Preface

Preparation for the 2011 Structures Congress required significant time and effort from the members of the Local Planning Committee, the National Technical Program Committee, and the staff at SEI. Therefore, much of the success of the conference is a reflection of the level of effort by this group of volunteers.

The committee would like to acknowledge the critical support of the sponsors, exhibitors, presenters, and participants who contributed to the success of the conference through their participation.

The Structures Congress technical program consists of over 100 concurrent technical sessions on topics that are redefining structural engineering in the areas of bridge and transportation structures, buildings, strategies for today's global economy and advances in research. The CASE Spring Risk Management Convocation and the Forensic Specialty Track supplement the Congress. All of these help enforce networking, interacting and forming partnerships with our structural peers.

Sharing in the success of the 2011 Structures Congress are our cooperating organizations, CASE, SEAOC, SEASoN, ACI, Las Vegas Chapter, ACEC Nevada, Southern Nevada Post Society of American Military Engineers, ASCE San Francisco Section, ASCE Los Angeles Section, ATC and ASCE Southern Nevada Branch.

On behalf of our dedicated volunteers and SEI staff, we would like to thank you for spending your valuable time attending the 2011 Structures Congress. It is our hope that you and your colleagues will benefit greatly from the information provided and make professional connections that lasts for years. By increasing communication skills, helping the practicing engineer expand his or her knowledge, leadership, and influence, we believe that delegates will learn how to excel in this new and exciting environment.

Dana Ames and Theodore L. Droessler
Co-Chairman, Local Planning Committee

Table of Contents

Bridges

Seismic Reliability and Performance Assessment of Bridges

System-Level Calibration of Bridge Component Damage States 1
K. R. Mackie

Seismic Fragility Estimates and Optimization of Retrofitting Strategies for Reinforced Concrete Bridges: Case Study of the Fabela Bridge in Toluca, Mexico 13
V. Bisadi, M. Head, and P. Gardoni

Effect of Ground Motion Suite Size on Uncertainty Estimation in Seismic Bridge Fragility Modeling 23
B. G. Nielson and W. C. Pang

Reliability and Redundancy of Bridge Systems under Lateral Loads 35
G. Anitori, J. R. Casas, and M. Ghosn

Long Term Structural Health Monitoring of Bridges

Anomaly Detection without Structural Behavior Models 47
I. F. C. Smith

Damage Detection and Localization in Structures: A Statistics Based Algorithm Using a Densely Clustered Sensor Network 53
Elizabeth L. Labuz, Shamim N. Pakzad, and Liang Cheng

Bridge Structural Health Monitoring Specification: 2020

Monitoring of Long Term Bridge Performance (LTBP) Program Bridges 65
Steven M. Petroff, Marvin W. Halling, and Paul J. Barr

Data-Driven Methods for Threshold Determination in Time-Series Based Damage Detection 77
Ruigen Yao and Shamim N. Pakzad

A Characterization of Traffic and Temperature Induced Strains Acquired Using a Bridge Monitoring System 89
Mustafa Gul, H. Burak Gokce, and F. Necati Catbas

Proposed Data Specifications for Bridge Structural Health Monitoring Sensor Data 101
Stephen Prusaczyk, Richard Christenson, John Dewolf, Alireza Jamilapour, and John Bartoletti

Cable Supported Bridges

Wind Engineering Studies for a Cable-Stayed Bridge in Talavera de la Reina, Spain 113
F. Nieto, S. Hernández, J. Á. Jurado, F. Pereira, and A. Díaz

Assessing and Retrofitting Steel Bridges for Fatigue

Detection of Critical Fatigue Cracks in Steel Bridge Materials with Remote Acoustic Emission Monitoring **123**
Jianguo Yu and Paul Ziehl

Improved Method for Bonding CFRP Overlays to Steel for Fatigue Repair **133**
Fatih Alemdar, Adolfo B. Matamoros, Caroline R. Bennett, Ron Barrett-Gonzalez, and Stanley T. Rolfe

Fatigue Repair of the Arkansas River Bridge **145**
Y. Zhao, K. W. M. Roddis, G. Ramirez, and J. P. Jones

Experimental Investigation of Bridge Response

Experimental Study of Shear Capacity of Reinforced Concrete Slabs **152**
Eva Lantsoght, Cor van der Veen, and Joost Walraven

Seismic Response of Bearings for Quasi-Isolated Bridges—Testing and Component Modeling **164**
J. S. Steelman, L. A. Fahnestock, J. M. LaFave, J. F. Hajjar, E. T. Filipov, and D. A. Foutch

Measurements of a Steel Orthotropic Deck under Crawl Loading **179**
S. Roy, R. S. D. Alapati, N. K. Manandhar, and J. W. Fisher

Innovative Bridge Design and Construction Approaches

Simplified Erection Guidelines for Double I-Girder Systems during Bridge Construction **190**
Quihong Zhao, Baolin Yu, and Edwin G. Burdette

Feasibility Analysis of Using UHPC in Prestressed Bridge Girders **203**
Christopher W. Taylor, Kristin F. Montoya, David W. Jáuregui, Craig M. Newtson, and Brad D. Weldon

Innovative Bridge Analysis Approaches

Effect of Secondary Elements on Load Distribution in Prestressed Bridge Girders **215**
M. R. Roddenberry, J. Chipperfield, and K. S. Tawfiq

Bridges Subjected to Impact Loads of Moving Vehicles Obtained from Vehicle Dynamics **227**
S. Jerath and S. B. Gurav

Elastic Nonlinear Analysis of Plane Truss Bridges **239**
Morteza A. M. Torkamani and Jyh-Hung Shieh

Innovative Seismic Analysis of Bridges

Seismic Analysis of Bridge Columns under Axial, Flexure, Shear, and Torsional Loadings **252**
T. Ravi S. Mullapudi and Ashraf Ayoub

Effect of Abutment Shear Keys on the Seismic Response of Bridges 265
M. W. Salveson and B. V. Fell

Computational Analyses of Quasi-Isolated Bridges with Fusing Bearing Components 276
E. T. Filipov, J. F. Hajjar, J. S. Steelman, L. A. Fahnestock, J. M. LaFave, and D. A. Foutch

Seismic Analysis of Integral Abutment Bridges Including Soil-Structure Interaction 289
Qiuhong Zhao, Reza Vasheghani-Farahani, and Edwin G. Burdette

Buildings

Long Span Stadium Roofs

Erection of the Cable Net Roof for the London 2012 Olympic Stadium 304
N. Cole and P. Hulme

Challenges of Retrofitting an Existing Domed Stadium with a New Retractable Roof—BC Place Stadium, Vancouver, BC 314
David M. Campbell and Karen A. Lynch

Design of the Retractable Roof for the Florida Marlins' New Ballpark 324
Stephen E. Blumenbaum and Aaron C. White

Wind Induced Torsional Loads on Buildings

Evaluation of Wind-Induced Torsional Loads on Buildings by North American and European Codes and Standards 337
M. Elsharawy, T. Stathopoulos, and K. Galal

Wind-Induced Torsional Loads on Low-Rise Buildings 349
M. Elsharawy, K. Galal, and T. Stathopoulos

Floor Vibration Serviceability

Floor Vibration Characteristics of Long Span Composite Slab Systems 360
T. Andres Sanchez, Brad Davis, and Thomas M. Murray

Impedance Modeling for Prediction of Train Induced Floor Vibrations 371
M. Sanayei, N. Zhao, P. Maurya, J. A. Moore, J. A. Zapfe, and E. M. Hines

Simplified Methods for Estimating the Response of Floors to a Footfall 383
C. J. Middleton and J. M. W. Brownjohn

Efficient Design of Floor Structures Using Active Vibration Control 404
M. J. Hudson, P. Reynolds, and D. Nyawako

Structural Performance in Fire

A Comparison between the Single Plate and Angle Shear Connection Performance under Fire 416
Serdar Selamet and Maria E. Garlock

Effects of Thermal Expansion and Support Restraints on Performance of Composite Floors in Fire 427
H. Mostafaei and F. Alfawakhiri

RC Bearing Walls Subjected to Elevated Temperatures 439
M. J. McGinnis, K. A. Mueller, Y. C. Kurama, and K. P. Graham

Experimental Evaluation of Composite Floor Assemblies under Fire Loading 451
Purushotham Pakala, Rustin Fike, Emily Wellman, Venkatesh Kodur, and Amit Varma

Behavior of Steel Columns under Fire Loading 463
Lisa Choe, Amit H. Varma, and Andrea Surovek

Integrating Life Cycle and Carbon Assessments

Carbon Emissions and Building Structure: What the Structural Engineer Needs to Know about Carbon in the 21st Century 472
Mark D. Webster, Helena Meryman, and Dirk M. Kestner

Life Cycle Assessment Using ATHENA Impact Estimator for Buildings: A Case Study 483
Elizabeth Stek, Dave DeLong, Terry McDonnell, and Jose Rodriguez

Integrating Life Cycle and Carbon Assessments: What Life Cycle Assessment Can Teach Structural Engineers about Design and Specification 495
Frances Yang

Infrastructure Sustainability: Streamlining Life Cycle Assessment for Practicing Bridge Engineers 507
Jeralee L. Anderson

Tall Building Design in Seismic Regions: Design Philosophies and Global Perspectives

Deflection Limits in Tall Buildings—Are They Useful? 515
Rob Smith

Structural Analysis and Design Challenges of the Ping An Tower under Consideration of the Upcoming China Code 528
Dennis C. K. Poon, Ling-en Hsiao, Yi Zhu, Steven Pacitto, Steve Zuo, Torsten Gottlebe, and Shenming Wang

Non-Linear Time History Analysis for the Performance Based Design of Shanghai Tower 541
Dennis C. K. Poon, Ling-En Hsiao, Yi Zhu, Leonard Joseph, Steve Zuo, Guoyong Fu, and Onur Ihtiyar

Reinforcing Topics for Concrete Structures

Effect of Stirrups on the Contribution of Concrete Compressive Strength and Tensile Steel to the Shear Strength of RC Beams Using Artificial Neural Networks 552
Hassan El-Chabib

Cyclic Response of Concrete Frame Members Reinforced with Ultrahigh Strength Steel 560
H. Tavallali, A. Lepage, J. Rautenberg, and S. Pujol

Nominal Shear Strength Limits for Short Diagonally-Reinforced Concrete Coupling Beams 571
Steven Barbachyn, Yahya C. Kurama, and Lawrence C. Novak

Existing Masonry Buildings Evaluation and Retrofit

A Simple Method in the Preliminary Assessment of Historic Masonry Buildings 583
James S. Cohen

Problems in the Repair of Historic Brick Masonry Buildings 594
James S. Cohen

Reliability Analysis of Masonry Members under Compression 605
S. Kazemi, M. Mahoutian, H. Moosavi, and Y. Korany

Wood Light Frame Design

Is Roof Eave Blocking Required to Transmit Wind/Seismic Forces? 616
Felix Martin

Truss Plates for Use As Wood-Concrete Composite Shear Connectors 626
Peggi L. Clouston and Alexander C. Schreyer

Effect of Support Restraint on Wood-to-Wood Joist Hanger Connection 636
William T. Bolduc and Samaan Ladkany

Contextualizing the Load Duration-Dependent Strength of Wood Members 650
G. R. Searer, T. F. Paret, and R. J. Kristie

The 14th Edition AISC Steel Construction Manual

The AISC 2010 *Specification* and the 14th Edition *Steel Construction Manual* 661
Larry Muir and Cynthia J. Duncan

Seismic Design of Cold Formed Steel and Metal Building Systems

Development of Seismic Design Provisions for Steel Sheet Sheathed Shear Walls 676
C. A. Rogers, N. Balh, C. Ong-Tone, I. Shamim, and J. DaBreo

Seismic Design of Diagonal Strap Bracing Using AISI S213 688
Greg Greenlee

Earthquake Simulator Testing of Metal Building Systems 693
C. M. Uang, M. D. Smith, and W. L. Shoemaker

Seismic Force Distribution for Metal Building Systems with Mezzanines 705
M. D. Smith and C. M. Uang

Innovations in Steel Plate Shear Walls

Behavior of Steel Plate Shear Walls with In-Span Plastic Hinges **716**
Ronny Purba and Michel Bruneau

Recent Experimental Research on Steel Plate Shear Walls in NCREE **724**
Chao-Hsien Li, Jing-Tang Chang, Keh-Chyuan Tsai, and Chih-Han Lin

Design and Testing of Coupled Steel Plate Shear Walls **736**
D. J. Borello and L. A. Fahnestock

Seismic Design and Analysis of Self-Centering Steel Plate Shear Walls **748**
Patricia M. Clayton, Daniel M. Dowden, Ronny Purba, Jeffrey W. Berman, Laura N. Lowes, and Michel Bruneau

Modular Construction of Steel Plate Shear Walls for Low and Moderate Seismic Regions **758**
Robert G. Driver and Hassan Moghimi

Nonlinear Seismic Analysis for Everyday Application

Nonlinear Dynamic Analysis of Structures Using Modal Superposition **770**
K. K. F. Wong

Use of Nonlinear Analysis in the Context of the ASCE 7 Seismic Load Provisions **782**
Finley A. Charney

Seismic Retrofit of Pre-Northridge Steel Moment Frame Building Using Nonlinear Static Analysis per ASCE 41-06 **791**
Methee Chiewanichakorn, Luis Toranzo, and Aaron Reynolds

Seismic Vulnerability Assessments of Marine Structures Using Non-Linear Static Analysis Procedures **803**
Edward H. Stehmeyer III

Use of Protective Systems to Achieve High Seismic Performance Goals

Seismic Design of a 15 Story Hospital Using Viscous Wall Dampers **815**
James Newell, Jay Love, Mark Sinclair, Yu-Ning Chen, and Amarnath Kasalanati

Seismic Analysis and Rehabilitation of a 15 Story Pre-Northridge Steel Moment Resisting Frame Building **827**
Timothy Graf, James O. Malley, Mark Sinclair, James Newell, Colin Blaney, Moisey Fraynt, Chia-Ming Uang, and Tamer Ahmed

"The Bowls Project"—A Prototype for Full Scale Testing As an Alternate Approval Process for Small Scale Base-Isolated Structures **839**
Gordon Wray, Mark Sinclair, and Michael H. Ramage

Seismic Isolation: Applications of WorkSafe Technologies Ball-N-Cone Isolator **852**
A. M. Nacamuli and K. M. Sinclair

Soil Structure Interaction and Seismic Isolation at Nuclear Facilities

Probabilistic and Deterministic Seismic Soil Structure Interaction Analyses for the Lotung Quarter-Scale Containment Model 864
D. W. Eggers, S. Bolourchi, and F. Ostadan

Seismic Isolation of Safety-Related Nuclear Structures 876
A. S. Wittaker, Y.-N. Huang, R. L. Mayes, and R. P. Kennedy

Site Response Analyses 886
C. J. Constantino, T. W. Houston, and M. C. Constantino

Detailing Issues for Steel Structures

Simple Shear Connections—Not So Simple 898
Erik Anders Nelson

Designing and Detailing Welded Skewed T-Joints 909
T. Green and T. Schlafly

Finite Element Analyses of Super Composite Column and Its Connections for Ping An International Financial Center Tower 918
Dennis C. K. Poon, Ling-en Hsiao, Zhu Yi, Steve Zuo, Steve Pacitto, Torsten Gottlebe, and Jianhai Liang

Steel Detailing Practices: Using Global Variation to Envision Innovation 929
K. Simonen

Lateral Force Systems

Out-of-Plane Stability of Buckling-Restrained Braces 938
Tsuyoshi Hikino, Taichiro Okazaki, Kouichi Kajiwara, and Masayoshi Nakashima

Dynamic Response of a Steel Concentrically Braced Frame 950
Taichiro Okazaki, Dimitrios G. Lignos, Tsuyoshi Hikino, and Kouichi Kajiwara

Self-Centering Buckling-Restrained Braces for Advanced Seismic Performance 960
David J. Miller, Larry A. Fahnestock, and Matthew R. Eatherton

Building Specific Seismic Strengthening and Design

A Celebration of Structure As Architecture—The Cathedral of Christ the Light 971
Mark Sarkisian, Peter Lee, and Eric Long

Performance-Based Seismic Evaluation of Ping An International Finance Center 983
Dennis C. K. Poon, Ling-en Hsiao, Yi Zhu, Steven Pacitto, Steve Zuo, Torsten Gottlebe, and Rohit Srikonda

Enhanced Seismic Design of the New San Bernardino Court 994
M. Sarkisian, P. Lee, L. Hu, and C. Doo

Seismic Retrofit of a Higher-Education Building Using Advanced Analysis to Optimize Use of Existing Building Components 1007
Devon Lumbard, James Newell, Qi-Song "Kent" Yu, and James O. Malley

Business and Professional Practice

Effect of I-35 Minnesota Bridge Failure on Bridge Inspection and Evaluation Program

Impact of I-35W Bridge Failure on State Transportation Agency Bridge Inspection and Evaluation Programs 1019

System-level calibration of bridge component damage states

K. R. Mackie[1]

[1]Assistant Professor, Department of Civil, Environmental, and Construction Engineering, University of Central Florida, Orlando, FL 32816-2450; PH (407) 823-2857; email kmackie@mail.ucf.edu

ABSTRACT

Post-earthquake repair costs and repair times are important for evaluating the performance of bridges in a fundamentally different way than the traditional component-level metrics such as bearing displacements and column ductility demands. Repair costs and times are metrics that address the system-level response of bridges to a suite of seismic events, especially when cast probabilistically in the form of fragility curves. Traditionally, bridges are assessed and fragilities are generated according to enumerated component damage states (e.g., DS1 is minor damage). However, the level of system functionality that corresponds to each component damage state and whether individual components have risk or performance consistent with the system are of considerable interest in seismic assessment. In this paper, repair costs and times are calculated for a typical multi-span reinforced concrete highway overpass bridge in California. This system-level information is then used to back calculate consistent component damage states. The initial damage states are compared to the back-calculated states for forward prediction on different bridge configurations, and it is shown that it is difficult to achieve consistent performance using constant component damage states.

INTRODUCTION

For the highway overpass bridges that comprise most regional transportation systems, there are two principal concerns that contribute to economic-based decision making. The total expected loss after an earthquake includes not only the cost associated with damage to the structure itself, but also the cost associated with the loss of function. Functional loss is particularly relevant in the case of a highway network system because the indirect losses to an urban area might greatly exceed the direct losses. Estimated costs due to repair and the loss of function are the subjects of large-scale simulations on urban regions and transportation networks. The goal of such simulations is to provide an economic impact analysis of damage to a transportation system in an extreme event, such as an earthquake, on an urban area. The economic impact can be defined in terms of damaged and failed links in the transportation network and link costs associated with traffic flow. Direct losses to the region include damage to components (bridges) as well as time delays in the damaged network. Indirect losses are due to the interruption of goods and services to those businesses affected by the earthquake. (Mackie 2010)

While downtimes may contribute more directly to the accumulation of indirect losses in the network after an event, they are also the most difficult to quantify because they are largely based on emergency response, resource management, and the decisions of reconnaissance, engineering, and management personnel. Therefore, the focus of the study presented in this paper is primarily on the direct costs associated with repair of the bridge to functionality. This task is achieved by performing a performance-based earthquake engineering (PBEE) analysis on individual bridge configurations. PBEE assessment is performed for both direct repair costs as well as repair efforts. The PBEE assessment procedure is briefly described in this paper; however, the emphasis is on quantifying the relationship between system and component limit states; therefore, references are provided for more detailed reading on the details of the procedure itself.

HAZUS (FEMA 1999) contains five damage limit states (DS1 to DS5) that are defined in terms of observable damage and response of different bridge components, such as piers, abutments, shear keys, and foundations. The five states are intended to correspond to the bridge states of none, minor, moderate, excessive, and complete, respectively. The performance that defines the boundaries of each particular state are subjective in nature and not necessarily easy to quantify based on either observed states of damage, nor based on quantitative results obtained from, for example, nonlinear finite element analysis. In addition, it may be desirable to be able to consistently group or identify different bridge components into the same damage states as the entire system. This would require a consistent risk or performance definition for both the component and system damage states. In general, while components are commonly described using component damage states (Padgett 2007, Nielson 2005, Mackie et al. 2008), there is no clear map between these and the corresponding performance of the system or vice versa.

In this paper, an implementation of the Pacific Earthquake Engineering Research (PEER) Center performance-based earthquake engineering framework (Cornell and Krawinkler 2000) is used to generate probabilistic estimates of repair cost and repair time. The complete analysis is accomplished using the local linearization repair cost and time methodology (LLRCAT), described by Mackie et al. (2009) and depicted conceptually in Figure 1. In the LLCAT methodology, each bridge system is disaggregated into independent structural or non-structural components or subassemblies defined as PGs that are damaged, assessed, and repaired together using a specific combination of different repair methods. Demands on the bridge system (and components) are determined using 3D nonlinear time history analysis under multiple-component earthquake excitation. The descriptor of earthquake intensity is designated an intensity measure (IM) and the measure of response is designated an engineering demand parameter (EDP). The damage in each of the PGs is characterized according to several discrete damage states (DSs) that are defined by distributions of critical EDPs. Different repair methods are employed for the various damage states of each PG or bridge component. The repair methods for each PG require a combination of several repair quantities (Qs). Repair quantities for all PGs are then combined with due consideration of the correlation between components. Repair costs (RC) are obtained through a unit cost (UC). Repair times (RT) are obtained through a production rate (PR). The PRs are in terms of crew

working days (CWD), representing one working day for a normal sized crew and can be combined later by construction management experts to obtain total site construction times.

$$\text{RC: } \lambda(RC > rc) = \int_{im}\int_{dm}\int_{edp} G(uc \cdot q|dm)dG(dm|edp)dG(edp|im)|d\lambda(im)|$$

$$\text{RT: } \lambda(RT > rt) = \int_{im}\int_{dm}\int_{edp} G(lpr|dm)dG(dm|edp)dG(edp|im)|d\lambda(im)|$$

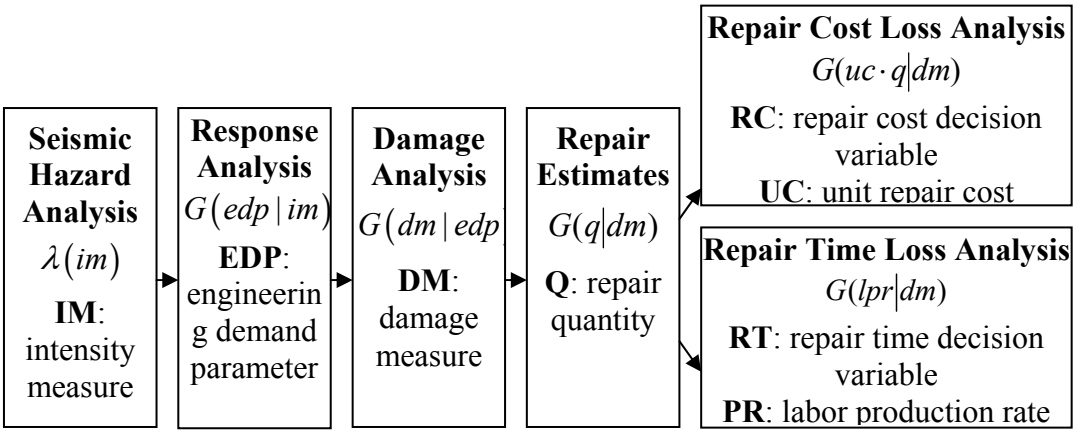

Figure 1. Schematic representation of the LLRCAT methodology.

BRIDGE CONFIGURATIONS

The two bridges considered in this study are from a series of bridge types presented by Ketchum et al. (2004) that were intended to be typical of post-tensioned concrete box girder construction in California. Specifically, the two configurations with common deck sections and single column bents were selected for this study. The two configurations are designated as Type 1A and Type 11B. The bridges have 3 internal spans of 150' and 2 external spans of 120' with a total length of 690'. The bridges are cast-in-place, pre-stressed (CIP/PS) 2-cell box girder bridges with the superstructure supported on neoprene bearing pads under each of the three box webs. The only difference is the clear column heights and column diameters; the Type 1A has 22' column heights and 4' column diameters, and the Type 11 has 50' column heights and 6' column diameters.

The testbed bridge is broken down into performance groups (PGs) for each major bridge superstructure, substructure, and foundation component. Each performance group represents a collection of structural components that act as a global-level indicator of structural performance and that contribute significantly to repair-level decisions. Performance groups are not necessarily the same as load-resisting structural components. For example, non-structural components may also form a performance group, since they also suffer damage and contribute to repair costs. The notion of a performance group also allows grouping several components together for related repair work. The correlation between repair items from the PGs is

handled at the demand model level in the methodology. A total of 27 PGs are considered for the testbed bridge: columns based on maximum displacement (1 PG per column), columns based on residual displacement (1 PG per column), deck/superstructure (1 PG per bridge span), abutment (1 PG per abutment), bearings (1 PG per abutment including all bearings), shear keys (1 PG per abutment including both external shear keys), approach (1 PG per approach), abutment piles (1 PG per abutment), and pile groups (1 PG per column). Further details regarding the testbed bridge and the analytical model that was developed for simulation are contained in Mackie et al. (2008).

REPAIR COSTS AND TIMES

Normalized costs of repair are obtained by using the repair cost ratio (RCR) between the cost of repair and the cost of original new construction. This ratio is useful for comparing the performance of different bridge design options for new construction. For the evaluation of existing structures, the RCR including demolition costs might be more useful. Constructing a new bridge on the same site after an earthquake would require both demolition of the damaged bridge and construction of its replacement. The cost of new construction can be obtained using different methods. Ketchum et al. (2004) computed construction costs based on quantity estimates for each of the testbed bridge models. Also, Caltrans bridge cost estimates for planning purposes are based on the deck and type of construction and provide a range of cost/SF of deck area. The cost of new construction was adjusted by the price index to make comparisons between current 2007 cost data and the new construction costs reported in Ketchum et al. (2004) that were based on 2003 cost estimates.

The unit costs (UC) for the individual repair items used in this paper study are given in Mackie et al. (2008). It is assumed that unit costs are constant regardless of the quantity. A simple lump sum contingency estimate can be used to display the magnitude of total repair cost uncertainty due to possible fluctuations in unit cost in this case. Repair times are also computed on the basis of each repair quantity Q. For any repair item, a probability of 50% that $Q > 0$ indicates that the associated repair time should be added to the total repair time for the project. Repair tasks that use the same repair items are assumed to occur simultaneously. So, when the repair times are added up, this estimate more closely approximates repair duration instead of repair effort. The repair task durations are based on estimated schedules from damage scenarios (Mackie et al., 2008). The repair durations were related to the individual repair quantities by summing the different tasks associated with each repair quantity. The mobilization required for several of the items dominated the repair time. For example, preparing the material and safety plan for methacrylate deck overlay takes 20 working days, while the actual cleaning and treating of the bridge deck takes only 2 working days.

Due to the methodology, the outputs from the methodology are the intensity-dependent first and second moments of the repair times and costs. In addition, final repair costs can be disaggregated into contributions from each repair quantity or performance group (for the expected costs as well as the cost variance). Retaining an intensity-dependent format, the total repair cost ratio for both bridge types is shown in

Figure 2. The ordinate is plotted in units of the percent of the replacement cost. The plot shows that both the first and second moments vary with intensity and that the RCR of the two bridge configurations is not necessarily equal, even when the structure-independent site intensity (measured in terms of the peak ground velocity) is the same. There is a range of intensities (80 < PGV < 180 cm/s) for which both bridges exhibit approximately constant RCRs. This is due to the fact that most of the superficial concrete repairs have been made (epoxy inject cracks, repair spalls, etc.) and do not continue to accumulate with increasing intensity until more serious damage occurs. For the range of intensities considered during the analysis, only Type 1A experiences a jump in RCR due to excessive deformation and damage to the columns.

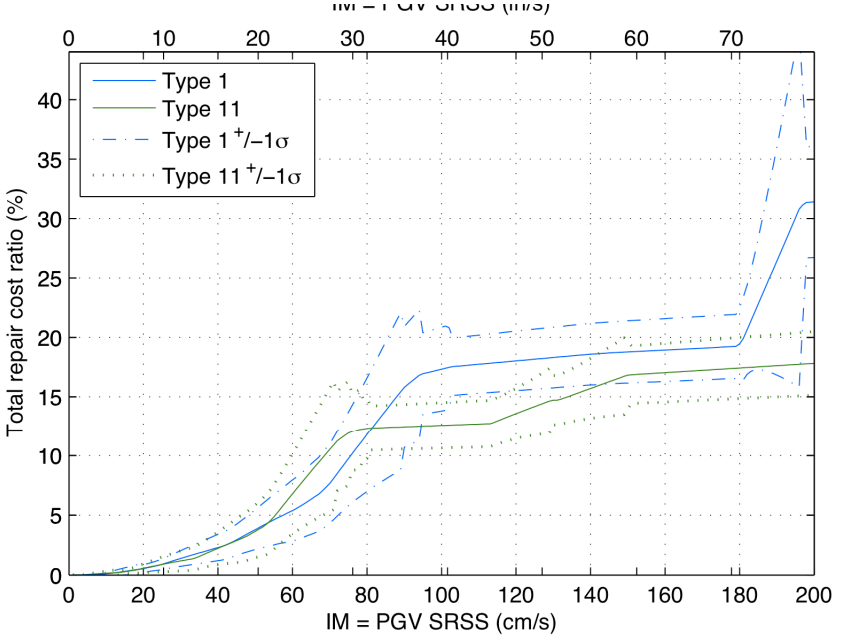

Figure 2. Intensity-dependent repair cost ratio for two bridge configurations.

COMPONENT DAMAGE STATE STUDIES

From data compiled for the Northridge earthquake, the HAZUS (Basöz and Mander 1999) document reports a modified repair cost ratio (RCR) as a function of damage for typical bridges. The HAZUS damage states of slight, moderate, extensive, and complete have mean RCRs of 12%, 19%, 48%, and 100%, respectively. As these were observations made on the inventory and damage cases observed in the region, they range all the way from 0 to 100%. However, the two bridge configurations in this study are intended to be of newer design and construction, and therefore considerably more ductile and less prone to shear and other brittle failures. Therefore, the target RCR levels were modified slightly for this study and are 2%, 5%, 15%, 30%, and 50% for DS1-DS5, respectively.

It is ostensible from Figure 2 that each repair quantity (and therefore each PG) contributes differently to the expected system-level metric of repair cost (or repair time). Not only this, but the relative contribution from each Q differs as the intensity

of the earthquake event changes. To better understand the discrepancy between the component damage states (presented in subsequent sections), the relative contributions of each PG for both bridge types are presented first. Figure 3 shows the disaggregation of the cumulative expected cost at each intensity for Type 1A. Because the repair cost is cumulative and normalized at each intensity, the range is always between 0 and 1 with the distance between lines indicating the contribution of each PG. For example, at and intensity of 120 cm/s, PGs 5 and 6 are the largest contributors (left and right abutment deck end displacement). However, at small intensities such as PGV < 25 cm/s, before gap closure occurs at the abutments, there is zero contribution from these PGs. The data at extremely small intensities (PGV < 10 cm/s) should not be considered as accurate, because the quantities are all being normalized by approximately zero.

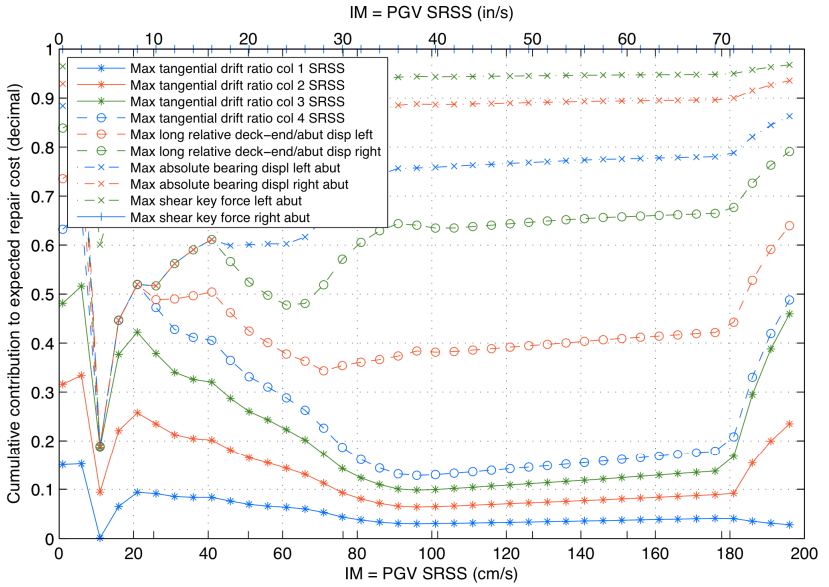

Figure 3. Disaggregation of expected repair cost by performance group (cumulative) for Type 1A.

Figure 4 shows similar information for Type 11B. It is immediately apparent from comparing the two figures that the range of intensities at which the relative importance of the columns and abutments is significantly different. In Type 11B, the columns have a minimal relative contribution to the total cost until a PGV of approximately 110 cm/s (does not imply small repairs and patching are not being performed earlier, only that the relative cost is small compared to the total). The majority of intensities considered in the study have repair costs governed by the abutments for Type 11B.

For each target system RCR, the corresponding distribution of intensity was calculated for each (distribution was assumed to be defined by the first two moments). Using this intensity distribution and the original probabilistic seismic demand models, the distribution of EDPs was obtained for each state and PG. The cumulative distribution function of this EDP was plotted for each PG to illustrate the component-level states that are consistent with the system-level states. It should be

noted that the variance is not strictly correct because it contains a contribution from the uncertainty obtained from the RCR-IM relationship, but only a forward estimate obtained from the demand model.

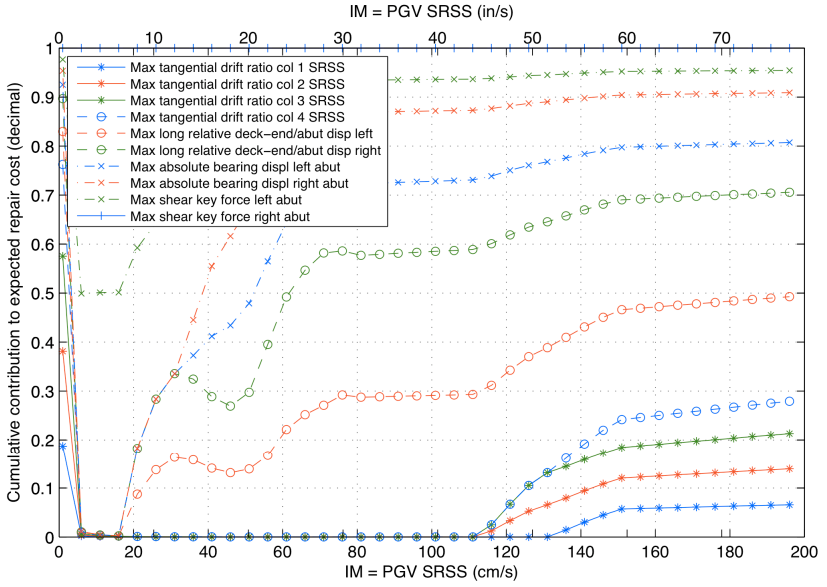

Figure 4. Disaggregation of expected repair cost by performance group (cumulative) for Type 11B.

Because the damage state median values are most often parameterized in terms of the geometric and material properties of the bridge (there is not a single EDP value that describes the onset of damage in columns for example), it is more logical to compare normalized damage fragility curves. The medians were normalized by the largest damage state median of the original damage states for each given PG. Note, in the original formulation, each PG may have a different number of damage states; however, in the proposed (new) comparison, there are a fixed number of damage states. Only the new damage states that fall within the range of system values for a given bridge are shown. For example, for Type 1A, there are only 4 states in the range of intensities considered, whereas for Type 11B, there are only 3 states.

The normalized median values are shown for Type 1A for the first 21 PGs in Figure 5. The remainder of the performance groups are not shown as the particular bridge model was run with elastic springs at the base of the bents; therefore, there are no residual pile deformations to trigger the foundation PGs. For the column PGs (1-4 for maximum, 5-8 for residual), the damage state medians consistent with the system RCR values selected are generally lower than the original damage state medians. This is because the original column damage states have only a lower level state followed by the more extreme cases immediately preceding collapse.

However, for the abutment damage states, the damage state medians consistent with the system are considerably higher, indicative of the fact that they trigger at lower intensities. The larger values (some on the order of two times the original) indicate that the consistent damage states should trigger at higher deformations level to limit the contribution of the abutment to the system RCR. These

relative contributions can be seen in the original disaggregation by PG in Figure 3 and Figure 4. The normalized median values for Type 11B are shown in Figure 6. Similar trends to Type 1 can be observed, although it is also immediately apparent that by normalizing the medians alone, there is no agreement between the consistent component damage state medians between the two bridges.

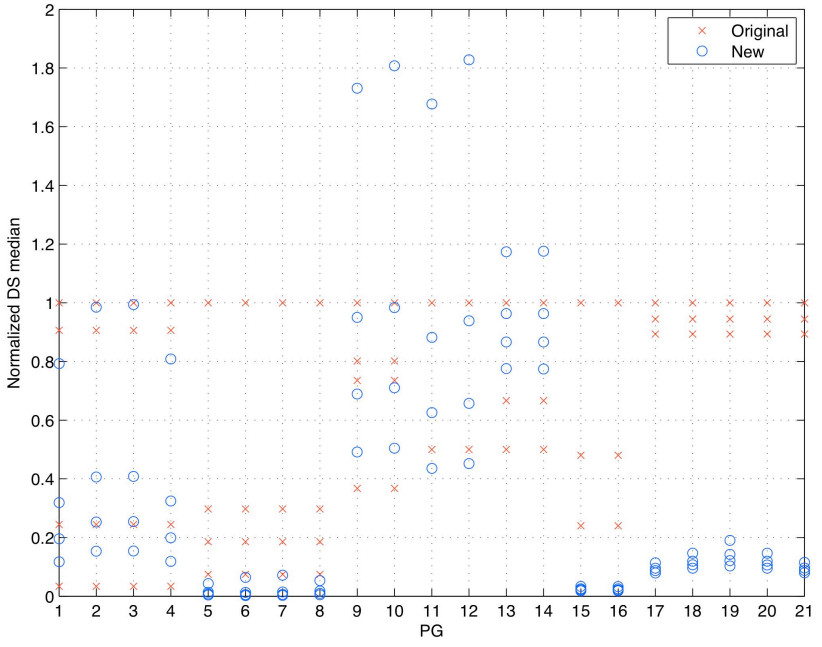

Figure 5. Normalized damage state medians for all performance groups of Type 1A (original and proposed).

The normalized damage state fragilities are shown for PG 2 (second column considering maximum drift ratio) in Figure 7 for both bridge configurations. The median values in the plot correspond directly to Figure 5 and Figure 6. As mentioned previously, there are four damage states that occur within the range of intensities considered for Type 1 and three damage states for Type 11. The only agreement between damage states DS3 and one could argue that DS1 of Type 1 matches DS2 of Type 11. Normalizing the damage states accounts for the differences in the performance of the columns between the two bridge configurations (i.e., in a similar manner as the original damage state medians were parameterized in terms of the bridge properties). However, as the consistent damage states are based on the system RCR, the normalization has no effect on the relative contributions of the columns to the system RCR. This is analogous to saying that the component to system map is different between the two bridges and should not be assumed constant, i.e., the columns do not always contribute a fixed percent to the system RCR, nor will the columns necessarily have the same state of damage or functionality as the rest of the bridge, as has been assumed in the past (Mackie and Stojadinovic 2004).

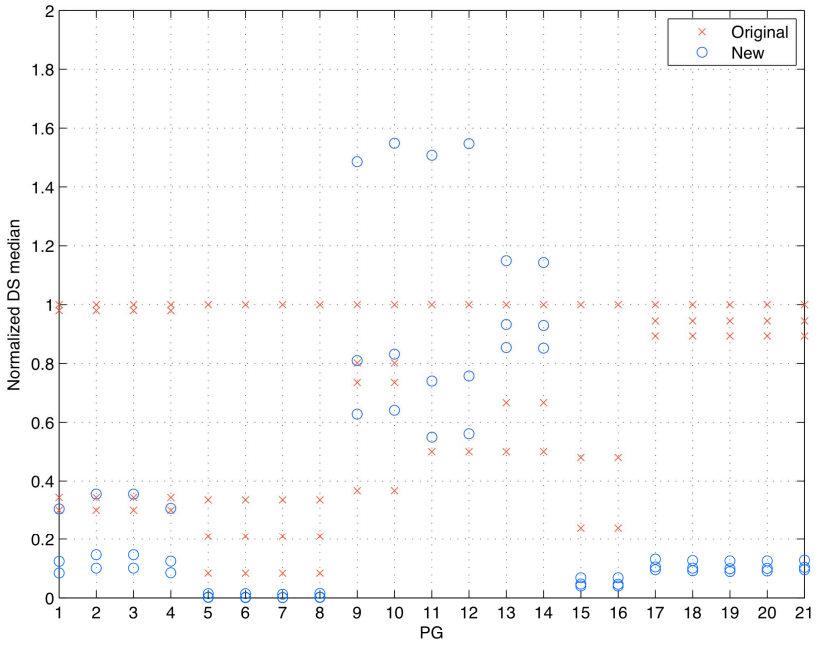

Figure 6. Normalized damage state medians for all performance groups of Type 11B (original and proposed).

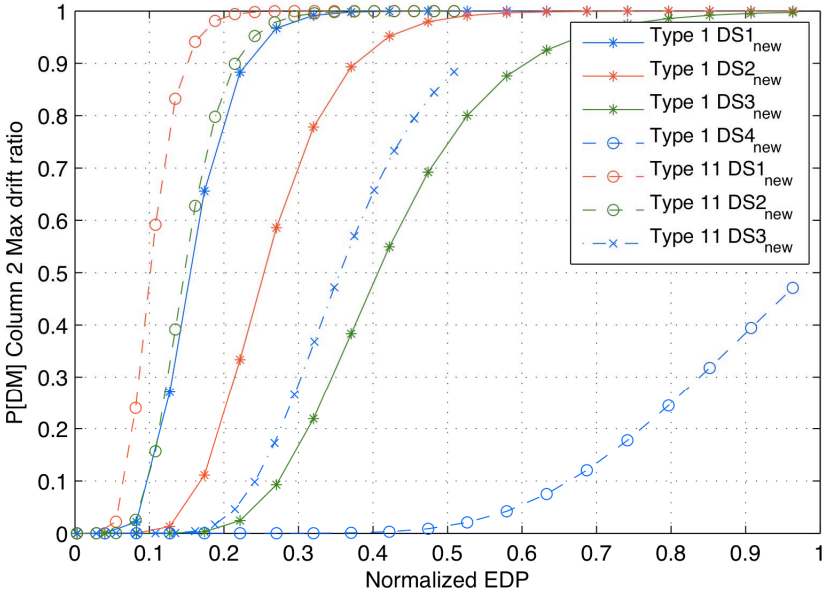

Figure 7. Comparison of normalized damage state fragilities at constant RCRs for performance group 2 (Column 2 maximum drift ratio).

The normalized damage state fragilities are shown for PG 9 (left abutment relative longitudinal displacement) in Figure 8 for both bridge configurations. As with

the column comparison, there is limited agreement between consistent damage states for each of the two bridge types. DS2 for Type 1 and DS1 for Type 11 are among those with approximate correspondence. For Type 1, DS2 corresponds to an intensity of 57 cm/s and DS1 for Type 11 is 38 cm/s. As an index into the disaggregation figures, the intensities correspond to decreases in the importance of the abutment PGs and a region where they are not the dominant contributor to the RCR. However, DS3 has an intensity of 88 cm/s and 134 cm/s for Type 1 and Type 11, respectively. In this region of intensities, the column contributions are approximately constant and the dominant RCR driver is the abutment PGs.

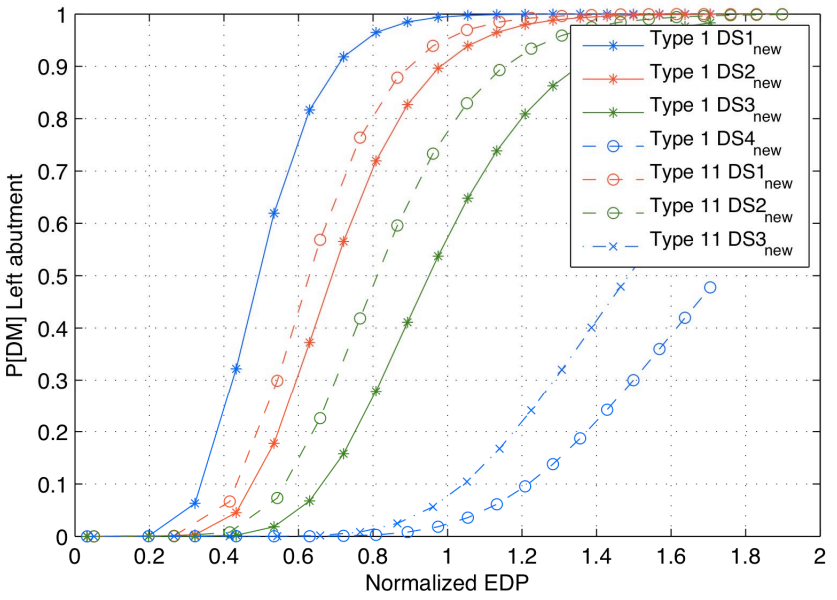

Figure 8. Comparison of normalized damage state fragilities at constant RCRs for performance group 9 (Left abutment relative longitudinal displacement).

A similar exercise could be performed for selected repair time performance levels. However, the repair times tend to be piecewise constant with finite ramps (in CWD-IM space). Therefore, and more intuitively, the system time and cost states were correlated to one another. The solid lines in Figure 9 show this correlation. In addition, approximate plus/minus one standard deviation lines are have been computed. The radial lines emanating from the original show constant intensities (only for the first three states). The Type 11 curve exhibits smaller RCR values throughout (radial lines to the left of Type 1). The two bridge types have a radial line that coincides for the third state, as consistent with the previous discussion.

A critical consideration not mentioned thus far is that a complete comparison between the original and consistent component damage states can only be performed by recomputing the system RCR-IM curve for each bridge. Using the current methodology; however, the exact same result would be obtained because of the local linearization that takes place between the median of the damage state and the repair quantities. This is akin to interpolation; however, the assumption is that the turning points in the locally linear relationship are defined by the original damage states; a

key assumption. Truly, one would need to return to basic damage scenarios based on the new consistent damage states and perform repair design, quantity take off, and cost estimation. This is prohibitive at this time, even for a single selection of component states, particularly because the state of damage defined by these consistent states may not have distinct meaning (onset of certain types of damage) at the damage scenario and repair design phases.

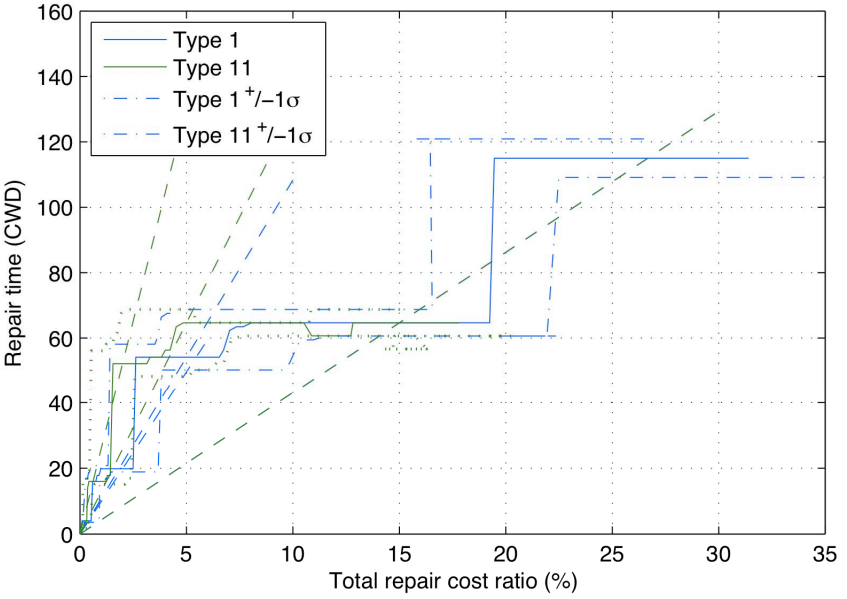

Figure 9. Consistency between RCR and RT estimates with radial lines of constant intensity.

Another important consideration is that the second moment of the consistent component damage states computed here is only approximate and that there is only a single permutation of component damage states that would allow one to arrive at the specified system RCR or RT level. This of course is not true and a more complete parameter estimation analysis would be required to investigate the best fit or most likely value of the median for each PG and damage state that would lead to the RCR distribution (in a probabilistic sense). However, in the absence of a mathematical expression for the DM-Q relationship, this becomes tedious for all but simulation approaches. This topic will be further explored in future work.

CONCLUSIONS

Post-earthquake repair costs and repair times are important system-level metrics for evaluating the performance of bridges. They are the result of the aggregation of costs and repair actions to individual performance groups (PGs) within the structure. In this framework, it is desirable to have a consistent definition of performance between PGs, as well as between the PGs and the system. The results in this paper represent a first step toward quantifying such a consistent relationship between component and system limit states. Here the consistency metric is selected

as different levels of repair cost that are then correlated to repair times. While it is straightforward to ascertain the PG damage state medians that are consistent with different levels of system performance using the LLRCAT methodology, the results indicate that significant challenges remain. Specifically, due to the linearization of the damage to repair model, the proposed damage state medians are merely linear interpolations between the existing median values. Therefore, when performing a separate analysis using the new damage states (in lieu of more scenarios and cost estimation), the same results will be generated. The second major shortcoming is that the component states (while consistent) are not constant between different bridge configurations. This leads to results of questionable usefulness when performing network vulnerability studies. The results demonstrate that the differences in the PG medians is largely due to the relative contributions of the performance groups to the repair cost ratio. However, the relative contributions change with intensity as well as bridge type. Therefore, at this time, more work is necessary to better understand the driving mechanisms behind the component to system level mapping.

ABSTRACT

Seismic fragility estimates are computed for the Fabela Bridge, a five-span single-column bent reinforced concrete bridge, located in Toluca, Mexico based on previously developed probabilistic models for the capacity and demand of typical reinforced concrete bridges. The seismic fragility estimates are computed considering deformation failures in the columns. The approach used in this study properly accounts for epistemic and aleatory uncertainties of the problem. The properties of the bridge used to develop the fragility curves are estimated by matching the frequencies of a 3D finite element model to field data. For this purpose, a 3D finite element model of the studied bridge is created based on the available information of the bridge including drawings and field observations. Then the model is updated based on the modal frequencies obtained from measured accelerations in a series of forced vibration tests on the bridge. Fragility curves are generated to assess the seismic vulnerabilities of the current bridge. Different retrofit strategies are also applied to the bridge model to generate new fragility curves for a retrofitted bridge. The optimal retrofit strategies are determined based on the developed fragilities.

INTRODUCTION

Several cases of bridge failures with single column piers during past earthquakes demonstrate that this type of bridges is vulnerable to ground motions. One of the most important failure cases is the failure of Hanshin Expressway viaducts during the 1995 Kobe earthquake (Hashimoto et al. 2005). Fragility estimates are helpful to quantify

the vulnerability of bridges subjected to seismic loads. This paper estimates seismic fragility of the Fabela Bridge, a five-span bridge with single column concrete piers, located in Toluca, Mexico. Considering the high volume of daily traffic that pass over the Fabela Bridge, its survival after earthquakes is very important. The fragility estimates for the Fabela Bridge are developed based on the current condition of the bridge, which is evaluated based on the results of vibration data resulting from forced vibration tests on the bridge.

This study estimates the fragilities of the bridge in different performance levels. Column drift is used as a measure to define performance levels. Seismic demands on the bridge are estimated using the probabilistic demand model proposed by Gardoni et al. (2003). The seismic demands on the bridge are related to the structural properties of the bridge. Therefore, accurate estimation of the structural properties plays an important role in developing reliable fragility curves. In this study, preliminary values are considered for structural properties based on the available information in construction drawings. Then, the considered values are updated by matching the vibration frequencies of a finite element model of the bridge to those obtained from field data.

An appropriate way to investigate the effectives of retrofit strategies is to evaluate their effect on the reduction of failure probability. Comparison of fragility curves before and after retrofitting the structure reveals the effectiveness of the retrofit strategy. In this study, four retrofit strategies are considered for the studied bridge: steel jacketing and concrete jacketing over the plastic hinge region at the bottom of the columns and also steel and concrete jacketing on all the heights of the columns. The effect of each of these strategies is studied on the fragility curves and based on the results a retrofit strategy is recommended to reduce the vulnerability of the Fabela Bridge to earthquake loads.

This paper has seven sections. First, the preliminary properties of the Fabela Bridge that are obtained from the design drawings are presented. The second section presents the results of the conducted vibration tests on the bridge. Then the updating process of structural properties using vibration data is discussed. Next, the details of each retrofit strategy are presented. Then we present the fragility estimates of the Fabela Bridge and investigate the effect of each retrofit strategy on the fragility curves. Finally, the last section presents the conclusions of this study.

PROPERTIES OF THE STUDIED BRIDGE

The Fabela Bridge is a five-span single-column concrete bridge that is located in Toluca, Mexico. Figure 1 shows the elevation of the Fabela Bridge and its geometrical properties. Three lanes of traffic pass over the bridge. The width of superstructure is 10.95m and it is composed of cellular prestressed concrete girders and a concrete slab. The Fabela Bridge has four single column circular piers with different heights. The diameter of columns are 2m and the height of columns A,B, C and D in Figure 1 are 5.90m, 6.87m, 7.55m and 7.28m, respectively. Columns are continuous to the deck. Joints 1, 3 and 5 in Figure 1 are specified as fixed joints in design drawings and joints 2, 4 and 6 are specified as moveable joints. Elastomeric bearings are used at all joints. Shallow foundations support the piers.

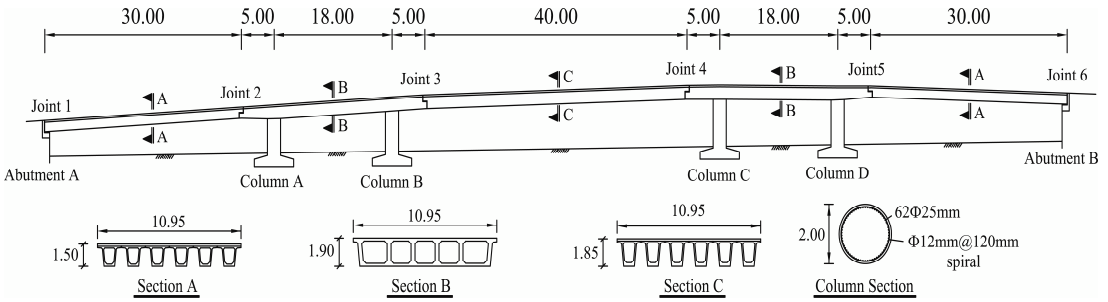

Figure 1. Elevation of the Fabela Bridge (dimensions are in meters unless otherwise mentioned).

VIBRATION TESTS

Vibration test data by Bisadi et al. (2011) has been used in this study. Two accelerometers on the bridge deck have been used to record the transverse accelerations during vibration tests with sampling time of 0.005 second. One of them was installed on the deck at the top of Column B and the other one was installed 20m away from the first one near the center of the bridge. Vibration tests were conducted using a two-axle truck with the weight of 164kN. The truck moved on the bridge with various speeds varying from 10km/h to 40km/h.

After recording accelerations, baseline correction and an eighth order bandpass filter are applied on them. The highpass and lowpass frequencies in the bandpass filter are considered equal to 0.3 and 20 Hz, respectively. Also, Hanning window (Oppenheim and Schafer 1989) is applied on the recorded accelerations to make the start and end points of the records match. Then, Fourier spectra of accelerations are computed and vibration frequencies are determined.

Four transverse vibration frequencies are obtained from recorded accelerations and are equal to 1.190Hz, 2.127Hz, 2.872Hz and 3.473Hz. It should be noted that these frequencies are limited to those transverse mode shapes of the bridge that produce vibrations at the location of accelerometers and are not necessarily the first four transverse vibration frequencies of the bridge. For example, the installed accelerometers do not capture vibration modes in which only the end parts of the deck (between joints) vibrate.

UPDATING STRUCTURAL PROPERTIES

Deterioration of bridge components during time makes changes in structural properties such as the stiffnesses of components that in turn change the vibration characteristics of the bridge. This is one of the reasons that the vibration frequencies of a model created based on the construction drawings does not match those obtained from measured data in field. Also, there are always some errors in the modeling assumptions that cause approximations in the results of analytical models. In this study, an analytical model is created first based on construction drawings and then structural properties in the model are updated to match the model vibration frequencies to those obtained from field data. The first part of this section describes the details of the finite element model of the Fabela Bridge and the second part explains the method used for updating structural properties of the created model.

Analytical modeling

Pushover analyses on the finite element model of the bridge are required in this study to compute the deterministic part of the demand model. Therefore, an appropriate finite element model of the bridge is needed. A 3D nonlinear finite element model of the Fabela Bridge is created in finite element package OpenSees (McKenna & Fenves 2009). Elastic frame elements are used to model bridge deck. The mass of the deck is considered as concentrated masses at the deck element nodes. Following Naeim & Kelly (1999) a bilinear force-displacement relationship is used for modeling the elastomeric bearings. Bridge foundations are modeled using translational and rotational linear springs based on the relations recommended in FEMA 356 (2000). For modeling of bridge abutments, Caltrans (2006) recommendation are used for the calculation of abutment stiffness in both longitudinal and transverse directions.
Columns of the bridge are modeled by assigning fiber sections to displacement beam-column elements in OpenSees. Confined concrete material properties are assigned to the core concrete of the columns and unconfined concrete material properties are assigned to the cover concrete. Confinement effectiveness coefficients are calculated based on the relations developed by Mander et al. (1988). Five percent damping are considered for the structure in the analytical model.

Updating method

The goal of updating structural properties is to match the model vibration frequencies to those obtained from field data. To achieve this goal the following error function has to be minimized:

$$e = \sum_{i=1}^{n} \frac{\hat{f}_i^2 - f_i^2}{f_i^2} \tag{1}$$

where e = the error term; $\hat{f}_i$ = vibration frequency of mode i from finite element model; f_i = target vibration frequency of mode i from field data; and n is the number of considered modes. Since four transverse vibration frequencies obtained from field data in this study, $n=4$ in the above equation. It should be mentioned that the vibration frequencies of the first four modes in the finite element model that cause displacements at the location of installed accelerometers are considered to compute error function.

The value of the $\hat{f}_i$ in Equation 1 depends on a vector of structural properties, **x**, that is used in the finite element model. Therefore, the value of **x** that minimizes the error term in Equation 1 has to be found. To effectively update the value of **x**, sampling based techniques such as Markov Chain Monte Carlo (MCMC) simulation technique (Gilks et al. 1996) can be used. In this study, we use MCMC simulation technique with the Geweke method (Geweke 1991) for convergence criteria.

Table 1 shows the initial, updated and target vibration frequencies. Table 2 shows the structural properties that are considered in updating process and their initial and updated values. Updated structural properties are used to estimate probabilistic capacity and demand models and fragility of the Fabela Bridge.

Table 1: Initial, updated and target frequencies.

	Vibration Frequency (Hz)			
	Mode 1	Mode 2	Mode 3	Mode 4
Initial	1.283	1.721	1.888	2.113
Updated	1.147	2.174	2.484	3.507
Target	1.190	2.127	2.874	3.473

Table 2: Initial and updated structural properties.

		Value	
Parameter	Unit	Initial	Updated
Foundation-transverse stiffness	kN/m	9.20×10^{5}	1.74×10^{6}
Foundation-rotational stiffness	kNm/rad	1.05×10^{7}	1.14×10^{7}
Abutment transverse stiffness	kN/m	9.15×10^{4}	7.37×10^{4}
Bearing stiffness at Joints 1,3 & 5	kN/m	8.41×10^{3}	8.88×10^{3}

EI of Deck	kNm^2	1.26×10^{9}	1.00×10^{9}

RETROFIT STRATEGIES

Four retrofit strategies are considered in this study and the effects on them on the fragility curves of the bridge are investigated. The first retrofit strategy is using steel jackets over the plastic hinge length at the bottom of bridge columns. Steel jacketing is the most common retrofit technique for concrete columns in bridges (Priestley et al. 1996; Tamai et al. 2000). Using steel jacketing increases the confinement stress that helps increase the ultimate strain and compressive stress of concrete. It is especially helpful for the unconfined concrete at the cover where there is no confinement stress. In this study, steel jacketing with 10mm thickness is considered for the first retrofit strategy. The second studied retrofit strategy in this paper is concrete jacketing at plastic hinge length at the bottom of the columns. Similar to steel jacketing, this retrofit strategy provides additional confinement at the location of the plastic hinge region at the bottom of the columns. For this retrofit strategy, using 12mm transverse reinforcement at center to center distance of 80mm is considered for the jacket. The third and fourth retrofit strategies are using steel and concrete jacketing over all the height of the columns, respectively, where all of the retrofit strategies are listed and described in Table 3. Figure 2 shows the cross section of the considered jackets in different strategies.

Table 3: Retrofit strategies considered in this study.

Retrofit Strategy	Description
Strategy 1	Steel jacketing on plastic hinge
Strategy 2	Concrete jacketing on plastic hinge
Strategy 3	Steel jacketing on whole column length
Strategy 4	Concrete jacketing on whole column length

FRAGILITY ESTIMATION

This study employs probabilistic demand models to estimate the fragility of the Fabela Bridge in three performance levels. Commonly accepted values of 1, 2 and 4% are used for the mean of column drifts at insignificant damage, moderate damage and severe damage performance levels, respectively. The failure of the bridge at each

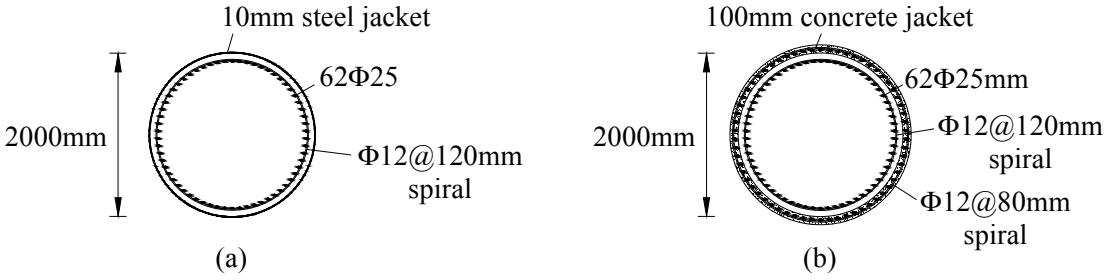

Figure 2. Properties of the considered jackets: (a) steel jacket (b) concrete jacket

performance level is defined as the failure of at least one column of the bridge. The limit state function for each column of the bridge in each performance level is defined as follows:

$$g_{i,j}(\mathbf{x},\boldsymbol{\Theta}) = C_j - D_{i,j}(\mathbf{x},\boldsymbol{\Theta}),\ i = A,B,C,D \tag{2}$$

where C_j= corresponding drift to performance level j; $\boldsymbol{\Theta}$=set of model parameters; and $D_{i,j}(\mathbf{x},\boldsymbol{\Theta})$= probabilistic demand model for column i at performance level j.

Multivariate probabilistic demand models proposed by Gardoni et al. (2003) are used in this study. The demand models are composed of the following three terms:

$$D_i(\mathbf{x},\boldsymbol{\Theta}_i,\boldsymbol{\Sigma}) = \hat{d}_i(\mathbf{x}) + \gamma_i(\mathbf{x},\boldsymbol{\theta}_i) + \sigma_i\varepsilon_i \quad i = A,B,C,D \tag{3}$$

where $\boldsymbol{\Sigma}$ =covariate matrix of the demand model and $\hat{d}_i(\mathbf{x})$= deterministic demand model for column i. $\gamma_i(\mathbf{x},\boldsymbol{\theta}_i)$=correction terms to consider bias inherent in the deterministic capacity model; σ_i= standard deviation of the model error; and ε_i = a random variable with normal distribution, zero mean and unit standard deviation. The deterministic demand part of the above models is computed based on a modification proposed by Gardoni et al. (2003) of the capacity-demand-diagram methods based on the inelastic design spectrum method originally developed by Chopra and Goel (1999). The correction terms for the demand models consist of explanatory functions and have the following form:

$$\gamma(\mathbf{x},\boldsymbol{\theta}) = \sum_{j=1}^{p_k} \theta_j h_j(\mathbf{x}) \tag{4}$$

where $h_j(\mathbf{x})$ are explanatory functions for demand models and have been defined in Gardoni et al. (2003).

Figure 3 shows the fragility curves of the Fabela bridge in different performance levels. Figure 3 reveals that the effect of the studied retrofit strategies on the fragility curves of the Fabela Bridge is not considerable. It is due to the good condition of the unretrofitted structure, which has enough capacity subject to the applied seismic loads and retrofit plans do not help it very much. The other reason is that the drift corresponding to each performance level is considered the same for original and retrofitted structure in this study. Further research is needed for defining the drifts corresponding to performance levels more accurately. However, Figure 3 reveals that the effect of the studied steel jacketing on the reduction of probability of failure of the Fabela Bridge is more than the studied concrete jacketing. It is also found that using the jackets along the entire height of the columns do not have any effect on the fragility curves rather than using the jackets on the plastic hinge length of the columns. It is illustrated in Figure 3 because the fragility curves of the retrofit strategies 3 and 4 match on the fragility curves of the retrofit strategies 1 and 2, respectively. Figure 4 shows the variation of the probability of failure of the structure with the drift capacity of the columns. Although there is not a considerable difference between the probability of failure of the original structure and retrofitted structure with different strategies in Figure 4, but that difference increases while pseudo acceleration increases.

SUMMARY AND CONCLUSIONS

This paper estimated the fragility curves for a five-span single-column concrete bridge in Toluca, Mexico. The results of experimental vibration tests were used to update the structural properties of studied bridge to obtain the current condition of the Fabela Bridge. Four retrofit strategies were proposed to decrease the failure probability of the studied bridge. The first two retrofit strategies were using steel and concrete jacketing over the plastic hinge area of the columns, respectively. The third and forth studied retrofit strategies were similar to the first two strategies but the steel and concrete jackets were considered along the entire height of the column. Fragility of the original structure and retrofitted structure with different retrofit strategies were estimated using Monte Carlo simulation. Three different performance levels of insignificant damage, moderate damage and severe damage with corresponding drift values of 1%, 2% and 4% were considered in this study. The results showed that the studied strategies did not help reduce the probability of failure considerably because of the existing good condition of the studied bridge. The existing good condition of the studied bridge was obvious based on the results from the vibration data, where the updated properties are for the most part better than what was specified in design drawings. The updated stiffness of the columns, which has an important role in affecting the probability of failure, was concluded to be more than its value based on design drawings. However, despite the small effect of the retrofit strategies on the probability of failure of the bridge, using steel jacketing over the plastic hinge length of the columns was found to be the most effective retrofit strategy among the studied strategies. The results showed that using jacketing on the entire column height does

not cause any additional reduction in the probability of failure than using jacketing over the plastic hinge length. Future work will include investigating the effect of the retrofit strategies on the corresponding drifts to performance levels, which are important parameters in the determination of the failure probability.

ABSTRACT

Seismic fragility modeling of highway bridges is becoming a well developed and accepted field among engineers. Within any fragility estimate exists many sources of uncertainty. One source of uncertainty which is key to robust fragility modeling is the aleatory uncertainty which exists within the ground motion suite itself. One obvious question an analyst must ask pertains to the appropriate number of ground motions which must be used to appropriately capture this aleatory uncertainty. This study looks to add to the existing knowledge base, established by previous research, by explicitly looking at the resulting uncertainty estimates as the size and make-up of the ground motion suite is altered.

To explore this issue of ground motion suite size four bridge models which are representative of bridges in the Central and Southeastern United States (CSUS) are developed. Median value estimates for all bridge modeling parameters are utilized and held constant and no uncertainty in component capacities is used in an effort to decouple the aleatory uncertainty in the ground motions from the epistemic uncertainty present in typical modeling parameters. Utilizing a suite of 160 recorded ground motions as a pool, numerous subsets of this suite are created and used to generate fragility curves. To keep variation in median and dispersion estimates reasonable this preliminary study recommends that a suite of 80 or more ground motions be used. Such information is essential as fragility modeling gets closer to being an everyday reality for the practicing engineer.

INTRODUCTION

As time passes more and more researchers and engineers across the country are becoming involved in the seismic fragility assessment of highway bridges. Of the three general approaches to fragility curve development (i.e. expert (ATC 1985; ATC 1991), empirical (Basoz and Kiremidjian 1999; Shinozuka et al. 2000b), analytical (Jernigan and Hwang 2002; Mackie and Stojadinovic 2006; Nielson and DesRoches 2007b; Shinozuka et al. 2000a)), the analytical procedure using full nonlinear time history analysis has become quite popular (Aygun et al. 2011; Oh-Sung and Elnashai 2010; Pan et al. 2010; Simon et al. 2010). One specific requirement of this approach is the assembly of a suite of ground motions which is of sufficient size so as to

adequately capture the underlying seismic demand on the bridge structure and to also be representative of the underlying stochastic process of the seismic hazard (Mackie et al. In Press). Thus, a fragility analyst is charged with assembling the correct type and number of ground motions to ensure that the epistemic uncertainty captured in the analysis is not too large.

For design purposes, the suite size for buildings can be taken as either three or seven depending on the specific application (ASCE 2010). However, ground motion suite sizes for fragility analysis must also be able to quantify and minimize the uncertainty in the estimates as well. To this end, the correct number of ground motions to be used is not something which is well understood or agreed upon by those working in the field. Some have used as few as 20 ground motions if the ground motions are selected to meet certain criteria (Wen and Wu 2001). However, many of the recent studies have used between 80 and 100 ground motions to meet the needs of the analysis (Mackie and Stojadinovic 2004; Nielson and DesRoches 2007a; Pan et al. 2010; Simon et al. 2010).

The current study takes a closer look at the impact ground motion suite size has on both fragility median and dispersion estimates. This is done by using an assembled suite of 160 recorded ground motions which are then repeatedly sampled to generate subsets of ground motions of different sizes. These subsets are then used to generate system level fragility curves for four different bridge models which identify some clear consequences of suite size.

GROUND MOTION SUITE

The base ground motion suite used for this study consists of 160 recorded ground motions which are taken from the PEER Next Generation Attenuation strong ground motion database (PEER 2010). This is the same suite which has been used in a previous bridge fragility based study (Mackie et al. In Press). The suite was assemble using a binning approach wherein the bins were divided into large (L) and small (S) earthquake magnitudes (M) and also long (L) and short (S) site-to-source distances (R). Furthermore, an equal representation of time histories from NEHRP soil types C and D was also sought (ASCE 2010). Figure 1 gives a visual understanding of the make-up of each bin. As seen in this figure, a magnitude of 6.5 is taken as the cut-off between large and small earthquakes while 30 km is taken as the cut-off between long and short distances. Thus, 20 ground motions for each soil type are given for each bin.

To provide a more complete picture of the suite make-up, the response spectra for pseudo-acceleration (S_a) and pseudo-velocity (S_v) are given for each ground motion in Figure 2. The 10^{th}, 50^{th}, and 90^{th} percentile spectra are also provided to illustrate the variability which is inherent in the compiled suite. The main energy content seen in the pseudo acceleration spectra is seen in the range of periods from 0.2 to 0.5 seconds. The spectral velocity is more dominated by the range of periods from 0.5 to 1.0 seconds. The rationale for creation of the ground motion subsets is provided later in the manuscript.

CASE STUDY BRIDGES

Two bridge classes common to the Central and Southeastern United States (CSUS) were selected for evaluation – namely the multi-span simply supported (MSSS) steel girder bridge and also the multi-span continuous (MSC) concrete girder bridge. Thorough descriptions of each bridge class and appropriate modeling parameters can be found in Nielson (2005). However, a basic description including typical details of these bridge classes is given in Figure 3. Each bridge is three spans with equal length approach spans (12.2 m) which are supported on three-column bents. The columns are circular reinforced concrete columns which are poorly detailed for resisting seismic forces. The steel girder bridge uses high-type steel bearings while the concrete girder bridge uses elastomeric bearings and pre-cast AASHTO I-girders. The girders are made continuous with a cast-in-place continuity diaphragm. Most of the bridge components are modeled to capture nonlinear behavior (bents, abutments, bearings and impact) while the superstructure uses linear models.

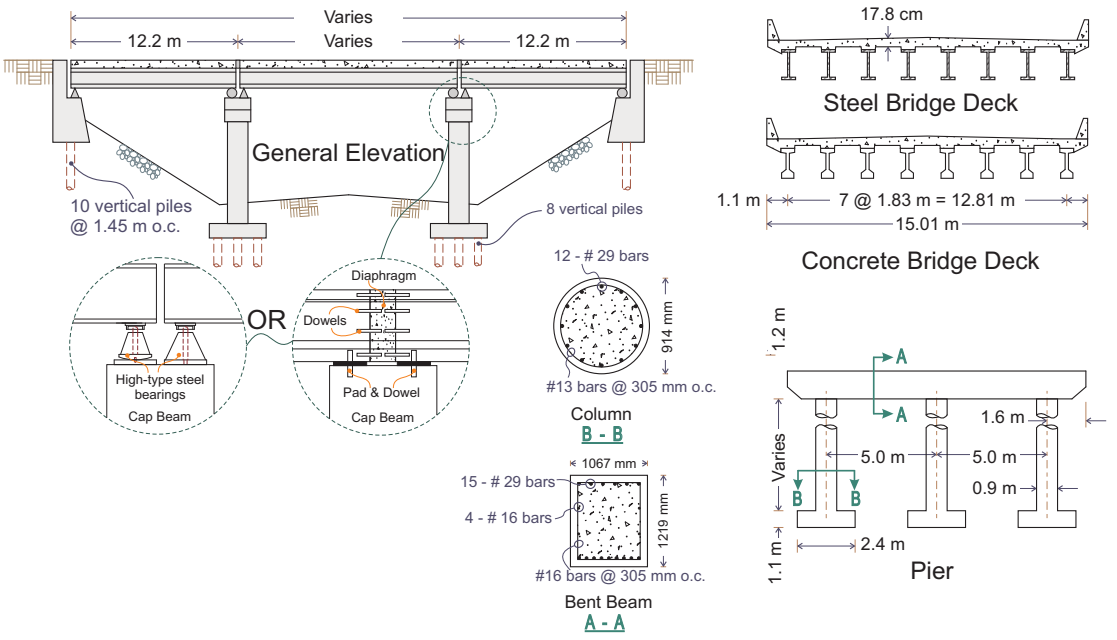

Figure 3. Typical details for MSSS steel girder and MSC concrete girder bridges

Two bridge models from each of the two bridge classes were generated to cover a wider range of structural periods to see if it had any impact on the findings. The center span lengths and columns heights were varied to ensure that different periods were realized. Table 1 provides a brief summary of the characteristics of each of the bridge models used in this study. One may note that the columns have either a 5.0 m or 7.0 m height which are the two most commonly occurring heights for bridges in the CSUS (Nielson 2005). The span lengths are either 16.25 m or 32.5 m. For the MSSS Steel bridge models the first longitudinal modal period is either 0.371 s or 0.252 s and are denoted as long period and short period respectively. The concrete girder bridges have fundamental periods of 0.719 s for the long period and 0.489 s for the short period bridge.

