at the bottom flange of girders. Vertical seismic bars were widely used to restrain the vertical motion of decks and they also performed well. Lateral steel stoppers were also used to provide vertical and lateral restraints on girders but were largely unsuccessful due to their weak connection to capbeams. Many spans of precast, prestressed, discontinuous girder bridges with continuous decks fell from their supports due likely to significant rotation of their superstructure. Other types of bridge damage were related to ground shaking, ground settlement and liquefaction-induced lateral spreading.

INTRODUCTION

The M8.8 offshore Maule earthquake occurred on February 27, 2010, at 3:34 a.m. local time on a thrust fault at the boundary between the Nazca and South

American tectonic plates [USGS, 2010]. The Nazca plate moved down and landward below the South American plate in the subduction zone, resulting in a sudden release of energy accumulated over time. The earthquake epicenter, located at Offshore Maule S35.909 and W72.733, was approximately 335 km SW of Santiago, 105 km NE of Concepcion, and 115 km WSW of Talca, Chile. The depth of the earthquake hypocenter was 35 km. The M8.8 event is the fifth largest earthquake recorded in modern times, followed by 21 aftershocks of magnitude 6.0 or greater by April 26, 2010.

The Chilean geological condition in the Maule region is eerily similar to that in the Northwestern United States such as the states of Washington and Oregon. Many bridges that experienced damage during the 2010 Maule earthquake were designed and constructed following similar practices to what is stipulated by the U.S. seismic codes. Due to the similarities in earthquake environments, bridge design specifications, and construction processes, the observations and findings of bridge performance during the Maule earthquake provided valuable data sets and insights to both the improvement of current bridge design provisions and to the advancement of earthquake engineering.

The February 27, 2010, Chile earthquake and associated tsunami(s) damaged about 200 bridges, including 20 that collapsed. This earthquake provided a unique opportunity to address several bridge design related issues, including (1) the damaging potential of subduction-type ground motions that have multiple pulses, long duration, and possible rotational components; (2) the tsunami effects; (3) the role of transverse diaphragms and their possible elimination for accelerated bridge construction; (4) the effects of the number of joints and joint detail; and (5) the consequences of liquefaction-induced lateral movement and settlement. The following sections will discuss in detail each of these critical issues using example bridges.

SUBDUCTION-TYPE GROUND MOTIONS

The 2010 Chile earthquake generated ground motions with long duration and multiple pulses [Boroschek et al., 2010]. In addition, the earthquake may also have induced significant rotational motions that can be inferred from the patterns of in-plane rotations of bridge superstructures. Figure 1 shows the 32 bridge sites that were visited by the Federal Highway Administration (FHWA) reconnaissance team and highlights in red 7 of them with significant rotations in bridge superstructures. Located near Santiago at relatively stiffer soil deposits, these seven sites are further away from the earthquake epicenter than Constitución and Concepción, but the bridges at these sites exclusively experienced significant rotations. The representative acceleration response spectra at the Hospital Station in Curicó are presented in Figure 2 [Boroschek et al., 2010].

For the bridges with significant rotations, Table 1 lists the name, orientation, skew angle, skew direction, material used in girder, presence of diaphragms, transverse displacement at intermediate bents, and direction of deck rotation. The combination of these parameters will help determine the mechanism of bridge deck rotations. Note that two parallel bridges were inspected at each of sites 1, 2, and 10. At sites 2 and 10, one bridge collapsed and the other bridge suffered minor damage. In Table 1, C denotes a clockwise rotation and C.C. represents a counter clockwise rotation.

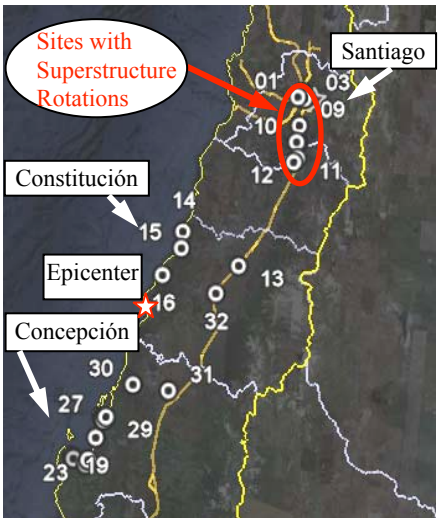

Figure 1. Bridge sites.

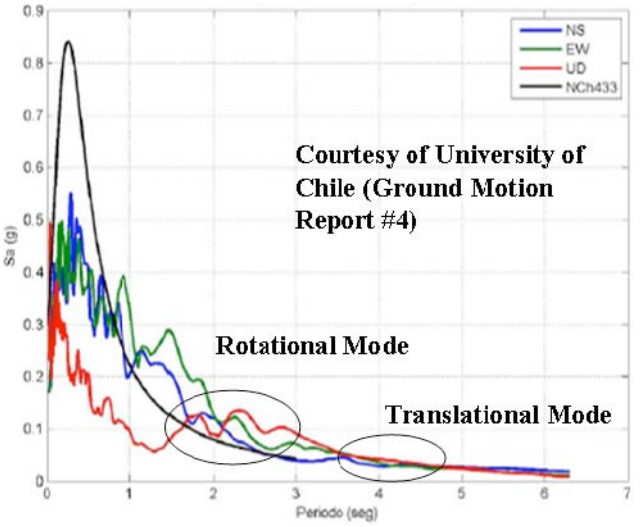

Figure 2. Mode response sensitivity.

Table 1. Bridges with Significant Rotations.

Bridge Characteristics					Movement Pattern	
Site	Name	Orientation	Skew/ Direction	Girder/End Diaphragm	Transverse Movement	Rotation
1a,1b	Miraflores	NE-SW	20°/C.C.	Concrete/No	Negligible	C.
2a	Lo-Echevers	NE-SW	33°/C.C.	Concrete/No	Negligible	C.
5	Matta-Quilicura	E-W	45°/C.C.	Steel/Yes	Negligible	C.
7	Romero	E-W	31°/C.	Concrete/No	Negligible	C.C.
8	Chada	E-W	0°/C.C.	Concrete/No	Negligible	C.C.
10b	Hospital	NW-SE	40°/C.C.	Concrete/No	Significant	C.C.
11	Las Mercedes	NW-SE	≈0°/C.C.	Concrete/No	Negligible	C.C.

The six skewed bridges (1a, 1b, 2a, 5, 7, and 10b in Table 1) rotated about the centroid of the bridge superstructure opposite to their respective skew direction or the direction of rotation from a transverse line perpendicular to the bridge centerline to the abutment back wall of the bridge, regardless of the bridge orientation, the magnitude of the skew angle, and the presence of diaphragms. The straight bridges (8 and 11 in Table 1) also rotated counter clockwise. The fact that all but one bridge experienced negligible transverse displacements indicates the rotation effect was dominant in these bridge superstructures with the acute corners (if skewed) of each bridge moving away from their abutments at both ends.

Considering both the skewed and straight bridges, observations can be made on the overall plausible reasons for bridge deck rotation. Skew of bridges is a significant but not necessarily a decisive factor contributing to bridge rotation. The high sensitivity of the rotational vibration mode of the bridge to ground motion, particularly rotational excitations, could be dominant. The fault directivity effect can play a role in the rotation of bridge superstructures since both straight bridges (8 and 11 in Table 1) are approximately oriented along the E-W direction.

As an example, the 2-span Chada overpass as shown in Figure 3 (a) is discussed in detail. The bridge superstructure was displaced significantly during the earthquake. The transverse offset between the deck and abutment seats ranged from 64 cm to 78

cm. The longitudinal gap between the end of girders and the abutment was up to 9 cm. The bottom flange and web of the exterior precast girder that hit the curtain walls at each abutment failed in shear as seen in Figure 3 (a). The failure of the bottom flange is clearly seen in Figure 3 (b). The two curtain walls at the intermediate bent were both damaged as shown in Figure 3 (c). The bridge experienced strong shaking as indicated by the induced gap around columns, Figure 3 (d). No structural damage was observed in the bridge columns.

When curtain walls at the intermediate bent and two abutments are not engaged, the in-plane motion of the bridge superstructure is governed by the mass of the superstructure, stiffness of seismic bars in round shape, and characteristics of ground motions. The period of the rotational mode of vibration is approximately 70% of the period of the two translational modes that are long due to flexible seismic bars used. In this case, the rotational mode of vibration is more sensitive to ground motions than the translational modes. An insignificant degree of eccentricity between the centers of mass and stiffness that likely existed during the earthquake, given the slumping of the abutment fills and duration of shaking would result in significant rotations even under translational ground motions. Once present, the rotational ground motions can amplify the bridge rotations substantially.

Figure 3. Damage to the Chada Bridge.

ROLE OF TRANSVERSE DIAPHRAGMS

The exterior prestressed concrete (PC) girders of the Romero and Chada bridges (7 and 8 in Table 1), which were constructed without diaphragms, experienced out-of-plane block shear failures due to transverse impact loads from shear keys as

illustrated in Figure 4 (a). When partial diaphragms were used between the girders such as in the San Nicholás bridge, the bottom portion of the exterior girder still experienced significant shear cracks as shown in Figure 4 (b). However, with the use of even partial concrete keys between girders as shown in Figure 4 (c), both exterior and interior prestressed concrete girders of the Llacolén bridge suffered no visible damage. This was because the concrete keys provided sufficient lateral restraints on most of the girders, making them work together and share the transverse seismic force. With full diaphragms, the 260-m-long East Ramadillas bridge across the Piteateo River survived the earthquake even though the deck of the bridge was vertically misaligned as a result of liquefaction-induced ground settlements.

(a) Chada bridge with no diaphragms (b) San Nicholás bridge with partial diaphragms

(c) Llacolén bridge with concrete key (d) East Ramadillas bridge with full diaphragm

Figure 4. Damage on exterior prestressed concrete girders.

To illustrate the role of diaphragms, two bridges oriented in the E-W direction at the Independencia/Américo Vespucio site were compared. Built in 2004, the bridge that carries eastbound traffic is a four-span structure with five discontinuous prestressed, precast, girders and a continuous deck. It almost collapsed during the earthquake, experiencing a lateral offset of greater than 0.5 m. The superstructure had steel stoppers but no intermediate or end diaphragms. Both the curtain wall of the abutment and the steel stoppers were significantly damaged. Each stopper was anchored with two bolts that were embedded into the capbeam for a depth of 90 cm.

The westbound bridge is a four-span structure with six discontinuous prestressed precast girders and a continuous deck as shown in Figure 5. Built in 1997, each bent has two flared wall piers. The bridge was designed with both intermediate and end diaphragms, and survived the earthquake with damage limited to concrete shear keys and excessive deformations in the seismic bars. In comparison to the eastbound bridge, the presence of diaphragms seemed to have helped maintain the

structural integrity of the westbound bridge. More importantly, the concrete shear keys likely served their design purpose during the earthquake as opposed to the steel stoppers in the eastbound bridge. For both structures, no visible foundation damage was observed.

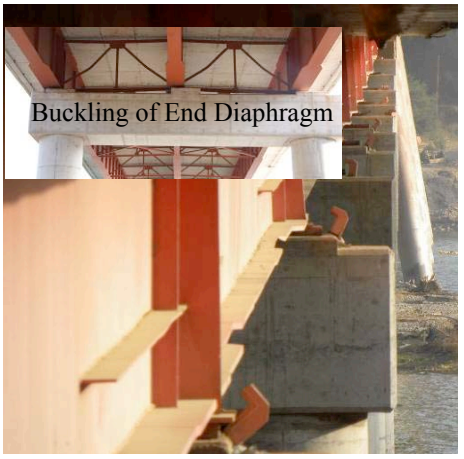
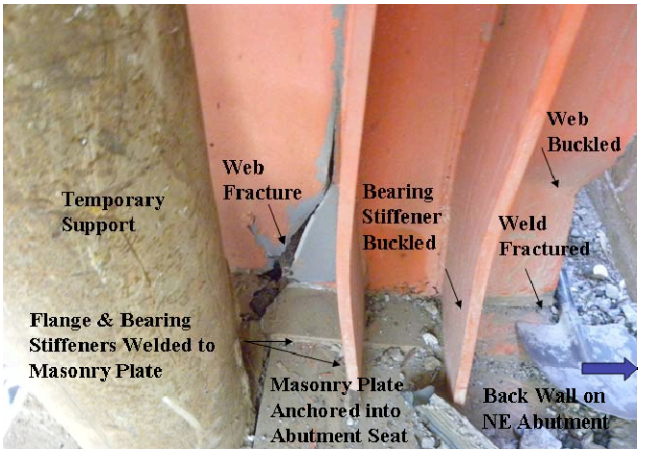
TSUNAMI EFFECTS

The 2010 Chile earthquake induced significant tsunami effects on bridges along the coast roads. Two bridges were inspected in detail for combined earthquake and tsunami effects: the Pichibudis bridge and Cardenal Raúl Silva Henŕiquez bridge. The second bridge is a river-crossing multi-span structure that suffered significant damage as discussed below. The nine spans of the SW portion of the bridge are supported on tall, steel pile bents as shown in Figure 6 (a). The legs of these bents are fabricated from 1.5 m diameter tubes with a wall thickness of 14 mm. Their overall height from pile tip to soffit ranges from 44.5 to 51.5 m. The maximum clear height above the water is about 25 m. This portion of the structure appeared to have performed relatively well during the earthquake compared to the NE portion, but suffered local damage at several locations due to tsunami effects. Four major waves were recorded near Constitución with arrival times ranging from 3:50 am to 5:20 am after the mainshock. Wave heights ranged from 6.9 to 11.2 m passing under the superstructure. Nevertheless these waves eroded river sands and gravels from around the piles, Figure 6 (b), to a depth of about 4.5 m, and wave-borne debris punctured a hole in the wall of one of the steel legs as shown in Figure 6 (c) (Courtesy of the Ministerio de Obras Públicas de Chile or MOP).



(a) Southern spans and pile bents (b) Erosion of alluvial materials (c) Debris impact

Figure 6. Damage to the Cardenal Raúl Henŕiquez Bridge (MOP).



EFFECTS OF THE NUMBER OF JOINTS AND JOINT DETAIL

Built in 2002, the Cardenal Raúl Silva Henŕiquez bridge is a 22-span, steel-girder structure crossing the Maule River near Constitución in the NE-SW direction. It is supported by two seat-type abutments and twenty-one intermediate bents. The first five bents from the NE abutment are supported on two RC columns and drilled shafts. The next six bents are supported on three RC columns and drilled shafts. The following eight bents are steel pile bents with three legs (one vertical and two inclined) with horizontal struts and diagonal braces interconnecting the legs in each bent, as illustrated in Figure 6 (a). The last two bents are supported on three RC columns that rest on footings. The superstructure comprises two continuous segments, each being 11 spans long. Fixed and expansion joints were designed at two abutments and at the middle of the bridge over bent 11, respectively. At each abutment, the bottom flanges of the three girders are welded to masonry plates embedded in the abutment seat. An elastomeric pad is provided over each intermediate bent to permit longitudinal movement. Transverse and vertical movements were restrained by steel stoppers, as shown in Figure 7 (a).

During the earthquake, the NE portion of the bridge moved transversely from west to east as shown in Figure 7 (a). All steel stoppers were deformed and girders were displaced from their elastomeric pads, resulting in the web and flange bending of the exterior girder about its weak axis at the NE abutment, as shown in Figure 7 (d). The transverse diaphragms at the intermediate bents and abutments buckled as shown in Figure 7 (a, c). At the NE abutment, the webs and bottom flanges were fractured in all three steel girders, and both bearing stiffener and web buckled as shown in Figure 7 (b). This type of damage is indicative of large longitudinal loads in the superstructure being attracted to the fixed bearing at the abutment. The weld detail at the abutment transferred the longitudinal loads into a significant bending moment, locally causing stress concentrations in the steel girders at the end of their supporting masonry plates. Note that the weld between the girders and the masonry plate did not fail. As shown in Figure 7 (d), due to severe damage in the web and flange of girders, a steel beam was used to temporarily transfer loads from the flange to the abutment seat bypassing the web of the girders.

(a) Girder offset and cross frame buckling

(b) Girder damage at north abutment

(c) Crossframe buckling (d) Temporary repair at NE abutment

Figure 7. Superstructure damage at the NE portion.

Although similar in connection details, the girders at the SW abutment were subjected to less damage than that at the NE abutment, limited to the buckling of the bearing stiffeners. The reason for this difference is probably due to the fact that the fillet welds connecting the girder flanges and bearing stiffeners to the masonry plates failed during the earthquake and large longitudinal loads were not attracted to this abutment, as shown in Figure 8 (Courtesy of MOP).

(a) The girder end (b) The transverse stiffeners

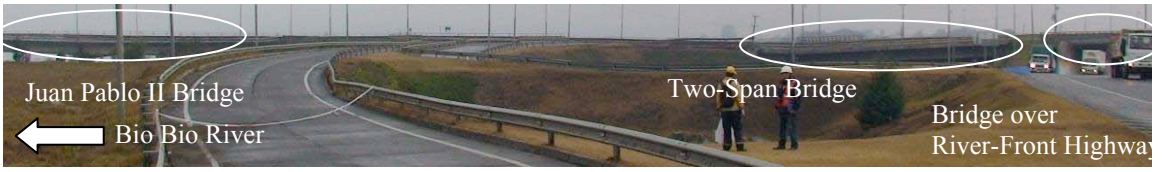
Figure 8. Damage at the SW abutment (MOP).

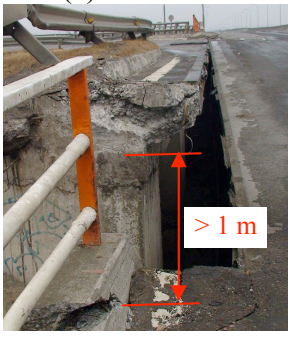
LIQUEFACTION-INDUCED LATERAL MOVEMENT AND SETTLEMENT

Liquefaction occurred in 15 out of 32 sites as indicated by surficial features such as sand boils. However, displacement of bridge foundations and columns due to lateral movement occurred only at a few liquefied sites, mainly along the Bio-Bio River. The NE side of the river experienced most of the liquefaction induced slope failures and structural damages. Although liquefied as well, the SW side of the river experienced little or no structural problems due to the flat ground conditions.

The Juan Pablo II Bridge is a crossing link over the Bio Bio River in Concepción and is oriented in the NE-SW direction. Built in 1973, the NE approaches to this bridge are part of an interchange that provides access to the bridge from a river-front highway as shown in Figure 9. In addition to on- and off-ramps, the

interchange comprises a 2-span approach structure, and a 2-span highway overpass as indicated in Figure 9. Each bridge superstructure consists of seven discontinuous prestressed precast girders and a continuous deck. The main river-crossing bridge is a multi-span structure supported on 18 m deep hand excavated caissons. The SW approach, built on elevated fills, suffered no damage.





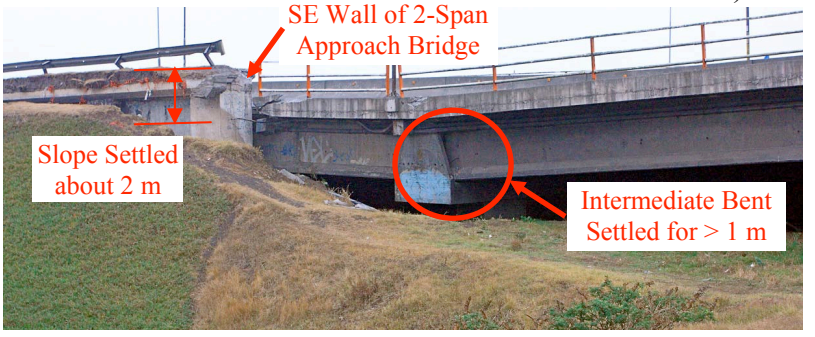


Figure 9 NE approaches to the Juan Pablo II Bridge.