The ground motion intensity measure (IM) used for the computed fragility curves for the bridges labeled as long is peak ground velocity (PGV) and the IM for the bridges labeled as short is peak ground acceleration (PGA). In all cases these IMs were selected because they were deemed to be the most efficient (i.e. the smallest dispersion estimates).

Table 1. Basic properties of the four evaluated bridges

Bridge No.	Bridge Description	Center Span Length (m)	Column Height (m)	Long* Period (s)	Trans** Period (s)
1	MSSS Steel – Long	32.5	7.0	0.371	0.358
2	MSSS Steel – Short	16.25	5.0	0.252	0.224
3	MSC Concrete – Long	32.5	7.0	0.719	0.553
4	MSC Concrete Short	16.25	5.0	0.489	0.374

* Long ➔ longitudinal ** Trans ➔ transverse

RESULTS

The probability that a bridge structure exceeds a prescribed damage state or fails to meet a performance expectation, conditioned on a seismic intensity measure (i.e. PGA, PGV, S_a and etc.), can be expressed using a fragility curve. A common way of determining the non-performance (fragility) of a bridge is to express the damage state in terms of demand (D) exceeding capacity (C) or $C < D$. If both the capacity and demand are lognormally distributed, the fragility (F_R) or conditional probability of failure for a given damage state can be computed using the following equation:

$$F_R(C < D \mid IM) = 1 - \Phi\left(\frac{\ln(m_C) - \ln(m_D)}{\sqrt{\beta_C{}^2 + \beta_D{}^2}}\right) \tag{1}$$

where m and β are the median and logarithmic standard deviation (i.e. the uncertainty), and subscripts C and D denote the capacity and demand, respectively. IM is the intensity measure, i.e. PGA or PGV.

Four damage states are defined in this study: slight, moderate, extensive and complete damage. The details of the damage state definition and description can be found elsewhere (Nielson 2005).

The median of the demand parameters (curvature ductility of columns and deformation of bearings) is estimated using a power equation (Cornell et al. 2002):

$$\begin{aligned} D &= b_o \left(IM\right)^b \varepsilon = m_D \varepsilon \\ \ln(D) &= \ln(b_o) + b\ln(IM) + \ln(\varepsilon) = \ln(m_D) + \ln(\varepsilon) \end{aligned} \tag{2}$$

where b_o and b are the regression constants. ε is a normally distributed error term with a zero mean. The demand uncertainty arises from the inherent randomness in the ground motions which is quantified by the logarithmic variance of ε (or variance of $\ln(\varepsilon)$).

In order to investigate the influence of the ground motion suite size on the estimation of the demand uncertainty (β_D), the bridge fragility curves were generated using eight different ground motion suite subset sizes (16, 24, 32, 48, 64, 80, 96, and 120 ground motions). Figure 4 shows four examples of ground motion subsets. For each ground motion subset, 20 ground motion suites (realizations) were randomly assembled by selecting an equal number of ground motions from each bin, grouped by moment magnitude and site-to-source distance. Thus if an analyst were to use only 16 ground motions using the binning approach, then each ground motion in a given bin would have equal probability of being selected for the suite. The demand parameters estimated using these ground motion suites were then used to generate component and system level fragility curves. It should be noted that the fragility curves presented in this paper do not include the capacity uncertainty (β_C). This allows one to quantify the effect of demand uncertainty on the fragility estimation without the influence of the capacity uncertainty.

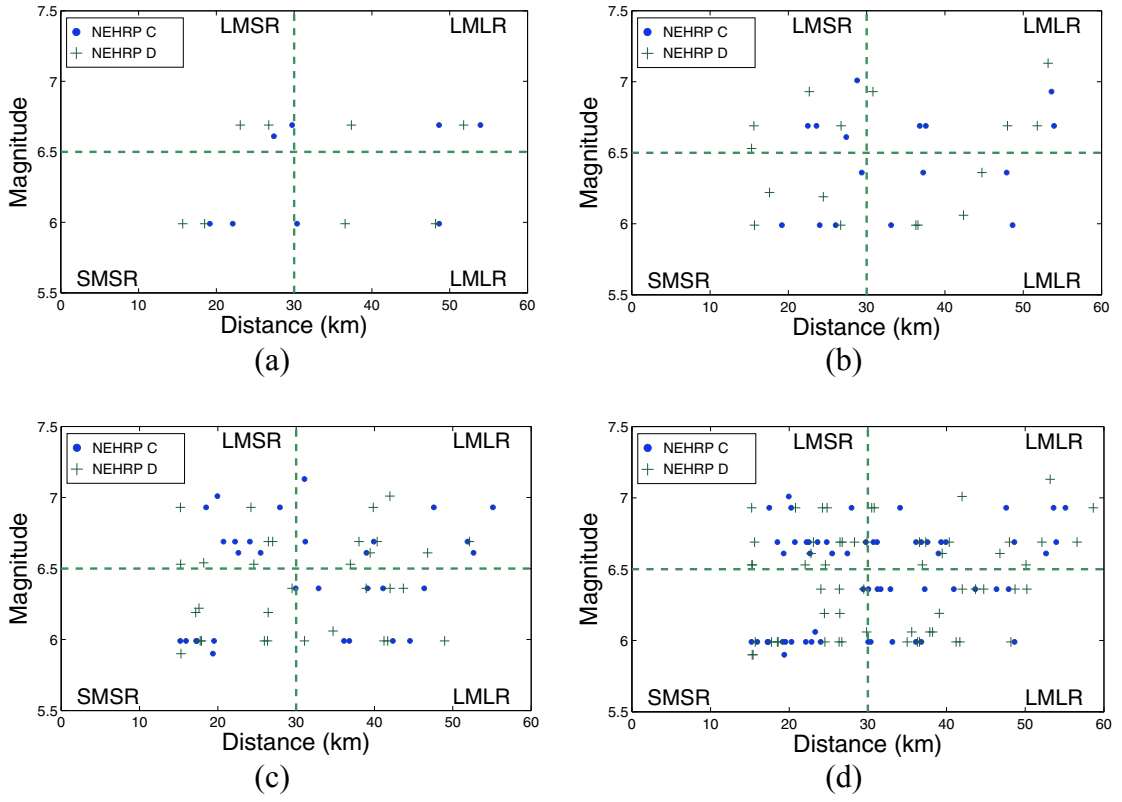

Figure 4. Examples of ground motion subsets (a) 16, (b) 48, (c) 80 and (d) 120

Figure 5 shows four representative sets of moderate damage state system fragility curves for bridge type 2 (MSSS Steel – Short) estimated using 16, 48, 80 and 120 ground motions. For all ground motion subsets, twenty fragility curves are determined and plotted in Figure 5 along with the 10^{th} and 90^{th} percentiles. These percentiles are bounds which represent the error band in the estimation of the fragility curve. It is clear to see that as the number of ground motions increases, the error band of the fragility curve reduces. Significant error may exist if one uses only 16 ground motions to generate the fragility curve for bridge type 2. Also shown in the figure is the fragility curve determined using all 160 ground motions. The fragility curve produced using all 160 ground motions is assumed to be the "true" or benchmark fragility curve. For example, if only 16 ground motions were used to estimate the fragility of a type 2 bridge located at a site with PGA equal to 0.5g (see Figure 5a), the probability of exceeding the moderate damage state may range from 0.44 to 0.96 while the "true" exceedance probability is approximately equal to 0.62.

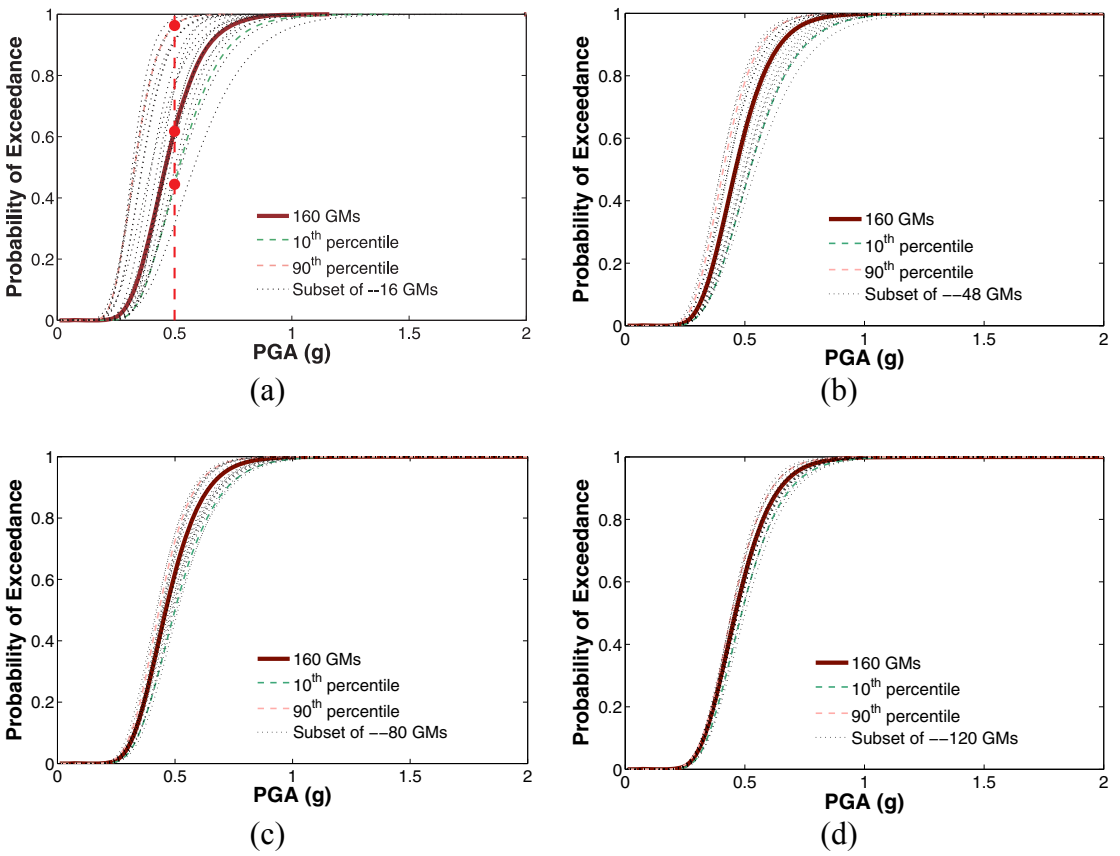

Figure 5. Bridge type 2 – Moderate damage state using the following number of ground motions (a) 16 , (b) 48, (c) 80 and (d) 120

Figure 6 gives the fragility curves for bridge type 2 at a complete damage state for the same four representative suite sizes (i.e. 16, 48, 80, 120). A comparison between the moderate damage state and complete damage state reveals that the error bands for the complete damage state is larger than that of the moderate damage state. This same trend exists for the other damage states and the other bridge types as well. This increase in the error band width with higher damage states is to be expected since the seismic demands generally stay close to the linear elastic range for the lower damage states. However, the demands of the higher damage states are usually associated with the highly nonlinear region of the structure response. The more nonlinear the structure becomes the more sensitive it will be to specific ground motion characteristics such as duration and intensity. Thus a larger variation in the demand and the subsequent fragility curves is expected.

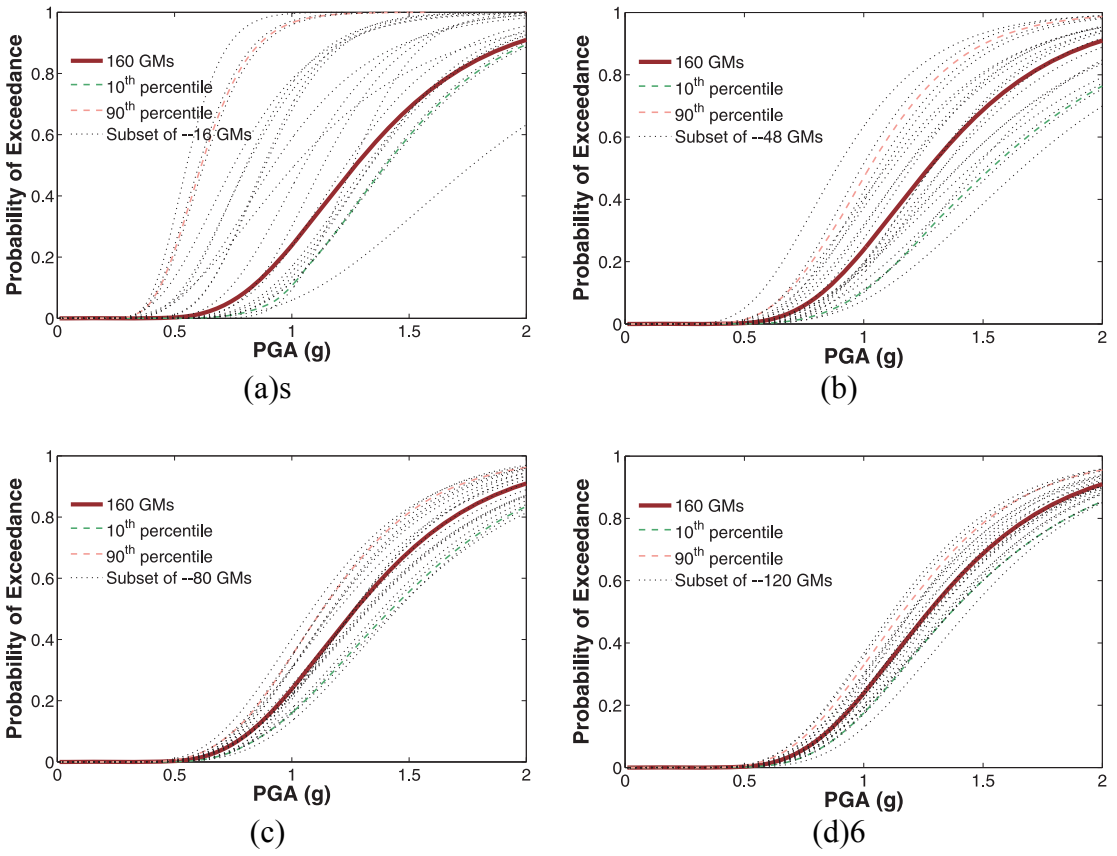

Figure 6. Bridge type 2 – Complete damage state using the following number of ground motions (a) 16 , (b) 48, (c) 80 and (d) 120

For illustration purposes Figure 7 is provided for the moderate damage state for bridge type 3 (MSC concrete – long). The combined effect of bridge construction type and ground motion suite size can be seen by comparing the fragility curves shown in this figure with those found in Figures 5 and 6 (MSSS steel - short). At a given damage state and for the same number of ground motions, the variation in the fragility estimation is larger in the type 3 concrete bridge than that of the type 2 steel bridge. This larger variation in one type over the other type can be attributed to the levels of contribution one gets from each of the bridge components. For example, the steel bearings and the concrete columns in the MSSS steel bridge both make significant contributions to the overall computed system fragility. The resulting dispersion values (for the 160 ground motions) are 0.31 for slight damage to 0.34 for complete damage. By comparison, computed dispersions for the MSC concrete bridge range from 0.56 for slight damage to 0.54 for complete damage where the columns play a much more significant role on the overall system fragility estimates. This inherent increase (approx 50%) in the dispersion estimates, which was also seen in a previous study (Nielson 2005), appears to map over to a larger variation in the fragility estimates for the type 3 bridge for a given ground motion suite size.

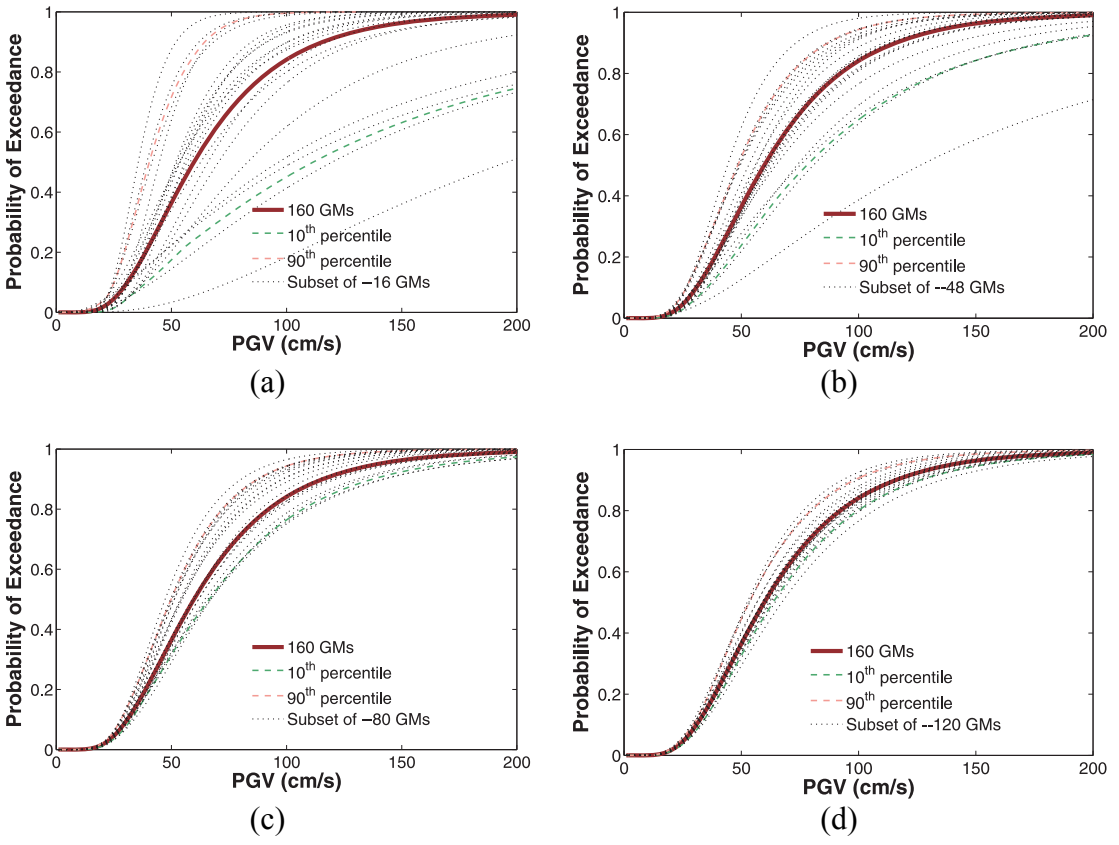

Figure 7. Bridge type 3 – Moderate damage state using the following number of ground motions (a) 16 , (b) 48, (c) 80 and (d) 120

Figure 8 illustrates the influence on the number of ground motions on the dispersion of the median estimates of the fragility curves for the four bridge types considered in this study. As expected, the dispersion of the median estimates of the fragility curves reduces as the number of ground motions increases. A similar trend is observed for the dispersion estimates of the fragility curves (Figure 9). The dispersion in the median estimates explains the horizontal spread of the fragility curves seen in figures 5 to 7 whereas the dispersion of the dispersion estimates of the fragility curves describes the variation of the slope of the fragility curves observed in the same figures. Since the calculated dispersions in Figure 9 are direct estimates designed to capture the aleatory uncertainty in the ground motion suite, then the scatter seen in these estimates represents the epistemic uncertainty associated with suite size and selection. The results of this preliminary study seem to suggest that, in order to obtain reliable estimates of both the median and dispersion of a fragility curve, a large number of ground motions (80 or more) should be used to perform the dynamic time history analysis. Using this number of ground motions, the bands on the dispersion estimates are no more than ±20% of the "true" dispersion. However, if only 16 or 24 ground motions are used then the error can be as large as 60-70% (See Figure 9).

CONCLUSIONS

This paper presents the results of a study to examine the effects of ground motion suite size on the aleatory uncertainty estimates of bridge fragility curves. Four bridge types were considered in this study, namely MSSS steel and MSC concrete bridges each with a long and a short fundamental period. The variation of the median and dispersion of the bridge fragility curves for four damage states were estimated using eight different ground motion suite subsets, ranged from 16 to 120 ground motions. The results show that using ground motion suites with 24 or less ground motions can result in erroneous bridge fragility estimation. In order to obtain reliable estimates of both the median and dispersion of a fragility curve, a relatively large number of ground motions, in the order of 80 or more, are needed.

The number of ground motions suggested for use may possibly be reduced if a more selective process is used to assemble the ground motion suite. When one uses a simple four-bin approach (M-R), three of the bins lend themselves to providing low intensity ground motions. As such, a subset of 16 ground motions may produce a suite of ground motions which are all low intensity but it can also produce a subset which has a higher percentage (up to 25%) of high intensity ground motions. This results in the high variability in the median and dispersion estimates seen in this

study. Placing specific intensity requirements on the M-R bins may result in less variability in the responses and if this happens the size of the ground motion suite may be eligible for reduction. This will be investigated in future studies.

ABSTRACT

A methodology is proposed to analyze the structural redundancy of bridge systems under lateral loads. The paper compares the results obtained from a probabilistic approach to those of a simplified deterministic analysis. A non-linear finite element analysis based on a 3-D frame model is performed for an example bridge considered to be representative of the behavior of structures with integral column-superstructure connections. The analysis accounts for material non-linearity using realistic models for the stress-strain relationships of the different constituents. The quantification of the available redundancy levels is evaluated using reliability as well as deterministic criteria previously proposed in NCHRP 458.

INTRODUCTION

The design of bridges has traditionally been performed on a member by member basis and little consideration is usually provided to the remaining capacity of the system after the failure of one structural element. As a consequence of several tragic collapses that followed the failure of single elements, the evaluation of the structural redundancy and robustness of bridges has become of primary importance.
The evaluation of the safety of structural members and systems and the calibration of bridge design and evaluation specifications are based on meeting target reliability levels (ISO 2394; 1998 and AASHTO LRFD; 2008). The target reliabilities are usually specified to match the performance of previous successful designs and are related to the expected social and economic consequences of failures as well as society's risk tolerance.
Target reliability indices are the bases for calibrating load and resistance factors and partial coefficients used in limit state design. Alternatively, the reliability index, β, can be calculated for each structure individually by evaluating the probability of limit state exceedance, P_f. The relationship between the two parameters may be represented by $P_f = \Phi^{-1}(-\beta)$ where Φ is the Normal cumulative distribution function (see figure 1). The reliability index can be used as a measure of the reliability of structural members as well as structural systems and accounts for both

the margin of safety implied by the design procedure and the uncertainties in estimating member strengths and applied loads.

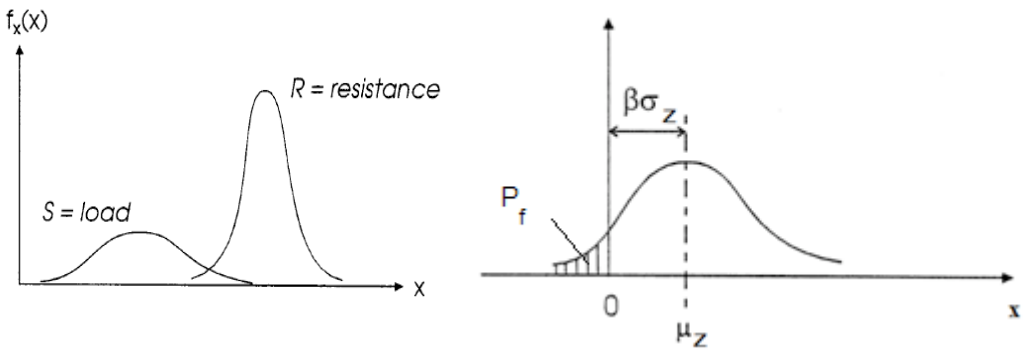

Figure 1. Representation of probability based evaluation of structural safety a) Probability distribution of load and resistance and b) probability distribution of limit state function.

Measures of Redundancy. Ghosn (1998) and Liu et al. (2000) defined redundancy as the capability of the system to continue to carry loads after the failure of one main member. Accordingly, Ghosn (1998) defined three measures of redundancy. Two measures compare the performance of an initially intact bridge system to the capacity of the first member to resist failure. The third measure compares the performance of a damaged system where a main load carrying member has been removed from the system. These measures are given in eq. (1) as:

$$\begin{aligned} R_u &= LF_u / LF_1 \\ R_f &= LF_f / LF_1 \\ R_d &= LF_d / LF_1 \end{aligned}, \qquad (1)$$

where:

LF_1 is the load that causes the failure of the first member;

LF_u is the load that causes collapse of the system;

LF_f is the load that causes the functionality limit state of the initially intact structure to be exceeded;

LF_d is the load factor that causes the collapse of a damaged structure which has lost a main load carrying member.

Ghosn (1998) also proposed three reliability measures of redundancy which are defined in terms of reliability indices as given in eq. 2:

$$\begin{aligned}\Delta\beta_u &= \beta_{ult.} - \beta_{member} \\ \Delta\beta_f &= \beta_{funct.} - \beta_{member} \\ \Delta\beta_d &= \beta_{damaged} - \beta_{member}\end{aligned} \quad (2)$$

Where β_{member} represents the reliability index related to the failure of one member $\beta_{ult.}$ the reliability index related to the collapse of the structure, $\beta_{funct.}$ the reliability index related to the loss of functionality of the structure, $\beta_{damaged}$ the reliability index related to the collapse of the damaged structure.
These relative reliability indices give measures of the additional safety provided by the system compared to the safety against first member failure.
The evaluation of the redundancy of typical bridge systems is illustrated in this paper using the example bridge described below.

EXAMPLE BRIDGE

An efficient approach for designing bridges against lateral loads consists of using integral connections between the columns and superstructures to form a monolithic structure with a higher resistance to lateral loads compared to bridges with typical bearing connections. The example bridge considered in this study is a four-span bridge where the longer span is 48m (see figure 2). The superstructure is a post-tensioned multibox girder with diaphragms above the piers and is rigidly connected to the columns (see figure 2).

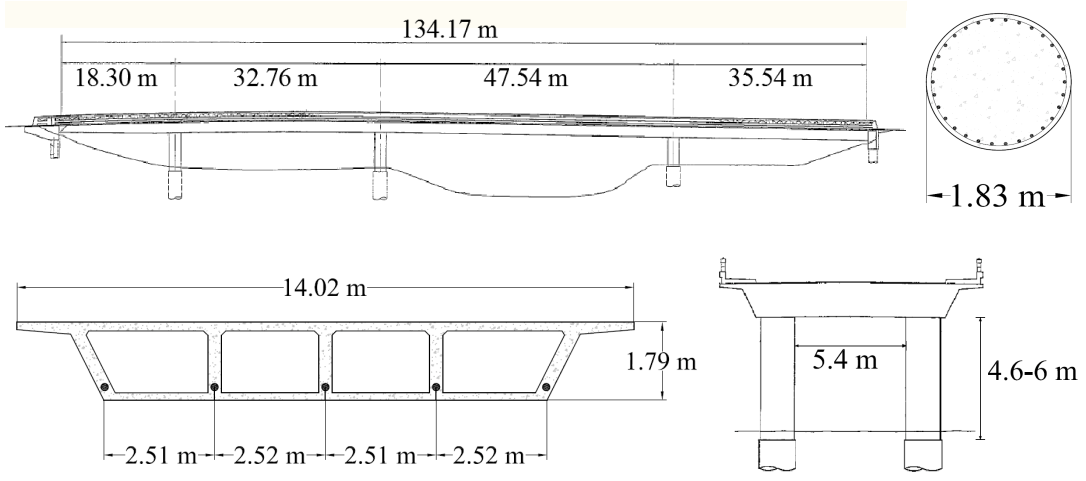

Figure 2. Example Bridge Configuration
a) Bridge profile, b) column cross section,
c) Cross section of bridge superstructure and d) pier profile.

Structural model. A FEM model based on one-dimensional beam elements has been developed to perform the nonlinear analysis of the bridge system. The mesh follows the 3-D space frame model proposed by Hambly (1991) and McLean et al. (1998), in which each element is provided with the proper stiffness characteristic (for longitudinal bending, torsion, distortion, and local transversal bending) as well as nonlinear strength properties in bending. Figure 3 shows the mesh for the 3-D space frame model.

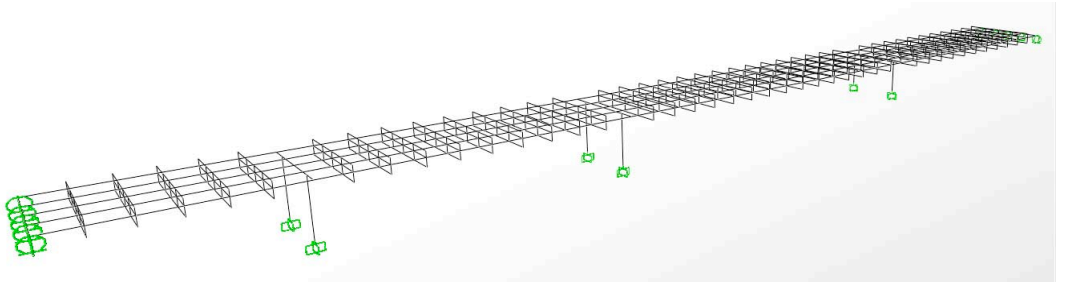

Figure 3. 3-D space frame model.

Material Nonlinearitity. Realistic stress-strain relationships are considered to simulate material non linearity. In particular Mander's (1984) model was adopted for confined and unconfined concrete, and Simple's (SAP2000 manual 2008) model for reinforcing and prestressing steel (see figure 4).

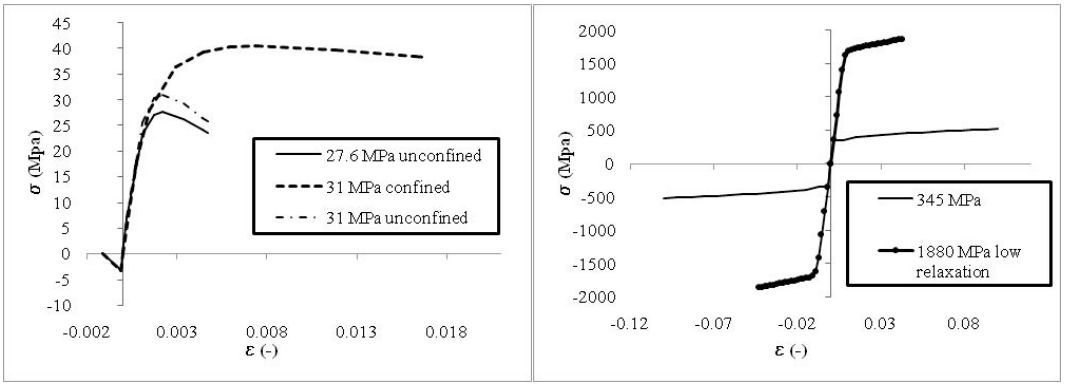

Figure 4. Stress-strain curves
a)concrete (Mander's model) and b) steel (Simple's models).

These realistic models are used to generate moment-curvature relationships for each bridge member. The generated relationships are subsequently simplified and modeled as tri-linear curves for implementation into the lumped plasticity model. As shown in figure 5, the model accounts for the effect of the axial load on the moment-curvature curves of the columns.

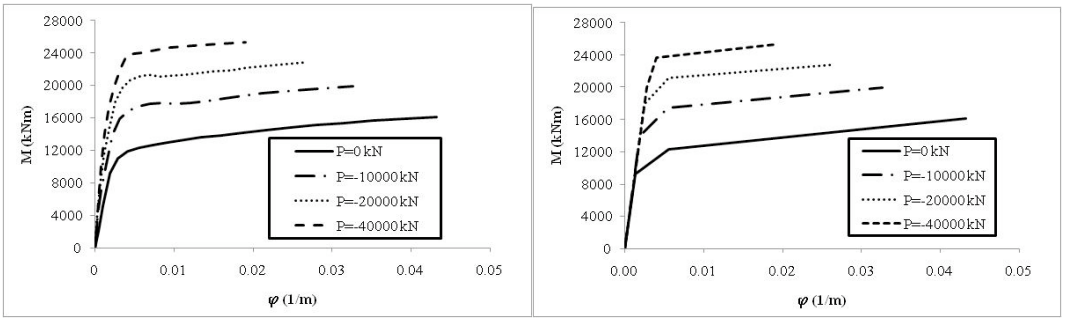

Figure 5. Moment curvature curves for different axial loads a) Original curves and b) simplified tri-linear curves.

Pushover Analysis. In order to represent the capacity of the structure a displacement-controlled nonlinear static analysis is performed. As shown in figure 6, a set of lateral forces is applied over each bent and the lateral displacement of a control point situated over the central pier is measured.

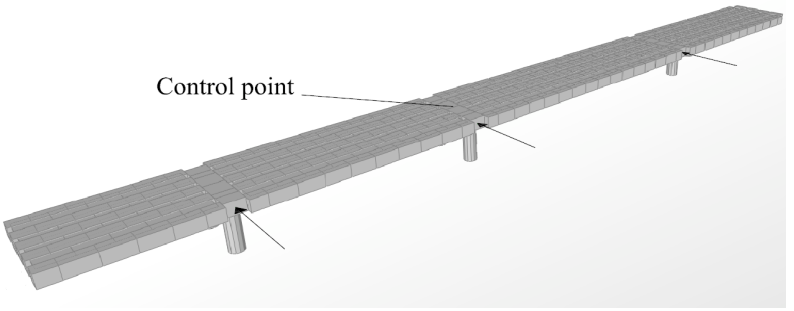

Figure 6. Lateral load distribution and control point.

The lateral distribution of forces is found by $f_{\mathrm{mod},i} = P_i \, \phi_i \Big/ \sum P_j \, \phi_j$,which accounts for the modal displacement of the more significant mode of vibration, more detail can be found in Anitori, (2009).

The P-delta effects are considered in the analysis to account for the geometric nonlinearity. This feature accounts for the second order moments due to the lateral displacement of members under axial load.

Damage scenarios. The analysis of the bridge is performed for the originally intact structure as well as for different damage scenarios. The damage scenarios represent the condition of the structure following an extreme event such as the collision of a truck in a column causing its brittle failure, the effects of a severe earthquake which may produce hinging in the column connections, or foundation settlement. The damages considered in this paper are represented by the failure of one column, which can be partial (loss of bending capacity at the connection but axial capacity remains) or total (the contribution of the element to the load carrying capacity of the bridge is totally removed). In this paper only the results related to the most critical damage scenario are presented which is the total failure of the column in the end bent (figure 7).

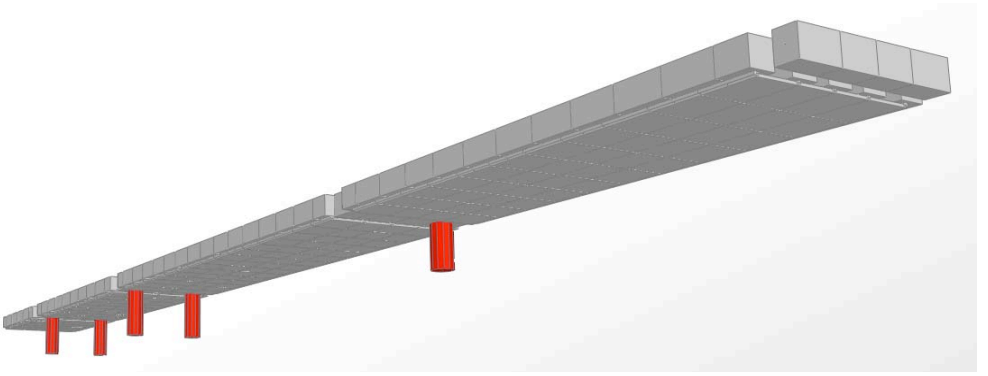

Figure 7. Most critical damage scenario (column in pier 3 totally damaged).

DETERMINISTIC ANALYSIS OF REDUNDANCY

A deterministic approach is necessary to permit the evaluation of structural redundancy using simple yet accurate methods. This is an important requirement if redundancy is meant to be used by practicing engineers as part of the bridge design and evaluation process.

Deterministic Redundancy criteria. The proposed deterministic criteria are based on the research conducted under the auspices of the U.S. National Cooperative Highway Research Program (NCHRP) in Report NCHRP 458 which developed approaches for the redundancy and reliability analysis of bridge superstructures and substructures. Liu et al., (2000) performed simplified reliability analyses of a large set of typical bridge bents and used those results to propose the following deterministic criteria which have been calibrated to meet a minimum level of system safety based on the performance of designs that have historically shown good system performance. The criteria are presented in terms of the redundancy measures previously defined in Eq. (1) and consist of the following:

$$\begin{aligned} R_u &= LF_u / LF_l \geq 1.20 \\ R_f &= LF_f / LF_l \geq 1.20 \\ R_d &= LF_d / LF_l \geq 0.50 \end{aligned} \tag{3}$$

The load factors LF_1, LF_f, LF_u and LF_d are respectively the expected value of the lateral load at which the first member fails, the system exhibits a maximum lateral displacement greater than column height/50, the originally intact system reaches collapse, and system that has exhibited major damage collapses. If the deterministic criteria provided in eq. (3) are met, the system may be defined as redundant.

Analysis of results. To deterministically evaluate redundancy following the procedure just presented only two analyses are needed (one for the intact and one for the damaged system). The analyses are performed at the nominal values for all the variables.

Figure 8 shows the results for the intact and for the damaged case, and table 1 summarizes the redundancy ratios found.

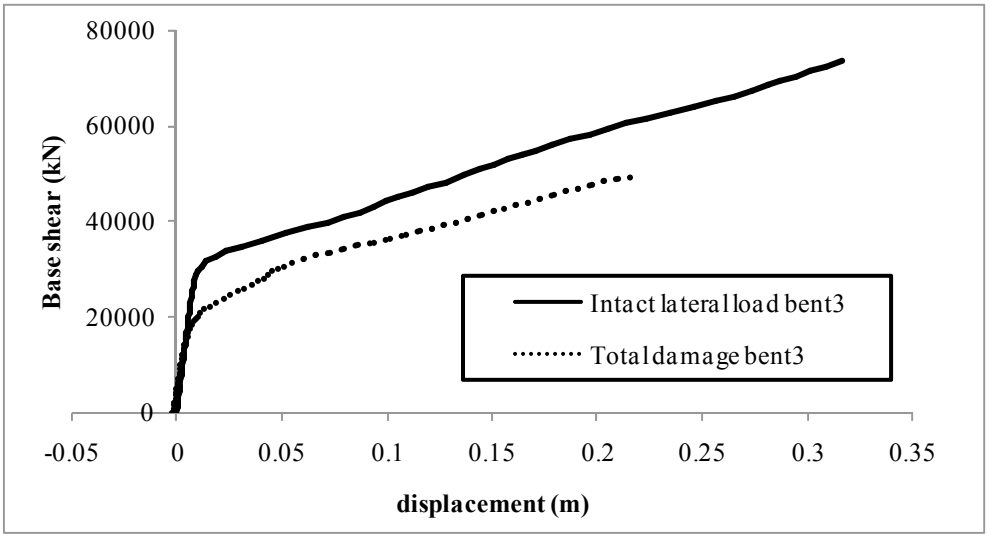

Figure 8. Load vs. displacement curves for intact and damaged system.

Table 1. Summary of redundancy analysis.

Event	Displacement	Force	Ratio	Ratio limit
First component failure	0.59 cm	20899.59 kN		
System collapse	26.54 cm	66217.67 kN	Ru=3.17	1.20
Excessive displacements (H/50)	12.00 cm	47064.74 kN	Rf=2.25	1.20
Collapse of damaged system (after removal of column in bent 3)	21.81 cm	49368.58 kN	Rd=2.38	0.50

As seen in Table 1, for this bridge the deterministic criteria set in Eq. (3) are fully satisfied for all three limit states. Thus, the structure can be defined as being redundant.

PROBABILISTIC APPROACH

The probabilistic approach for evaluating bridge redundancy consists of performing simulations that account for the uncertainties associated with estimating the most important parameters that control the evaluation of the structure's capacity to resist lateral load. The parameters considered in this study are the ones that define the material properties. These are considered to control the variability of the

response of the structure. These parameters are treated as random variables having the statistical properties listed in table 2.

Table 2. Random variables properties.

Variable	Description	Bias	COV	Distribution
f'c	Concrete compressive strength	1.15	0.15	lognormal
fcu	Concrete stress at crushing	1.00	0.10	normal
fy	Reinforcing steel yielding stress	1.10	0.11	lognormal
ε_u	Reinforcing steel ultimate strain	1.33	0.15	lognormal
fu	Reinforcing steel ultimate stress	1.10	0.11	normal

Generation of samples. The Latin Hypercube Sampling (LHS) method has been selected to generate a representative number of samples for the parameters considered as random variables Florian A. (1992). This LHS procedure is a modification of the Monte Carlo Sampling (MCS) method but overcomes the problem of performing a large number of analyses by selecting the samples from a partitioned domain divided into segments of equal probabilities as compared to MCS that selects samples randomly in the domain of probabilities of each variable (see figure 9).

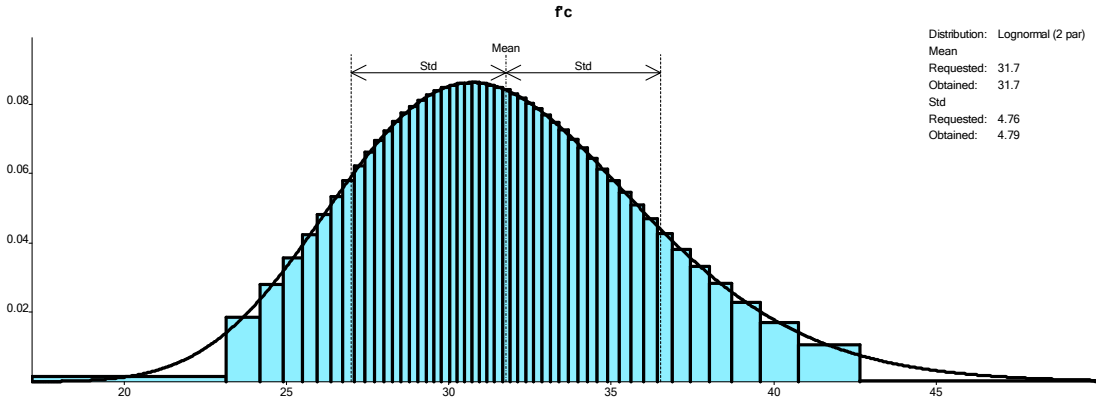

Figure 9. Partitioning of a variable domain into segments of equal probability.

Although, LHS can give accurate values for the mean and standard deviation of the limit state function, it cannot give accurate estimates of the probability of failure, because the number of unsafe runs is not sufficient to represent low probable events such as those associated with estimating the probability of failure of structural systems. Thus, the probability of failure is evaluated by fitting the response into a probability distribution function and then evaluating the probability that this response is lower than an established safety limit.

In the present study following a sensitivity analysis performed on simple models, the probability domains of the random variables are divided into 50 equi-probable segments.

In order to find the reliability indexes for first member failure, ultimate capacity of the intact system, the functionality limit state and the capacity of the damaged system respectively denoted as β_{member}, $\beta_{ult.}$, $\beta_{funct.}$ and $\beta_{damaged}$, the probability distributions of the capacity of the system to resist lateral loads for each limit state respectively represented by LF_1, LF_f, LF_u, and LF_d are obtained from the implementation of the LHS scheme.

Analysis of results. Figure 10 shows the capacity curves for the 50 runs performed for the intact structure and for the damaged structure.

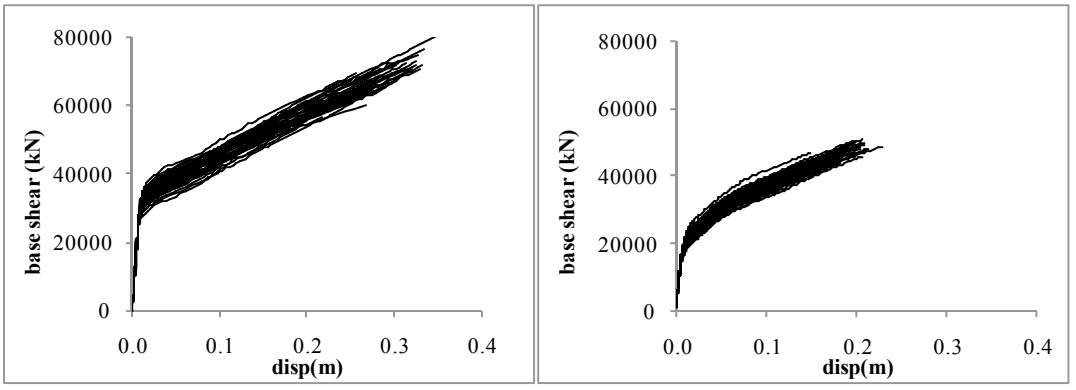

Figure 10. Probabilistic results for a)intact system and b)damaged system.

The capacities to resist lateral loads for the four limit states previously defined are fitted into appropriate probability distributions. The most adequate distribution is obtained using statistical tests on the goodness-of-fit. Table 3 summarizes the results which are also illustrated in figure 11.

Table 3. Response results.

Variable	Mean	COV	Probability distribution
LF1	20217.63	0.07	Log-normal
LFf	45259.32	0.18	Min.Extreme
LFu	65802.53	0.11	Weibull
LFd	44986.32	0.11	Min. Extreme

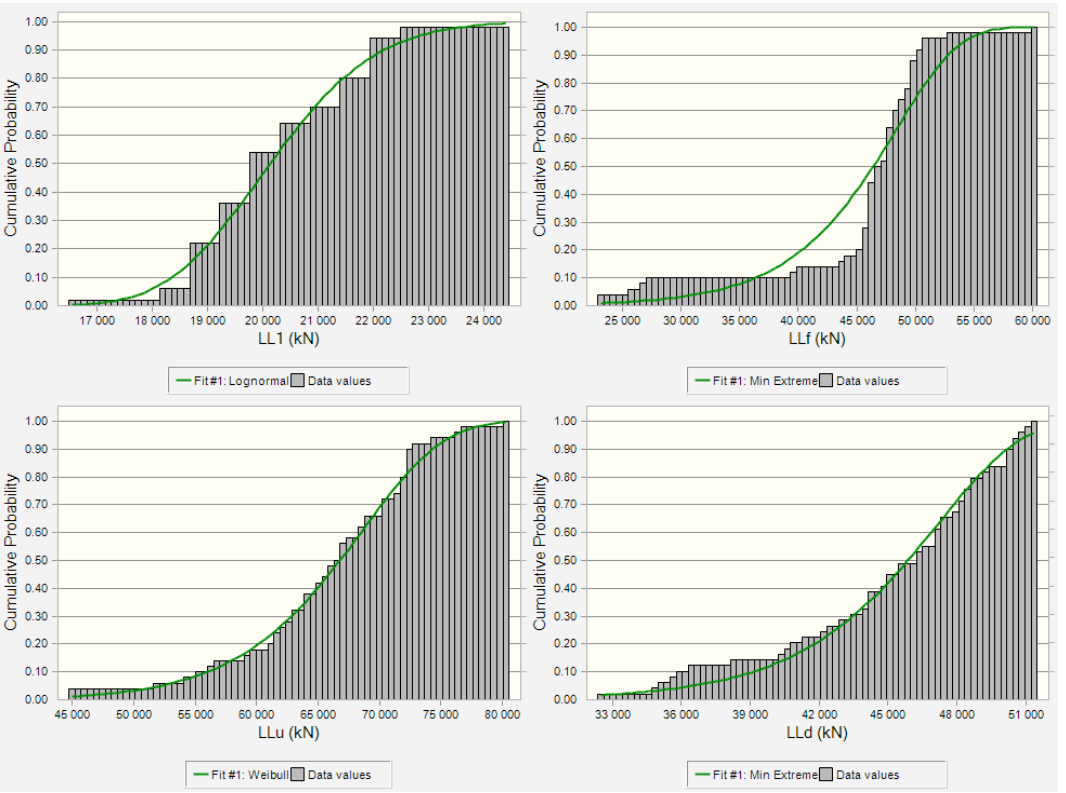

Figure 11. Fitting of response data by probability functions for a)LF1, b) LFf, a)LFu and b) LFd.

The expected applied lateral load is assumed to be equal to the seismic design load and is calculated by the following expression:

$$LL = \frac{m\, a(T_i)}{q} \tag{4}$$

where:

- m is the total mass of the structure;
- $a(T_i)$ is the acceleration related to the fundamental period of the most significant mode of vibration of the structure. In this paper, this acceleration is found from the CALTRANS 2006 design spectra for a type C soil;
- q is the ductility factor accounting for the dissipating behavior of the structure and is equal to 3.5.

A reduced expected lateral force is considered for the damaged state according to Liu et al.(2000) which suggests that a lateral load expected in a 2-year return period. The following formula is used to relate the 2-year load to the design-life load be used for that limit state:

$$LL_2 = 0.38\, LL\,. \tag{5}$$

In the analysis, the applied lateral forces are considered as deterministic. The resulting relative reliability indices are shown in table 4.

Table 4. Relative reliability index for the three limit states.

Event	RRI	RRI Limit
System collapse	$\Delta\beta_u$=2.61	0.50
Excessive displacements (H/50)	$\Delta\beta_f$ =1.02	0.50
Total damage of bent 3 column	$\Delta\beta_d$ =1.23	-2.00

The results confirm the high redundancy level of the structure especially for the damaged system. In fact, the loss of one member in the case of integral design can lead to a significant number of alternative load paths leading for high level of redundancy for the damage limit state

COMPARISON BETWEEN PROBABILISTIC AND DETERMINISTIC APPROACHES

The results of the two methods proposed to evaluate bridge redundancy are compared to verify that the two approaches are consistent. In that aim, the redundancy ratios are calculated for each run of the probabilistic simulation, then the average and the coefficients of variation are calculated for each LF_u/LF_1, LF_f/LF_1 and LF_d/LF_1 ratio. Table 5 shows the results and and demonstrates that they are very similar to the ones obtained by the deterministic approach.

Table 5. Comparison of redundancy ratios.

	Deterministic	Probabilistic	
		mean	COV
Ru	3.17	3.28	0.15
Rf	2.25	2.25	0.17
Rd	2.38	2.19	0.19

CONCLUSION

This paper uses non-subjective and quantifiable measures to evaluate the redundancy of bridge systems subjected to lateral loads. A deterministic and a probabilistic approach for the analysis of bridge redundancy are used. Integral bridge designs which have been recently used in seismic zones to achieve high lateral load capacity and high ductility levels have been demonstrated to produce highly redundant structures so that the system would not be likely to collapse following the failure of one column.

The deterministic approach has been demonstrated to provide good accuracy in estimating the level of redundancy as compared to the more rigorous probabilistic approach. The accuracy and ease of implementation of the deterministic approach in routine design would facilitate the consideration of redundancy during the design of new bridges and the load capacity evaluation of existing bridges.

Anomaly Detection without Structural Behavior Models

I.F.C. Smith, F.ASCE

Applied Computing and Mechanics Laboratory, Swiss Federal Institute of Technology (EPFL), IMAC-IIC-ENAC, Station 18, CH-1015 Lausanne, Switzerland; Ian.Smith@epfl.ch

ABSTRACT

Measurement-data interpretation is especially costly when structural modeling is required. This paper summarizes results of three studies of anomaly detection without structural behavior models. In the first study, five signal-analysis methods were compared using an eight-year temperature/traffic loading vs. time history on a simulation of a two-span beam with four cases of damage scenarios occurring after four years and nine months. Moving principal-component analysis was identified to be able to detect damage most reliably. In the second study, ten signal analysis methods were compared using the same loading vs. time history as the first study. Fifteen cases of variations in daily temperature, traffic loading and sensor noise were used in this comparison. Results showed that moving principal-component analysis and robust regression detect damage more effectively than the other methods, especially in the presence of outliers and missing data. The third study involved the application of temperature cleansing methods to increase damage detectability and decrease detection time when using moving principal components analysis. The advantages of this method were compared with those of the robust regression method. Both methods are complementary. Complex relationships between frequency filtering, sensor/damage locations, traffic loading and noise were found to determine detectability and detection time. This has lead to several avenues for further study.

INTRODUCTION

It is difficult to convince practicing engineers to commit money to long-term structural health monitoring. Often the most important issue is neither the cost of purchasing and placing sensors nor the cost of data storage. Engineers are hesitant because of difficulties associated with data interpretation. Data interpretation is particularly arduous when detailed structural models are necessary for structural identification, especially when complete information is not readily available from design and construction phases.

Less cumbersome approaches to structural health monitoring involve the application of signal-analysis methodologies to monitoring data. Such methodologies do not require structural behavior models. Over the years, tens of research papers

have proposed strategies such as auto-regressive methods (Omenzetter and Brownjohn 2006), (Lu and Gao 2005), (Nair et al. 2006), Fourier analyses (Balan et al. 2000), wavelet methods (Moyo and Brownjohn 2002), (Sun and Chang 2002), robust regression (Jajo 2005), principal component analysis (Posenato et al. 2008), correlation analysis (Ide et al. 2007), instance-based methods (Berry and Linoff 2000) and Box-Jenkins analysis (Moyo and Brownjohn 2002) for anomaly detection. An ASCE state-of-the-art report that provides further detail of such methods is in preparation (ASCE 2010).

Few research projects involved a systematic comparison of several methodologies. Furthermore, comparison of results between projects was hindered by differences in sensitivity to damage (and other anomalies), sensor locations and signal noise level. Also, practical structural-engineering contexts are much different than other measurement contexts due to the presence of yearly and daily temperature cycles, large numbers of outliers (up to 20%) and common situations where data are missing. Finally, some methods indicate the presence of an anomaly only after several days, sometimes weeks, following its occurrence.

This paper provides a summary of three comparative studies of signal analysis methods that have been applied to two structural cases. Each study is described below. For further details, the reader is referred to the original papers.

STUDY ONE

This study (Posenato et al. 2008) examined results from five data analysis techniques in terms of their ability to detect four damage scenarios. Due to difficulties in retrieving databases from real structures with a range of damage severities, a finite-element model of a beam was used to evaluate the efficiency of algorithms to detect damage. The behavior of a bridge (a continuous beam over two 5m spans) was simulated in healthy and various damaged states. A thermal load simulated structural behavior under varying environmental conditions. In the FE model, it was possible to simulate both thermal and applied moving loads as well as damaged elements in one or more sections of the beam with stiffness reductions. The response was measured by means of a ‘virtual’ monitoring system installed in the structure. The monitoring system was composed of six pairs of elongation sensors; six sensors were located at the lower surface and six at the upper surface. Cracks were simulated in order to model local degradation in material properties. Structural behavior was studied in both healthy and damaged states to test the ability of five statistical algorithms to detect when and where damage occurs. Four damage severities were simulated.

Each simulated time series was representative of a structural response measured at predefined sensor locations over eight years, assuming four measurements per day (11000 measurements). Damage occurred after 1750 days. The time series showed harmonic variations due to seasonal variations of temperature in both healthy and damaged states. However, no obvious correlation to

damage formation was directly observed from the elongation-sensor time histories. Only in cases of severe damage was a small shift of periodicity observed. As a consequence, signal-analysis methods are required to interpret data in order to detect damage.

The example deformation history in this study had harmonic variability due to the seasons and therefore, the training period was taken to be two years and the size of the moving window was one year. Once a sequence of values exceeded a threshold defined statistically from observed variations during the undamaged state, damage was assumed to be detected.

Results have shown that two signal-analysis methods, moving principal component analysis and the moving correlation method work more effectively than other methods for long-term structural health-monitoring tasks such as the example in this study. These approaches can be applied over long periods to a range of structural systems in order to discover anomalous states even when there are large quantities of data. For quasi-static monitoring of civil structures, these new methodologies perform better than wavelet methods, short term Fourier transform and the instance-based method. Another important characteristic is adaptability. Once new behavior is identified, adaptation allows detection of further anomalies.

STUDY TWO

In this research (Posenato et al. 2010) compared ten methods in terms of their ability to detect damage in the presence of noise, outliers and missing data. Also, clustering methods are evaluated for their ability to reduce difficulties associated with computational complexity. The loading history was the same as for Study One. Fifteen cases of variations in daily temperature, traffic loading and sensor noise were used in this comparison.

The following algorithms were compared:

- Auto Regressive with Moving Average (ARMA)
- Box-Jenkins (BJ)
- Seasonal ARIMA
- Discrete Wavelet Transform (DWT)
- Wavelet Packet Transform (WPT)
- Robust Regression Analysis (RRA)
- Instance Based Method (IBM)
- Short-term Fourier Transform (SFT)
- Correlation Anomaly Scores Analysis
- Moving Principal Components Analysis (MPCA)

While all ten methods are able to detect damage when there are no noise sources, outliers and missing data, few remain able in their presence, especially at levels that are typically expected in civil-engineering situations. Full-scale bridge

examples were also used to illustrate the most promising methods. For details of this study the reader is referred to the original paper.

This study has resulted in the following conclusions:

- Moving Principal Component Analysis and Robust Regression Analysis are useful for identifying and localizing anomalous behavior in civil engineering structures. These approaches discover anomalous states over long periods of time even when there are large quantities of data.
- For quasi-static monitoring of civil structures with noise in measurements, MPCA and wavelet packet transform perform better than other wavelet methods, auto regressive analysis, instance-based methods and correlation anomaly scores. MPCA out-performs WPT since it can distinguish between permanent and temporary anomalies.
- Robust regression has shown lower performance than MPCA and wavelet analysis but has the advantage of being insensitive to outliers and missing data.
- MPCA combined with Interquartile Range Analysis accommodates outliers in the measurements.
- MPCA can also be adapted to situations when measurements are missing completely and when a single measurement is missing.
- A clustering algorithm extends the use of MPCA to those applications where a significant number of sensors are present in the structure, thus allowing the MPCA to remain tractable for full scale applications.

STUDY THREE

The third study (Laory et al. 2011) compared damage detectability and time to detection for moving principle component analysis with the robust regression method. Comparisons were carried out when removing seasonal variations, for various damage locations with respect to sensors and for various levels of noise and traffic loading. A case study of a 80m-span steel-truss railway bridge was used to illustrate results.

This study resulted in the following observations:

- The time to detection of RRA was shorter than that of MPCA.
- MPCA provided greater damage detectability than RRA.
- Removing seasonal variations decreased the damage detectability of MPCA.
- Removing seasonal variations had a small influence on damage detectability of RRA.
- Decreases in traffic loading increased damage detectability of both MPCA and RRA.
- When damage detectability was high (in case of high damage levels and low traffic loading), Removing seasonal variations may shorten the time to damage detection of MPCA.

- The negative effect of traffic loading and damage level on time to detection using RRA was less than that using MPCA.

From these observations the following conclusions have been drawn:

- Moving principal component analysis (MPCA) is generally better than robust regression analysis (RRA) in terms of damage detectability. On the other hand, RRA is better than MPCA in terms of time to damage detection.
- RRA is not sensitive to seasonal variations.
- For MPCA, there is a trade-off between damage detectability and time to damage detection when removing seasonal variations.

From evaluating the performance of MPCA and RRA, it is recommended that these two methods should be considered complementary since they are most appropriate in different contexts.

CONCLUSIONS

Choice of the right behavior-model-free analysis method for measurement-data interpretation depends on factors such as the presence of outliers, missing data, noise, the extent of damage that needs to be detected and the maximum allowable time to detection. In many cases, there will be several complementary methods that can be used in parallel. These studies have revealed that MPCA and RRA are useful and complementary methods and therefore, they deserve a place in the computational toolboxes of engineers who interpret continuous-monitoring data taken from measurements of civil-engineering structures.

More work is required in the areas of definition of the training period, window sizes, damage detection thresholds and matching the best measurement system configuration to the data-interpretation methods that are employed. These topics are the subjects of current research.

ACKNOWLEDGEMENTS

This research was funded by the Swiss Commission for Technology and Innovation and the National Science Foundation. PhD students Dr. Daniele Posenato and Irwanda Laory are thanked for their contributions. Dr Thahn Trinh helped in the third study. The University of Genoa (Prof. A. Del Grosso and Dr. F. Lanata) contributed to definition of the load/temperature history for the first two studies. Our industrial partner is Smartec SA, Lugano and we are grateful to Dr Daniele Inaudi for his support.

ABSTRACT

Damage prognosis for structural health monitoring is a challenging and complex research topic in civil engineering. Early and accurate damage detection is essential to maximizing the useful life of structures. The use of densely clustered sensor networks provides promising applications in the analysis of structural components and identification of local damage. The proposed localized damage detection method utilizes a linear regression analysis to monitor changes in the linear behavior of a structure with the onset of damage. The structural responses at various sensor locations along a structure are compared to those of other locations and pair-wise influence coefficients are estimated. These coefficients serve as damage indicators when damaged values are compared to healthy-state values. By statistically comparing the change in influence coefficients, structural damage can be accurately and effectively identified. The method is verified using simulations and an experimental prototype of a local beam-column connection, as well as a simulated model of a two-span bridge girder.

INTRODUCTION

Structural health monitoring (SHM) plays an integral role in maintaining the integrity of important civil, mechanical, and aerospace engineering systems. Structures experience a number of dynamic influences on a daily basis ranging from typical ambient vibrations to more extreme wind and earthquake loadings. Whether the damaging effects of these load cases are visible immediately or appear more gradually in time, it is important to be able to detect the damage before it becomes detrimental to the entire structure and its surroundings. Not only will money be saved by being able to repair more manageable damages at earlier detection, but also fatal catastrophes can be prevented. As an increasing number of structures are beginning to reach the limit of their service lives, the need for effective, efficient, and affordable damage detection methods is becoming more apparent.

Traditional non-destructive evaluation (NDE) techniques include but are not limited to visual inspection, liquid penetrant, magnetic particle, radiography, eddy

currents, ultrasonic waves, acoustic emission, and infrared thermography (Trimm 2007). While these methods are useful in certain circumstances, they require *a priori* knowledge of the location of damage and are subject to the trained eye of the inspector. Also, in order to implement these techniques one must have direct access to the location of damage, which may be difficult to reach. Furthermore, NDE techniques are costly, difficult to use with complex equipment, and provide only a temporary means of SHM.

Both advancements in sensor technologies as well as improved understanding of the modal properties of structures have given rise to vibration-based damage identification methods. These methods find a basis in the vibration behavior of a structure, namely the connection between the modal parameters of a structural system—natural frequencies, mode shapes, and modal damping—and its physical properties—mass, stiffness, and damping (Doebling *et al* 1998; Alvandi and Cremona 2006). Parametric changes signify changes in the physical properties, i.e. structural damage in the form of mass or stiffness loss. Also, the advancements of wireless networks make it possible to implement these vibration-based methods on a semi-permanent basis for continuous monitoring of structures.

However, current SHM practices involving global-based damage detection require knowledge of specific structural properties, including mass, stiffness, or damping ratio, for which it is often difficult to determine correct values (Koh *et al* 1995; Morassi and Rovere 1997; Sohn and Law 1997; and Ratcliffe 1997). Additionally, global detection techniques, which are based on global properties, are not sensitive to local damage and, therefore, cannot determine damage locations. Other proposed local damage detection methods, for example the damage locating vector (DLV) method (Bernal 2002), also require the knowledge of structural properties or require homogeneity of the structural properties as in the two-dimensional gapped smoothing method (Yoon *et al* 2005).

An effective damage detection method has been proposed that is sensitive to local damage (Labuz *et al* 2010). The method uses vibration responses collected via densely clustered sensors to achieve localized damage detection without the need for exact knowledge of structural properties. Influence coefficients, obtained from linear regression between pairs of node responses, are used as the index for determining the existence of damage. This study presents both simulated and experimental results to demonstrate the effectiveness of the proposed local damage detection method.

DAMAGE DETECTION ALGORITHM

The algorithm implemented is based on the assumption that a structure exhibits linear behavior, and is thus applicable for identifying damage in structures that fall within this category. In order to capture this behavior, linear regression analysis is used to find pair-wise influence coefficients, α_{ij}, between two nodes i and j, based on the structural response data u_i and u_j at time instance t_k with ε_{ij} and β_{ij} being time-variant and invariant linear regression parameters along with α_{ij} to be estimated as follows:

$$u_j(t_k) = \beta_{ij} + \alpha_{ij} \cdot u_i(t_k) + \varepsilon_{ij}(t_k).$$

The structural response will change as damage occurs, which is then reflected in the influence coefficients. Therefore, the comparison of the resulting influence coefficients from the initial undamaged state with those of the damaged state of the structure serves as a *damage indicator* when it yields a significant change in the value of the coefficients from state to state. This characteristic allows for the identification of the damage location by observing the pattern of influence coefficients exhibiting significant changes. Because this method only involves processing of the structural response, this is an output-only method and, thus, can be easily applied regardless of loading conditions. Figure 1 outlines the procedure for the damage detection algorithm.

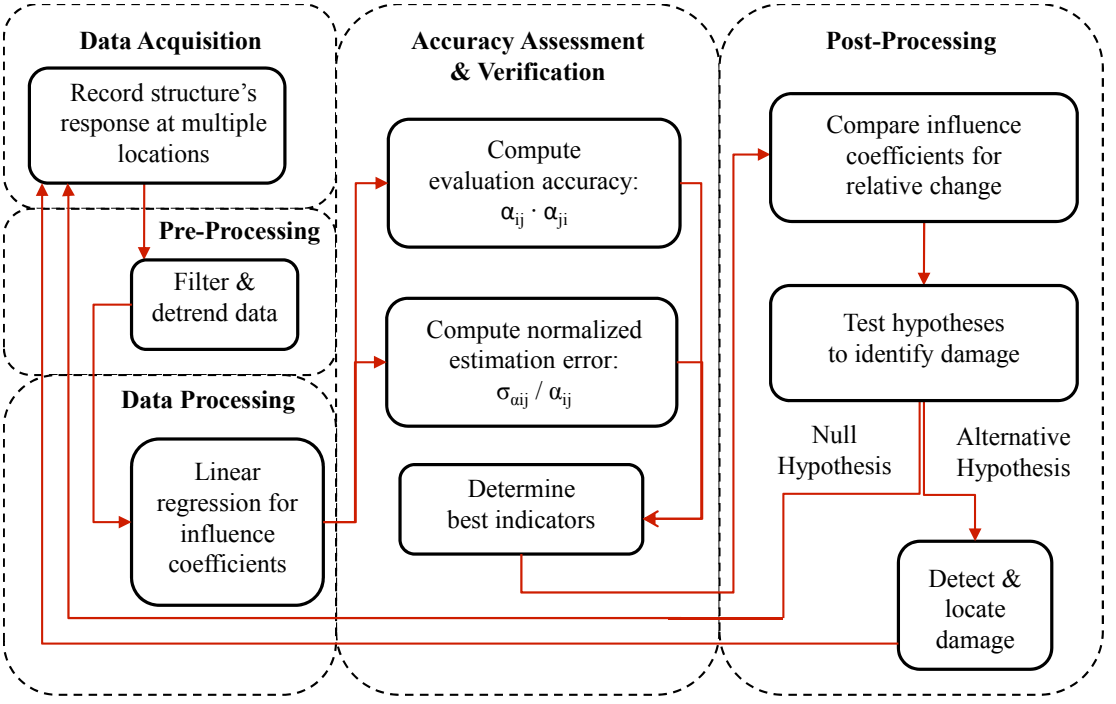

Figure 1. Damage detection algorithm procedure.

INFLUENCE COEFFICIENTS AND NORMALIZED ESTIMATION ERROR

Once the coefficients have been calculated, the accuracy of the data must be assessed and verified before damage detection can be performed. By minimizing the error in the parameters, the occurrence of false alarms will also be minimized. Two parameters are considered for this purpose: the evaluation accuracy and the normalized estimation error associated with each pair-wise coefficient. The product of influence coefficients α_{ij} and α_{ji}, yields the evaluation accuracy, EA_{ij}, of these coefficients, indicating which node responses are linearly related to one another with the least amount of regression error, ε_{ij}, and thus are more accurate predictors. An evaluation accuracy of 1.0 signifies a strong accuracy of estimation, while a product of less than 1.0 corresponds to progressively higher values of noise and nonlinear behavior of the physical structure.

The second parameter that is used for data verification is normalized estimation error, which is calculated by

$$\gamma_{ij} = \frac{\sigma_{\alpha_{ij}}}{\alpha_{ij}}.$$

Normalized estimation error allows for a direct comparison of the amount of error exhibited within the measured data. A low estimation error will correspond to a more accurate predictor. Based on these two parameters the strongest damage indicating influence coefficients are identified for use in damage detection. These coefficients are post-processed and monitored for significant changes to localize the damage.

SIMULATED BEAM-COLUMN CONNECTION

A simulated model is used to demonstrate the application of this method. Consider a simple beam-column connection, representing a local joint, with nine node locations, as shown in Figure 2. The column portion of the joint is fixed at both ends while the beam cantilevers out from the centerline of the column. Two simulation conditions were performed which include (1) an undamaged baseline condition and (2) a damaged condition, characterized by a 40% reduction in the beam stiffness. For each of these models, displacement data was simulated for a white noise excitation applied at the free end of the beam in the y-direction. Measurement noise was accounted for by adding additional noise to the response.

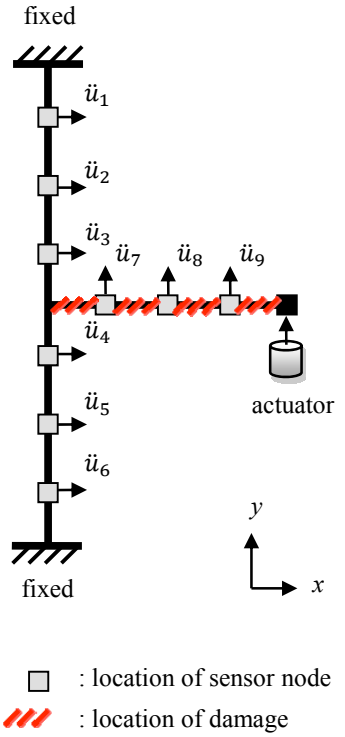

Figure 2. Local beam-column joint with nine node locations used for simulated beam-column model.

SIMULATION RESULTS

The algorithm was then applied to the simulated displacement data and the parameters were extracted. A selection of the influence coefficient changes are shown in Figure 3. The influence coefficients $\alpha_{ij},\ 1 \leq i,j \leq 6$ all experience very small (less than 1%) changes between the undamaged and damaged states. This implies that the physical relationship between these nodes has not changed. However, the coefficients of nodes 1 through 6 paired with nodes 7, 8, and 9 show relative changes between 30-40%. When nodes are on opposite sides of the damage, i.e. nodes 1 through 6 are on the undamaged column, while nodes 7, 8 and 9 are on the damaged beam, the physical relationship between the paired nodes change. The beam experiences more flexibility in the form of higher displacements, whereas the column nodes see small displacements similar to the undamaged state. This physical change is reflected in a more significant relative change in the value of influence coefficients. Furthermore, the influence coefficients $\alpha_{ij}, 7 \leq i,j \leq 9$ also experience changes in coefficients between 3-10%. This signifies that the physical properties of the structure between α_{78}, α_{79}, and α_{89} have changed. Therefore, damage must exist between these nodes. This is consistent with the known damage condition. Thus, the application of influence coefficients and local damage indicators is demonstrated.

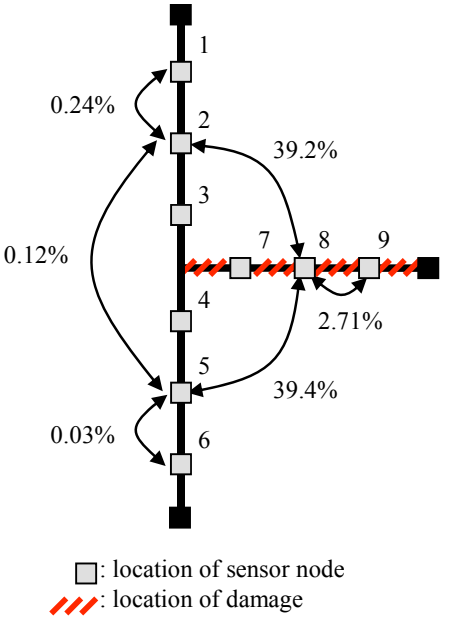

Figure 3. Relative change in pair-wise influence coefficients for the simulated beam-column structure.

EXPERIMENTAL BEAM-COLUMN CONNECTION

A small-scale steel beam-column connection, based on the simulated model, was constructed in the ATLSS Center at Lehigh University and was used for experimental verification of the algorithm. As is shown in Figure 4, the two ends of the column have fixed supports and the beam cantilevers from the centerline of the column. The intention was to model the beam-column connection area in which this prototype

represents only a portion of these members. The free end of the cantilever was attached to an actuator and excited by harmonic force at a 15 Hz forcing frequency, and the acceleration responses were collected at each of the nine sensor nodes. Furthermore, to avoid nonlinear behavior of the elements, an amplifier controlled the amplitude of the excitations. This portion of the experiment served to establish a baseline response for the undamaged structure.