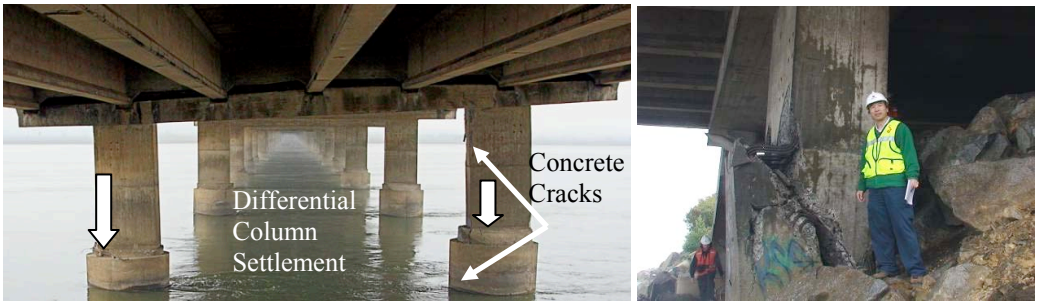
Whereas the river-front overpass was generally undamaged, the 2-span approach structure was damaged both globally and locally at the intermediate bent as shown in Figure 10 and Figure 11. It is clearly seen in Figure 10 that the intermediate bent has settled for over 1 m with respect to the two end bents, leading to a substantial depression in the roadway surface. However, the wall at the SE corner of the approach structure settled little though the surrounding slope settled about 2 m. Supported on drilled shafts, the wall seemed to be newer than the approach structure, probably built with more stringent foundation design requirements together with the NE off-ramp on approach fills that suffered no damage during the earthquake.

(a) Overall settlement of the Juan Pablo II Bridge (facing the Bio Bio River)

(b) SE wall of approach spans (c) Intermediate bent settlement of approach spans

Figure 10 Uneven settlement of the Juan Pablo II Bridge.

As indicated in Figure 11 (a, b), the intermediate bent comprises two rectangular columns which experienced uneven, liquefaction-induced, settlement during the earthquake. The consequential change in stiffness between the two columns shifted the longitudinal seismic force from one to the other column which then failed in



shear as shown in Figure 11 (b). The transverse reinforcement of the failed column was spaced at 46 cm. It is noted that the ground further settled against the undamaged column and the cap-beam above the undamaged column experienced cracking.

The spans of the main bridge also have experienced uneven support settlement as shown in Figure 10 (a), which then tilted the columns and rotated the bridge deck about the centerline of the bridge as seen in Figure 12 (a). In addition, lateral spreading of the NE bank attempted to move the columns of the bent at this position towards the river. But this movement was restrained by the superstructure and the columns were consequently placed in single shear. One failed catastrophically in shear as shown in Figure 12 (b) and the other was seriously damaged. The difference in behavior between the two columns might be due to the uneven settlement and rotation of the bridge deck. The longitudinal movement of the first column (upstream side) was approximately 56 cm at the top of the shear plane and 41 cm at the bottom. While the bridge did not collapse due to severe differential settlements and lateral slope movements, it was seriously damaged and closed to traffic.

IMPLICATIONS TO BRIDGE DESIGN

The long-duration and multi-pulse features of the Chile earthquake ground motions can generally affect the inelastic behavior and progressive collapse mechanism of bridges. The rotational component of ground motions is critical to the design of bridges with sensitive rotational modes of vibration. The Chile earthquake-induced tsunami generated significant waves and currents that added both

horizontal and vertical loads on bridges and caused the erosion of soils around the bridge foundations. The additional loads can further stress a bridge that can be damaged by the earthquake, leading to the collapse of the structure. The scour effect on the stability of bridge foundations is a direct threat to the safety of transportation networks as indicated by the past 40 years of bridge operation in the United States. Although scour design provisions are included both in the Chilean and US Bridge Design Specifications, the combined earthquake and scour effects are not considered in design.

Concrete keys on the top of cap-beams can be a good alternative to cross diaphragms between bridge girders to distribute seismic loads among the girders. They can effectively prevent girders from shear failure by reducing the maximum load on individual girders. Such an alternative goes well with an accelerated bridge construction strategy using precast/ prestressed concrete girders. In addition, it provides a new dimension of managing the load path and energy dissipation together with shear keys so that a cost-effective design can be made to ensure that bridge foundations are subjected to little or no damage. A trade-off should be made between the redundancy of a bridge and the number of joints in the bridge superstructure in order to achieve a cost-effective design of the bridge. As the number of joints decreases, the connection detail at the joints becomes more critical in design.

As clearly reminded by the Chile earthquake, liquefaction-induced foundation settlement and lateral movement is one of the main reasons for the brittle shear failure of columns. Appropriate mitigation methods should be adopted in bridge design to minimize the effects of ground and slope failures on bridges.

ACKNOWLEDGMENTS

Financial support for the post-earthquake reconnaissance trip to Chile was mainly provided by the U.S. Federal Highway Administration with Sheila Duwadi serving as point of contact for the U.S. team members. The last author would like to acknowledge the financial support by Earthquake Engineering Research Institute. The findings and opinions expressed in this paper are those of the authors only; they do not necessarily reflect those of the sponsors. Special thanks are due to José Miguel Ortega for his support and coordination with local authorities to make the reconnaissance trip a success, Mauricio Guzmán and Sandra Achurra for their escort and introduction to various bridge sites visited by the reconnaissance team, Alex Union Villarroel for his post-trip assistances, and Rodrigo Oviedo for his participation throughout the reconnaissance trip.

ABSTRACT

The earthquake that shook the island of Hispaniola on January 12, 2010 devastated Haiti. The resulting damage was widespread due to the construction methods, poor material quality and lack of rigorous design procedures. Post-event reconnaissance has brought to light deficiencies in all these areas. Construction, especially residential, is typically completed by the building owner who may or may not have the necessary skills to design or build safe structures. Very few structures are designed by an engineering professional. The two most common construction materials are masonry block and reinforced concrete. Building response to the ground shaking is demonstrated through damage surveys in downtown Port-au-Prince and Leogane and specific case studies generated through reconnaissance efforts which highlight the infrastructure problems which led to the deadly structural performance.

INTRODUCTION

In the late afternoon of January 12, 2010 an earthquake struck the eastern portion of the island of Hispaniola. The epicenter was located at 18.443°N latitude, 72.571°W longitude, 15 miles southwest of the largest population center in Haiti, Port-au-Prince (USGS, 2010). Several other population centers were also severely affected. According to official estimates reported by the USGS, 222,570 were killed, 300,000 injured and 1.3 million displaced (USGS, 2010). The damage to Haitian infrastructure was severe. The primary port, the power grid and the availability of clean water were nearly completely disabled. The effect from the initial shock was compounded by the significant number and magnitude of aftershocks. People were scared to live in homes that were undamaged or lightly damaged due to the aftershocks and the observed collapses of similar homes. The Haitian people were completely unprepared for this natural hazard.

While the citizens and the infrastructure of Haiti were not ready for a major earthquake, Hispaniola has a history of significant seismicity. The island is on the boundary of the Caribbean and North American tectonic plates. On the western half of the island, two faults capable of producing M_W 7 or greater earthquakes have been identified. The southern section of the east-west fault system in eastern Hispaniola responsible for the recent event has not produced a severe event since 1860. Prior to

that, Port-au-Prince was destroyed in 1751 and 1770 by significant earthquakes thought to be generated by the same fault (USGS, 2010). Due to the long period of inactivity, the government and the citizens of Haiti were not aware of the possibility of significant earthquakes. Haitians are accustomed to significant natural disasters in the form of hurricanes. Four major storms hit the island in 2008. Given the known hurricane hazard, it would be expected that some kind of building code would exist for safety. However, this is not the case. Haiti has no building code, no inspection process, and limited engineering practice.

The most prevalent building type in Haiti, particularly in the Port-au-Prince region, consists of non-engineered, lightly reinforced concrete frame structures with concrete masonry block infill. These low rise buildings are used for single family dwellings and small businesses. Large openings for windows and reduced wall area are very common and contributed to numerous floor collapses, both at the ground level and at singular floor levels above. These building are typically one or two stories, though three or four stories is not uncommon. Floors and roofs are reinforced concrete slabs, typically four to eight inches thick with a single layer of bi-directional reinforcement. Concrete blocks are commonly cast into the slab to minimize the use of concrete. Corrugated steel over a sparse wood or steel truss is also common roof system. Many residences are constructed over a long time period, as the homeowner acquires funds or the family's needs expand. Most are designed and constructed by the owner or a local mason.

When these building types are excited during an earthquake, initially lateral load is resisted by the combination of the reinforced concrete frame and the infill walls. Because the walls are typically not load-bearing their strength capacity is reduced because of a lack of friction development between the masonry units. Due to the lack of reinforcing, the infill walls have no ductility and therefore once cracked become non-structural mass. Following infill cracking, the concrete frame is left as the sole lateral resisting element. Interaction between wall panels and columns results in localized damage, notably in the columns. Lateral capacity of the slender columns was generally insufficient to resist acceleration demands on the structure. P-delta effects ensued, proliferating collapse. Toppling and out of plane failures of wall panels were commonplace and a primary driver many complete structural collapses. Even when they didn't contribute to collapse, these out-of-plane wall failures caused innumerable injuries and deaths.

More detailed presentations of the damage incurred by the earthquake can be found in the many reports from the different reconnaissance teams (Eberhard et al., 2010; EERI, 2010a; EERI 2010b; Fierro and Perry, 2010). The significant damage that occurred was due to the lack of engineering design, substandard and uncontrolled construction, and poor material quality. The lack of resources applied to civil infrastructure and citizen education to prepare for the eventuality of an earthquake are evident in the post-event response. The damage that occurred will be presented in the form of local damage surveys and four case studies. Local surveys completed on the ground in downtown Port-au-Prince and Leogane provide approximations of the percentage of collapsed structures. The surveys were accomplished using photos taken along a route and pre- and post-event satellite imagery to determine the number

of structures in existence prior to the event. The four case studies highlight the different flaws in Haitian buildings.

DAMAGE SURVEYS

The route in downtown Port-au-Prince is shown in Figure 1. The path was rectangular with a long side of 1200 ft and a short side of 350 ft. The Presidential Palace can be seen in the bottom right of Figure 1. The total number of structures along the path was estimated to be 107. Of those structures, 30 were classified as collapsed or severely damaged. The red pushpins show the location of the 30 structures.

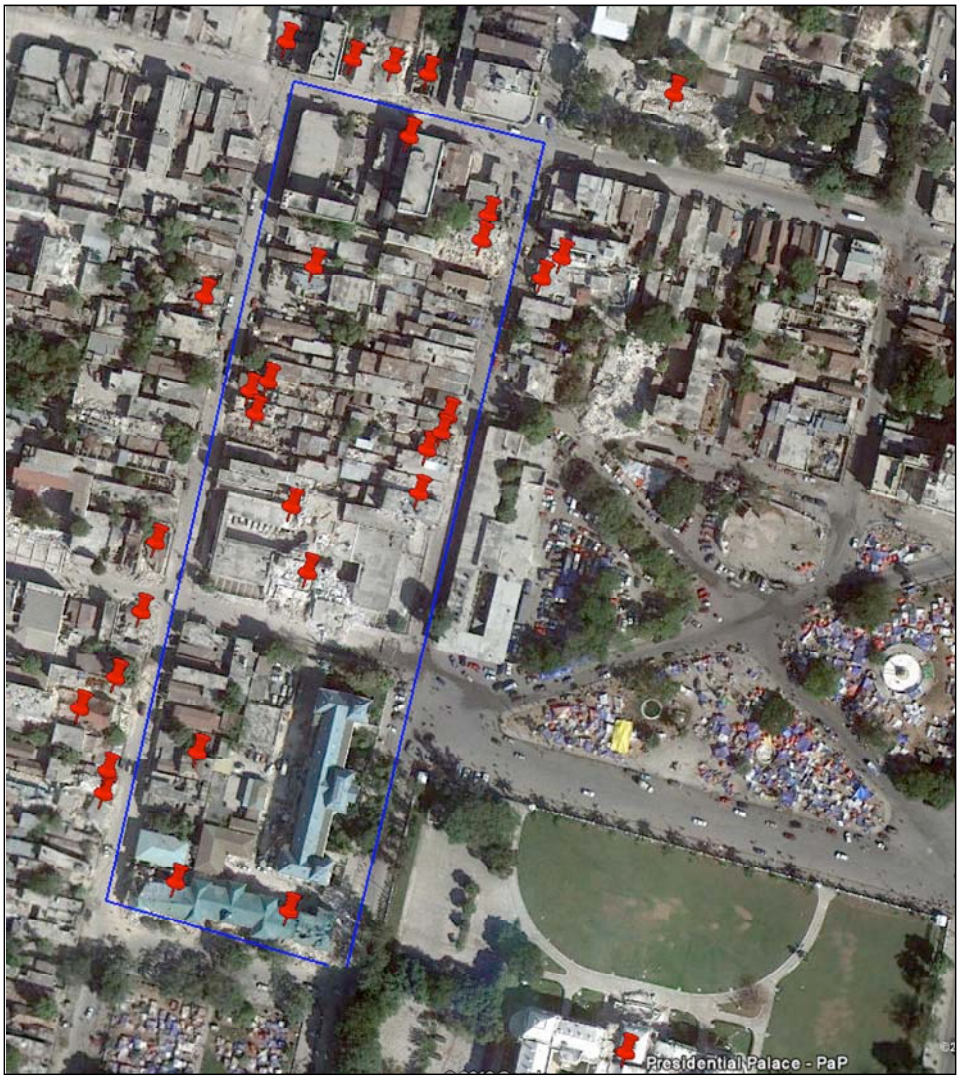

Figure 1 – Damage Survey Route in Downtown Port-au-Prince

A similar survey was completed in Leogane which is 7 miles from the epicenter having a population of approximately 80,000 (CityPopulation, 2010). Due to the epicenter proximity, the percentage of collapsed structures is higher. There could also be differences due to soil conditions which has not been accurately determined. The survey route in Leogane is shown in Figure 2. The route was L-shaped with a long

side of approximately 1200 ft and a short side of 360 ft. The total number of structures was more difficult to estimate due to the amount of damage. Fifty-two total structures were estimated from the photos and overhead imagery. Only four were classified as undamaged. These are shown with green pushpins in Figure 2. The number of collapsed or partially collapsed structures was approximated at 32 which results in a collapse ratio of 68%. This high collapse percentage may be an anomaly. However, compared with reconnaissance in other areas, Leogane was more severely impacted. A residential neighborhood about 4 miles from downtown Leogane experienced significant damage. Although the collapse rate was not as high, a very high percentage of structures were severely damaged.

Figure 2 – Damage Survey Route in Leogane

CASE STUDIES

A series of case studies is presented here to highlight the causes and effects of Haiti's fragile infrastructure. Each case study emphasizes a different flaw in the materials, planning, construction or engineering which resulted in failure.

UNIH UNIVERSITY BUILDING

The UNIH University Building sits alone along Highway 2 about 3.75 miles east of the center of Leogane. This building had not been completed at the time of the earthquake. Prior to the event it was three stories tall with column reinforcing steel protruding from the top deck in preparation for a fourth floor. There did not appear to be any signs of recent construction activity at the site indicating that the project may have stalled. While the concrete frames in each direction of this building were completed for the first three floors, it still suffered catastrophic total collapse. The building was relatively simple and repetitive in plan measuring approximately 61 ft

wide (three 16.5 ft bays with a 5.75 ft cantilever at each end) x 158 ft long (nine 16.25 ft bays with a 5.75 ft cantilever at each end). Measurements were taken of both the concrete and reinforcing steel elements to try to determine the design of the building. The damage was severe enough to expose both the column and beam steel at the lowest level of the building.

The structural floor framing included a grid of 10 in. x 14 in. beams in each direction supporting a 5 in. thick slab. The in. beams were reinforced with three #5 bars top and bottom and #2 stirrups at 9 in. on center. The #5 bars were hooked at the ends of the beam with 90 degree bends and only a 3 in. hook length, substantially shorter than the 10 in. required by ACI. The typical columns were only 10 in. x 10 in. in plan and were estimated to be approximately 12 ft tall. Typical interior column reinforcement included four #5 vertical bars and #2 column ties at 9 in. on center. Typical corner column reinforcement included four #4 vertical bars and #2 column ties at 8 in. on center. In some of the columns, both the vertical and tie reinforcement consisted of smooth bars. Typical column ties had non-seismic 90 degree hooks in lieu of 135 degree hooks required by ACI in seismic regions. The reinforcing steel for both the columns and beams was fairly minimal. The only concrete masonry wall debris observed was on the back (north side) of the building and may have still been a work in progress. An ETABS (CSI, 2007) analysis model of the building indicated that the structural frame would work for gravity loads but would be highly overstressed for lateral seismic loads. The demand-to-capacity ratios assuming 3,000 psi concrete under gravity load only range from 0.64 at the corners to 1.03 at the interior columns. Under lateral loads, the same ratios range from 4.5 at the corners up to 7.3 at the exterior columns on the short side indicating a complete lack of design for lateral loads. Figures 3 and 4 show photos taken during the reconnaissance showing the collapsed structure and the exposed construction details. This case study highlights the fact that for a structure as important as a university building, rigorous design procedures including potential seismic loads was not utilized to ensure safety.

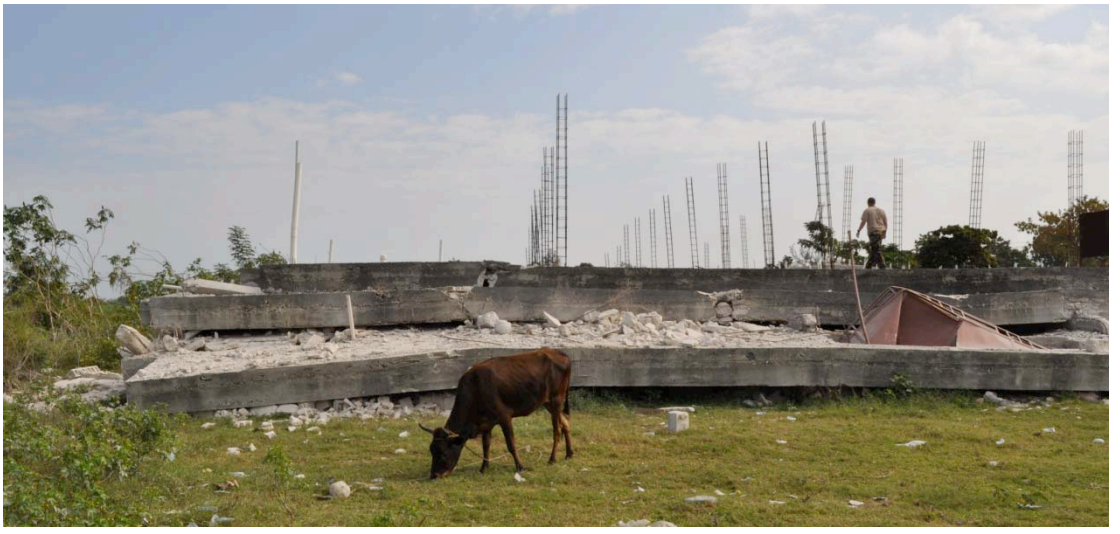

Figure 3 – Pancake Collapse of UNIH Building

Figure 4 – Exposed Connection Details of UNIH Building

"ENGINEERED" SCHOOL BUILDING

There were examples of buildings engineered to U.S. building codes, most noticeably the U.S. Embassy compound which received no permanent damage. The only damage seen in the embassy itself was displaced ceiling tiles and popped rubber seals on a few windows. This would be an example of a building designed and constructed in accordance with the most current and highest level of seismic requirements. Another example of a seismically resistant design is a three-story reinforced concrete frame school building with construction drawings indicating design in accordance with ACI Standard 318-89. The drawings included well detailed frame elevations indicating seismic detailing. The details included tight tie spacing in hinge zones, continuity of beam reinforcing (both top and bottom steel), and code compliant column vertical reinforcing. The drawings also indicated details for isolating CMU partition walls from the concrete frames to ensure ductile behavior and limit masonry cracking. There was however damage in the columns, typically in the middle third, and throughout much of the CMU partition walls. A majority of this damage appeared to be the result of poor quality control in the concrete and masonry materials and lack of inspection needed to ensure conformance to the details specified in the construction documents. Two notable discrepancies were column ties that did not match the seismic ties indicated in the drawings (90 degree versus 135 degree hooks) and CMU partition walls that were not isolated from the frames. Figure 5 shows the damage that occurred which highlights the lack of attention to the details during construction. This study illustrates the need for building officials to ensure the as-built structure conforms to the well-detailed design documents.

Figure 5 – Improper Reinforcing Tie Details

HANDS TOGETHER SCHOOLS

Many buildings in Haiti are combinations of multiple structures of different shapes, roof heights and number of stories. This results from the economic necessity to use existing structures as support for or components of new buildings. This method can be effective and efficient if the appropriate construction details and structural designs are implemented to account for the additional forces on the existing structural elements and dynamic differences between building sections. This could be accomplished through strengthening or by providing seismic expansion joints to allow the two sections to respond at the individual fundamental frequencies. The typical practice in Haiti is to use the wall of an existing structure as a wall for a new structure thereby reducing construction costs. This practice was commonly observed during reconnaissance missions. The post-event detailed structural inspection of eight school sites and one medical clinic run by Hands Together, a nonprofit organization based in the United States, provided multiple examples of this behavior. All of the Hands Together sites are in Cite Soleil.

The St Francois compound, located at 18.5871^{o} north 72.3276^{o} west, is a high school complex. It consists of six buildings, many of which are connected to one or more adjacent structures. A high resolution Google Earth image of the compound is shown in Figure 6. The letters shown in the figure are used to reference the different structures. All the campus buildings are constructed of reinforced concrete frames with masonry infill. Building A is a two-story classroom structure. It experienced very limited damage during the earthquake in the form of masonry wall cracking and damage to the stairway leading to the second story. It is the only structure that is not connected to any other building. Building B is a classroom building. The first two

stories are enclosed while the third floor is a covered patio supported by reinforced concrete columns and a half-height masonry wall. Building B itself experienced some wall cracking. The most significant damage occurred in the stairwell which connects buildings B and D at the second and third story. The damage to the second floor slab is visible from above in Figure 6. Due to the difference in orientation of buildings B and D, the stairwell became the fuse element between the two structures and was severely damaged during the ground motion (See Figure 7).

Figure 6 – Aerial Image of Saint Francois School Compound

Building C, the newest in the complex, is a two-story classroom building. Future expansion upwards is expected as reinforcing cages above the roof slab were installed showing the low level of reinforcing in the frame elements. The building was minimally damaged in the form of cracked masonry around the windows and doors. The only severe damage was at the interface with buildings C and D. Building D is the largest building on the complex. The bottom two stories are enclosed classrooms. The top floor is a covered patio with reinforced concrete columns. It is attached at both ends to the adjacent structures. This was the most seriously damaged building in the complex. It was damaged at both interfaces with adjacent structures. The large difference in plan dimensions resulted in full depth slab cracking at the interface between buildings D and E. Building D also experienced significant cracking of masonry walls and serious damage to the reinforced concrete columns and beams supporting the third floor timber trussed roof. Some of this damage was due to the elimination of every other block just below the slab to allow for lighting into the class rooms. This resulted in early fracture of the single blocks which then transferred the load to other internal walls which also had large voids. Buildings E and F experienced

minimal damage with the exception of the previously mentioned damage at the joint between D and E. Overall, the compound performed well. Had the structures not been linked together or been linked to account for movement, the most significant damage could have been avoided.

Figure 7 – Damage to Stairwell Between Buildings B and D

This case study as well as many other examples of this type of performance are prevalent in Haiti. A medical clinic located in the same region had a single story addition supported on the walls of an existing two-story structure. The single story separated from the two-story structure during the ground shaking, leaving the roof very close to collapse. Sainte Anne's elementary school was another case where the common wall of two different buildings experienced severe cracking due to different plan geometries and an offset in roof height. The practice of building onto existing buildings without considering transfer forces or providing a movement joint resulted in a significant amount of damage. In these cases, it was not fatal, however the repair costs are significantly higher due to the added damage and there are likely cases where this type of behavior was fatal.

PRE-ENGINEERED METAL BUILDINGS

Most industrial or warehouse buildings in Haiti are constructed of long span steel trusses supported on masonry infilled reinforced concrete frame walls. In the United States many of these buildings would be pre-engineered metal buildings (PEMB). Due to the cost and availability of steel in Haiti, they were the exception. The typical construction of PEMBs in Haiti utilized a masonry façade. During reconnaissance efforts, several PEMBs were encountered and the damage to each of them was similar. The masonry façade failed while the primary structural framework was

undamaged. Photos of this failure are shown in Figures 8, 9 and 10. Figures 8 and 9 are pictures of a retail building located across the street from the U.S. Embassy. All five of the front sections detached from the framing although some of them had not fallen. The building is being repaired and the masonry exterior walls are being replaced by insulated metal sheathing. This upgrade will make this structure much more resilient for future events. This out of plane failure of the masonry on the gable end of PEMBs was common on nearly all metal buildings seen during the reconnaissance. Figure 10 shows wind girts attached to a masonry that were damaged during the event by out of plane wall action. The building shown in Figure 10 also experienced the out of plane wall failure on the gable end wall. PEMBs in Haiti did not experience dramatic structural failure with the exception of the warehouse building at the Port-au-Prince port which failed due to significant lateral spreading between the foundations. The consistent failure mechanism of the masonry façade highlights the fact that even with a pre-designed, resilient structural system, not having an engineering professional design all aspects of a structure and including proper detailing for attachment of non-structural components can result in dramatic failure with the potential for significant fatalities.

Figure 8 – Masonry Wall Failure of Retail Metal Building

Figure 9 – Retail Complex Across from U.S. Embassy

Figure 10 – Damaged Wind Girts in Pre-Engineered Metal Building

CONCLUSION

Haitian infrastructure was completely unprepared for the earthquake which struck on January 12, 2010. With rare exception, buildings are not planned, designed or constructed with the necessary detailing to survive significant seismic events. While some buildings may have been designed, the necessary channels are not in place to verify compliance during construction. The damage surveys and case studies presented here highlight many of these deficiencies. In order to avert a disaster of this magnitude in the future, the people of Haiti need to be instructed in the proper

material quality, planning, design and construction of all infrastructure, especially during recovery and rebuilding from this event.

ACKNOWLEDGEMENTS

Numerous individuals and organizations contributed to the work presented in this paper. The reconnaissance efforts were funded by the Earthquake Engineering Research Institute's Learning From Earthquakes program (funded by the National Science Foundation), the Applied Technology Council, and the United States Geologic Service. Invaluable assistance in country was provided by United States Southern Command (SOUTHCOM); the soldiers, marines, sailors and airmen of Joint Task Force Haiti; the U.S. Embassy; and the U.S. Agency for International Development.

February 27, 2010 Chile Earthquake: Preliminary Observations on Structural Performance and Implications for U.S. Building Codes and Standards

John W. Wallace[1]

[1] Ph.D., P.E., M. ASCE, University of California, Los Angeles, Department of Civil & Environmental Engineering, 5731 Boelter Hall, Los Angeles, California, 90095-1593 USA, (PH) (310) 206-7124; FAX (310) 206-2222; email: wallacej@ucla.edu

ABSTRACT

Performance of reinforced concrete buildings in Viña del Mar, Chile following the M7.8 1985 earthquake led to changes to the Uniform Building Code (UBC-94) and the American Concrete Institute Code for design of reinforced concrete buildings (ACI 318-99). In 1996, Chile adopted, with minor modifications, the ACI 318-95 Code. Reinforced concrete buildings are the predominant form of construction in Chile for buildings over four stories. Over the last 10 to 15 years, a construction boom similar to that in the US and other countries resulted in the construction of a substantial number of new buildings. Thus, the Feb. 27, 2010 earthquake provides a unique opportunity to assess the performance of modern reinforced concrete buildings designed using modern codes similar to those used in the US. Preliminary observations on building performance and the potential impact on US codes and practices, particularly with respect to ACI 318 seismic provisions, is presented.

Keywords: Shear wall; Wall; Chile; earthquake, 2010, reconnaissance; damage, code;

1. Introduction

On March 3, 1985, a strong earthquake of surface magnitude 7.8 occurred near the central coast of Chile (EERI, 1986). Approximately 400 modern, reinforced concrete buildings, designed for lateral forces comparable to those used in the highest seismic risk regions of the United States, were subjected to the strong shaking. Reconnaissance reports (EERI, 1986) and subsequent studies (Wallace and Moehle, 1989) indicated that the stiff, shear wall structures constructed in Chile performed extremely well, with little to no apparent damage in the majority of buildings. Later investigations (Wallace and Moehle, 1992, 1993) revealed that although the seismic code requirements (design forces) in Chile were similar to those used for high seismic risk regions in the U.S., detailing requirements were less stringent.

Research following the March 3, 1985 M7.8 earthquake near the central coast of Chile (EERI, 1986; Wallace and Moehle, 1992, 1993) led to significant U. S. code changes for reinforced concrete shear wall buildings in both the Uniform Building Code (Wallace, 1996) and eventually the ACI building Code (Wallace and Orakcal, 2002). Prior code provisions (ACI 318-95) for shear walls, based on simple elastic modeling, were considered easy to use; however, they typically resulted in

excessively conservative assessment of the need for confined boundary regions for most walls. In addition, the required boundary transverse reinforcement typically was required to be extended over a significant height of the wall, which some engineers consider unnecessary. There also were concerns that the procedure lead to excessive flexural over-strength, which could lead to high demands in wall shear, as well as diaphragm and foundation forces.

The UBC-94/97 provisions were developed to address some of the perceived shortcomings of ACI 318-95 (and early versions, since the provisions for shear walls remained essentially the same from ACI 318-83 through ACI 318-95). Provisions in UBC-97 addressed issues for flanged walls and provided a detailed approach for assessing requirements for transverse reinforcement at the boundaries of cantilever walls. Although the provisions for assessing detailing at wall boundaries were quite elaborate, some issues were not addressed, such as the need to check the flexural strength distribution over the height of the wall and detailing requirements for walls that satisfy UBC-97 triggers where no special transverse reinforcement was required. Also, by eliminating the 318-95 approach in UBC-97, there were many cases of irregular walls where the UBC-97 provisions did not apply, yet no design guidance was given.

The ACI 318-99 provisions were introduced to address concerns with ACI 318-95 and UBC-97. The provisions retained the displacement-based approach introduced into UBC-94 but also retained the basic approach of ACI 318-95 to provide an alternative (and simple and familiar) approach, as well as to address cases that do not conform to the geometric limitations and assumptions associated with a displacement-based design approach. To accommodate concerns related to flexural over-strength, changes were introduced to require that wall design for flexure and axial forces be based on section analysis identical to that used for column cross sections. Use of this approach encouraged the engineer to include the entire wall cross section to resist gravity loads and overturning moments rather than concentrating the design resistance in the boundary elements.

In 1996, Chile adopted a new code for design of reinforced concrete buildings based on ACI 318-95 (NCh 433.Of96). The provisions for shear walls are essentially the same as those in ACI 318-95; however, based on the good performance of wall buildings in Viña del Mar in the 1985 earthquake, the Chileans eliminated the ACI 318-95 provisions requiring (in most cases) special transverse reinforcement at wall boundaries to confine the concrete and restrain rebar bucking.

From 1995 through 2010, a construction boom similar to that in the US and other countries resulted in the construction of a substantial number of new buildings designed to the new Chile Code. Over this same period, Chilean engineers were discarding the rather simple and conservative design approaches used to design pre-1985 buildings and introducing design based on computer modeling using programs such as ETABS. The introduction of computer design approaches generally led to the use of fewer and/or thinner walls; building heights were generally increasing from the 10-15 stories common for pre-1985 buildings to 15-25 stories.

Given this history, the Feb. 27, 2010 M_w 8.8 earthquake provides a unique opportunity to assess the performance of modern reinforced concrete buildings designed using modern codes similar to those used in the US. Preliminary

observations (EERI Newsletter) indicate relatively few people lost their life in modern reinforced concrete buildings; however, the degree of damage significantly exceeded that reported following the 1985 earthquake. Preliminary findings are presented in the following sections to assess potential reasons for the observed damage as well as to assess areas where changes are needed to U.S. code requirements.

Recorded Ground Motions

General information related to the intensity of the recorded ground motions in Chile were reported by University of Chile researchers (Boroschek et al, 2010); however, digitized records still have not been released. Therefore, at this time, only general observations are included here.

Plots of recorded ground acceleration and response spectra for Viña del Mar indicate that the peak ground acceleration, duration of shaking, and spectral amplitudes were similar for the 1985 and 2010 earthquakes. It is noted that the spectral displacement demands increase essentially linearly to a peak value of about 15 cm for periods between 0.0 and 1.0 sec, but remain roughly constant for larger periods. This same trend was observed for displacement spectra computed from ground accelerations recorded in the 1985 earthquake. Therefore, spectral displacement demands do not increase for buildings greater than approximately 15 stories, since the cracked fundamental period of buildings in Chile can be approximated as $T_1 = N/15$, where N is the number of stories. Despite the similarities in demands between 1985 and 2010, substantially more damage was observed in Viña del Mar following the 2010 earthquake, particularly in newer buildings.

Displacement spectra for a record obtained in Concepción, Chile are presented in Figure 1. The spectra indicate that spectral displacement demands near the epicenter where significantly greater than recorded in Viña del Mar (represented with an approximately bilinear relation) and that very large demands are observed for periods between 1.5 and 3.0 seconds. Larger displacement demands produce larger local demands (strain, curvature) at critical wall sections, typically near the wall base; one possible reason for observed damage in the large percentage $(\approx 10\%)$ of buildings greater than 10 stories in Concepción.

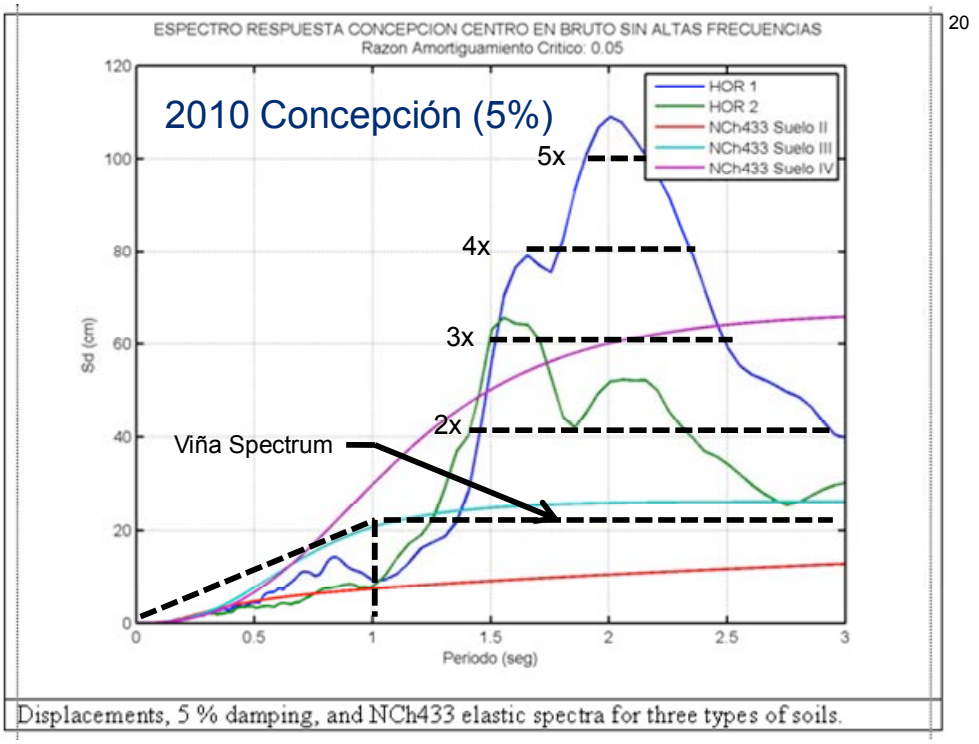

Figure 1 Displacement spectra – Concepción

Typical Construction

A floor plan of a typical pre-1985 Chile building is shown in Figure 2(a). The ratio of wall cross sectional area to building floor plan area $\left(A_w/A_f\right)$ is approximately 3% in each direction (Wood et al, 1987; Wallace and Moehle, 1993). It is also noted that typical wall thicknesses over the first four stories are 20 to 30 cm, with more prominent walls being 30 cm. Very few beams are used. The relatively large ratios of A_w/A_f were identified (Wallace and Moehle, 1992, 1993; Wallace 1994, 1995) as a primary reason for the excellent performance of buildings in the 1985 earthquake. For post-1985 buildings, the ratio of wall cross sectional area to building floor plan area in each direction tends to be considerably less, on the order of 1.0 to 1.5%, because fewer and thinner walls are typically used. As well, the walls are typically arranged with a central corridor in one direction and multiple transverse walls (Figure 2(b)). Wall thickness of 15 to 20cm is common, even for buildings from 10 to 20 stories.