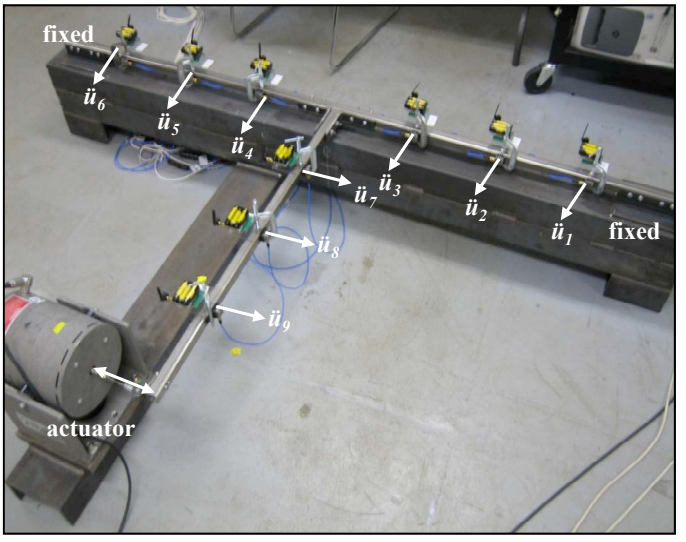

Figure 4. Experimental beam-column instrumented with nine tethered accelerometers.

For the second portion of the experiment, the beam member was replaced by a member of 40% reduced wall thickness in order to simulate damage to the structure. The excitations were repeated similarly to the undamaged case.

Acceleration data at each sensor location was collected at a 200 Hz sampling rate and 0.005 sec time step, with each test lasting 10 seconds total. Both the undamaged and damaged structures were tested 50 times, for a total of 100 tests, each containing 2000 samples per sensor location. All data was pre-processed and influence coefficients were computed to locate the damage.

EXPERIMENTAL BEAM-COLUMN RESULTS

Once the 72 influence coefficients were calculated from the acceleration data, they were assessed to identify the most significant indicators to be used for damage detection. This involves two parameters: evaluation accuracy, *EA*, and normalized estimation error, γ. By inspection of these parameters, eight different trends can be identified in the undamaged and damaged parameters, with lower estimation errors coinciding with greater evaluation accuracies and vice versa. These trends have been designated as eight different regions, whose mean values are presented in Table 1. Region 1 in the table corresponds to the least estimation error and highest accuracy, and region 8 corresponds to the greatest estimation error and lowest accuracy. Parameters in region 1, consisting of $\alpha_{ij},\ 7 \leq i,j \leq 9$, are the most accurate and have the least error. This is a reasonable outcome as nodes 7, 8, and 9 are all located in a

row along the same structural element (the beam). Therefore, the accelerations at node 7, for example, will be more highly correlated to those at node 8 or 9.

Table 1. Average Estimation Error (γ) and Evaluation Accuracy (*EA*).

Region	Influence Coefficients	γ_{ii} Average	EA_{ij} Average
1	α_{78}, α_{79}, and α_{89}	0.0002	0.9999
2	α_{23} and α_{45}	0.0015	0.9947
3	α_{27}, α_{28}, α_{29}, α_{37}, α_{38}, α_{39}, α_{47}, α_{48}, α_{49}, α_{57}, α_{58}, and α_{59}	0.0044	0.9554
4	α_{12}, α_{13}, α_{46}, and α_{56}	0.0057	0.9377
5	α_{17}, α_{18}, α_{19}, α_{67}, α_{68}, and α_{69}	0.0074	0.8997

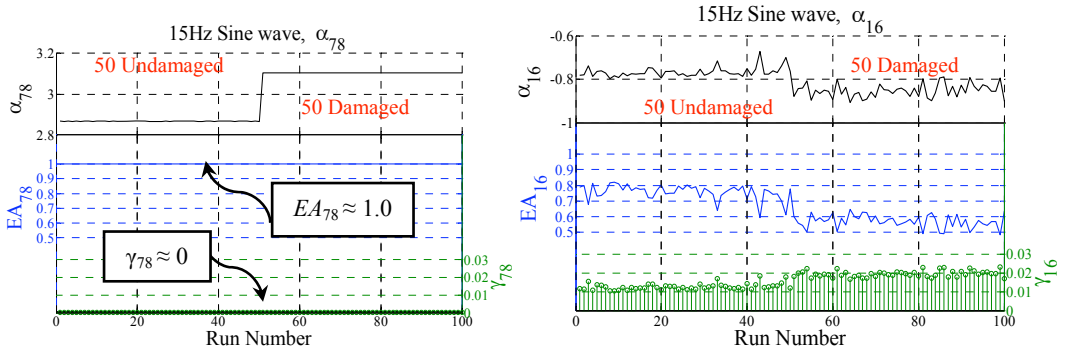
8	α_{16}	0.0161	0.6626



On the contrary, region 8, which consists of parameter α_{16}, exhibits the poorest accuracy and the greatest estimation error. This can be accounted for by the fact that each of these nodes is located at either end of the column near the fixed connections. These boundary conditions create large additional noise, which contributes to the fact that α_{12} or α_{56} exhibit lower accuracy than α_{78} or α_{89} despite the similar configuration of the nodes with respect to one another. Figures 5(i) and (ii) show examples of α, *EA*, and γ results from regions 1 and 8, respectively. Figure 5(i) shows that the *EA* is almost equal to unity and the γ is almost equal to 0 for region 1, while Figure 5(ii) shows a much lower *EA* and a noticeably higher γ for region 8. Moreover, Figure 5(i) shows a more decisive change in the influence coefficient value than Figure 5(ii). Based on similar data for all 8 regions, it can be concluded that regions 1 through 4 contain useful damage indicators. On average, these influence coefficients exhibit accuracy greater than 93% and estimation error less than 0.006.

The experimental results of the relative changes in the influence coefficients, α_{ij}, between the undamaged and damaged tests are shown briefly in Figure 6. Observing these coefficient changes is the first step in post-processing the data. The changes associated with α_{78}, α_{79}, and α_{89}, which are 8%, 12%, and 4% respectively, are potential indicators of a property change between nodes 7 and 9. This is consistent with the damage, or stiffness reduction, that was created along the full length of the beam portion of the test structure.

The coefficients of region 2, α_{23} and α_{45}, experienced 3% and 8% changes. This is less consistent with what would be expected in comparison to the very low (less than 1%) changes that were seen in the simulated results. One major cause of this is ambient noise, which is difficult to control in an experimental setting, but even more so in a real structure.

Influence coefficients from region 3 were more in line with the prediction of the simulated results, with the exception of α_{49} (2%) and α_{57} (3%), which were low compared to the 5-40% range of the others. Again, these two discrepancies are likely accountable to noise. However, the majority of the coefficients in this region showed noticeable fluctuations from the undamaged state to the damaged state. These changes, along with the model results, show that nodes on opposite sides of the damage location experience the largest changes, which is consistent with the simulated results. Again,

the changes in coefficients point to the location of damage in the structure (i.e. damage between nodes 2 and 7, 3 and 8, and so forth).

(i) **(ii)**

Figure 5. Comparison of *α*, *EA*, and *γ* results: (i) Region 1 and (ii) Region 8.

While the results for the first three trend regions were mostly consistent with the simulated results, the remaining regions were not as consistent. A prime example is region 6, consisting of parameters α_{24}, α_{25}, α_{34}, and α_{35}. According to the model, these coefficients, whose nodes are all located on the same side of the damage, should experience very little fluctuation from the undamaged to damaged states. However, their experimental changes range from 12-20%. Recall that in the previous verification stage region 6 showed the third lowest accuracy and the third highest error; therefore, these coefficients are not considered to be significant damage indicators and can be neglected.

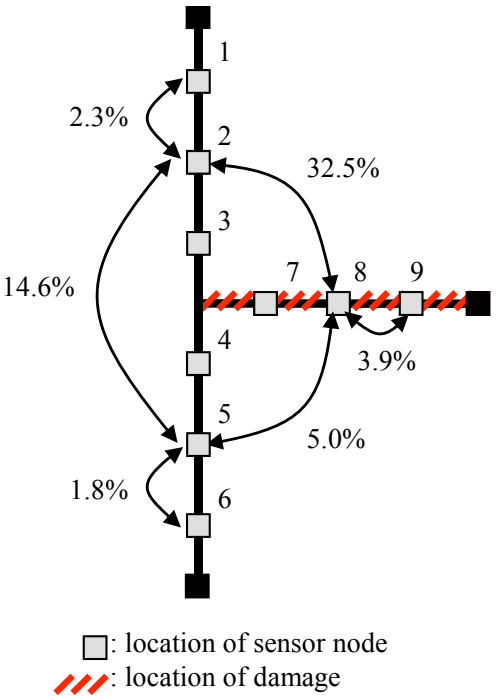


Figure 6. Relative change in pair-wise influence coefficients for the experimental structure.

SIMULATED TWO-SPAN GIRDER

In order for the proposed damage detection method to be adequately verified for practical application, it must be applied to more complex structures. Therefore, a small-scale two-span steel bridge girder has been simulated. The girder was modeled as a two-dimensional frame with short columns with fixed supports and uneven spans as shown in Figure 7. This configuration was chosen as it can model the behavior of a bridge girder, as well as that of a building frame. Furthermore, the uneven spans allow for more variety in the results and damage scenarios. The model has 21 total nodes, which coincide with the sensor locations, with six at each corner joint and nine at the center joint. A white noise excitation was applied in the x-direction to produce displacement responses at each node. Measurement noise was accounted for by adding random noise to the response. Two simulation conditions were considered which include (1) an undamaged baseline condition and (2) a damaged condition, characterized by a 50% reduction in the stiffness of an 8-inch portion of the center column between node C7 and the beam as noted in Figure 7. It is important to note that this corresponds to only a 0.7% decrease in stiffness of the column as a whole. The rest of the structure maintains the same stiffness properties as the undamaged structure.

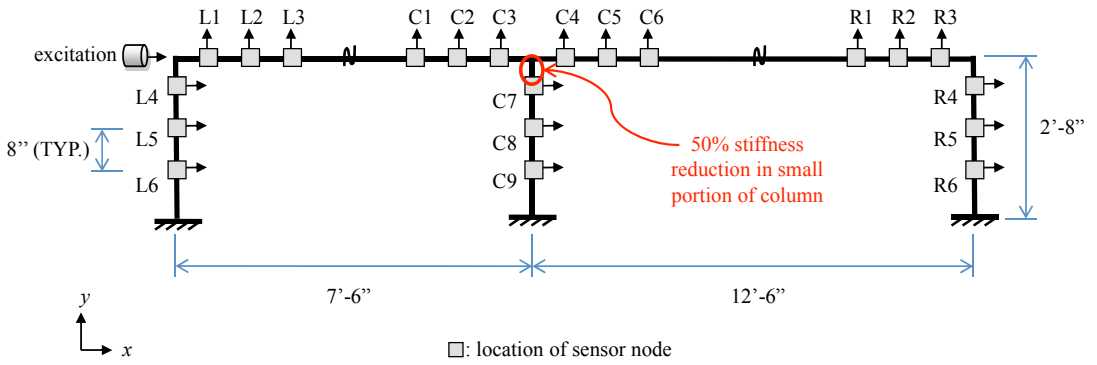

Figure 7. Simulated two-span bridge girder with 21 sensor node locations.

SIMULATION RESULTS

Results were generated considering 100 (50 undamaged, 50 damaged) separate sets of 2000 simulated samples per node. The damage detection algorithm was then applied to the simulated displacement data and the influence coefficients were determined. The plots in Figure 8 demonstrate pair-wise relationships that show (i) the significant change in coefficients on opposite sides of the damage (C2 to C8) versus (ii) the negligible change in coefficients on the same side of the damage (L5 to L6). Even with added noise, both examples show high accuracies and low errors. Thus, both coefficients are considered as significant damage indicators. These change patterns are consistent with those found in the beam-column simulations and experiments.

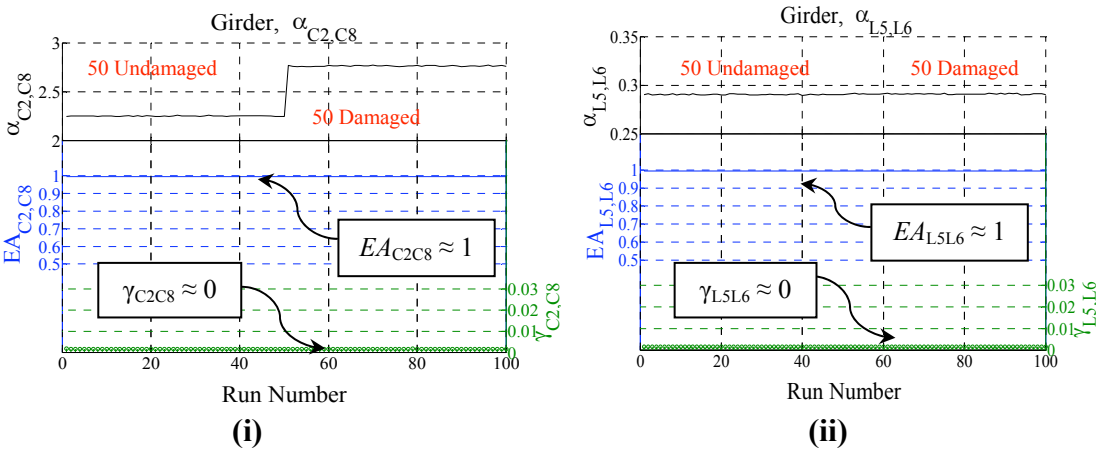

Figure 8. Comparison of α, EA, and γ for (i) nodes surrounding damage and (ii) nodes remote from damage.

Figure 9 shows the average change in influence coefficients throughout the structure resulting from the damage. As can be seen, the center beam nodes (C1 through C6) change more than two or three times that of the other nodes. This is consistent with the known 50% localized stiffness reduction at the central connection. Therefore, the algorithm is sufficient in identifying the general location of damage within the structure as a whole, even though the overall stiffness reduction of the structure was negligible.

Furthermore, the modal properties of the structure change insignificantly with the occurrence of damage at the central joint. This can be seen in Table 2, which shows the modal frequencies of the first three modes for the undamaged and damaged conditions. The percent changes range from approximately 0.5% to 1.5%. These minor changes would be undetectable in any modal-based global detection method with consideration of reasonable errors. However, the proposed localized method detects the damage effectively regardless of minimal changes in global properties.

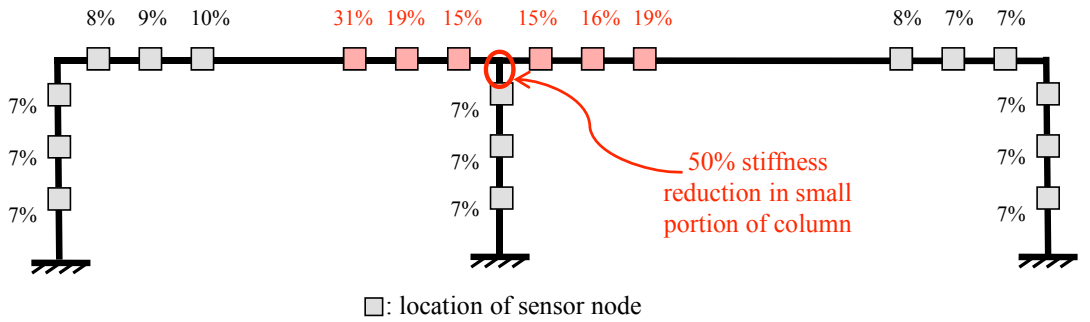

Figure 9. Average relative change in pair-wise influence coefficients for the simulated beam-column structure.

Table 2. Modal frequencies in Hz for the undamaged and damaged models.

	Undamaged	Damaged	% Change
Mode 1	2.67 Hz	2.64 Hz	1.16%
Mode 2	4.45 Hz	4.42 Hz	0.59%
Mode 3	6.81 Hz	6.70 Hz	1.53%

CONCLUSION

A densely clustered sensor network was successfully implemented for local damage detection of both a simulated model and experimental prototype of a steel beam-column connection. The proposed output-only method effectively used linear regression to estimate influence coefficients from vibration-induced acceleration responses of the structure. Changes in the influence coefficients correctly reflected changes in the vibration properties of the structure, thus, revealing the existence and location of damage. Although the experimental structure exhibited more noise error than the simulated results, both the simulation and the experiments identified the location of damage.

Additionally, results showed a significant difference in performance between coefficients with high EA and low error and those with low EA and high error. Therefore, coefficients must be evaluated for strong damage indicating characteristics as this noticeably contributes to the effectiveness of damage detection. In real-world applications earlier damage detection will allow for more manageable repairs and reduce the risk of structural failures.

Finally, a structure in the form of a bridge girder with two unequal spans was simulated. This model was used to investigate the application of the algorithm for more complex structures with more realistic damage scenarios. Using simulated displacement data and applying the algorithm, the resulting influence coefficients correctly identified the central local joint as the location of damage. This is especially significant because both global stiffness and modal frequencies of the structure remained nearly unaffected by the occurrence of damage. This suggests that other detection methods that are based on global properties would fail to detect this damage, whereas the proposed method identified not only the existence but also the location of the damage.

ONGOING AND FUTURE WORK

While the localized damage detection method has been shown to be effective for the scenarios presented, it is important to continue to verify this method for increasingly complex and realistic structures. Although only one damage scenario is presented for the two-span girder simulation, ongoing research involves the investigation of a variety of damage combinations and loading cases. Also, an experimental prototype similar to the simulated girder will be constructed and tested at Lehigh University using three types of sensors: tethered piezoelectric accelerometers, wireless piezoelectric accelerometers, and strain gauges. Moreover, it is important to determine the smallest amount of damage to which this algorithm is sensitive.

ACKNOWLEDGMENTS

The research described in this paper is partially supported by the National Science Foundation through Grant No. CMMI-0926898 by Sensors and Sensing Systems program, and by a grant from the Commonwealth of Pennsylvania, Department of Community and Economic Development, through the Pennsylvania Infrastructure Technology Alliance (PITA).

Monitoring of Long Term Bridge Performance (LTBP) Program Bridges

Steven M. Petroff[1] Marvin W. Halling[2] , Ph.D, P.E., F.ASCE;
Paul J. Barr[3], Ph.D., M. ASCE;

ABSTRACT

The Long Term Bridge Performance (LTBP) Program, sponsored by the Federal Highway Administration, is currently in the pilot phase. During this phase, seven bridges distributed throughout the United States have been subjected to an initial round of of bridge performance testing. This preliminary testing was conducted to establish a baseline for comparison with future bridge testing, monitoring, and evaluation. Long term instrumentation systems have been designed and installed at these sites. This paper will focus on three of the pilot bridges. For each bridge, the preliminary testing conducted and long-term instrumentation layout will be provided.

INTRODUCTION

Utah State University (USU) was contracted with Rutgers University and the Federal Highway Administration (FHWA) under the Long-Term Bridge Performance (LTBP) Program to conduct preliminary testing and carryout long-term monitoring on bridges selected for the pilot study west of the Mississippi River. Researchers at Virginia Tech are supervising the testing of the bridges east of the Mississippi River. Through these tests, the program will collect, store, and analyze data to be used for improved maintenance and bridge owner decisions.

Following a rigorous selection process, each bridge underwent extensive preliminary testing including dynamic, live load, NDE/NDT, material testing, in addition a detailed visual inspection. This initial data, along with years of maintenance records, were analyzed to determine an appropriate long-term instrumentation. Preliminary testing for six of the pilot bridges is currently complete. Current scheduling plans are to conduct the preliminary testing on the final pilot bridge in February 2011. Long-term monitoring systems have been installed on four of the seven bridges with systems planned for the remaining three. The focus of this paper will be on the pilot bridges located in Utah, California, and Minnesota. These three bridges are located west of the Mississippi river and therefore fall under the responsibility of Utah State University to conduct preliminary testing and long-term monitoring.

UTAH PILOT BRIDGE

Bridge Description

The Utah Pilot Bridge is a single span, pre-cast, pre-tensioned, bulb-tee concrete girder bridge. The bridge carries two lanes of northbound I-15 traffic over Cannery Street in Perry, Utah. The bridge is located approximately 97 km (60 miles) north of Salt Lake City, Utah. It was built in 1976. The deck is made of 203 mm (8 in.) thick reinforced concrete with a varying asphalt overlay ranging from 152 mm (6 in.) to 203 mm (8 in.). The total clear span length of the bridge is 24.38 m (80 ft) with actual girder lengths of 25.15 m (82.5 ft). The bridge has a total width of 13.56 m (44.5 ft) and a roadway width of 12.8 m (42.0 ft) comprised of two 3.66 m (12 ft) wide travel lanes, in addition to 1.83 m (6 ft) and 3.66 m (12 ft) wide shoulders. Figure 1 shows an elevation view of the Utah Pilot Bridge

Figure 1: Elevation view of the Utah Pilot Bridge.

Preliminary Testing

Dynamic Testing

Dynamic testing allowed for the determination of the first four modal frequencies and corresponding damping ratios. For the Utah Pilot Bridge, an electromagnetic harmonic shaker was used to provide forced vibrations. This method of excitation was chosen because of its ability to provide highly accurate and known excitations, which improves analysis and determination of modes and frequencies.

A 4-channel data acquisition demonstration version module was used to record sensor response. One of the four channels was used to record the forced vibration input into the bridge. The remaining three channels were connected to 1Hz velocity transducers and used to record the bridge response. The real time FFT, windowing, anti-aliasing, and other controls of the data acquisition module allowed for easy viewing of the bridge response. Multiple testing scenarios were run in order to provide specific information of the bridge and to study the capabilities of the data acquisition module. Analysis of the recorded data yielded information on the first four modes, and their associated frequencies and damping ratios, see Table 1.

Table 1: Dynamic response summary

Mode	Frequency	Damping
1	6.78	4.16%
2	7.86	3.89%
3	9.55	3.49%
4	14.36	2.99%

Live Load Testing

In addition to dynamic testing, a quasi-static live load test was also conducted on the Utah Pilot Bridge. Two heavily loaded, three axle dump trucks were used to provide the load for the test. Due to the high average daily traffic, around 22,000 vehicles per day, a complete closure of the bridge was not possible. UDOT required that the test be conducted on a Sunday morning, when traffic volume was at a minimum. In order to have the testing system ready for the load test, installation of sensors occurred prior to the day of testing. Before testing began, all sensors were checked to verify they were reading properly.

A Bridge Diagnostics Inc. (BDI) wireless structural monitoring system was used to record the bridge response. The system was composed of a base station CPU that communicated with six wireless nodes. Each node was capable of monitoring four sensors. In all, seven deflection sensors and twenty surface mounted strain sensors were monitored throughout the test. At each strain gauge location, two gauges were installed vertically over the height of the girder. One strain gauge was installed on the bottom flange of the girder and one was installed at the top of the web, as shown in Figure 2. Figure 3 shows a plan view of the bridge with the locations of installed sensors.

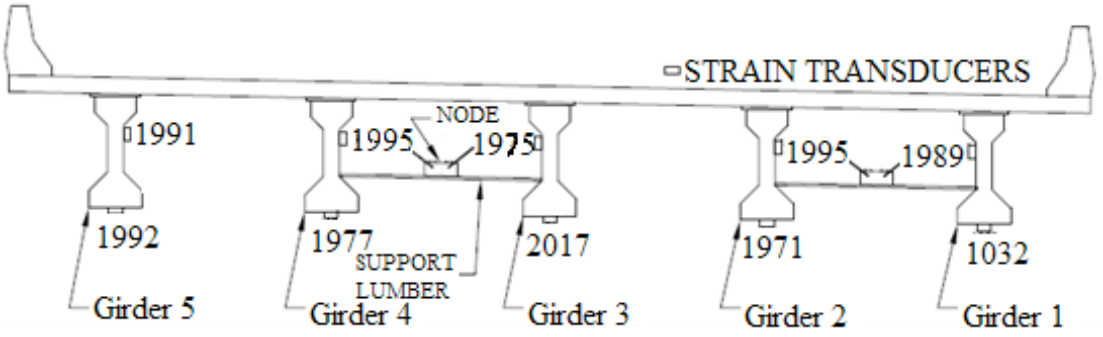

Figure 2. Cross-sectional view of Section A-A with gauge identification numbers.

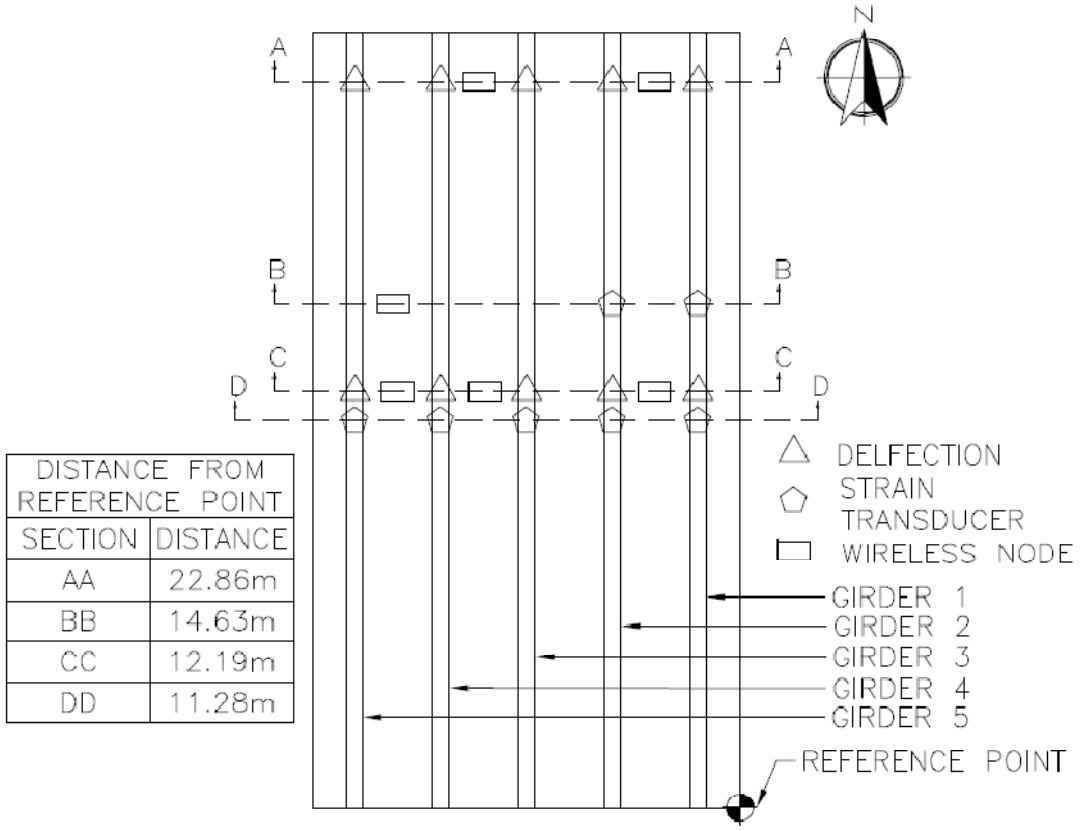

Figure 3: Plan View of instumenation with sectional divisions.

Additional Preliminary Tests

Other tests conducted on the Utah Pilot Bridge included NDE/NDT, material testing, and a detailed visual inspection. The NDE/NDT and material testing focused their scope to deck evaluation. Due to the thick asphalt overlay, the NDE/NDT tests did not produce useable results. Material testing required the removal of the asphalt overlay to access the concrete deck. Individual tests on the deck through the material testing included: chloride ion penetration, half-cell potential, corrosion resistance, and Schmidt Hammer testing.

Long-Term Monitoring Plan

Following the preliminary testing and evaluation, an instrumentation plan was developed to monitor long-term bridge response. Preliminary testing provided essential information for determining the sensor type, quantity and location. The final decision of make and model of instrument to use was based on the type of information desired for a particular response category. Sensors chosen included velocity transducers, foil strain gauges, vibrating wire strain gauges, tilt meters, thermocouples, weather station, and a traffic camera. The weather station includes an ambient air temperature probe, relative humidly probe, solar radiation pyranometer, a wind speed/direction anemometer, and a precipitation gauge that records if a precipitation event is occurring and the duration of the event. The traffic camera is capable of high quality streaming data, recording video footage and still shots based on a triggered event. All data is remotely accessible via an internet connection. Power

for the system is provided via solar panels and a battery backup array. The data acquisition system is a Campbell Scientific CR5000 with an AM16/32B multiplexer, an AVW200 Vibrating Wire Spectral Analyzer, and a wireless CalAmp 882 CDMA Cellular modem. The weather station, traffic camera, and solar panels are installed on an instrumentation tower. The tower is secured to a solid foundation and is adjacent to the instrumentation cabinet, as shown in Figure 4.

Figure 4: Left: Instrumentation tower, box, and fence. Right: Data Acquisition box.

CALIFORNIA PILOT BRIDGE

Bridge Description

Constructed in 1975, the California Pilot Bridge carries two lanes of southbound I-5 traffic over Lambert Road. Lambert Road is located in Sacramento County, approximately 50 km (30 miles) south of the city of Sacramento. This portion of I-5 is located on an important connecting route between Sacramento and San Francisco. For that reason, the average daily traffic on the structure is 25,000 vehicles per day with approximately 21% of that being attributed to truck traffic.

The bridge superstructure is a two span, cast-in-place, post-tensioned, box-girder structure. Span length is 39.62 m (130 ft) long for a total of 79.25 m (260 ft). The bridge has a skew of 8°. A single pier at midspan supports the bridge. The deck is 203 mm (8 in.) thick and made of reinforced, cast-in-place concrete with a clear polymer overlay. The roadway width is 12.8 m (42 ft) with two 3.66 m (12 ft) wide travel lanes, and 1.83 m (6 ft) and a 3.66 m (12 ft) wide shoulders. Figure 5 shows an elevation view of the bridge looking from the west to the east.

Figure 5: Elevation view of California Pilot Bridge.

Preliminary Testing

Dynamic Testing

Following the success of the Data Physics demonstration module used for the dynamic test of the Utah Pilot Bridge, an 8 channel data acquisition system was used for the dynamic test on the California Pilot Bridge. This increase in sensor capacity allowed for more simultaneously monitored channels during each test setup. No lane closures were needed to conduct the dynamic test on the California Pilot Bridge. In contrast to the Utah Pilot Bridge, all the instruments were placed inside of the box girder cells, as seen in Figure 6, thus providing safe access for the researchers at all times, regardless of the traffic on the bridge deck. The electromagnetic harmonic force shaker, used to provide the necessary excitation, was also located inside one of the box girder cells.

One challenge that was prevalent during the dynamic test was the difficulty in filtering out the heavy impact of truck traffic on the bridge. Since there were no lane closures, on the bridge during the dynamic test, traffic flowed at the posted freeway speed limit. This created a considerable amount of noise that required rigorous filtering and windowing in the data analysis software. Test settings were selected that used tight filtering around specific frequencies, multiple averages, and a very small frequency step for the shaker excitation. These settings reduced the magnitude of noise after the test.

Figure 6: View of shaker and instruments inside box girder cell.

Live Load Testing

For the California Pilot Bridge a combination of quasi-static and dynamic live load tests were performed. Two different types of heavily loaded trucks were used to provide the load for the test. A three-axel super dump truck was used in combination with an 18-wheel side dump. Both were loaded to the legal limit for their axle configurations. Due to the high average daily traffic a complete closure of the bridge was not possible. However, Caltrans and the California Highway Patrol allowed for a controlled slow down that provided windows of eight to ten minutes of no traffic on the bridge. During each testing window, trucks were positioned on the bridge according to predetermined load paths and slowly driven across the structure.

A Bridge Diagnostics Inc. (BDI) wireless structural monitoring system was used to record the bridge response. The system was composed of a base station CPU that communicated with fourteen wireless nodes. Each node was capable of supporting four sensors. On this bridge, a total of eight deflection sensors, forty-two surface mounted strain sensors, two string-pot displacement sensors, and one uniaxial rotation sensor was used. Figure 7 shows the bridge instrumentation plan.

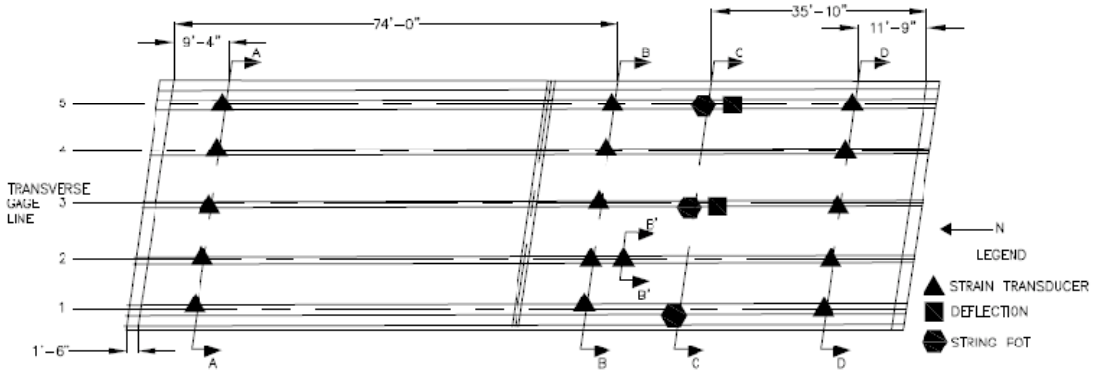

Figure 7: Instrumentation plan for California Live load Testing. Top figure is North Span, bottom figure is South span.

Additional Preliminary Tests

Other preliminary tests and evaluations conducted on the California Pilot Bridge include NDE/NDT, material testing, and a detailed visual inspection. The NDE/NDT and material testing focused their scope to deck evaluation. The thin polymer over lay initially applied on the bridge deck was essentially worn off over most of the bridge, especially in the travel lanes. This allowed for all testing to be conducted directly on the exposed, bare concrete deck. Additional nondestructive testing was conducted to determine voids in the post-tensioned ducts.

Long-Term Monitoring Plan

The California Pilot Bridge long-term monitoring plan was developed after the initial testing was performed. Preliminary testing provided valuable information for determining the sensor type, quantity and location. Sensors chosen were similar to those of the Utah Pilot Bridge and include velocity transducers, foil strain gauges, vibrating wire strain gauges, tilt meters, thermocouples, and a traffic camera. The traffic camera is capable of high quality streaming data, recording video footage and

still shots off a trigger, and remotely accessible via an internet connection. Power for the data acquisition system is provided via an AC connection.

The data acquisition system is a Campbell Scientific CR5000 with three AM16/32B multiplexers, an AVW200 Vibrating Wire Spectral Analyzer. The CR5000 was chosen because of its high frequency sampling rate and capability to run multiple sensors with varying types of measurement protocols. The multiplexers were used to expand the channel capabilities of the CR5000 for thermocouple, tilt meter, and vibrating wire strain gauge sensors. A single program controls the sampling rate, type, and analysis processing for each of the sensors.

Overall, the California Pilot Bridge was instrumented with sixteen foil strain gauges, four vibrating wire strain gauges, four velocity transducers, three tilt meters, fourteen thermocouples placed adjacent to fourteen foil strain gauges, and a total of twenty thermocouples installed over the depth of the deck at two locations. Sensor locations are distributed across the length of the bridge as well as along the exterior and the interior of two of the cells. Locations were chosen based on the analysis of the preliminary test data. Figure 8 shows a typical sensor location for an interior and exterior installation. The traffic camera is installed on an instrumentation tower located approximately 15.24 m (50 ft.) south of the south bridge abutment.

Figure 8: Typical monitoring sensor location at California Pilot Bridge.

MINNESOTA

Bridge Description

The Minnesota Pilot Bridge is located approximately 145 km (90 mi.) north of Minneapolis, Minnesota. The bridge carries State Road 123 over the Kettle River.

State Road 123 runs through the town of Sandstone, Minnesota. The bridge is listed on the Minnesota Historical Bridge inventory and much of the land under the bridge is part of a state park. These two factors stress the importance that this bridge and location have on the people of Minnesota.

The structure is 122 m (400 ft) long and 12.2 m (40 ft) wide. The original deck was 146 mm (5.75 in.) thick with a 76 mm (3 in.) bituminous overlay. In 1984, the deck was replaced with a 178 mm (7 in.) thick reinforced concrete deck with a thin polymer overlay. The south side has a large parapet section for a sidewalk and higher railing. The original design had a 102 mm (4 in.) diameter gas line passing through the sidewalk. In the 1984 reconstruction, the gas line was moved to a location under the first interior girder from. The sidewalk is 1.27 m (5 ft) wide. The deck carries two 3.66 m (12 ft.) wide travel lanes and two 1.22 m (4 ft) wide shoulders. Figure 9 shows a cross-sectional view of the deck and parapets and Figure 10 shows an elevation view of the bridge.

As seen in Figure 10, the bridge superstructure is pinned at two intermediate supports, each 30.5 m (100 ft) from either end of the bridge. The main span has a total length of 61 m (200 ft). There are piers on either side of the river. The east most pier is supported on an elastomeric bearing whereas the west support is pinned. Expansion joints are located at both ends of the bridge, as seen in Figure 10. Figure 11 is a photograph of the Minnesota Pilot Bridge.

Constructed in 1948, the Minnesota Pilot Bridge was designed as a truss arch bridge. Maintenance records document a complete remodeling and overhaul of the entire structure in 1984. Since that time, typical maintenance has been performed on the bridge.

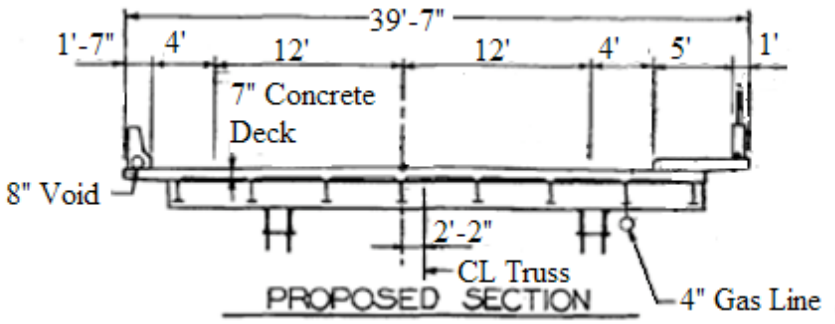

Figure 9: Scross-sectional view of the Minnesota Pilot Bridge

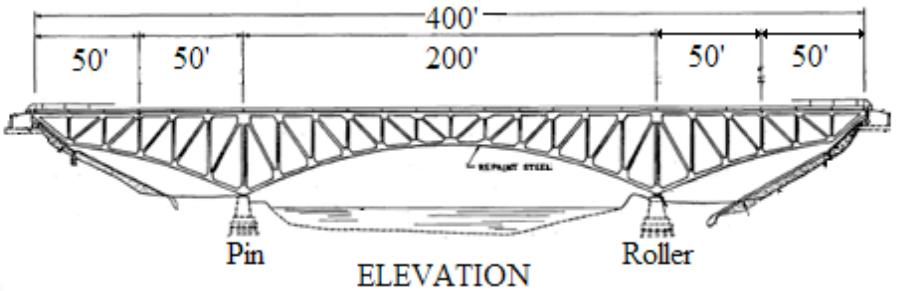

Figure 10: Elevation view of the Minnesota Pilot Bridge

Figure 11: Photograph of the Minnesota Pilot Bridge.

Preliminary Testing

Dynamic Testing

In order to accurately monitor the dynamic response of this relatively large structure, a data acquisition system capable of recording 24 channels was used. The system provided the necessary input variables for controlling the type of test and an easy to read real-time output for system verification. The average daily vehicle traffic on this bridge is relatively low, approximately 2,000 which allowed for fairly easy filtering, windowing and anti-aliasing of data. The greatest disturbance to dynamic measurements during the day was the presence of two large under bridge inspection trucks. The engines from these trucks created a large harmonic vibration that required very tight filtering to eliminate the influence of the trucks on the data. For this reason, testing through the night proved to yield the highest quality data. Researchers were able to conduct multi-hour tests with essentially no traffic on the bridge. During those tests, coherence between the electromagnetic shakers and sensors was consistently above 0.95.

Three shaker orientations were used to determine the maximum number of modes. The shakers were first oriented to vertically excite the bridge. Following that, two variations of horizontal shaking were applied. The first was a purely transverse loading. The second had the shakers oriented at 45°, to excite transverse and longitudinal modes. Interestingly, the orientation of 45° produced the greatest information for transverse modes. In total, nine distinct modes were identified. Table 2 contains a summary of this modal information.

Table 2: Summary of Minnesota Dynamic Test Results

Mode #	Frequency	Run Used	Prominent Direction	Damping Ratio
1	1.71	44	Transverse	1.46
2	2.44	20	Vertical/ Longitudinal	2.43
3	3.76	11	Vertical	0.96
4	4.37	47	Transverse	2.46

5	5.04	12	Vertical	0.71
6	5.53	22	Vertical	1.64
7	6.46	6	Vertical	2.63
8	7.67	13	Vertical	0.90
9	9.76	14	Vertical	0.57
10	10.16	14	Vertical	0.81

Live Load Testing

A joint effort between USU and Bridge Diagnostics Inc. (BDI) was employed to conduct the live-load test on the Minnesota Pilot Bridge. The reason for a joint effort was due to the large size of the structure and the need for a large amount of instrumentation on the structure. Researchers at USU worked jointly with BDI to assist in developing an installation plan for the bridge and in carrying out the test. BDI supplied a testing system that included 128 total sensors distributed across the North Truss, South Truss, and Floor System of the bridge. USU supplied another system with an additional 32 sensors, distributed in an area that covered the western third of the bridge structure. In all, the data acquisition system consisted of 160 strain sensors and ten displacement transducers.

Loading for the test was provided by two large under bridge inspection units (UBU's). These units were already on site to provide access for the visual inspection and instrument installation where a ground based boom lift was not adequate. During the test, these trucks were driven into position and slowly driven across the bridge. Uninterrupted access of the bridge deck was allowed due to controlled closures of the bridge travel lanes for periods of ten to fifteen minute intervals. Traffic control was set up at both ends of the bridge and coordinated closure of the traveling lanes with researchers conducting the live load test. Figure 12 shows the two trucks used for loading during the live load test.

Figure 12: Trucks driving across the Minnesota Pilot Bride during the Live-Load test.

Additional Preliminary Tests

Other preliminary tests conducted on the Minnesota Pilot Bridge include NDE/NDT, material testing, and a detailed visual inspection. The NDE/NDT and

material testing focused their scope to deck evaluation whereas the visual inspection was performed for the entire structure.

Long-Term Monitoring Plan

Though still in its preliminary approval stage, a plan for the long-term instrumentation of the Minnesota Pilot Bridge has been designed. An overview document has been sent to the MnDOT for approval and comments. Initial reviews of the plan have been very positive. The plan proposed by the LTBP team will include a combination of foil strain gauges, tiltmeters, vibrating wire strain gauges, velocity transducers, thermocouples, deck thermal gradient devices, linear displacement sensors (joint, bearing, and structure expansion), and a traffic camera.

Similar to the Utah and California Pilot Bridges, a data acquisition system capable of both dynamic and static measurements will be used. It is anticipated that multiple multiplexers and vibrating wire interfaces will be used to efficiently record the sensor readings from the many instruments planned for installation. An instrumentation tower is expected to be installed west of the bridge to house the traffic camera.

CONCLUSION

As part of the Federal Highway Administration's (FHWA) Long Term Bridge Performance Program (LTBP), Utah State University was contracted to perform initial testing on three bridges located in Utah, California and Minnesota. The responsibility of USU was to conduct a Live Load test, a Dynamic test, prepare a Long-Term Monitoring plan, and carry out the long-term monitoring.

Results from the initial testing provided a current estimation the current bridge structural health. Long-term monitoring is currently underway. Early monitoring results show excellent comparison with preliminary testing results. Changes in future bridge behavior will be used to determine long-term trends for bridge performance.

ABSTRACT

Structural vibration monitoring has received a lot of attention from the research community in the past few years. The objective is to create automatic structural assessment techniques that can be realized through programmed vibration analysis. Till now many vibration-based damage features have been proposed, yet to truly automate the damage identification process, reliable damage threshold construction techniques are also need. In this paper, two data-driven methods based on resampling and nearest neighbor rule are applied for threshold construction for damage features from autoregression (AR) analysis of vibration signals. Both threshold calculation techniques are rooted in empirical feature probability estimation. The proposed thresholds are then tested on features extracted acceleration measurements collected from a 5 DOF test specimen. The resampling method is applied to Mahalanobis distance of AR model coefficients, while the nearest neighbor rule is used on a combination of coefficient distance feature and the residual autocorrelation feature. Both methods perform well in this case study.

KEYWORDS: Structural health monitoring; damage detection; time series analysis; autoregressive modeling; statistical pattern recognition; Mont Carlo method.

INTRODUCTION

For years researchers have been working on automatic damage detection in the hope of reducing a structure's maintenance cost by minimizing human involvement in the process. The rapid development in vibration data acquisition systems for the infrastructure has stimulated a vast interest in vibration-based damage detection and structural assessment, and accordingly a lot of literature are produced [Doebling et al. 1998]. Modal properties are among the earliest damage indicators adapted to this end [Alvin et al. 2003; Doebling 1998], but were found to be insensitive to local damage

and computationally expensive. Recently, time series analysis for vibration signals is being investigated in hope of establishing a more sensitive vibration-based damage detection approach [Farrar et al. 1999].

Time series analysis techniques have long been applied to fault detection in mechanical systems [Fassois and Sakellariou, 2007] before they were introduced into the field of civil engineering. This is essentially a data-driven approach that will 'let the data speak for itself'. The general strategy of time- series based damage detection includes five steps: 1) obtain data from baseline/healthy state structure; 2) extract a statistical quantity/damage feature Q from the data via time series analysis; 3) obtain data from current/unknown state structure; 4) extract the Q quantity from the data using the same method; 5) compare Q from the unknown state with that from baseline state using hypothesis testing. If the difference is statistically significant, the system is deemed damaged. The critical quantity Q can be a function of estimated time series model properties or signal spectrum.

Several time-series analysis methods have already been employed to identify damage in civil structures [Sohn and Farrar, 2001; Worden and Manson, 2007; Gul and Catbas, 2009]. The results reported in these papers are encouraging, since structural damage does result in a substantial change in the Q quantity in all cases. The main problem is that the extracted Q quantity can be affected by many other non-relevant factors such as environmental noise and excitation levels, and will suffer some oscillation even when the structural conditions remain the same. Therefore, it is important to set the damage threshold properly such that the number of false alarms and missed cases is minimized.

Statistical hypothesis testing [Koch 1999] is the recognized standard approach for threshold determination. It assumes that the features follow a certain probability distribution, and the threshold is set at a point beyond which the chance for a feature value to occur is small. This approach is theoretically optimal as long as the assumed feature distribution is valid. Hypothesis testing may do well for fault identification in machinery, as the excitation force is well known and the damage types are well-defined. For civil engineering applications, however, there are more uncertainties. When the probability distribution of damage features are too complex to be accurately represented by analytical distribution functions available, threshold constructed using hypothesis testing will yield poor results in damage identification and an alternative approach is needed.

In this paper a data driven threshold determination scheme using cross-validation and resampling techniques [Good, 1999] will be introduced and applied to the Mahalanobis distance [Mahalanobis 1936] feature described in Section 2. This feature is shown to be unstable, and its distribution is unknown. Yet the data-driven method

still yields an effective threshold. Also the Mahalanobis distance feature is paired with the autocorrelation feature to improve the damage detection performance of time-series based methods. A nearest-neighbor approach [Duda et al. 2000] is used to set the significance threshold for the feature pair.

The paper is organized as follows: Section 2 is dedicated to a brief review of time-series analysis techniques for damage detection. The damage features can be obtained from either autoregressive (AR) model coefficients or AR model residuals, and hypothesis tests are devised according to their respective theoretical distributions.

In section 3, new data driven approaches for threshold determination are presented. Section 4 contains an application of the Mahalanobis distance feature to detect damage in a lab specimen, and the results using the new threshold construction scheme are presented. Section 5 includes a discussion of feature combination and its application to the same specimen as in section 4.

DAMAGE DETECTION METHODS USING TIME SERIES ANALYSIS

Autoregressive (AR) model is perhaps the most widely adopted time series analysis tool [Brockwell and Davis, 2002]. The definition of a univariate AR model of order p is as below:

$$x(t) = \sum_{j=1}^{p} \phi_{xj} x(t-j) + \epsilon_x(t). \quad (1)$$

In this equation, $x(t)$ is the time series to be analyzed, ϕ_{xj} are the AR model coefficients, and $\epsilon_x(t)$ is the model *residual*. This model basically attempts to express the value of signal at time t as a linear combination of its previous values up to lag p.

According to classical structural dynamics theory, the discretized structural response under random excitation can always be approximated by an AR process of large order. Damage features from AR modeling can be grossly divided into two categories; model coefficients based and model residual based. AR model coefficients can be estimated directly from the data using one of the standard algorithms, and the residual sequence can henceforth be obtained from eqn. (1). In the remainder of this section, two damage features, one from each category, will be presented.

Mahalanobis distance of AR model coefficients

It has been proved that if the signal is really an AR process, then any regular coefficients estimator$\{\phi_{xj}\}$ from the signal is asymptotically unbiased and normally distributed with covariance matrix $\sigma_e^2\Gamma_p^{-1}$[Brockwell and Davis, 2009]. Therefore, a metric that represents the deviation in the probability space of normal distribution seems a good choice of damage feature. Mahalanobis distance is such a metric defined from the definition of multivariate normal distribution. The estimator of the Mahalanobis distance between a potential outlier vector x_ξ and baseline sample set can be obtained as

$$D_\zeta = (x_\xi - \bar{x})\hat{\Sigma}^{-1}(x_\xi - \bar{x}).$$

where $\bar{x}$ is the average of the baseline sample feature vectors, and $\hat{\Sigma}$ the estimated covariance matrix. When applying this method, the baseline signals are first segmented (often with large overlap) and for each segment an AR coefficient vector are estimated. Signals from current structural state are processed likewise and for each coefficient vector obtained its Mahalanobis distance to the baseline coefficients set will be computed. These Mahalanobis distance features are then compared with the Mahalanobis distances within baseline set. When the structural system is damaged, it is expected that the Mahalanobis distance feature for AR coefficients will increase significantly (Fig 1).

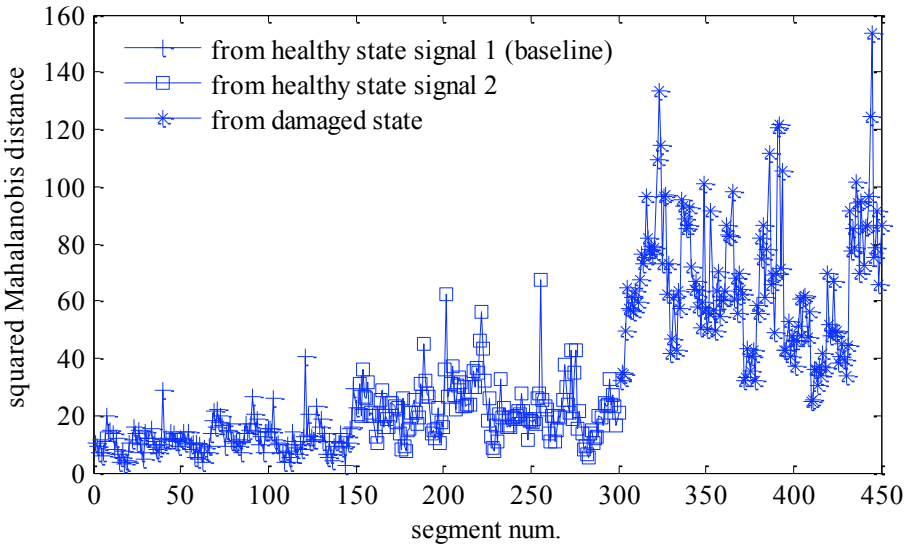

FIG. 1. MAHALANOBIS DISTANCE OF MODEL COEFFICIENTS. SEGMENT SIZE IS 350. THE OVERLAP BETWEEN CONSECUTIVE SEGMENTS IS 300.

Auto-correlation function (ACF) of AR model residuals

It is clear from (1) that if the AR model used to filter the signal is the same as the model from which the signal is generated, the residual series should be a white noise. Otherwise, the residual series will carry certain identifiable patterns that can be captured by its autocorrelation function. ACF can be estimated from residual sequence as:

$$\hat{\rho}(\tau) = \frac{\sum_{i=1}^{i=N-\tau+1}[\epsilon(i+\tau)-\bar{\epsilon}]\,[\epsilon(i)-\bar{\epsilon}]}{\sum_{i=1}^{i=N}[\epsilon(i)-\bar{\epsilon}]^2}.$$

From the baseline signal a baseline AR model can be estimated, which will then be fitted to new signals from unknown structural state. If the structural condition is unchanged, the ACF will resemble a Dirichlet delta function. It can be shown that for large N the sample autocorrelations of a white noise sequence at nonzero lags are approximately identically and independently distributed $N(0,1/n)$ [Brockwell and Davis, 2009], hence the 95% confidence bounds can be drawn at $\pm 1.96/\sqrt{n}$, as 1.96 is the .025 quantile of the standard normal distribution. Accordingly, the system can be identified as damaged when the number of ACF function value outside the bounds become statistically significant (Fig.2).

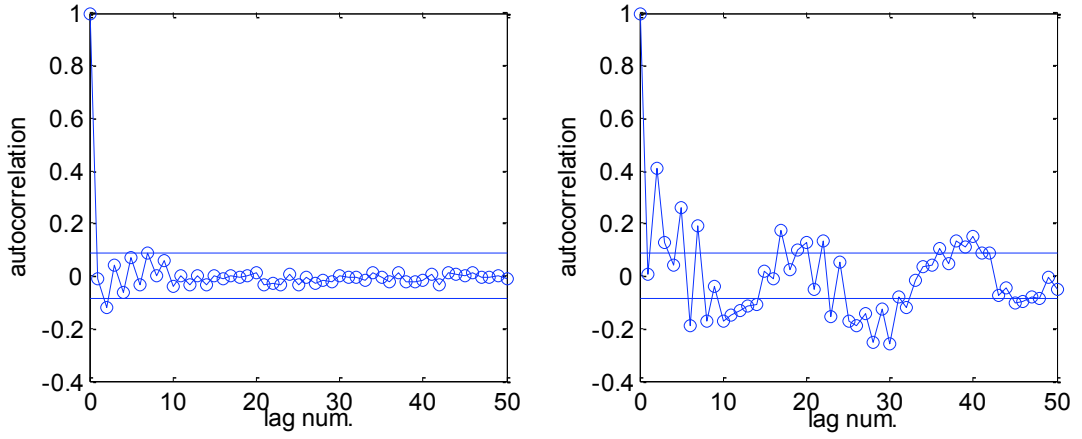

FIG. 2. RESIDUAL AUTOCORRELATION AS DAMAGE INDICATOR; LOTS OF OUTLIERS APPEAR WHEN MODEL NO LONGER FIT THE DATA WELL. THE LENGTH OF RESIDUAL SEQUENCE IS 520.

THRESHOLD CONSTRUCTION SCHEMES FOR DAMAGE FEATURES FROM TIME SERIES ANALYSIS

A desirable threshold is one that strikes up a balance between false alarms and missed cases. Now in most engineering practices this value is determined in an *ad hoc*

manner. Statistical hypothesis testing has been tried for automatic threshold construction, but its effectiveness is not guaranteed unless the actual feature distribution is the same as assumed. Here, tow data-driven methods will be introduced for threshold construction.

Threshold calculated from resampling: the 'cross-one-out' method

From Fig. 2 it is clear that the Mahalanobis distance feature suffers from large fluctuations within the baseline sample set. Also, when the baseline samples are extracted from vibration signal segments with overlap, the sample set is in fact not a very good representation of the actual feature probability space. Therefore, hypothesis testing exploiting the multivariate normal distribution will tend to yield a conservative threshold.

The first problem is perhaps resulted from environmental variations and statistical modeling and estimation deficiencies and cannot be helped; one solution to the second problem is to use vibration signals without overlap for feature extraction. However, when the data available is limited, this method is not practicable.

To address this problem here a 'cross-one-out' resampling technique is adopted. First a segment is cut from the baseline signal at a random time point and reserved for testing, and sample segments of the same size are cut with a preset overlap from the remaining signal. The Mahalanobis distance between the AR model coefficients of left-out segment and those of the sample set is then computed and stored. This process is repeated for a large number of times and the value beyond which 5% of the tests occur is used as threshold in subsequent analysis. This is essentially an estimation of the feature distribution by recomputing the statistic for many a time by leaving out a certain portion of observation, and can be viewed as a combination of jackknife and cross-validation technique [Shao and Tu, 1995].

Other methods have been proposed for threshold determination of Mahalabnobis distance feature; a Monte Carlo method has been used [Sohn, 2001] to produce the desired threshold by calculating the 5% quantile of empirical feature distribution of simulated coefficient vectors whose components are drawn independently from standard normal distribution. However, as noted in previous text, the AR coefficients are not mutually independent and may not have a unit variance. The assumption of this simulation is not well-grounded, thereby this approach is not used here though reported successful in a couple of literatures.

Empirical density estimation for multiple features; the nearest neighbor rule

Threshold determination becomes complicated when there is more than one feature in the algorithm. Fortunately, the nearest neighbor rule (Fig. 3) provides an intuitive way for empirical density estimation, from which damage threshold can be derived.

Suppose a dataset $\{x_i\}$ is generated from a certain probability distribution $p(x)$, then an empirical estimate of the probability density at x_i can be obtained exploiting the condition below

$$\hat{p}(x_i) \propto 1/\min d^n(x_i, x_j) \ (i \neq j).$$

Here n stands for the feature vector dimension, and (x_i, x_j) is the distance between point x_i and x_j. It is clear that the larger the distance from a point to its nearest neighbor, the smaller is its probability to occur.

A decision strategy for multiple features can hence be established as follows; for each feature vector from unknown state, search for its nearest neighbor in the baseline feature set and record the squared Euclidean distance. When the number of feature vectors above threshold exceeds a certain amount, the system is identified as damaged.

Therefore, the only thing remains to be determined for applying this strategy is the threshold value and its corresponding significance level. In the application presented in Section 5, a 5% significance level threshold is used. The threshold value for the test (unknown state) sets is four times the distance value D^* that has 5% of within-baseline nearest neighbor distances above it. This decision is based on following considerations; assume that both baseline and test features follows a same unimodal distribution that decays exponentially with respect to the distance to feature mean, then around 2.5% of the total features will be expected to have squared nearest neighbor distance beyond $2D^*$ given that the baseline and test set are of equal size. Since in the proposed decision strategy only baseline features are used for nearest neighbor search, this will increase the threshold to $4D^*$ because only half of the samples remain. To simply data processing, here the threshold is tested against 5% of the test features instead of 2.5% of the total features. It is but a slight relaxation

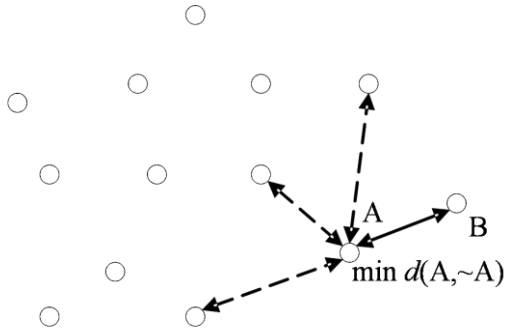

FIG. 3 ILLUSTRATION OF THE NEAREST NEIGHBOR RULE

of conditions, as few of the baseline features will go beyond this critical value.

APPLICATION OF THE RESAMPLING THRESHOLD CONSTRUCTION SCHEME

The damage detection algorithms are applied to acceleration measurements collected from a 5 degree-of-freedom structure (Fig 4) subjected to base excitation. Wired accelerometers are mounted to the shaking table and each floor. Damage is simulated by adding weight to the 4th floor. For each structural scenario, two sets of acceleration signals are recorded from two random excitation experiments. The sampling frequency is 100 Hz for all datasets.

FIG. 4 THE PLEXIGLASS 5 DOF LAB SPECIMEN

Fig 5 displays some of the results from Mahalanobis distance method. (a) is the result from 2nd floor response using threshold from proposed technique; (b) is the result from 4th floor response using threshold from proposed technique; (c) is the result from 4th floor response using threshold from hypothesis testing based on multivariate normal assumption. The significance level in all cases is 5%.

The AR model order adopted is 5, and 350-point segments are cut from acceleration signals with 300 overlap. It is obvious from Fig. 5 (a) and (b) that the change in feature value becomes more prominent at sensing locations more close to structural damage. Also, a comparison between Fig. 5 (b) and (c) shows that the threshold determination technique proposed here does yield a superior performance to that of frequentist hypothesis testing. In all the plots in Fig. 5 logarithmic scale is used for the y axis in order to decrease the oscillation of feature values.

Because in this case a controllable artificial excitation source is used in all the experiments, the overall statistical characteristic of Mahalanobis distance feature does not vary much over time. When this method is applied for damage detection from ambient vibration responses, this feature can become even more unstable. However, this resampling-based technique is still proved reliable in a couple of experiments on a space truss under ambient load, on the condition that there is enough data available.

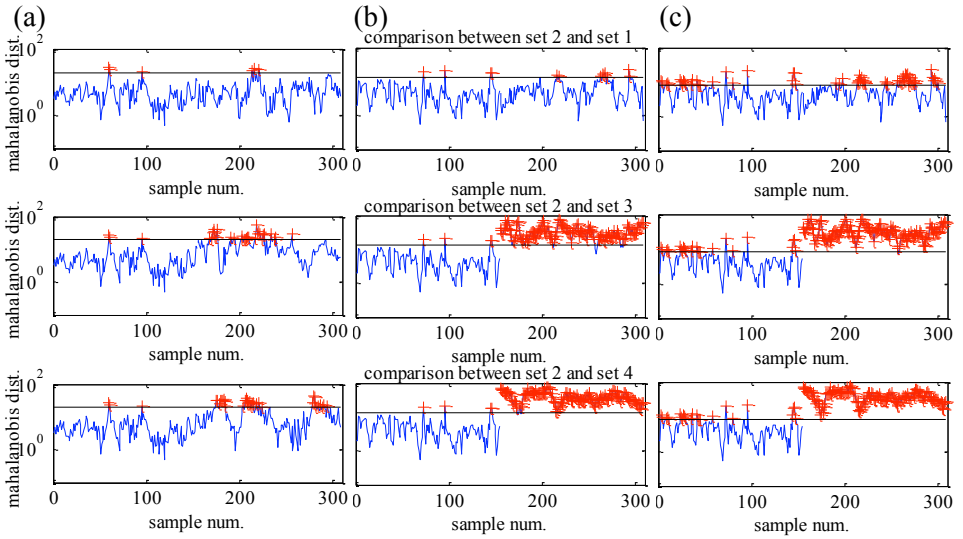

FIG. 5 DAMAGE DETECTION USING THE MAHALANOBIS DISTANCE OF AR MODEL COEFFICIENTS.

FEATURE COMBINATION

Most of the current research on damage detection by time series analysis employs only a single feature, or a set of features from either residual analysis or model parameter analysis. More damage sensitive methods can probably be established by taking features from both categories into consideration, as they in some sense reflect different aspects of the vibration signals. Thus here the two features mentioned in section 2 will be combined for damage identification.

To begin with, two feature pair sets of equal size are extracted from baseline and unknown signal, respectively. The extraction of Mahalanobis distance feature is still the same as before, i.e. for baseline signal feature values are generated using the 'cross-one-out' method introduced in Section 3, and for unknown state signal they are obtained using the routinely procedure described in Section 2. Note here that the logarithm of the distance is used to reduce the oscillation of feature values. Correspondingly, the residual sequence of each signal segment is obtained by filtering each data segment with the AR model estimated from the whole baseline signal. The autocorrelation feature value is then computed from the formula below;

$$Q_2 = \sum_{i=-10}^{10} |\rho(i)|$$

Where $\rho(i)$ is the ACF of the residual sequence. The segment size and overlap length adopted are still 350 and 300.

Fig 6 contains two scatter plots of baseline and test feature clusters extracted from acceleration responses at 4th floor of the lab specimen afore mentioned. Test features in the left plot come from healthy state, while those in the right one are from damaged state. It can be seen that when the structural condition remains same, the two clusters largely overlap each other; when damage has occurred, the test cluster will drift away from the baseline.

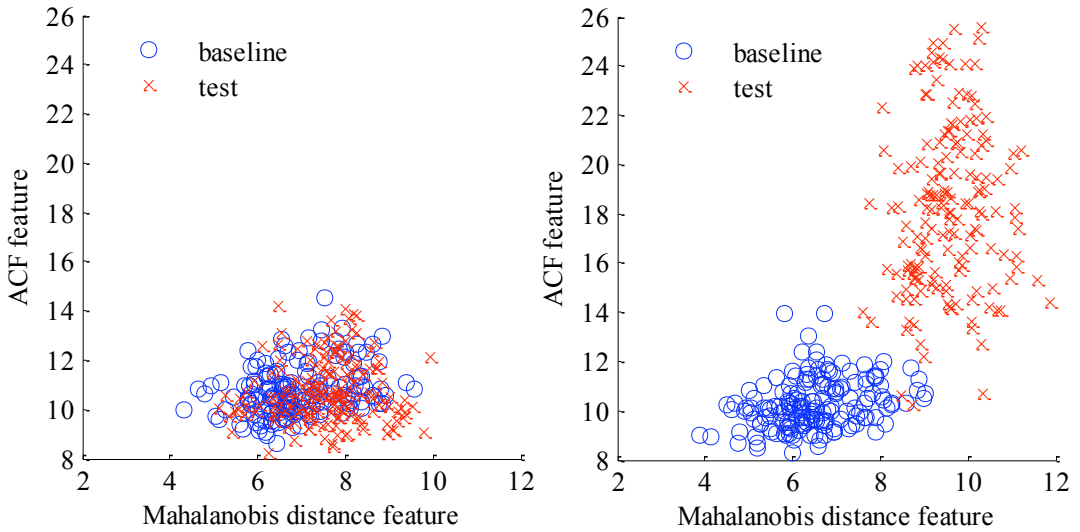

FIG.6 SCATTER PLOTS OF DAMAGE FEATURE PAIRS.

The nearest neighbor scheme is applied here to determine the damage threshold, and the results are summarized in table 1. The value before the slash is the number of outliers, and after the slash is the decision on structural state. The notation in statistical hypothesis testing is used; H_0 denotes healthy state, while H_1 denotes damaged state. Feature variables are all normalized beforehand with respect to the corresponding baseline standard deviation so that contribution of the two features to damage identification is equal. In each comparison the size of both baseline and test set is 166, and the threshold value for the number of outliers is accordingly set at 9. For each sensor location different AR model order is used to better fit the data. The performance of this algorithm is excellent in this case, with only one false alarm for the healthy state and perfect recognition for damaged case. It seems that the responses at 1st and 4th floor are most affected by the simulated damage.

TABLE 1 DAMAGE IDENTIFICATION RESULT USING NEAREST NEIGHBOR SCHEME.

Sensor location / Dataset num.	` 1st floor	2nd floor	3rd floor	4th floor	5th floor
1 (healthy state; baseline)					
2 (healthy state; validation)	$7/H_0$	$7/H_0$	$7/H_0$	$3/H_0$	$14/H_1$
3 (damaged state)	$126/H_1$	$78/H_1$	$32/H_1$	$161/H_1$	$88/H_1$
4 (damaged state)	$112/H_1$	$37/H_1$	$27/H_1$	$159/H_1$	$30/H_1$

CONCLUSION

For this case studies presented in this paper, thresholds based on data driven techniques are proved successful. They tend to generate fewer false alarms than frequentist hypothesis testing, yet still correctly report damage for most tests. All of these techniques employ some sort of empirical density estimation. Although the procedure is somewhat computationally complex, it provides a relatively reliable way to construct thresholds for features with large variation or of unknown distribution and thus automate the process of damage detection.

However, it must be stated that neither improved schemes for threshold construction, nor combination of features, can replace the quest for features that are more stable and damage-sensitive. Features are always the most important topic in damage detection. Adjusting threshold determination methods and combining features can help well-chosen features to perform better, but they cannot save a bad feature from yielding bad performance. Such features based on autoregression on single node response are innately ‘fragile’ because the information is limited and can be affected by other factors. When the loading condition or operation environment of the structure monitored is subjected to change, features based on longer data or data from several sensing locations will probably be more reliable. This will be a good subject for future research.

ABSTRACT

This study reviews different data analysis approaches to demonstrate possible means for getting information at different levels from the most commonly used strain sensors in an SHM system for short term and long term applications. The different methods are discussed from a real life monitoring study. First, the test bridge is presented with a brief introduction of the monitoring system and the sensor locations. Then, pre-processing and evaluation of raw strain data is discussed to identify the functionality of the installed sensors. Afterwards, strain data characterization by means of traffic and temperature induced strains is shown for more in-depth data analysis techniques. Finally, a new damage identification methodology based on strain correlation is discussed briefly. It is shown that there should be a suite of techniques and features to be available for implementation in SHM systems since one particular technique/feature may not be very reliable or sufficient for a particular case and/or structure.

INTRODUCTION

Structural Health Monitoring (SHM) is the research area focusing on condition assessment of different types of structures. One of the objectives of SHM systems is to provide an automated tool for tracking the health of a structure by combining different sensing technologies and data analysis techniques. As the SHM technology becomes more available and affordable with the recent developments in sensing and computing technologies, the challenges regarding analysis and management of the acquired data also increase.

In the last decades, the aging transportation network has directed the interest of civil engineering community to bridge health monitoring due to the critic nature of these structures. Different studies for bridge health monitoring can be found in literature from different perspectives such as damage detection, reliability, maintenance-cost, structural identification (Brownjohn et al. 1995; Aktan et al. 1996; Enright and Frangopol 1999; Fujino 2002; Catbas et al. 2007).

The implementation of the sensors and data acquisition systems can be considered as the first step for developing an SHM system. The next step is establishing the data collection and data analysis methodologies to assess the condition of the structure. The data analysis methodologies can be utilized for different objectives such as visual checks, statistical analysis, traffic characterization, environmental effect characterization and damage identification. After the data collection and analysis step, the last step for the SHM system is the decision making for repair and maintenance operations. These steps can help the infrastructure owners by indicating the worsening conditions such as graduate deterioration or instantaneous damage. This information which is generated with the help of SHM system can also be used by the owners in scheduling repairs or preventive maintenance to maximize the service life of the structure. Moreover, the root causes of the problems can be identified and future designs can be improved using the information generated using the monitoring system.

Objective and Scope

The objective of this study is reviewing different data analysis approaches to demonstrate possible means for getting information at different levels from the most commonly used strain sensors in an SHM system for short term and long term applications. First, the real life structure is discussed with the monitoring system and the sensor locations. Then, pre-processing and evaluation of raw strain data is discussed to identify the functionality of the installed sensors. Afterwards, strain data characterization by means of traffic and temperature induced strains is shown as fundamental applications for comprehensive data analysis techniques. Finally, a new damage identification methodology based on strain correlation is discussed briefly.

EXPERIMENTAL SETUP AND DATA COLLECTION FROM SUNRISE BOULEVARD BRIDGE (SBB)

The west bound of the Sunrise Boulevard Bridge (SBB) in Ft. Lauderdale, Florida (Figure 1) is selected to implement a comprehensive SHM system. Monitored span of this bascule type movable bridge, which was constructed in 1989, has a total span length of 35.7 m, a width of 16.3 m and carries three traffic lanes. The bridge opens every 30 minutes when requested and usually less than 10-15 times a day.

The instrumentation plan is designed to monitor the most critical electrical, mechanical, and structural components of the bridge. The current installation consists of strain gages, accelerometers, tiltmeters, strain rosettes, pressure gages, etc. with a total number of 162 sensors. In this paper, data from 36 Hitec-weldable-dynamic strain gages (at a data collection rate of 250 Hz) and 36 Geokon low speed vibrating wire strain gages (collecting data every 15 minutes) is used. These strain gages are located on top and bottom flanges of the main girders (48), floor beams (16) and stringers (8). More details about full instrumentation plan can be found in Catbas et al. (2010). The locations for the strain gages and corresponding nomenclatures are given in an inset in Figure 2. For example, WN refers to West North and ES refers to East South. Three pre-scheduled 5 minute-long time slots (morning, early and late afternoons), corresponding to peak hours of operation, are selected for daily high speed data collection. Low speed strain data is collected once in every 15 minutes. In

the following sections different data analysis methodologies will be discussed to extract useful information from high and low speed strain data.

Figure 1: Sunrise Boulevard Bridge (SBB)

PRE-PROCESSING AND EVALUTION OF RAW STRAIN DATA

Visual check of the raw strain data can be considered as the first step to detect non-working and malfunctioning strain gages. This process consists of viewing a graphical representation of real-time or archived data from a sensor channel and inferring from the predicted behavior of that sensor, whether or not that sensor channel is working properly. A common issue with the strain gage is the sensor drift, which can be defined as general trend of the data to shift to higher or lower readings during the collection. It is important to note that the condition of a sensor is not a constant. For example, a once working sensor may become a non-working sensor if it encounters some sort of trauma. For this reason, visual checking of the raw strain data is a continuous process for data quality control. In Figure 2, a video time frame and corresponding strain data coming from EN3 top and bottom flanges are shown. In these plots, it is seen that the strain level is coming back to its original level after the bus crosses the bridge. It should be noted here that visual check of the data may not be feasible in case of an automated SHM system and the above mentioned procedures for checking the data should be automated for such applications.