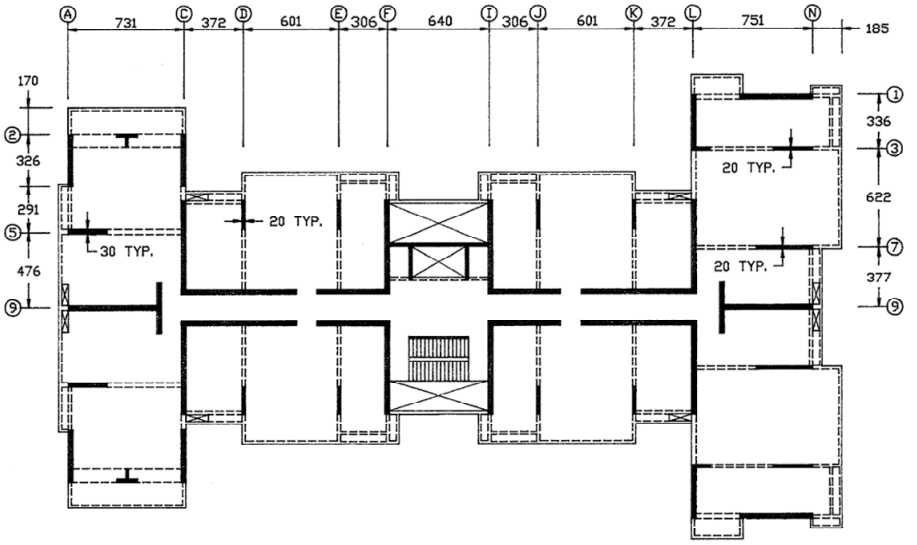

Figure 2(a) Festival Building in Viña del Mar (1978 construction)

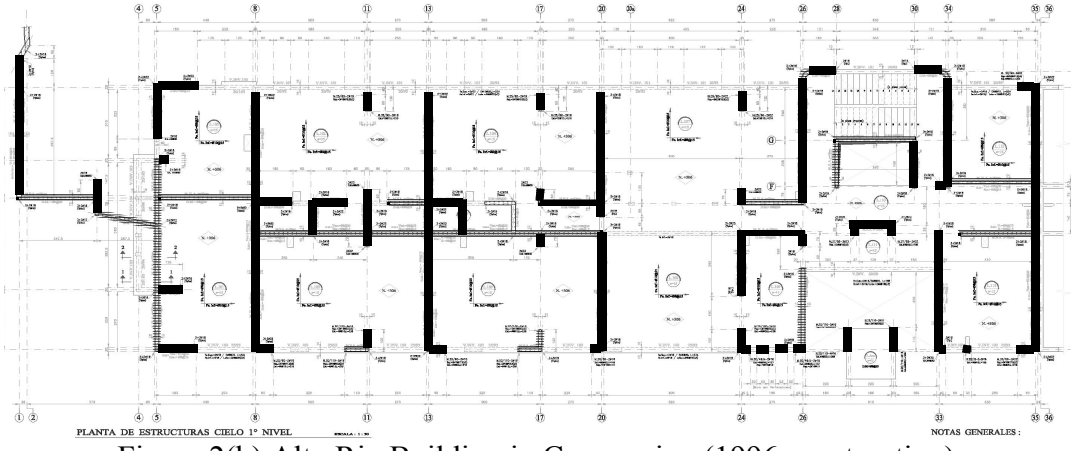

Figure 2(b) Alto Rio Building in Concepcion (1996 construction)

Observed Damage

Widespread and significant damage to shear walls, particularly at or near the ground level, was observed in buildings in Santiago, Viña del Mar, and Concepcion (the major population centers in Chile). Photos of wall damage for four buildings are shown in Figure 3. In general, crushing and spalling of concrete and buckling of vertical reinforcement were observed, often over a large extent of the wall. Typically, the damage was concentrated over a short distance of one to three times the wall thickness, apparently because buckling of vertical bars led to concentration of damage. Closer inspection of the wall boundary region (Figure 4) revealed the relatively large spacing of hoops (20 cm) and horizontal web reinforcement (20 cm), as well as the 90-degree hooks used on hoops (which typically opened due to concrete crushing and/or buckling of vertical reinforcement). In some cases, buckling of the entire wall was observed, presumably from large compression forces acting on relatively thin (15cm) walls. Damage also was common in lintels along corridor walls, sometimes extending over the entire height of the wall, in cap beams, and in corridor slabs.

ASSESSMENT AND POTENTIAL US CODE ISSUES

A wall damage observed in Chile raises a number of issues that need to be assessed. For example, what role did axial stress, wall configuration, and the lack of well

detailed regions at the wall boundaries play in the degree of damage observed? Are there other important findings that might apply to U.S. buildings and codes? These issues are systematically assessed in the following sections.

The Role of Axial Stress:

Neither the Chilean (NCH 433.OF96) or the ACI code (ACI 318-08) put a limit on the level of axial stress allowed for gravity load or combined gravity and lateral loads. A limit of $P_{gravity} < 0.35P_0$ was incorporated into UBC-94/97. A simple study is conducted to assess the likely level of axial stress in Chilean buildings. Two approaches are considered, one based on tributary area and the other based on ratios of A_w/A_f. For A_w/A_f of 3% in each principal building direction, the unit weight of buildings in Chile is estimated to be 200 kg/m^2 (Wallace and Moehle, 1989), whereas a unit weight of 150 kg/m^2 is estimated for buildings with A_w/A_f of 1%; linear interpolation is used for A_w/A_f ratios between 3 and 1%. Typical values of wall tributary area were found to range between 30 and 42 m^2 based on a review of structural drawings for several buildings constructed around 2005. Results are presented in Figure 5. The results presented in Figure 5 suggest axial load ratios of roughly 12 to 18% in pre-1985 buildings in the range of 10 to 15 stories (A_{trib}=30 m^2 or A_w/A_f = 0.03); however, ratios of 0.3 to 0.5 are computed for newer buildings between 12 and 20 stories (A_{trib}=42 m^2 or A_w/A_f = 0.01). The results suggest that newer buildings, with fewer and thinner walls, and larger tributary area, were subjected to large levels of axial stress due to gravity load. This finding is supported by wall design axial stress ratios obtained from one designer for ten different buildings. The buildings were designed between 2000 and 2006 and the loads include axial stress due to both gravity and lateral earthquake load. The results indicate that axial stress levels range from approximately 20 to 50% with a mean value of about 35%.

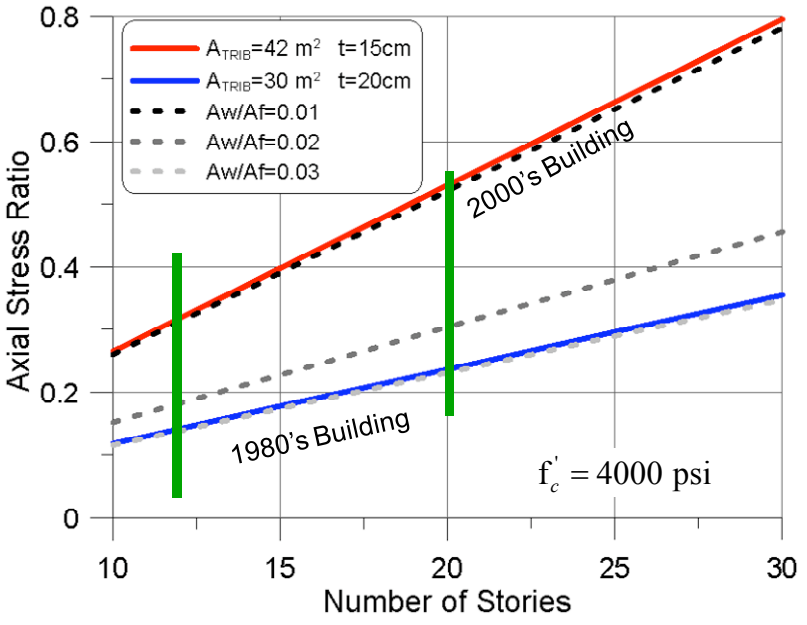

Figure 5 Estimated Wall Axial Stress Ratios

Moment-curvature analysis was used to assess the potential impact of such large axial stress ratios on typical Chilean walls. Using information from a 12-story building in Santiago, moment-curvature relations were calculated for a wall cross section of 7m x 0.15m wit 8-25 mm diameter bars at each wall boundary and 9mm vertical web bars at 20cm spacing. Two levels of axial stress are considered, 0.2 and $0.3A_g f'_c$; ratios of c/l_w, or neutral axis depth to wall length, also are plotted (Figure 6). The relations plotted reveal negative slope beyond the yield curvature (concrete crushing) with relatively low curvature capacity. It is noted that the buckling of vertical bars is not considered in this study. The plot of c/l_w indicates that this ratio is never less than approximately 0.45 for $0.3A_g f'_c$.

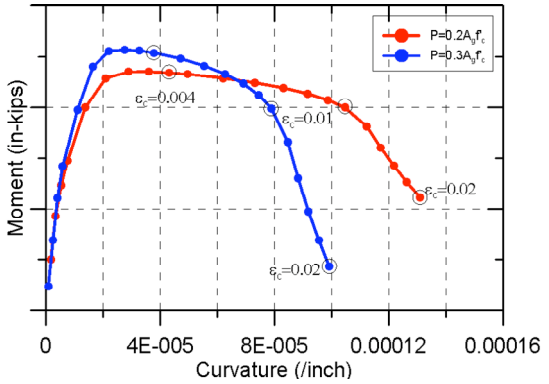

Figure 6(a) Moment - curvature relations

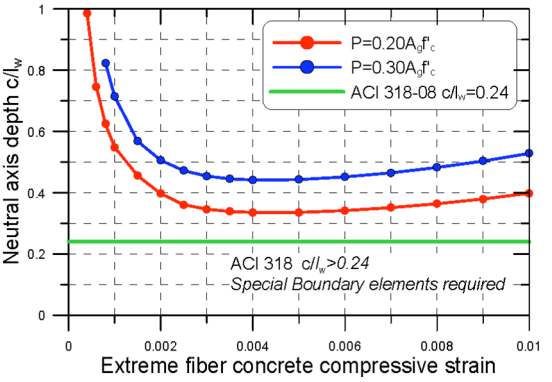

Figure 6(b) Neutral axis depths

ACI 318-99 (and subsequent versions) include a requirement that the design displacement divided by the wall height (δ_u / h_w) cannot be taken less than 0.007. As shown by Wallace and Orakcal (2002), imposing this requirement is equivalent to requiring special transverse reinforcement at wall boundaries for cases where the neutral axis depth exceeds $0.24l_w$. This result is significant because use of special transverse reinforcement at wall boundaries will be required for many U.S. walls in cases where axial stress becomes significant; however, no such provision exists in the Chilean code. Figure 6(b) indicates that ACI 318 (-99 to -08) would require special transverse reinforcement (for the prescribed levels of axial stress considered); therefore, it is likely that substantially improved performance would have resulted if the walls had satisfied ACI requirements.

Although ACI would require special transverse reinforcement at wall boundaries for most walls in Chilean buildings, the question remains whether ACI 318 or ASCE 7 should limit the level of wall axial stress, or like beams, require tension-controlled sections where the reinforcement is required to reach a specified strain level (e.g., 0.005) prior to concrete reaching a compressive strain of 0.003. Another option that could be considered is to required boundary elements to resist all compression (due to axial load and earthquake overturning forces) if a wall is not tension-controlled.

The role of wall configuration

As noted in Figure 2, common floor plans used for buildings in Chile, with long corridor walls in one direction and perpendicular walls in the transverse direction (sometimes referred to as a backbone and rib pattern, or a fishbone pattern), results in

walls with large flanges. Prior research on walls with T-shaped cross-sections has revealed that these walls behave substantially different than rectangular walls with symmetrically placed longitudinal (vertical) reinforcement (Wallace, 1994, 1996; Thomsen and Wallace 1995, 2004). For a wall with a T-shaped cross section, the boundary of the web is typically subjected to large compressive forces; therefore, this region must be well confined to avoid concrete crushing and reinforcement bar buckling. Restraining buckling is particularly challenging, because the bars at the web boundary are subjected to large compressive strains and then very large tensile strains on load reversal.

Load versus displacement results are presented for TW1 (poorly-detailed) and TW2 (well-detailed) in Figure 7. Significant loss in lateral-load capacity was observed for wall TW1 at a little greater than 1% lateral drift when all eight vertical boundary bars and some vertical web bars buckled. In contrast, wall TW2 reached lateral drift ratios in excess of 2.5% before lateral strength degradation initiated. For wall TW2, strength loss resulted due to lateral buckling of the well-confined web boundary, after concrete cover spalled. Because the walls were reduced-scale, the wall thickness was only 4 inches (10 cm); therefore, spalling of the concrete cover resulted in a substantial reduction in the wall thickness.

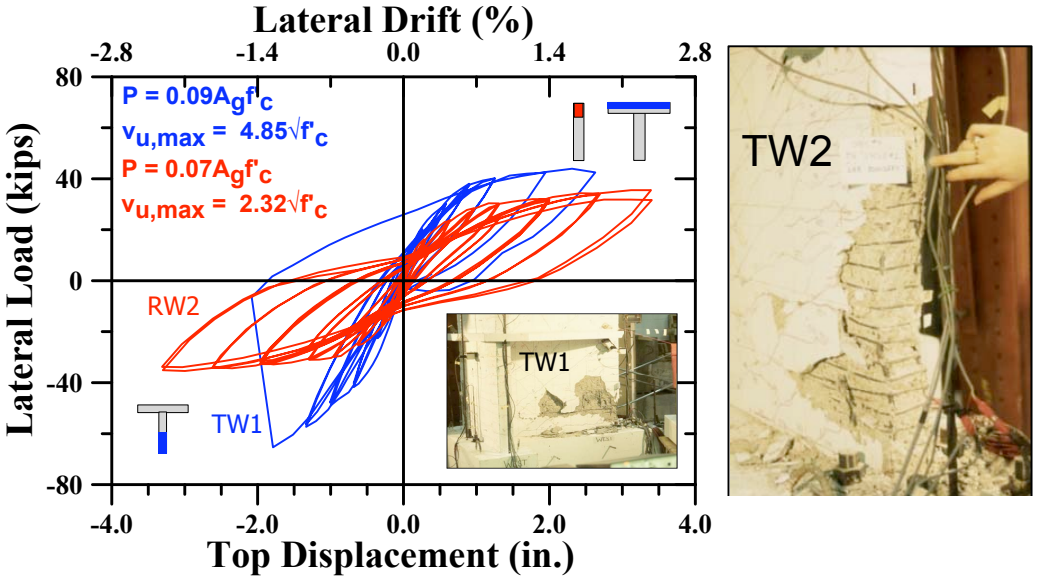

Figure 7 Load-Displacement relations for TW1 and RW2

There was ample evidence of wall damage similar to that observed for TW1 in Chilean buildings following the 2010 earthquake. As well, fracture of web boundary vertical reinforcement also was observed in a number of locations (Figure 8).

Displacement-based design provisions and assumptions

Sections 21.6.2 of ACI 318-99 and 21.9.6.2 of ACI 318-08 include provisions that are derived from a displacement-based approach (Wallace and Orakcal, 2002). Embedded in this approach is the assumption that yielding occurs over a specified (plastic hinge) length of $l_w/2$. An examination of wall damage in Chile (Figure 3) suggests that inelastic deformations do not spread out in poorly-detailed walls; therefore, it is important to reassess approach used to develop the ACI 318 provisions.

The model used to develop ACI 318-99 provisions is shown in Figure 7. Given this model, the design displacement $\delta_u(ACI) \equiv \delta_x = C_d \delta_e / I\,(ASCE\ 7)$ is related to local plastic hinge rotation and extreme fiber compressive strain as:

$$\theta_p = \frac{\delta_u}{h_w};\quad \theta_p = \left(\phi_u = \frac{\varepsilon_c}{c}\right)\left(l_p = \frac{l_w}{2}\right) \;\therefore\; \varepsilon_c = 2\left[\frac{\delta_u}{h_w}\right]\left[\frac{c}{l_w}\right] \tag{1}$$

If the compressive strain exceeds a limiting value, typically taken as 0.003, then special transverse reinforcement is required. In ACI 318-99 [see ACI 318-08, Equation 21-8], this approach was rearranged to define a limiting neutral axis depth versus a limiting concrete compressive strain as:

$$c_{\text{limit}} = \frac{0.003 l_w}{2(\delta_u/h_w)} = \frac{l_w}{667(\delta_u/h_w)} \approx \frac{l_w}{600(\delta_u/h_w)} \tag{2}$$

In this approach, it is obvious that the result is sensitive to the value used for the plastic hinge length.

The approach presented by Wallace and Orackal (2002) is modified here to assess the potential impact of variation of the plastic hinge length on the need for special transverse reinforcement at wall boundaries (or SBE, for Special Boundary Elements) for rectangular, symmetrically reinforced walls. Based on observed damage, the plastic hinge length is selected to be a multiple of the wall thickness, i.e., $l_p = \alpha t_w$, where α is taken to be 2, 5 and 8 for poorly, moderately, and well-detailed walls,

respectively. With this modification, the relationship between design displacement, wall geometry, material properties, and extreme fiber concrete compressive strain is:

$$\frac{\delta_u}{h_w} = \varepsilon_{cu}\left(\alpha\frac{t_w}{l_w}\frac{l_w}{c}\right)\left(1-\frac{\alpha}{2}\frac{t_w}{h_w}\right)+\frac{\varepsilon_{sy}}{(1-c/l_w)}\left(\frac{11}{40}\frac{h_w}{l_w}-\alpha\frac{t_w}{l_w}+\alpha^2\frac{t_w}{h_w}\frac{t_w}{l_w}\right) \quad (3)$$

Where t_w is the wall thickness, c is the neutral axis depth, h_w is the wall height, l_w is the wall length, and ε_{sy} is the tensile reinforcement yield strain. The constant 11/40 results based on the assumed distribution of lateral force over the height of the wall (Wallace and Moehle, 1992). In (3), the relationship between the wall neutral axis depth, concrete compressive strain, and drift is computed for various ratios of l_w/t_w and h_w/l_w for the three assumed values of plastic hinge length. For this preliminary study, wall aspect ratio h_w/l_w is set to 3.0 and the ratio of l_w/t_w is set to 15 for U.S. construction and 45 for Chilean construction (because they tend to use thin walls). Concrete compressive strain is set to 0.003; therefore, the results presented in Figure 9 define when special transverse reinforcement would be required at wall boundaries. Results for a plastic hinge length of $l_p = l_w/2$, as implied in current ACI 318-08 provisions, also is included.

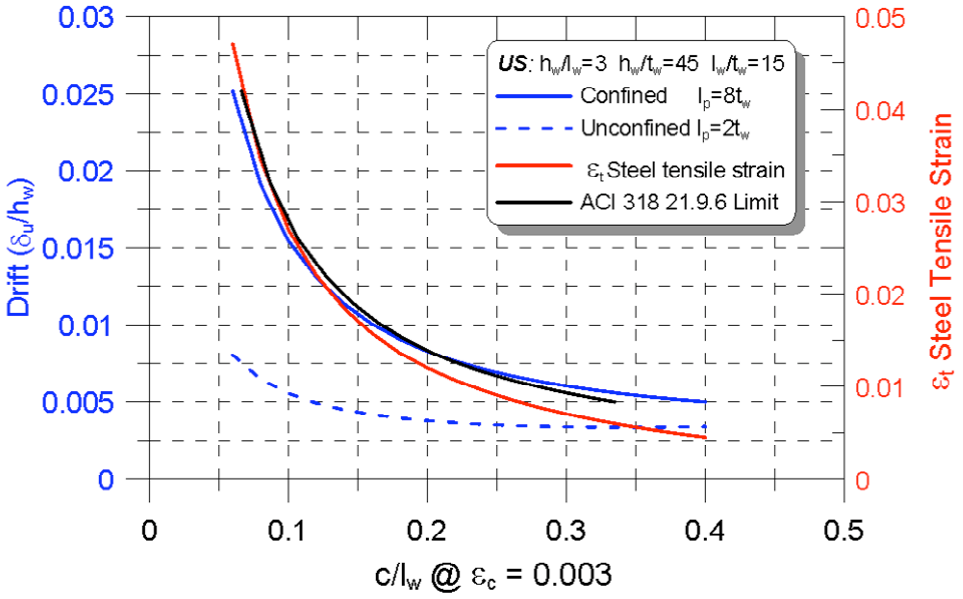

Figure 9(a) Impact of plastic hinge length on SBE – US Construction

The results presented in Figure 9(a) indicate that a use of a plastic hinge length of $l_p = (\alpha = 8)t_w$ is essentially the same as using $l_p = l_w/2$ for typical U.S. construction. In this case, if the drift ratio is 0.01, the neutral axis must exceed $0.15l_w$ before SBE are required. However, for the same neutral axis depth of $0.15l_w$, if inelastic deformations are concentrated over a short height $\left(l_p = (a = 2)t_w\right)$, less than one-half this drift ratio, approximately 0.004, can be tolerated before SBE are required. Results presented in Figure 9(b) reveal that the thinner walls used in Chile are more likely to need SBE and that at least moderate detailing should be provided in all walls.

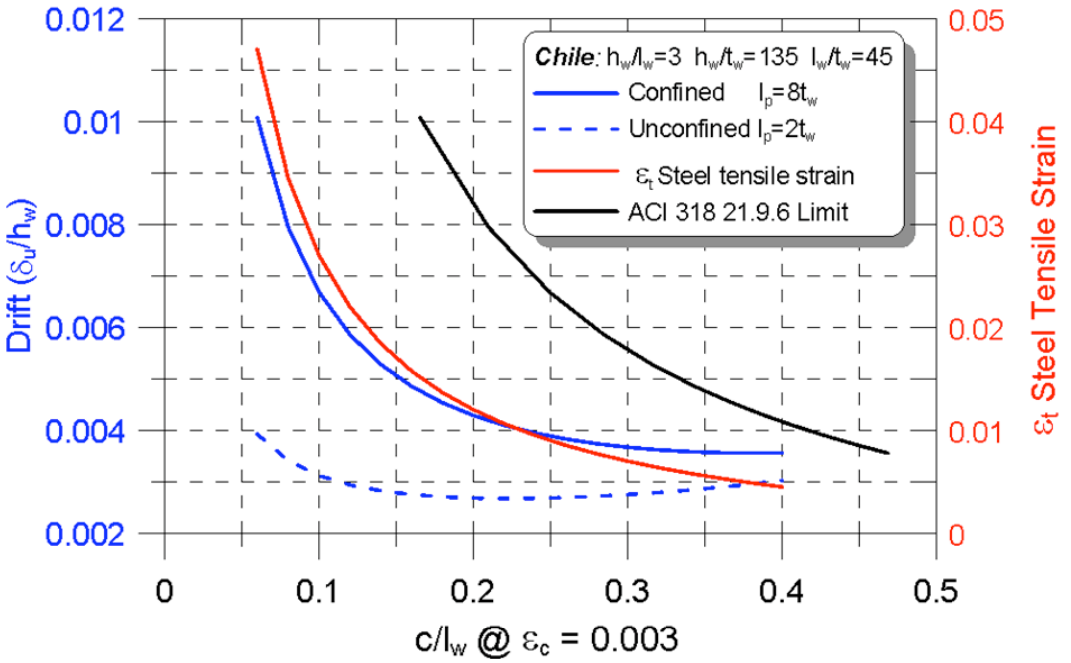

Figure 9(b) Impact of plastic hinge length on SBE – Chilean Construction

Conclusions

The M_w 8.8 earthquake that struck Chile on February 27, 2010 provides a unique opportunity to study the performance of reinforced concrete buildings designed using a modern code based closely on ACI 318-95. Based on reconnaissance efforts and subsequent preliminary studies, a number of issues have been identified to help us understand the observed damage to shear walls in Chile as well as to identify areas where changes to ACI 318-08 may be warranted. Based on this preliminary work, the following observations are noted:

- Spectral displacement demands in Viña del Mar the 1985 and 2010 earthquakes were similar, reach a peak value at a period of about 1 sec, and remain essentially constant for larger periods.
- Pre-1985 buildings in Chile typically performed well because of the large ratios of A_w/A_f, relatively low wall axial stress (typically $0.10 A_g f_c'$), and the relatively low displacement demands.
- Post-1985 buildings, and particularly buildings constructed since 2000, tended to use fewer and/or thinner walls which are likely to produce axial stress ratios in the range of 0.20 to $0.50 A_g f_c'$. Walls with such high axial stress ratios have neutral axis depths exceeding 0.35 to $0.45 l_w$ and low deformation capacity. ACI 318-08 would require special transverse reinforcement at wall boundaries for neutral axis depths exceeding $0.24 l_w$.
- Wall configuration likely played a significant role in the wall damage observed following the 2010 earthquake. Post-2000 buildings in Chile commonly include central corridor walls and multiple transverse walls. Large reinforcement tensile strains accompanied by large concrete compressive strains are expected at web boundaries of walls with T-shaped cross sections. For poorly-detailed web boundaries, sudden loss of lateral strength due to buckling of vertical boundary and web bars has been observed in tests.

- The displacement-based design approach used in ACI 318-99 (and subsequent versions, including ACI 318-08) assumes a plastic hinge length of $l_p = 0.5l_w$. Damage observed following the 2010 earthquake indicates that inelastic deformations concentrate over a much shorter distance in poorly-detailed walls. A reexamination of the ACI 318-08 provisions using a plastic hinge length equal to a multiple of wall thickness $\left(l_p = \alpha t_w;\ \text{with } \alpha = 2, 5, 8\right)$ indicates that use of $\alpha = 8$ is essentially the same as using $l_p = 0.5l_w$, appropriate for well-detailed walls. Use of $\alpha = 2$ reveals that the equation (21-8) used in ACI 318-08 to determine the critical neutral axis depth is not appropriate for poorly-detailed walls, especially for typical Chilean walls because they are much thinner than typical walls in U.S. buildings.

Acknowledgements

The author would like to thank the members of the EERI reconnaissance team for reinforced concrete buildings and our collaborators in Chile: The EERI team: Co-Team Leaders Jack Moehle (UC Berkeley), Rafael Riddell (U Catolica), and Rubén Boroschek (U Chile); Team Members Alvaro Celestino (Degenkolb Engineers), Jeff Dragovich (NIST), Carlos Sempere (Forell/Elsesser). Additional individuals from three Chile universities who contributed generously to the EERI team reconnaissance include: From the Federico Santa Maria Technical University - Professors Patricio Bonelli and Carlos Aguirre, with Arturo Millán; from the Pontificia Universidad Católica de Chile - Professors Juan Carlos De La Llera, Matias Hube, and Carl Lüders, with Vicente Ariztía, Juan Jose Besa, Alvaro Carboni, Claudio Frings, Juan Pablo Herranz, Cristobal Moena, Rodrigo Oviedo, Victor Sandoval, Nicolas Santa Cruz, César Sepúlveda, Benjamin Westenenk; from the Universidad de Chile - Professors María Ofelia Moroni, Leonardo Massone, Rodolfo Saragoni. All of the members listed provided tremendous assistance, especially the students from Pontificia Universidad Católica de Chile and Federico Santa Maria Technical University. Opinions, findings, conclusions, and recommendations in this paper are those of the author, and do not necessarily represent those of the sponsor or others mentioned.

Engineering Aspects in Evaluation of Pile Capacity by Dynamic Testing

Mark R. Svinkin, Ph.D., M.ASCE[1]

ABSTRACT

High strain dynamic pile testing is widely spread in the pile driving industry. Evaluation of pile capacity from field testing is the primary application of the dynamic method, but the accuracy and the area of utilization (soil conditions and pile type) of this method are vague. The application of hardware and software is only partially established because different hardware and software produce substantially diverse pile capacities. Engineering evaluation of pile capacity is not established at all. Statistical analysis of pile capacities is unable to find out applicability of the method to specified site conditions. Uncertainties are available in signal matching technique and comparison of the results of static and dynamic tests. Quality of dynamic measurements together with the software features and the engineering factors affect pile capacity obtained by dynamic testing. Engineering research is needed to ascertain the accuracy and the area of application of high strain dynamic pile testing.

INTRODUCTION

Modern dynamic pile examination in the field or so-called high strain dynamic pile testing (HSDPT) is based on the application of stress wave theory to piles and comprises signal matching technique for computed and measured force and velocity at the pile head. The application of the HSDPT method to driven piles has certain advantages in assessment of the hammer-pile-soil system and in data acquisition during pile driving and restrikes. This method provides verification of hammer performance and energy transferred to a pile, and also evaluation of driving stresses and pile integrity. HSDPT is a significant tool for driveability analysis.

Nevertheless, evaluation of pile capacity at the time of testing is the basic purpose of high-strain dynamic pile testing, but this area of the HSDPT application has some uncertainties and discrepancies (Svinkin, 2004 and 2010).

Dynamic testing is often used to replace static load tests (SLT). Therefore, it is imperative to ascertain the adequacy of HSDPT and SLT. Static methods predict pile capacity as the long term capacity after soil consolidation around the pile is complete. Independently of the time elapsed after driving a test pile, the ratio of pile capacity from static analysis to pile capacity from SLT is used for approximate evaluation of

the reliability of design methods. According to the traditional approach, the main criterion for assessment of pile capacity from HSDPT is the ratio of capacities obtained by dynamic and static tests or vice versa.

In assessment of HSDPT accuracy, the ratio of pile capacities from restrikes to SLT has been considered for various pile types and lengths, soil conditions and time intervals between comparable tests lumped together as shown in Figure 1. Such a mixture of pile capacities depends on a number of factors and confuses the readers. Some papers such as Goble et al. (1980), Denver and Scov (1988), Hannigan (1990), and Likins et al. (1996) have underlined good agreement between dynamic and static tests for all considered piles in spite of ignoring the time between compared tests and specifics of pile types and soil conditions. Other papers, for example, Hannigan and Webster (1987), Paikowsky et al. (1994), Lee et al. (1996), and Liang and Zhou (1997) have revealed considerable over and under estimation of pile capacity by HSDPT.

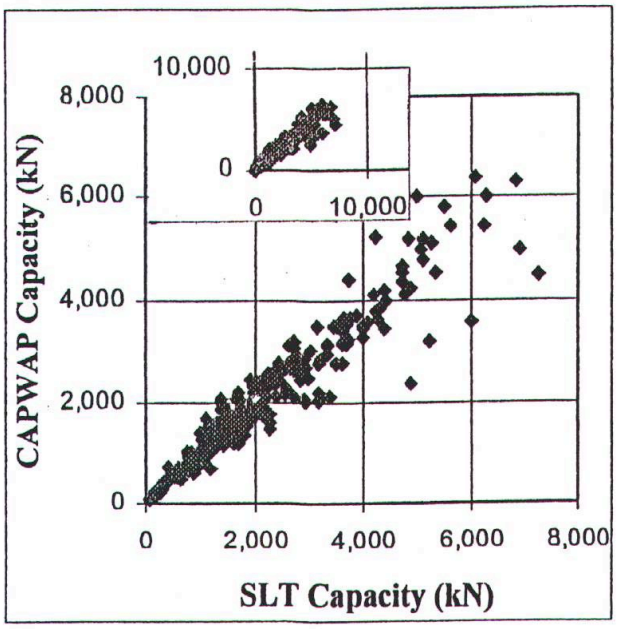

Figure 1. Correlation study of CAPWAP versus SLT. The same results are shown in different scales. Data were modified from Likins and Rausche (2004)

There are three similar but not identical signal matching software: CAPWAP, TNOWAVE, and SIMBAT. These computer programs were made by three companies which use similar dynamic measurements at the pile head, but the programs' procedures are substantially different in signal matching analysis. CAPWAP is the most popular program in USA.

Likins and Rausche (2004) have used CAPWAP analysis for dynamic pile testing and correlated the calculated pile capacities with the results of static load tests. They have summarized the two previous major studies (Goble et al.1980 and Likins et al. 1996) and compiled the results of pile testing from case histories published in the proceedings of six Stress-Wave Conferences. In total, correlation was performed for 303 piles. They have concluded that CAPWAP is generally and statistically conservative and

comparison of CAPWAP results with static load tests on the same piles shows excellent agreement. It seems that these conclusions are inaccurate because they have not presented the whole picture of pile capacity evaluation by HSDPT.

During design and construction of pile foundations, it would be beneficial to know applicability of HSDPT to specific site conditions like soil stratification, pile type and length. The existing publications recommend the use of HSDPT at any construction site. It is very doubtful because any great method has the certain area of applications and restrictions.

A DISTINCTIVE CASE HISTORY

Briaud et al. (2000) have presented a unique distinctive study of static capacity assessment by dynamic methods for three bored piles. This study was chosen toward correlation between the results of dynamic and static tests for two reasons: first, this study presented comprehensive research on determining pile capacity of bored piles by dynamic methods, and second, the research study provides a rare opportunity to compare the pile capacities determined for each of three piles by three companies specialized in the application of dynamic methods to piles: GRL and Associates, Inc., TNO Building and Construction Research, and ESSI – Testconsult. References to static and dynamic pile testing are available in Briaud et al. (2000).

Site and Pile Data

Three bored piles were tested at the two national Geotechnical Experimentation Sites at Texas A&M University. All three piles were planned to be 0.915 m in diameter and varied in length between about 10.7 and 11.7 m. Pile 2 at the sand site was purposely built with defects: mud cake of about 15 mm thick on the side wall, a soft bottom, and a concrete contamination at 5.3 m below the pile head. One more unplanned defect occurred at 5 m below the pile head and resulted in a 45% reduction in area. Pile 4 at the sand site was planned as no-defect pile, but during construction, an unplanned bulging defect resulting in a 10% average increase in diameter between 1.2 and 7.5 m below the pile head. Pile 7 at the clay site was planned and constructed as a perfect pile.

The construction schedule and the testing sequence for each pile are given in Table 1. The piles were constructed by following good drilling and construction practices including desanding of the drilling mud and minimizing slurry stagnation between the end of drilling and the beginning of concreting. Pile 2 at the sand site was an exception. Details of the soil properties at the site and the actual pile shapes are available in Briaud et al. (2000).

Table 1. Construction and Testing Schedule. Data were modified from Briaud et al. (2000)

Pile Number	Soil	Drilling	Concreting	Static Load Test 1	Drop Weight Test	Static Load Test 2
2	sand	11-16-1990	11-19-1990	11-28-1990	12-6-1990	12-8-1990
4	sand	11-19-1990	11-19-1990	11-30-1990	12-7-1990	-
7	clay	11-15-1990	11-15-1990	12-3-1990	12-8-1990	-

Results of Static and Dynamic Pile Tests

There are various criteria to define pile capacity from static load tests. Pile capacities from the load-deformation curves were defined according to the Davisson criterion ($D/120$ + 3.8 mm + PL/AE), and the $D/10$ criterion ($D/10$ + PL/AE). The designations are as follows: D is the diameter of the pile, 3.8 mm is the compression of the pile, P is the load applied, L is the length of the pile, A is the cross section area of the pile, and E is the modulus of the pile material. The values of pile capacities determined from static load tests are shown in Tables 2 for three piles tested.

After static load tests, drop weight tests were performed in 8 days for Pile 2, 7 days for Pile 4, and 5 days for Pile 7. SLT 2 for Pile 2 was made in 2 days after dynamic testing. Three companies, which performed dynamic pile testing, used similar experimental technique in measurement of force-time signals from the strain gages, acceleration-time signals from the accelerometers, and permanent displacements at the pile head for each hammer blow. However, three companies use significantly different software for signal matching of experimental data to determine, not predict, the static capacity and the load-settlement curve. The results of HSDPT and errors in determination of the pile capacity by HSDPT are shown in Tables 2 as well.

Table 2. Comparison of Static Capacity of Piles Determined by Static and Dynamic Tests

Pile No.	Pile Capacity Criterion	SLT Static Capacity kN	CAPWAP		TNOWAVE		SIMBAT	
			Static Capacity kN	Error %	Static Capacity kN	Error %	Static Capacity kN	Error %
2	$D/10$	1068	1300	+22	4900	+359	2100	+97
STL 1	Davisson	472	1300	+175	4900	+938	2100	+345
2	$D/10$	1602	1300	-19	4900	+206	2100	+31
STL 2	Davisson	1112	1300	+17	4900	+341	2100	+89
4	$D/10$	4004	2900	-28	5800	+45	2300	-43
	Davisson	2892	2900	0	5800	+101	2300	-20
7	$D/10$	3025	4250	+40	2850	-6	2500	-17
	Davisson	2491	4250	+71	2850	+14	2500	0

Accuracy of Static Capacity Determined by HSDPT

It is important to clarify what capacity values should be compared. On the one hand Briaud et al. (2000) have preferred the $D/10$ criterion to the Davisson one because the former yields the pile capacity about 1.4 times higher and an average pile head penetration about 7.8 times higher. On the other hand Fellenius (1980) has stated that the Davisson limit has widespread use in conjunction with the wave equation analysis of driven piles.

It seems that the range between the Davisson and D/10 criteria would be appropriate for correct determination of pile capacity from HSDPT. For Pile 2, a comparison was made with the result of SLT 2 because it is obvious that planned and unplanned defects decreased the capacity of Pile 2 at the time of SLT 1. A CAPWAP and TNOWAVE determination of pile capacity is based on a single blow, but an

average of two blows is sometimes used. SIMBAT software employs a series of blows with varying energy to determine pile capacity.

The accuracy of pile capacity calculations by different software on the basis of similar experimental data measured at the pile head are shown in Table 3. It can be seen that CAPWAP provided good results in sand for Pile 2 (+17 & -19) and Pile 4 (0 & -28) but substantially overestimated capacity in clay for Pile 7 (+71 & +40), TNOWAVE largely overestimated capacity in sand for Pile 2 (+341 & +206) and Pile 4 (+101 & +45) but provided good results in clay for Pile 7 (+14 & -6), SIMBAT substantially overestimated capacity in sand for Pile 2 (+89 & +31) and substantially underestimated one at the same site for Pile 4 (-20 & -43) but provided good results in clay for Pile 7 (0 & -17).

Table 3. Evaluation of Static Capacity of Piles Determined by Dynamic Methods

Dynamic Methods	Sand Piles 2& 4 Error (%)	Clay Pile 7 Error (%)
CAPWAP	Good results between Davisson and D/10 for Pile 2: +17 & -19 for Pile 4: 0 & -28	Overestimation +71 & +40
TNOWAVE	Overestimation for Pile 2: +341 & +206 for Pile 4: +101 & +45	Good results between Davisson and D/10 +14 & -6
SIMBAT	Overestimation for Pile 2: +89 & +31 Underestimation for Pile 4: -20 & -43	Good results between Davisson and D/10 0 & -17

Effect of the Time Elapsed between Compared Tests

An assessment of the effect of the time elapsed between compared tests is presented below.

CAPWAP. For Pile 2 with 2 days between dynamic and static test, errors will be almost the same. For Pile 4 with 7 days between static and dynamic test, the capacity from HSDPT will increase within the Davisson and *D*/10 criteria. However, for Pile 7 with 5 days between static and dynamic tests, an increase in the capacity from HSDPT will increase an error.

TNOWAVE. For Piles 2 and 4, the effect of the elapsed time will almost not change the largely overestimated capacity in sand. For Pile 7 with 5 days between static and dynamic tests, an increase in the capacity from HSDPT will move the capacity close to the *D*/10 limit.

SIMBAT. For Pile 2, with 2 days between dynamic and static test, errors will be almost the same. For Pile 4 with 7 days between static and dynamic test, it will be underestimation with less errors. For Pile 7 with 5 days between static and dynamic tests, the capacity from HSDPT will increase within the Davisson and *D*/10 criteria.

One more Distinctive Case History

Similar pile tests were accomplished in California at two sites, but static load test results were known to companies which performed HSDPT before dynamic pile testing was made, Baker et al. (1993). At the Cupertino site, the soil consisted of clay, gravel, and sand layers. Five bored piles with 0.9 m in diameter and 28 or 33 m in length were constructed. Four of them had planned defects. At the San Jose site, the soil profile indicated different layers of clays. Six bored piles with 0.9 m in diameter were constructed. A length of two piles was about 10 m, and four piles had a length between 18.3 and 19.5 m. Some of these piles had planned defects. Details of the soil properties at the site and the actual pile shapes are available in Baker et al. (1993).