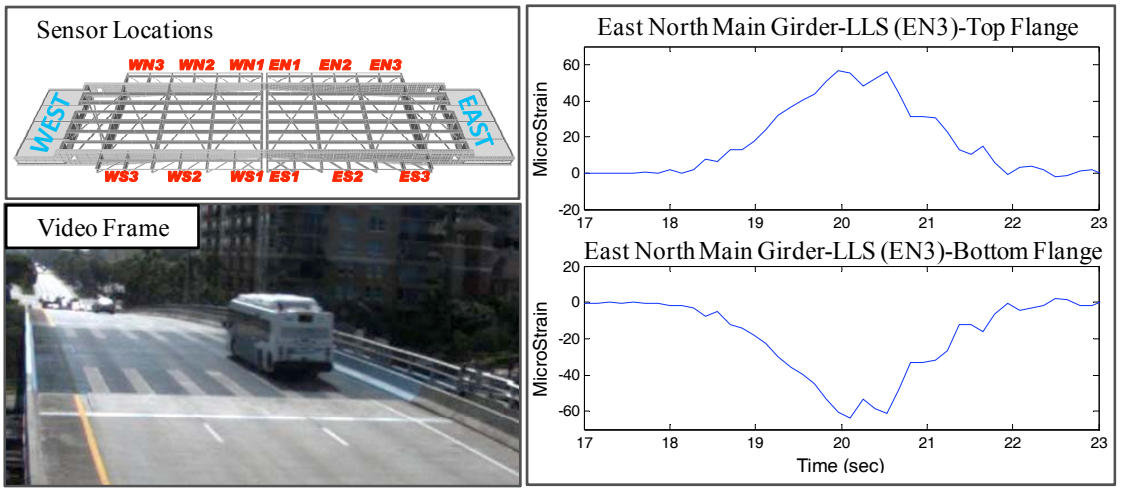

Figure 2: SBB sensor location nomenclature, video frame and corresponding strain data from EN-3

CHARACTERIZING TRAFFIC INDUCED STRAINS

Extracting statistical information, such as maximum, minimum, mean, standard deviation, correlation and root mean square can be considered as another type of data analysis approach, which helps the engineer, not only to understand the data behavior, but also to interpret the data. In addition to these advantages, statistics also help for identification of traffic behavior by identifying the truck induced stress levels, ADTT numbers etc. Figure 3 shows the daily maximum and minimum strains coming from the bottom flange of the East South stringer from the period of October 15 to January 15. Since the stringers are the starting point of the load distribution and have smaller cross-sections, higher strain values at stringers are observed compared to some of the other components such as floor beams and main girders. Higher strain values were observed mainly during the rush hour times of each day. Extreme value distribution can also be obtained using the statistical information about the strain. A three months strain data histogram coming from East South stringer is shown in Figure 4 that can be utilized for system reliability estimation and fatigue analysis.

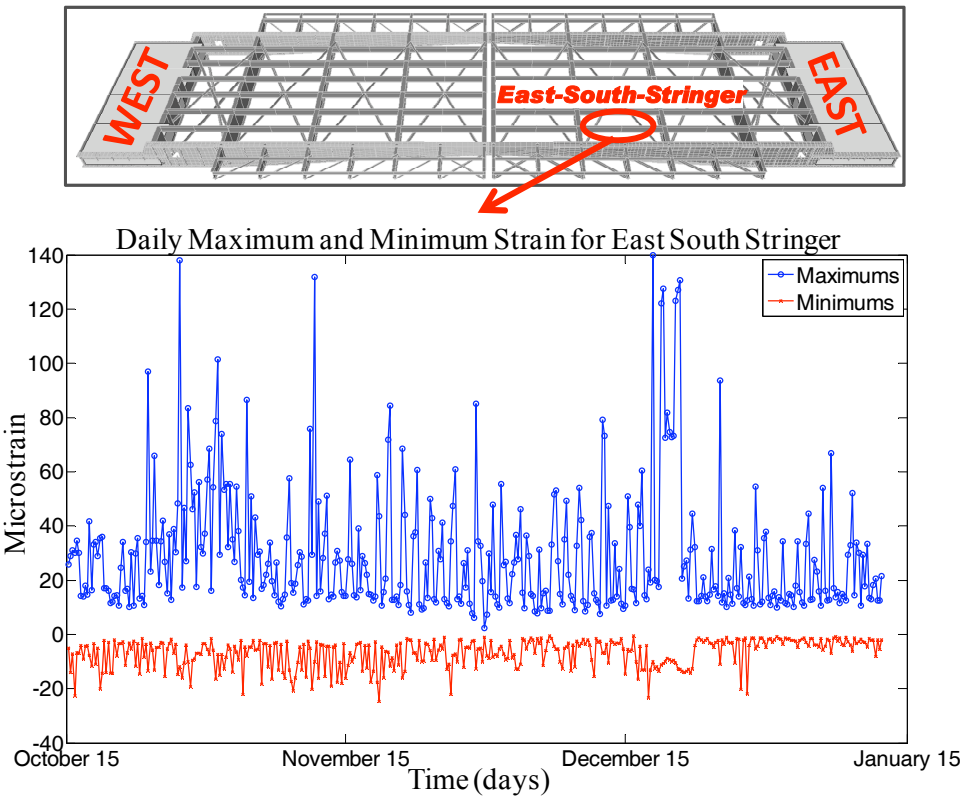

Figure 3: Daily maxima and minima strain for each day from East South stringer

CHARACTERIZING TEMPERATURE INDUCED STRAINS

Slow speed strain gages were employed to measure stress-induced strain and temperature data simultaneously. Some previous studies showed that the daily or seasonal temperature effects may create critical stress levels, even higher than traffic induced stresses. Therefore, the strain temperature relationship is extremely important for long term monitoring. With a long term strain-temperature data, it is possible to obtain daily and seasonal cycles over the time. Fitting some models to this data may offer an effective tool for prediction of the stress cycles on the structure as well.

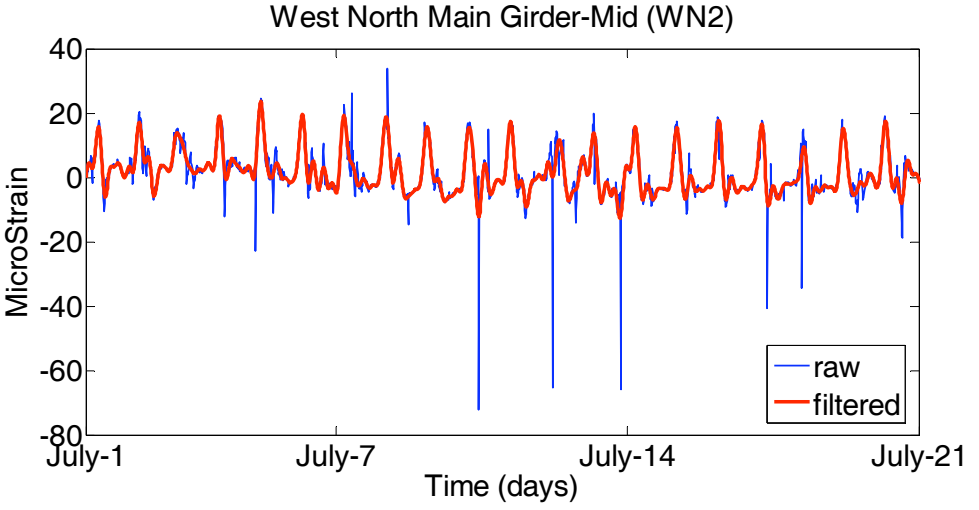

Figure 5:WN2 vibrating wire strain gage raw and filtered data (July 1–July 21)

When the three-week data set, shown in Figure 5, from vibrating wire strain gages was inspected, it was seen that there were some spikes in the data. In a fixed bridge, these can be attributed to vehicular traffic; however, in this case, opening and closing of the bridge was the main reason for these high strain values in addition to possible truck induced effects. These strain values were not created due environmental effects; therefore, filtering these spikes out of the data enabled a better correlation of the temperature and structural response (Figure 6). A low pass filter was designed to eliminate the effects of traffic and opening-closings. These outliers were eliminated to see only the effects due to environment inputs to the bridge. From Figure 6, a 30% strain temperature correlation is seen before filtering the strain data. After filtering the data, the correlation between the strain and temperature is increased to 60% which can be more clearly observed.

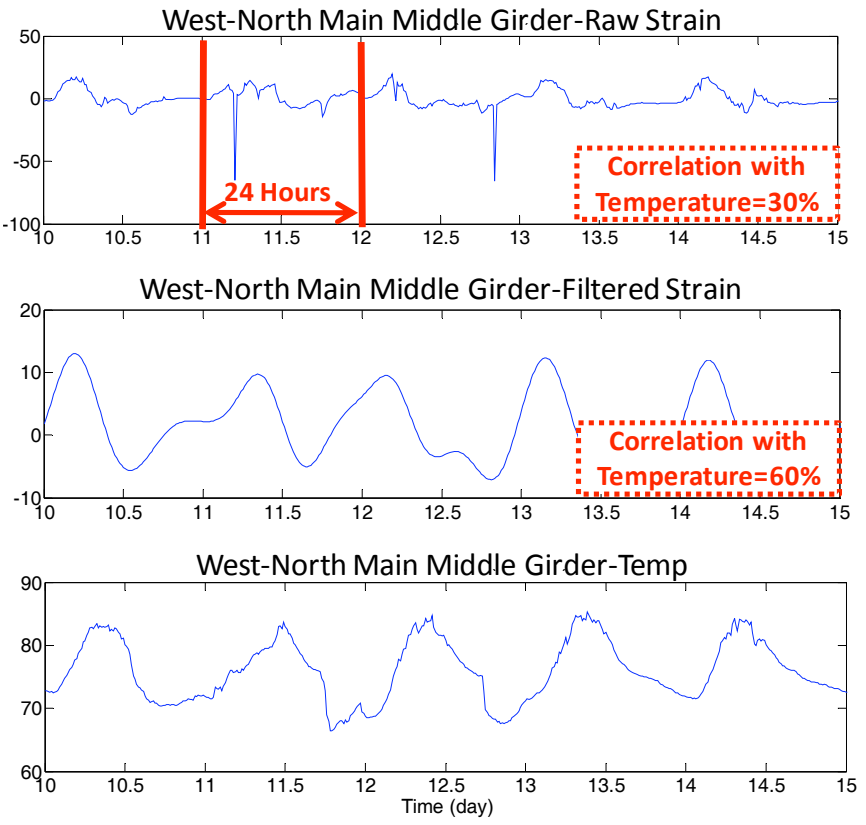

Figure 6:WN2 strain and temperature raw and filtered data (July 8–July 13)

Because of the cyclic nature of the temperature and its correlation with strain, it would be appropriate to investigate the temperature and strain responses by means of Fourier Series with the expansion form as given below.

$$f = a_0 + \sum_{n=1}^{N} a_n \sin(n\omega t) + b_n \cos(n\omega t)$$

The main idea here is to characterize the temperature induced strains and be able to make predictions for the future stress levels of the structure with expected temperatures with this characterization. For this reason, strain and temperature models using Fourier Series with eight terms (*N=8)* can capture the observed daily cycles efficiently as shown in Figure 7. Furthermore, it is seen that the correlation is raised to a level of 80% when the Fourier models of temperature and strain are considered. This increase promises for better characterization of temperature induced strains thereby an accurate strain temperature model can be created with long term monitoring data.

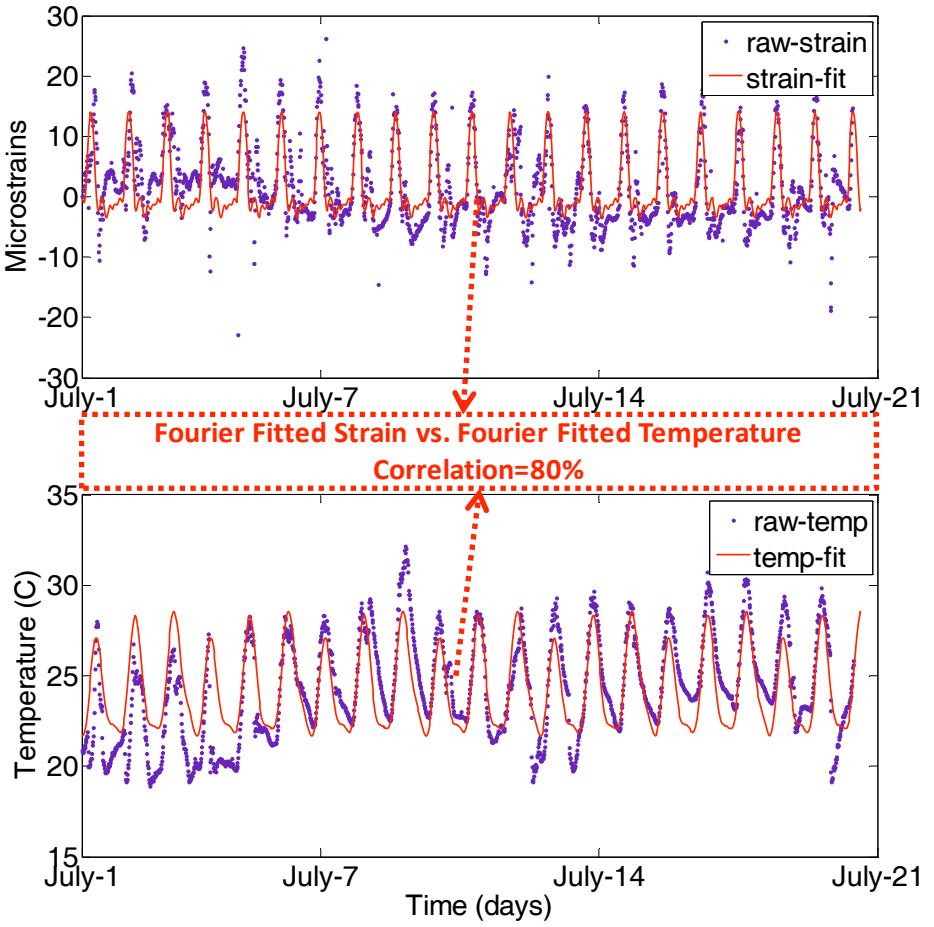

Figure 7:WN2 vibrating wire strain gage raw and Fourier fitted strain and temperature data

ANALYSIS OF STRAIN DATA FOR DAMAGE IDENTIFICATION

After collecting the basic statistical information from each sensor channel for each data set, some data analysis methods can be used for structural damage identification. In this part of the study, strain correlation based damage identification is presented. Cross correlation which is a measure of similarity of two data sets in vector form giving a value between +1 and -1. Having similar behavior in data sets gives higher correlation while low correlation indicates either low or no correlated response. General cross correlation coefficient formula is as follows:

$$\rho_{X,Y}=\frac{\sum_{i=1}^{n}(x_i-\bar{X})\times(y_i-\bar{Y})}{(n-1)\times S_X\times S_Y}$$

where $\bar{X}$ and $\bar{Y}$ are means and S_X and S_Y are the standard deviations of each vector. Ideally, the strain channels should have a correlation with the neighbor, or symmetric locations, and the outcome of this correlation will show consistency in the strain levels. In the light of this information, the authors decided to investigate the possible change in the correlation coefficients due to structural changes on the movable bridge.

Structural Alterations on SBB

The Live Load Shoes (LLS) are the support locations of the main girders when the bridge is in closed position (Figure 8). If misaligned or improperly balanced, the bridge may not fully sit on the LLS. In that case, the dead load and traffic load are transferred to the gears and shafts, which cause damage to mechanical assemblies. Small gaps also lead the girders to pound on the live load shoes, which results in further misalignment, additional stresses, fatigue damage, and excessive wear. For this study, LLS shim removal (Figure 8) is chosen as a damage scenario based on the inspection reports of bascule type of movable bridges in Florida. The West South LLS (WS3) shims which are removed to see the effect of a gap around 3.2 mm up to 4.8 mm.

Results

Correlation coefficients of the strain channels are tracked for a 25 different data sets before, during and after damage from a three weeks period. First, 10 data sets are collected in 10 days to illustrate the before damage correlation coefficients. Then, five data sets are collected for LLS shims removal case on same day due to time consideration to illustrate the during damage correlation coefficient. Finally, 10 more data sets were collected in a 10 day period to see if the correlation coefficients are becoming their original level.

The correlation coefficient change between the ES3 and WS3 strain gages during the three weeks period are shown in Figure 8. It can be easily seen that the correlation coefficients before damage case are around -0.8, during LLS damage are around -0.3and after damage these coefficients came back to the -0.8 level again but

this time with a smaller standard deviation. The reason behind this is the significant effect of the maintenance. The trends of the correlation coefficients are also tracked for different strain gages but they are not presented here for the sake of brevity. More data and results will be reported in another publication which is dedicated to this approach and results.

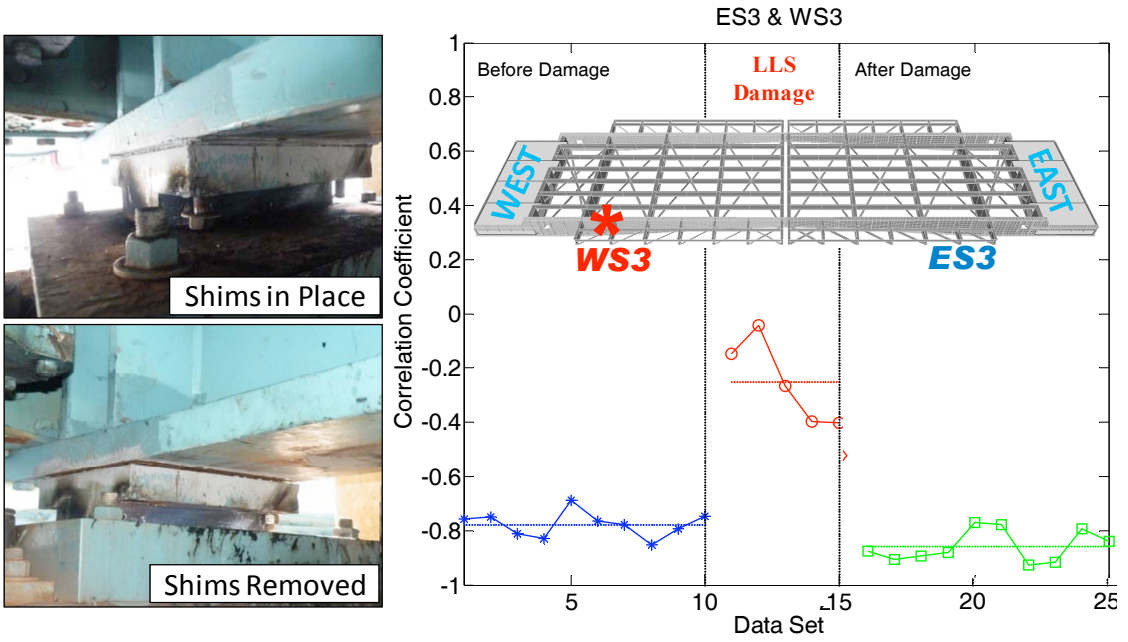

Figure 8:LLS shims and correlation coefficient change before, during, after damage

SUMMARY AND CONCLUSIONS

In this paper, different data analysis approaches are presented to extract meaningful information from high and slow speed strain data. It is observed that raw data analysis is necessary to identify functionality of the sensors and to evaluate data quality whereas statistical analysis is a fundamental step for advanced analysis methodologies. Moreover, traffic induced strain analysis is important to identify traffic characteristics that can be used for identifying fatigue cycles, ADTT numbers and extreme value distributions for structural reliability estimation. In addition, strain and temperature are crucial to continuously monitor and fit different models to make predictions because structural components subjected to high stresses or stress reversals due to temperature cycles. Finally, an effective way of handling strain data by means of correlation based damage identification methodology is presented. Based on the results, it is seen that this new methodology can help to track and detect any

permanent change by means of strain measurements under any traffic loading. It is shown that there should be a suite of techniques and features to be available for implementation in SHM systems since one particular technique/feature may not be very reliable or sufficient for a particular case and/or structure.

ACKNOWLEDGMENTS

The research project described in this paper is supported by the Florida Department of Transportation (FDOT) and Federal Highway Administration (FHWA). The writers would like to thank and cordially remember Mr. Marcus Ansley, P.E. for his support and guidance throughout the project. The writers would like to express their profound gratitude to Dr. Hamid Ghasemi of FHWA for his support of this research. The support of both agencies and their engineers is greatly recognized and appreciated. The opinions, findings, and conclusions expressed in this publication are those of the authors and do not necessarily reflect the views of the sponsoring organizations. Several graduate students and research collaborators are also to be acknowledged for their contributions at different levels for this study.

ABSTRACT

Bridge structural health monitoring involves the collection and analysis of systematic measurements obtained from installed sensors on the bridge. While there are many quality certification systems available for civil engineering systems, e.g. American Society for Testing and Materials (ASTM), typical bridge monitoring specifications do not explicitly address performance requirements. As the applications of bridge structural health monitoring becomes more varied and advanced it will become necessary to ascertain the quality of measured data in order to check its suitability for new and varied applications.

The quality of measured data has a direct impact on the results obtained from data analysis in structural health monitoring. The quality of measured data for a bridge monitoring system should meet three basic criteria: First, measured data should be devoid of anomalies such as signal clipping, intermittent noise spikes, temporary signal dropouts, and spurious trends. Second, the errors, including aliasing and quantization, and system noise should be within an acceptable range. Lastly, the measured data should satisfy required assumptions, such as stationarity and normality.

Data qualification is defined as validating the quality of measured data and quantifying errors and noise to ensure the measured data sufficiently satisfies the above mentioned criteria. Despite the tremendous impact the quality of measured data has on bridge structural health monitoring, data qualification has not been formalized for bridge monitoring to provide a basis for bridge monitoring data specifications. This paper proposes measures of data qualification that can be used as a foundation for data specifications in bridge structural health monitoring. This paper will use data collected from monitored bridges in the Connecticut Long Term Bridge Monitoring program as examples of issues faced when using long term bridge monitoring data acquisition systems.

INTRODUCTION

Structural health monitoring of highway bridges has proven to be extremely beneficial for engineers, state agencies, and researchers. These systems allow for determination of structural integrity to supplement physical inspections. Physical inspections can be limited by lack of physical access to areas on the structure, availability of manpower, or economic reasons. Also, the frequency of physical inspections may not observe the onset of damage and be able to prevent catastrophic structural failure (DeWolf et al. 1995a, DeWolf et al. 1995b). Structural health monitoring, as a supplement to bridge inspections, can be used to determine the condition of the entire structure on a continuous and long term basis. Also, unlike physical inspections, structural health monitoring can provide inspectors with actual values for stress, accelerations, or any other parameter being measured (DeWolf et al. 2002). With a combination of structural health monitoring and physical inspections, the health of a bridge structure can accurately be tracked over time.

Bridge health monitoring systems allow the collection and analysis of data which can describe the behavior of bridges over long periods of time. This analysis can help bridge owners such as state agencies determine optimal bridge maintenance and replacement strategies (DeWolf et al. 1995a). Vibration based monitoring is of particular use for damage detection and monitoring deterioration of structures (DeWolf et al. 1991a, DeWolf et al. 1998, DeWolf et al. 2002). Vibration monitoring has been shown to effectively assess the global condition of highway bridges (DeWolf et al. 1991b, DeWolf et al. 1992, DeWolf et al. 1995a, DeWolf et al. 1995b). Strain monitoring has also been effectively implemented to determine the levels of stress and structural performance of particular structural members and connections (DeWolf et al. 1995b, DeWolf et al. 1998, DeWolf et al. 2002). This type of analysis had been used to determine whether or not a bridge structure is behaving as designed (DeWolf et al. 1998). The analysis of bridge data can provide additional information on the structural health of the bridge and supplement bridge inspections (DeWolf et al. 2002). The benefits of bridge monitoring are generally recognized by the bridge engineering community with an increasing number of applications throughout the country (DeWolf et al. 1995a, DeWolf et al. 1995b).

A number of different types of structural health monitoring systems have been installed and used on highway bridges (DeWolf et al. 1995, DeWolf et al. 1995 Application). As observed, the applications of bridge structural health monitoring are becoming more and more varied and advanced. Bridge monitoring systems are applied to different types of bridges, employ a variety of sensor types, and acquire the data in a variety of manners.

There are numerous quality certification systems available for civil engineering systems, e.g. American Society for Testing and Materials (ASTM), American Society of Civil Engineers (ASCE), and American Association of State Highway and Transportation Officials (AASHTO). In particular, AASHTO presents the code for the structural performance of bridges. AASHTO presents engineers with the loads to be applied to bridge structures along with design considerations to be taken (AASHTO 2009). In 2008, the Federal Highway Administration (FHWA) also has implemented a Long Term Bridge Performance (LTBP) program to better understand long term performance of highway bridges and the associated issues (FHWA 2011).

The design and implementation of a structural health monitoring or the long term performance of bridge structures is not included in these specifications. Furthermore, typical bridge monitoring specifications do not explicitly address performance requirements for the sensor data.

This paper presents proposed specifications for highway bridge structural health monitoring sensor data. The proposed specifications are based on experiences with bridge monitoring systems installed on a variety of bridges in Connecticut over the past decade as part of a joint research program between the Connecticut Department of Transportation and the University of Connecticut. The proposed set of specifications are intended to serve as a starting point from which further discussions can be based to ensure future bridge structural health monitoring systems can achieve their maximum potential.

PROPOSED SPECIFICATIONS

The basis for the proposed bridge structural health monitoring specifications for sensor data has been provided by the experiences of the Long Term Bridge Monitoring Program in Connecticut. Long Term Bridge monitoring in Connecticut is a joint research effort of the Connecticut Department of Transportation and the University of Connecticut. Since 1994, six bridges in Connecticut have been installed with bridge monitoring systems (DeWolf et al. 2006, Olund et al. 2009, DeWolf et al. 2009). Recently, some of the data acquisition equipment on the bridges has been updated. There are a variety of bridges being monitored, using a number of different types of sensors, and, over the course of the research, a range of data acquisition systems. Both concrete and steel bridges are being monitored, with superstructure types varying from box girders, traditional slab-on-girder, to truss. The sensors installed on these bridges include: foil, vibrating wire and piezoelectric strain gages; piezoelectric and capacitive accelerometers; RTD temperature sensors; tilt meters; and linear variable differential transformer (LVDT) displacement transducers and string potentiometers. Both wired and wireless sensors are used in the research. The diversity of this monitoring program is drawn upon in the proposed specifications.

Critical to any bridge monitoring efforts is the data analysis used to identify the structural health of the bridge. The quality of measured data has a direct impact on the results obtained from data analysis in structural health monitoring. Structural health monitoring techniques such as peak picking (DeWolf et al. 1991a, DeWolf et al. 1998,) require data undistorted in the frequency domain. Strain monitoring of structures requires data in the time domain that is void of excessive noise and data anomalies (DeWolf et al. 1998, DeWolf et al. 2002). As structural health monitoring analyses continue to improve and advance, the reliance on high quality data becomes more critical.

The quality of measured data for a bridge monitoring system should meet three basic criteria: First, measured data should be devoid of anomalies such as signal clipping, intermittent noise spikes, temporary signal dropouts, and spurious trends. Second, the errors, including aliasing and quantization, and system noise should be within an acceptable range. Third, the measured data should satisfy required assumptions, such as stationarity and normality. Verifying assumptions such as stationarity and normality are necessary prior to data analysis, however, this

particular criteria is inherent to the bridge's loading and subsequent response and is not part of the proposed bridge structural health monitoring specifications. The proposed specifications, as discussed in this paper, will address: data anomalies, including signal clipping, intermittent noise spikes, temporary signal dropouts, spurious trends, and periodicies; errors, associated with aliasing and quantization; and measurement noise associated with the sensor, cabling or data acquisition hardware.

Data Anomalies. The presence of data anomalies in a bridge health monitoring system should be checked and documented once the system is installed, and at regular intervals during the life of the system. The bridge monitoring system should be devoid of any data anomalies. Data anomalies may include signal clipping, intermittent noise spikes, temporary signal dropouts, spurious trends, and periodicity. While it is difficult to anticipate these anomalies, their presence can be eliminated through changes of the system or appropriate post processing of the data. These aforementioned data anomalies are indentified through the inspection of collected data in both the time and frequency domains.

One anomaly is signal clipping, which occurs when the maximum value of the sensor or data acquisition system is exceeded. This anomaly can be seen as a flat top when the signal is viewed in the time domain. Signal clipping can be avoided by properly selecting sensors and data acquisition systems that can handle the expected measurements from the bridge. If signal clipping is not prevented in the original installation of the structural health monitoring system, the sensors and data acquisition system should be replaced with a system that can handle the measurements.

Another anomaly that can occur during the collection of data from a highway bridge is intermittent noise spikes. This likely occurs when the cables connecting the components of the structural health monitoring system incur relative motion. As with signal clipping, intermittent noise spikes are noticed in the time domain of the measured data. Intermittent noise spikes are characterized by random large spikes in the time history. To avoid the presence of intermittent noise spikes, all cables in the system should be securely fixed/tied down. The connections of all cables should also be inspected to ensure a snug fit.

An example of intermittent noise spikes was observed on the Sikorsky Bridge monitoring system. The Sikorsky Bridge, National Bridge Index (NBI) #761, pictured in Figure 1, is a five span steel plate girder bridge spanning a distance of approximately 1800 feet over the Housatonic River in Stratford/Milford Connecticut. This bridge carries the limited access traffic of The Merritt Parkway (Route 15) north and southbound. The sensors installed on this bridge include piezoelectric accelerometers, foil strain gages, LVDTs, and tilt meters. A 16-bit data acquisition unit is used to collect data from the 48 sensors installed on the bridge. Figure 1 shows the time history for an accelerometer (Accelerometer 1) located on the southernmost span (Span 1) of the Sikorsky Bridge. While the normal response of the bridge is less than 0.1g, three intermittent spikes are observed in the 10 second interval with amplitudes around 1g. This suggests that there may be an issue with the cables connecting the sensors to the data acquisition unit for the Sikorsky Bridge system.

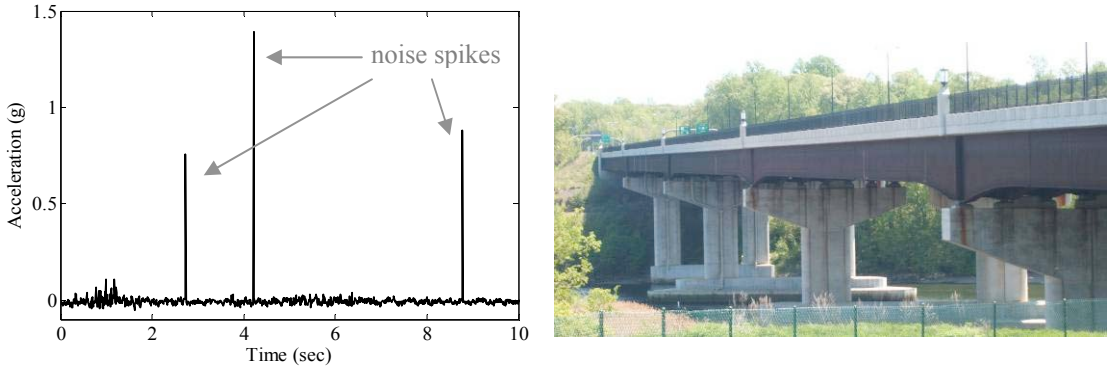

Figure 1. Intermittent Noise Spikes from Sikorsky Bridge System – Accelerometer 1, Span 1, 10 second Time History and Picture of Southbound Bridge.

A third anomaly, temporary signal dropouts, can occur when the measured signal suddenly vanishes into the noise floor of the data for a period of time. This data anomaly can be attributed to a number of different components in a structural health monitoring system. It can be a problem with the wiring or connections of the system, or a problem with the sensors themselves. If temporary signal dropouts occur the system should be carefully inspected for issues.

A spurious trend is a time varying change in the mean value of a set of data. When strain gages are not compensated for changes in temperature a spurious trend can occur. These temperature trends can be resolved by using full bridge strain sensors, or by removing any bias in the post processing of the data. Spurious trends are of significance when they do not occur because of a change in temperature. In this case, the sensor should be carefully inspected.

The final data anomaly addressed here that can be experienced in a bridge health monitoring system is a periodicy. A periodicy is a signal added to the actual signal that repeats at a regular interval. In bridge health monitoring this is likely due an improperly grounded system. This ground loop results in a 60 Hz periodic signal. The existence of a periodic signal can be most easily observed as a large spike in the frequency domain of the data set. If a periodic signal is encountered in a bridge monitoring system the grounding of all AC electrical components should be checked.

An example of periodicies was observed during the recent installation of a bridge health monitoring system installed on an I-91N overpass in Meriden CT. The Meriden Bridge, NBI #03051, shown in Figure 2, is a single span slab-on-girder bridge with a total span of 85 feet. The sensors installed on this bridge include 18 foil strain gages, 4 piezoelectric strain sensors, 8 piezoelectric accelerometers, 4 capacitance accelerometers, and 4 resistance temperature detectors. Data is collected using a 24-bit data acquisition unit. A 60 Hz periodicy was initially observed in the measured strain gage data. An auto-power spectral density function of the foil strain gage located at the top midspan of the center girder (M1) is shown in Figure 2. The auto-power spectral density function transforms the time domain strain measurement into the frequency domain. The auto-power spectral density function is a measure of the energy content of the signal as a function of frequency. From the plot in Figure 2, it is obvious that there is significant energy localized at 60 Hz.

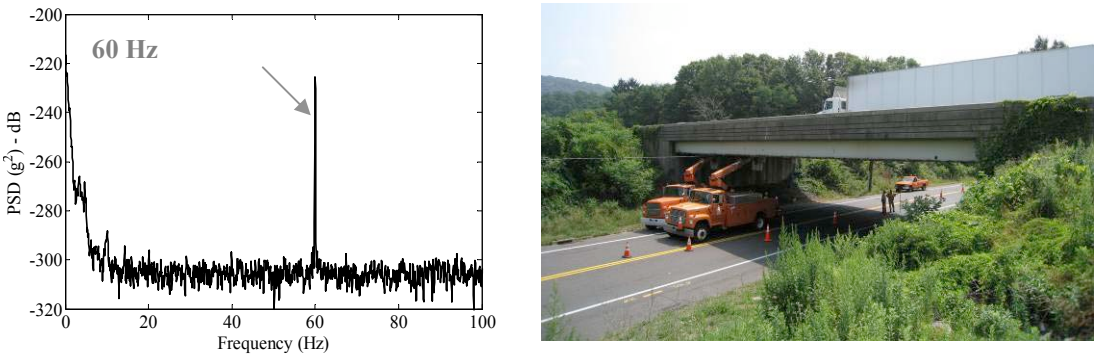

Figure 2. Periodicy Observed on Meriden Bridge System –
Auto-Power Spectral Density Function of Strain Measurement and Picture of Bridge.

Five data anomalies have been identified for the proposed specifications that may be encountered when working with a bridge structural health monitoring system. The existence of all or any of these anomalies should be checked initially for the system as well at regular time intervals and the appropriate action should be taken to eliminate any anomalies when identified.

Aliasing and Filtering. The potential for aliasing exists when digitally measuring analog signals. Aliasing occurs when a high frequency signal appears as a lower frequency signal. Once measured data is aliased, it is impossible to reconstruct the original signal or even tell that the sample has been aliased. It is therefore imperative to be proactive and prevent aliasing from occurring in the first place. This can be done by either carefully selecting the sampling rate or installing anti-aliasing filters.

In order to eliminate aliasing using the sampling rate, a rule of thumb is that data should be sampled at a rate ten times higher than the resonant frequency of the sensor. This is not an issue with certain sensors that have low resonant frequencies. For example, a tilt meter with a resonant frequency of 2 Hz should be sampled at 20 Hz. Piezoelectric accelerometers, however, can have resonant frequencies of 3500 Hz. This would require sampling the data at a rate of 35 kHz. Due to system capabilities and data storage this may not be feasible. In such cases anti-aliasing filters can be employed. Appropriate anti-aliasing filters the measured data prior to the analog to digital conversion such that the frequency content of the measured signal larger than the Nyquist frequency (one half of the sampling rate) is effectively removed. It is recommended that all dynamic measurements be passed through anti-aliasing filters to prevent aliasing. Current technology allows standard implementation of 8-pole filters which can effectively prevent aliasing.

The bandwidth of the filter used in an anti-aliasing filter must be carefully selected. Of first concern, as identified above, is that the bandwidth of the filter be less than the Nyquist frequency, or one half of the sampling rate. Depending on the natural distortion of the specific filter used, the usable bandwidth will be some frequency less than the Nyquist frequency.

An example of an anti-aliasing filter that leads to a restricted bandwidth was experienced on the Flyover Bridge monitoring system. The Flyover Bridge, NBI #05868, located in Hartford, Connecticut, is shown in Figure 3. This bridge is a multi-span, continuous, double steel box girder bridge with a composite concrete deck. The

original data acquisition system had a two-pole low-pass filter with a cutoff frequency of 2 Hz used for anti-aliasing. With a sampling rate of 100 Hz, this filter provided sufficient anti-aliasing protection. However, the 2 Hz cutoff frequency of this filter resulted in measured data with distorted frequency content above this 2 Hz. A new data acquisition system on the bridge provides a bandwidth of 500 Hz. Figure 3 shows a plot of the auto-power spectral densities of an accelerometer (A4) located on the fourth span (Span 4) of the bridge from both the original and the current system. It is observed in the auto-power spectral density functions that the original signal was attenuated above 2 Hz. While this was not a problem for the original structural health monitoring analysis that considered only the fundamental frequency of the bridge, at 1.5 Hz, current approaches (Scianna, et al., 2011) are using multiple lower frequency modes.

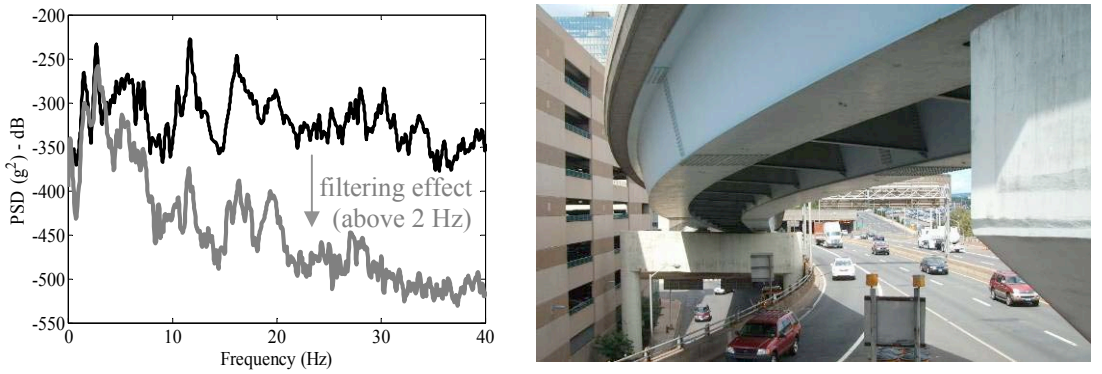

Figure 3. Filtering Issues – Accelerometer 4 on Flyover Bridge Auto-Power Spectral Density Function and Picture of Bridge.
(Original Data Acquisistion (DAQ) – gray; Current DAQ – black)

Quantization. Quantization error is inherent to analog sensors and digital processing. When a continuous analog signal is saved as a digital signal, the amplitude of each sample is expressed using a finite number of bits in binary terms by the analog to digital (A/D) converter. A round-off error is created due to this conversion, which is called quantization error. The quantization error can be reduced by using an analog to digital converter with a high total number of bits. Common A/D converters available today are 24-bit. These seem to minimize quantization error sufficiently, providing accurate data results.

An example of quantization is observed between the original and current monitoring systems on the Cromwell Bridge. The Cromwell Bridge, NBI #03078, shown in Figure 4, is located in Cromwell, Connecticut. The bridge carries I-91S traffic over the Mattabessett River. The bridge is a three-span, simply supported, slab-on-girder bridge. In November of 2004, the original structural health monitoring system was installed on the Cromwell Bridge. The original system consisted of 20 strain gages and a 16-bit data acquisition system. In July 2010, a new 24-bit data acquisition system replaced the original system. This improved the resolution of the sensor measurements from 1 με (microstrain) to 0.06 με. Figure 4 shows comparative time histories for strain gage 8. The original data was recorded at 10 Hz, while the new data is recorded at 1600 Hz and passed through an 8-pole Butterworth filter with a cutoff frequency of 100 Hz. Figure 4 above shows the time history response of a

vehicle crossing over the bridge for the original system with 1 με resolution and a vehicle crossing over the bridge with the finer 0.06 με resolution of the current system. The finer resolution can provide more accuracy of the dynamic response of the structure for both health monitoring and weigh-in-motion calculations.

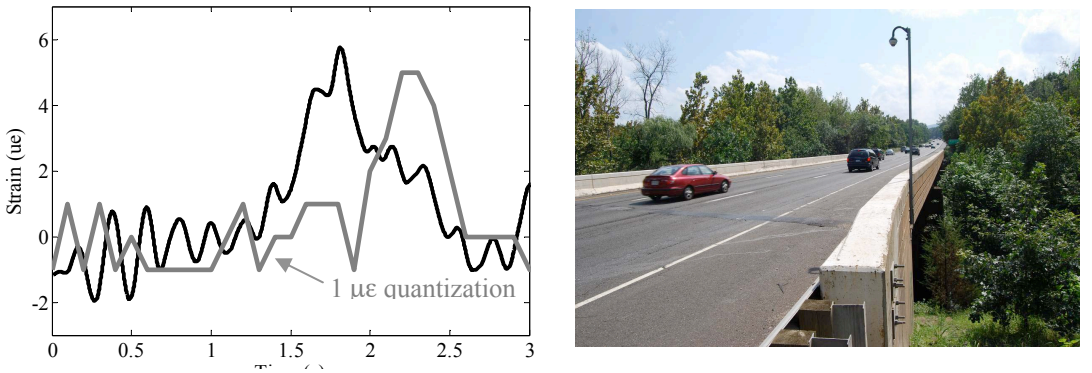

Figure 4. Quantization of Cromwell Bridge System and Picture of Bridge (Original Data Acquisistion (DAQ) – gray; Current DAQ – black)

Measurement Noise. It is important to reduce the amount of noise in a structural health monitoring system. Noise measured in a signal may be due to the sensors, data acquisition system, means of data transmission such as cables, or any other intermediary in the system between the system and data acquisition unit.

Large levels of noise in a system can hide the actual response of the bridge being measured. This reduces the usefulness of the measurement. The amount of noise in a signal is quantified by the signal-to-noise ratio (SNR). A signal-to-noise ratio is defined as the ratio of signal power to the noise power corrupting the signal, and can be presented as the ratio of the variance of these two signals.

There are a number of ways to effectively reduce the amount of noise in a bridge health monitoring. First, sensors with a measurement range only slightly larger than the peak values to be measured should be used. Also, cable lengths should be kept as short as physically possible. Lastly, the signal being sent to the data acquisition unit should be amplified to a similar magnitude as the analog voltage input.

Another issue for bridge monitoring applications is the definition of what exactly constitutes noise in the measurement. For applications in Connecticut when the excitation is considered the vehicles passing over the bridge, noise might be considered to include additional sources of ambient vibration including wind excitation, vehicles on adjacent bridges or roadways, fluids in any piping attached to the bridge, etc. As such, to identify SNR in the field measurements are taken from the bridge during high or peak travel times and in the late night/early morning when, using traffic cameras and remote data capture, it can be confirmed there is low or no traffic on the bridge, which is meant to closely represent the noise floor.

What has been observed from field measurements on a number of the bridges in Connecticut is that a range of higher frequency signal content is present in both the high and low traffic periods. The SNR determined using the signals with this higher

frequency energy content is correspondingly low. This higher frequency energy in the low traffic signal may likely be due to high frequency vibrations due to the other ambient vibration sources cited above. The higher frequency energy content should, in such a case, not be considered when determining the SNR. It is proposed that the SNR be calculated for measured signals filtered at a cutoff frequency where a distinction between the high and low traffic periods can be distinguished in the frequency domain.

The previously mentioned Sikorsky Bridge system is considered again for this example. The plots in Figure 5 show the acceleration recorded by Accelerometer 1 of Span 1 at periods of both high and low traffic excitation. The plot on the left shows the acceleration measurements including the high frequency content. The corresponding SNR is calculated to be 1.6. The high and low traffic periods are both observed to contain similar levels of energy above 30 Hz for this particular bridge span. The plot on the right is for the time histories filtered in post processing to remove energy content above 30 Hz. The SNR is calculated from this signal to be 36.3. This example illustrates the importance of understanding the frequency content of the measured signals when quantifying noise and in subsequent structural health monitoring calculations.

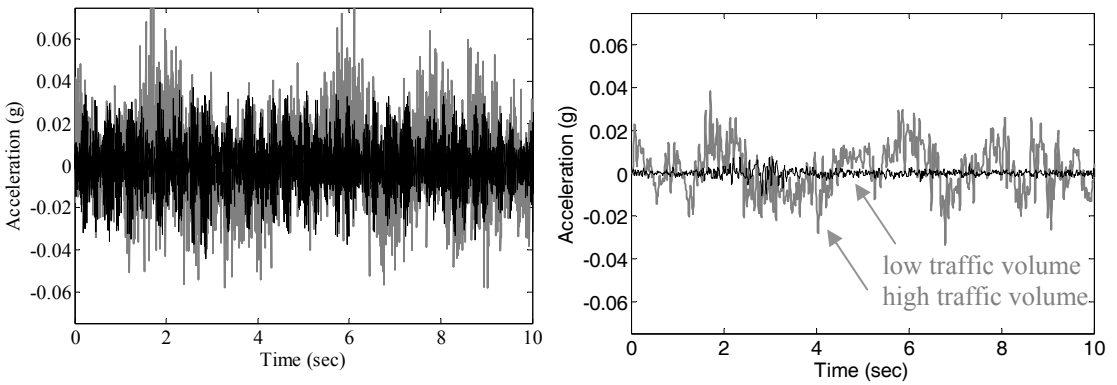

Figure 5. Inherent Noise Levels in Sikorsky Bridge System Accelerometer 1 Span 1 – Left with high frequency content; Right with high frequency content removed (High Traffic Volume – gray; Low Traffic Volume – black)

CONCLUSION

The previously described data anomalies along with considerations for aliasing, quantization and noise should be considered to derive a set of specifications for the installation and implementation of structural health monitoring on bridge structures and in particular specifications for the measured data from these systems.

Specification 1 – Data Anomalies. In dealing with data anomalies, the presence of any and all data anomalies experienced with the system should be checked periodically and documented accordingly. If a data anomaly is experienced, the proper action should be taken to fix the problem. To avoid signal clipping, expected measurements for strain, acceleration and any other parameter should be

approximated before the installation of a permanent system. This can be done through thorough structural analysis or the installation of temporary sensors once the bridge is constructed. Once the maximum expected values are determined, sensors should be carefully selected that are able to capture the dynamic behavior of the structure. If a temporary signal dropout occurs the most likely issue is a poor cable connection. The connections between all elements in the structural health monitoring system should be carefully inspected periodically and particularly if a signal dropout is experienced. To avoid intermittent noise spikes all cables in the system should be adequately fixed/tied down to avoid relative motion. If intermittent noise spikes are experienced, the cables should be checked to insure adequate support. Spurious trends in strain gages can be eliminated by specifying temperature compensating strain gages. Spurious trends due to temperature variations in other types of sensors can be effectively managed in the post processing of the data. When a large spike is encountered in the frequency domain for a sensor at 60 Hz, there may be an issue with the grounding of the system. All wiring during the installation of the health monitoring system should be performed carefully and grounded properly. The structural monitoring system design documents should be reviewed, signed, and sealed by a professional Electrical Engineer to avoid electrical issues with the system.

Specification 2 – Aliasing and Filtering. As previously mentioned, aliasing of data can deem a set of random measurements useless. It is therefore essential that anti-aliasing filters be implemented on all dynamic sensors. These filters should be carefully selected so that the data collected is not distorted in regions of research interest.

Specification 3 – Quantization. Quantization error in a health monitoring system can be eliminated through the use of an analog to digital converter with a high total number of bits. Current technology allows the use of analog to digital converters with 24 bits.

Specification 4 – Noise. By minimizing the volume of noise in a structural health monitoring system, the best quality data can be obtained and analyzed. A number of different approaches should be taken to minimize the noise in an installed bridge health monitoring system. First, the expected peak measurement values should be determined as previously mentioned for eliminating signal clipping. Sensors should then be selected that have a measurement range only slightly larger than these peak values. Also, cable lengths should be kept to a minimum to minimize the chances of external noise getting into the system. Noise can also be minimized by ensuring that the signal sent to the data acquisition unit is amplified to a similar magnitude as the analog voltage input. Many new data acquisition units are able to consider a small voltage range, minimizing noise from the data acquisition system. The frequency content of the measured signal should be used to identify and help classify what constitutes noise and the signal in the measured signals.

These specifications are intended to provide a guide to the design of structural health monitoring systems for the use on highways bridges. The specifications should be updated and adapted to take advantage of advancements in technology and current practices.

ABSTRACT

The recently designed highway for by-passing the city of Talavera de la Reina in Spain is currently under construction. The main structural element in the project is a cable-stayed bridge which for sure will become a landmark in the region. The bridge has a main span of 318 m, comprising a concrete box deck 36 m width and a single inclined pylon 164 m high.
The singularity of the bridge has recommended a comprehensive analysis regarding wind effects on the structure. The aerodynamic coefficients of the deck have been obtained from wind tunnel tests and they have also been computed using CFD software considering two different turbulence models. Also the flutter functions have been evaluated by means of sectional model tests and the flutter velocity has been obtained. It has been found that the bridge enjoys a safe design for wind actions.

INTRODUCTION

Long span bridges are wind prone structures which can suffer from a number of different phenomena such as: flutter, vortex-shedding, buffeting and so on. In cable-stayed bridges wind effects must be considered along the design process as they can suffer adverse effects. Some examples of cable-supported bridges which have suffered adverse wind effects are the Kessock Bridge in the United Kingdom which showed important deck oscillations due to vortex-shedding (Owen et al., 1996) or the Vasco de Gama Bridge in Portugal (Mendes and Branco; 1998) whose design had to be carefully checked as at the early design stage. Also the Great Belt Bridge showed

vortex-shedding excitation which entailed the application of mitigation measures before its inauguration.
Engineers have nowadays a set of tools to tackle with wind effects in bridges: code stipulations, sectional model wind tunnel test, boundary layer wind tunnel tests of complete bridge aeroelastic models and numerical simulations using CFD software. These approaches do not exclude each other, nevertheless they are complementary and the combined application of all of them allows a better comprehension of the bridge performance. In this work, the application of some of the mentioned tools in the design of a cable-stayed bridge in Spain is commented and the main results are presented.

BRIDGE DESCRIPTION

Talavera de la Reina is a middle size city located in central Spain in the route connecting Madrid (Spain) and Lisbon (Portugal). Actually a new highway for by-passing the city at its Southern limit is being constructed and its main structural element is cable-stayed bridge. In figure 1 two images of the bridge location are provided.

Figure 1. Bridge location

In the figure 2 several images of the structure are showed. The bridge has only one span of 318 m. At one side there is a pylon which has 164 m of height and a studied geometry from the aesthetics point of view. From the pylon two planes of cables connect both sides of the deck and at its back zone there are another two planes of cables which balance the pylon by transmitting the forces to the foundation. The ruled surfaces shape of these set of cable results very attractive. As it is shown at figure 2, the deck is a multi-cell box girder of concrete with two lateral cantilevers. Its width is 36 m and its depth is 2.77 m. The upper slab of the deck resists the traffic of vehicles and the lateral cantilevers are for the pedestrians. The bridge enjoys a formal design that can be appreciated in several images of a virtual model that are presented in figure 3.

AERODYNAMIC COEFFICIENTS

Aerodynamic coefficients are important information required to carry out aeroelastic analysis aimed to identify the safety level of cable supported bridges against wind induced phenomena. They allow the calculation of the static action caused by the wind. They are also present in the expression of buffeting forces, therefore studies of bridge behaviour under turbulent flow need to obtain previously that set of coefficients. And they also give qualitative information about the expected flutter performance of a deck cross-section as to avoid one degree of freedom instability the first derivative of lift and moment coefficients must be positive according to the criteria of figure 6; additionally, the greater the value of those derivatives is the lower the flutter critical wind speed of the structure is (Larose and Livesey, 1997; Diana et al., 2007). The aerodynamic coefficients are obtained by carrying out a test of a fixed deck sectional model measuring in the wind tunnel the drag force D, the lift L and the moment M (see figure 6 for positive sign convention) that exerts air flow over the model. The dimensionless values of these actions use the dynamic pressure of wind and the deck width B to determine the following coefficients:

$$C_D = D/(\tfrac{1}{2}\rho U^2 B)$$
$$C_L = L/(\tfrac{1}{2}\rho U^2 B)$$
$$C_M = M/(\tfrac{1}{2}\rho U^2 B^2)$$

Experimental evaluation. The wind tunnel of the School of Civil Engineering of the University of La Coruña used for the experiments appears on figure 5 The test section of the tunnel has one square meter, which is enough for testing the sectional model of the Talavera Bridge at a geometric scale 1/100. A picture of the model is shown also in figure 5 and it has the same geometry as the real prototype considering barriers and any element which can affect to the aerodynamic responses.

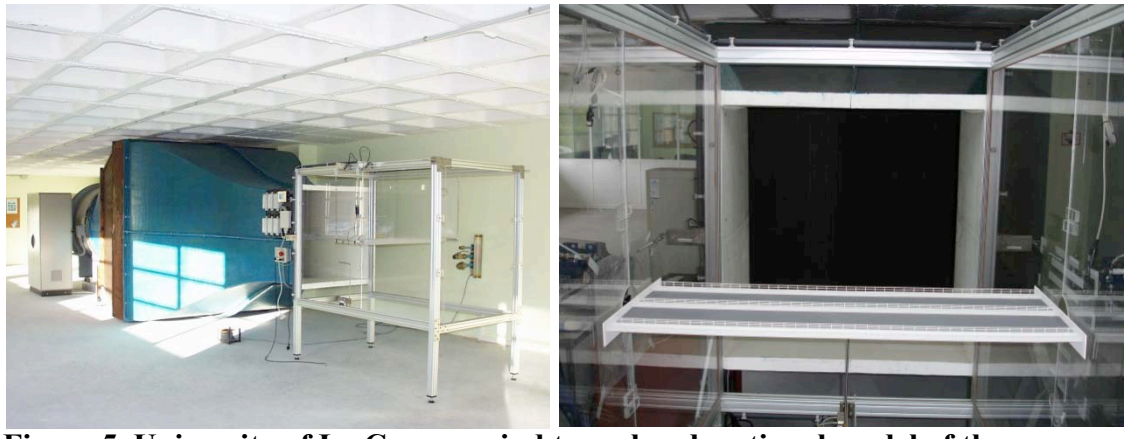

Figure 5. University of La Coruna wind tunnel and sectional model of the Talavera Bridge.

In figure 6 the aerodynamic coefficients obtained experimentally for the Talavera Bridge cross-section are presented along with the sing convention employed in this work. It can be seen that both lift and moment coefficients present low positive slopes in the range of analyzed angles of attack (-8º, +8º), which is an indication of a good flutter performance.

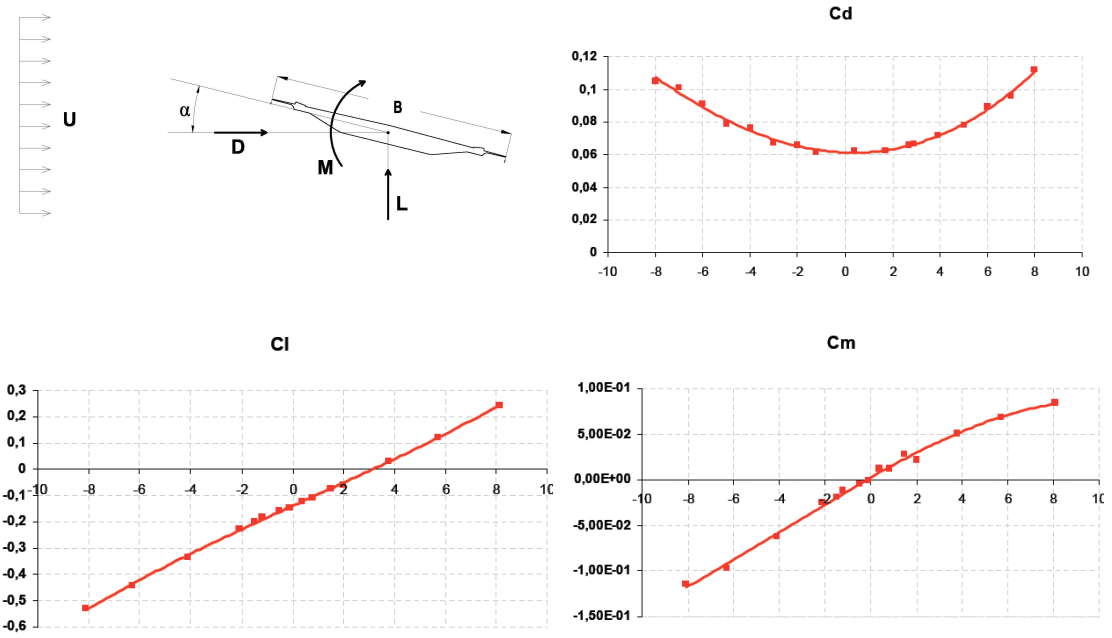

Figure 6. Sign criteria and experimental aerodynamic coefficients.

Numerical evaluation. In recent years the number of applications of CFD (Computational Fluid Dynamics) in bridge engineering has grown as numerical methods are capable of providing time-effective information in the preliminary aerodynamic design of bridge decks (Cochran and Derickson, 2010; Nieto et al., 2010). Two CFD simulations have been carried out by the authors with the aim of evaluating the general performance of numerical methods in the evaluation of aerodynamic coefficients in bridge decks. In first place, the aerodynamic coefficients were computed for a 2D model of the geometry of the cross section without barriers (bare deck section) considering steady state and k-ε turbulence model with enhanced wall treatment. A second CFD model was considered, including the barriers in the 2D model and adopting k-ω SST turbulence model. Some authors have suggested that amongst the RANS (Reynolds Averaged Navier-Stokes) turbulence models k-ω offers more accurate results in bridges than k-ε as the later over-produces the turbulence kinetic energy near the walls and it may change the flow patterns (Sun et al, 2005). In figure 7 the results computed for both models are presented along with the experimental results for validation. It can be seen that both turbulence models offer a good approximation to the experimental values from a qualitative point of view. More in detail, k-ω provides a more accurate simulation especially for the moment coefficient. On the other hand, the drag coefficient evaluated considering the k-ε model is very close to the wind tunnel result.

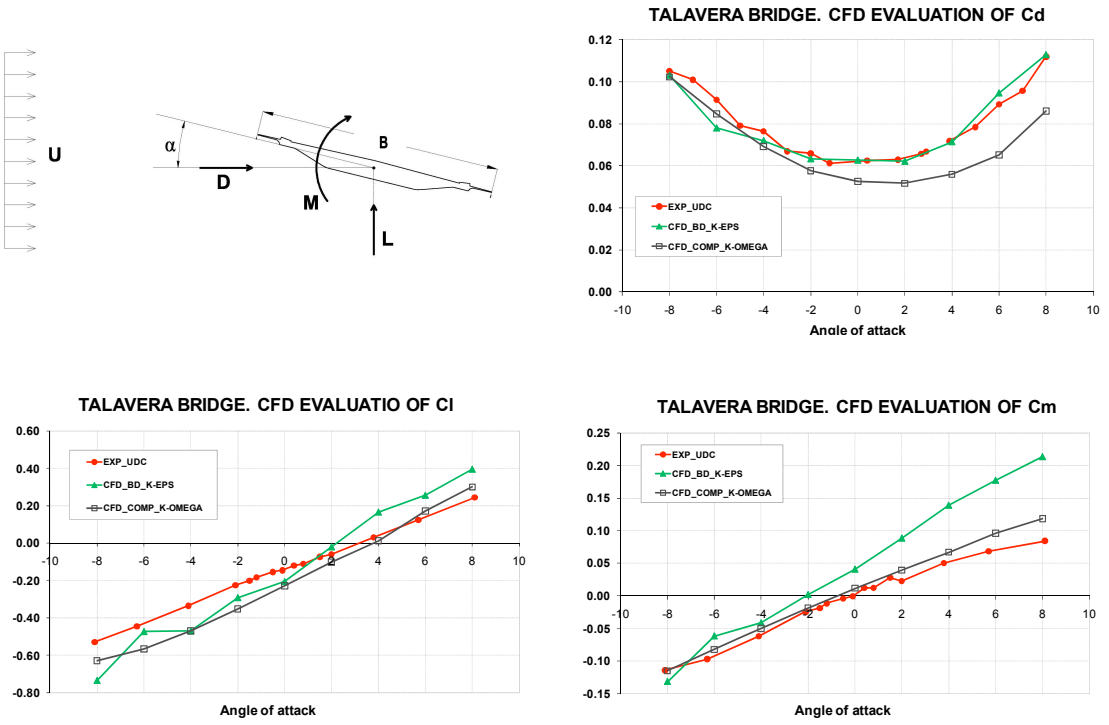

Figure 7. Comparison between experimental and CFD aerodynamic coefficients.

FLUTTER RESPONSE

The set of eighteen flutter derivatives is important information required to carry out aeroelastic analysis of bridges aimed to identify the safety level against wind induced instability. Flutter derivatives are the components of the aeroelastic damping and stiffness matrices that relate the lift, drag and moment forces to the vector of displacements and velocities of bridge deck, as it can be seen in the next equation. The standard way to evaluate flutter derivatives is using wind tunnel tests, although currently CFD evaluation of flutter derivatives is a field of research (Ge and Xiang, 2008).

$$\mathbf{f}_a = \begin{Bmatrix} D_a \\ L_a \\ M_a \end{Bmatrix} = \frac{1}{2}\rho U^2 KB \cdot \begin{pmatrix} P_1^* & -P_5^* & -BP_2^* \\ -H_5^* & H_1^* & BH_2^* \\ -BA_5^* & BA_1^* & B^2A_2^* \end{pmatrix} \begin{Bmatrix} \dot{v} \\ \dot{w} \\ \dot{\varphi}_x \end{Bmatrix} + \frac{1}{2}\rho U^2 K^2 \cdot \begin{pmatrix} P_4^* & -P_6^* & -BP_3^* \\ -H_6^* & H_4^* & BH_3^* \\ -BA_6^* & BA_4^* & B^2A_3^* \end{pmatrix} \begin{Bmatrix} v \\ w \\ \varphi_x \end{Bmatrix}$$

$$\mathbf{f}_a = \mathbf{C}_a \dot{\mathbf{u}} + \mathbf{K}_a \mathbf{u}$$

where B is the deck width, ρ is the air density, U is the mean wind speed, $K = B\omega/U$ is the reduced frequency with ω the frequency of the response, and $P^*_i(K)$, $H^*_i(K)$, $A^*_i(K)$ $i = 1...6$ are the flutter derivatives which are functions of K. $\mathbf{K}_a$ and $\mathbf{C}_a$ are aeroelastic stiffness and damping matrices.

In this work the free vibration approach with the sectional model of the deck supported by eight vertical and four horizontal springs was used. The complete set of eighteen coefficients A^*_i, P^*_i, H^*_i (i = 1,…6) was identified. The stiffness of the springs determines the vibration frequencies of the system that together with the wind velocity in the tunnel, U and the model width, B, determines the range of reduced velocities, U^*, in order to be able to obtain flutter functions. Two spring sets were used in order to vary the natural frequencies of the model and include a wider range of reduced velocities. In tables 1 and 2 the main data of the sectional model and the range of reduced velocities considered in this work are summarized. Also figure 8 shows the obtained flutter functions for Talavera de la Reina Bridge.

Table 1: Properties and natural frequencies of the sectional model of Talavera Bridge.

	SECTIONAL MODEL MASS			3.2 kg		
	SECTIONAL MODEL INERTIA			5.1 kgm^2

TEST 2	5<U*<16	4<U*<10	1<U*<4

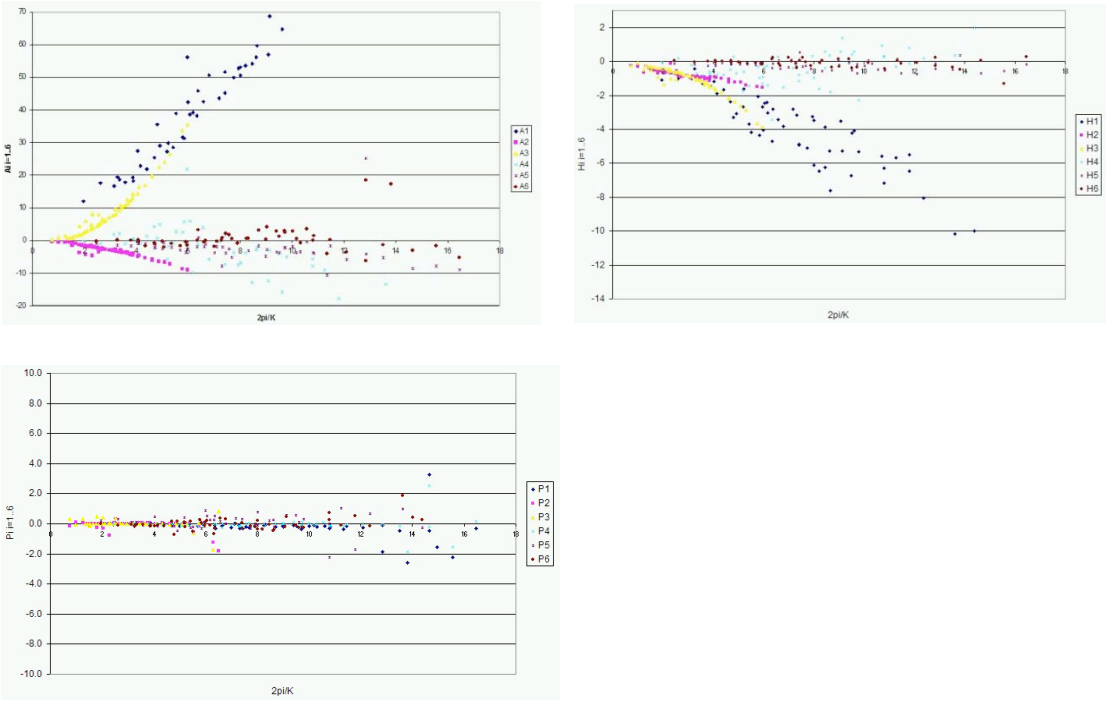

Figure 8. Flutter derivatives of the Talavera de la Reina Bridge.

Once flutter derivatives are obtained, flutter speed of the complete bridge can be calculated by solving of a non linear eigen-problem which comes from the dynamic equilibrium equation for the deck.

The imaginary part β of the eigenvalues μ counts on the frequency ω, while the real part α of the eigenvalues is associated with the damping ratio ζ. The condition of flutter corresponds to the lowest wind speed U_f which gives one eigenvalue with vanished real part. Figure 9 shows graphs with the evolution of the eigenvalues of the problem for increasing wind velocities. It is observed that the critical flutter velocity for the Talavera Bridge is 77 m/s.

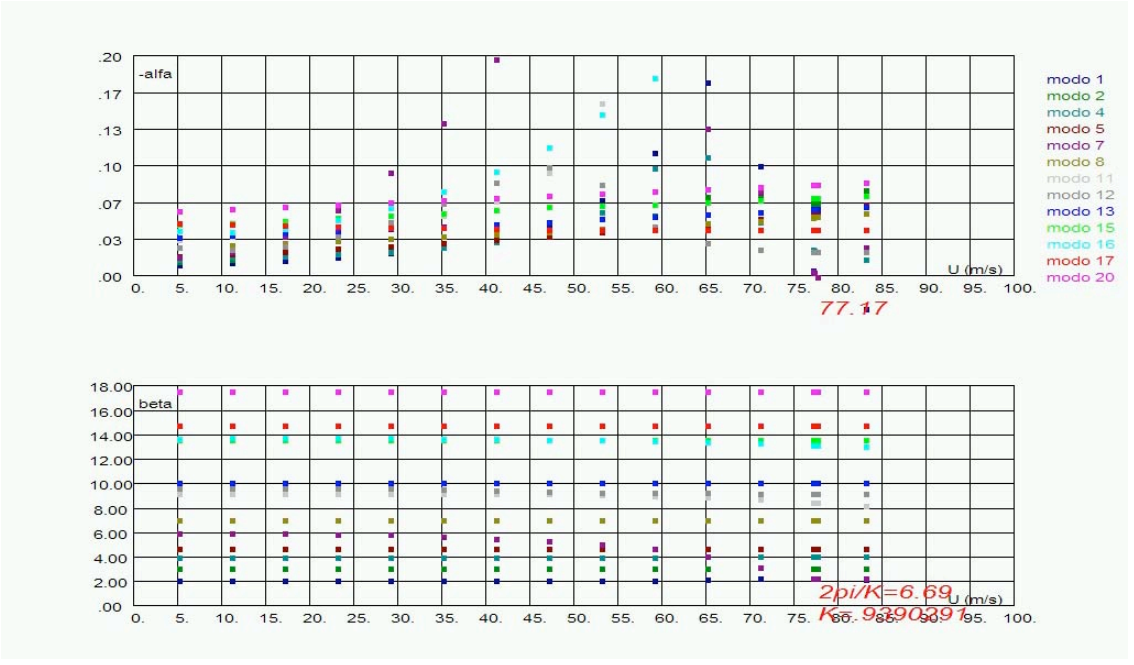

Figure 9. Evolution of eigenvalues with respect to wind velocity *U* until flutter condition with a null damping.

CONCLUSIONS

The main characteristics of the Talavera de la Reina cable-stayed Bridge have been described and virtual images of the bridge have been presented.

The aerodynamic coefficients of the deck have been obtained by means of sectional model wind tunnel tests in the range of angles of attack (-8º, +8º). CFD has been also employed to compute the aerodynamic coefficients considering a 2D model, steady state and two different RANS turbulence models. In both cases the numerical results are close to the experimental ones.

The flutter derivatives have been obtained using the free vibration approach. The flutter velocity obtained has been 77 m/s (277 km/h) which is well above 500 years return period wind speed at the deck level (41.5 m/s or 149 km/h).

In general, the Talavera de la Reina Bridge enjoys a safe design for wind actions.

Abstract

Catastrophic failure of steel bridge components can occur if the fatigue cracks reach critical levels. The purpose of the study described is to characterize the acoustic emission (AE) corresponding to crack extension from the stable to the unstable stage in steel bridge material. AE monitored fatigue tests were conducted using specialized compact tension (CT) specimens made of ASTM A572G50. A combined approach involving Swansong II filters and investigation of waveforms is employed in the discrimination of AE signals caused by cracks or noise. This approach is appropriate for data filtering and interpretation of sparse data as may be expected from field tests where wireless monitoring is essential. The results indicate that AE parameters from reduced datasets can provide warning for critical fatigue cracks under different test conditions. The transition of fracture mechanisms is reflected in the reduced AE dataset.

Keywords: Acoustic emission (AE); fatigue cracks; stress intensity; bridge health monitoring

1. Introduction

As described in the ASCE 2009 Report Card (ASCE, 2009), a large number of bridges are structurally deficient and functionally obsolete. Traffic flow and environmental factors induce cyclic loads and may initiate fatigue cracks in steel components, as shown in Figure 1. In the case of fracture critical regions, the cracks may result in the failure of the entire bridge if they come into the stage of unstable propagation. AE techniques have shown promise for nondestructive evaluation of fatigue damage in steel materials (Sinclair and Connors 1977, Ohira et al. 1980, Gong et al. 1992, Bassim et al. 1994, Chen and Choi 2004, Oh et al. 2004) and civil infrastructure in general (Ziehl 2008, Yu et al. 2010).

Crack growth behavior is determined by the type of material and the set of loading conditions. Stephens (2000) demonstrated that for positive load ratios increasing of the mean load level can accelerate crack growth. Vasudevan and Sadananda (2001) presented that the crack growth curves have a tendency to merge at the upper end of load ratios where the stress intensity range approaches the threshold. Based on these two former studies, crack growth behavior under different load ratios are

demonstrated in Figure 2. For a given material the set of loading conditions decides the crack growth behavior. Substantial differences in crack growth behavior occur for different load ratios. With a specific load ration, R, the crack growth rate curve (crack growth rate versus stress intensity range) is unique. Each crack growth rate curve has three stages: threshold region, stable propagation and unstable propagation. Stage III may result in catastrophic failure. The critical crack is the transition point between stage II and stage III. The transition points on the crack growth rate curves are shifted to lower stress intensity range as the load ratio increases. The correlation between AE characteristics and critical fatigue cracks should be obtained for steel bridge material prior to the widespread application of AE for structural health monitoring and prognosis.

Previous efforts have focused on the prediction of fatigue life through the AE characteristics corresponding to the crack propagation behavior within the stable stage (Hamel et al. 1981, Daniel et al. 1997, Roberts and Talebzadeh 2003). It would be difficult and time consuming to test under every loading condition to determine specific relationship between AE and crack growth behavior. Additionally, the AE signals corresponding to the transition of crack propagation stages may not be collected if the study focuses only on the stable stage. Lindley et al. (1978) presented an improved correlation model that covers both stage II and stage III. This model involved fracture toughness, K_c, which depends on the thickness of the material subjected to cyclic loads (Dowling 2007). For the actual bridge components with different dimensions, and subject to variable-amplitude loads, the models presented in former studies require substantial tests for data correlation.

The possibility exists that AE may characterize critical crack growth because a common nature exists in each transition of crack propagation from stage II to stage III. For each crack growth rate curve as shown in Figure 2, two driving forces, stress intensity range and maximum stress intensity, govern the crack growth behavior (Vasudevan and Sadananda 2001, Yu and Kujawski 2010). The cyclic driving force, stress intensity range, dominates stages I and II under plane strain conditions. The stress intensity and size of the plastic zone ahead of the crack tip increase as the crack advances. After the fracture toughness has been reached, the static driving force (maximum stress intensity) controls stage III under plane stress conditions. It has been reported that AE parameters have demonstrated major jumps when the stress intensity reached a certain value (Chen and Choi 2004).

Emission identification is a necessary step to obtain accurate AE evaluation of fatigue damage. In addition to active crack growth, AE sensors are also sensitive to the noises from grating between fracture surfaces, friction between target structure and fixtures, and the environment. The grating emission can be minimized by collecting and analyzing signals in the vicinity of the peak load (Sinclair and Connors 1977, Lindley et al. 1978). The spatial filtering techniques based on source location, guard sensors and time of arrival (Berkovits and Fang 1995, Daniel et al. 1997, Lopez Pumarega et al. 2003) can be employed to separate extraneous noise from crack bursts in laboratory testing, based on the prediction that the crack initiates ahead of the notch tip and grows along the notch plane. Waveform-based techniques also have been proposed to distinguish the AE signals (Martin 1995, Hamstad and McColskey

1997, Choi et al. 2000, Pullin et al. 2005). Because typical parameters such as rise time, duration, amplitude, and counts in a burst-type waveform are employed to identify the signals, the waveform-based techniques are suitable for both laboratory studies and field tests where sparse data sets are required.

In this paper, the AE characteristics associated with the crack growth behavior of the material used for in-service bridges were collected through conventional fatigue crack testing. AE parameters that fit for indicating crack extension from stage II to stage III were determined based on test results and association of AE signal characteristics with crack growth behavior. The critical damage level of fatigue cracks and corresponding critical level of AE signals were characterized for the successful application of structural damage evaluation. The application of passive piezoelectric based sensing is described for cyclically loaded compact tension (CT) specimens. The specimens are representative of steel bridge construction and were specially designed and fabricated for this purpose. The plan dimensions of the CT specimens were considerably increased from those traditionally used. This was done to minimize reflections that could lead to difficulties with interpretation of the AE signals. Tests for collecting AE from grating and extraneous noise were also performed. Signals were filtered through a combined approach involving Swansong II Filters and visual investigation of waveforms. The cleaned dataset was interpreted using linear elastic fracture mechanics (LEFM).

2. Experimental procedures

CT specimens, made of structural steel ASTM A572 Grade 50, were used in AE-monitored conventional fatigue tests. The geometry of the specimens is displayed in Figure 3. The thickness of the specimens was selected to be representative of bridge construction. Custom fixtures were designed and fabricated to mount the CT specimens. The cyclic tension loads were applied to the specimen using a servo-hydraulic mechanical testing machine and the surface cracks were monitored optically with a high resolution recording microscope. A clip gage was employed to measure the crack mouth opening displacement (CMOD) to clarify crack opening and closure and to determine the crack length. The measurement locations of the clip gage are at the edge of the specimen as shown in Figure 3.

Instruments manufactured by Mistras Group were employed to detect, collect and process AE signals. Standard resonant sensors of type R15I-AST with integral 40 dB preamplification were utilized to detect and collect the signals associated with crack growth behavior. The layout of the five sensors is shown in Figure 3. Sensors were attached to the specimen with vacuum grease and held in place with plastic clamps. AE data was processed and displayed through a 16-channel Sensor Highway II-Remote Asset Integrity Monitor system. The axial displacement, axial loads and CMOD were introduced into the signal processor along with AE signals.

Pencil lead break (PLB) tests were performed before each fatigue test to check the status of each sensor and the location capability of the sensor arrangement. In addition, waveforms and their characteristics obtained in the PLB tests were used as a frame of reference from genuine hits for data filtering.

3. Data filtering procedures

In the application of passive piezoelectric sensing techniques, genuine hits from cracking and "false" hits from noise can both be recorded. One type of "false" hit is induced by the grating between fracture surfaces, another is from extraneous noise. The extraneous noise mainly comes from the hydraulics, machine start and stop, slippage and abrasion of the load train according to the test setup. To minimize grating emission signals the data collected below 80% of the peak load was removed from the dataset. This approach to filtering the grating emission is of interest to the field evaluation of bridges where it is important that sparse data be used for interpretation. To reduce the "false" hits induced by the test setup in loading and unloading procedures, pins in the specimen fixtures were wrapped with cloth and gaps between the specimen and fixture were filled with plastic shims. While this greatly reduced the extraneous noise, the noise could not be completely eliminated through these simple methods.

Verification tests were performed to determine the intensities of the friction emission using a specimen with crack length of 40 mm. In these tests the maximum load in the cycles was decreased to a lower level. The lower peak load was selected to be insufficient to produce crack growth. All of the AE events at this lower peak load were therefore assumed to be due to friction emission. Emission having the characteristics of friction emission was then filtered from the dataset used for later evaluation. To obtain a high threshold of friction emission and a conservative evaluation of the crack growth detection, the maximum emission in each signal bin was scanned. This amplitude threshold (60 dB) was determined to minimize friction emission from the dataset.

The waveforms and their characteristics obtained from friction emission tests and PLB tests were employed as a reference to identify the "false hits" for data filtering.. The technique of the Swansong II filter was employed to further filter the friction signals based on the relationship between amplitude and duration of AE events. For the specific Swansong II filter in this study, "false" hits are defined by their peak amplitude and duration. Typical parameters in AE waveforms include peak amplitude, rise time, duration, and emission counts. The waveforms from fatigue cracks, friction emission and PLB tests are also demonstrated in Figure 4. The waveforms caused by friction generally have long duration and poorly defined peak amplitudes. In fatigue cracks and PLB tests, the shorter duration and higher peak amplitude are indicative of genuine AE, as is the clean front-end of the waveform.

4. Results and discussion

The characteristics of the AE associated with the parameters of fracture mechanics are useful for damage evaluation of in-service structures. The collection and interpretation of signal characteristics are essential to achieve a successful application of the AE technique to the structure of interest. Based on the filtered datasets, AE parameters were associated with corresponding parameters in crack growth behavior to obtain their critical values which indicate crack development from the stage of stable propagation to the stage of unstable propagation.

The maximum stress intensity and cumulative hits versus load cycles in the test for CT1 are displayed in Figure 5. It can be observed that the cumulative hits increased dramatically after the maximum stress intensity, K_{max}, passes through the value of 81.4 MPa$\sqrt{\text{m}}$. As load ratio, R, is 0.02, the stress intensity range, $\Delta K = (1 - R)K_{max}$, is equal to 79.8 MPa$\sqrt{\text{m}}$.

The rapid increases ('jumps') as shown in Figure 5, which also exist in the CT2 test results, are not attributable to friction signals but mainly from the transition of fracture mechanisms (Daniel et al. 1997). As shown in the photo embedded in Figure 5, the smooth fracture surface indicates that plane strain dominates the crack growth, while the rough surface indicates that plane stress dominates crack growth. This phenomenon exists in many steels. In this transition zone the variation of the cyclic plastic zone and strain intensification were reflected in the AE dataset.

The crack length and cumulative counts versus load cycles from the CT2 test results are shown in Figure 6. The cumulative counts increased exponentially similar to that of the crack length as the number of load cycles increased. The increment of cumulative counts became visibly larger after the crack length was beyond 20.8 mm.

It has been shown in this study that for typical steel bridge materials AE characteristics corresponding to crack growth behavior were caused by different cyclic loading conditions. In addition, AE cumulative hits and cumulative counts work well for the determination of critical fatigue crack growth. Additional parameters such as signal strength and hit rate will also be investigated to increase the robustness of the correlations.

5. Conclusions

Passive piezoelectric sensing techniques were utilized to monitor fatigue crack growth in CT specimens that were specially designed and fabricated to be representative of steel bridge construction. Reference tests such as friction emission and pencil lead breakage were performed to obtain reference waveforms from friction and simulated cracks. A Swansong II filter combined with a waveform-based approach was used to minimize "false" signals in the AE dataset. The correlation between AE characteristics and crack growth behavior was built through the association of AE parameters with corresponding parameters in fracture mechanics. Based on this study, the following conclusions can be drawn:

1. AE characteristics associated with crack growth behavior can effectively determine the critical level of fatigue crack growth under different cyclic loading conditions. AE cumulative hits and cumulative counts can provide warning signs at the critical point where fatigue cracks come into the stage of unstable propagation. The critical values of the AE parameters depend on the loading conditions.

2. AE can characterize and reflect crack growth behavior such as the transition between fracture mechanisms in steels that are representative of bridge construction.

3. Friction emission testing can provide reference waveforms to aid in the differentiation of noise from cracking, but did not provide all-inclusive reference

parameters for data filtering. This is because the loads are decreased to keep the crack length constant during the friction emission testing.

4. The combination of a Swansong II filter with a waveform-based approach was found to be appropriate for data processing and interpretation. This combined method holds promise not only in the laboratory studies but also in field testing. It is important to define the waveforms associated with background noise and crack growth if this method is to be used.

6. Acknowledgements

This work is performed under the support of the U.S. Department of Commerce, National Institute of Standards and Technology, Technology Innovation Program, Cooperative Agreement Number 70NANB9H9007. The authors wish to acknowledge those involved at Mistras Group, especially Valery Godinez; and joint venture partners University of Miami (Antonio Nanni) and Virginia Tech (Dan Inman).

We also thank DRPA, Virginia DOT, South Carolina DOT and Florida DOT for providing access to bridges and related information for this project.

ABSTRACT

Experiments and computer simulations were carried out at the University of Kansas to investigate the use of composite materials for strengthening and repair of fatigue-vulnerable steel bridges. Prefabricated CFRP overlays were attached to welded coverplate specimens using a layer of epoxy resin. The specimens were then subjected to three-point bending under cyclic loading at a constant stress range. Early tests showed that bonding CFRP overlays to steel was an effective method to reduce the stress demand in areas susceptible to fatigue damage, and that this strengthening method could lead to substantial increases in crack initiation life. Fatigue tests also showed that maintaining the bond between the CFRP overlays and the steel was the most critical factor in the effectiveness of this strengthening technique. It was observed that the presence of a layer of breather fabric embedded within the layer of epoxy resin was the most important parameter affecting bond behavior under fatigue loading.

This paper describes monotonic and fatigue tests carried out to evaluate the effect of the presence of breather fabric and thickness of the resin layer on bond strength and on the performance of the resin layer under fatigue loading. It was found that the mode of failure of the resin under monotonic and fatigue loading changed significantly due to the presence of the breather cloth. Although the presence of breather cloth had a negligible effect on the bond strength of thin resin layers, its effect on strength increased with the thickness of the resin layer. It was also found that the presence of the breather fabric had a very significant effect on the post-peak behavior of monotonic tests, which partially explains its beneficial effect on behavior under fatigue loading.

BACKGROUND

Techniques to repair connections vulnerable to fatigue damage in steel bridges must be developed considering the specific geometry and other relevant characteristics of the particular connection detail. This is particularly the case for fatigue repairs using composite material overlays, in which the geometry and location of the overlays should be optimized for the shape of the connection detail. Nonetheless, several studies have found that regardless of geometry a critical factor in the implementation of this repair technique is maintaining the bond between the composite material and the steel for the intended fatigue life of the repair. There is a wealth of studies investigating bond between resins and metal.

Two studies closely related to the type of repair discussed in this paper were carried out by Nozaka et al. (2005; 2005a), who investigated the effectiveness of carbon-fiber-reinforced polymer (CFRP) strips for increasing fatigue life of steel girders. Testing described in Nozaka et al. (2005) was

designed to compare how several types of adhesives and laminates would perform in different configurations. Two different CFRP types and a total of five adhesives were evaluated. A testing rig was used which consisted of a W14x68 girder 14.1-ft long with a large hole and a wide slit machined at mid-span to represent a crack in the tension flange and to focus the tensile force in that area. CFRP strips were bonded onto individual steel plates which were then bolted to the tension flange of the girder. Specimens were then loaded monotonically in four-point bending under displacement control. Nozaka et al. found that the specimens did not fail due to tensile failure of the CFRP, but rather due to a mixture of tensile failure and debonding.

In a continuation study, Nozaka et al. (2005 a) evaluated several options to properly test the bond strength of CFRP strips. Two commonly used tests use single-lap and double-lap specimens. These have been extensively used to test the shear strengths of adhesives to metals. One of the concerns expressed by Nozaka et al. was that a single-lap test would cause the joint to rotate. This is due to the misalignment of neutral axis between the separate parts, and it results in a peeling stress along with a shear stress acting on the interface between the resin and the steel girder. Therefore a single-lap specimen would not result in a failure due to solely shear stress, but rather a combination of shear and peeling stress. To evaluate the various bond tests Nozaka et al. (2005) started by investigating the stresses on a fatigue-damaged girder repaired with composite materials. The model consisted of two CFRP strips bonded to the inner surface of the tension flange of the girder. One CFRP strip was located on each side of the web.

The specimen was modeled using ABAQUS (2007) with the CFRP modeled as an elastic material, and the steel and adhesive modeled as elastic-perfectly-plastic materials. By modeling the specimen in this fashion it was possible to calculate the shear, peeling, and normal stresses. By comparing the shear stresses near the CFRP, with and without the CFRP strip, it was possible to determine that the stress was reduced when the CFRP strip was applied. These effects contributed to the transfer of forces from the girder flange to the CFRP. It was also shown that shear and peeling stresses increased on both edges of the strip due to an edge effect, which can cause debonding.

Nozaka et al. explored alternate specimen types to properly test the bond of the CFRP. In an attempt to minimize peeling stress during testing, three separate test specimens were considered. The chosen specimen consisted of a 0.5 in. thick plate of 12 in. length. The thickness of the end of the plate was increased in an attempt to align the neutral axis of each section. Restraints were then applied to the end of the specimen to limit rotation.

The first step of testing was to examine the effect of varying steel thickness. Three different thicknesses were tested including 0.5, 0.7 and 1.0 in. By examining the results it was found that changing the steel thickness had no major effect on the shear stress. With further investigation it was found that the tensile stress in the steel adherent was beyond the yield strength of the steel (Nozaka et al., 2005 a). This occurred before the CFRP strip failed; therefore this type of specimen could not be used for testing. For this reason it was concluded that single-lap specimens were inadequate to measure the true bond strength of CFRP strips bonded to steel (Nozaka et al. 2005 a).

Nozaka et al. (2005) concluded that the test specimen had to be attached to the girder by bonding the CFRP strips to steel plates which were then bolted to the tension flange of the girder. This test arrangement was also used for the testing in their previous study. A large hole and slit was machined at the mid span of the girder to represent a fatigue crack in the tension flange. By doing this the applied compression force would be isolated through the crack, optimizing the effect on the crack. The specimen was then tested under four-point loading with supports 5.0 in. from the edges of the girder.

The studies by Nozaka et al. (2005; 2005 a) highlight the fact that when composite overlays are utilized, depending on the geometry of the overlay, there can be a combination of tensile (peel) and shear stresses transferred along the interface between the steel and the composite overlay, and that the relative magnitude of the two actions is dependent on the geometric configuration of the overlay and the connection being repaired. This aspect is of particular significance when using composite overlays to repair welded connections.

Several studies conducted at the University of Kansas have investigated the concept of using composite materials to strengthen fatigue-vulnerable connections in steel bridge structures. An example

of the type of specimen used at Kansas to evaluate this strengthening technique is shown in Fig. 1. The specimen consists of two plates welded together and subjected to three point bending under fatigue loading. This specimen was chosen because a severe discontinuity exists at the point where the two plates are welded, and the stress concentrations in the discontinuity lead to fatigue failure under cyclic loading.

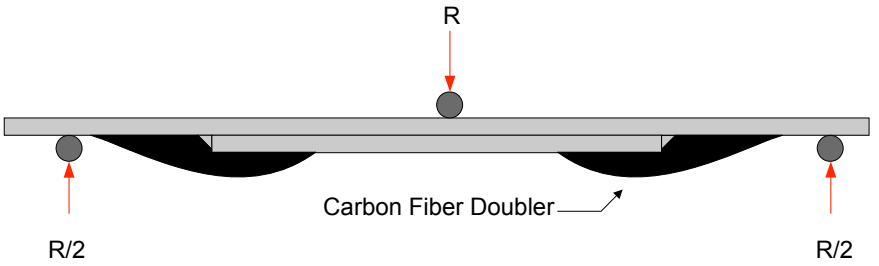

FIGURE 1 Three-Point Bending Fatigue Specimen Strengthened with Composite Overlays

Computer simulations of the specimen shown in Fig. 1 performed for this study using the finite element analysis software ABAQUS showed that attaching overlays made with composite materials to areas of the specimen affected by stress concentrations (areas adjacent to the welds) led to significant reductions in the localized stress demand. This effect is shown in Fig. 2, which shows the maximum stress demand at the weld region of the specimen for configurations with and without a composite overlay. The finite element results indicated that the composite overlays were effective in providing an alternate load path to the force transmitted between the two steel plates, spreading the stress demands over a larger area and consequently reducing the stress gradient.

One of the most significant challenges associated with the implementation of this retrofit technique is developing a fabrication process that results in stiff overlays that are properly bonded to steel elements. Although composite plies can be applied directly in the field, better results are obtained by prefabricating the overlays in shop and subsequently attaching them to a bridge. However, this fabrication sequence brings about challenges, for example, because the composite overlay may not align perfectly with the steel, and because a method of properly bonding the overlay to the steel must be developed. In this study, composite overlays were prefabricated following the procedure described by Kaan (2008) and attached to three-point bending specimens shown in Fig. 1 by means of a layer of epoxy resin between the composite overlay and the steel. Finite element models were developed to investigate the effect of varying the thickness of the layer of epoxy resin on the stress demand at the toe of the weld, and on the shear and tensile stresses at the interface between the resin layer and the steel (Petri 2008).

Stress demands calculated using the finite element model are shown in Fig. 3. In the case of the three-point bending specimen, the thickness of the resin layer had a significant effect on the peel stress between the epoxy resin and the steel. A similar effect was observed for the peel stress between the epoxy resin and the composite overlay. The magnitude of the maximum peel stress was significantly different on each side of the epoxy resin layer and it was found to increase with decreasing thickness of the epoxy resin layer.

Kaan (2008) and Alemdar performed tests to experimentally evaluate the results from the finite element study. Results are illustrated in Fig. 4. The diamond shapes in Fig. 4 represent the initiation life of four control specimens tested at nominal stress ranges of 20 and 28 ksi at the weld toe (Kaan, 2008). Average initiation life of the control specimens tested at a nominal stress range of 20 ksi was 425,000 cycles. The horizontal line with points labeled TRI 06 corresponds to a fatigue test performed by Kaan (2008) and later by Alemdar (round marker) as part of this study. Kaan and Alemdar used a single three-point bending specimen strengthened with composite overlays, cycled at a nominal stress range of 20 ksi. Kaan (2008) performed his test with a layer of epoxy resin 1/16 in. thick. The X-shaped markers correspond to points at which Kaan (2008) observed debonding of the composite overlay. Each time after debonding was observed, the specimen was inspected and the overlay re-attached. Kaan (2008) loaded

the specimen for a total of 2.1 million cycles without any observable fatigue crack. There were a total of 5 debonding events, with an average of 431,500 cycles between debonding events. Loading of the specimen was later continued by Alemdar (shown by the round markers in Fig. 4). He used a ¼ in. thick epoxy resin layer with embedded breather cloth. Alemdar was able to load the specimen for an additional 1.5 million cycles without any debonding events. After loading for 1.5 million additional cycles (for a total of 3.7 million cycles) the overlay was removed and an inspection showed that there were no observable fatigue cracks.

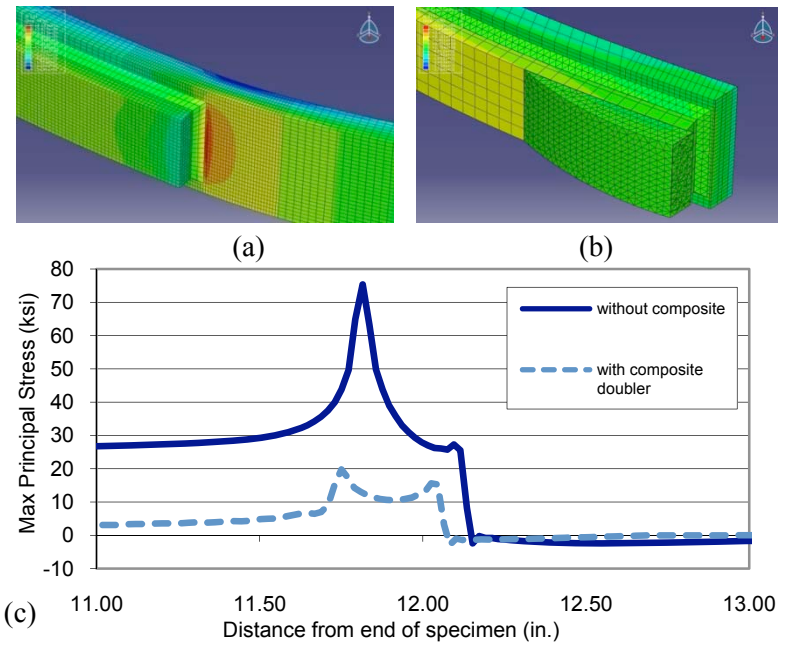

FIGURE 2 Calculated Maximum Principal Tensile Stress for Specimens With and Without Composite Overlays.

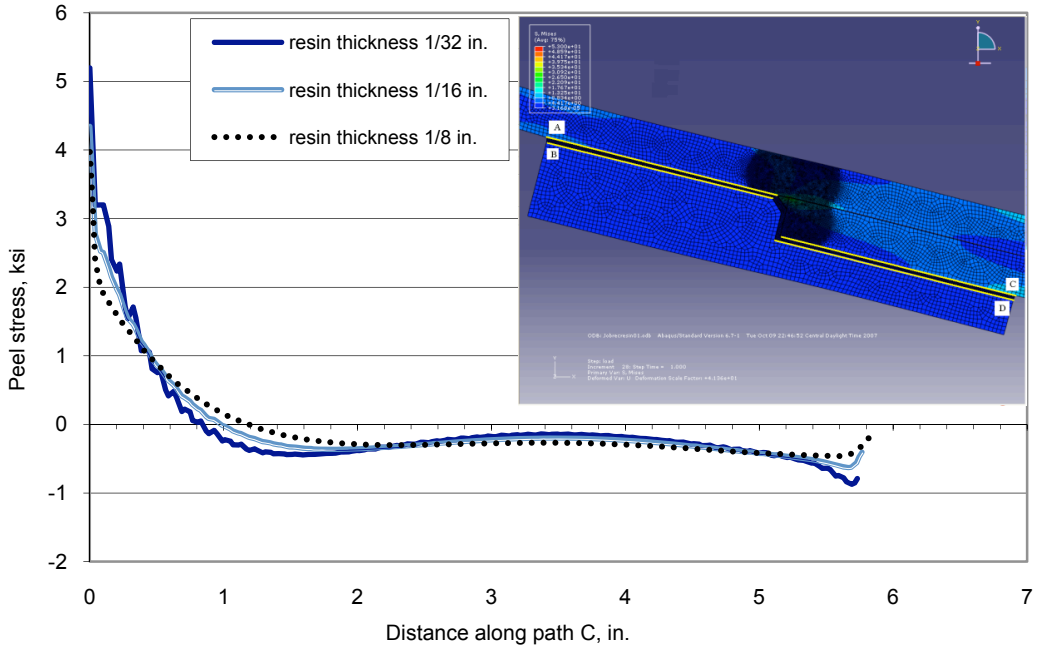

FIGURE 3 Peel stress demand along path C for various thicknesses of epoxy resin layer.

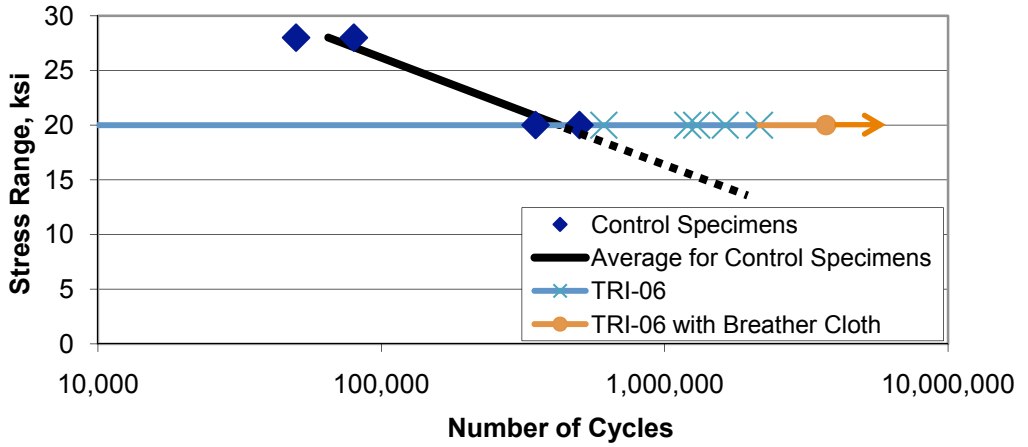

FIGURE 4 Crack Initiation Life for Three-point Bending Specimens Tested by Kaan and Alemdar.

The tests performed by Alemdar and Kaan (2008) showed that the use of composite overlays increased the initiation life of the specimen from 425,000 cycles to infinite fatigue life, confirming the observations from the finite element analyses. The aforementioned tests also showed that the presence of breather cloth increased the fatigue life of the epoxy resin layer from an average of 431,000 cycles to infinite fatigue life. Proper bond is critical to the performance of this strengthening method because if an overlay debonds, the specimen continues to cycle in the unreinforced configuration until a repair is implemented. For this reason, and because the observed fatigue life of specimens with breather cloth was significantly higher than those without breather cloth, a series of experiments was undertaken to study the effects of embedding breather cloth on the bond strength and fatigue life of the epoxy resin layer.

EXPERIMENTAL STUDY

The effects of embedding breather cloth on the strength and fatigue life of the epoxy resin layer were further studied by performing two series of monotonic tests. The monotonic tests were designed to simulate the state of stress in the epoxy resin layer of three-point bending specimens. For the first series of tests a composite overlay similar to those used to strengthen the plate-coverplate specimen was attached through a steel plate using a layer of epoxy. The test apparatus and its dimensions are shown in Fig. 5.

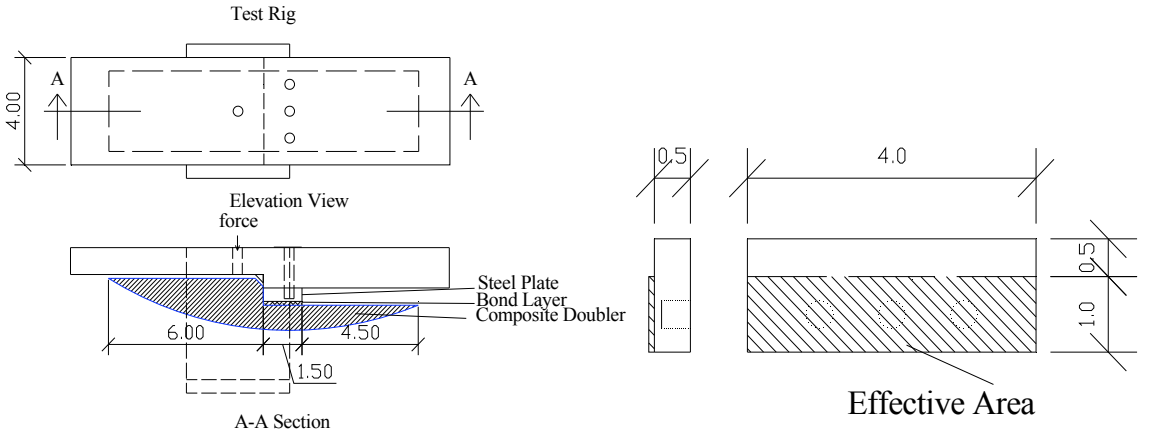

FIGURE 5: Test Apparatus for Peel Tests (all dimensions shown in inches.)

Properties of the materials used in the experiments are presented in Table 1. Monotonic tests were performed according to the following protocol. The composite overlay was bonded to the steel plate with a layer of epoxy of a pre-determined thickness. The steel plate was subsequently bolted to the reaction apparatus, which was attached to the testing machine. The specimen was loaded using a pin that was pushed through a hole in the plate (Fig. 6), inducing a state of stress in the resin layer that combined the effects of direct tension and bending (Fig 7). The part of the plate opposite the loading pin was machined to avoid direct contact between the composite and the reaction plate (Fig. 6).

Finite element analyses were performed to compare the state of stress in the resin layer of the monotonic tests and the resin layer of the three-point bending specimen. Results from the finite element analysis are shown in Fig. 7. Although the stresses shown in Fig. 7 do not constitute a perfect match of those in Fig. 3, important features are repeated. In both cases, the normal stresses vary following a gradient from tension to compression, indicative of combined tension and bending, with peak values at the edge of the resin layer.

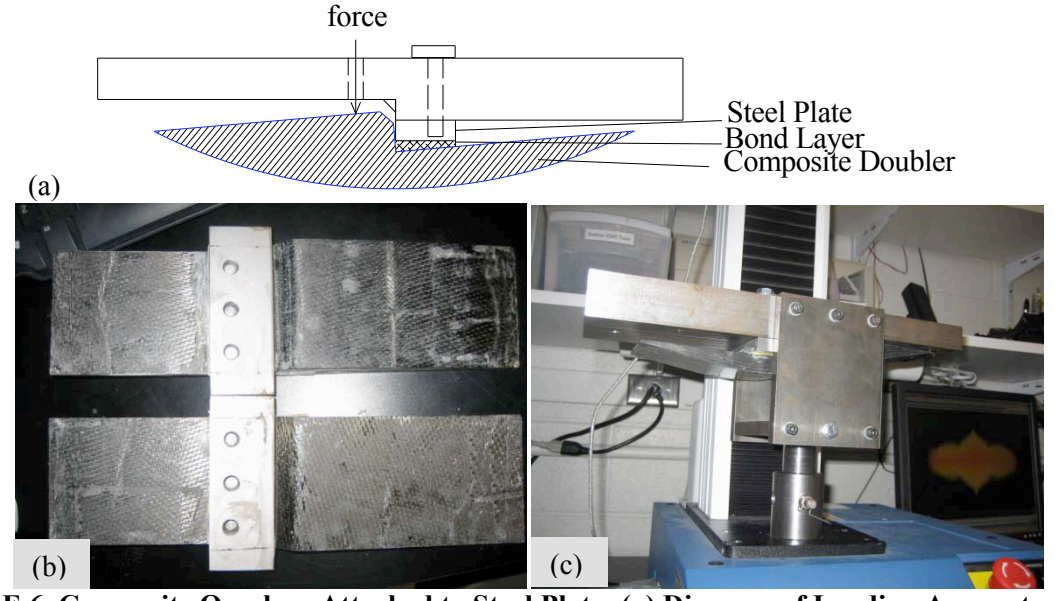

FIGURE 6. Composite Overlays Attached to Steel Plate: (a) Diagram of Loading Apparatus, (b) Steel Plates Bonded to Composite Overlays, (c) Reaction Apparatus Installed in Testing Machine.

RESULTS

For the first series of monotonic tests, in which the resin layer was used to bond a steel plate to the composite overlay, most failures were due to delamination within the composite overlay instead of loss of bond between the resin layer and the steel (Fig. 8). This was likely due to the fact that the resin used to bond the composite to the steel (Hysol ®) was stronger than the resin used to fabricate the composite overlay. Measured load-deflection relationships for the specimens tested are shown in Fig. 8. The dashed lines in Fig. 8 correspond to resin layers with embedded breather cloth, while the solid lines correspond to specimens without breather cloth. As shown in Fig. 8, the average peel stress ranged between 100 and 300 psi.

The failure of one of the specimens without breather cloth illustrates one of the most important effects of embedding breather cloth within the resin layer. Due to the low viscosity of the resin, large voids formed in the resin layer during fabrication, resulting in much weaker bond between the resin layer

and the steel. This was the only instance in which failure occurred due to loss of bond between the resin layer and the steel instead of debonding of the composite.

Table 1 : Material Properties

CFRP			
Number of Layers in Coupon	Number of Coupons	Avg. Modulus of Elasticity GPa (ksi)	Standard Deviation GPa (ksi)
1	3	85.8 (12,438)	10.0 (1,445)
3	4	75.3 (10,926)	10.9 (1,581)
5	3	61.7 (8,944)	0.3 (42)
9412 Hysol® Resin			
Coupon Thickness mm (in.)			
6.4 (0.25)	6	2.1 (303)	0.2 (25)

The main objective of the study was to evaluate the bond between the resin layer and the steel, therefore, the test was modified to avoid premature failure due to delamination of the composite. In a second series of tests, the composite overlay was replaced by a steel plate, guaranteeing that failure would be caused by loss of bond between the epoxy and the steel.

The steel plate used to replace the composite overlay had dimensions of 1-½ in. wide, 4 in. long, and ½-in. thick. Only a 1-in. wide strip of the steel plate was bonded to the resin. The remaining ½ in. was covered with Teflon tape to prevent bond with the steel (Fig. 5). In the same manner as the first group of tests, there were specimens with and without breather cloth embedded in the epoxy resin layer.

The specimens were prepared according to the following procedure. The surface of the two plates was roughened with a grinder and subsequently cleaned with acetone and methanol. The edge of the area to be bonded was covered with adhesive tape in order to build a dam for the resin. In specimens with embedded breather cloth, the cloth was cut leaving a hole to allow placing of a spacer to maintain consistent thickness of the resin. At this point the resin was mixed and poured in the bond area. When cloth was used, it was verified that the cloth absorbed the resin evenly, and that sufficient resin was absorbed by the cloth. The second steel plate was then placed on top of the resin pool making sure that the plate was in contact with the spacer. Pressure was maintained with a clamp throughout the curing process.

A total of 14 peel tests were performed to evaluate the effect of resin layer thickness and presence of breather cloth on the average tensile stress at failure. Resin layers tested had thicknesses of 1/16 in., 1/8 in., and 1/4 in. Specimen characteristics and the average peel stress at failure are summarized in Table 1. The average peel stress was calculated as the maximum measured force divided by the effective bond area. This simple quantity was considered adequate to establish a basis of comparison between the different configurations.

Load-displacement curves for the peel tests are shown in Fig. 9. Curves with dashed lines correspond to specimens with cloth, while solid lines correspond to load-deformation curves for specimens without cloth. In general, specimens with breather cloth achieved significantly higher deformations at failure. Another observed trend was that specimens without breather cloth exhibited sudden failure leading to a total loss in bond between the two plates. Specimens with breather cloth retained a residual capacity of approximately 30% of the maximum stress.

14	0.2500	y	434.3

Figure 10 shows the resin layer of specimens with and without breather cloth after failure. It is apparent that while the resin layer without cloth developed voids (Fig. 10a), the resin layer with breather cloth did not. Furthermore, it was observed that failure occurred through the middle of the resin layer in the resin layer with breather cloth, with residues remaining attached to both steel plates. This is an indication that the tensile strength of the resin was the limiting factor, and not the bond strength between the steel and the resin.

Figure 11 shows the appearance of the steel plates after failure for specimens with a resin layer thickness of 1/8 in. and 1/4 in. Another feature observed was that in specimens with thinner resin layers, failure tended to occur through the middle of the resin layer, while in specimens with thicker resin layers the tendency was for a greater amount of resin to remain attached to one of the two plates.

Figure 11 shows the relationship between the tensile (peel) strength of the resin layer and the thickness of the resin layer for specimens with and without breather cloth. Figure 11 shows that the strength of the resin layer decreased with increasing thickness, and that the reduction in strength with thickness was less pronounced for specimens with breather cloth. Also, it was observed that for specimens with very thin resin layers the presence of breather cloth had a negligible effect on strength, while for layers 1/4 in. thick, the difference in strength was on the order of 25%. These results suggest that using a resin layer with a thickness of at least 1/8 in. with embedded breather cloth will provide the best results. The observed benefits of breather cloth were: a lower propensity to develop voids in the resin layer; higher strength (for layers with a thickness of at least 1/8 in.); and a significant residual strength after cracking, which is likely to slow crack growth under fatigue loading.

CONCLUSIONS

Results of a study on improved methods for bonding CFRP overlays to steel specimens showed that excellent performance for this type of fatigue repair could be achieved by prefabricating composite overlays and attaching them to the steel structures using a layer of epoxy resin with embedded breather cloth. Monotonic tests were performed to develop a better understanding of the effects of the thickness of the resin layer and the presence of breather cloth on the fatigue life of the epoxy resin layer. It was found that use of breather cloth eliminated the presence of large voids in the resin layer, which can act as a trigger for fatigue cracks and significantly reduce the fatigue life of the bond layer. Although thicker

epoxy resin layers resulted in lower peel strength, thicker layers were less susceptible to problems due to large voids. Another benefit associated with the use of breather cloth was in terms of ductility. The monotonic tests showed that after failure of the resin took place, the breather cloth was capable of tying together the two sides of the failure surface, resulting in a residual capacity of approximately 30% of the strength of the resin. In terms of fatigue behavior, this type of post-peak behavior indicates that breather cloth likely has the effect of retarding the growth of fatigue cracks that form within the bond layer. Both of these effects result in a significant improvement in the bond strength under fatigue loading between composite overlays and steel elements, which are consistent with the improvements in fatigue life observed in fatigue tests of three-point bending specimens.

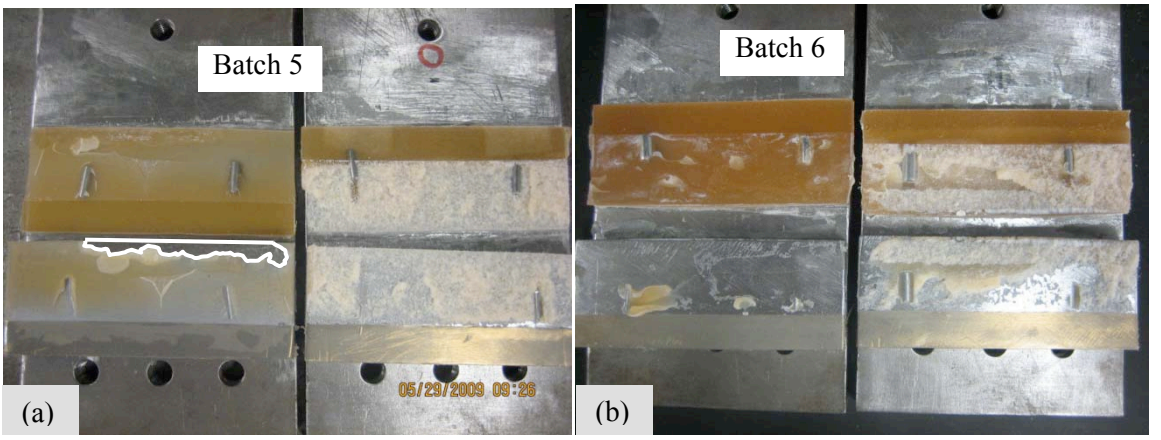

FIGURE 10 Appearance of Resin Layer after Failure for Specimens from (a) Batch 5 (1/8-in. thick) and (b) Batch 6 (1/4-in. thick).

In summary, computer simulations and fatigue tests performed in this study showed that composite overlays were capable of significantly extending the fatigue life of steel structures as long as

adequate bond was maintained between the overlays and the steel. Excellent bond performance under fatigue loading was achieved by attaching prefabricated composite overlays to the steel using a layer of epoxy resin with embedded breather cloth with a thickness of at least 1/8 in.

BACKGROUND

Since the Kansas Department of Transportation (KDOT) started its fracture critical bridge inspection program around the mid-1980s, many welded steel bridge details at the diaphragm (or floorbeam) to girder connections were found to have developed fatigue cracks, often due to the cause of out-of-plane distortion. While proper fatigue design philosophy has been developed and incorporated into the current AASHTO bridge design specifications, repair of existing bridges with fatigue cracking remains a challenge to the bridge engineering community, especially when the repair details happen to reside in locations with geometrical complexity, or when cracking is compounded by corrosion or impact damage.

Beginning 1996, a series of research studies were performed through the collaborative effort between the KDOT State Bridge Office and the University of Kansas (KU). Five candidate structures were selected to examine the overall fatigue problem experienced by the KDOT steel bridges, using state-of-art finite element (FE) modeling technique. Two of these five bridges were then strain gauged, both before and after the repair, to ensure that the fatigue details were eliminated and the chosen repair method was effective.

This paper discusses the research and repair findings of the first case study sponsored by KDOT, the Arkansas River Bridge.

FATIGUE CRACK DEVELOPMENT

The Arkansas River Bridge was constructed in 1955 on highway K-96 over the Arkansas River in Hutchinson, Kansas. It is a 1020-ft long noncomposite steel bridge with three continuous units and 17 equal spans (Figure 1). The superstructure consists of a typical girder-floorbeam-stringer system and has an 8 ¼ in. concrete deck (Figure 2). The total bridge cross section width is 60.42 ft, including four 12 ft driving lanes, two 2 ft shoulder lanes, and two 4.21 ft side walks. All main structural members are rolled steel sections.

During the 1995 and 1996 bridge inspections, the KDOT Special Inspection Team noticed fatigue crack development at about 110 welded connections in the bridge.

Based on the location of occurrence, cracks were categorized into three major types: Type 1 broken welds at the stringer bottom flange to floorbeam top flange attachment (Figure 3), Type 2 vertical cracks at either the stringer-to-floorbeam or floorbeam-to-girder connections next to the expansion joints (Figure 4), and Type 3 horizontal cracks at the floorbeam to exterior girder connections due to out-of-plane distortion (Figure 5).

Figure 1 The Arkansas River Bridge

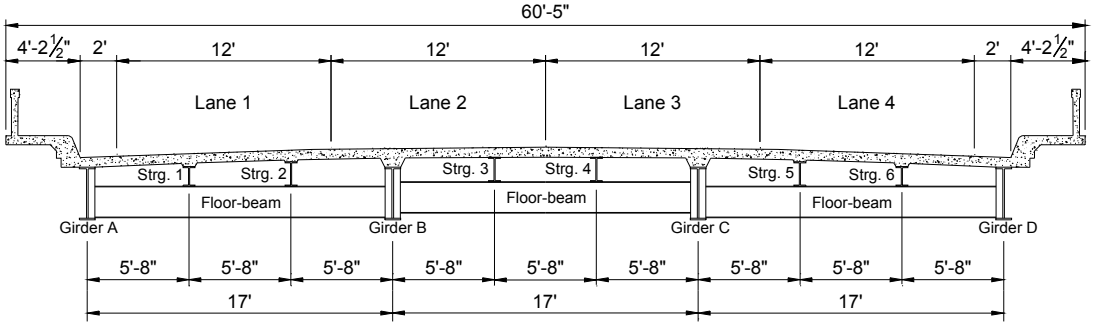

Figure 2 Bridge Cross Section

For Type 1 cracks, since the load path from stringer to floorbeam would not be interrupted even if the welds were completely detached, no major repair was deemed necessary at this crack location. Type 2 cracks could affect the bridge load-carry capacity to some extent, but no collapse mechanism should form due to the structural redundancy at the bridge piers. As a result, instead of applying local repair at each individual crack locations, a simple strengthening solution was proposed by adding new floorbeams next to the existing floorbeams at the expansion joints. Type 3 cracks were found only at the intermediate floorbeam to exterior girder connections. The

floorbeams of the Arkansas River Bridge were attached to the girder connection stiffeners by a 4 in. horizontal weld at the coped top flange, two 4 in. vertical welds at the top and bottom of the web, and five 2 in. slot welds along the web depth. This detail subjected the top horizontal welds to high cyclic stresses when the supporting girders deflected differently on the opposite ends of the floorbeam. Cracks were all found to have started from the outside edge of the connection stiffener, and then propagated following the weld path along the width of the stiffener plate. There are 68 floorbeam to exterior girder connections in this bridge, 39 of them had developed Type 3 cracks by 1996. Since this type of cracking could grow directly into the girder web and cause section loss of the main load-carrying members, it was considered the primary focus of the research and repair investigation, during both the FE modeling and field instrumentation.

It is interesting to point out that Type 3 cracks were not found at the two interior girders, apparently due to the lower fatigue stresses developed at the floorbeam to interior girder connections. Type 3 cracks were not found at the end of the units or negative moment regions either, as no differential girder deflection should develop at the support locations.

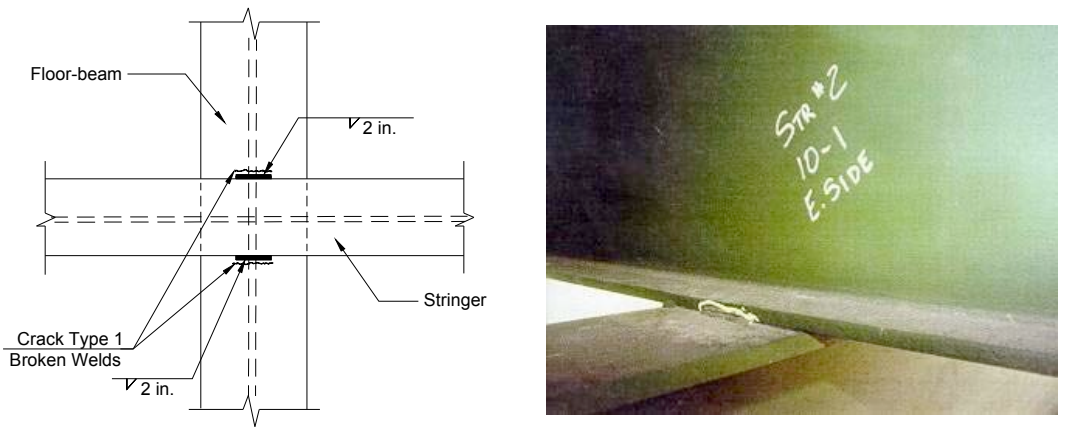

Figure 3 Crack Type 1

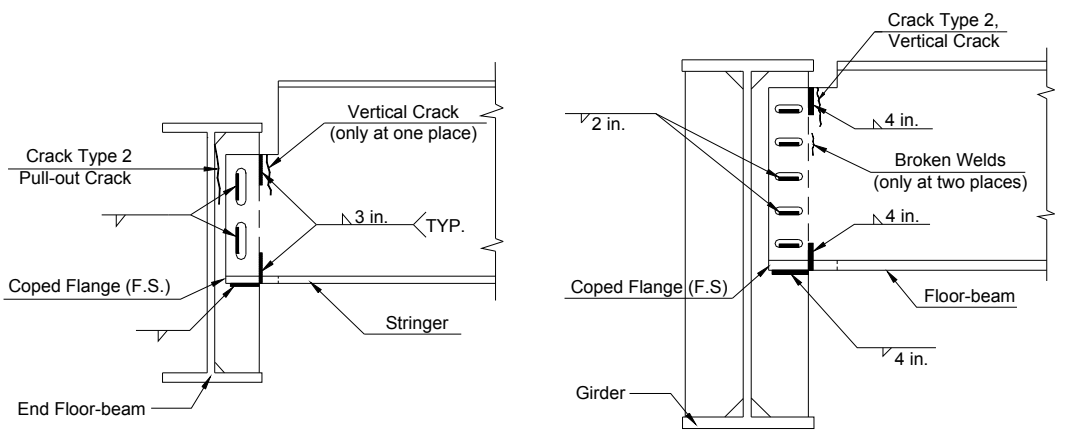

Figure 4 Crack Type 2

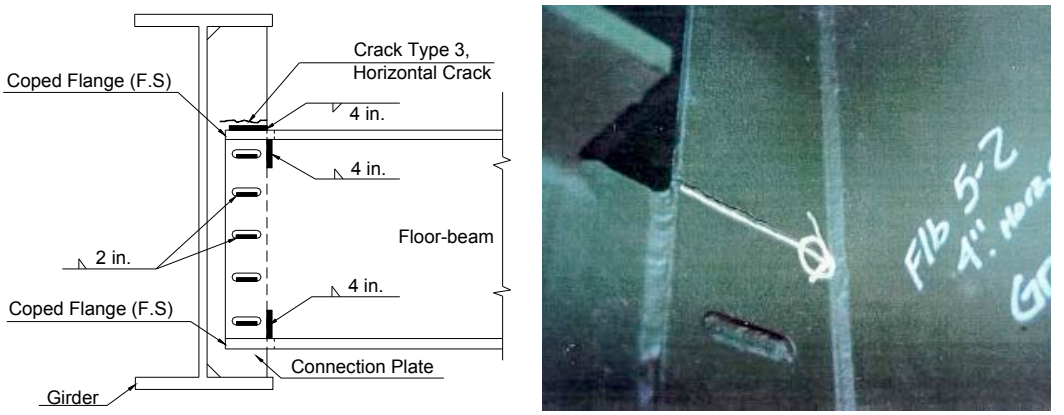

Figure 5 Crack Type 3

FINITE ELEMENT MODELING

Two consecutive spans of the 2nd unit from Pier No. 10 to Pier No. 12 were chosen for the FE study, due to the fact that they were found with the most cracks in the bridge. Computer program ANSYS was used for the FE modeling and analysis. All bridge superstructure components were first built into a large coarse model, and the mostly stressed floorbeam to girder connection was then "cut out" and analyzed further at the submodel level with refined element mesh. An AASHTO HS15 fatigue truck plus 10% impact was used for load application. Wheel loads were placed along the center of driving lane close to Girder D, and moved in 5 ft increments from Pier No. 12 to Pier No. 10 for a total of twenty load cases.

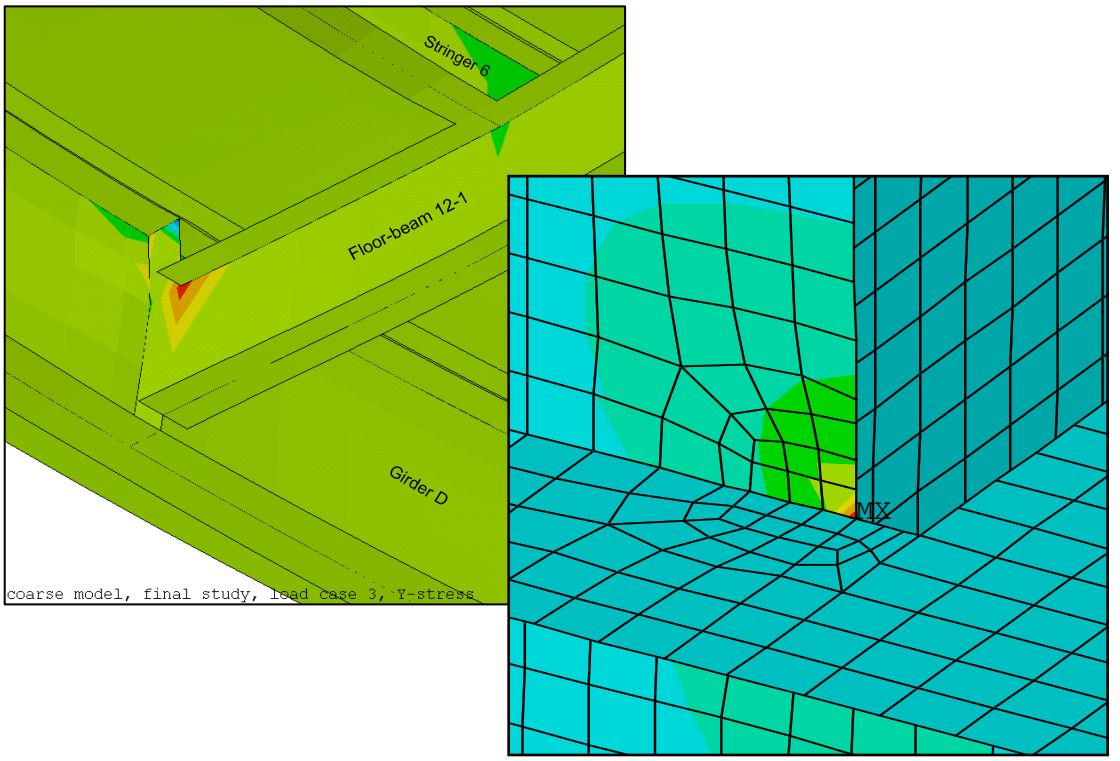

Figure 6 FE Models (Left: Coarse Model, Right: Submodel)

From the coarse-to-sub model analysis, the largest stress variation was found at Floorbeam 12-1 to Girder D connection, right at the edge of the connection stiffener where it was welded to the floorbeam top flange (Figure 6). The maximum stress occurred at Load Case 3, 34.2 ksi; and the minimum stress occurred at Load Case 15, -1.3 ksi. This resulted in a total stress range of 35.5 ksi. There is no specific fatigue detail category that matches the case of the Type 3 crack detail in the Arkansas River Bridge, but it is reasonable to conclude based on the available codes and specifications that the detail resistance would not be any better than Category C. The constant amplitude fatigue threshold (CAFT) of Category C is 10 ksi. Taking into account the occasional heavy truck loading, the current AASHTO LRFD specifications require the detail stress ranges to be designed below ½ CAFT if an infinite life is required. As a result, the stress range that occurred at the Type 3 crack locations in the Arkansas River Bridge was much higher than the detail capacity, even for a finite fatigue life design. The hot-spot revealed by FE modeling matched what had occurred in the actual bridge, and the stress results explained why more than 50% of the floorbeam to exterior girder connections had already developed Type 3 cracks.

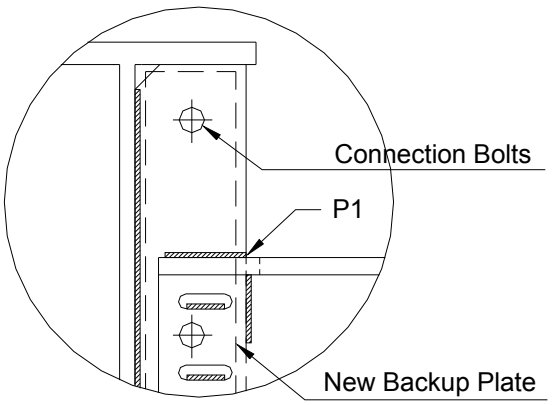

Figure 7 Repair Plan 1

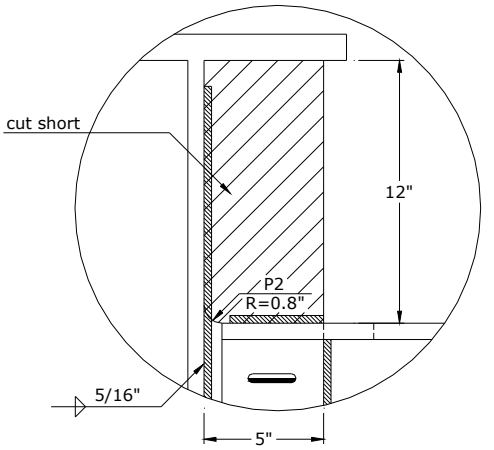

Figure 8 Repair Plan 2

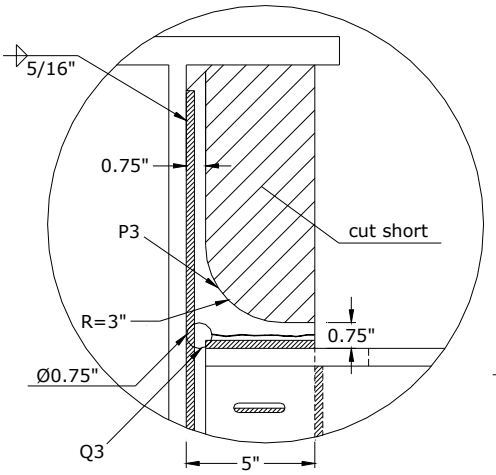

Figure 9 Repair Plan 3

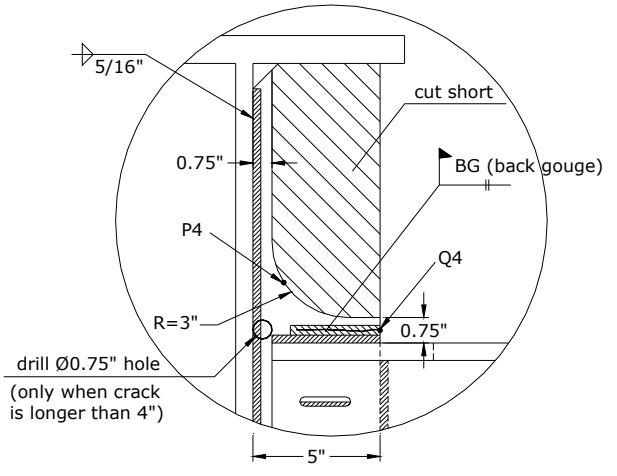

Figure 10 Repair Plan 4

Once the FE model was validated, repair analyses were followed, again using the coarse-to-submodel approach. Four different repair plans were investigated. Repair plan 1 was to bolt a backup plate to the existing stiffener to splice the cracked surfaces (Figure 7). Interestingly, the FE analysis results showed that for the uncracked locations, the maximum stress range was reduced by 40%, but still at a high magnitude of 20.7 ksi and located at the same concentration point on the outside edge of the existing stiffener. For the cracked locations, an increasing horizontal stress was observed at the bottom circumference of the repair hole drilled at the crack tip. This may allow cracks to develop at the stiffener to girder web welds. Repair plan 2 was to cut short the stiffener completely from above the floorbeam top flange, including all the cracks and weld attachments (Figure 8). The maximum stress range was found to be 33.0 ksi at the curved transition between the horizontal and vertical cut surfaces. Although this is a Category A detail, the predicted stress range was higher than CAFT. Surface finish of the repair was also a concern, as there had been cases where rough surfaces were left in place and caused new crack development at the repaired details. Repair plan 3 was to cut short the stiffener partially and drill a hole at the inside stiffener edge in order to capture the crack when it proceeded to that point (Figure 9). Although this repair was much simpler compared to Repair plan 2 from the construction perspective, the FE analysis indicated that high fatigue stress could develop at either the crack tip or the repair hole, and thus lead to further crack growth along the welds. The fourth repair plan was to partially cut short the stiffener and reweld the crack (Figure 10). The stress variation at the outside stiffener edge was found significantly reduced, from 35.5 ksi to 2.2 ksi, due to the fact that a large portion of the stiffener plate above it was removed so the geometry constraints were relieved. The maximum stress range now shifted to the mild curved edge with a magnitude of 23.7 ksi. If the cut edge was properly finished, a fatigue resistance consistent with Category A detail could be obtained. However, infinite fatigue life might not be reached because the maximum stress range was only slightly lower than CAFT and higher than ½ CAFT.

The fatigue lives allowed by the four different repair methods were then calculated, based on the stress range results obtained from the FE models. Since a new Hutchinson Bypass would be constructed soon to serve the main artery of the city, traffic volume of the Arkansas River Bridge was expected to decrease in the future. Repair plan 4 was found to yield a longer life than the other three repairs. The estimated fatigue live was 15 yr, 30 yr, or 60yr, respectively, if the future truck traffic was assumed 100%, 50%, or 25% of the 1996's.

Based on the analytical study, Repair plan 4 was chosen eventually during the final repair design of the bridge, due to its advantages over the other three repairs in terms of overall stress reduction and fatigue life extension. Although the softening mechanism has been previously used in the crack repair of other bridges, its application in this particular crack configuration is probably the first of its kind.

FIELD INSTRUMENTATION

To verify the computational results and the effectiveness of the repair, field tests were performed at selected connections, both before and after the repair of the Type 3 cracks. Two sand trucks, each has an equivalent weight of an HS15 truck, were supplied by KDOT. Traffic was closed and construction work was also temporarily suspended during the tests. A total of 21 loading conditions were tested prior to the retrofit, and a total of 15 loading conditions were tested after the retrofit. Each loading condition was executed twice.

Figures 11 and 12 show the strain gauges installed prior to and after the retrofit, respectively. The measured stress range data from the pre-retrofit test turned out to match very well with the FE results. The direct stress measurements from the post-retrofit test turned out to be higher than the FE results. This was probably due to the difference between the dimensions assumed in the analytical models and the actual resulting geometries at the repair details. A two-step scaling procedure was then used in order to realistically bracket the stress ranges for future fatigue life estimate. At the time the field tests were conducted, construction of the Hutchinson Bypass had been finished, so an updated traffic forecast indicated only 5% truck traffic for the Arkansas River Bridge for the next 20 years. An estimated fatigue life of 25-65 years was then obtained for the repaired details, based on the scaled stress measurement and the updated traffic count. This was also very close to what was predicted by the FE repair analysis, and the result was considered acceptable by the KDOT engineers.

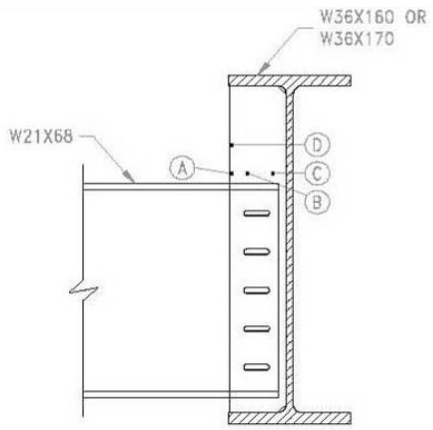

Figure 11 Strain Gauges Installed before the Retrofit

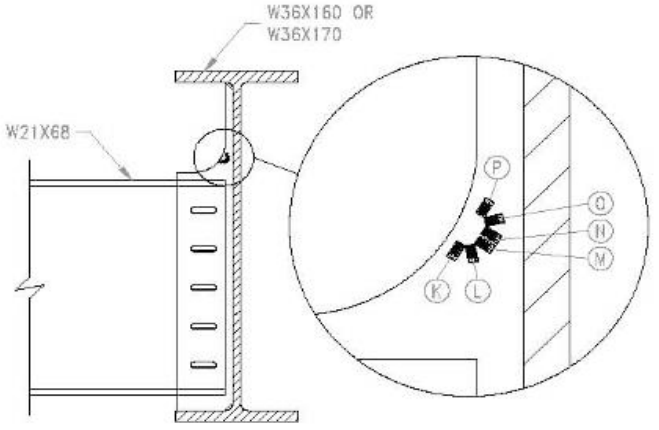

Figure 12 Strain Gauges Installed after the Retrofit

SUMMARY

The bridge was repaired in 2003 and no crack development or reinitiation has been reported to this date. The research effort not only helped put the bridge back to normal service, but resulted in a significant saving to KDOT and the taxpayers. The total structural repair cost is $500,000, in contrast to the estimated $5 million for bridge replacement. The research approach and the repair method also provided useful guidance to the repair of other KDOT bridges, as well as bridges of other state DOTs that developed similar crack scenario.

Experimental Study of Shear Capacity of Reinforced Concrete Slabs

Eva Lantsoght[1], Cor van der Veen[1] and Joost Walraven[1]

[1]Concrete Structures, Delft University of Technology, Stevin II-North 2.06, Stevinweg 1, 2628 CN Delft, The Netherlands; PH 0031(0)152787449; FAX 0031(0)152787438; email: E.O.L.Lantsoght@tudelft.nl

ABSTRACT

When assessing the capacity of existing reinforced concrete slab bridges under the increased traffic loads prescribed in the current codes, shear may become the critical failure mode. To better evaluate the shear capacity of reinforced concrete slab bridges, a series of experiments is carried out on continuous one-way slabs loaded close to the support. Eight continuous slabs of 5m x 2,5m x 0,3m are tested. The loading position is taken at different *a/d* ratios. Six slabs with a standard concrete mixture and two slabs with a higher strength concrete are tested. The influence of the loading history, the shear span to depth ratio and the concrete compressive strength is discussed. Conclusions on the influence of these parameters on the one-way shear capacity of reinforced concrete slabs are drawn.

INTRODUCTION

Over the past decades traffic loads have increased significantly. Therefore, the capacity of existing reinforced concrete bridges, designed for lower traffic loads, is currently under discussion. In particular the shear capacity of existing slab bridges is sometimes found to be insufficient, if checked with the current codes.

The governing design methods present a lower bound solution and usually are a conservative prediction of the shear capacity. Generally structural members are designed in such a way that flexural failure will occur before shear failure. Regarding existing structures, residual bearing capacity is expected from factors such as the increase of the concrete strength due to decades of further hydration of the cement and possibly a higher concrete strength under long-term loading. The shear capacity of deck slabs loaded close to the supports might also be higher than expected. Most publications about shear in reinforced concrete concentrate either on one-way shear in beams or on punching shear (two-way shear) in slabs. One-way slabs typically are designed using beam shear formulas. For loads close to the supports and very wide slabs a certain effective width b_{eff} is assumed. This effective width represents the width of the support which carries the load. The shear stress v is taken as uniformly distributed over the effective width. In practice this load spreading for wheel loads is assumed to occur under 45° from the load towards the support, Figure 1. A minimum value of $2d$ for loads in the middle of the width and of d at the edge and corner of the slab is used in practice. Even though the design values of the shear capacity are

found to be very low and sometimes insufficient, previous small-scale testing (Regan, 1982) has shown a considerable additional shear capacity for slabs under concentrated loads close to the supports.

To investigate this phenomenon an extensive experimental program is conducted at Delft University of Technology, The Netherlands. The variables in this test program are:

- the shear span to depth ratio (*a/d*),
- the reinforcement layout,
- the concrete compressive strength,
- the width of the slab,
- the position of the load along the width,
- the size of the loading plate,
- the type of support (simple or continuous),
- the type of reinforcement (deformed bars versus plain bars),
- the support layout (line support or bearing) and
- the loading history.

More background to the test program can be found in (Lantsoght et al., 2010b). The influence of the size of the wheel load, the amount of transverse flexural reinforcement, the type of the support (simple or continuous) and a comparison with code provisions and with Regan's method (Regan, 1982) for the first four tested slabs is given in (Lantsoght et al., 2010a).

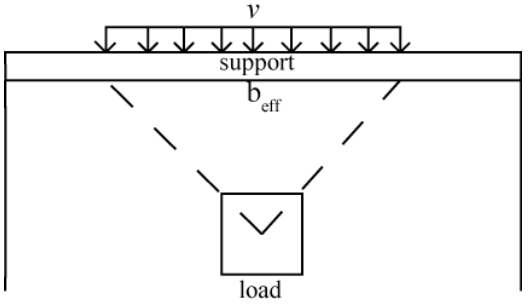

Figure 1: Effective width assuming 45° load spreading, top view showing concentrated load and line support.

EXPERIMENTS

Test setup. Slabs of 5m x 2,5m x 0,3m representing bridge decks on scale 1:2 are tested. A sketch of the top view and side view of the test setup is presented in Figure 2. The load can be moved along the width and span of the slab and can be placed both close to support 1 (sup 1 in Figure 2) and support 2 (sup 2 in Figure 2). Loading plates of 200mm x 200mm and 300mm x 300mm are used to simulate a wheel load. The supports are line supports and consist of a steel beam of 300mm wide, a layer of plywood eccentric from the center line of the steel, away from the span, and a layer of felt of 100mm wide. Support 1 represents a simple support. Prestressing bars are used to restrain the rotation at support 2, simulating a continuous support. The prestressing force is applied before the start of every test. When the load increases during testing (ΔP), the rotation over support 2 increases ($\Delta\theta$). The prestressing bars

counteract the increase in rotation, which leads to an increase in the force in the prestressing bars (ΔF_{ps}). The mechanics of the increasing force in the prestressing bar during testing is shown in Figure 3. In reality, the settlement of the support (felt and plywood) and the elongation of the prestressing bars result in $\Delta\theta \neq 0^{o}$.

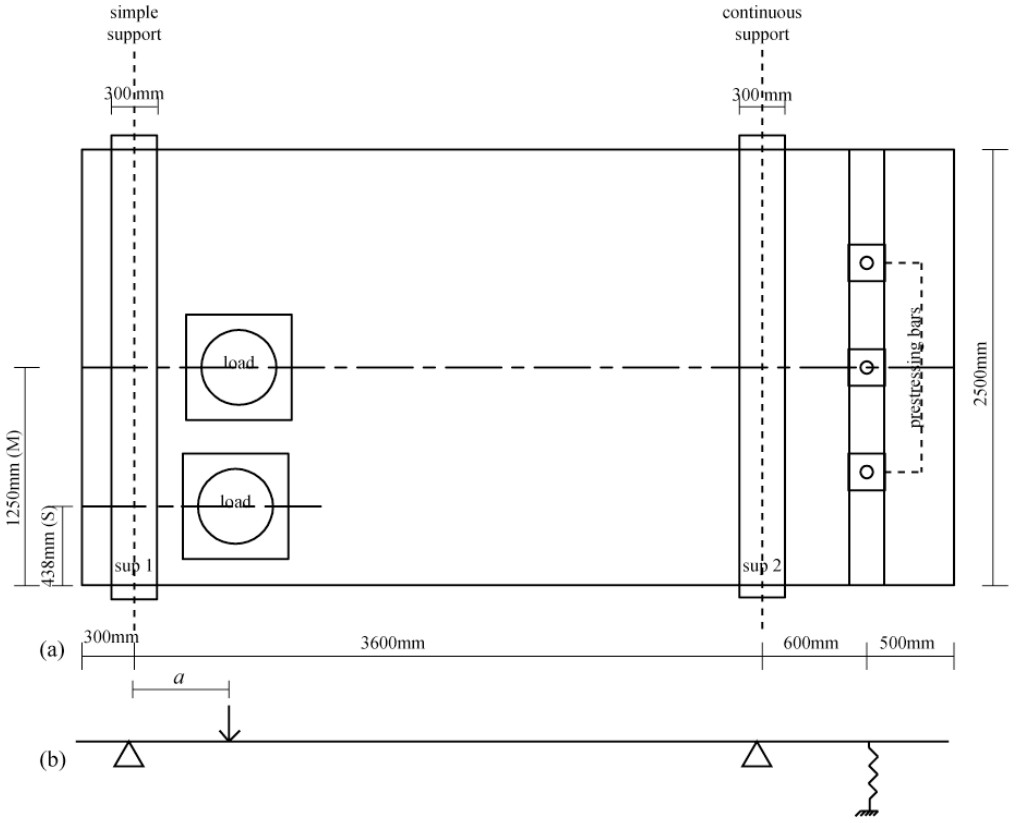

Figure 2. Sketch of test setup, (a) top view, (b) side view, dimensions in mm.

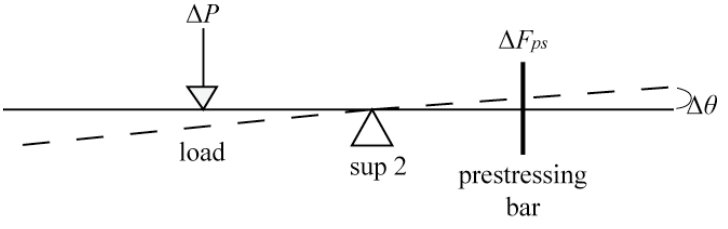

Figure 3. Increase in force in prestressing bar during testing.

Specimens. An overview of the properties of the eight tested slabs can be found in Table 1, in which:

f_c' the cube compressive strength of the concrete at the age of testing the slab,
f_{ct} the splitting tensile strength of the concrete at the age of testing the slab,
ρ_l the amount of flexural reinforcement in the span direction,
ρ_t the amount of flexural reinforcement in the transverse direction,
a/d the shear span to depth ratio,

a the distance between the center of the load and the center of the support,
d the effective depth,
M/S the position of the load along the width; middle (M) or side (S),
A_{load} the size of the square loading plate.

Table 1. Properties of slabs S1 to S8.

Slab	f_c' (MPa)	f_{ct} (MPa)	ρ_l (%)	ρ_t (%)	a/d	M/S	A_{load} (mm x mm)
S1	35,8	3,1	0,996	0,132	2,26	M	200 x 200
S2	34,5	2,9	0,996	0,132	2,26	M	300 x 300
S3	51,6	4,1	0,996	0,258	2,26	M	300 x 300
S4	51,7	4,2	0,996	0,182	2,26	S	300 x 300
S5	48,2	3,8	0,996	0,258	1,51	M	300 x 300
S6	50,6	3,9	0,996	0,258	1,51	S	300 x 300
S7	82,1	6,2	0,996	0,258	2,26	S	300 x 300
S8	77,0	6,0	0,996	0,258	2,26	M	300 x 300

On every slab six tests were carried out, except for S3 (five tests), S5 (five tests) and S8 (three tests). M denotes initial loading at the middle of the slab width. S denotes initial loading at the side at 438mm from the free edge, Figure 2. In case of M-loading, subsequent S-loading is carried out on a fully cracked and locally failed slab which indicates the residual capacity for S-loading. In case of S-loading, subsequent M-loading is carried out on a fully cracked and locally failed slab which indicates the residual capacity for M-loading.

The maximum aggregate size was 16mm. Slabs S1 to S6 contained blast furnace cement and S7 and S8 contained Portland cement, blast furnace cement and fly ash. During casting, two slabs were cast simultaneously. As a result, there are always two slabs (for example S1 and S2) which were made out of the same concrete mixture and thus have the same concrete properties. Two types of concrete were used: normal strength concrete with a target value for f_c' of 43MPa (C28/35) for slabs S1 – S6 and high strength concrete with a target value for f_c' of 73MPa (C53/65) for slabs S7 and S8.

The layout of the reinforcement of S1 and S2 is shown in Figure 4(a) and Figure 4(b). The layout of S3 and S5 – S8 is shown in Figure 4(c) and the layout of S4 is shown in Figure 4(d). Reinforcement S500 with an average yield stress of 580MPa and ultimate stress of 710MPa is used. The amount of flexural reinforcement ρ_l was determined as necessary to resist a bending moment created by a load of 2MN (maximum capacity of the jack) at position M along the width and 600mm along the span (a/d = 2,26). The amount of transverse flexural reinforcement ρ_t is traditionally taken as 20% of ρ_l. In this series of tests 13,3% of ρ_l is used in S1 and S2 and 25,9% of ρ_l is used in S3, S5, S6, S7 and S8. In S4 the amount of transverse flexural reinforcement is only doubled in the vicinity of the supports, Figure 4(d).

The influence of the support is important for a/d-values of 2,5 and less (Kani, 1964). Slabs S1 – S4, S7 and S8 were loaded at 600mm from the center of the

support, resulting in an *a/d*-ratio of 2,26. Slabs S5 and S6 were loaded at 400mm from the center of the support, resulting in an *a/d*-ratio of 1,51.

The different sizes of the loading plate were chosen to simulate different sizes of tires. The 200mm x 200mm load is a 1:2 scale representation of the 400mm x 400mm axle load used in load model 2 of EN1991-2:2002.