Pile capacity from HSDPT were determined by three signal matching techniques and compared with capacity from static load tests. The Davisson criterion was used. For Piles 2 and 4 at the Cupertino site, CAPWAP analysis underestimated the pile capacities on 8 %, TNOWAVE analysis overestimated the pile capacities on 12 %, and SIMBAT analysis overestimated the pile capacities on 16 %. The report concluded that such variation is acceptable for engineering purposes. Nevertheless, a different conclusion was made regarding a comparison of dynamic and static test results obtained for all of the tests when the average value of the three methods yielded overestimation of 61 % and underestimation of 41 %. The range of variation was much greater and less acceptable.

Additional Comments

Two issues considered in Briaud et al. (2000) were discussed in Svinkin and Woods (2009). First, the pile capacity from the CASE method was presented as a function of the pile permanent set or hammer blows per 300 mm (blow count). The lower blow count the higher pile capacity. However, the same blow count can represent much lower pile capacity during easy driving when the much lower energy applied to a pile. It seems that that pile capacity as a function of blow count should be connected with energy value applied to the pile. Second, the CASE method used an average of all blows, and SIMBAT also used a series of blows with varying energy to receive the load-deformation curve. In spite of a similarity of using measured data, the results in determination of pile capacity for the same pile are diverse. For example, the pile capacity of Pile 4 is 2850 kN from CASE method and 2300 kN from SIMBAT. The difference is 24 % only for account of using different signal matching techniques. It means that software features of each method can affect pile capacity determination. Therefore, signal matching software has to be calibrated.

UNCERTAINTY IN HIGH STARIN DYNAMIC PILE TESTING

Limitations of HSDPT

General limitations of high strain dynamic pile testing are presented in Svinkin (2004 and 2010).

HSDPT has limitations in comparison with static load test because the long-term behavior can be represented only approximately over short time dynamic testing is carried out.

HSDPT provides *direct* measurement of data on strain (force) and acceleration (also velocity and/or displacement) at the pile head undergoing a hammer impact force. These data are utilized for *indirect* determination of pile capacity using signal matching procedure.

There are several methods for interpretation of the load-movement of the pile head measured *directly* from SLT. However, there is only one way for verification of pile capacity determined *indirectly* from dynamic pile testing. This capacity is compared with the result of a static load test found in accordance with the Davisson's criterion. The adequacy of static load test and HSDPT has to be confirmed by proper correlation of dynamic testing results.

ASTM D 4945 (1989) states that this test method (dynamic) is not intended to replace Test Method D 1143 (static load test). However, in practice, high-strain dynamic pile testing replaces static load test in violation of ASTM D 4945.

Problems of Signal Matching Technique

The CAPWAP computer program (GRL and Associates, Inc. 1995) is most popular signal matching software, particularly in USA. This program is widely distributed among users of the Pile Driving Analyzer. Comments on CAPWAP are shown below, and similar remarks obviously can be made regarding other signal matching software.

Screwvala (1973) has written that he does not have much confidence in the suggested method for assessment the resistance along the entire length of the pile. Also, he underlined that procedures should be established to identify where non-conservative results can apparently be obtained.

Danziger et al. (1996) performed back analysis of field records of offshore piles driven in calcareous sands and concluded that CAPWAP solutions are not unique. Different sets of soil parameters can produce similar simulated velocities curves at the pile head.

According to Rausche (1986), the match quality in CAPWAP analysis is evaluated by summing the absolute values of the relative differences between the computed and measured pile top variables. For the purpose of match quality determination, the total analyzed time period of variables considered is subdivided into four intervals. There are the overlaps of intervals 2, 3, and 4. Therefore, it can be concluded that values of the pile capacity affect the overall match quality number more than other soil resistance parameters.

Svinkin (2004) emphasized that signal matching is a specific approximation process. It is necessary to point out that the time intervals in signal matching are assigned very conditionally and two questions of the general problem of approximation have not been answered: 1) does the best approximation of a measured curve exist? and 2) is the best approximation determined uniquely? Furthermore, feedback of the pile capacity to the match quality number is an evidence of some uncertainty in determination of pile capacity by signal matching.

Comparison of HSDPT and SLT

As it was mentioned above, the main criterion for assessment of the pile capacity estimated from HSDPT is a ratio of capacities obtained by dynamic and static tests or vice versa. It is necessary to point out that the ratio of HSDPT/SLT or vice versa, taken for arbitrary time between compared tests, is not a verification of dynamic testing results. It is well known that HSDPT yields the real static capacity of piles at the time of testing, Rausche (1985). Besides, the static capacity from SLT is considered as a unique standard for assessment of dynamic testing results. It is a major error. As a matter of fact, pile capacity from SLT is a function of time and the so-called actual static capacity from SLT is not a constant value, Svinkin (2002).

For a general case of assessment of the HSDPT reliability, the ratio of restrikes to SLT results has been considered for various pile types and lengths, soil conditions and time of testing lumped together. Such a mixture has no real meaning. It is not a verification of dynamic testing at restrikes and it is not an assessment of real set-up factor because everything is lumped together without taking into account the time between different tests. Such a comparison of the pile capacities from static load test and dynamic testing is invalid for piles driven in soils with time-dependent properties because the soil properties at the time of dynamic testing do not correspond to the soil properties at the time of static load test, i.e. soil consolidation between two compared tests is taken into account for the latter test and not considered for the former test. As a matter of fact such a comparison uses pile capacity values which are incompatible from the point of verification of dynamic testing (Svinkin and Woods 1998; Svinkin 2000 and 2004).

Effects of Various Factors on Pile Capacity Evaluated by HSDPT

On the one hand previous studies demonstrated numerous cases of good correlation between HSDPT and SLT, but on the other hand there are a number of cases with wrong results of dynamic pile testing. It is necessary to correctly compare the results of dynamic and static pile tests and take into consideration the effects of several factors.

The major part of verification of HSDPT results performed for 303 piles is shown in Figure 1, Likins and Rausche (2004). The same data are displayed in different scales, and the graph in a larger scale demonstrates obvious discrepancies between the results obtained from dynamic and static tests. It means that visual observation of correlation data displayed in a small scale could be misleading.

Various factors can affect the results of HSDPT. It is necessary to consider the effects of soil conditions, the pile type and the pile length, the time between compared tests, the time after pile installation, the sequence of tests, the high blow count, the signal matching technique, and the quality of dynamic records. Besides, the rate of pile capacity change after pile installation should be considered. It was found that the rate of pile capacity change per day decreases with an increase of the elapsed time after EOID and a margin of errors about 10-15 % would be reasonable for a few days after performing the first of two compared tests, Svinkin (2002).

Statistical analysis of pile capacities from HSDPT cannot take into account all factors mentioned above and find out applicability of HSDPT to specified sites. By way of illustration, Svinkin (2002) analyzed pile capacities determined dynamically and statically for 39 piles which are available at FHWA-GRL database. This database was used by Likins et al. (1996) and Likins and Rausche (2004). The elapsed time between compared tests was 1-2 days. For 11 piles (28 %), pile capacities from HSDPT exceeded acceptable margins of 10-15 %. Calculated capacities for 5 among 11 piles had errors from 20 to 25 %. The worst results were obtained in CAPWAP analysis of 6 piles (15%) which were analyzed with errors between 30-54 %. These piles are shown in Table 4. Pile numbers in parentheses are pile numbers from the database. First three piles have underestimated results (30, 42 and 42 %), but other three piles have overestimated pile capacity (31, 54, and 44 %). Obviously, statistical analysis of pile capacities evaluated by CAPWAP was irrelevant for 15-28 % of 39 tested piles analyzed from FHWA database. Comments about the worst obtained results are presented in Svinkin (2002).

Table 4. Comparison Static Capacity of Piles Determined by HSDPT and SLT

Pile			Soil	SLT	Time between SLT & HSDPT	HSDPT		
No.	Description	Length				Time after EOID	Pile Capacity	Error
		m		kN	hours	days	kN	%
2(3)	610 mm PSC 305 mm v. D	20.20	Sand & Clay HWT	3160	+ 24	12	2216	-30
7(48)	762 mm PSC 457 mm v. D	31.10	Sand HWT	6635	+ 48	31	3836	-42
10(51)	762 mm PSC 457 mm v. D	30.02	Sand HWT	6439	+24	26	3751	-42
23(102)	HP 299x79	22.86	Sand & Clay	1664	+5	1	2185	+31
35(169)	CEP 324 mm x 13 mm	21.00	Clay & Silt HWT	788	-24	14	1504	+54
36(170)	CEP 324 mm x 13 mm	17.00	Clay & Silt HWT	712	-24	14	1148	+44

Prediction or Determination of Pile Capacity by HSDPT

The assertions in some publications like "The ability to accurately predict static capacity from dynamic pile testing has resulted in many studies" are incorrect. This is a misleading interpretation of HSDPT which does not have any connection with Class A type prediction defined by Lambe (1973). No in-situ pile test can predict pile capacity as a function of time after pile installation. Only static analysis and wave equation analysis without pile testing are truly predictive methods. It is well known that HSDPT cannot in principle predict pile capacity and only provides determination of pile capacity at the time of testing, Rausche et al. (1985) and Svinkin (2004). Besides, the accuracy of HSDPT is unknown, Svinkin and Woods (1998).

Impact Loads for Dynamic Pile Testing

To properly use HSDPT, it is essential to know the values of impact loads applied to piles during dynamic testing. There are no requirements in existing standards regarding such loads except the common and indistinct condition that the pile capacity be fully mobilized at the time of dynamic pile testing. Svinkin and Woods (2009) proposed an equation to calculate short-duration impact loads for pile testing as a function of the pile capacity, P_u, and the dominant circular natural frequency, ω, of the pile-soil system

$$I = \frac{P_u}{\omega} \tag{1}$$

This new procedure is a step toward increasing the engineering understanding of HSDPT.

CONCLUSIONS

High strain dynamic pile testing is a convenient tool in the pile driving industry, but the actual accuracy and the area of application of this method (pile types and soil conditions), and also the understanding of the results of dynamic pile testing are vague. Previous studies demonstrated numerous cases of good correlation between the results of dynamic pile testing and static load tests. However, there are a number of cases with wrong results of dynamic pile testing. For practical application, it is important to know in advance the accuracy of HSDPT depending on the pile type and soil conditions.

A distinctive case history demonstrates outcomes of application of different hardware and software for dynamic testing of the same piles. For the conditions at the particular testing sites, testing results were various: CAPWAP yielded good results in sand and substantially overestimated pile capacity in clay, TNOWAVE yielded good results in clay and largely overestimated pile capacity in sand, SIMBAT yielded good results in clay and substantially overestimated and underestimated pile capacity in sand. It is difficult to give preference to any one of three methods.

There are uncertainties in high strain dynamic pile testing like limitations of HSDPT, problems of signal matching technique, and difficulties in comparison of HSDPT and SLT. Besides, various factors can affect the results of HSDPT. It is necessary to consider the effects of soil conditions, the pile type and the pile length, the time between compared tests, the time after pile installation, the sequence of tests, the high blow count, the signal matching technique, the quality of dynamic records, and the rate of pile capacity change after pile installation.

Statistical analysis of pile capacities from HSDPT cannot take into account all factors affected pile capacity and find out applicability of HSDPT to specified site conditions. It was demonstrated that statistical analysis of pile capacities evaluated by CAPWAP was irrelevant for assessment of the accuracy of pile capacity determined for 15-28 % of 39 tested piles available in FHWA-GRL database.

There is a need for engineering research and calibration of signal matching techniques to ascertain the accuracy and the area of application of high strain dynamic pile testing.

ABSTRACT

A low-rise high school building constructed on the site of an existing construction debris landfill included initial site preparation using Deep Dynamic Compaction (DDC) to mitigate potential future settlement of the building's first-floor slab on grade. Within the first six years of building occupancy, the first-floor slab on grade settled up to 6 in. because of consolidation of the landfill. Differential settlement of the first-floor slab relative to the pile-supported building frame caused severe distress to the interior partition walls, buried storm and sanitary drainage systems, interior piping, mechanical and electrical systems, and other finish work.

This paper presents our evaluation of the landfill consolidation effects using precision settlement surveys as well as measurements from vibrating-wire borehole extensometers to model the settlement rates throughout the entire building footprint. The paper also summarizes the final repair design and construction procedures used to mitigate future settlement damage. The cost for repairs completed to date is approximately $10MM.

INTRODUCTION

The existing 195,000 sq ft, low-rise high school building was constructed in the late 1990s over a construction-debris landfill. Subsurface conditions at the site consisted of 5 to 8 ft of imported fill, over 2 to 18 ft of construction debris, over 0 to 12 ft of stiff clay, over 10 to 20 ft of dense glacial till, over bedrock. During the original planning for the new building, the following two options for the first floor slab were considered by the original design team – 1) a structural slab supported on concrete grade beams and steel H-piles and 2) a nonstructural slab supported on structural fill overlying the construction-debris stratum. For both options, the columns for the building frame and the perimeter walls were supported on concrete pile caps and grade beams with steel H-piles driven to rock. Ultimately, the slab on grade

approach was selected because of possible construction cost savings. To reduce the amount of expected slab settlement, the original design team proposed Deep Dynamic Compaction (DDC) to densify the construction debris, to reduce the amount of consolidation, and to drive the top of the construction debris below the lowest estimated groundwater level.

Figure 1. Settlement of Slab Relative to Grade Beam.

Within the first six years of building occupancy (1999 to 2005), the Owner noticed that the first-floor slab on grade was settling significantly. By 2006, settlement varied throughout the building footprint reaching up to 6 in. in some areas. The building had many utility ruptures, cracks in flooring and walls, misaligned doors and frames, glass failures, settlement of the main entry canopies, and a partial collapse of a concrete masonry unit (CMU) wall. Most notably, the slab on grade settled relative to the exterior grade beams around the entire inside face of the perimeter walls (Figure 1). Since the perimeter walls and interior columns supporting the second floor, third floor, and roof were firmly founded below the construction debris and were not settling, the building was subject to significant differential settlement between the first-floor slab and the pile-supported building frame elements.

This paper summarizes the detailed investigations, modeling used to evaluate the settlement, and permanent repairs used to mitigate the settlement issues.

INVESTIGATIONS

We correctly suspected that the cause of the settlement was consolidation of the construction debris. To evaluate the impact of the settlement and the options for repair, we developed an investigative plan to understand the extent of the settlement; to confirm the cause of the settlement; and to determine whether the settlement was ongoing and at what rate. The investigation included precision settlement surveys, soil borings, vibrating-wire borehole extensometers, ground penetrating radar surveys, and periodic visual damage and condition assessments. Each of these investigative elements is discussed in detail below.

Precision Settlement Surveys:

Settlement data is instrumental in developing a predictive settlement model. We engaged a Licensed Land Surveyor to perform annual and, at times, semiannual settlement surveys of the slab on grade. Nine surveys, incorporating 130 settlement monitoring points (SMPs), were performed between 2003 and 2010. The SMPs

were located approximately at the centerline between interior pile caps, where the slab is likely in contact with the settling soil below. We also installed some SMPs on the finished flooring that extended over a portion of the grade beams, which are not settling, to provide an estimate of the initial elevation of the slab immediately after construction and a reference to estimate the total settlement.

The accuracy of the survey is important when planning the time between surveys and the number of rounds; i.e., for slow settlement rates the time between surveys must be long enough to allow the settlement to be measured based on the expected accuracy of the survey. In general, we found that a single survey round was accurate to +/- 1/8 in. at one standard deviation (s). The accuracy of a survey can be improved by increasing the number of rounds (see Equation 1). In our investigation each survey always contained two rounds, which increased the accuracy by 41% when compared with only one round of measurements.

$$\hat{\sigma} = \frac{\sigma}{\sqrt{n}} \qquad \textbf{Equation 1}$$

$n =$ *Number of Rounds*
$\hat{\sigma} =$ *Standard Deviation of Mean*
$\sigma =$ *Standard Deviation of Single Round*

The total slab settlement between 1999 and 2006 is shown in Figure 2. The settlement data shows that the total settlement varies significantly throughout the building.

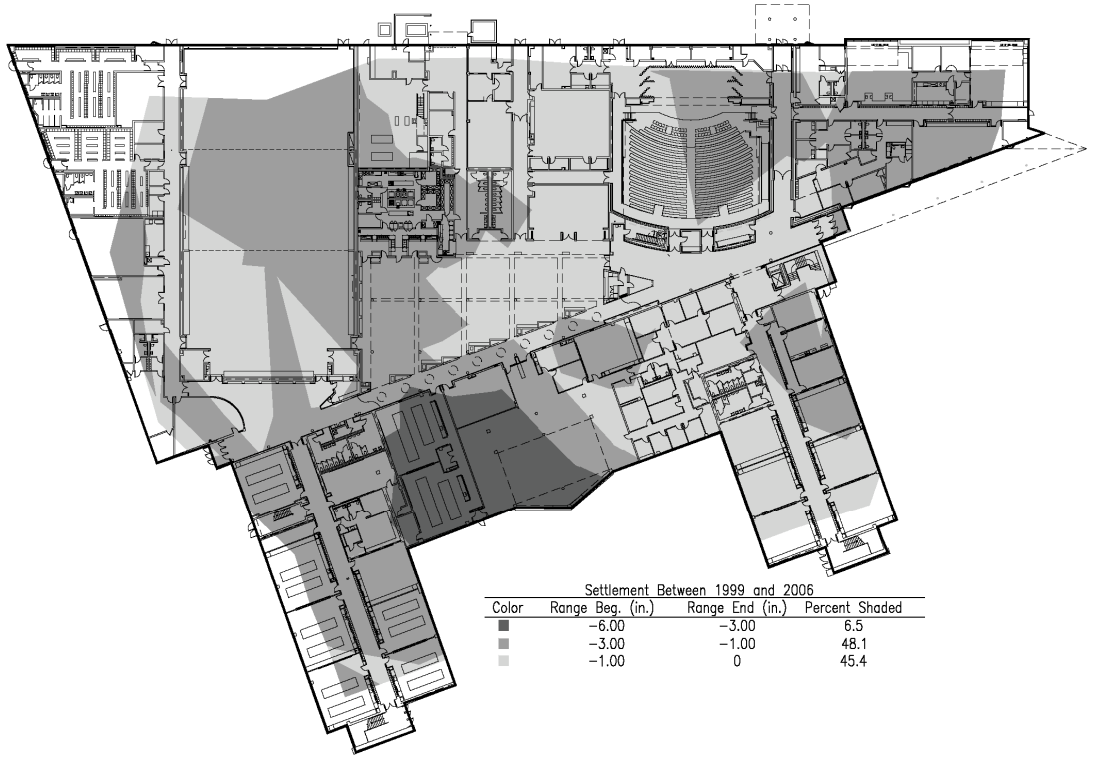

Figure 2. Settlement Between 1999 and 2006.

Soil Borings:

The thickness of the construction-debris stratum is essential to understanding the differences in the settlement magnitudes. Approximately 100 borings and test pits were performed on the site; most were done by others during the original building construction. Several additional borings were performed after the DDC and building construction to confirm the top of the construction-debris stratum.

Vibrating-Wire Borehole Extensometers:

We installed three vibrating-wire borehole extensometers to accurately measure settlement versus time at several discrete points. The extensometers are useful to confirm the settlement model due to their high accuracy (+/- 0.008 in. per the manufacturer); however, the cost to purchase and install each device (+/- $12,000 each in 2005) limits the number that can be economically installed. Each extensometer was installed in a boring and anchored into the construction debris, clay, and glacial-till strata. The glacial-till stratum provided a stable reference.

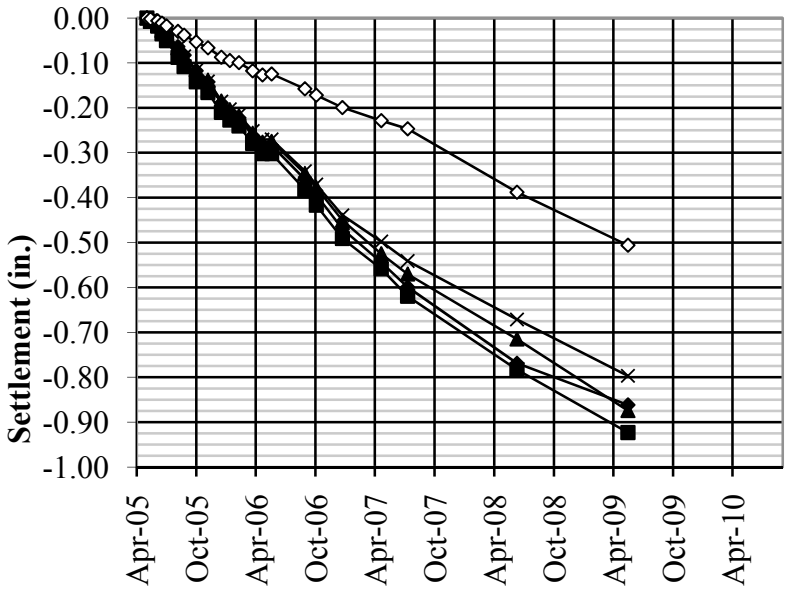

Figure 3. Extensometer Settlement Data.

Vibrating-wire strain gauges provided a direct measurement of the movement of each anchor and were monitored periodically to provide a measure of movement. A plot of the settlement of the anchors versus time for one extensometer is shown in Figure 3. The high accuracy of the extensometer data provides a very accurate confirmation of settlement trends and confirmed the cause of the settlement.

Ground Penetrating Radar:

We performed a ground-penetrating-radar (GPR) survey over the majority of the first floor to search for voids between the slab and the sub-grade. We also performed core holes through the slab to confirm the GPR survey results. The survey confirmed that the slab was generally in contact with the soil at the centerlines between interior pile caps and that regular voids existed near columns and along the perimeter grade beams.

Visual Damage and Condition Assessments

We performed periodic inspections of the building and classified the condition in each building area as Negligible, Slight, Moderate, or Severe based on the criteria given in Boscardin and Cording, 1989.

MECHANISIMS CAUSING SETTLEMENT

The consolidation characteristics of landfills have been compared to the secondary consolidation of organic soils and can be characterized by 1) mechanical compression (bending, crushing, and particle reorientation under self-weight), 2) biological decomposition of organic wastes, 3) physiochemical changes such as oxidation, corrosion, and combustion, and 4) raveling of fines into large voids. (Lukas and Seiler, 1994)

The predictability of the magnitude of consolidation of construction debris landfill sites will be low because of the high variability in the materials. Therefore, monitoring the landfill is the best way to estimate the future consolidation magnitudes. Hossain, Gabr and Barlaz, 2003 indicate that the decomposition will also vary with time.

Methane, carbon dioxide, and oxygen levels are measured at the site. Little landfill gas has been measured, except for high methane levels and low oxygen levels measured across the site in the last year. The settlement data has not reflected any change in settlement rate since the increased landfill gas generation was detected.

Lukas and Seiler, 1994 indicates that the time required for a landfill to become biologically inactive is a function of the climate and the amount of water available, which is required for the decomposition process. The expected duration of the decomposition process is uncertain. In some instances, settlement has been reported to be complete within twenty-five years, and, in others, it has continued for over thirty years with no sign of being complete. In our evaluation, we assumed that the settlement will continue for the entire fifty-year expected service life of the building.

SETTLEMENT MODEL

Evaluation of the survey and extensometer data confirmed that the settlement of the first floor slab on grade is solely and directly related to the consolidation and decomposition of the construction-debris stratum. In order to determine the expected future settlement, we modeled the historic measured settlement based on secondary consolidation theory as outlined in Equation 2 from Bowles, 1996.

Since the thickness of the debris stratum and the settlement magnitudes vary significantly across the building footprint, we separated the building into thirty-six zones based on similar debris thickness, settlement magnitudes, and damage levels. We prepared settlement models for each zone based on the survey measurements of the historic settlement magnitudes, and we back-calculated the C_α value for each zone. Figure 4 shows a sample plot of measured settlement compared to our

$$\Delta H_s = C_\alpha \times H_f \times \log_{10}\frac{t_j}{t_i} \quad \textbf{Equation 2}$$

ΔH_s = Change in Construction Debris Thickness, ft
C_α = Secondary Consolidation Index, unitless
H_f = Original Thickness of Construction – Debris Stratum, ft
t_i = Time from Loading to Beginning Time of Interest, days
t_j = Time from Loading to End Time of Interest, days

settlement model versus time for one building zone. The measured settlement data correlates well with the model.

The back calculated C_α values at this site vary between 0.002 and 0.05 with an average of 0.012. We also performed a further evaluation of the settlement trends using the extensometer data to confirm that the consolidation of construction debris follows the same log-time curve that is the premise of the model.

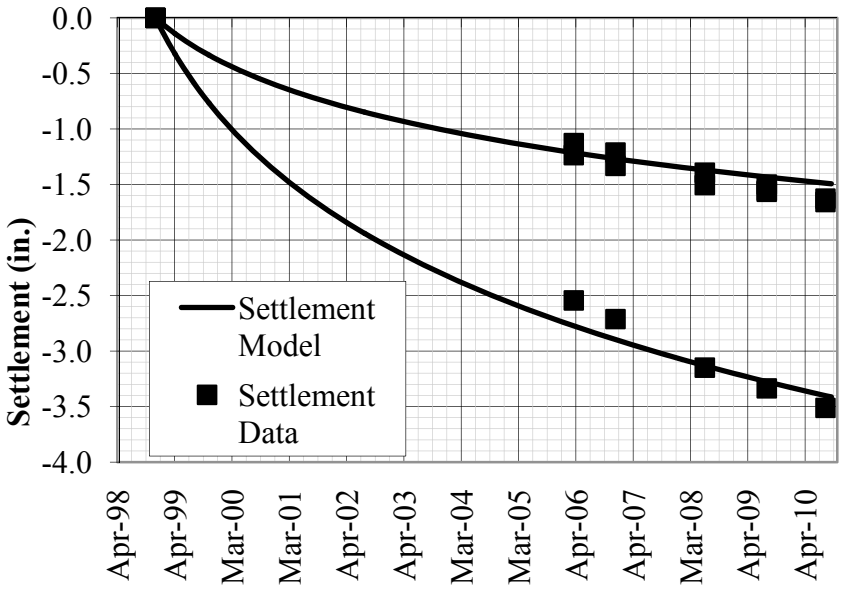

Figure 4. Settlement Model versus Measured Settlement.

We estimated the range of future settlement of the slab on grade as a percentage of the total building area (see Table 1). The settlement magnitude clearly increases with time.

Table 1. Total Settlement versus Time.

Total Settlement	2006 (Actual)	2024 (Estimated)	2049 (Estimated)
0 to 1 in.	45%	14%	10%
1 to 3 in.	48%	46%	42%
3 to 6 in.	7%	40%	48%

DAMAGE MODEL

Total settlement alone is not a true indicator of expected damage as span lengths between the center of a slab panel and the pile caps (providing inadvertent support) vary. For example, a classroom with 2 in. of settlement and a 30 ft span between column pile caps will have significantly more damage than the gymnasium with the same settlement and a 100 ft span. Traditionally the effect of span length on the allowable deflection, or in this case settlement, is handled with a distortion factor. Equation 3 defines the distortion factor.

$$Distortion\ Factor\ (DF) = \frac{Span\ Length\ (in.)}{Settlement\ (in.)} \qquad \textbf{Equation 3}$$

We correlated our calculated distortion factors to damage that we classified by our visual inspections. We found that severe damage corresponds to distortion factors less than 250; moderate damage is between 250 and 350; slight damage is between 350 and 580; and negligible damage is greater than 580. This seems appropriate considering that ACI 318-08 suggests distortion limits of 240 where nonstructural elements are not likely to be damaged and 480 where nonstructural elements need to be protected from damage.

Figure 5 shows the change in distortion factor/damage level in various building zones versus time, where each line represents a zone of the building. Dashed lines represent predicted distortion factors. By 2007, several zones have moderate to severe damage, and by 2025, about half the building service life, we estimate that most of the building will have severe damage if no repairs are performed. It is clear that repairs must be made if the structure is to achieve its fifty-year service life.

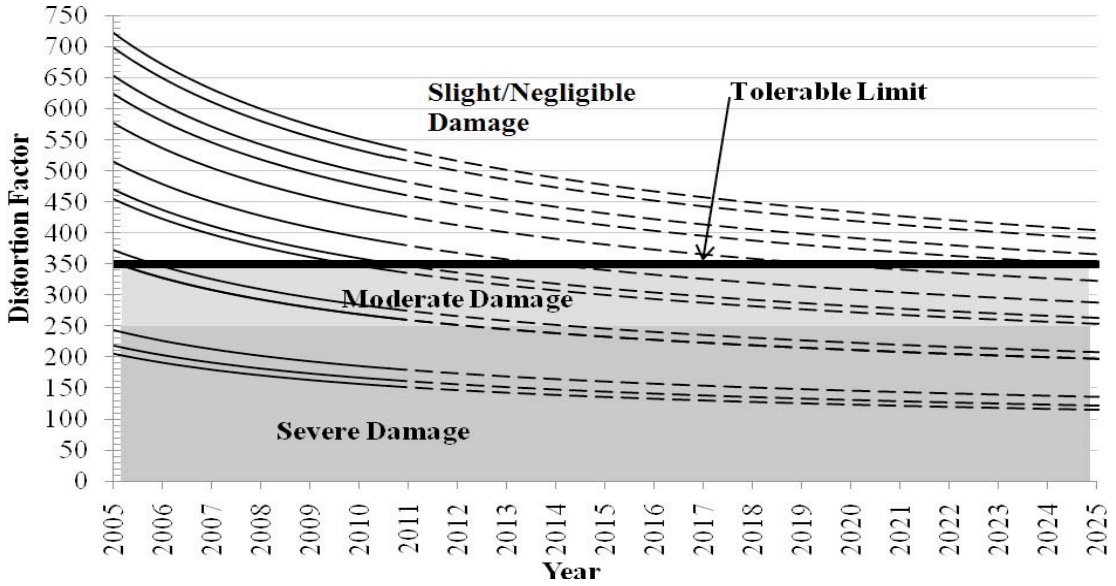

Figure 5. Distortion Factor vs. Time.

PERMANENT SLAB REPAIRS

In many areas of the building, where settlement and damage were greatest, we determined that the only feasible long-term repair option was to replace the existing slab on grade with a new structural slab founded in the stable glacial till and bedrock below the construction-debris. The design of the repairs presented many challenges; the most pertinent are discussed below:

Salvage and Selective Demolition:

Since the building was relatively new, many items were deemed salvageable and required removal, storage, cataloging, and reinstallation during the proposed reconstruction. A detailed review was performed to determine which items could be economically salvaged, including items such as lockers, toilets, sinks, and mechanical equipment. Other items such as casework, doors (mostly because they had been cut many times because of twisting door frames), electrical outlets and below-slab conduit, and ceiling grids could not be economically salvaged.

The existing 6 to 8 in. thick slabs were removed by sawcutting into small sections that were removed by skid-steer loaders equipped with air scrubbers.

Micropile Foundation Support:

We determined that, in many locations, the existing piles and pile caps had sufficient reserve capacity to support the new structural slab. Micropiles were installed for additional support in areas where the piles and pile caps did not have sufficient capacity or because of details associated with the construction phasing. Most of the supplemental micropiles were required in the one-story section where, understandably, lower capacity H-piles were installed during the original construction compared with the three-story section. The micropiles were beneficial over other new foundation options, since they could be installed with a relatively small piece of equipment designed for low-head room installations, see Figure 6.

Figure 6. Micropile Drill Rig.

We used two different types of micropiles with maximum capacities of 60 kips and 240 kips bonded into the glacial till and bedrock, respectively. This allowed the pile lengths to be economized based on design loads. A rotary duplex drilling method was used with a roller bit and internal flush. The use of a roller bit allowed the drill operator to drill through almost all types of debris. Out of forty-seven total micropiles used on the project, only one pile needed

to be abandoned and redrilled. Proper drill flush control was essential, since all drill flush and spoils needed to be controlled and disposed of as contaminated waste due to the landfill. All drill flush was controlled at the surface with a PVC liner attached to a temporary 5 ft long oversized casing. The temporary casing was used to eliminate the risk of losing potentially contaminated drill flush into the uncontaminated fill between the existing geomembrane[1] and the slab.

Each micropile consisted of a 7.625 in. OD steel casing, with a 0.5 in. thick wall, extending 1 ft into the top of the bond zone; with the roller bit advancing approximately 3 in. below the cutting shoe.

For micropiles anchored in the glacial till, the casing was temporarily extended the full depth of the bond zone and withdrawn to the correct elevation during grouting to eliminate the risk of sand infiltrating the drill hole. A No. 14 threaded bar was used as the core reinforcement. These micropiles were tremie grouted with a 75 psi seating pressure applied after casing withdrawal.

For micropiles anchored in bedrock, the cutting shoe was drilled 1 ft into the bedrock and, then, the roller bit was advanced into the bedrock for the required bond length. A No. 28 threaded bar was used as the core reinforcement. Before grouting, the micropiles in bedrock underwent a falling head-watertightness test to determine if there was a significant water loss in the rock socket. If the pile passed the watertightness test, the micropile was tremie grouted. If the hole failed the water test, it was grouted and redrilled at a later date. Static, compression-load tests of a micropile bonded just in the glacial till and another just in bedrock were conducted to confirm the capacities of the two micropile types.

Construction Sequencing and Phasing to Maintain Occupancy:

Detailed construction sequencing was essential, since the Owner was unable to vacate the building during the repairs. To provide a solution that worked, the Owner, School Department, and Design Team worked closely to sequence the work and allow the school to operate with a student, faculty, and staff population of more than 1,000. The design documents provided a detailed sequence to maintain occupancy over four phases that included the following:

- Maintaining electrical room panels that are located on the first floor and that service the occupied upper floors.
- Relocating all electrical conduits located in the floor before slab demolition.
- Installing temporary walkways to maintain pedestrian circulation.
- Underpinning CMU walls surrounding the stair towers while the stair towers remained in operation at the floors above. The demolition of first floor stairway slabs was coordinated to provide appropriate egress.
- Constructing temporary walls and slabs in entryways to maintain circulation.

[1] An existing 60 mil geomembrane liner was located across the entire footprint with an air ventilation system to collect and dispose of any landfill gases.

- Underpinning of corridor walls from one side to maintain circulation and to allow use of adjacent spaces.
- Working second shift hours in areas when the rooms above were occupied during normal hours.
- Relocating essential building equipment in tel/data rooms that could not be shut down while the school was occupied, during summer months.

New Structural Slab:

The new structural slab is a 12 in. thick two-way flat plate with No. 8 reinforcing bars at 6 in. centers, top and bottom, each direction. Because of the irregular support geometry, continuous reinforcement at the top and bottom was used. We prepared a finite element model of the slab using two-dimensional plate elements using an iteratively cracked section analysis to confirm reinforcement requirements and maximum slab deformations.

The slab was supported at the perimeter by doweling into the existing exterior grade beams. Where the interior pile caps had sufficient capacity to support the loads, the new slab was cast against the top of the pile cap's pier. Where the existing pile caps had insufficient capacity, a geo-inclusion material was used to prevent loading the pile caps. Since the slab was doweled into the existing grade beams, shrinkage cracking due to restraint was a concern; therefore, the design required pour strips (Figure 7) around the perimeter to allow a significant portion of the shrinkage in the slab to occur before placement of the pour strips. A shrinkage-reducing admixture (SRA) was used in the concrete mix design to minimize shrinkage. Mortar bar tests in accordance with ASTM C157 were conducted to confirm the SRA dosage and resulting shrinkage. The reduction in shrinkage cracking can reduce the estimated long-term deflection of the slab significantly.

Figure 7. Structural Slab on Grade with Pour Strips.

In our experience and based on published literature, two-way slabs may experience deflections in excess of those calculated using ACI 318-08. In particular, ACI 435R-95, Reapproved 2000 reports that "a number of authors have suggested that the ACI 318 long-term multiplier is too low for application to two-way slab systems and is based on poor correlation between calculated long-term deflections and field measured deflections." In addition, ACI 435R-95 reports that total long-term deflection multipliers could be as much as five times the immediate deflections due to the combined effects of creep, shrinkage, warping, cracking due to restrained early volume change, and cracking due to early construction shoring loads. For

calculation of long-term deflection, we adjusted both the elastic modulus and the creep deflection multiplier considering a time of loading equal to one year, which is approximately equal to the timeframe after placement when we expect the subgrade will settle enough to cause the slab to act as a structural slab. This adjustment will provide a better estimate of the predicted long-term deflections.

Underpinning of Main Corridor, Fire Wall, and Stair Towers:

One of the phasing lines was located along a wall of the main corridor to separate the occupied area from the construction area. The existing corridor wall was constructed of brick masonry with metal stud backup or CMUs. Underpinning of the wall in place required the excavation of underpinning approach pits on the construction side of the wall spaced at about 5 to 7 ft centers and the installation of grout bags to provide temporary support under the wall while the space between the grout bags was excavated for new permanent concrete support elements. The stair tower walls were underpinned using a combination of steel "needle beams" and grout bags (Figure 8).

Figure 8. Underpinning of Stair Tower.

An existing reinforced concrete firewall served as another phasing line. The wall was supported on a spread footing that was also settling and required underpinning. Permanent re-support was provided by coring an oversized hole in the footing and installing the micropile through the footing. Shear rings were provided on the outside of the casing, and the annular space between the casing and the core-hole was filled with non-shrink grout. The micropile used to underpin the footing was also detailed to support the edge of the new slab. A load test of the micropile-to-slab connection was performed to confirm its capacity.

Permanent Sub-Slab Drain Support:

All sub-slab drain lines were hung from the underside of the new structural slab to ensure proper alignment and prevent continued settlement. Lightweight EPS geofoam was used as a backfill material above the utilities to eliminate any downdrag load on the piping due to settlement of the subgrade.

CONSTRUCTION COSTS

Approximately 50,000 sq ft of the first floor slab was repaired between 2007 and 2009. The total construction cost as of 2009 was approximately $10MM, or $200 per

square foot. The unit cost to install the micropiles was approximately $375 per linear foot of pile, which is a significant portion of the total construction cost. We attribute the relatively high cost of micropile installation to the difficult site conditions, obstruction drilling, and work necessary to control the drill spoils.

CONCLUSION

In conclusion, the consolidation of a construction debris landfill can be accurately represented by secondary consolidation theory; to estimate the settlement of a specific landfill, the landfill should be monitored to determine the appropriate site specific secondary consolidation coefficients. Borehole extensometers are one accurate tool that can be used to measure this movement and allow a fairly quick measure of the settlement rate.