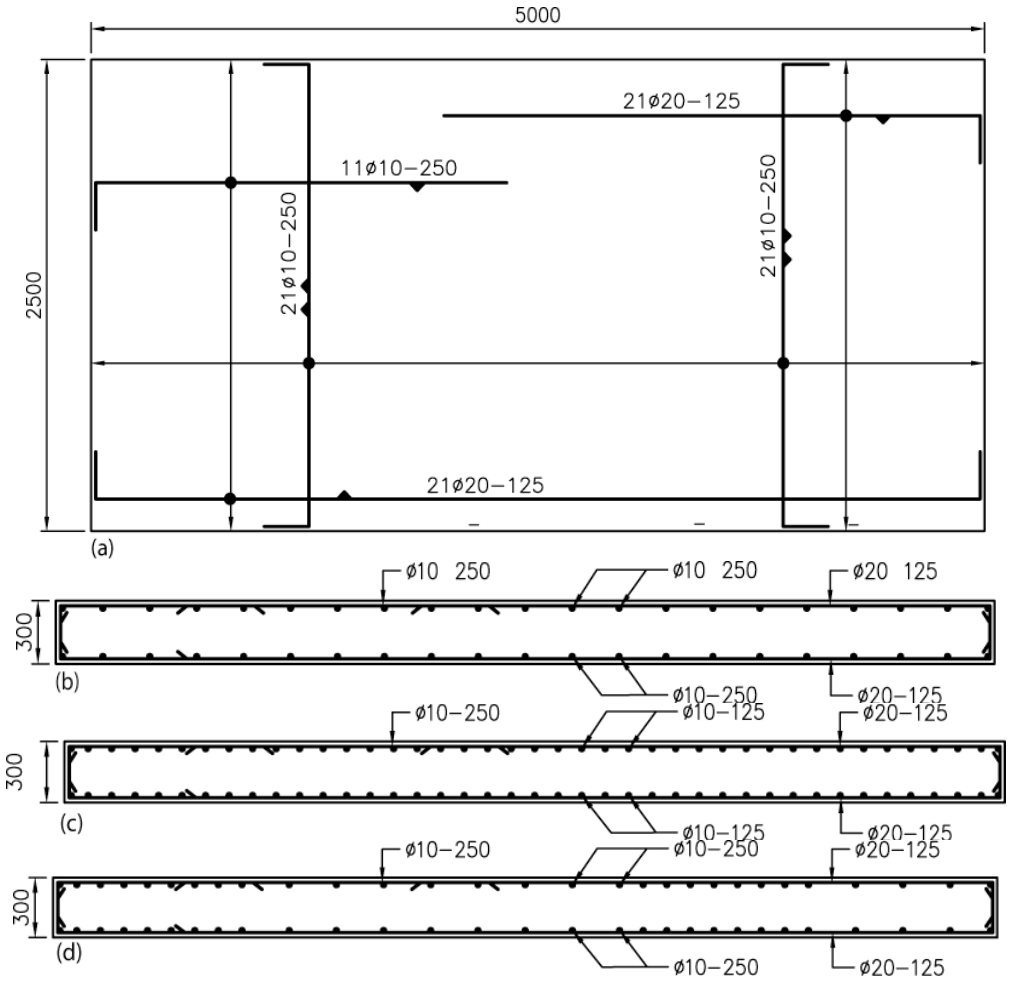

Figure 4. Reinforcement layout: (a) plan view of slabs S1 and S2, (b) cross-section of slabs S1 and S2, (c) cross-section of slabs S3, S5-S8, (d) cross-section of slab S4.

Test results. The values of the peak loads obtained for S5 to S8 are summarized in Table 2, in which the following abbreviations are used:

b_r	the distance between the load and the free edge taken along the width,
SS	the load is placed close to the simple support,
CS	the load is placed close to the continuous support,
P_u	the peak load,
s	the test gives a shear capacity, obtained on a virgin specimen,
r	the test gives a residual shear capacity, obtained on a predamaged specimen.

The results of slabs S1 up to S4 can be found in Lantsoght et al. (2010a).

Table 2. Results of tests of S5 to S8.

Name	*a/d*	b_r (mm)	SS/CS	P_u (kN)	s/r
S5T1	1,51	1250	CS	1804	s

Figure 5 shows how the peak load is determined from the measured load-deflection diagram during testing. Typical brittle shear failures (Figure 5(a)) are observed as well as shear failures with a limited amount of post-peak ductile behavior (Figure 5(b)).

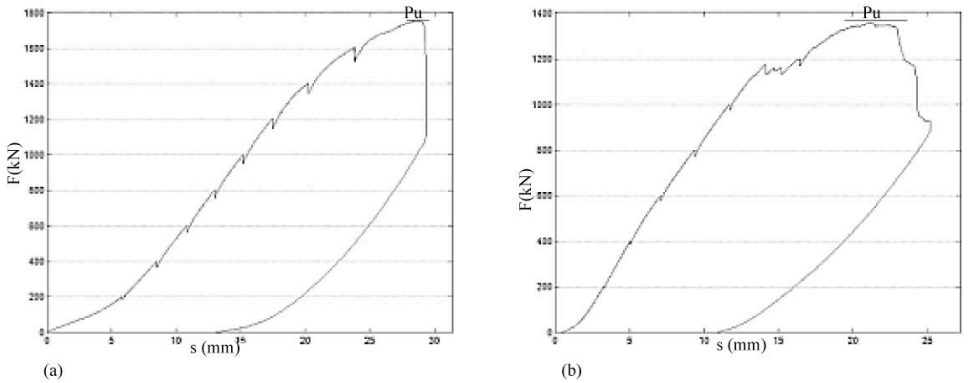

Figure 5: Determination of the peak load (P_u) for (a) S5T4, brittle failure and (b) S8T2, with post-peak ductility.

Figure 6 shows the loading sequence and the meaning of s and r. First, test S5T1 is carried out with the load close to the continuous support and results in a virgin shear capacity denoted by "s". This test causes local failure and heavy damage to the slab at the side of the continuous support. An example of damage caused by testing the shear capacity is shown in Figure 7. Next, S5T2 is carried out on the damaged slab. The result of this experiment is influenced by the cracking and failure caused by S5T1 and therefore gives a residual shear capacity, denoted r. Bridges which might have been in service for several decades, do not have locally failed areas like the specimens tested for residual capacity. As a result, the measured residual shear capacity is a conservative lower bound of the capacity of existing bridges that are fully cracked in bending and might have been overloaded in the past.

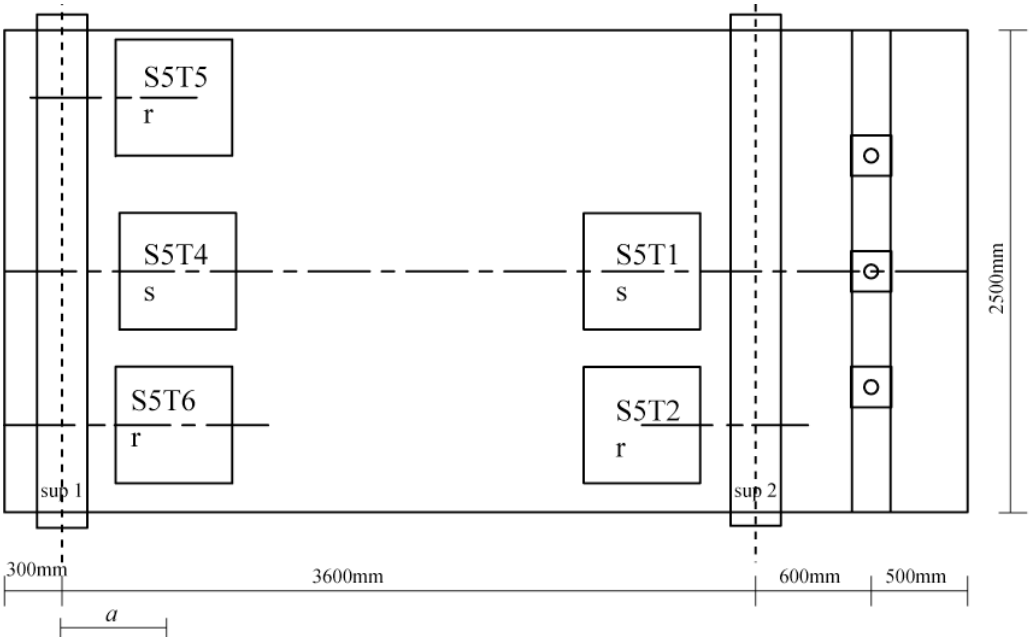

Figure 6: Explanation of s and r.

Figure 7. Cracking caused by S2T1, bottom face.

RESULTS AND DISCUSSION

Loading history. The residual shear capacity gives a lower bound estimate of the shear capacity of bridge slabs which are fully cracked in bending and have been in service for several decades. Therefore experiments were carried out slabs locally

failed due to previous testing, with results denoted by "r" in Table 2, loading sequence shown in Figure 6. To study the influence of predamaging, the results of tests on S3 and S4, on S5 and S6 and on S7 and S8 are compared. For these pairs of slabs, all parameters were held constant, only the load history was altered. It was observed that the width of cracks due to previous testing increased during testing for residual capacity. In only one case the test gave a 5% higher residual capacity, as shown in Table 2 for S5T1 and S6T3 (tests in the middle of the width at the continuous support). All other comparisons gave lower residual capacities, as expected. The results per pair of slabs are given in Table 3, in which:

P_r the capacity obtained in an experiment for residual shear capacity, denoted r in Table 2,

P_s the capacity obtained in a shear capacity experiment on an undamaged slab, denoted s in Table 2.

The overall average is a residual capacity of 84% of the undamaged shear strength. This result is surprisingly high, as it was not expected that slabs which had been tested up to their ultimate capacity and showed cracks of sometimes a few centimeters wide (Figure 7) would be able to resist again considerable levels of loading.

Table 3. Residual capacity.

Slabs	P_r/P_s
S3 – S4	0,80
S5 – S6	0,95
S7 – S8	0,78

Shear span to depth ratio. The shear span to depth ratio is known as an important parameter influencing the shear capacity of reinforced concrete beams. This influence is traditionally shown in Kani's valley (Kani, 1964). The influence of the shear span to depth ratio on reinforced concrete slabs subjected to point loads is less clear. A 45º load spreading as shown in Figure 1 leads to a decreasing effective width for a decreasing distance to the support. The theoretical ultimate shear stress v_u remains the same, but the smaller effective width would lead to a smaller maximum shear load $V_u = v_u b_{eff} d$. Therefore, the shear span to depth ratio (a/d) was studied in this series of experiments.

The slabs S3 and S5 are similar with regard to their properties. They are both loaded at the middle (M), but for different values of a/d (2,26 and 1,51 respectively). Also, the slabs S4 and S6 are similar. They are both loaded at the side (S) but for different values of a/d (2,26 and 1,51 respectively). Only test results obtained on virgin specimens, denoted by s in Table 2, are considered. Figure 8 shows the results as a function of a/d. It is clear that in all cases the shear capacity increases with decreasing value of a/d.

In EN1992-1-1:2005 the shear span to depth ratio is incorporated for small shear spans. §6.2.2 (6) prescribes: "For members with loads applied on the upper side within a distance $0{,}5d \le a_v \le 2d$ from the edge of a support (or center of bearing where flexible bearings are used), the contribution of this load to the shear force V_{Ed} may be multiplied by $\beta = a_v/2d$. … This is only valid provided that the longitudinal reinforcement is fully anchored at the support. For $a_v \le 0{,}5d$ the value $a_v = 0{,}5d$

should be used." For slabs S3 and S4 β = 1 is obtained and for S5 and S6 β = 0,66. A 51% increase in shear capacity is expected using this procedure. Comparing the test results shows an average increase in capacity of 26% with a coefficient of variation of 6%. The observed increase in shear capacity for slabs is thus less than expected on the basis of the factor β from the EN 1992-1-1:2005. This factor was derived based on results from shear tests on beams.

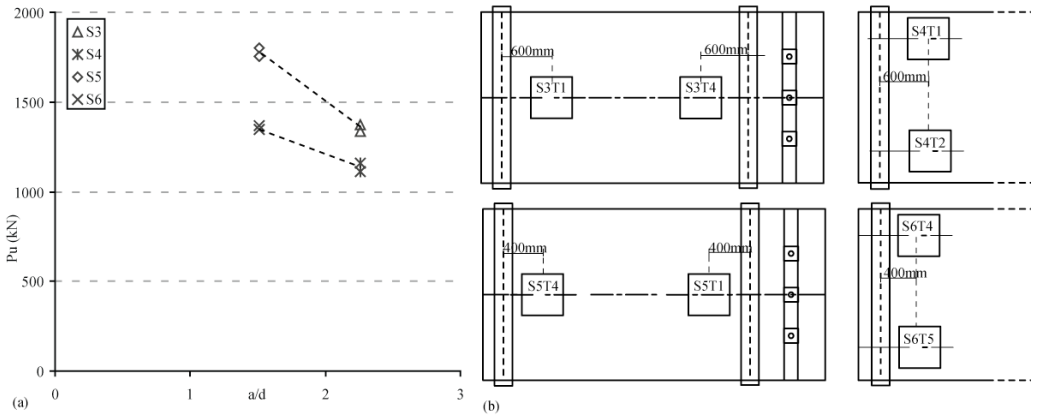

Figure 8. Influence of distance of load to support on shear capacity for normal strength concrete.

A possible reason for the influence of the shear span to depth ratio is related to the formation of a direct compression strut between the load and the support. When the load is applied close to the support, an internal compression strut can develop between the load and the support. Hence, another mechanism of shear transfer is activated: the strut-and-tie action, in which the beam transfers the force between the load and the support through a direct compression strut.

When applying this concept to the shear capacity of slabs under concentrated loads, a lower increase in capacity for decreasing *a/d* could be explained. The width of the element influences the possibility of developing a direct compression strut between the load and the support. A three-dimensional strut-and-tie model can now develop. In beams, the only possible load path is directly from the load to the support at small *a/d* ratios. In slabs, different load paths can develop. As a result of these different load paths, the average value of *a/d* will be larger, Figure 9.

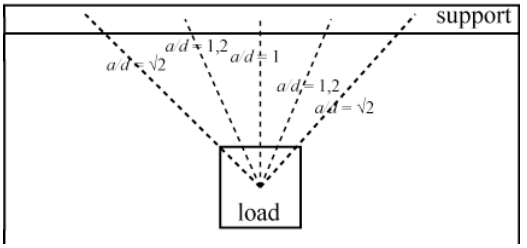

Figure 9: Larger average *a/d* ratio for slabs as compared to beams.

Concrete compressive strength. Traditionally, the concrete tensile strength is seen as the most important factor influencing the shear strength of beams. For design purposes, the tensile strength is calculated based on the concrete compressive strength with a square root (for example, ACI 318-08) or cube root (for example EN 1992-1-1:2005) relationship. Design methods for the punching shear resistance of concrete slabs also involve the concrete compressive strength.

To experimentally study the influence of the concrete compressive strength on the one-way shear capacity of slabs, the results of S2, S3, S4, S7 and S8 are compared. S2, S3 and S4 are produced with normal strength concrete, while S7 and S8 are produced with high strength concrete. The results are shown in Figure 10. All tests were carried out at a/d = 2,26. S2 contained less transverse flexural reinforcement (ρ_t in Table 1), but it has been previously shown that the influence of ρ_t on the ultimate load is small (Lantsoght et al., 2010a). Only the results of the undamaged slabs (denoted s in Table 2) are used. No increase in capacity with increasing compressive strength is observed. An increase in scatter is observed for the test results with high strength concrete. The measured average increase in shear capacity for S3 and S4 versus S7 and S8 is 0,46% for an increase in concrete compressive strength of 54%. The expected increase in capacity is 24% for a square root relationship between the concrete compressive strength and the tensile strength and 15% for a cube root relationship. The experimental data do not reflect this observation. The splitting tensile strength increased even with 47%, as shown in Table 1. Comparing S2, S3/S4 and S7/S8 leads to the similar conclusions.

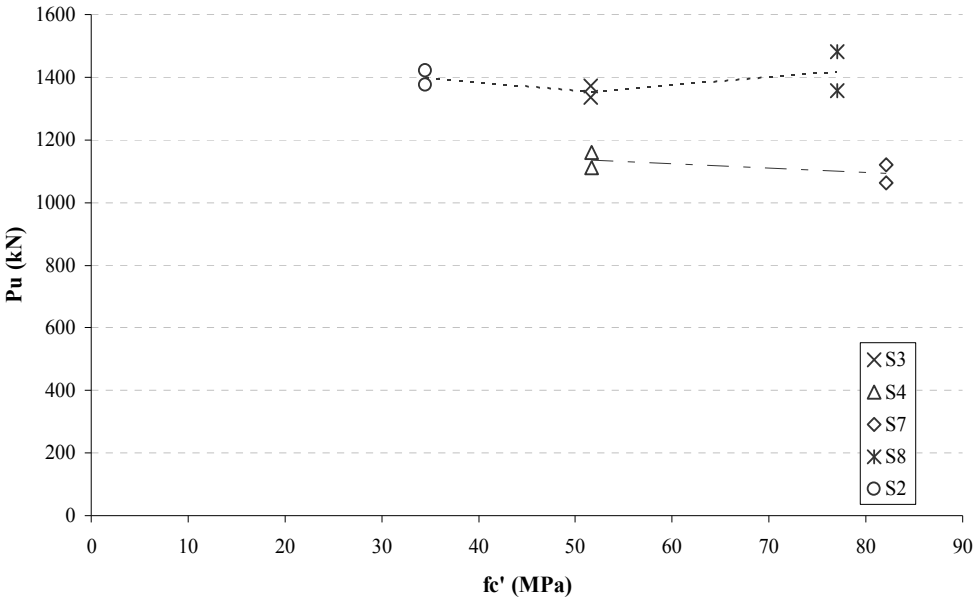

Figure 10. Influence of the concrete compressive strength (cube strength), for *a/d* = 2,26, for loading at the middle (upper series) and loading at the side (lower series).

The concrete compressive strength influences the shear capacity of beams because it directly influences the concrete tensile strength, the dowel capacity limited to the tensile strength of the concrete cover supporting the dowel, the aggregate interlock capacity and the strength of the compression zone. However, for high strength concrete the aggregate interlock capacity is reduced. The aggregate itself is then the weakest element through which the shear crack passes. The result is a very smooth crack surface. It was observed in S7 and S8 that the shear crack indeed cut through the aggregates. (Sherwood et al., 2007) suggest that 70% of the shear capacity is carried by aggregate interlock. The reduced aggregate interlock capacity of the high strength concrete might explain why no increase in shear capacity is observed for an increasing concrete strength. However, the relation between high strength concrete and their aggregate interlock capacity is still a point of discussion. The same observation has been made by (Angelakos et al., 2001). They reported: "high cylinder strengths do not necessarily result in high values of failure shear stress".

Another possible explanation is that the mechanism of shear transfer works in a different way for slabs under point loads than for beams in shear. Due to the width of the element, redistribution of forces can occur. Therefore, a three-dimensional strut-and-tie model should be developed in order to explain the observations.

CONCLUSIONS

To evaluate the capacity of existing reinforced concrete slab bridges a series of large-scale experiments on reinforced concrete slabs have been carried out. Test results concerning the loading history, the shear span to depth ratio and the concrete compressive strength are discussed. The results and conclusions are summarized in the following:

1. Heavily cracked and locally failed slabs still have about 84% of the shear capacity of an undamaged slab when loaded again in the vicinity of an already failed region.
2. The shear capacity clearly increases for a decrease in distance to the support, but the increase is smaller than expected based on the Eurocode formula for beam shear.
3. No increase in capacity with increasing concrete compressive strength was observed. The smaller aggregate interlock capacity in high strength concrete might explain this.

The experimental results show that the mechanism of shear transfer in slabs under wheel loads is different from the mechanism in beams. Redistribution of forces along the width might result in a three-dimensional system of forces which needs to be evaluated through a three-dimensional strut-and-tie model.

Future work includes:

- experiments on slabs with a different width,
- experiments on slabs reinforced with plain bars, and
- experiments on slabs supported by elastomeric bearings.

ABSTRACT

In areas of moderate seismicity, such as Mid-America, there is interest in developing alternate bridge design and construction methodologies to the typical approaches that are employed in high-seismic regions. One such method is to design so that various bearing components will exceed their ultimate capacities during a major seismic event in a specific sequence, leading to a global bridge structure response similar to a seismically-isolated system. Because the bridge would typically exhibit a stiff response, only developing an isolated response during major earthquakes, the bridge superstructure response may be described as quasi-isolated. This paper presents results for elastomeric bearing components obtained for an experimental program performed to investigate and characterize various bearing types that are being used for quasi-isolated designs. The elastomeric bearings investigated displayed approximately linear elastic response before sliding with a friction coefficient in the range of 0.3 – 0.45, at a shear strain in the range of 150 – 250%. The experiments also investigated the response of anchored retainer brackets used to prevent transverse motion for service loads and small earthquakes to characterize the combined effects of shear and overturning up to and including rupture of the concrete anchor. The test data indicate that the required horizontal force delivered by a bearing to a retainer to cause a failure of the anchor is slightly higher than the ultimate pure tensile strength of the anchor.

INTRODUCTION

Seismic isolation has been implemented as an effective means of earthquake damage mitigation in structural engineering, with some of the earliest patents dating back to the turn of the 20th century, and increasing frequency from the 1970s onward (Buckle and Mayes, 1990). Isolation systems have typically been used in high-seismic areas, such as the west coast of the United States, Japan, and New Zealand, where additional design and construction costs are justifiable in light of the seismic hazard. For bridges outside of high-seismic areas, however, commonly employed components to permit thermal displacements of superstructures inherently possess properties suitable for isolation systems. Consequently, a quasi-isolated design that relies on thermal expansion devices to also provide seismic energy dissipation can be an appealing alternative within the suite of earthquake protection design options, providing the benefits of reduced force demands, as long as the structural system is designed to account for the associated increased displacements of an isolated response.

The Illinois Center for Transportation (ICT), working in conjunction with the Illinois Department of Transportation (IDOT), is currently investigating the behavior of bridge systems to calibrate and refine IDOT's Earthquake Resisting System (ERS) methodology. The IDOT ERS philosophy relies on prescribed sequential "fusing" (i.e., exceeding ultimate capacity) of specific components, arranged by levels ranging from 1 to 3 (Tobias et al., 2008). The dual use of thermal expansion components for seismic energy dissipation is a key feature of the IDOT ERS. Level 1 requirements are intended to provide a force capacity threshold to ensure elastic response to service loads and small to moderate earthquakes, and Level 2 requirements address displacement demands following Level 1 fusing.

IDOT bridges commonly employ elastomeric bearings to permit thermal deformations of the superstructure. The experimental program includes tests of two types of elastomeric bearings: steel-reinforced elastomer only (IDOT Type I), and steel-reinforced elastomer combined with a flat Teflon sliding surface (IDOT Type II). Both types of elastomer bearings include stiffened L-shaped retainer brackets to restrain transverse motion of the superstructure. The first tests of the experimental program focused on the response of the components of Type I bearings and individual retainer response.

EXPERIMENTAL TESTING SETUP

The experimental tests were performed at the Newmark Structural Engineering Laboratory at the University of Illinois, using a testing apparatus shown in Figure 1, designed to realistically reflect field conditions for the typical, full-scale bridge bearing specimens.

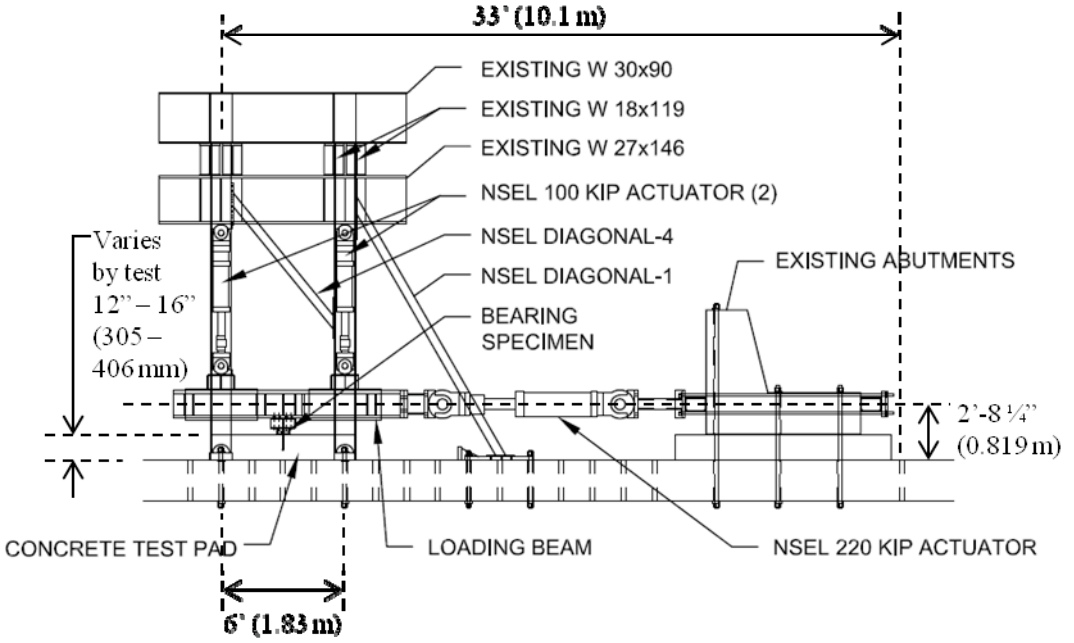

Figure 1. Testing Setup Elevation

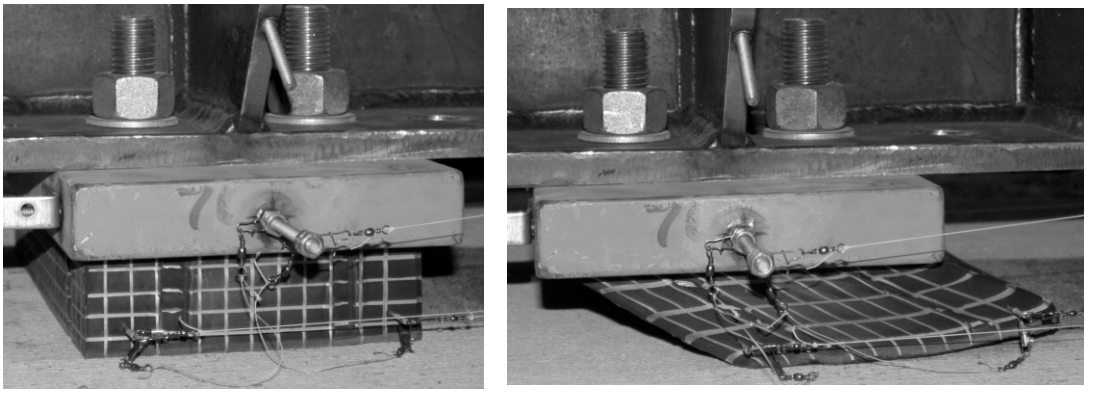
The primary objective of the testing program was to simulate large lateral deformations of elastomeric bearings that may occur due to seismic excitation. Based on preliminary analyses of full bridges in conjunction with a review of literature documenting previous tests of elastomeric bearings (Stanton and Roeder, 1982; Roeder et al., 1987; Kulak and Hughes, 1992; Mori et al., 1999), a target of 400% shear strain was selected for the testing program. The largest bearings included in the testing program were comprised of 5 layers of 5/8" (15.9 mm) elastomer layers, for an equivalent rubber thickness of 3.125" (79.4 mm), and an associated 400% shear strain of 12.5" (317.5 mm). A 30" (762 mm)-stroke, 220 kip (980 kN) capacity actuator was employed to provide the required 25" (635 mm) horizontal displacement capacity for fully reversed cyclic tests.

The vertical loading and support was designed to capture the lateral response realistically. Vertical loading was imposed on the bearings using a pair of 100 kip (445 kN) capacity actuators reacting against a steel frame secured to the laboratory strong floor with pretensioned anchors. The use of a pair of actuators allowed the vertical load to be maintained at a specified target of simulated gravity load, regardless of the lateral displacement of the bearing. Concrete pads were cast to simulate typical bridge substructures, including a brushed finish as specified by IDOT (IDOT, 2007), to ensure that the frictional response of elastomers bearing on concrete was captured realistically. A concrete pad is secured to the strong floor during a test by using pretensioned anchors around the perimeter of the pad.

The experimental results presented in this paper are for specimens and parameters listed in Table 1. Dimensions of test specimens conformed to standards used by IDOT, and full details for the test specimens may be found in the IDOT Bridge Manual (IDOT, 2009). The specimens in Table 1 represent only a portion of the



complete testing program. The complete program also includes tests of 13c bearings, Type II 7c bearings, and fixed bearings, with tests performed on bearings oriented to simulate both longitudinal and transverse loading for all types of bearings.

ELASTOMERIC BEARING EXPERIMENTS

Displacements of Type I and Type II bearings include both shear deformations in the elastomers, and frictional sliding, so deformations are referred to using "equivalent shear strain" for convenience. For the Type I bearings, sliding occurs at the elastomer-concrete interface. The first experiments imposed horizontal displacements simulating deformations parallel to a bridge span. Images captured at the initiation of lateral displacement and incipient sliding are shown in Figure 2.

(a) Initiation of Lateral Displacement **(b) Incipient Sliding**

Figure 2. Still Captures of Test Specimen #1 during Test #1

The bearing shown in Figure 2 is a typical Type I 7c bearing, composed of a steel top plate bonded to a block of steel-reinforced elastomer during vulcanization. The top steel plate measures 8" x 14" in plan, and 1-1/2" thick (203 x 356 x 38.1 mm), and the reinforced elastomer is composed of 5 layers of elastomer, each measuring 7" x

12” x 3/8” (178 x 305 x 9.53 mm), with each layer separated by a 3/32” (2.38 mm) thick steel shim. With 5 layers of 3/8” elastomer, the equivalent rubber thickness of the bearing is 1.875” (47.6 mm), corresponding to a maximum displacement during tests of 7.5” (190.5 mm). The steel top plate is tapped with four holes so that the plate can be bolted to the bottom flange of a steel girder in the field, which was simulated with a built-up steel plate fixture for the experiments. Lines were drawn on the sides of the elastomer so that deformations could be more easily seen. Horizontal lines correspond to locations of internal steel shims, and vertical lines were added to construct a grid of approximately square spaces. Steel studs were welded to the top plate, and needles were inserted into the elastomer so that string potentiometer lines could be attached and used to record displacements of the specimen.

Elastomeric bearings used by IDOT are designed based on vertical load limitations of 1.38 to 5.52 MPa (200 to 800 psi). Based on discussions with an internal technical review panel assembled within IDOT, a typical simulated gravity load was set at 3.45 MPa (500 psi). Initial tests to identify fundamental constitutive response were performed by imposing monotonic horizontal shear deformations from rest up to 400% equivalent shear strain. Data from the initial tests is shown in Figure 3 through Figure 5.

All tests in Figure 3 were performed with a common simulated gravity load of 3.45 MPa (500 psi). All loading was removed from test specimens for approximately 1 day between tests so that the elastomer could recover from any scragging that may have developed in a previous test. In the case of these tests, however, deterioration of the bearing elastomer was not limited to hyperelastic material response. When the elastomer is ground against the surface of the concrete, portions of the elastomer are permanently removed by abrasion, in particular at the leading edge of the elastomer base in the direction of motion. The bearing edge appeared chamfered at a roughly 45º angle after the first test. The mechanism appeared to stabilize in the succeeding tests however, based on the difference in lateral force versus displacement evident between Test 1 and Tests 2 and 3.

Large deformations of elastomers reported in the literature typically consider bearings with different construction details (e.g., use of both top and bottom plates to secure bearing to super- and substructures) and material properties (high damping versus low damping elastomers). Consequently, one of the primary points of interest for these bearing experiments was to establish the response of bearings that have not been specifically designed for seismic effects when subjected to deformations larger than typical non-seismic limitations of 50 – 70% shear strain. In general, elastomers are expected to stiffen significantly when subjected to large deformations, regardless of whether the elastomeric material would be classified as high-damping or low-damping. For the tests represented in Figure 3 through Figure 5, a material softening branch was not observed, and a stiffening branch appeared to be precluded by the initiation of sliding.

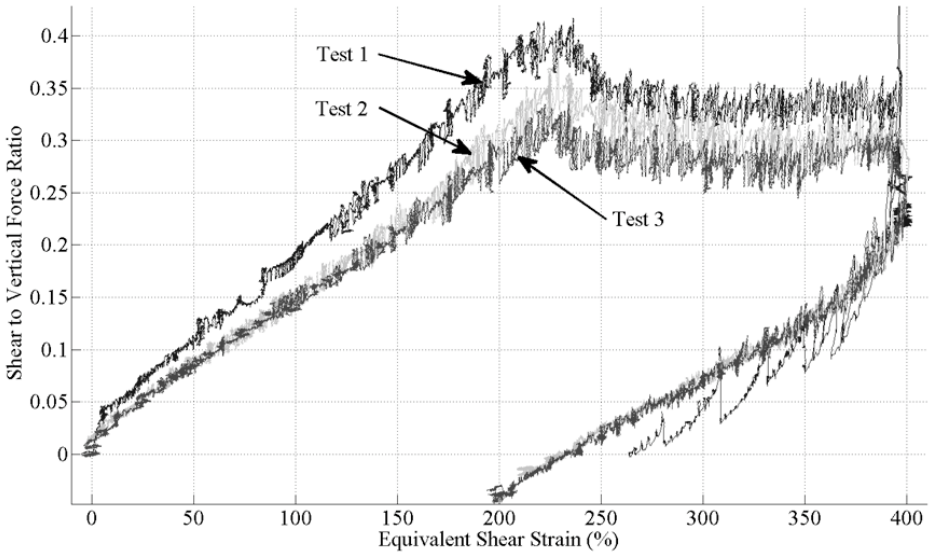

Figure 3. Successive Monotonic Tests of Type I bearing, all tests with 3.45 MPa (500 psi) simulated gravity load

To investigate the response of the bearing when subjected to varying gravity load cases, a series of monotonic tests were performed in the opposite direction from the first three tests. Tests were performed successively, with the typical delay between tests to allow for scragging recovery, in a sequence of 3.45, 2.59, 1.38, and 3.45 MPa (500, 375, 200, and 500 psi). As would be expected, the slip load of the bearings decreases as the applied vertical load decreases, and so the lower vertical load also results in less shear deformation, and a larger proportion of sliding for the imposed monotonic displacement, as seen in Figure 4. The variation in slip load is not, however, linearly scaled with imposed vertical load. Whether due to a reduced curling of the elastomer base with the lower gravity load, or differences at a microscopic level of interaction at the interface of the elastomer and roughened concrete, the data shown in Figure 5 indicate that the coefficient of friction is correlated inversely with the applied vertical load. At a load of 3.45 MPa, based on Figure 3 and Figure 5, the coefficient of friction for sliding is approximately 0.3 – 0.35, and slightly higher at 2.59 MPa, tending to fall at or slightly above 0.35. When the vertical load is decreased further, to 1.38 MPa, the coefficient of friction increases to approximately 0.45.

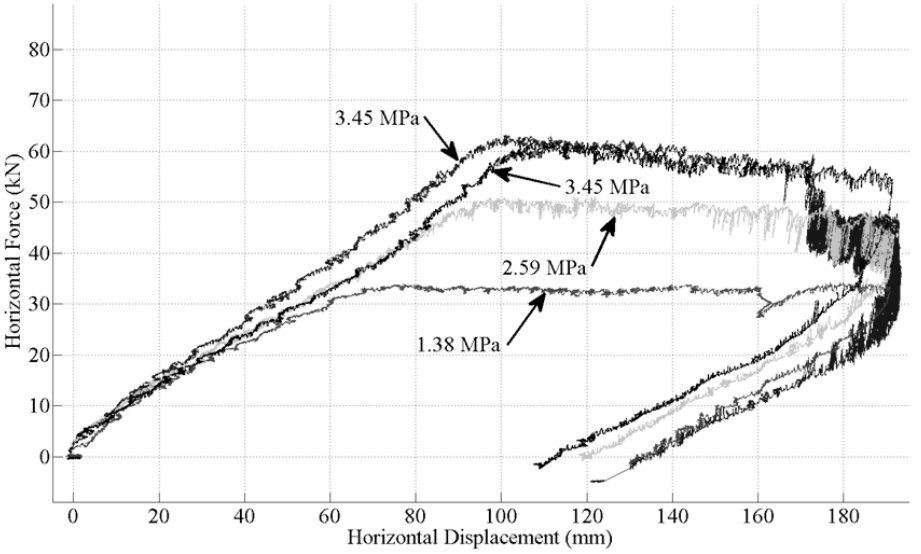

Figure 4. Successive Monotonic Tests of Type I bearing, varying simulated gravity load, load versus displacement

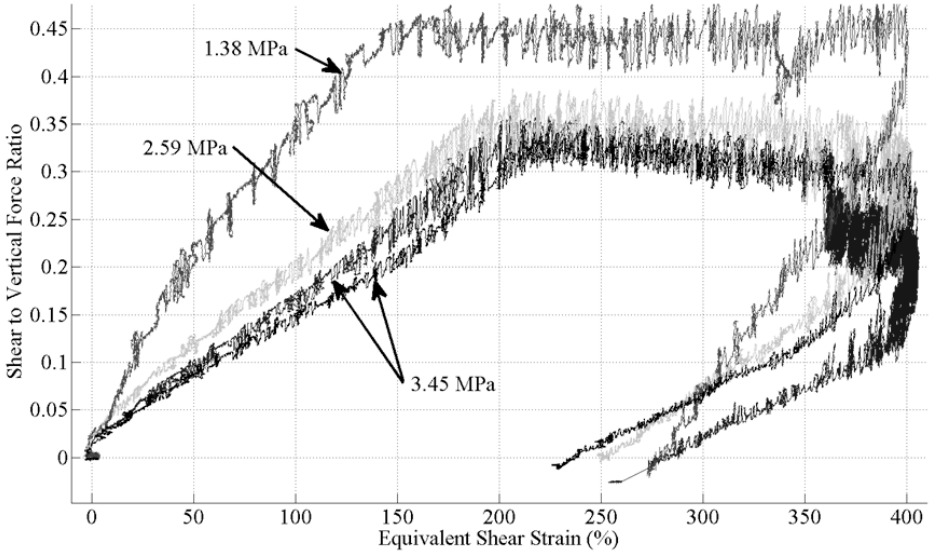

Figure 5. Successive Monotonic Tests of Type I bearing, varying simulated gravity load, horizontal to vertical load ratio versus shear strain

To investigate the cyclic response of Type I bearings, tests were also performed with cyclic loading protocols as follows: seven fully reversed cycles @ 25% and 50% equivalent shear strain, three fully reversed cycles @ 100%, 200%, 300%, and 400% equivalent shear strain. Tests were also performed for several levels of simulated gravity load. The first test, using a new bearing, was conducted with a simulated gravity load of 1.38 MPa (200 psi), and provided the data shown in Figure 6. The next test, also using a new bearing, was conducted with a simulated load of 3.45 MPa (500 psi), and generated the data shown in Figure 7. Finally, the bearing that had

been tested with a 1.38 MPa simulated gravity load was retested with the maximum permissible simulated gravity load of 5.52 MPa, shown in Figure 8.

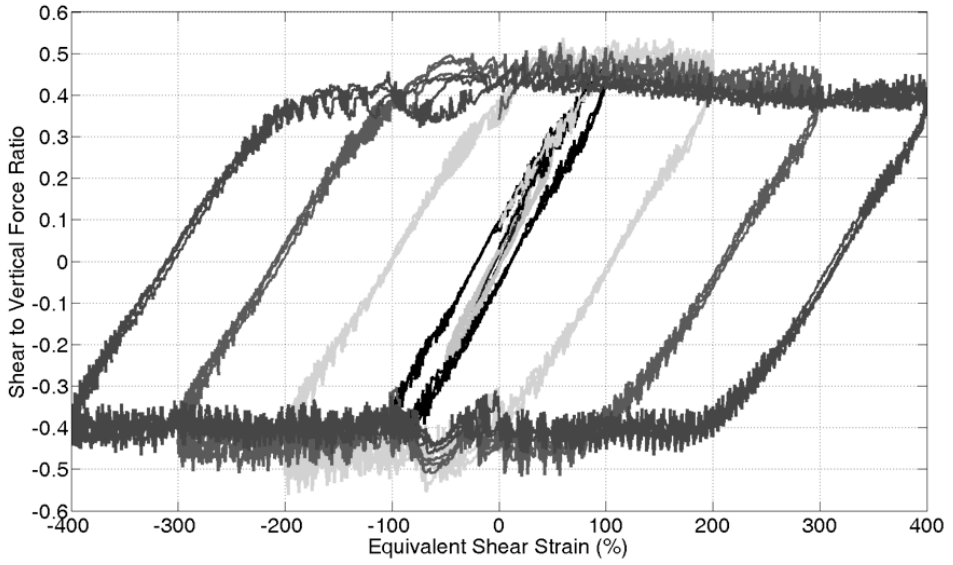

Figure 6. Cyclic Tests of Type I bearing, 1.38 MPa simulated gravity load

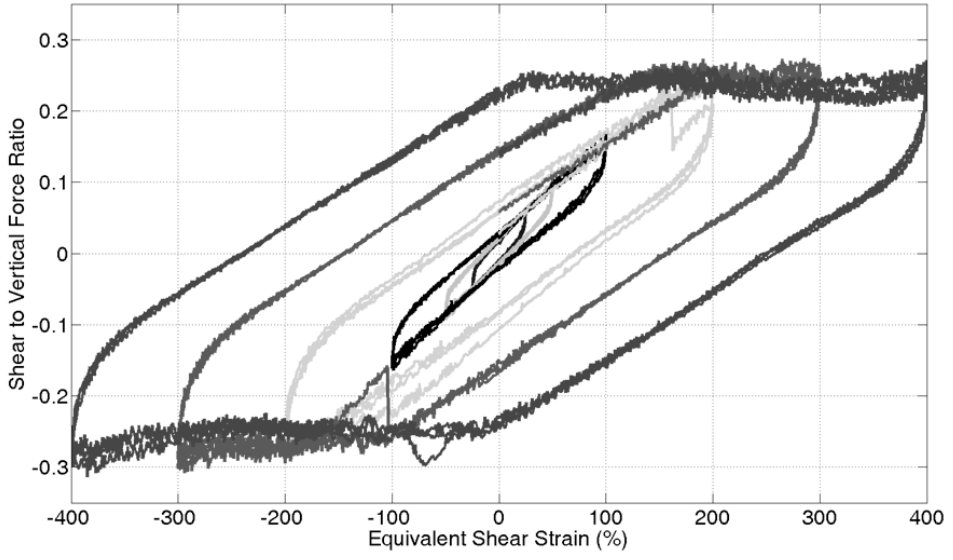

Figure 7. Cyclic Tests of Type I bearing, 3.45 MPa simulated gravity load

The three sets of test data reflect results similar to the monotonic tests for similar testing parameters. For example, the slip coefficient for the bearing subjected to the lightest simulated gravity load was significantly higher than for the tests at higher gravity loads, similar to Figure 5. The values ranged from approximately 0.4 – 0.5 at 1.38 MPa, to approximately 0.2 – 0.25 at 5.52 MPa. Other aspects of the response can only be observed in the cyclic tests, rather than the monotonic, such as the apparent degradation of bearings with successive cycles. Rather than being

consistent across all results, however, the influence of the cyclic degradation appears to be correlated to the testing parameters.

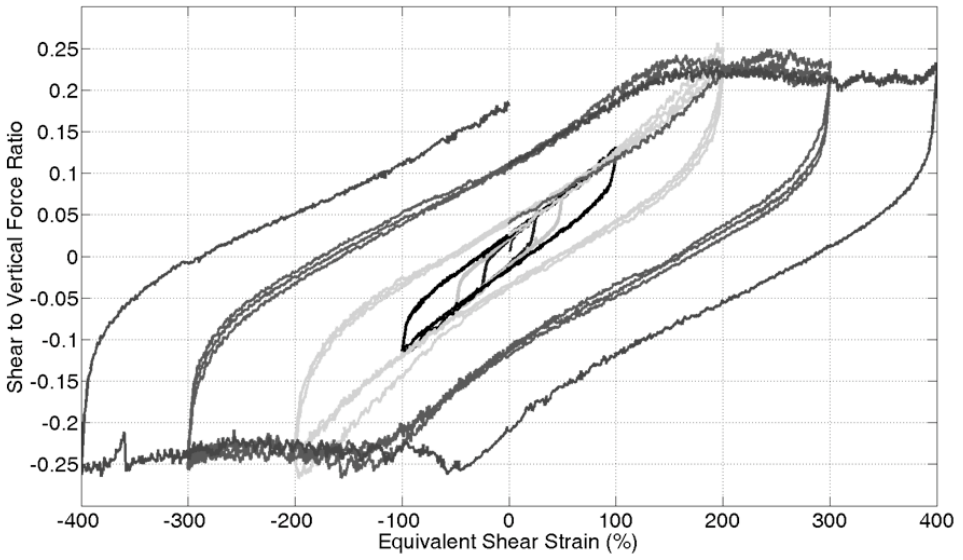

Figure 8. Cyclic Tests of Type I bearing, 5.52 MPa simulated gravity load

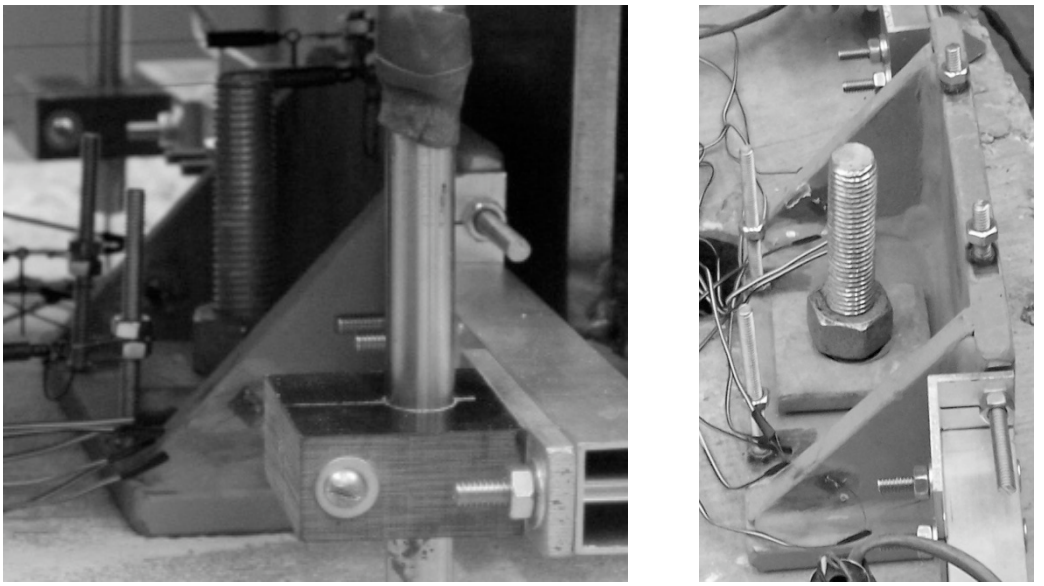

The data in Figure 6 show a continuous degradation in slip force with increasing cycles, suggesting that the degradation is tied to the bearing's travel on an abrasive surface. For the other two cases, however, in Figure 7 and Figure 8, degradation does occur on successive cycles, so long as the maximum displacement does not increase. When the maximum displacement increases for a new stage of the loading protocol, however, the frictional resistance increases at the maximum and minimum limits of displacement. This suggests that the degradation is partially influenced by abrasion of the elastomer base, but also by the condition of the concrete surface, so that "clean" surfaces which the bearing is traveling over for the first time possess greater frictional resistance than locations where the bearing has already deposited portions of elastomer by previous abrasions.

Regardless of the source of these variations, the effect appears to be minor overall. For large deformations, there is a stable response of linear elastic loading followed by frictional slip, with no visible damage other than minor abrasion of the elastomer base for gravity load up to 3.45 MPa. The test with 5.52 MPa was terminated prematurely for reasons other than the condition of the testing specimen. However, upon inspection following the test, the bearing had been deformed and ground against the concrete so severely that the edge of the lowest internal shim was visible.

RETAINER BRACKET EXPERIMENTS

To resist lateral translations of the bridge superstructure under service conditions and small seismic events, IDOT uses a standard detail for a stiffened L bracket, with a single holddown anchor installed into the concrete substructure. Figure 9 shows the

first tested retainer bracket mounted in the testing setup, prior to the test, and dismounted after the test is performed. Displacements were measured during the test with a combination of four string potentiometers and two LVDTs mounted with brackets to the sides of the retainer. Visible damage was limited to the threaded anchor and the concrete near the embedded anchor.

(a) Installed and Instrumented Prior to Test **(b) Dismounted After Test**

Figure 9. Still Captures of Retainer #1

A schematic view of the test setup prior to the start of the test is shown in Figure 10. The anchor is installed to an embedment of 9 inches (230 mm). The top plate of a Type I bearing was simulated by using the steel fixture of the testing frame to push against the face of the retainer.

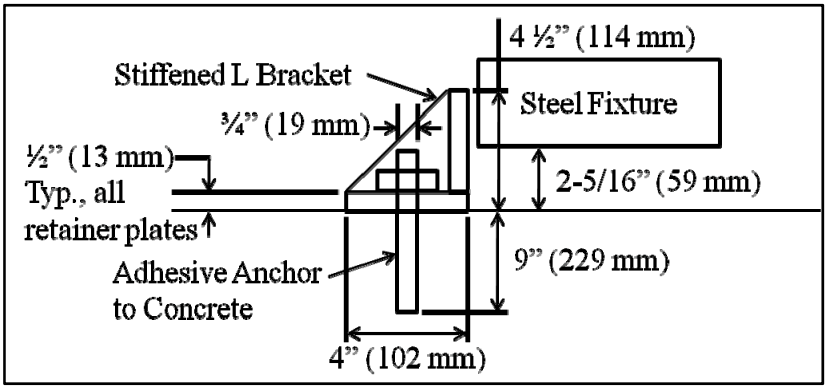

Figure 10. Schematic of Retainer Test Setup, Prior to Test

The contact height of the steel fixture caused the retainer to rotate as well as slide, as shown in Figure 11, and inducing the loading shown on the free-body diagram in Figure 12.

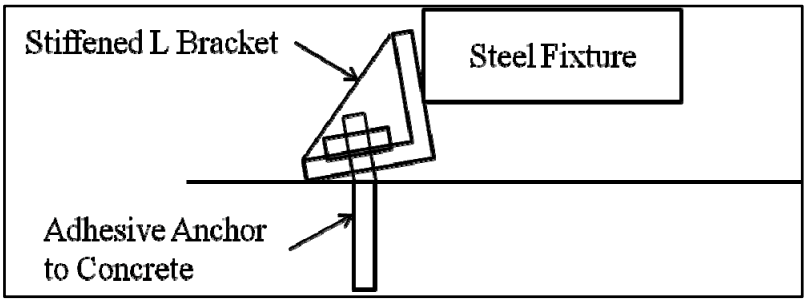

Figure 11. Schematic of Retainer Test at Incipient Failure of Anchor

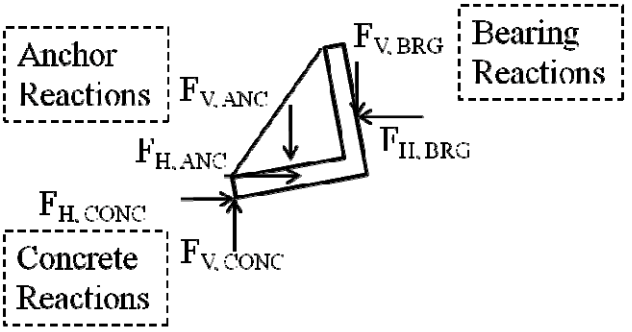

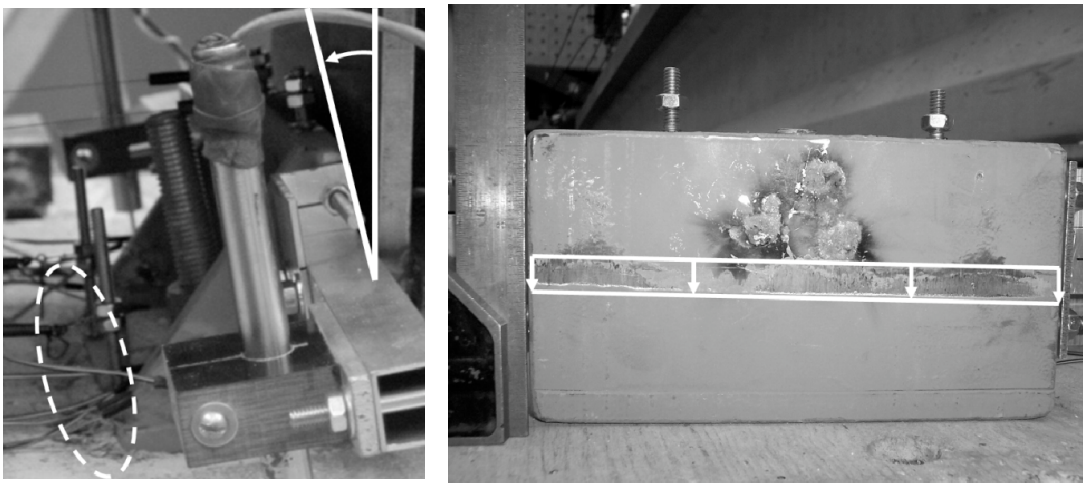

Figure 12. Free-Body Diagram of Reactions on Retainer at Incipient Anchor Failure

(a) Mounted, at Incipient Failure **(b) Face of Retainer After Test**

Figure 13. Still Captures of Retainer #1 Overturning Effects

As the retainer began to rotate, the toe of the retainer was driven into the concrete, as seen in Figure 13(a). An oval in the lower left of the image has been drawn to highlight the concrete being crushed at the toe of the retainer. The gap opening at the top of the retainer due to rotation is also indicated on the right-hand side of the image. Simultaneously, the retainer was developing a vertical load, at the contact location of the steel fixture, also contributing to the prevention of retainer rotation, and relieved by intermittent slips of the steel fixture along the vertical face of the retainer. This effect was evidenced by jumps in the vertical load recorded during the experiment,

combined with the scraping of paint where the steel fixture slipped against the retainer, shown in Figure 13(b).

The maximum horizontal force recorded during the retainer test was 29.6 kips (132 kN), using a 3/4" (19 mm) threaded anchor to the concrete test pad. Anchor material was specified as ASTM F1554, Grade 36, however, random selection of three anchor samples for tension tests indicated that the material was likely rejected Grade 55 material. Ultimate strengths obtained from the three tension test specimens were 84.7, 73.9, and 73.5 ksi (584, 510, and 507 MPa). Dividing the maximum horizontal force by the effective area of the threaded anchor (per ASTM F1554), the resulting stress is 88.5 ksi (610 MPa), slightly higher than the average ultimate strength of the tension test specimens.

The typical IDOT design procedure for the retainer used in this test would have estimated the "fuse" capacity to be 9.5 kips (42.3 kN) for Grade 36 material, or 11.9 kips (52.9 kN), even if Grade 55 had been assumed. These values are determined by accounting for tension demands on the concrete anchor with a reduced resistance factor. The current design approach neglects shear resistance at the toe and induced vertical load on the bearing plate on the retainer face. With respect to the overarching design strategy, this test indicated that the force required to transition to a quasi-isolated response would be approximately 3 times greater than expected, regardless of material strength assumed, indicating that the calculation methodology to estimate fuse strength of retainers should be calibrated for future versions of the IDOT ERS to prevent the development of unexpectedly high lateral forces in the structural system.

COMPUTATIONAL MODELING

Computational modeling is in development using Abaqus (2010), which will use the experimental data for calibration. The computational models will then be used to consider variations in parameters beyond those tested, such as material strength of various components, to investigate the associated effects on the bearing response. Preliminary models of elastomeric bearings are 2D plain strain models, with quad elements used for elastomeric material and the steel top plate, and beam elements used to model the thin internal steel shims. The Yeoh (1993) model was selected to capture the hyperelastic response of the elastomer. The top steel plate and internal shims are tied rigidly to the surrounding elastomer elements, and both the base and sides of the elastomer are modeled with hard contact and friction slip interactions relative to the rigid part representing the concrete test pad. Images showing the bearing with 3.45 MPa gravity load applied at the start and at the end of a monotonic displacement are shown in Figure 14 and Figure 15.

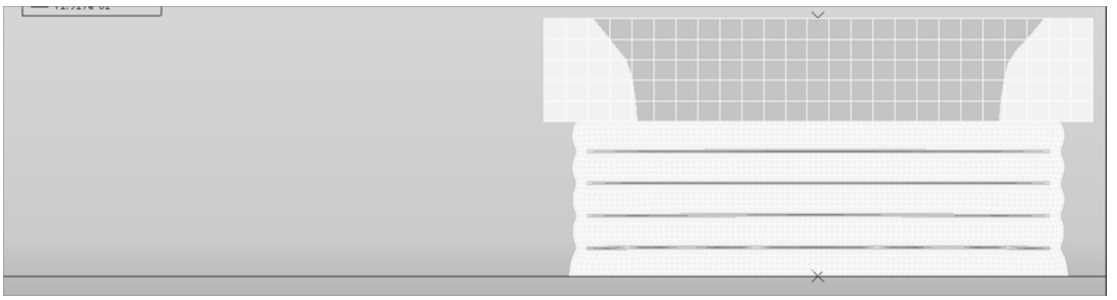

Figure 14. Type I 7c Bearing Model, Gravity Load Only

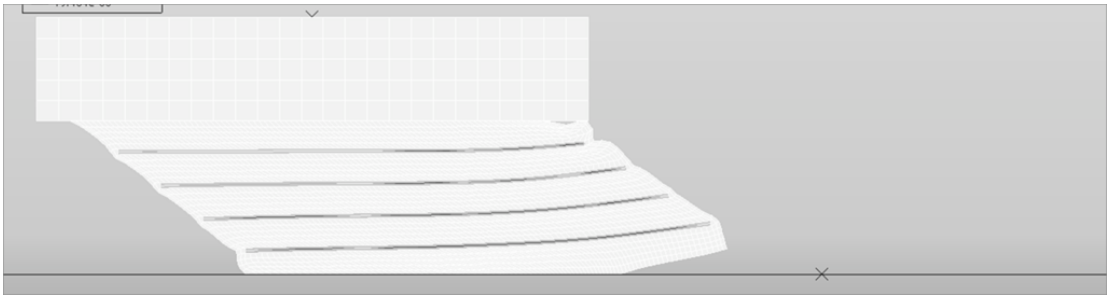

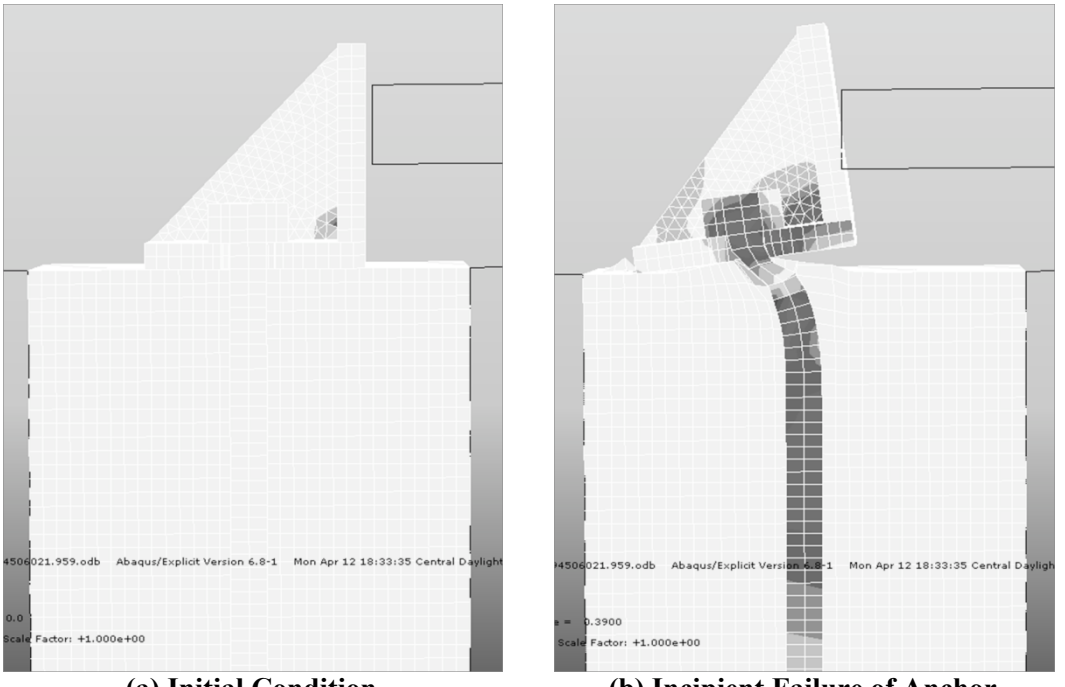

Figure 15. Type I 7c Bearing Model, Displaced to 400% Equivalent Shear Strain

(a) Initial Condition **(b) Incipient Failure of Anchor**

Figure 16. Computational Retainer Model

The preliminary retainer model includes a damage evolution model with element removal for the steel, to capture the degradation and rupture of the concrete anchor. The bottom and side of the retainer are modeled with contact interactions to permit contact and separation of the bearing top steel plate on the side, and the concrete surface on the bottom, using both hard contact for normal interactions and friction sliding for tangential interactions. Screen captures of the initial condition and

incipient failure of the anchor from the retainer model in Abaqus are shown in Figure 16, above.

CONCLUSIONS

The experimental testing program has generated data indicating that typical Type I bearings used by IDOT, incorporating low damping elastomers, can generally be characterized with linear elastic response for light to moderate loads, even at large displacement demands on the order of 250% shear strain, because the elastomer is permitted to slide on the concrete substructure, thereby precluding a stiffening branch. A stiffening branch may, however, begin to appear in the constitutive response for very large gravity loads.

Furthermore, repeated monotonic tests on a single bearing, along with cyclic tests incorporating multiple reversed cycles up to 400% equivalent shear strain, indicate that the bearings are remarkably resilient. Scragging and deterioration effects appear minor in most cases. The bottom surface of the elastomer is visibly worn and roughened by being dragged across concrete through multiple cycles of large displacements, but the visible abrasions appear to have only a minor influence on force-displacement response. Furthermore, delamination was not observed externally, and the only visible damage extending to the internal shims was for the case of the highest tested vertical load.

Characterization of retainer response can be relatively complex. The retainer is subject to overturning resistance at the toe, as well as an induced vertical load at the bearing plate. The orientations and magnitudes of the loads are therefore somewhat difficult to predict, and the fuse capacity of the sacrificial retainer during a major seismic event may be significantly underestimated by current design techniques in use by IDOT. The data indicate that for the retainer tested, the shear resistance is equivalent to slightly more than the full ultimate capacity of the concrete anchor.

The data presented in this paper are representative of only an initial set of experiments. The completed experimental program will also include experiments of larger, 13c Type I bearings, Type II 7c bearings, and fixed bearings. All bearing types and sizes are tested for loading in both longitudinal and transverse orientations. The complete set of experiments will be used to calibrate a suite of computational models, and the parametric variations of the computational models will be used to formulate appropriate models to capture the response characteristics of quasi-isolated full bridge structures in global bridge models.

ABSTRACT

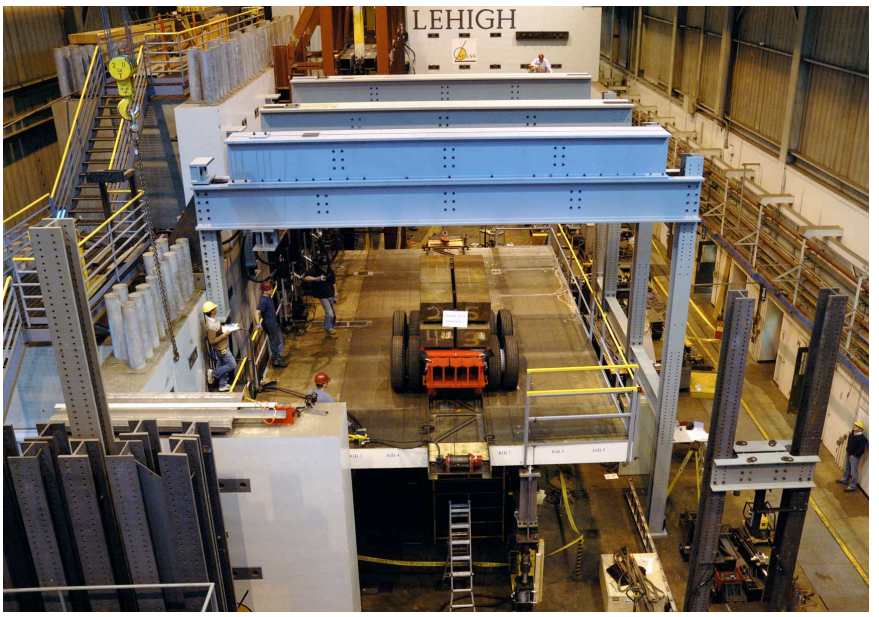
Recently a full scale prototype of a steel orthotropic deck was evaluated for a signature bridge in the ATLSS Engineering Research Center, Lehigh University. The deck was innovatively designed to be integral with the existing deck framing system. Since fatigue critical live load stresses at welded connections in an orthotropic deck can be produced by different loading dispositions, the response of the prototype deck was determined under a rolling tandem axle bogie in eight transverse positions. Global displacements at the specimen boundary were simulated by three under deck hydraulic actuators. The deck was instrumented using more than 300 sensors at critical locations. A 3D finite element model of the prototype deck was analyzed corresponding to the discrete axle positions and compared with experimental results. The prototype testing and the analytical studies provided critical understanding of the complex behavior of the deck and the influence surface/response envelopes under local wheel loads.

INTRODUCTION

Background. Steel orthotropic deck form is a natural choice for long span bridges, both for new design and rehabilitation. This light weight redundant deck form helps in reducing dead load stresses on the supporting cables, thereby increasing the life cycle of the main supporting elements and the bridge. In addition, a thin wearing surface on the orthotropic deck provides sufficient overlay for durability, improved riding quality and low maintenance. Despite these advantages and successful implementation of this deck system around the world, the use of orthotropic deck form in the United States has been limited, primarily because of increased efforts required for advanced analysis and design, relatively high initial cost owing to intensive fabrication, and higher possibility of in-service fatigue cracking from a large number of welded connections. Particularly several of the welded details are the bulkhead/sub-floor beam to rib connections and the rib to deck welds that are subjected to complex in-plane and out-of-plane deformations under localized wheel

loads (Gajer et al. 1996). Response of orthotropic decks are mostly manifested locally under wheel loads. Depending on the longitudinal and transverse disposition of loads, the deck elements can be subjected to a complex combination of in-plane and out-of-plane stresses that are significantly larger compared to the global nominal stresses. The critical live load stresses at a connection can be produced by different loading dispositions, and accordingly designing orthotropic deck requires a knowledge of the influence surface under wheel loads.

Recently the fatigue performance of a full scale prototype of an orthotropic deck was evaluated at the ATLSS Engineering Research Center, Lehigh University. The deck was proposed to replace the upper level deck of a signature double-decker bridge and was innovatively designed to be integral with the floor system and the stiffening truss. The test specimen comprised a quarter of the deck between the panel points of the stiffening truss, and included part of one floor beam and two stringers. To determine the critical live load disposition for the fatigue test, the deck response was determined under a rolling tandem axle bogie that was moved across the deck at about 5 mph. The tandem configuration was as per the AASHTO specification and the bogie was rolled in eight transverse positions. Global displacements at the boundary of the prototype deck were simulated by three actuators located under the floor beam and the two stringers. The deck was instrumented using more than 300 sensors at critical locations. A 3D finite element model of the prototype deck was analyzed corresponding to the discrete tandem axle positions and compared with experimental results to understand the complex behavior of the deck and to develop influence surface/response envelopes under local wheel loads. The prototype testing and the analytical studies provided critical understanding of the behavior of an orthotropic deck that was integral with the deck framing system, and provided valuable information for design improvement and optimization in achieving more than 100 years service life.



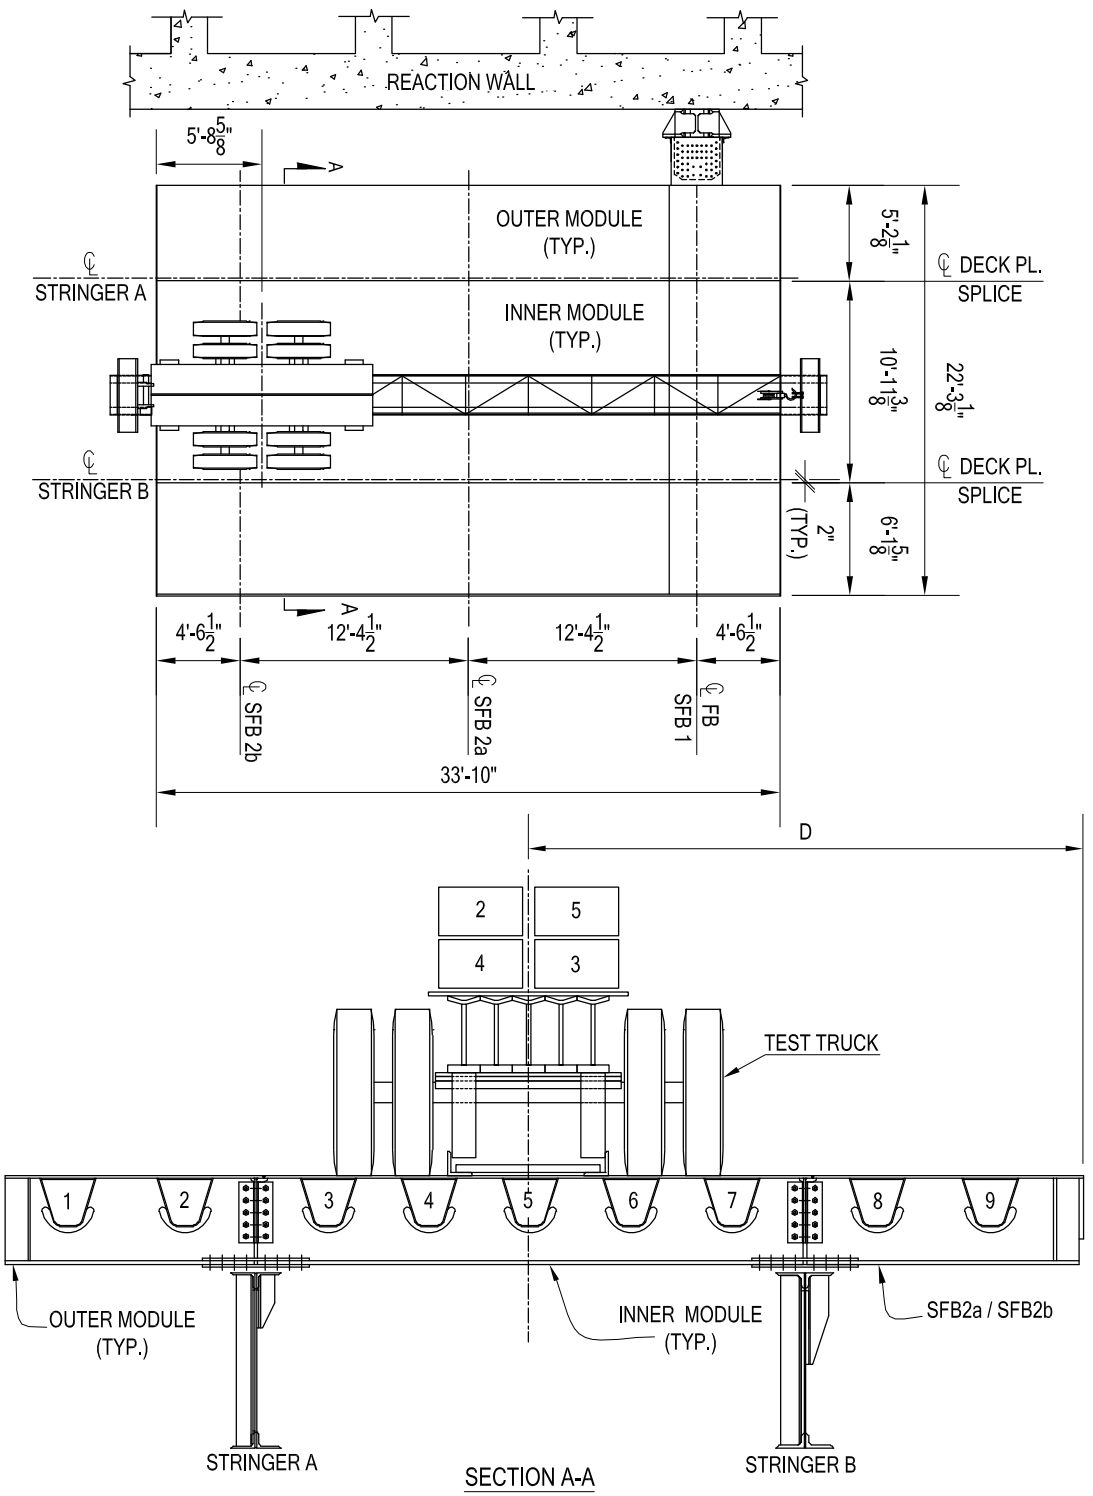


Figure 1. Test setup in the ATLSS Center, Lehigh University.

Test setup. The test setup at the multi-directional testing facility in the ATLSS Engineering Research Center, Lehigh University is shown in Figure 1. To reproduce realistic conditions, the test setup comprised part of the upper level floor framing of the bridge including full size stringers and floor beams. The horizontal members of the transverse box at each node of the stiffening truss constituted the floor beams to the upper and lower decks. These members consisted of built-up box sections that were evidently quite stiff and were expected to form fixed end connections with the vertical members. Accordingly, the west end of the floor beam in the prototype deck was rigidly connected to the strong wall to simulate fixed end support. The stringers, framing into the floor beam in the bridge, were cantilevered off the floor beam in the setup. The east end of the floor beam and the south ends of the stringers were supported by actuators reacting vertically against the strong floor to impose continuity boundary condition only in the vertical direction. The top and bottom clevises of the actuators were arranged such as to allow axial displacement of the stringers and the floor beam. The play in the clevises allowed sufficient movements in the other four degrees of freedom. Another 4 ft 6½ in of the stringers were cantilevered to the north of the floor beam to support a part of the deck that was included to simulate the transverse field splices.

Description of prototype deck. The prototype deck was 6.8 m (22 ft 3 in) wide and 10.3 m (33 ft 10 in) long, and included a standard inner module, and two outer modules, and typical longitudinal and transverse field welds between the deck panels. No wearing surface was provided on the 16 mm (5/8 in) thick deck plate. The typical inner module consisted of five trapezoidal ribs at 635 mm (2 ft 1 in) spacing. The outer module had two ribs at 2 ft 5 in spacing. The ribs were 305 mm (1 ft) deep and 8 mm (5/16 in) thick.

The deck was made integral with the supporting stringers and floor beams using stringer extensions and sub floor beams. The prototype deck contained three transverse sub-floor beams at 3.8 m (12 ft 4½ in) centers. One sub-floor beam was fastened to the main floor beam and identified as SFB1. The other intermediate sub-floor beams, identified as SFB2a and SFB2b, were 560 mm (22 in) deep and had 16 mm (5/8 in) thick web. The sub-floor beams were provided with cutouts for pass-through ribs. At the sub-floor beam connections, the ribs were provided with full depth internal bulkheads (diaphragms). The bulk-head plates were 8 mm (5/16 in) thick. The edges of the orthotropic deck were maintained free.

The prototype deck was fabricated with ASTM A709 Grade 50 steel.

Figure 2. Crawl test plan.

CRAWL TESTS

Crawl truck. The response of the prototype deck was determined under a bogie with tandem axles that was rolled along the deck at a slow rate of about 0.038 mph. The bogie represented the tandem axles of a tractor-trailer with tandem configuration in accordance to HL-93 loading of the AASHTO LRFD Bridge Design Specifications. The axles were spaced 1.2 m (4 ft) apart. A pair of wheels were attached to each axle. The center-to-center distance between the wheel pairs in the transverse direction was 1.8m (6 ft). Retreaded truck tires, pressurized to 0.6 MPa (90 psi), were used on the wheels. To compare with the recommendations of the AASHTO Specifications, the tire contact for each wheel was measured on the laboratory floor. The average measurement of tire contact area was approximately 0.276 m × 0.532 m (10.88 in × 20.97 in).

The self-weight of the crawl truck was 7 tons (14.1 kip). The crawl truck was loaded with four steel billets identified in Figure 2 that weighed 9.1 kip, 10.6 kip, 10.5 kip and 9.4 kip respectively. The combined weight of truck and four billets was 24.5 tons (53.7 kip), which was about 2.2 times the trailer axle load of the AASHTO notional fatigue truck. The loads at each wheel pair of the loaded truck, measured using a portable scale (provided by PennDOT), were respectively 13.0 kip, 13.5 kip, 13.2 kip and 14.1 kip in clock wise rotation from front-left to rear-left wheel pairs.

Test procedure. To determine the load positions that produced the most critical live load stresses in the deck elements, the crawl truck was rolled along the deck in eight transverse positions. The centerline of the truck was positioned between ribs 3 and 7, which resulted in the outer wheel pairs being located between ribs 2 and 8. In the first position, the left wheels were located symmetrically above stringer extension B. In subsequent positions, the truck was positioned such that either one wheel or a wheel pair was located symmetrically on the deck plate in between the stiffening ribs, or over a rib. A typical position (position 5) is shown in Figure 2, where the right wheel pairs are located symmetrically on the deck plate between ribs 6 and 7. A truss along the length of the deck was used underneath the test truck to guide the truck in a straight line (Figure 2). The truck was pulled by a hydraulic winch attached to one end of the guide truss with the rope hooked underneath the test truck. For each position the truck was pulled forward and backward at an average speed of about 0.065 km/h (0.038 mph).

Instrumentation and data acquisition: The deck was extensively instrumented using about 400 data channels to determine the global response of the test deck and to monitor the local stresses at the fatigue sensitive rib-to-sub floor beam and rib-to-deck connections. About 250 bondable or weldable encapsulated metallic resistance strain gages of 6 mm (¼ in) gage length in uniaxial, biaxial and rosette configurations were installed.

Most of the strain gauges were installed on SFB1 and SFB2a at junctions with ribs 2, 3, 7 and 8, to capture the variation of stresses around the cutout and in the bulkhead plate. A typical arrangement of strain gauges at SFB2a and Rib 7 intersection is shown in Figure 3 All gages at the sub floor beam were placed back to back on the north and south faces of the web, to measure out-of-plane bending

stresses, except for the two rosettes at the cutouts in SFB2a below the ribs that were provided only on the south face. Rosettes were installed adjacent to cutouts abutting the sub-floor beam-to-rib weld, to measure the principal stresses at the cutout stress concentration, that could lead to fatigue cracking.

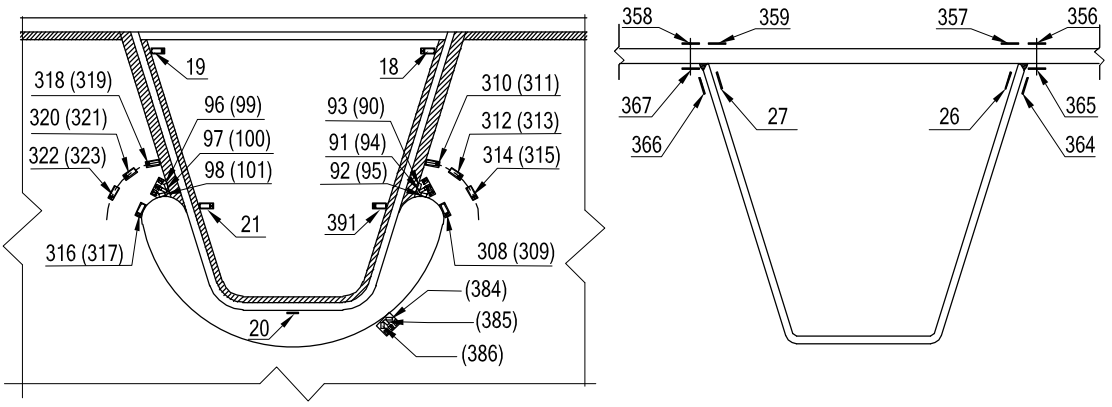

Figure 3. Typical gauge arrangement: (a) SFB2a; (b) Rib 7.

On the internal bulkhead plates in ribs 3 and 7, four strain gages were installed abutting the bulkhead-to-rib weld as shown in Figure 3. High temperature resistant weldable strain gages of 6 mm (1/4 in) length were used at the bulkhead plates so that they could survive the heat generated during the welding of subfloor beams to the ribs and the ribs to the deck plate. Two strain gauges of same type were installed on the internal face of rib wall in Rib 7 near the rib-to-deck weld at two sections 49.5 in and 99.0 in north of SFB2a. Conventional strain gauges were placed on the outer face of the rib wall, matching these internal gauges, to measure out-of-plane bending of rib wall. Similar back-to-back strain gauges were provided on the deck plate to the west of rib-to-deck welds at the same section (channel numbers 364 and 366), also to capture the bending stresses in the deck plate under wheel loads. The gauge arrangement at the section 49.5 in north of SFB2a is shown in Figure 3

Additional strain gauges were installed on: the deck plate at center line of sub floor beams; at deck splices; at soffit of ribs 3 to 7; at copes and seat angles of stringer extension; and at floor beam to wall connection plates. In addition, displacement of the deck was measured by Linear Variable Displacement Transducers (LVDT) at 10 locations. One LVDT was installed under SFB2a at the mid span between Stringer Extensions A and B, while the remaining nine LVDTs were installed underside the deck at the mid span section between SFB1 and SFB2a.

Data collection was performed by Campbell Scientific CR9000 digital data loggers.

FINITE ELEMENT ANALYSES

Modeling. FEA of the prototype deck including the floor beams and stringers was conducted using a commercially available package ABAQUS (Dassault Systèmes. 2010) to better understand the response characteristics of the deck. The model included all features of each component. The welded and bolted connections were not

modeled; instead all welded and bolted connections in a component were considered as integral and all bolted connections between components were displacement constrained. The boundary conditions were defined consistent with the test setup. Solid 20 node second order isoparametric reduced integration serendipity elements were used for modeling the components. The model consisted of 691,000 elements, 4,400,00 nodes and 13,200,000 degrees of freedom.

Analyses. The model was analyzed for the for eight discrete load dispositions in the longitudinal direction simulating the crawl tests. All eight transverse positions were analyzed. The loads were applied as pressure on 10 in × 20 in tire footprints according to the AASHTO LRFD Bridge Design Specifications.

All analyses were conducted on a distributed memory parallel execution computer cluster of 16 machines, each having eight central processing units (cpu). The analyses were linear elastic and used direct solver.

A deformed configuration of the model is shown in Figure 4

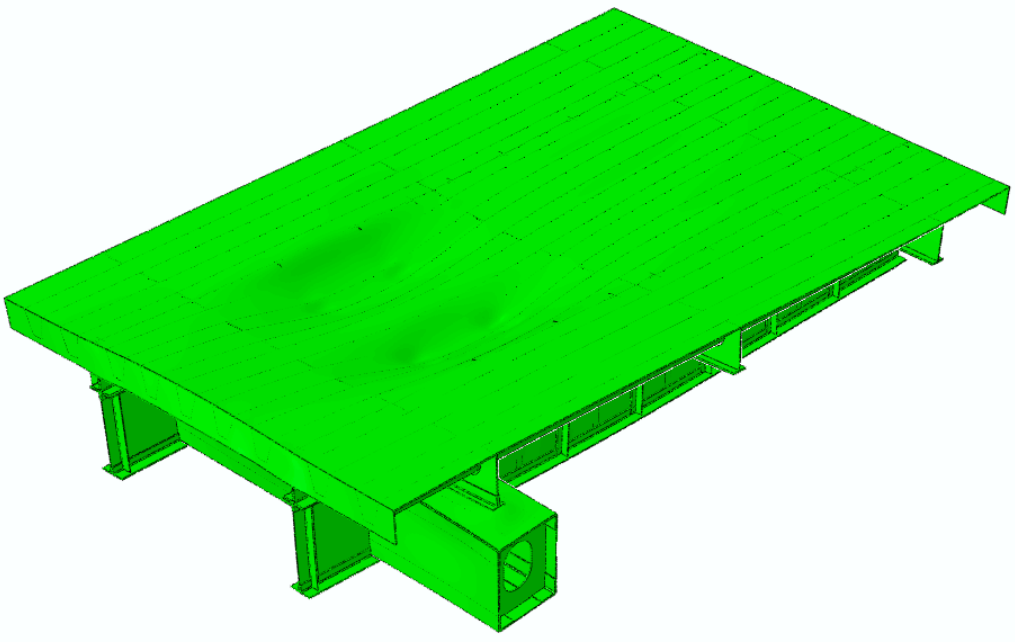

Figure 4. Deformed configuration of deck.

DISCUSSION OF RESULTS

Rib-to-deck connection. Response of the rib-to-deck plate connection under longitudinally and transversely varying wheel positions are shown in Figure 5 and Figure 6 with respect to Rib 7 at the instrumented section 49.5 in and 99.0 in north of SFB2a. These figures show the variation of stress measured at a gauge as the crawl truck traversed along the deck in transverse position 5 from south to north. The horizontal axis of the plots show the position of the crawl truck centerline (center of the wheels) with respect to SFB2a, which is taken as origin. Also shown on the plots

are the results obtained from FEA and the truck positions corresponding to the peak stresses.

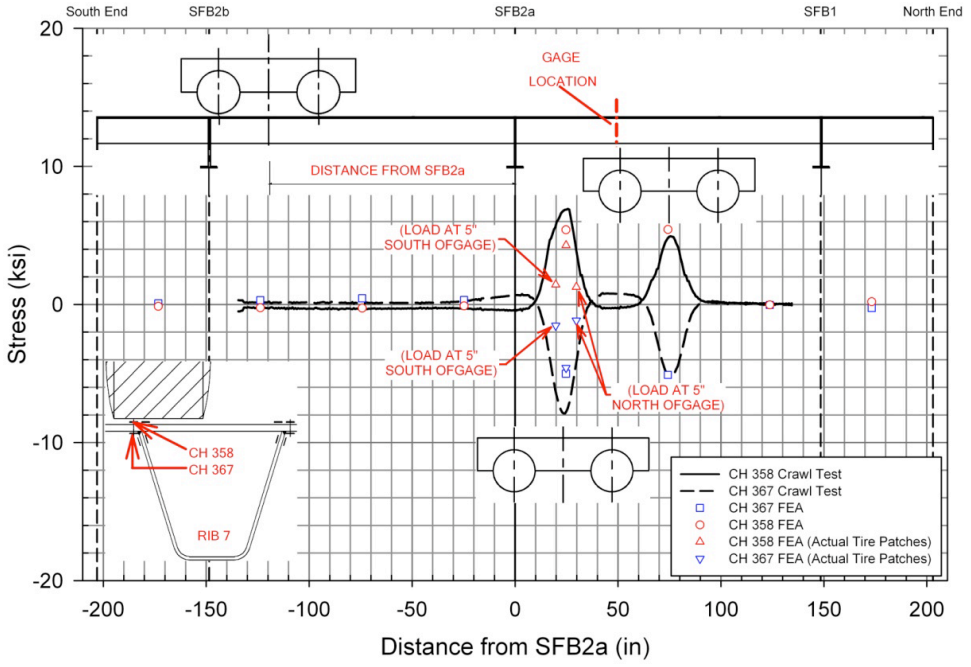

Figure 5. Crawl test result in deck plate at rib-to-deck connection: Position 5

Typically the response of the rib-to-deck connection at a section was manifested by the presence of wheel load in the vicinity of the section. As the truck rolled across the deck, peak stresses were observed at the wheel locations. Figure 5 shows the normal stresses in the transverse direction measured at the back-to-back uniaxial gauges on the deck plate that were located ahead of the rib-to-deck plate weld toe. As is evident, peak stresses occurred at these gauges when the wheels of the crawl truck were at the section. In this particular position one of the tires in both wheels was directly over the gauges. The stresses were negligible when the wheels were away from the section, and changed rapidly as the wheel was in the vicinity. This observation was also verified by FE simulations, where wheel loads were positioned at 5 in on either side of the section, and rapid change in stresses were noted. Tensile and compressive stresses of almost equal magnitude developed at the top and bottom gauges respectively, indicating almost pure bending of the deck plate under wheel loads. Two peaks occurred due to the passage of the crawl truck — one due to the front wheel and the other due to the rear wheel — indicating that the deck plate experiences two stress cycles due to the passage of one tandem axle.

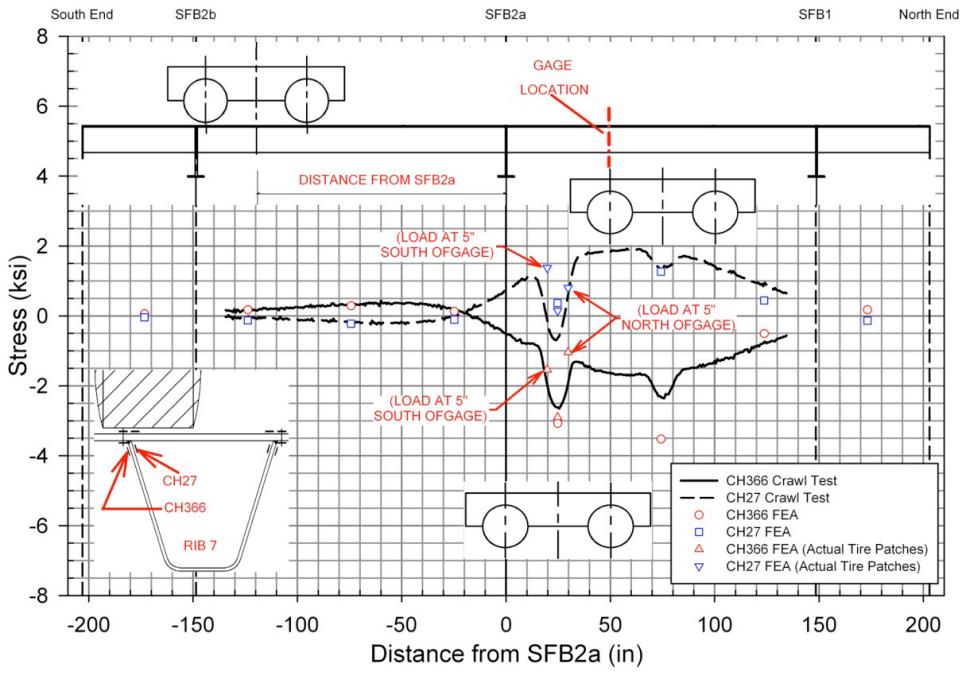

Figure 6. Crawl test result in rib wall at rib-to-deck connection: Position 5

Figure 6 shows the normal stresses at the faces of the rib wall measured in the back-to-back uniaxial gauges located near the rib-to-deck connection. Stresses in the gauges were negligible when the truck was on the span between SFB2a and SFB2b. However, tensile and compressive stresses of almost equal magnitude developed in the internal and external gauges respectively, as the truck approached SFB2a and was on the span between SFB2a and SFB1, except as follows. When one of the wheels was in the vicinity of the section of interest, the stresses changed rapidly. With the wheel at the section, the tensile stress in the inner gauge became compressive and the compressive stress in the outer gauge increased. This change was more noticeable when only one wheel was on the span and the other wheel was on SFB2a. It is evident that the rib wall was predominantly subjected to bending due to wheel loads, except at a section under the wheel, where significant axial compressive stresses developed in the rib wall. The FEA simulations generally agreed well with the measurements, except when the rear wheel was on the section.

Sub-floor beam-to-rib connection. Figure 7 shows the stresses measured in the (near) horizontal legs of the back-to-back rosettes at the rib-cutout in SFB2a for position 5. These gauges were identified as CH98 on the north face and CH101 on the south face. The stresses were predominantly in plane as the crawl truck rolled across the span between SFB2a and SFB2b from the south. As the truck approached the sub-floor beam, the stresses in the north gauge reduced compared to the south gage, indicating bending of the sub-floor beam along with Rib 7. The bending stresses existed while the truck was on the span between SFB1 and SFB2a. The maximum bending stresses occurred when the truck was on the span SFB1-SFB2a, with one wheel on the subfloor beam. The figure also indicates that for a single passage of test

truck, the rib-cutout in SFB2a experienced only one stress cycle, and the sub-floor beam does not experience the effects of individual axles.

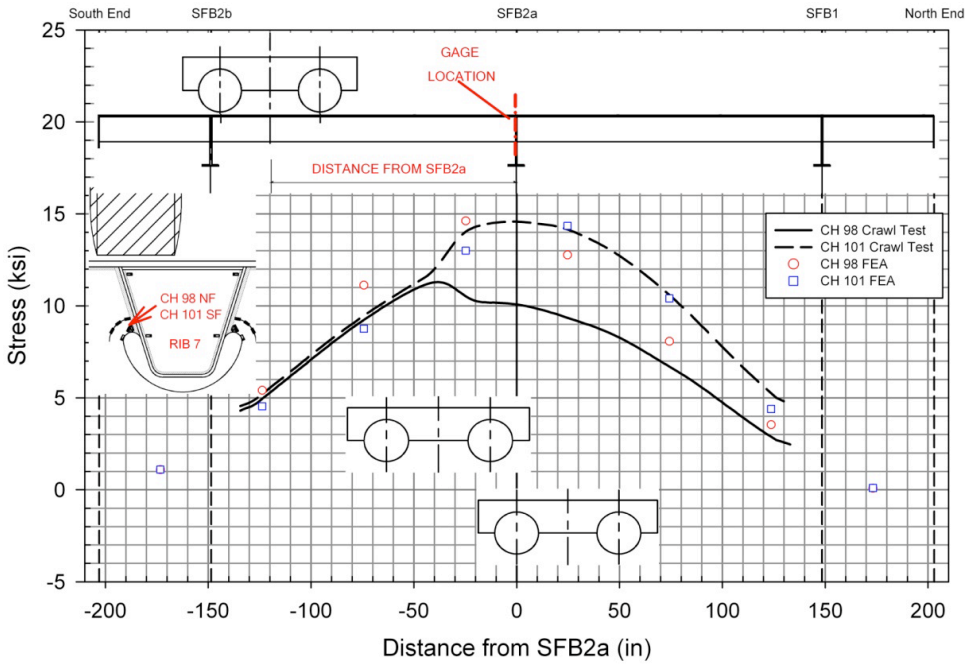

Figure 7. Crawl test result in deck plate at rib-to-deck connection: Position 5

Effect of transverse disposition of load. To demonstrate the effects of transverse and longitudinal disposition of the crawl truck, the stresses measured in the back-to-back uniaxial gauges (CH27 and CH366) on Rib 7 wall are tabulated in Table 1, for positions 3, 4, 5 and 6 under both truck axles. The gauge CH27 was on the inner face and gauge CH366 was on the outer face of the west wall. In position 3 both walls of Rib 7 were under the wheels. In position 4, one wheel was on the deck plate in the middle of Rib 7 and the other wheel was in between ribs 6 and 7. In position 5, one wheel was on the west wall of Rib 7 and the other wheel was on the east wall of Rib 6. In position 6, one wheel was on deck plate in between ribs 6 and 7, and the other wheel was on deck plate in Rib 6.

As is evident from Table 1, the stresses obtained in the rib under the front and the rear axles were not same, although loads on both axles were similar. In particular, the results in position 4 appears interesting. In this position the wheels were located symmetrically about the west rib wall, which resulted in only in-plane stresses in the rib wall, when the front axle was on the section. When the rear axle was on the section, the magnitude of in-plane stress remained the same, whereas a significant bending stress (causing tension on the inside face) developed in the rib wall. Existence of this bending stress can be explained from Figure 6, which shows that the wheel loads generated bending stresses at sections away from the loaded section. This suggests that the front axle contributed to the stresses at the section loaded by the rear axle, and resulted in the difference in observed stresses.

The table also shows that as the transverse position of the axles changed, the stresses changed in the rib, sometimes causing reversal in bending stresses. For

example, the position 5 generated bending stress in the rib wall that is compressive on the inside face, where as the positions 4 and 6 generated bending stresses that are tensile on the inside face. Due to the presence of high tensile welding residual stresses at the weld toe, the entire reversal can be effective in causing fatigue damage.

The maximum bending stress occurred in the rib wall in position 6, where the rib was eccentrically loaded.

Table 1.

	Stresses due to front axle (MPa)				Stresses due to rear axle (MPa)			
Crawl Test Positions	Gage #27	Gage #366	Bending	In-plane	Gage #27	Gage #366	Bending	In-plane

CONCLUSIONS

The measurements indicated that the response of the rib-to-deck connection at a section was manifested by the presence of wheel load in the vicinity of the section. The measurements also showed that the critical live load stresses varied with different loading dispositions in the transverse direction, as well as with the longitudinal position of the axle loads. Accordingly, designing orthotropic deck requires a knowledge of the influence surface under wheel loads. The deck connections experience one stress cycle due to the passage of each axle. The stresses were predominantly in sub-floor beams. A single passage of tandem axle produced only one stress cycle at the rib-cutout. The 3D finite element analyses provided good correlation with the measurements and provided valuable insight into the complex behavior of the deck and helped in developing the influence surface. The positions of hydraulic actuators for fatigue testing of the deck were determined based on these crawl test results.

Abstract

In the current design specifications, only the individual girder inside the double girder system is checked for lateral torsional buckling between the intermediate cross-frames. However, the overall lateral torsional buckling of double girder systems may be critical under bridge erection, due to the limited lateral bracing present at this stage. Therefore, close attention should be paid to the overall stability of double I-girders during construction, and research has been conducted for the simply supported case and the cantilever case under self-weight only. The results are presented in this paper.

Through extensive finite element analyses, established formulas on the overall lateral torsional buckling capacity of simply-supported double girder systems were verified and then modified for the cantilever case. A stability index L/S was developed for estimating the stability of double girder systems under erection, which equals to the ratio between the girder span L and the girder spacing S. Formulae were then derived for the maximum span L_{max} and the maximum stability index $(L/S)_{max}$, beyond which the double girder system would lose stability under its self-weight. Parametric studies were conducted to determine the dominant parameters for L_{max} and $(L/S)_{max}$ for various girder sections with different spacing. A quick and reliable method was also established to check the stability of double girder systems under erection using the L/S ratio.

Introduction

Double I-girder systems are widely used in highway and railroad multi-girder bridges, which consist of two I-girders connected by intermediate cross-frames as well as top and bottom diagonal braces. During the construction stage, the double

girder system is erected before the concrete deck is added, and it is subjected only to the self-weight of the girder and weight of construction equipment and workers, which are much smaller than the service loads. However, since the lateral supports provided by the concrete deck at the top flange are generally weak until concrete hardens, the system is particularly vulnerable at this stage, due to its slenderness and relatively low lateral and torsional stiffness (Kozy and Tunstall, 2007; Hastings, 2010). Therefore, close attention should be paid to the stability of the double girder system during the erection stage.

Traditionally, the stability check of a double girder system has focused on evaluating the stability of each single girder within the unbraced length between the cross-frames (Yura et al, 2008). However, in terms of overall integrity, there is the possibility of overall lateral torsional buckling of the entire girder system, especially when the two girders are closely spaced. An example was shown as the recent Marcy Bridge collapse in New York with overall lateral torsional buckling failure of a tub girder system (Yura and Widianto, 2005), as shown in Figure 1 below, which could be considered similar to a closed-spaced double girder system. On the other hand, the stability of steel girders under erection is usually considered a construction issue to be addressed by contractors and/or the subcontractors, who may not have either the time or expertise to conduct a thorough stability analysis during construction. Therefore, it is important to develop simplified erection guidelines to assist the erectors in conducting a quick and reliable check on the stability of double girder systems under erection.

FIGURE 1 The collapse of the Marcy Bridge in New York (Exponent, 2009)

There had not been much research conducted on the overall buckling of double girder systems until the occurrence of the Marcy Bridge collapse. Kozy (Kozy and Tunstall, 2007) noticed the danger of overall lateral torsional buckling of the tub girder under construction, and a case study on a three-span continuous composite steel plate girder bridge was conducted using finite element buckling analysis and non-linear incremental collapse analysis. It was concluded that overall lateral torsional buckling could control the strength of a double girder system and should be considered in the design. Yura also did considerable research on the overall lateral torsional buckling of double girder systems (Yura et al, 2008; Yura and Widianto, 2005), where a thorough analysis was conducted to determine the lateral and torsional stiffness of double girder system, and a formula

was derived for the lateral torsional buckling capacity of a simply-supported double girder system:

$$M_g = C_b \frac{\pi}{L}\sqrt{EI_y GJ + \frac{\pi^2 E^2 I_y C_w}{L^2}} \quad (1)$$

Eq. 1 was simplified by Yura into Eq. 2 by combining the dominant parameters

$$M_{gs} = C_b \frac{\pi^2 SE}{L^2}\sqrt{I_y I_x} \quad (2)$$

where M_g = global lateral torsional buckling capacity of double girder system; M_{gs} = simplified global buckling capacity; C_b = moment diagram modification factor; L = span length; E = modulus of elasticity; G = shear modulus of elasticity; I_x, I_y = moment of inertia about horizontal and vertical centroidal axes, respectively; S = girder spacing; C_w = warping constant. It was also concluded that for a simply supported double girder system, the C_b factors under a uniform distributed load (C_b = 1.12) and under a concentrated load at midspan (C_b =1.35) for single girders were applicable based on finite element analyses (Yura et al, 2008).

Derivation of Simplified Erection Guidelines for Double Girder System

Eq. 2 provided the theoretical basis to check the lateral torsional buckling of double girder systems under erection. For any double girder system under the girder self-weight, the maximum external bending moment (M_u) increases with the girder span L, while the global lateral torsional buckling capacity (M_{gs}) decreases with the girder span L. Therefore, a certain span limit L_{max} exists, beyond which $M_u \geq \phi M_{gs}$ and global lateral torsional buckling of the double girder system will occur, as shown in Figure 2.

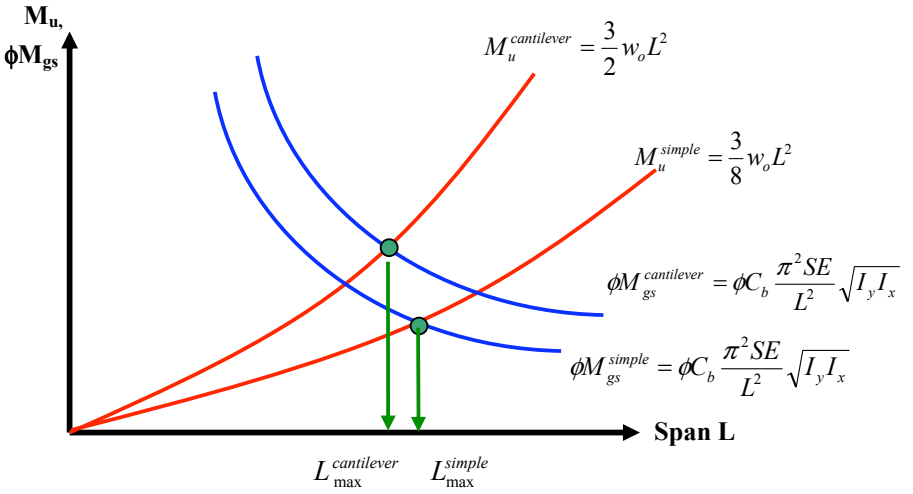

FIGURE 2 Span limit L_{max} for double girder systems under erection

Considering Load Combination IV in the AASHTO LRFD code, which equals to 1.5 times the girder self-weight, the maximum external bending moment (M_u^{simple}) for the simply supported case during the erection stage would be

$$M_u^{simple} = \frac{1}{8} \times (2 \times 1.5 w_o) L^2 = \frac{3}{8} w_o L^2 \quad (3)$$

where, w_o= uniform load on one girder due to self-weight, $w_o = A \cdot D_{steel}$; A = area of single girder section; D_{steel} = steel density. From Eq. 2, the design lateral torsional buckling capacity for simply supported double girder systems would be

$$\phi M_{gs}^{simple} = \phi C_b \frac{\pi^2 SE}{L^2} \sqrt{I_y I_x} \quad (4)$$

where ϕ = 1.0 resistance factor, C_b = 1.12 for simply supported girder under uniform load. Solving $M_u^{simple} = \phi M_{gs}^{simple}$, L_{max} for a simply supported double girder system is given below

$$L_{\max}^{simple} = 1.32 \cdot \sqrt[4]{\frac{\pi^2 SE}{w_o} \sqrt{I_x I_y}} \quad (5)$$

Similarly, considering Load Combination IV in the AASHTO LRFD code, the maximum external bending moment for the cantilever case during the erection stage would be

$$M_u^{cantilever} = \frac{1}{2} \times (2 \times 1.5 w_o) L^2 = \frac{3}{2} w_o L^2 \quad (6)$$

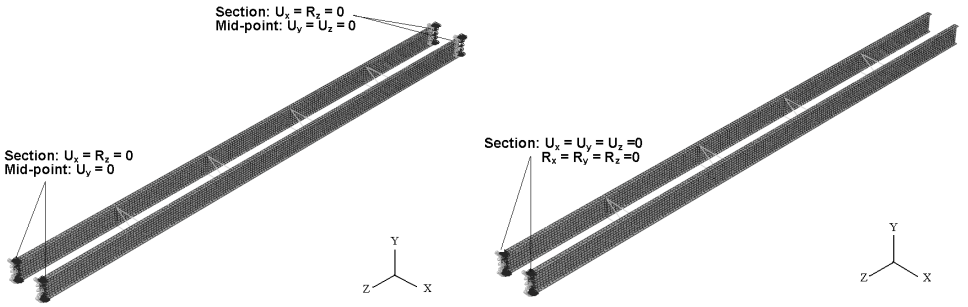
By extending Eq. 2 to the cantilever case, the design lateral torsional buckling capacity for cantilever double girder systems would be

$$\phi M_{gs}^{cantilever} = \phi C_b \frac{\pi^2 SE}{L^2} \sqrt{I_y I_x} \quad (7)$$

where ϕ = 1.0 resistance factor, C_b = 2.04, which according to Timoshenko's *Theory of Elastic Stability* (Timoshenko and Gere, 1961), is the lower bound of C_b for a cantilever single girder under uniformly distributed load. Solving $M_u^{cantilever} = \phi M_{gs}^{cantilever}$, L_{max} for a cantilever double girder system is

$$L_{\max}^{cantilever} = 1.08 \cdot \sqrt[4]{\frac{\pi^2 SE}{w_o} \sqrt{I_x I_y}} \quad (8)$$

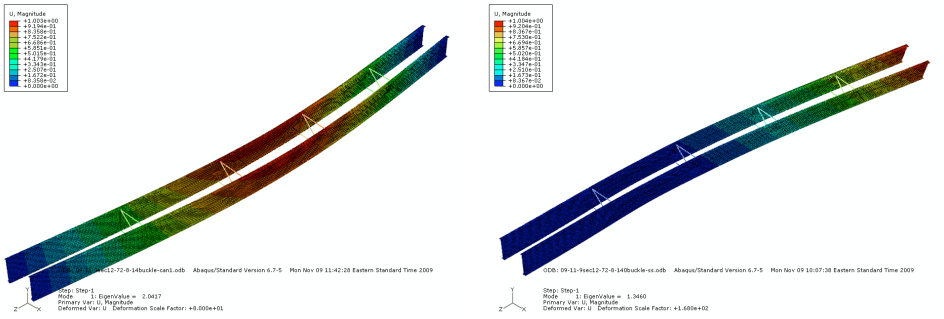
Eq. 5 and Eq. 8 could be used to check the double girder free span under erection with the maximum allowable span L_{max}, and prevent the overall lateral torsional buckling of double girder system under erection. However, in Yura's studies, Eq. 1 and Eq. 2 were only verified by finite element analysis on a few simply-supported cases, and no analyses were conducted on the cantilever cases to verify the applicability of Eq. 2 as well as the C_b factor. Therefore, it was unclear if these formulae were applicable for a wide range of double girder systems under both simply-supported and cantilever situations, which are the two most common cases during erection. Finite element analyses were then conducted on a wide range of double girder systems in order to 1) check the accuracy of the formulae for the simply supported case; 2) extend the formulae to the cantilever case, which are described in the following section.



Verification of Capacity Formulae for Double Girder Systems through FEA

A group of double girder systems with various section properties were investigated in order to cover the typical range in actual bridge projects. The flange varied from 305mm x 25mm to 914mm x 38mm, and the web varied from 1245mm x 13mm to 2400mm x 17mm, which was similar to the previous research conducted by the authors on single girders (Hastings, 2010). The girder spacing varied from 1.83m to 4.27m, based on the large database obtained from literature survey (Brockenbrough and Merritt, 2006; Mabsout et al, 1997; Mabsout et al, 2002). The girder span was chosen such that the girder is still in the elastic stage under its self-weight. According to a parallel study (Zhao et al, 2010), the section area and spacing of cross-frames were chosen such that the stiffness and strength requirements for bracing were satisfied (Yura, 2001), which would barely affect the stability of double girder system.

Finite element analysis program ABAQUS was used to model the double girder system and conduct the static and buckling analysis (ABAQUS, 2008). The girders were modeled with four-node shell elements S4R, and the intermediate cross-frames were modeled with two-node truss elements T3D2 with a pin connection at both ends (Kozy and Tunstall, 2007; Yura et al, 2008). The mesh size of each model was proportional to the span. The steel material was M 270, Gr. 50W, modeled as a elastic material with a modulus of elasticity of 2.01GPa and a Poisson's ratio of 0.30.



Load Combination IV of the current AASHTO LRFD specifications (1.5D) was used. In order to avoid the effects of loading location, the external load was applied as a uniform body force (force per volume) to the girder model with a value of $1.5W_{steel} = 115{,}454\ N/m^3$, where W_{steel} is the weight density of steel. For the simply supported model, the torsional rotations and lateral displacements normal to the web were restrained with free warping for all the nodes at both end sections. The vertical displacements of the midpoints at both end sections were restrained, while the longitudinal displacement was restrained at one end section and free at the other. For the cantilever model, one end was fixed by constraining all 6 degrees of freedom for each node, and the other end was free with no constraints (White and Jung, 2007). A view of the finite element model is shown in Figure 3.

Elastic static analyses under 1.5D were firstly conducted to calibrate and verify the finite element model. Eigenvalue buckling analyses were then conducted to obtain the overall lateral torsional buckling capacity of each double girder system, as well as indentify major buckling modes. The Eigen values (λ) and mode shapes of the double girder system are shown in Figure 4 for the simply supported case and the cantilever case respectively. It is obvious that, for both cases, the primary buckling mode (mode 1) is lateral torsional buckling of the double girder system as a whole, instead of buckling of individual girders between the cross frame (Mode 2 and 4 for the simply supported case, Mode 3 and 11 for the cantilever case). Therefore, the Eigen values (λ) corresponding to the global buckling mode was used to calculate the critical buckling moments in later study.

FIGURE 4 Eigen values and mode shapes of double girder system

The critical elastic lateral torsional buckling moment (M_{cr}) of each double girder system was calculated by multiplying the Eigen values (λ) with the maximum external bending moment along the girder span, and then compared with Yura's formula in Eq. 2 (M_{gs}) for both the simply supported and the cantilever case, as shown in Table 1 below. It is obvious that for the simply supported case with a uniform load (C_b = 1.12), the discrepancies between the FEA results and Yura's formula for most models are below 5%, and Yura's formula turned out to be quite accurate for simply supported double girders. On the other hand, there were considerable differences (30-40%) between the finite element results and Yura's formula for the cantilever case with C_b = 2.04. A modification factor C_d was then introduced to account for the differences, which might be due to factors such as the rigidity of the cross-frame connection or the difference in the moment distribution between a cantilever double girder system with lateral movement and a single cantilever. The C_d values for each model are listed in Table 1, with an average of 1.37 and a standard deviation of 0.04.

52	41478	43107	3.8	110618	78516	1.41

Therefore, Yura's formula could be extended into the following form for cantilever double girders under a uniformly distributed load:

$$M_{gs}^{cantilever} = C_d C_b \frac{\pi^2 SE}{L^2} \sqrt{I_y I_x} \tag{9}$$

where $C_d = 1.37$ the modification factor; $C_b = 2.04$. Accordingly, the L_{max} formula for cantilever double girder system would be modified into the following form:

$$L_{\max}^{cantilever} = 1.17 \cdot \sqrt[4]{\frac{\pi^2 SE}{w_o} \sqrt{I_x I_y}} \tag{10}$$

Verification of Simplified Erection Guidelines for Double Girder System

Based on Eq. (10), a parametric study was conducted to investigate the effects of girder geometric properties on the span limit L_{max} for the cantilever case, with parameters shown in Table 2. The same tendency will be observed for the simply-supported case since the L_{max} values are proportional.

TABLE 2 Parametric studies on L_{max} of double girders under erection

Case #	Flange Width b_f (mm)	Flange Thickness t_f (mm)	Web Depth D_w (mm)	Web Thickness t_w (mm)	Girder Spacing S (m)
1	305 - 914	25 - 38	1245	13	1.83 – 4.27
2	305	25	1245- 2400	13 - 17	1.83 – 4.27
3	305	25 - 51	1245	13	1.83 – 4.27
4	305	25	1245	10- 25	1.83 – 4.27

In Case 1 analyses, the web depth and thickness were held constant, while the flange width, the flange thickness and the girder spacing varied in order to investigate the effects of flange width and girder spacing on the span limit L_{max}, and the results are shown in Figure 5. In Case 2-4 analyses, the investigation was mainly on the effects of web depth, flange thickness and web thickness on the span limit L_{max}. From the parametric studies, it is clear that the span limit L_{max} increases with the flange width, the flange thickness, the girder spacing, and the web depth, while L_{max} decreases with the web thickness, probably because increasing web thickness would lead to a much faster increase of girder self-weight and external bending moment than the increase of girder lateral bucking capacity, therefore the net result is a decrease in the span limit L_{max}.

From the analyses, the flange width and girder spacing were found to be the two most important parameters for L_{max}, where L_{max} increased 45-54% when the flange width increased from 305mm to 914mm, and L_{max} increased 23% when the girder spacing increased from 1.83m to 4.27m. In comparison, the web depth, flange thickness and web thickness only had limited influence on L_{max}, since the maximum differences in L_{max} are 5.9%, 5.9% and 8.9% respectively.

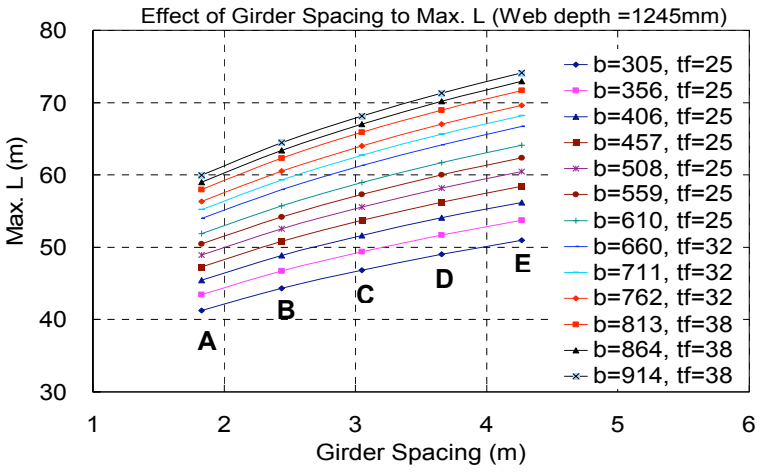

FIGURE 5 Effect of girder spacing and flange width on max. span (Case 1)

Since simplified erection guidelines have been developed for single steel I-girder under erection using the L/b ratio, where L is the unbraced length and b is the compression flange width (Hastings et al, 2010), similar erection guidelines could also be established for double girder system by introducing a stability index. From the previous parametric studies, the girder spacing S, which is the distance between the centers of two I-girders, has great influence on the lateral torsional stiffness of the double girder systems and could be taken as the "flange width" of the whole system. A stability index was then introduced as L/S, which is the ratio between the girder span L and the girder spacing S. For each double girder system, a unique $(L/S)_{max}$ ratio exists, beyond which the system would have global lateral torsional buckling under its self-weight. For any given double girder geometry, the $(L/S)_{max}$ ratio for the simply supported system as well as the cantilever system would be shown in Eq. 11 and 12 below, which are proportional to each other, as shown in Eq. 13.

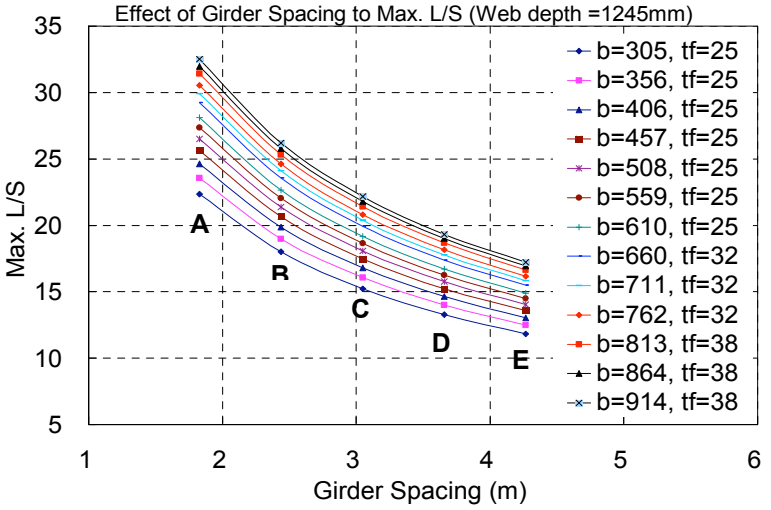
$$(L/S)_{\max}^{simple} = 1.32 \cdot \sqrt[4]{\frac{\pi^2 E}{w_o S^3}\sqrt{I_x I_y}} \tag{11}$$

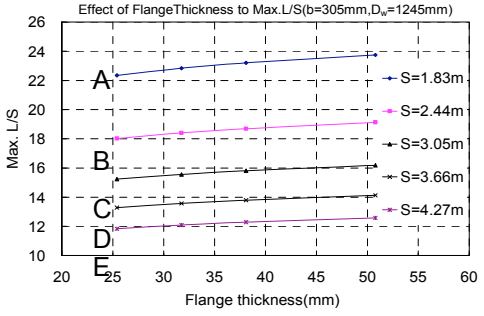
$$(L/S)_{\max}^{cantilever} = 1.17 \cdot \sqrt[4]{\frac{\pi^2 E}{w_o S^3}\sqrt{I_x I_y}} \tag{12}$$

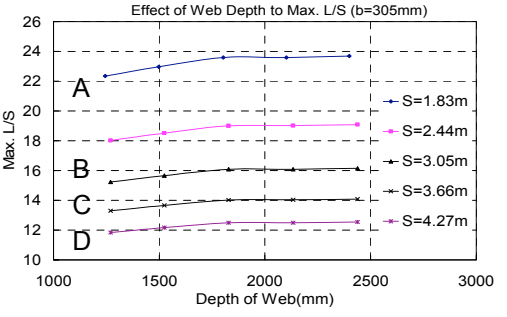
$$(L/S)_{\max}^{simple} = 1.125(L/S)_{\max}^{cantilever} \tag{13}$$

Due to the complicated formula, checking the possibility of lateral torsional buckling of the whole double girder system directly with $(L/S)_{max}$ ratio might not be easy. Data from the previous parametric study were then re-processed in order to investigate the effect of each parameter on the $(L/S)_{max}$ ratio, and more importantly, identify the upper and lower limits of $(L/S)_{max}$ for a quick stability check. Results are shown in Figure 6 and 7, where it is clear that the $(L/S)_{max}$ increases with the flange width, the flange thickness, and the web depth, while decreases with the girder spacing and the web thickness. The flange width and girder spacing would affect the $(L/S)_{max}$ ratio much more than the web depth, flange thickness and web thickness.

If the geometry of a cantilevered double girder system falls into the parametric study, the $(L/S)_{max}$ ratio could be directly read or interpolated from the curves in Figure 6, in order to conduct a preliminary check on double girder system stability. Moreover, for cantilever double girder systems, the absolute lower bound of the $(L/S)_{max}$ ratio, below which lateral torsional buckling of the whole system would not occur under erection, could be conservatively taken as 10. The absolute upper bound of the $(L/S)_{max}$ ratio, beyond which lateral torsional buckling of the whole system would occur under erection, unless temporary supports are provided, could be conservatively taken as 35. According to Eq. 13, the absolute lower and upper bound of the $(L/S)_{max}$ ratio for simply supported double girder system could be conservatively taken as 11 and 40.







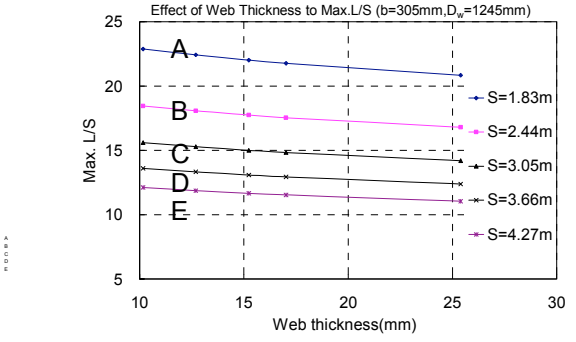


FIGURE 6 Effects of girder spacing and flange width on max. L/S (Case 1)

Conclusion

The work presented here supports the following conclusions:

1. Based on buckling analyses of double girder systems with a wide range of section properties, Yura's formula (Eq. 2) for the overall lateral torsional buckling capacity of double girder systems turned out to be quite accurate for the simply supported case under uniformly distributed load ($C_b = 1.12$);
2. Based on buckling analyses, Yura's formula was modified for cantilever

double girders under uniformly distributed load (C_b = 2.04), by introducing a modification factor C_d =1.37;

3. For double girder systems under erection, formulae for span limit L_{max} were derived for both the simply supported and the cantilever cases, beyond which lateral torsional buckling of the whole system would occur under girder self-weight;
4. A stability index L/S, which is the ratio between the girder span to the girder spacing, was introduced for the convenience of checking the possibility of lateral torsional buckling of double girders under erection. Formulae for the $(L/S)_{max}$ ratio were also derived;
5. Parametric studies were conducted to investigate the effects of various geometric parameters on the L_{max} and $(L/S)_{max}$ ratio. The flange width and girder spacing were found to have the most influence, while the web depth and thickness, and the flange thickness, only had minimal effects;
6. For the shapes investigated, double girders with an L/S ratio less than 10 for the cantilever case, and 11 for the simply supported case, should not require a stability check. Double girder systems with an L/S ratio larger than 35 for the cantilever case, and 40 for the simply supported case, would probably need temporary support during erection;
7. If a double girder system falls into the range in Figure 7, then $(L/S)_{max}$ could be directly read or interpolated from Figure 7, in order to conduct a preliminary check on system stability. For the simply supported case, the values should be increased by 12.5%.

ABSTRACT

Ultra high performance concrete (UHPC) is an emerging material which develops very high compressive strengths and exhibits improved tensile strength and durability properties. Recent construction of three UHPC bridges in the United States has sparked interest in the use of UHPC for prestressed bridge girders in several states. UHPC offers many advantages including longer spans, improved durability, and smaller structural members, making it an appealing material to use in prestressed bridge construction. This paper presents a case study conducted to investigate the feasibility of implementing UHPC in bridge design in New Mexico. Using a modified LFD procedure, bridge designs were developed considering the compressive strength, modulus of rupture, and modulus of elasticity of UHPC as well as design requirements for flexure and shear, girder cross-section geometry, and prestressing strand area. Comparisons with as-built bridge configurations show that using UHPC with compressive strengths between 100 MPa and 150 MPa may potentially lead to a reduction in required girder lines and reduce or eliminate mild steel shear reinforcement. Compared to regular concrete, a cubic yard of commercially available UHPC can cost as much as 10 times more, making designers and precasters hesitant to adopt this material. An economic analysis, assuming that local materials can be used to produce UHPC, indicates that the initial high cost can be offset by careful selection of materials, reduced construction time and maintenance, and the increased service life of the structure. Costs were evaluated based on local material prices, design parameters of the bridge, modified production practices, and a projected maintenance schedule. This study aids in the development of design procedures and recommendations for implementing UHPC as a prestressed concrete girder material.

INTRODUCTION

Ultra High Performance Concrete (UHPC) is an emerging material which develops very high compressive strengths (up to 200 MPa) and also exhibits improved tensile strength (up to 50 MPa) and durability properties (Graybeal 2006). Several characteristics of UHPC offer advantages for structural applications, specifically prestressed concrete bridges, including:

- Increased strength and ductile behavior allowing the concrete to deform and support flexural and tensile forces, even after initial cracking.

- Durability characteristics similar to those of an impermeable material reducing the effects of corrosion and concrete contamination.
- A higher resistance to abrasion than that of normal strength concrete (NSC).
- Reduced creep and shrinkage, making the material very suitable for applications in prestressed concrete.
- The ability to replicate both the macro- and micro-texture of the formwork, resulting in high-quality textured or smooth surfaces.

Historically, conventional structural design has used concrete to support large compressive loads with steel reinforcement to resist tensile forces. Using UHPC, steel reinforcement may be reduced or eliminated. Additional advantages for using UHPC include: reduced material quantities; smaller geometry and weight of members; simpler detailing and construction; reduced maintenance; and longer lifespan. Recent events have shown the importance of durable long-lasting infrastructure. The use of UHPC helps to achieve goals of higher standards for U.S. infrastructure and meeting the increasing demands for reduced labor, materials, construction time, and environmental impact, while increasing safety, security, durability, and service life.

This paper describes an investigation regarding the feasibility of UHPC for prestressed concrete bridges in New Mexico using typical New Mexico Department of Transportation (NMDOT) bulb-tee girders. A parametric design study was conducted for a simple span bridge using both high performance concrete (HPC) and UHPC. Based on the actual bridge drawings and specifications, girder designs were developed with the aid of CONSPAN®, a commercially available, comprehensive design program for prestressed concrete bridges. Due to the unique characteristics of UHPC, both 15 mm and 18 mm strands were considered in the re-design. HPC versus UHPC bridge designs were compared based on the required number of girders (i.e., concrete volume), number of prestressing strands, deck thickness, and shear detailing. Due to the high cost of UHPC (up to 10 times the cost of NSC), the design goal was to optimize the usage of UHPC in the bridge girders. Additionally, using the design results, an economic analysis was conducted that considered the life-cycle costs of UHPC and the use of local New Mexico materials.

BRIDGE CASE STUDY

The simple span bridge investigated in this paper was the I-25/Doña Ana Interchange located near Las Cruces, New Mexico (Figure 1). This bridge was designed using HPC. The parametric flexure and shear study compared the as-designed/as-built bridge with HPC and a modified bridge that is re-designed using UHPC. Several UHPC material characteristics identified from literature influence prestressed concrete girder design. These characteristics include: modulus of elasticity, modulus of rupture (i.e., allowable tensile stress), creep, and shrinkage. Both the modulus of elasticity and modulus of rupture were considered based on literature findings related to UHPC properties. Creep and shrinkage were calculated by the current AASHTO specifications because without specific material testing, modified design values cannot be accurately determined (AASHTO 2007).

UHPC PARAMETRIC STUDY: FLEXURE

The I-25/Doña Ana Interchange Bridge (Figure 1) is a simple span structure with a length of 34.29 m and no skew. The cross-section has six typical NMDOT BT-63 girders, spaced at 2.21 m (Figure 2), and a 191 mm cast-in-place deck of conventional concrete with a compressive strength of 27.6 MPa. The deck is 13.11 m wide with travel way dimension of 12.19 m, allowing for two traffic lanes, and an overhang of 1.03 m. The beams are braced by intermediate 9.53 mm steel bent plate diaphragms at the third points along the span. The traffic barrier is a 1.07 m concrete guard rail.

Figure 1: Photograph of I-25/Doña Ana Interchange (North Bound).

For ease of comparison, several parameters were kept constant including: deck width; ratio of deck overhang to girder-to-girder spacing (46.6%); deck compressive strength; harped strand pattern; and girder length. Parameters that were varied included: number of girder lines; deck thickness; release and final girder compressive strengths; modulus of elasticity; modulus of rupture (i.e., allowable tensile stress); and diameter of prestressing strands. The BT-63 in the design plans has modified dimensions; however, the other girder sizes (e.g., BT-54) considered in this study were based on NMDOT standard dimensions. The bridge was designed based on the Load Factor Design (LFD) method of the AASHTO Standard Specifications (17th edition) and the 2002 interims. Thus, comparisons made with UHPC are made using the LFD method.

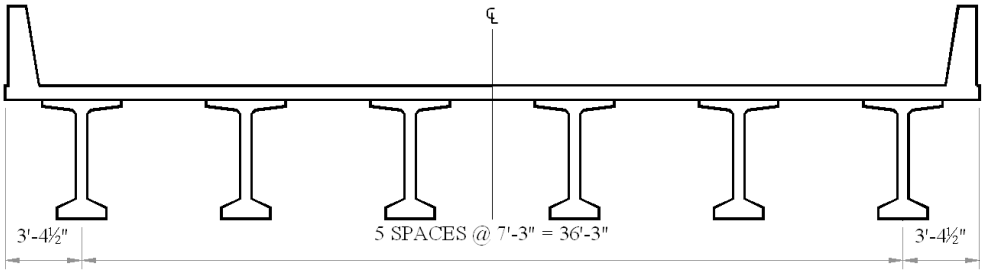

Figure 2: Cross-Section of I-25/Doña Ana Interchange.

For each cross-sectional configuration, final compressive strengths of 65.5, 103.4, 120.7, 137.9 and 155.1 MPa were used; however, only the results for 155.1 MPa are presented in this paper. For each compressive strength, the required number of 15 mm and 18 mm strands was determined based on the modulus of elasticity estimated from equations found in literature. In addition, the modulus of rupture was calculated by the AASHTO code and then prestressing strands are manually removed so that tensile stress limits from the literature control the number of strands for the serviceability limit state.

Effects of Modulus of Elasticity

Two design equations from the literature were used to estimate the modulus of elasticity for UHPC. The first is from the Association Française de Génie Civil (AFGC) French specification (2002) and is:

$$E_c = 262{,}000\sqrt[3]{f'_{ATT}} \text{ (psi)} \quad (1)$$

where, f'_{ATT} is the compressive stress of UHPC after thermal treatment. The second equation is given in Graybeal (2005) as:

$$E_c = 46{,}000\sqrt{f'_c} \text{ (psi)} \quad (2)$$

These equations were considered to evaluate the influence of the modulus of elasticity on UHPC girder design. Equation 1 assumes that the specimen undergoes thermal treatment. Equation 2 can be used to predict the modulus of elasticity regardless of the curing method (Graybeal 2005).

Using Equations 1 and 2 for the modulus of elasticity, the required number of strands is similar, with Equation 2 occasionally resulting in fewer strands. Equation 1 gives larger values for the modulus of elasticity than Equation 2; therefore, the fewer strands required using Equation 2 can be attributed to the smaller modular ratio between the NSC deck and the UHPC girders.

Calculating the modulus of elasticity using Equation 2 results in larger live load deflections than Equation 1. However, it was found that live load deflections are not a controlling limit state for any of the viable bridge designs in this study. Thus, Equation 2 was adopted to compute the final design values for the UHPC modulus of elasticity in this study. This equation results in the fewest strands and adequate stiffness to control live load deflections. Additionally, Equation 2 is applicable over a large range of compressive strengths, 27.6 to 193.1 MPa.

Effects of Modulus of Rupture

Equations presented in the literature for the modulus of rupture are based on those developed for the commercially available UHPC material Ductal®. These equations are sensitive to the curing method used. In this study, it was assumed local materials would be used for the UHPC mixture proportions. Thus, to analyze the effects of the UHPC's increased strength in tension, limiting values for tension reported in the literature were used. For the range of compressive strengths considered herein, Gowripalan and Gilbert (2000) suggest the lower bound value for tensile strength of 8.0 MPa. Graybeal (2008) uses 9.0 MPa as a limiting value for tensile strength. It is important to note that in much of the literature, UHPC is considered to have a range of compressive strengths from 150.0 to 220.0 MPa (Ahlborn *et al.* 2008, Graybeal 2008, Gowripalan and Gilbert 2000), which is higher than the range of compressive strengths considered in this study (ranging from 103.4 to 137.9 MPa). Therefore, the tension stress limit was assumed to be 8.0 MPa as recommended by Gowripalan and Gilbert (2000) when no specific data is available.

It should be noted that the limiting value of 8.0 MPa is a characteristic value for flexural tensile strength that has a safety factor of four compared to measured values from direct and flexural tension tests (Gowripalan and Gilbert 2000). Due to the conservative nature of this value, it is reasonable to assume that this limiting value is applicable to all the final compressive strengths used in this study.

Prestressing Strand Dimensions

Two sizes of prestressing strands were used in this study, 15 mm diameter and 18 mm diameter. The primary difference is the cross-sectional area. The 18 mm strands provide 35% more cross-sectional area than the 15 mm strands, with only a 17% increase

in diameter. The advantage of the larger prestressing strands is the labor savings and the increased prestressing force available using fewer strands (Schuler 2009).

UHPC PARAMETRIC STUDY: SHEAR

The shear design of UHPC girders differs significantly from the design of HPC girders. The steel fibers contained in a typical UHPC mixture contribute to the shear capacity of the section at the ultimate limit state (i.e., after the girder section cracks). The combined contribution of the concrete and steel fibers to shear capacity can be sufficient to carry factored shear forces without the need for traditional, transverse mild steel stirrups. Thus, the mild steel reinforcement may be reduced or eliminated according to AFGC Section 7.3.2 (2002).

Desgin Shear Strength Procedure for Steel Fiber Reinforced UHPC

The shear strength procedure described in this section is based on the "Recommendations for the Design of UHPC" by MIT. This procedure uses the French based AFGC recommendations and the research conducted at MIT on Ductal®. The formalized procedure can be found in the white paper produced by Dr. Franz-Josef Ulm of MIT for the Mars Hill Bridge built in Wapello County, Iowa (Ulm 2004).

For the shear portion of this study, shear loads and forces were calculated using the AASHTO LRFD specifications. Justification for using LRFD methods is twofold. First, LRFD uses state of the art methods for determining the anticipated shear failure angle, θ, based on the Modified Compression Field Theory. Secondly, the procedures developed by Ulm (2004) use the LRFD load factors to determine the factored shear force on the UHPC girder.

The ultimate limit state (ULS) for shear is based on the premise that crack-bridging steel fibers carry a part of the shear load, very similar to shear reinforcement. The design strength of the section is expressed as:

$$\varphi_V V_R^{ULS} = \varphi_c V_c + V_p + \varphi_f V_f + \varphi_s V_s$$

where, $\varphi_v V_R^{ULS}$ is the design shear; φ_c is a strength reduction factor, taken as 0.66 to account for material variability; V_c is the contribution of the concrete; V_p is the contribution of the harped prestressing strands; φ_f is a strength reduction factor, taken as 0.66 to account for non-ideal randomization of the fibers; V_f is the contribution of the steel fibers; $\varphi_s$is the LRFD strength reduction factor for shear, taken as 0.9; and V_s is contribution of the mild steel stirrup. For prestressed concrete applications, the concrete contribution to shear strength is expressed as:

$$V_c = 0.09\sqrt{f_c'}\, b_w\, z$$

where, f'$_c$ is the 28 day design compressive strength of the concrete; b_w is the web width; and z is the lever arm at the ultimate moment equal to the distance between the centroid of the compression block and the centroid of the prestressing strands (Graybeal 2006). The term V_p represents the vertical force component of the harped prestressing strands after losses and the steel fiber contribution to shear strength is given as:

$$V_f = \frac{A\,\sigma_p}{\tan(\theta)}$$

where, A is the area of the shear plane (i.e., effective fiber area), and is computed as 90% of the web width multiplied by the lever arm at ultimate moment (i.e., $A = 0.9 b_w z$). The term σ_p is the residual tensile strength carried across the shear crack from the time of

cracking until a limiting strain is achieved. According to Graybeal (2006), the value for residual tensile stress is determined experimentally from tension tests. In the absence of experimental data for the UHPC and the girders of this parametric study, typical values from literature were examined and a conservative value of 6.9 MPa. This is a reasonable value to assume without experimental testing because it is below the expected tensile cracking limit of the UHPC. The final term is tan(θ), which is the tangent of the compression strut angle in the shear area measured from the horizontal (θ has a lower bound of 30°). Under the LRFD code option in CONSPAN®, θ is calculated directly and is output. The method used by CONSPAN® to calculate θ is specified in LRFD Art. 5.8.3.4.2.

Finally, if mild steel stirrups are required then V_s is computed according to LRFD Equation 5.8.3.3-4:

$$V_s = \frac{A_v f_y (\cot\theta + \cot\alpha)\sin\alpha}{s}$$

where, A_v is the area of the transverse reinforcement (i.e., stirrups); f_y is the yield strength of the mild steel (equal to 414 MPa); θ is as described above; α is the angle of the transverse reinforcement (taken as 90°); and s is the spacing of the stirrups.

Results using 15 mm Diameter Strands

The as-designed bridge has 36 - 15 mm strands; 24 straight, 6 harped, and 6 debonded-partial length strands (in the top flange) to control stresses and provide the required flexural moment capacity. For the parametric study, only harped strands were used to obtain consistent comparisons. Harped strand patterns were developed in a two step process. First, CONSPAN® was used to determine an initial strand pattern. This initial pattern was then modified manually by adding and removing strands and adjusting the harped strand pattern to ensure that the final strand pattern was a sound design. In this manner a straight/harped strand pattern was generated for the as-designed bridge. The resulting pattern required a total of 28 - 15 mm strands (26 straight, 2 harped) as shown in Figure 3. The difference in strands between the as-designed and baseline bridge occurs at two locations. There are two less straight strands in the bottom bulb for the baseline bridge girder. Also the as-designed bridge girder plans call out 6 debonded-partial length strands in the top flange. For the purpose of the parametric study six BT-63 girders with 28 (26 straight, 2 harped) - 15 mm diameter strands was considered to be the baseline design of the I-25/Doña Ana Interchange Bridge.

Using LFD, Equation 2 to estimate the modulus of elasticity, and limiting the modulus of rupture to AASHTO provisions (i.e., the higher tensile strength of UHPC is not considered), the number of girder lines and the girder size decrease from six BT-63 girders to five BT-54 girders, for a total savings of 23% in girder concrete volume. This concrete volume reduction results in a 71% increase in the required number of 15 mm strands for UHPC compressive strengths 155.1 MPa. The deck thickness was increased by 13.3%.

Increasing the limit of the modulus of rupture to 8.0 MPa, decreases the number of girder lines from six BT-63 girders to four BT-63 girders, for a total savings of 33% in girder concrete volume with a 50% increase in the required number of 15 mm strands and a 26.7% increase in the deck thickness. This configuration saves an additional concrete volume of 11% compared to five BT-54 girders that are viable under the LFD code.

These comparisons show that with the increase in compressive strength and the improved tensile strength of UHPC, greater concrete savings are possible in the girders that are not possible with HPC. Allowable live load deflections were checked and satisfy serviceability requirements.

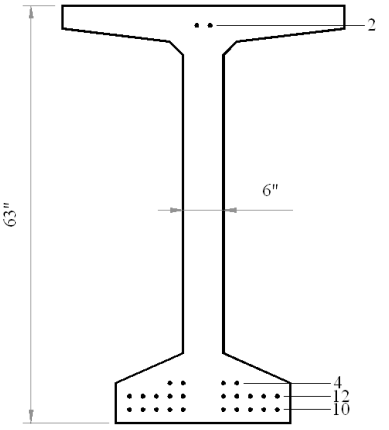

Figure 3: End Cross-Section of Baseline Design (BT-63) with 28 - 15 mm Strands Using HPC.

Shear Design

Using the final bridge configuration using four UHPC typical BT-63 girders, the shear capacity of the section can be determine following the procedure described above.

The computed shear failure angle at the critical section was below the limiting value of 30°; thus, the angle used to determine the steel fiber contribution to the strength of the section was taken as 30°. Recall that the fiber contribution is not related to the compressive or tensile strength of the concrete, but is a function of the shear failure plane and residual tensile stress in the fibers after the concrete cracks. It should further be noted that the fiber contribution to the shear capacity is much larger compared to the concrete and the harped strand contribution. The fiber contribution represents approximately 77.2% of the design shear strength of the girder section.

The girder section has sufficient capacity to carry the ultimate shear forces with no change to the cross-sectional geometry.

Results using 18 mm Diameter Strands

For the purpose of the parametric study six BT-63 girders with 22 (20 straight, 2 harped) 18 mm diameter strands is considered to be the baseline design of the I-25/Doña Ana Interchange.

Using LFD, Equation 2 to estimate the modulus of elasticity, and limiting the modulus of rupture to AASHTO provisions (i.e., the higher tensile strength of UHPC is not considered), the number of girder lines decreases from six BT-63 girders to four BT-63 girders using UHPC, for a total savings of 33% in girder concrete volume. This concrete volume reduction results in a 55% increase in the required number of 18 mm strands and 26.7% increase in the deck thickness.

Increasing the limit of the modulus of rupture to 8.0 MPa decreases the number of girder lines and the girder size from six BT-63 girders to four BT-54 girders, for a total savings of 38% in girder concrete volume. This concrete volume reduction results in a 109% increase in the required number of 18 mm strands and 26.7% increase in the deck thickness. This configuration saves an additional concrete volume of 5% compared to four BT-63 girders that are viable under the LFD code.

These comparisons show that the improved compressive and tensile strength of UHPC in combination with 18 mm strands, will yield greater concrete savings that are not possible with HPC and 15 mm strands. Allowable live load deflections were checked and satisfy serviceability requirements.

Shear Analysis

Using the final bridge configuration with four UHPC typical BT-54 girders, the shear capacity of the section was determined following the procedure described above.

The typical BT-54 girders have a 150 mm web thickness and have insufficient capacity at the critical section. Two options are possible to meet the required shear strength capacity:

1. Increase the web width 25 mm. If this option is selected, girder concrete reduced by 33%. The increase of width did not change the amount of prestressing strands required for flexure.
2. Use No. M16 mild steel stirrups at 610 mm on center, shown in Figure 4. If this option is selected there will be a 38% reduction in required amount of girder concrete.

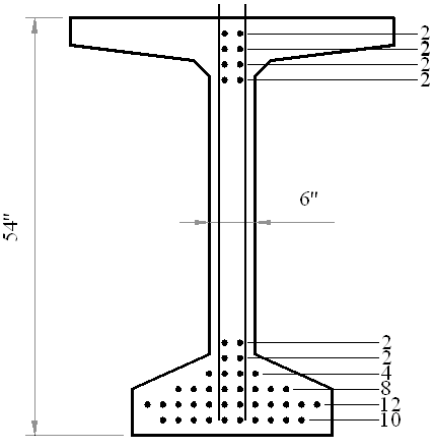

Figure 4: End Cross-Section of Four BT-54 Girders with 48 - 18 mm Strands Using UHPC.

Confinement Steel

The bursting force effect is addressed in LFD Art. 9.22. According to this article, stirrups and nominal reinforcement should be placed over a distance at least equal to the depth from the end of the beam. If 18 mm strands are used, the final bridge configurations required stirrups in this region of the beam. Thus the inclusion of confinement steel would be a simple task and would not significantly add to the total overall cost of a UHPC girder. However, if 15 mm strands are used, the final bridge configurations do not require stirrups to provide adequate shear strength in the bursting region.

ECONOMIC ANALYSIS

For the economic analysis, the as-designed bridge is compared to the re-design of the bridge using UHPC girders.

Cost Comparison of UHPC Girders

The cost of one BT-63 girder with HPC is approximately $2,602, based on a cost of $\$163/m^3$. For one BT-63 girder with UHPC the cost is approximately $14,260, estimating the cost of UHPC using local materials at $\$896/m^3$. The cost of one BT-54 girder with UHPC is $13,180.

The smallest number of girders possible was found to be four BT-54 girders. This design was only possible with the use of 18 mm strands. If it is not possible to use 18 mm strands, five BT-54 girders is the best choice.

When 18 mm strands are used, the design shear capacity was insufficient with a 150 mm web. To have adequate shear capacity either the web thickness of the BT-54 girder would have to be increased in width by 25 mm or mild steel stirrups would be required. Based on the cost of concrete, if the web thickness is increased, the cost of the girder concrete increases by approximately $1,080.

Prestressing Strand Comparison

Strand size greatly affects the overall design which in turn affects the cost. In this case, using 18 mm strands is almost twice as expensive as using the 15 mm strands. This

cost was developed based on a strand unit cost of $1.18/m for 15 mm stands and $2.13/m for 18 mm stands.

The cost of the 15 mm strands in the baseline bridge is $6,860. The total cost of 15 mm strands in a bridge configuration with four BT-63 girders is $6,680, which is a 0% increase compared to the baseline design. The total cost of 18 mm strands in a bridge configuration with four BT-54 girders is $13,570, which is a 49.4% increase over the baseline design.

Steel Fibers Constituent Costs

The steel fibers are the most expensive constituent in UHPC. In this study, a cost analysis was performed for a beam that has steel fibers at 2% by volume with minimal mild reinforcement that is used for composite action with the deck. The total material cost for a single BT-63 girder is $14,680 with 2% fiber content. To reduce this cost, the possibility of reducing the steel fibers content from 2% to 1% by volume could be explored. However, additional testing would be required for this option.

Mild Steel Costs

When developing the costs for UHPC girder designs, some assumptions had to be made. It was assumed that all mild reinforcement could be removed for the UHPC girders except for deck composite action mild steel. Another assumption was that the amount of reinforcing needed for the BT-54 girders was the same as the amount needed for the BT-63 girders. This is justified because the difference in the amount of mild steel is small, approximately 0.7 kg. The cost of the mild reinforcement was determined based on a unit cost of $0.88 per kg.

The amount of mild reinforcement needed was obtained from the plans of the I-25/Doña Ana Bridge. The total cost of mild steel for the baseline design is $1,475. The only cost of steel for the four BT-63 girders is $45, this is the mild steel to provide composite action with the NSC deck. The total cost of mild steel for the four BT-54 girders is $75, this is for the composite action with the deck and bulb confinement. Recall, the cost of UHPC required to provide sufficient shear capacity by increasing the web thickness was $1,170. It is clear that using mild steel stirrups is more cost effective.

Normal Strength Concrete Deck Cost

The NMDOT has standard concrete deck details specified in section 4.3.1 of the NMDOT Bridge Procedures and Design Guide (2005). The thickness of the NSC deck varies with the effective span beam girders, while the spacing and amount of mild steel deck reinforcement remains constant, as the spacing increases between girders, the thickness of the deck increases, thus increasing in volume. The cost of NSC was estimated to be $\$131/m^3$.

The deck of the as-designed bridge has a thickness of 190 mm, width of 13.11 m and a length of 34.60 m. The cost of the as-designed deck is $11,447. The increase in cost for a four BT-54 or four BT-63 girders is 13.3%.

Total Cost for I-25/Doña Ana Interchange

An overall cost comparison table was developed and shown in Table 1. It is evident that the four BT-63 girders design is the least expensive design that uses UHPC with a total cost of $120,014. The total cost for four BT-54 girders is $124,030, this is 3.3%

higher than the four BT-63 girder design. The best design based on initial cost is six HPC BT-63 girders.

Table 1: I-25/Doña Ana Interchange Comparison Final Costs.

	6 HPC BT-63 Girders (15 mm strands)	4 UHPC BT-63 Girders (15 mm strands)	4 BT-54 Girders (18 mm strands)	4 Modified BT-54 Girders (18 mm strands)
Girder Conc.	$15,610	$57,040	$52,720	$57,030
Strands	$6,860	$6,860	$13,570	$13,570
Mild Reinf.	$8,850	$180	$300	$300
Labor Cost	$38,817	$43,130	$43,130	$43,130
Deck Conc.	$11,297	$12,804	$14,310	$14,310
Total Cost	$81,434	$120,014	$124,030	$128,340

Future Worth

The typical life span of bridge girders is designed for 75 years. Based on Ahlborn *et al.* (2008), it was assumed that the life span of the UHPC girders would be twice as long as that of the HPC girders. Based on the life spans stated above, the current bridges will need girder replacements in 75 years. Consideration of the life-cycle cost is important in this study. If the only financial parameter considered is initial cost it is clear that HPC is the least expensive. However life-cycle costs of HPC and UHPC should also be considered.

The future worth of these bridges is determined by:

$$F = P(1+i)^n \tag{3}$$

where, F is the future worth after n years; P is the present worth; i is the inflation rate taken as 3.85% (based on 2009 inflation rate); and n is the life span of the bridge, taken as 75 years for the HPC girders and 150 years for the UHPC girders.

The future worth is then adjusted to a net present value (NPV) and is determined by:

$$NPV = F(1+r)^{-n}$$

where, F is the future worth calculated by Equation 3; r is the discount rate, taken as 3.85% and n and described previously.

Table 2 provides a summary of the future worth analysis. The value $162,868 is twice the present value of the bridge. The reasoning behind this is that if the HPC were to be built today the initial cost would be $81,434 to construct the bridge and $81,434 would have to be set aside in savings. This money, set aside at an interest rate of 3.85% will generate the future cost of the HPC bridge in 75 years. Within a 75 year life span there will be no cost to rebuild the UHPC bridges. Therefore, there is a life-cycle cost benefit to using UHPC for the I-25/Doña Ana Interchange. The least expensive option is four UHPC BT-63 girders with 15 mm strands.