Designers should be very cautious when specifying a slab on grade on materials with high secondary consolidation potential; close coordination between the Architect, Structural Engineer, and Geotechnical Engineer is necessary to understand the site constraints and provide a solution to preclude severe distress from consolidation of the underlying soils as repairs can be costly. Repairs to mitigate future settlement and damage by using a new structural slab on piles is not ground-breaking but details to implement the solution in an occupied building can be and require innovation. Close coordination between the Owner and Designer is necessary to provide a repair sequence and a detailed design that can be constructed. During the design, the details and phased approach for dealing with many of the constraints needs to be developed; designers should not rely on a contractor means and methods approach to construction.

Loose Mortar-Set Roof Tile Falsehood

Mel Underwood, P.E.[1]

[1]Senior Consultant, Engineering Systems, Inc. (ESI), 9990 S.W. 77th Ave, Suite 325, Miami, FL 33156; PH (786) 301-5491; email: maunderwood@esi-fl.com

ABSTRACT

In south Florida, mortar-set roof tile applications are commonplace. This type of installation, when completed properly, can perform as a durable and long lasting roofing system. A properly installed system includes the tiles having been rigidly affixed to the roofing underlayment by mortar paddies. Problems can arise, for a homeowner experiencing an improper installation, when they discover that the tiles are not rigidly attached and that many individual tiles are loose and easily lifted by hand, during inspection. This is usually discovered sometime after a hurricane event and well after the original installation. Subsequently, the homeowner's insurance company may be called upon during a roof related property loss claim and tasked with determining what, if any, loose roofing tile is categorized as damage due to winds from a presumed and associated storm and/or other causes, unrelated to storm events.

Mortar-set installation of roofing tiles is generally covered by the Concrete and Clay Roof Tile Installation Manual. The mortar paddy is intended to provide the necessary bond between the tile and the roofing underlayment, in order to create resistance against wind uplift forces. Uplift resistances for available properly-installed systems are documented with published values obtained through rigorous testing, which is required prior to a "Notice of Acceptance" (NOA) being issued for each and every roofing system included on the product approval list in Miami-Dade County, Florida. Each approved system has a corresponding NOA that provides documented values, in tabular form, which indicate resistances for an individual tile due to self weight alone, as well as the resistance provided by the "mortar-set fastening/attachment method", which has been documented to provide anywhere from 3 to 5 times additional uplift resistance. This resistance helps to prevent wind forces from removing the tiles from the roof.

The NOA is a valuable resource to aid in determining if/that an existing tile condition, being "loose"/"not bonded" on any particular home, is not automatically or necessarily the result of storm induced wind uplift forces. The fact that the loose tile remains on the roof, in its original position as installed, helps to affirm that the wind forces in question were not large enough to overcome simply the tile's own weight.

BACKGROUND

The purpose of this paper is to help inform the involved parties (homeowner, insurance adjuster, public adjuster, roofing contractor, architect/engineers, etc.) with regard to a mortar-set tile roof and about the history, along with the associated issues, that have been experienced by this type of tile roofing system. There are mortar-set roofing installations which have performed as originally intended and which have withstood tropical storm and hurricane force winds. There are other mortar-set roofing installations which have not performed as intended and this is not necessarily, nor automatically, related to wind storm events.

This paper does not intend to address issues regarding a homeowner who may have been involved in a bad faith claim, may have been wronged by an insurance company, or who may have been provided with a claim payment which was an insufficient amount. This paper does however attempt to address the instance of a homeowner/homeowner's representative who believes and/or has been informed that their mortar-set tile roof exhibits hurricane related wind damages and that the insurance company "owes" them a new roof. This assertion/belief is usually unfounded and/or subscribed to by the homeowner without them having been provided any technical expertise, technical reports or otherwise, which may serve to substantiate the causes of the existing damages/deficiencies. This action, usually occurring years after the subject storm event, may unfairly raise expectations of the homeowner such that they feel that they are entitled to a new roof. This action may also create unwarranted fees for the involved insurance company, fees ultimately passed along at the expense of every homeowner who pays a property insurance premium, especially in Florida.

ROLE OF THE PUBLIC ADJUSTER IN FLORIDA

Homeowners may choose to be represented by a public adjuster in their property loss claim reconciliation. The Florida Association of Public Insurance Adjusters website (FAPIA) defines the role of a public adjuster. This profession is stated to offer, among other services, immediate review of a homeowner's policy, determination of extent of coverage, preparation of details for the property damage, and compilation of necessary documentation. All of this may be performed by the adjuster in order to protect the insured's rights, by handling all associated matters which may be essential with regard to a legitimate loss and claim adjustment.

A public adjuster should be an authority on property loss adjustments and they may be hired by an insured for assistance in adjusting a valid property insurance claim. A public adjuster is employed solely by the insured and they are required to be licensed in Florida (Agent and Agency Services). Public adjusters are required to participate in continuing education and they should act in accordance with their industry's code of ethics, established by the association and governing state agency.

The number of public adjusters ballooned after several hurricanes affected Florida in 2004 and 2005. Numbers increased from approximately 400, to in excess of 2500 (Fred E. Karlinsky et al, 2009). The number of public adjusters in 2010 was stated to be approximately 2500, which decreased from approximately 2900 in 2009 (Public Adjusters [2011-203]).

There are laws and rules which govern the conduct of the citizens of Florida. The current laws are known as the Florida Statutes and they are organized by Titles. Within each title there are chapters, parts and sections. Title XXXVII covers insurance and contains chapters 624 to 651 which are relevant to this paper's topic (The 2010 Florida Statutes). Chapter 626, Insurance Field Representatives and Operations, Part VI, Insurance Adjusters, governs public adjusters and their conduct.

The department within the state of Florida which licenses public adjusters is the Department of Financial Services (DFS) (Public Adjusters [2011-203]). Florida Statutes, Title XXXVII, Chapter 626, Part VI, Section 626.878 Rules; code of ethics, requires that public adjusters shall subscribe to the code of ethics which are specified in the "rules" of the department. In order for a department to "oversee" an entity, such as public adjusters, they need to create and administer "rules" which are similar to laws, but which are created/administered by the department in accordance with Florida statute, Title X, Chapter 120, Administrative Procedure Act (Florida Administrative Code). A "rule" is the department statement of general applicability which implements, interprets, or prescribes law or policy. It also describes procedural or practice requirements of the department. So for example, Rule 69B-220.051, Conduct of Public Adjusters, sets forth the general conduct in matters affecting public adjusters. Rule 69B-220.201, Ethical Requirements, sets forth guidelines to which they are required to conduct themselves. Any and all Florida "rules" are compiled in a document known as the Florida Administrative Code.

A statute of limitations sets a finite timeframe, a legal deadline, after which a property loss claim cannot be legally reopened (Hurricane Losses and the Statute of Limitations). This is covered by Florida Statutes, Title VIII Limitations, Chapter 95 Limitations of Actions; Adverse Possession, Section 95.11 Limitations other than for the recovery of real property. Section 95.11(2)(b) requires that any legal and equitable action sought against a written contract, obligation, or liability be commenced within five years. This includes insurance policy claims against covered losses, as they relate to residential and commercial properties.

Some public adjusters have been attempting to get homeowners to reopen old (previously submitted) claims and/or submit new claims for loss dates that are still within the Florida statute of limitations. Any contractual requirement related to hurricane damage of an insured property from the 2004 hurricane season, which may have gone unclaimed, has expired. The last major hurricane to hit Florida was Hurricane Wilma, an October 2005 storm, and any contractually covered loss-related damages caused by this storm have also passed the 5 year statute limitation.

In 2010 the Florida legislature tried to enact a bill to reduce the statute of limitations to 3 years for new, reopened or additional claims for a subject loss event. This was vetoed by the Governor however and the 5 year Florida limitation currently remains in affect (Public Adjusters [2011-203]).

As statute limitation deadlines approached, public adjusters advertised and solicited that they could get more money for homeowners above and beyond what insurance companies may have already paid. Public adjusters typically required no upfront fees. Very little investment, time-wise or other, would be required on the part of a homeowner to sign on and this has been part of the allure to utilize a public adjuster rather than to pay comparably higher attorney fees by utilizing the legal profession, if legal action was instead pursued. While there may have been valid instances where an insured did not receive appropriate or complete compensation, many reopened claims required insurance companies to expend additional time, monies and resources in an effort to refute the less than "legitimate" losses. Insurance companies have stated that they have paid many, what they feel to be illegitimate claims and/or that they have incurred wasteful costs in an effort to defend and deny those claims. In most cases, the increased costs incurred by the insurance companies have directly affected and have been passed on to homeowners through increased insurance premiums in local and regional markets. Some insurance companies have even gone as far as to no longer write homeowner's policies altogether, in select markets, while others have gone out of business indefinitely and/or completely.

There is a particular property loss category that was frequently pursued by many public adjusters and roofing contractors. This property loss category specifically involved mortar-set tile roof installations. See Figure 1.

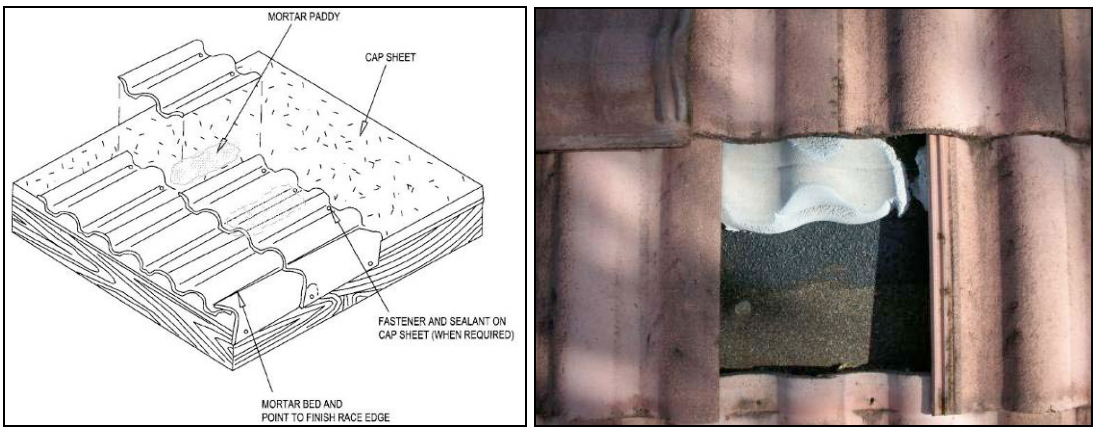

Figure 1 – Mortar paddy application of roof tile with schematic representation (Concrete and Clay Roof Tile Installation Manual, 2005) and an example of an improper mortar paddy installation

The mortar-set tile roofing system was seemingly more frequently misunderstood and subsequently more often submitted/resubmitted to insurance companies as windstorm damage type claims. This is somewhat counterintuitive because, historically speaking, roof related damages have been documented to be the leading cause of building and

residential performance related problems during severe storm/hurricane type wind producing events. One might therefore think that a better understanding of the mortar-set tile roofing system should therefore exist (Hurricane Charley in Florida). Because of the lack of understanding of the mortar-set roofing system issues, combined with misinformation related to this roofing system, this paper has been written with the intent to help educate and inform appropriately involved parties (homeowner, insurance adjuster, public adjuster, roofing contractor, architect/engineers, etc.) with regard to mortar-set tile roofing systems and their history, including associated issues that have been experienced with this particular roofing system over the years.

MORTAR-SET ROOF TILE INSTALLATION TECHNIQUE

Mortar-set application of roofing tile systems is generally covered in the Concrete and Clay Roof Tile Installation Manual. This provides installation guidelines under system #3 included in the manual. These guidelines recommend that the tile is set in a paddy/bed of approved mortar, also currently required to be factory premixed and bagged with Florida Building Code product approval. They recommend that the mortar application occur over a 10 inch minimum length trowel, applied vertically to the underlayment beneath the tile. It states to not apply the mortar under the headlug of a tile, or onto the underlock of an adjacent tile. The mortar is intended to provide the necessary bond between the tile and the roof in order to help resist wind uplift forces. Many of the roof investigations ESI has conducted exhibited improper/inadequate installation methods and techniques which were not in accordance with industry guidelines, industry standards and building code requirements. See Figure 2 for a depiction of tile roof components and associated terminology.

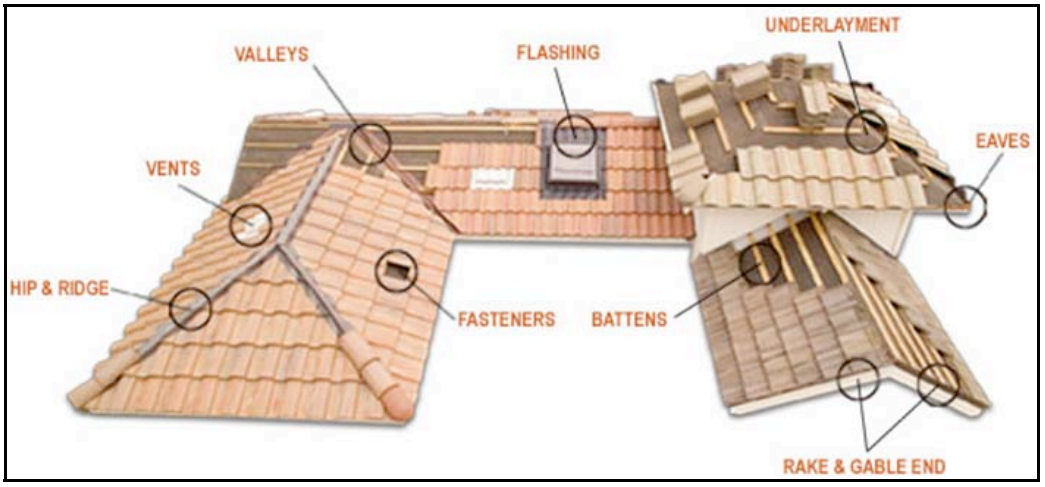

Figure 2 – Tile Roof terminology and schematic diagram courtesy of Boral Roofing (MonierLifetile)

MORTAR-SET ROOF TILE LACK OF BOND WITH MORTAR PADDIES

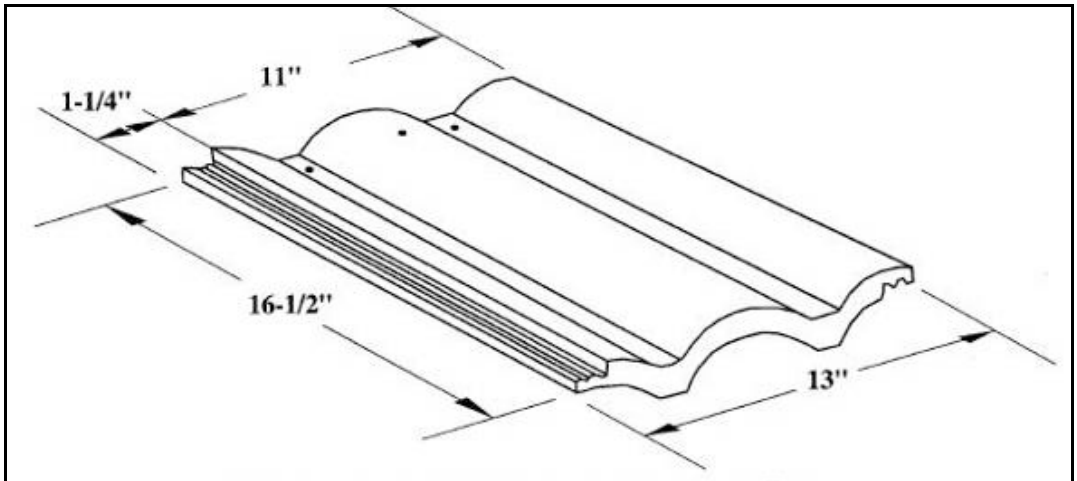
The first real test and documentation that there was an issue with this installation method, its durability and its usefulness over time became apparent after the 1992 Hurricane Andrew event. It was a known problem that recent tile roof installations had been experiencing bonding problems as early as just after installation, prior to Hurricane Andrew. But this hurricane triggered a widespread awareness of the installation method's shortcomings. Typically the tile covering the roof is intended to stay attached and provide a service life at least equal to the life of the water proofing element of the roofing system, the underlayment. The underlayment is most often some form of rolled roofing material, weighing roughly 90# per square and may be comprised of a modified bitumen material and/or an organic (asphalt impregnated paper) material.

Lack of and/or Loss of bond between the mortar-set "fastening" components has been documented and attributed to several issues. It has been stated that there are more than 30 ways for the mortar-set technique to go wrong and some governmental agencies/reports have even gone as far as to recommend against the use of the mortar-set alternative as a chosen method to secure roof tile (Summary Report Building Performance), (Installing Wind Resistive Tile Roof Covering). Other governmental agencies/reports have similarly recommended the mechanical or the foam-adhesive attachment method as opposed to the mortar-set procedure (Tile Roofing for High-Wind Areas). It has been sufficiently documented that manufacturing processes related to roof tile is much more thoroughly controlled and better overseen as compared to tile roof installation oversight and control on the construction site (Professor Wilson C. Barnes et al, 1994). "Lack of bond", implying that bond was never allowed to occur or never adequately developed, can be produced due to many reasons (poor workmanship, improper mortar mix, mortar drying out before tile applied to roof, overheating of tiles due to sun during installation, inadequate wetting of the tiles prior to installation, inadequate mortar quantity utilized during installation, mortar bed shrinkage upon drying, incorrect location of mortar application under the tile, walking on the roof before tile/mortar bond is properly set, extruded tile manufacture verses tile produced in molds, maintenance activities/footfall, etc.).

As with any specialized field constructed product, a quality installation will produce intended results while a poorly or improperly installed product may not provide intended results. The Florida Building Code (FBC) acknowledges that installation techniques are a major issue and have thus provided safety measures in the form of required inspections which must occur during the time of the installation and prior to the subsequent permit approval process.

MORTAR-SET ROOF TILE CODE REVISIONS AND ADDITIONS RELATED TO THIS SYSTEM'S APPLICATION, FUNCTIONAL IMPROVEMENT AND PUBLIC WELL BEING

The FBC has implemented improvements and safeguards over the years, in the recent past, in order to try and prevent mass building system failures, such as what had been witnessed with mortar-set tile roof installations. In 2005, the improved structural building-envelope provisions within FBC were tested by real life conditions and associated wind events. The data obtained, from the 2005 category 2 wind forces, was believed to be far more valuable, superior and useable than corresponding data that might be obtained through testing under laboratory conditions (Post Hurricane Wilma Progress Assessment). Chapter 9 of the FBC, Residential, Section R905.3 and Chapter 15 of the FBC, Building, Section 1507.3 each state that installation of clay and concrete tile shall follow the recommendations provided in the Concrete and Clay Roof Tile Installation Manual, previously discussed. Also, it should be noted that installation requirements are mandated to be performed in accordance with the Test Protocols Manual of the FBC. More specifically, mortar-set roof tile application requirements are set forth in Roofing Application Standards (RAS) Chapter No. 120, Mortar and Adhesive Set Tile Application.



FBC Chapter 15 and Chapter 44, Section R4402.1.4.2.4, each currently require that all newly constructed mortar-set tile roofs shall be static-uplift tested, on a specific percentage of the roof square footage basis, to ensure that an appropriate mortar bond exists, after installation has been completed and prior to construction-building permit finalization. This test procedure and its requirements are thoroughly documented in the Test Protocols Manual of the FBC. More specifically, it is documented in Testing Application Standards (TAS) Chapter No. 106, Standard Procedure for Field Verification of the Bonding of Mortar-Set Tile Systems. This protocol is a quality control test to be utilized for verification of a new product application/installation in order to meet building permit requirements, but it is not, nor was it ever intended to be a test to be utilized on an in-service roof that has experienced a wind event.