The last column of Table 2 shows the cost of four modified (i.e., increased web width) UHPC BT-54 girder. This cross-section is required to provide adequate shear strength if mild steel stirrups are excluded. Compared to the cost of four typical BT-54 girders it is 3.5% more expensive to increase the web width than to use mild steel stirrups.

Table 2: I-25/Doña Ana Interchange Future Worth.

	6 HPC BT-63 Girders (15 mm strands)	4 UHPC BT-63 Girders (15 mm strands)	4 UHPC BT-54 Girders (18 mm strands)	4 Modified UHPC BT-54 Girders (18 mm strands)
Present Value	$81,434	$120,014	$124,030	$128,340
Future Worth	$1,384,509	$34,690,156	$35,851,130	$37,096,892
Net Present Value	$81,434	$120,014	$124,030	$128,340

There are many variables that influence the cost of UHPC. Mixture proportions, the curing regimen, the percent volume are all factors that can be optimized to lower the cost of UHPC. However, further research is needed to investigate these different parameters. In addition, design standards and specifications are not readily available for using UHPC. Thus, many of the properties of UHPC are not fully utilized. Once additional research and more design applications using UHPC have been conducted, a better understanding of this material will exist, in which we can fully optimize the manner in which we use this material. This will once again lower the cost.

From the bridge analyzed in this economic analysis, it can be seen that the initial cost of implementing UHPC is high. However, if the lifecycle costs are included UHPC has the potential to save money.

CONCLUSIONS AND RECOMMENDATIONS

Based on the results of this study, the following conclusions were drawn:

- UHPC girders with traditional 15 mm diameter strands require fewer girder lines and less concrete material as compared to high strength concrete.
- Larger diameter prestressing strands (i.e., 18 mm) strands can further reduce the member sizes and thus, the required concrete material.
- Incorporating the tensile strength of UHPC into the design can significantly impact the number of required prestressing strands.
- The required shear capacity can be achieved by considering the shear capacity of the crack-bridging fibers. In cases when the required tensile strength cannot be met by the UHPC contribution alone, traditional transverse mild steel reinforcement can be included in critical regions, or the size of the structural member can be modified (i.e., increasing the girder web width). Note that the amount of required traditional transverse mild steel reinforcement is significantly reduced compared to a high strength concrete girder.
- UHPC has the potential to reduce the life-cycle costs of bridge girders. UHPC is expected to provide at least twice the service life expected from HPC. Savings are made at 75 years when the HPC girder bridge has to be replaced and the UHPC girder bridge does not.

UHPC has the potential to offer many advantages for structural design applications. These properties enable the design and construction of bridges with longer spans, improved durability, and smaller structural members. The improved durability properties also improve the longevity of bridges, potentially doubling the service life of the structure.

As more research is conducted on this new material, design procedures and equations to model the behavior of UHPC will become available which could potentially further impact the efficiency of UHPC.

ACKNOWLEDGEMENTS

The authors would like to thank Bryce Simons, Ray Trujillo, Ted Barber, Ben Najera, Jim Camp, Keli Daniell, and Virgil Valdez (Research Bureau, NMDOT) for their guidance and support throughout the project. The authors also acknowledge the assistance of several individuals: Dr. Benjamin Graybeal, FHWA Turner-Fairbank Research Center; Dr. Franz Josef Ulm, Massachusetts Institute of Technology; Dean Bierwagen, Iowa Department of Transportation; Brian Moore, Wapello County Engineer; Brain Keierleber, Buchannan County Engineer and Ned Johnson, Buchannan County; Dr. Sri Sritharan, Iowa State University, and Brian Silvis, Virginia Department of Transportation for their assistance gathering information and answering questions. Shannon Applegate and Steven Ruiz of Coreslab, Albuquerque, NM; Steve Darrah, BASF The Chemical Company; and Megan May, Fibercon International assisted in determining cost of materials used in this study. The findings and conclusions in the paper are those of the authors and do not necessarily reflect the views of the organizations or the individuals acknowledged above.

ABSTRACT

Secondary bridge elements, such as barriers, curbs, or diaphragms, are not accounted for when calculating the distribution of load effects to interior and exterior girders, using the American Association of State Highway and Transportation Officials (AASHTO) Load and Resistance Factor Design (LRFD) Bridge Design Specifications (AASHTO 2007). This paper shows that including the effect of barriers changes the distribution of loads and, therefore, bending moments in girders. The Florida Department of Transportation (FDOT) Structures Research Lab made field strain measurements on two bridges: a Florida Bulb-T girder bridge and an AASHTO Type IV girder bridge. The Florida Bulb-T bridge strain measurements were taken before and after barriers were placed, and the AASHTO girder bridge was tested only with the barriers. The bridge test results were used to calibrate finite element models, which showed that the barrier, the barrier joint, and the diaphragms affect both interior and exterior girder strains.

INTRODUCTION

Since the 1930s, bridge engineers have used the concept of distribution factors to evaluate the distribution of live loads to, in the case of a girder bridge, the interior and exterior girders. The live load Distribution Factors (DF) are specified in AASHTO LRFD Bridge Design Specifications, and they do not account for secondary stiffening elements, e.g., barriers, diaphragms, and sidewalks.

It is possible that, by considering the effect of secondary stiffening elements, the distribution factors could be decreased, giving the bridge a higher load rating with the ability to theoretically carry larger loads (heavier trucks). Although it may not be desirable to count on secondary elements for design, because the elements may become damaged, it may be beneficial for the purpose of permitting to allow heavy trucks to cross on a temporary basis.

Higher levels of accuracy can be obtained from modifications to the original DF equations, which consider different variables not taken into account in the AASHTO LRFD equations (Eamon and Nowak 2005). Some researchers found that

the secondary stiffening elements such as barriers and diaphragms were able to reduce live load distribution factors significantly. This is dependent on the geometry of the bridge. A lot of bridges today, in essence, could carry increased loads due to the stiffening elements (Akinci et al. 2008).

Abendroth et al. (1995) discusses the effectiveness of diaphragms in prestressed concrete bridges. One of the reasons for having intermediate diaphragms in bridges is to reduce the risk of overturning of the girders during construction. Green et al. (2004) explained that the addition of intermediate diaphragms reduced deflections by about 19% in straight bridges. This shows a positive correlation with the addition of intermediate diaphragms the stiffer the girders become.

Mabsout et al. (1997) observed a 5% to 30% increase in the capacity of an interior girder due to sidewalks and railings. Cai and Shahawy (2004) studied the effects of diaphragms, bearing stiffness, and skew angles on load distribution and strains. An increase in diaphragm stiffness reduced the maximum strain up to 30%.

Akinci et al. (2008) knew the barrier effect caused a decrease of about 30% in the DF and wanted to see if the joints in the barriers change the distribution. When discontinuous barriers were present, there was an increase in stresses at the bottom of the girder. "Discontinuous parapets have full depth joints or gaps that may be introduced at locations other than the deck joints to reduce transverse parapet cracking" (Akinci et al. 2008).

Much research has been done on the effects of the barriers and diaphragms on a bridge, but with very little focus on the barrier joints. This research examines what effects the barrier joint has on the bridge both locally and globally. Field tests on two bridges in service and finite element modeling were performed to make comparisons and draw conclusions. Field test data is not reported herein; the data was used to calibrate the finite element models for the before-barrier and after-barrier conditions.

STRUCTURES CONSIDERED

Two bridges were examined in this study: a Florida Bulb-T girder bridge (Bridge 1) and an AASHTO Type IV girder bridge (Bridge 2). Erected in 2003, Bridge 1 is a prestressed concrete girder bridge with a cast-in-place, reinforced concrete slab. It has an overall width of 58'- 2.875". The bridge consists of six FBT78 (Florida Bulb-T 78 inch) girders, spaced at 9'-11.25", and an 8.25" thick slab (see Figure 1). The bridge accommodates two 11'-9.75" lanes, two 9'-10.125" shoulders, and two F-shaped traffic barriers. A typical unit contains three spans between expansion joints, with the slab being continuous over the two interior piers. The center span is where the test data was collected and, therefore, was the focus for this research. The span length is 152', with a center-to-center spacing between bearing pads of 149'-6". The prestressed girder concrete had a specified 28-day strength, f'_c, of 8,500 psi and a theoretical modulus of elasticity, MOE, of 5,306 ksi; the deck had a specified strength of 4,500 psi with MOE of 3,863 ksi; and the barriers had a specified strength of 3,336 psi with MOE of 3,292 ksi. The bridge's barriers have 0.788" wide joints at the midspan and at each pier, and diaphragms at the piers provide horizontal bracing for the girders.

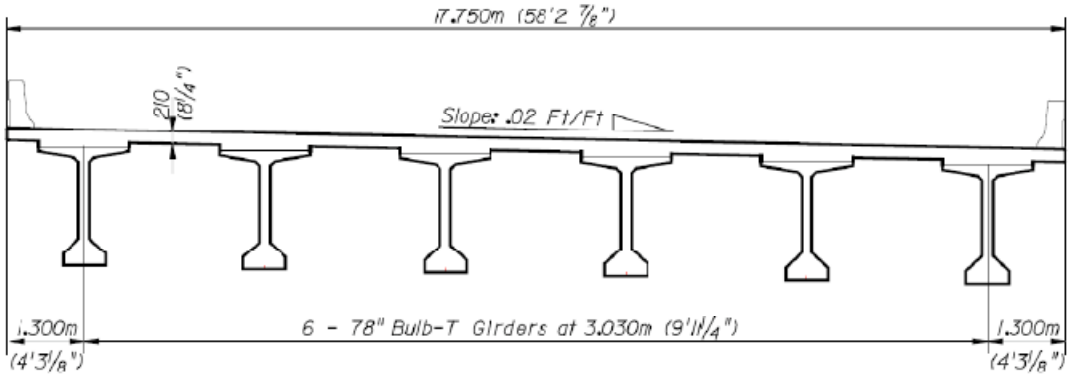

Figure 1. Cross section of Bridge 1.

Bridge 2, constructed in 1981, is a simply supported 118'-8" span which consists of a reinforced concrete slab and thirteen AASHTO Type IV girders equally spaced at 4'-5" (see Figure 2). The 59'-1" width includes three 12' lanes of traffic, two 10' shoulders, and two F-shaped barriers. The girder concrete had a specified strength of 5,000 psi, and the deck and barriers had a specified strength of 5,500 psi. The barriers have a joint at midspan, and diaphragms are located at 39'-4" from each approach slab (approximately third-points on the span). The modulus of elasticity of the concrete is stated in the plans: 3,860 ksi for the barriers and deck, and 3,627 ksi for the girders. The girders contain 49-0.5" diameter pretensioned 270 ksi low-relaxation strands.

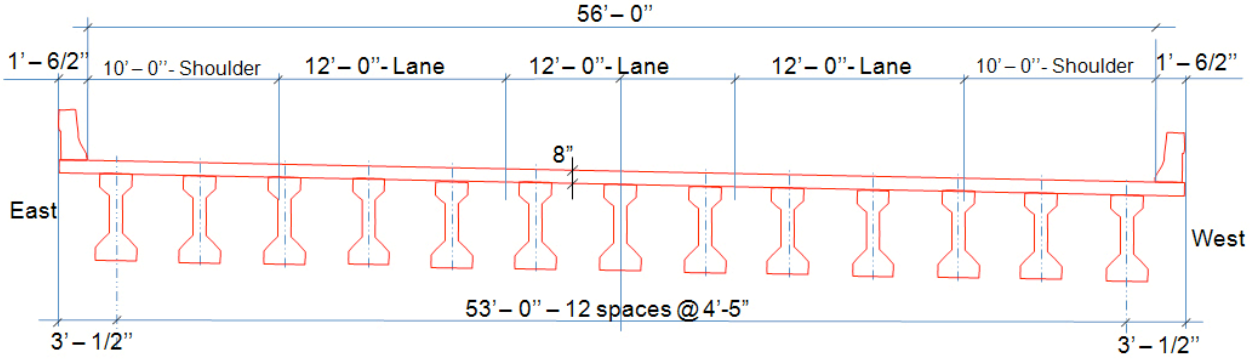

Figure 2. Cross section of Bridge 2.

OBJECTIVE OF STUDY

The Florida Department of Transportation (FDOT) Structures Research Lab made field measurements on both bridges. On Bridge 1, measurements were taken both before and after the barriers were placed, whereas on Bridge 2, measurements were taken only for the post-barrier condition. The bridges were incrementally loaded with the FDOT test vehicle and varying amounts of 2-ton blocks. The trucks were placed in order to create large bending moments in the exterior and first interior girders at midspan. Strain gages were used to measure longitudinal strains on the bottom of the

girders at midspan. These strains were used to validate and calibrate the finite element models.

Finite element modeling (FEM) of the bridges was conducted to determine how much effect the secondary elements have on live load distribution. Specifically reported herein are the results concerning the effect of the barriers, barrier joints, and diaphragms. FEMs were made for the case of no barriers, barriers without a midspan joint, barriers with a midspan joint, and barriers with third-point joints; models were also made with and without diaphragms. The objective was to determine how the diaphragms and different barriers affect the live load distribution and if the effects are local or global.

FINITE ELEMENT MODELING AND ANALYSIS

The FEMs of the bridges included the structural components that add to the stiffness of the bridge, namely the deck, barriers, diaphragms, and girders. The two bridges were modeled using the same techniques and element types; Solid 65 elements were used for 3-D modeling of reinforced concrete. This element is defined by eight nodes, each having three degrees of freedom with translations in the nodal x, y, and z directions. These elements allowed for the modeling of reinforcement as a smear, using a "real constant", by adding the total amount of reinforcement by a percentage of the volume it takes up in each element. The real constants were applied in each element in up to three directions. Because solid elements were used instead of shell or beam elements, the models were very large. FEM strains were compared to the load tests and were then used to make conclusions about the barrier, barrier joint, and diaphragm effects. Figure 3 shows a typical model.

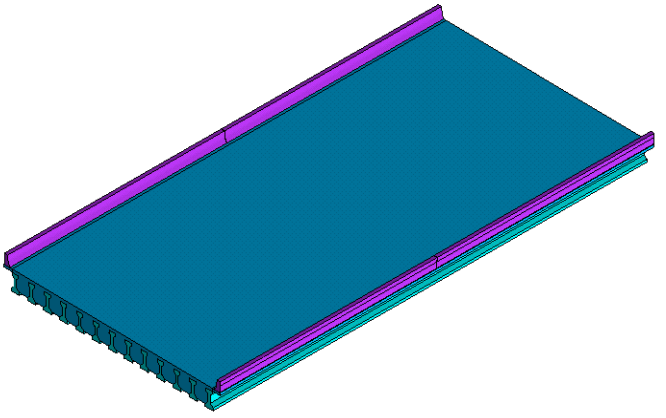

Figure 3. Typical Finite Element Model.

The theoretical material properties from the bridge plans were adjusted slightly to calibrate the models. For Bridge 1 FEM, the girder's MOE was taken as 5,306 ksi. For the deck and diaphragms, it was taken as 3,863 ksi; and for the barrier, 3,292 ksi. For Bridge 2, the MOE for the girders was 3,000 ksi and for the deck, diaphragms, and barriers was 3,200 ksi. Poisson's ratio of 0.2 was used for all concrete. The reinforcing steel MOE was 29,000 ksi with a Poisson's ratio of 0.35 for both bridges.

This study focused on live load distribution and, therefore, dead load effects were not modeled.

RESULTS

Barrier Effects. For Bridges 1 and 2, three FEMs were analyzed for each: no barriers, barriers without joints, and barriers with joints. For Bridge 1, FEMs simulate the FDOT load test truck loaded with 30 2-ton blocks. This load case was used to calibrate the FEM to the load test results. From Figure 4, compared to 90.4 με for the bridge with no barrier, the continuous barrier caused 87.5 με -- about a 3.2% decrease -- in the first interior girder (Girder 4-5) strains. When a joint in the barrier was added, the strain was 87.1 με, which is almost no change in strain.

Figure 5 shows the effects of the barrier and joint on the exterior girder (Girder 4-6). Compared to no barrier, the addition of the barrier causes an overall reduction in strain along the length of the girder. For the maximum strain, no barrier causes 101.9 με, whereas a continuous barrier causes 92.7 με. With a joint in the barrier, localized strain increases occur in the vicinity, longitudinally, of the joint – the maximum strain of 103.6 με is about the same strain when there is no barrier.

For Bridge 2, FEMs simulate the FDOT load test truck loaded with 36 2-ton blocks; this load case was used to calibrate the FEM to the load test results. Although Bridge 2 has diaphragms, in order to isolate the effect of the barriers, the diaphragms were not modeled in the first FEMs. Figure 6 shows that the continuous barrier decreases the maximum strain in the first interior girder (Girder 12) by 15.8%, from 125.3 με to 105.5 με, when compared to the no barrier case. The strain decreased, longitudinally along the entire span length when barriers were added. Also, the barrier without a joint causes a 7.5% lower maximum strain (105.5 με) than the barrier with a joint, and it affected the strains over about 40% of the span length.

From Figure 7, for the exterior girder (Girder 13), the addition of the barrier decreases the maximum strain by 20.2%, from 149.8 με to 119.6 με, compared to no barriers. The strain decreased longitudinally along the entire span length when barriers were added. With a joint in the barrier, the maximum strain of 170.7 με is 42.7% higher than without a joint in the barrier. The importance of these results is that the jointed barrier causes a girder strain that is 14% higher than without the barrier.

Diaphragm Effects. Figures 8 and 9 show the effects of diaphragms on Bridge 2 girder strains. The maximum strains with diaphragms (located at third-points) and barriers (with a joint at midspan) present decreased from 114.0 με to 106.0 με (7.0%) and from 170.7 με to 142.4 με (16.6%) in interior and exterior girders 12 and 13, respectively, compared to having barriers but no diaphragms.

Abendroth et al. (1995) mentioned that the vertical load distribution is independent of the type and location of the intermediate diaphragms. Cai and Shahawy (2004) reported that increasing the stiffness of diaphragms reduces maximum strain. The strain decrease effects from the diaphragms act globally along the length of the girder, reducing the strains along the span.

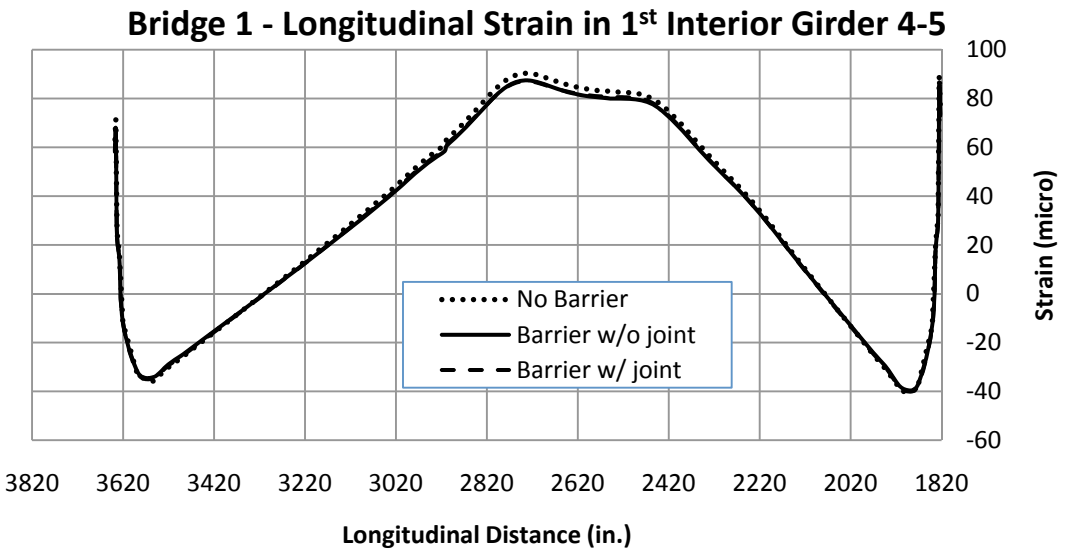

Figure 4. Bridge 1, strains in first interior girder 4-5 due to barrier and barrier joint at midspan.

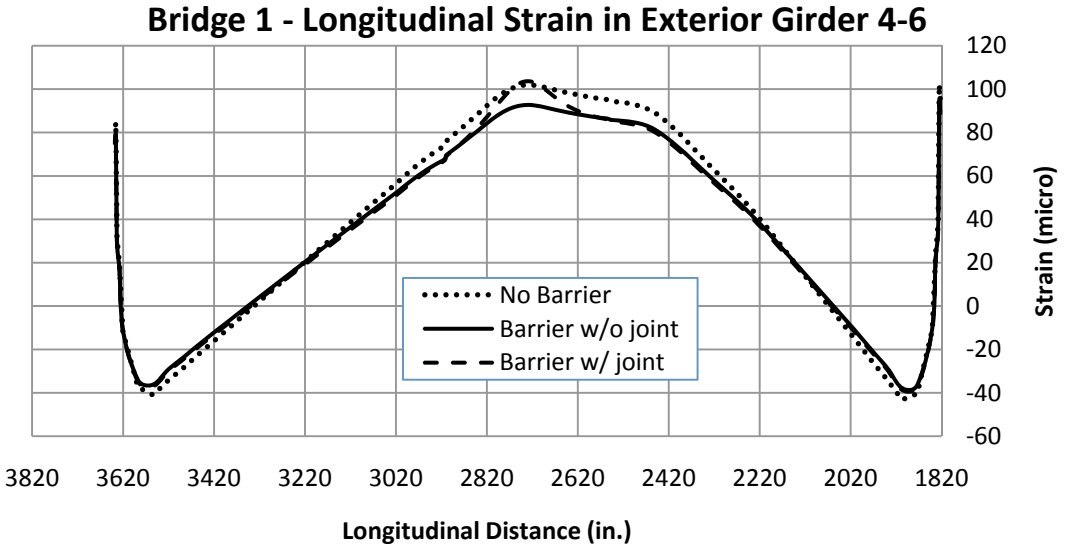

Figure 5. Bridge 1, strains in exterior girder 4-6 due to barrier and barrier joint at midspan.

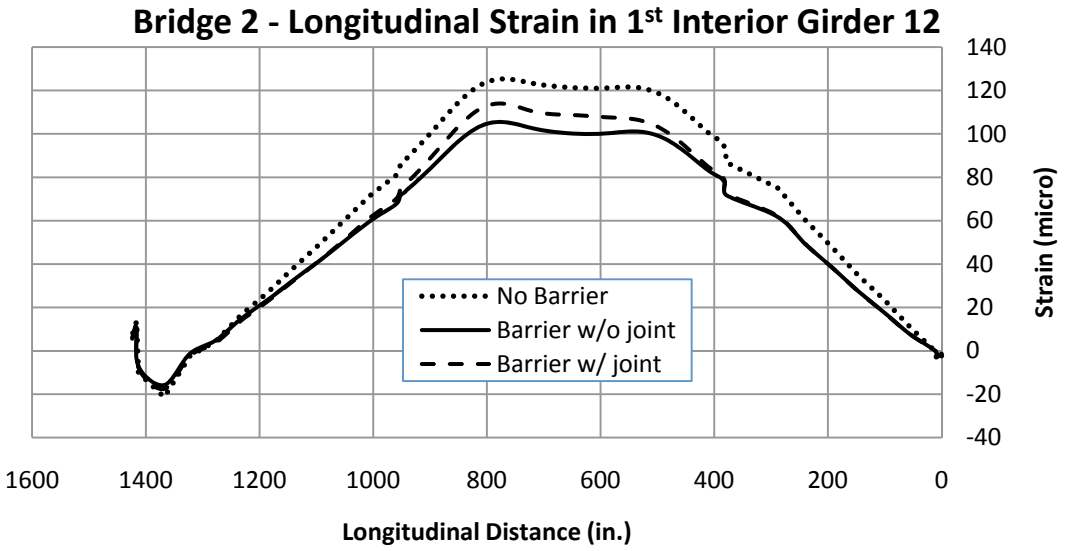

Figure 6. Bridge 2, strains in first interior girder 12 due to barrier and barrier joint at midspan.

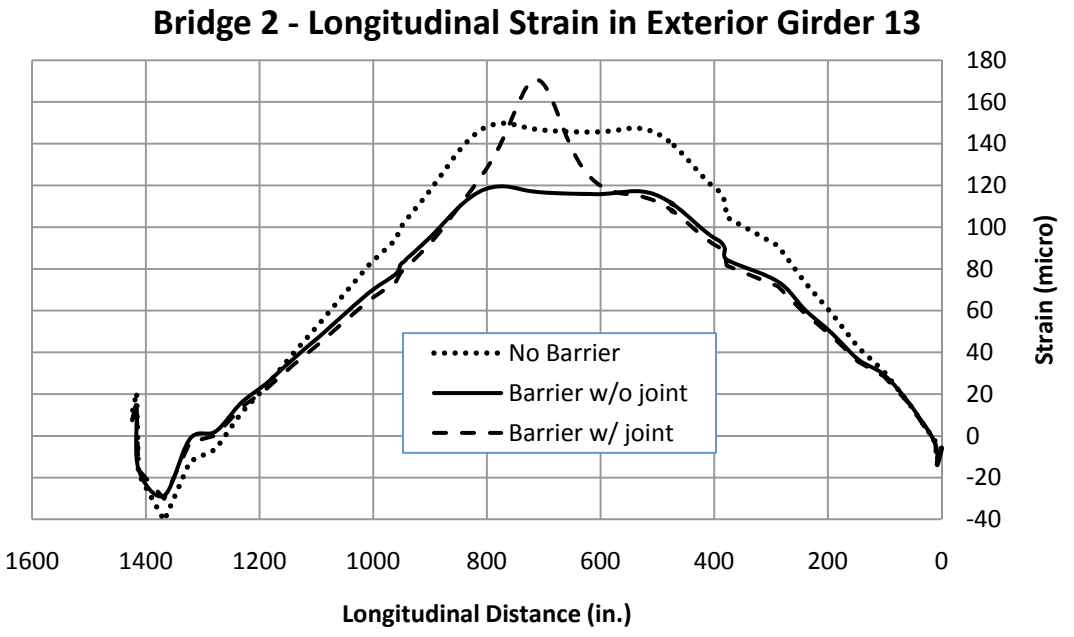

Figure 7. Bridge 2, strains in exterior girder 13 due to barrier and barrier joint at midspan.

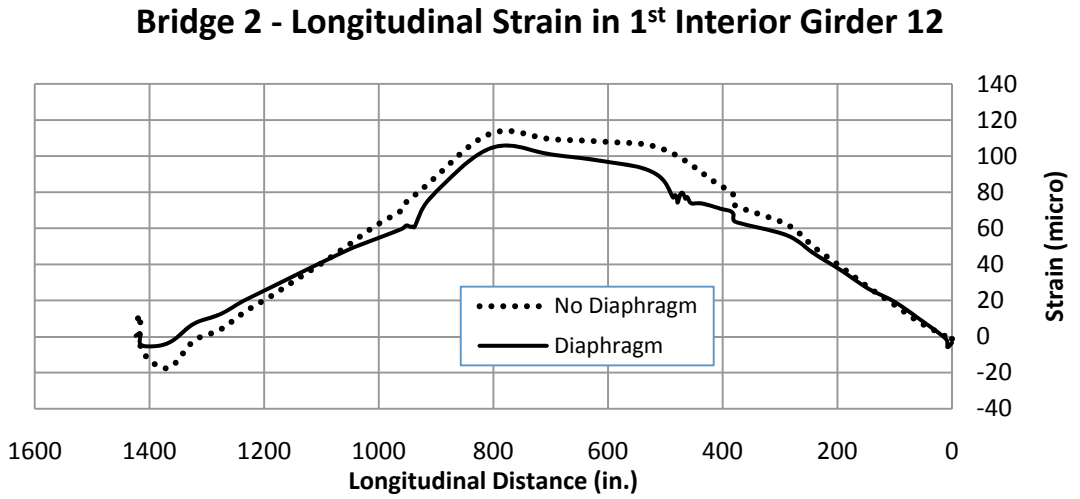

Figure 8. Bridge 2, strains in first interior girder 12 due to diaphragms, with barrier and joint.

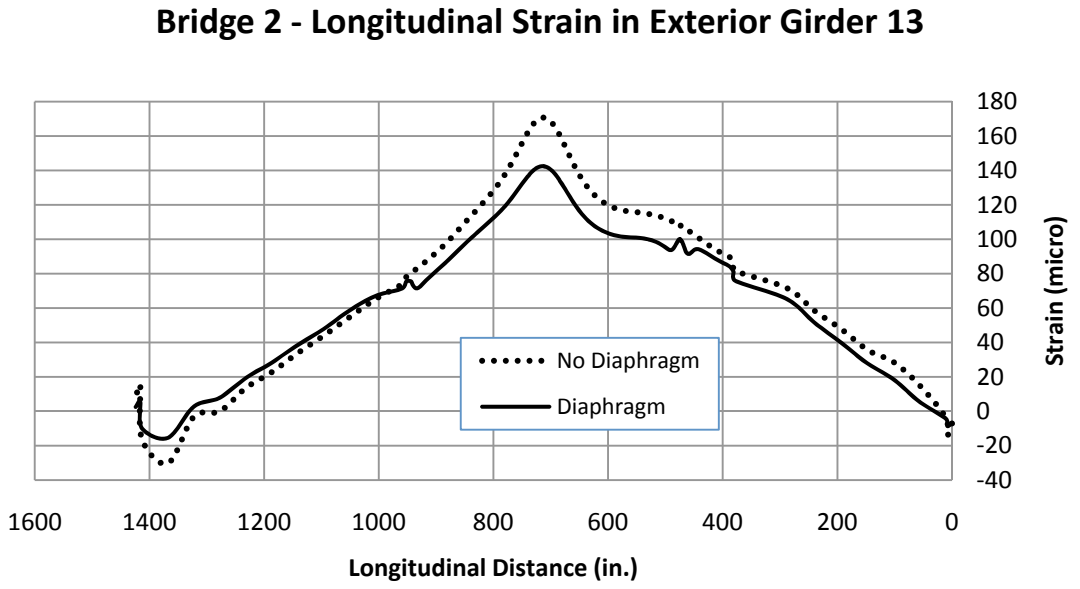

Figure 9. Bridge 2, strains in exterior girder 13 due to diaphragms, with barrier and joint.

Figures 10 and 11 show the longitudinal strains with no barriers, both with and without diaphragms. The strain decreases 16.38% and 22.53% in interior and exterior girders 12 and 13, respectively, when diaphragms are added. The increase in strain when the diaphragm is removed is much larger than when the diaphragm was removed with the barriers present, for both the first interior and exterior girders.

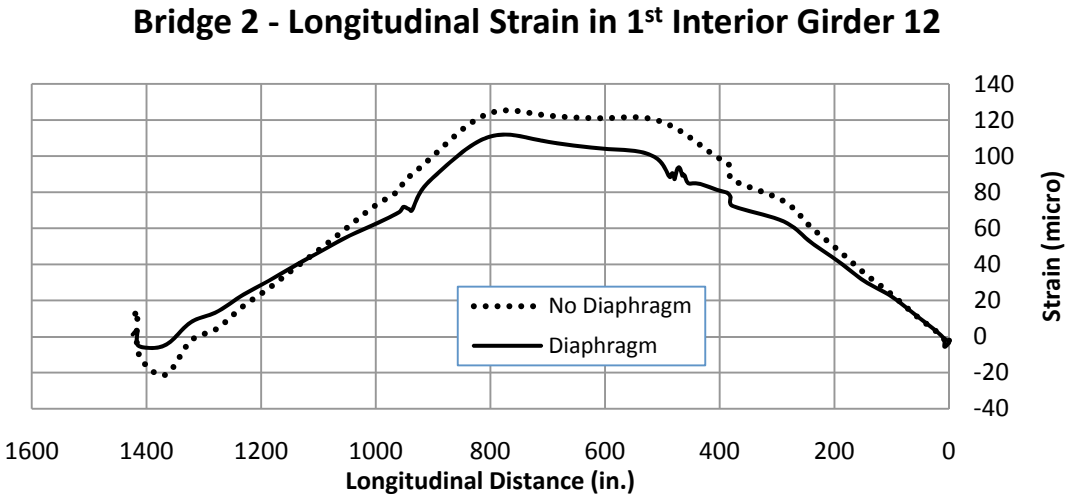

Figure 10. Bridge 2, strains in first interior girder 12 due to diaphragms, without barriers.

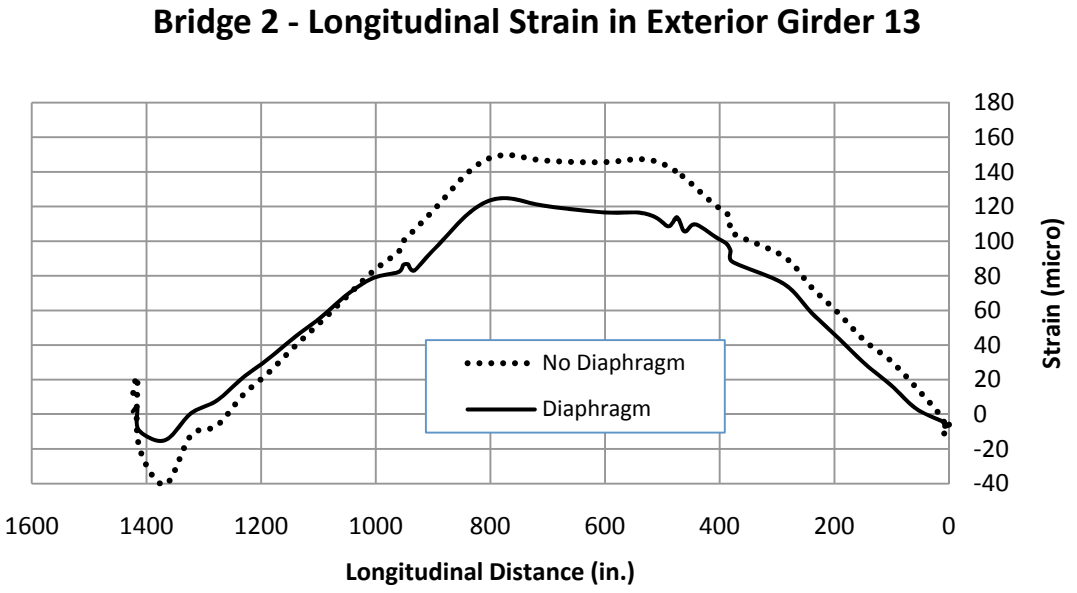

Figure 11. Bridge 2, strains in exterior girder 13 due to diaphragms, without barriers.

RECOMMENDATIONS

Figures 12 and 13 show, for Bridge 1, the effect on girder strains of barrier joints placed at third-points, compared to no joints and a joint at midspan. Placing the joints at third-points would move the localized strain increase away from the midspan (place of maximum moment). For this scenario, the maximum strain is still located at midspan. The third-point barrier joints have a localized effect only and contribute

only to the area around the joint location. The localized strain increase over the joint located around 2420 in. is larger because that is the side that the load is on.

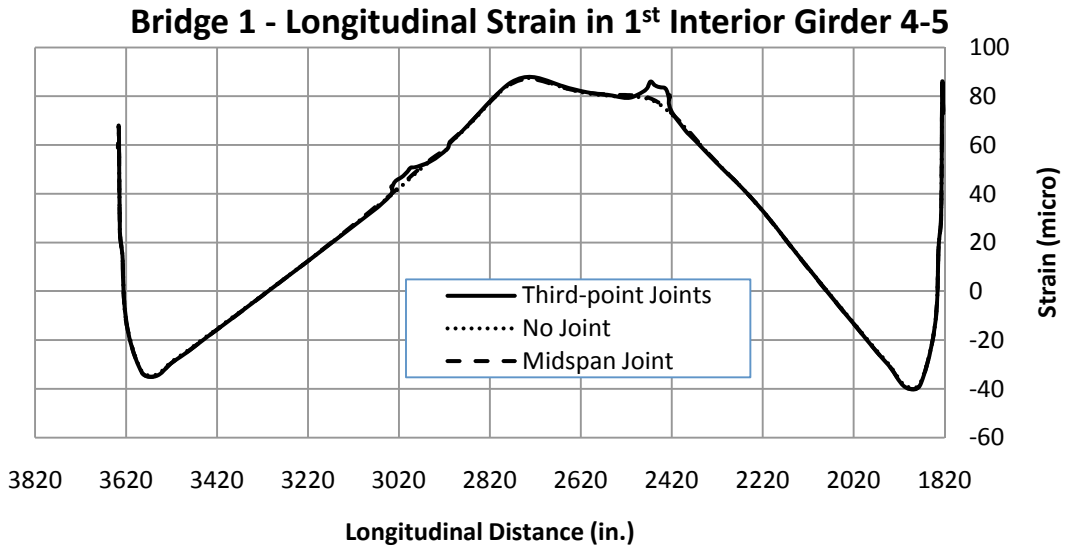

Figure 12. Bridge 1, strains in first interior girder 12 due to third-point barrier joints.

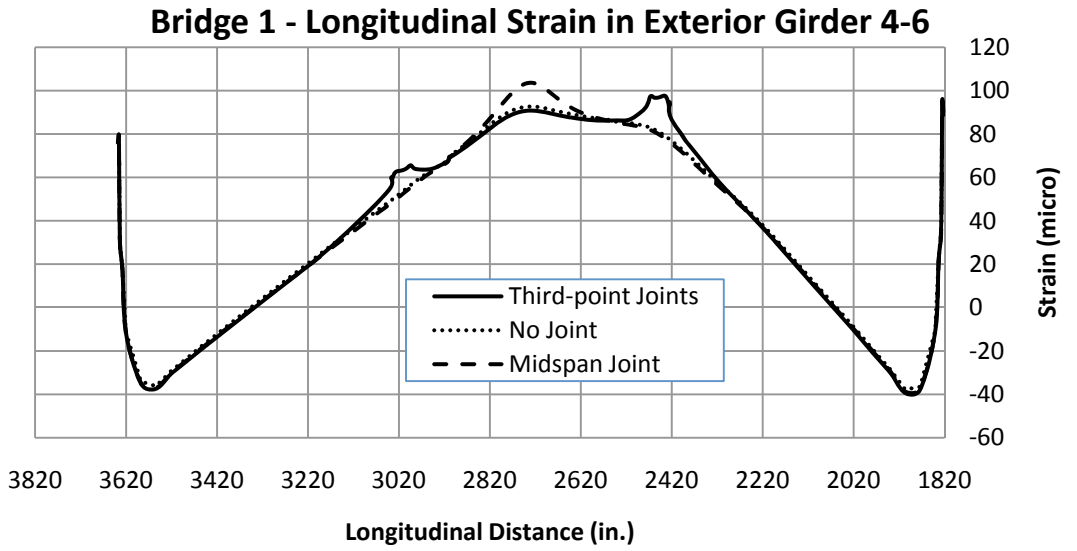

Figure 13. Bridge 1, strains in exterior girder 13 due to third-point barrier joints.

For existing bridges, if the joint is not necessary, it would be possible to retroactively fill in the joint with concrete or grout to create a continuous barrier condition. This would eliminate the strain concentration on the exterior girder of

bridges. For the joint fill to be effective, the concrete would need to have an adequate bond with the already existing barrier concrete.

CONCLUSIONS

The following conclusions may be made based upon the finite element models of the two bridges:

1. The addition of barriers reduces the strains in the exterior girder.
2. Intermediate diaphragms cause a decrease in the longitudinal girder strains globally, along the span of the bridge.
3. A joint in the barrier causes a localized strain increase in the exterior girder, in the longitudinal vicinity of the joint.
4. If barrier joints are deemed necessary, placing them at third-points along the span may be better than at midspan.
5. The effects of the barriers being added to the bridge are global, changing the strains along the span of the bridge.
6. A joint in the barrier has a small effect on the interior girder strain, and the effect spreads over one-third of the span length. The joint greatly affects the exterior girder strain, and the effect is local near the joint.
7. For load testing, using strain gages for measurement, special attention should be paid to the location of barrier joints that are present, so that their effects can be properly assessed, i.e., by the addition of extra strain gages or by extra monitoring around the longitudinal vicinity of the joints.

ABSTRACT

In this paper the cumulative effect of road surface roughness, vehicle dynamics, vehicle weight and speed is considered to find the impact factor for highway bridges. AASHTO HS20-44 vehicle is considered running on a very good road. The roughness of the road surface profile is found by using the power spectral density function. The AASHTO truck is modeled as a 12 degree of freedom system to consider the vehicle dynamics. First the forces coming on the bridge deck are calculated taking into account the road surface roughness, then the forces are input to find the vertical deflection by orthotropic plate theory. The deflection obtained is compared with the static deflection to find the impact factor. The impact factor thus obtained is compared with the impact factor calculated from the AASHTO formula. This study shows that the AASHTO formula underestimates the impact factor.

INTRODUCTION

Moving loads cause vibrations in the bridges, the resulting deformations and stresses are much higher than the static deformations and stresses. Peculiar feature of the moving loads on the highway bridges is that they are variable both in space and time. An impact factor, I, given by AASHTO is: $I = \frac{50}{L+125}$, where I is the impact factor with a maximum value of 30%. L is the length in feet of the portion of the span that is loaded to produce maximum stress in the member. Impact factor given by AASHTO depends only on the span length of the bridge, whereas, road surface profile, weight, speed, dynamics of a vehicle, and bridge geometry all affect the impact factor when moving loads are traveling on a bridge. The objective of this paper is to calculate the increased forces that act on a bridge deck by considering the road surface roughness, and the vehicle dynamics for an AASHTO HS20-44 truck at various speeds. The increased forces are applied on a bridge deck considered as an orthotropic plate to calculate the deflections. Bridges decks act differently in longitudinal and transverse directions because of their structural configuration and hence can be modeled as orthotropic plates. The increased forces and deflections are compared with the static forces and deflections to calculate the impact factor.

ROAD SURFACE ROUGHNESS

Road surface roughness is one of the factors that affect the impact factor for a bridge design. Dodds and Robson (1973) developed the Power Spectral Density (PSD) function to describe the road surface roughness as follows:

$$S(\phi) = A\left(\frac{\phi}{\phi_0}\right)^{-w} \quad (1)$$

Where, $S(\square)$ = PSD (m^2/cycle/m), $\square$ = wave number (cycle/m), A = roughness coefficient (m^3/cycle), $\square_0$ = discontinuity frequency = $\left(\frac{1}{2\pi}\right)$(cycles/m), and w = roughness exponent. The roads are classified as motorways, principal roads, and minor roads. Each of these classifications is further divided into very good, good, average, poor, and poor categories. In this paper the roughness exponent, w, has been taken as 2 for simplifying the road surface roughness. Jerath and Gurav (2008) used the PSD procedure to develop the road surface profile that is used here to find the roughness profile of a very good road for a T-beam bridge deck shown in Figure 1.

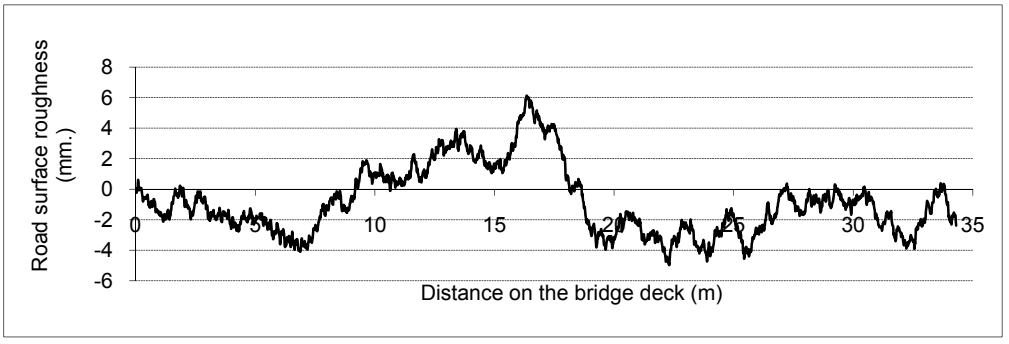

Figure1. Road surface roughness of a very good road for a T-Beam bridge

The data points are shown on the horizontal axis along the length of the bridge deck. Span length of the bridge in consideration is 112.5 ft (34.29 m) and it is divided into 2048 (2^{11}) sample points in Figure 1. The vertical axis shows the vertical distance between the tip of the road surface at a point from an imagined zero surface level in meters. The variation of the road surface is +6 to -5 mm (0.24 to -0.20 in.) for a very good road along the length of the bridge deck. The road surface roughness is used as input to the AASHTO HS20-44 vehicle model to calculate the forces that will act on a bridge deck.

VEHICLE DYNAMICS

The AASHTO HS20-44 truck is modeled as consisting of five rigid masses: tractor, semi-trailer, steer wheel/axle set, tractor wheel/axle set, and trailer wheel/axle set shown in Figures 2 and 3. Tractor and semi-trailer are assigned three degrees of freedom (y, θ, $\square$) individually. Two degrees of freedom (y and $\square$) are assigned to each wheel axle set. Thus there are 12 degrees of freedom (DOF) in the vehicle.

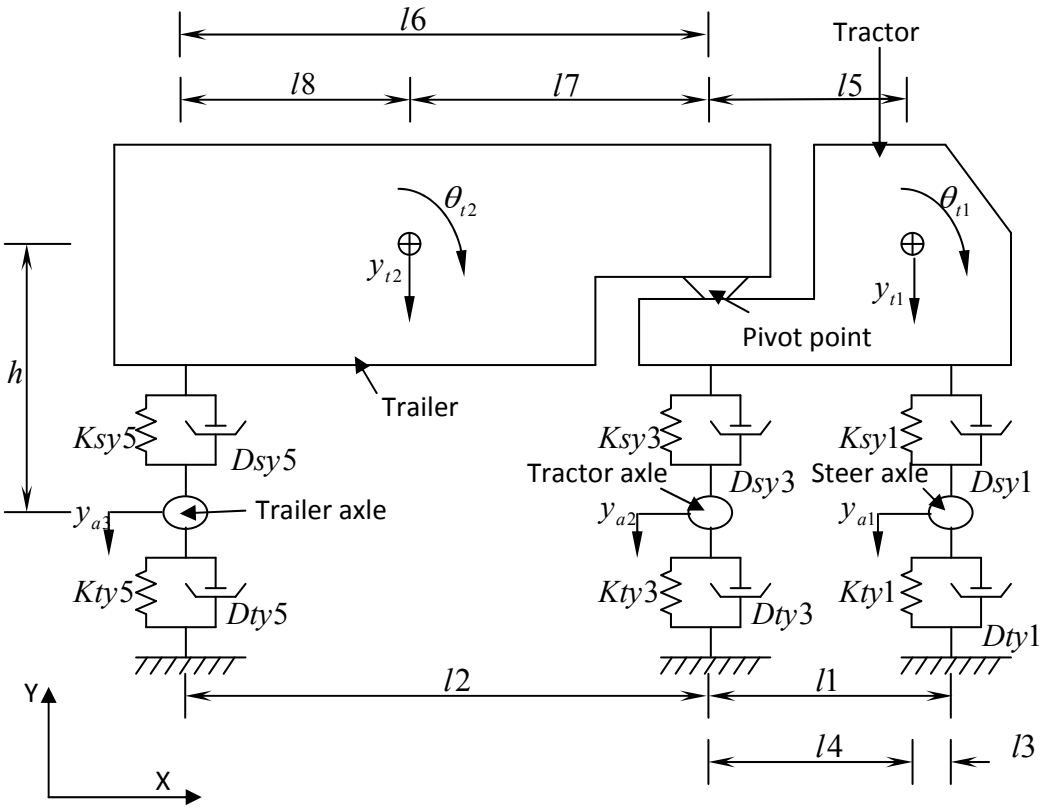

Figure2. Side elevation of AASHTO HS20-44 vehicle model

The equations of motion for the system are derived using Lagrange's formulation:

$$\frac{d}{dt}\left(\frac{\partial T}{\partial \dot{q}_i}\right)+\frac{\partial D}{\partial \dot{q}_i}-\frac{\partial T}{\partial q_i}+\frac{\partial V}{\partial q_i}=Qnc_i \qquad (2)$$

Where T, D, and V are total kinetic energy, dissipation energy, and potential energy of the vehicle consisting of springs, dampers, and masses shown in Figures 3 and 4. q_i and $\dot{q}_\iota$ are the generalized displacements and velocities, and Q_{nci} is a generalized force, I = 1,2,------, 11,12. The masses and the degrees of freedom of each rigid body are as follows:

y_{t1}, m_{t1}= Tractor vertical displacement and mass; ϕ_{t1}, I_{xt1}= Tractor roll displacement and mass moment of inertia about X axis; θ_{t1}, I_{zt1}= Tractor pitch displacement and mass moment of inertia about Z axis; y_{t2}, m_{t2}= Trailer vertical displacement and mass; ϕ_{t2}, I_{xt2}= Trailer roll displacement and mass moment of inertia about X axis; θ_{t2}, I_{zt2}= Trailer pitch displacement and mass moment of inertia about Z axis;

y_{a1}, m_{a1}= Steer axle vertical displacement and mass; and ϕ_{a1}, I_{xa1}= Steer axle roll displacement and mass moment of inertia about X axis; y_{a2}, m_{a2}= Tractor axle vertical displacement and mass; ϕ_{a2}, I_{xa2}= Tractor axle roll displacement and mass moment of inertia about X axis; y_{a3}, m_{a3}= Trailer axle vertical displacement and mass; and ϕ_{a3}, I_{xa3}= Trailer axle roll displacement and mass moment of inertia about X axis.

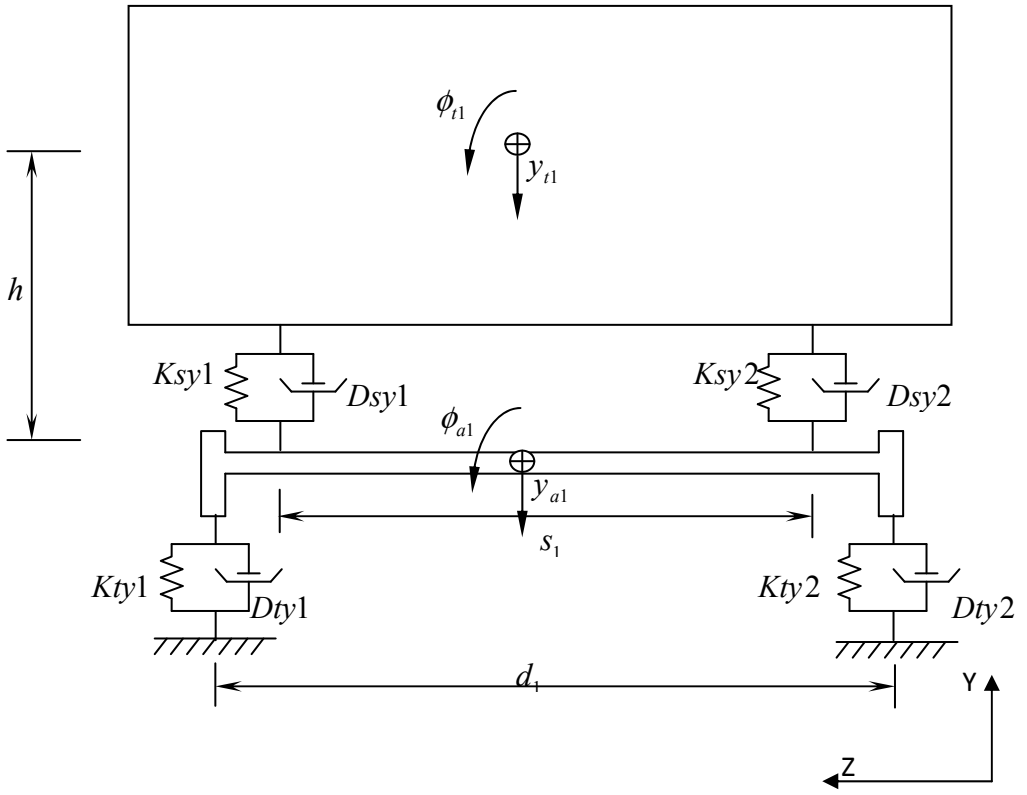

Figure3. Front elevation of AASHTO HS20-44 vehicle model

The relative displacements at the spring locations are given by

Suspension springs:

$$U_{sy1} = \left(y_{t1} - y_{a1} - \frac{l_3}{l_5} y_{t2} \right) + \left(s_1 / 2 \right)\left(\phi_{t1} - \phi_{a1} \right) + l_3 \theta_{t1} - l_7 \frac{l_3}{l_5} \theta_{t2}$$

$$U_{sy2} = \left(y_{t1} - y_{a1} - \frac{l_3}{l_5} y_{t2} \right) - \left(s_1 / 2 \right)\left(\phi_{t1} - \phi_{a1} \right) + l_3 \theta_{t1} - l_7 \frac{l_3}{l_5} \theta_{t2}$$

$$U_{sy3} = \left(y_{t1} - y_{a2} + \frac{l_4}{l_5} y_{t2} \right) + \left(s_2 / 2 \right)\left(\phi_{t1} - \phi_{a2} \right) - l_4 \theta_{t1} + l_7 \frac{l_4}{l_5} \theta_{t2} \qquad (3)$$

$$U_{sy4} = \left(y_{t1} - y_{a2} + \frac{l_4}{l_5} y_{t2} \right) - (s_2 / 2)(\phi_{t1} - \phi_{a2}) - l_4 \theta_{t1} + l_7 \frac{l_4}{l_5} \theta_{t2}$$

$$U_{sy5} = \left(y_{t2} - y_{a3} - \frac{l_8}{l_7} y_{t1} \right) + \left(s_3 \big/ 2 \right)(\phi_{t2} - \phi_{a3}) - l_8 \theta_{t2} - l_5 \frac{l_8}{l_7} \theta_{t1}$$

$$U_{sy6} = \left(y_{t2} - y_{a3} - \frac{l_8}{l_7} y_{t1} \right) - \left(s_3 \big/ 2 \right)(\phi_{t2} - \phi_{a3}) - l_8 \theta_{t2} - l_5 \frac{l_8}{l_7} \theta_{t1}$$

Tire springs:

$$U_{ty1} = y_{a1} + \left(d_1 \big/ 2 \right) \phi_{a1} + (u_{sr1})$$

$$U_{ty2} = y_{a1} - \left(d_1 \big/ 2 \right) \phi_{a1} + (u_{sr2})$$

$$U_{ty3} = y_{a2} + \left(d_2 \big/ 2 \right) \phi_{a2} + (u_{sr3}) \qquad (4)$$

$$U_{ty4} = y_{a2} - \left(d_2 \big/ 2 \right) \phi_{a2} + (u_{sr4})$$

$$U_{ty5} = y_{a3} + \left(d_3 \big/ 2 \right) \phi_{a3} + (u_{sr5})$$

$U_{sr1\text{----}6}$ = Vertical displacement of road surface, it is considered positive if upwards.

The total kinetic energy, $T = \sum T_i$ of the system is

$$T = \frac{1}{2} m_{t1} \dot{y}_{t1}^2 + \frac{1}{2} Ix_{t1} \dot{\phi}_{t1}^2 + \frac{1}{2} Iz_{t1} \dot{\theta}_{t1}^2 + \frac{1}{2} m_{t2} \dot{y}_{t2}^2 + \frac{1}{2} Ix_{t2} \dot{\phi}_{t2}^2 + \frac{1}{2} Iz_{t2} \dot{\theta}_{t2}^2 + \frac{1}{2} m_{a1} \dot{y}_{a1}^2 + \frac{1}{2} Ix_{a1} \dot{\phi}_{a1}^2$$

$$+ \frac{1}{2} m_{a2} \dot{y}_{a2}^2 + \frac{1}{2} Ix_{a2} \dot{\phi}_{a2}^2 + \frac{1}{2} m_{a3} \dot{y}_{a3}^2 + \frac{1}{2} Ix_{a3} \dot{\phi}_{a3}^2 \qquad (5)$$

The total potential energy, $V = \sum V_i$ of the system is

$$V = \frac{1}{2} K_{sy1} U_{sy1}^2 + \frac{1}{2} K_{sy2} U_{sy2}^2 + \frac{1}{2} K_{sy3} U_{sy3}^2 + \frac{1}{2} K_{sy4} U_{sy4}^2 + \frac{1}{2} K_{sy5} U_{sy5}^2 + \frac{1}{2} K_{sy6} U_{sy6}^2$$

$$+ \frac{1}{2} K_{ty1} U_{ty1}^2 + \frac{1}{2} K_{ty2} U_{ty2}^2 + \frac{1}{2} K_{ty3} U_{ty3}^2 + \frac{1}{2} K_{ty4} U_{ty4}^2 + \frac{1}{2} K_{ty5} U_{ty5}^2 + \frac{1}{2} K_{ty6} U_{ty6}^2 \qquad (6)$$

The dissipation energy, $D = \sum D_i$ of the system is

$$D = \frac{1}{2}D_{sy1}\dot{U}_{sy1}^2 + \frac{1}{2}D_{sy2}\dot{U}_{sy2}^2 + \frac{1}{2}D_{sy3}\dot{U}_{sy3}^2 + \frac{1}{2}D_{sy4}\dot{U}_{sy4}^2 + \frac{1}{2}D_{sy5}\dot{U}_{sy5}^2 + \frac{1}{2}D_{sy6}\dot{U}_{sy6}^2$$

$$+\frac{1}{2}D_{ty1}\dot{U}_{ty1}^2 + \frac{1}{2}D_{ty2}\dot{U}_{ty2}^2 + \frac{1}{2}D_{ty3}\dot{U}_{ty3}^2 + \frac{1}{2}D_{ty4}\dot{U}_{ty4}^2 + \frac{1}{2}D_{ty5}\dot{U}_{ty5}^2 + \frac{1}{2}D_{ty6}\dot{U}_{ty6}^2 \qquad (7)$$

Substituting the relative displacements in terms of 12 DOF from Equations (3) and (4),and using Equations (2), (5), (6), and (7), we get twelve equations of motion given by Gurav (2006). These equations of motion can be written in matrix form as

$$[M]\{\ddot{q}\} + [C]\{\dot{q}\} + [K]\{q\} = \{F\} \qquad (8)$$

Where, $[M]$ = global mass matrix; $[C]$ = global damping matrix; $[K]$ = global stiffness matrix; and $\{F\}$ = global force matrix. The generalized displacements and their derivatives are given by

$$\lfloor q \rfloor = \lfloor y_{t1}\ \theta_{t1}\ \phi_{t1}\ y_{t2}\ \theta_{t2}\ \phi_{t2}\ y_{a1}\ \phi_{a1}\ y_{a2}\ \phi_{a2}\ y_{a3}\ \phi_{a3} \rfloor$$

$$\left\lfloor \dot{q} \right\rfloor = \left\lfloor \dot{y}_{t1}\ \dot{\theta}_{t1}\ \dot{\phi}_{t1}\ \dot{y}_{t2}\ \dot{\theta}_{t2}\ \dot{\phi}_{t2}\ \dot{y}_{a1}\ \dot{\phi}_{a1}\ \dot{y}_{a2}\ \dot{\phi}_{a2}\ \dot{y}_{a3}\ \dot{\phi}_{a3} \right\rfloor \qquad (9)$$

and $$\left\lfloor \ddot{q} \right\rfloor = \left\lfloor \ddot{y}_{t1}\ \ddot{\theta}_{t1}\ \ddot{\phi}_{t1}\ \ddot{y}_{t2}\ \ddot{\theta}_{t2}\ \ddot{\phi}_{t2}\ \ddot{y}_{a1}\ \ddot{\phi}_{a1}\ \ddot{y}_{a2}\ \ddot{\phi}_{a2}\ \ddot{y}_{a3}\ \ddot{\phi}_{a3} \right\rfloor$$

The MATLAB was used to get the solutions of $\{q\}$ and its derivatives. From these displacements the suspension forces in the springs and tire forces are calculated. The spring suspension and tire forces are given by

$F_{syi} = K_{syi}U_{syi} \pm F_{yi}$ - Suspension spring force.

$F_{dsyi} = D_{syi}\dot{U}_{syi}$ - Damping force in the suspension.

$F_{tyi} = K_{tyi}U_{tyi}$ - Tire spring force.

$F_{dtyi} = D_{tyi}U_{tyi}$ - Damping force in the tire.

i = 1 to 6, and F_{yi} = Friction force at the ith suspension.

The data regarding distances, stiffness of the springs and tires, damping coefficients, and friction forces required to solve Equation (8) are given by Gurav (2006).The calculated tire forces are shown in Table 1. The ratio of the tire forces and the static forces give the impact factors for various speeds of the vehicle. The impact tire force varied from 24.72% for the trailer axle tires to 51.74% for the tractor axle tires when the speed of the vehicle was increased from 40 to 90 mph (64 to 144 km/hr). The increased forces are considered for the analysis to find the deflection of the deck of a simply supported T-Beam concrete bridge of span 112.50 ft (34.29 m)

and width of 42.66 ft (13.00 m). The analysis of the bridge is performed by using the orthotropic plate theory.

Table 1. Comparison of tire forces at different speeds for HS20-44 truck on a T-beam bridge deck.

Speed (mph)	Static (Kips)	Fty1 (Kips)	%Impact	Static (Kips)	Fty3 (Kips)	%Impact	Static (Kips)	Fty5 (Kips)	%Impact
40	3.99	4.67	17.16	15.97	21.53	34.80	15.99	19.94	24.72
45	3.99	4.71	17.98	15.97	24.23	51.74	15.99	19.82	23.92
50	3.99	4.74	18.79	15.97	22.29	39.54	15.99	19.20	20.09
55	3.99	4.58	14.76	15.97	21.73	36.08	15.99	18.86	17.96
60	3.99	4.82	20.73	15.97	22.28	39.51	15.99	19.23	20.27
65	3.99	4.72	18.19	15.97	22.64	41.75	15.99	19.64	22.83
70	3.99	4.79	19.95	15.97	22.82	42.88	15.99	19.81	23.87
75	3.99	4.86	21.90	15.97	23.94	49.91	15.99	19.34	20.93

85	3.99	5.08	27.27	15.97	23.30	45.92	15.99	19.89	24.36
90	3.99	5.17	29.57	15.97	23.84	49.28	15.99	19.44	21.59

Note: Fty2, Fty4, and Fty6 are same as Fty1, Fty3, and Fty5 respectively. 1 Kip = 1000 lbs =4.5 kN, 1 mph = 1.6 km/hr.

ORTHOTROPIC PLATE THEORY UNDER MOVING LOADS

In this the bridge deck is modeled as an orthotropic rectangular plate with two edges simply supported and the other two edges as free shown in Figure 4. The strain energy of an orthotropic plate is given by Timoshenko (1959) as

$$U = \frac{1}{2}\int_0^a\int_0^b \left[D_x\left(\frac{\partial^2 w}{\partial x^2}\right)^2 + \left(D_x v_{yx} + D_y v_{xy}\right)\frac{\partial^2 w}{\partial x^2}\frac{\partial^2 w}{\partial y^2} + D_y\left(\frac{\partial^2 w}{\partial y^2}\right)^2 + 4D_{xy}\left(\frac{\partial^2 w}{\partial x \partial y}\right)^2 \right] dxdy \qquad (10)$$

Where, $D_x = \frac{E_x h^3}{12(1 - v_{xy}v_{yx})}$, $D_y = \frac{E_y h^3}{12(1 - v_{xy}v_{yx})}$ and $D_{xy} = \frac{G_{xy} h^3}{12}$

E_x = Modulus of elasticity in X direction, E_y = Modulus of elasticity in Y direction,

v_{xy} = Poisson's ratio associated with a strain in the Y direction for a load in the X

direction, v_{yx} = Poisson's ratio associated with a strain in the X direction for a load in the Y direction, G_{xy} = Shear modulus of the plate.

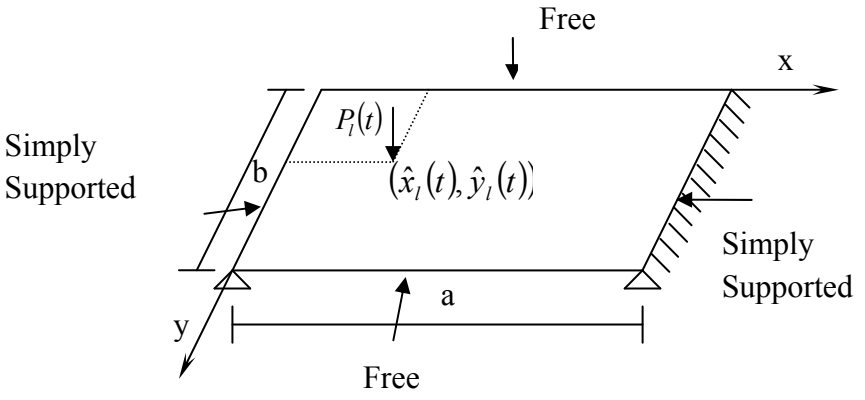

Figure4. Orthotropic plate with moving load

The kinetic energy of the plate is given by

$$T = \frac{1}{2}\int_0^a \int_0^b \dot{w}(x,y,t)^2 \rho h dx dy \tag{11}$$

Where, ρ = Mass density of material of the plate, h = Thickness of the plate.

The work done due to damping in the plate is given as

$$W_c = -\int_0^a \int_0^b w(x,y,t) c_b \dot{w}(x,y,t) dx dy \tag{12}$$

Where, c_b = Damping coefficient of the plate.

The external work done by the force $P_l(t)$ can be written as

$$W = \int_0^a \int_0^b \sum_{l=1}^{N_p} P_l(t)\delta(x-\hat{x}_l(t))\delta(y-\hat{y}_l(t))w(x,y,t) dx dy \tag{13}$$

Where, $P_l(t)$, $(l = 1,2,...,N_p)$ = Moving loads, $\hat{x}_l(t), \hat{y}_l(t)$ = Coordinates of the position of moving load $P_l(t)$, $\delta(x-\hat{x}_l(t))$, $\delta(y-\hat{y}_l(t))$ = Dirac Delta function.

The displacement function of the plate can be written as a summation of the normal mode function in the X and Y coordinates as,

$$w(x,y,t) = \sum_{m,n} w_{mn}(x,y) q_{mn}(t) \tag{14}$$

Where, $w_{mn}(x,y) = Y_{mn}(y)\sin\left(\frac{m\pi x}{a}\right)$ = Normal modes of the plate, $q_{mn}(t)$ = The corresponding generalized coordinates.

By using the Lagrange's equation,

$$\frac{d}{dt}\left(\frac{\partial T}{\partial \dot{q}}\right) - \frac{\partial T}{\partial q} + \frac{\partial U}{\partial q} - \frac{\partial W_c}{\partial q} = \frac{\partial W}{\partial q} \tag{15}$$

Equation of motion is given by

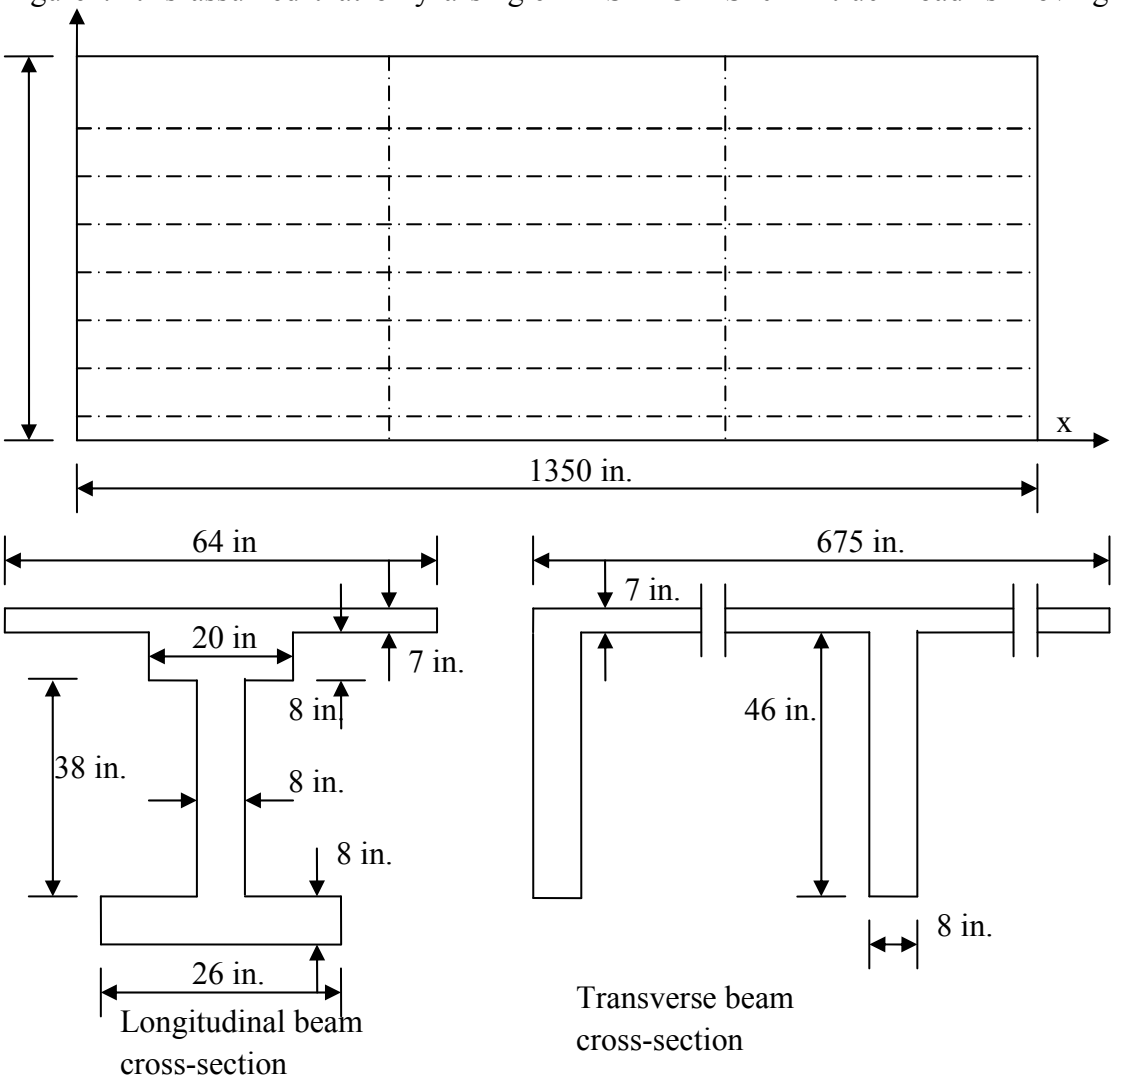
$$\{M\}\{\ddot{q}\} + \{C\}\{\dot{q}\} + \{K\}\{q\} = \{P\} \tag{16}$$

Where,

$$M = \int_0^a \int_0^b w^2{}_{mn}(x,y)\rho h dx dy \tag{17}$$

$$C = \int_0^a \int_0^b w^2{}_{mn}(x,y) c_b dx dy \tag{18}$$

$$K = \int_0^a \int_0^b \left[\begin{array}{l} D_x\left(\frac{\partial^2 w_{mn}}{\partial x^2}\right)^2 + \left(D_x v_{yx} + D_y v_{xy}\right)\frac{\partial^2 w_{mn}}{\partial x^2}\frac{\partial^2 w_{mn}}{\partial y^2} \\ + D_y\left(\frac{\partial^2 w_{mn}}{\partial y^2}\right)^2 + 4D_{xy}\left(\frac{\partial^2 w_{mn}}{\partial x \partial y}\right)^2 \end{array} \right] dx dy \tag{19}$$



$$P = \int_0^a \int_0^b \sum_{l=1}^{N_p} P_l(t)\delta(x - \hat{x}_l(t))\delta(y - \hat{y}_l(t)) w_{mn}(x,y) dx dy \tag{20}$$

The equation of motion (16) is solved for the generalized coordinate q_{mn} by MATLAB. The normal modes of the plate $w_{mn} = Y_{mn}(y) sin\left(\frac{m\pi x}{a}\right)$ required in the Equation (16) are obtained from the eigenvalue analysis of the orthotropic plate given by Gurav and Jerath (2006).

ANALYSIS OF T-BEAM BRIDGE BY ORTHOTROPIC PLATE THEORY

A simply supported T-Beam bridge of span 112.5 ft = 1350 in. (34.29 m) and width of 42.66 ft = 512 in. (13.00 m) is considered as shown in Figure 5. The bridge is built on a very good road whose road surface roughness profile is shown in

Figure1. It is assumed that only a single AASHTO HS20-44 truck load is moving

1 in. = 25.4 mm

Figure5. Simply supported T-Beam bridge

along the center line of the bridge deck at different speeds. The tire forces that have a cumulative effect of road surface roughness and vehicle dynamics from Table 1 are multiplied by 2 to get the total axle force for the steer, trailer, and tractor axles. The axle forces are shown in Table 2 at different speeds.

The physical properties of the bridge deck in Figure 5 are:

a = 112.5 ft (34.29 m), b = 42.66 ft (13.00 m), h = 0.58 ft (176.78 mm), mass density ρ = 4.658 slugs/ft^3 (2400 kg/m^3), υ_{xy} = 0.2, D_x = 2.3285x10^9 lb.ft (3.1574x10^9 N. m), D_y = 0.2575x10^9 lb.ft (0.3492x10^9 N.m), $2H$ = 0.0342x10^9 lb.ft (0.0464x10^9 N.m).

Table 2. Axle load of AASHTO HS20-44 truck on the T-beam bridge deck.

Speed mph (km/hr)	Total axle load					
	Steer axle		Tractor axle		Trailer axle	
	lbs	kN	lbs	kN	lbs	kN
40 (64)	9340	42.03	43060	193.77	39880	179.46
45 (72)	9420	42.39	48460	218.07	39640	178.38
50 (80)	9480	42.66	44580	200.61	38400	172.80
55 (88)	9160	41.22	43460	195.57	37720	169.74
60 (96)	9640	43.38	44560	200.52	38460	173.88
65 (104)	9440	42.48	45280	203.76	39280	176.76
70 (112)	9580	43.11	45640	205.38	39620	178.29
75 (120)	9720	43.74	47880	215.46	38680	174.06
80 (128)	9740	43.83	46200	207.90	39020	175.59
85 (136)	10160	45.72	46600	209.70	39780	179.01
90 (144)	10340	46.53	47680	214.56	38880	174.96

The maximum vertical displacements at the center of th T-Beam bridge deck under AASHTO HS20-44 moving with different speeds are calculated by the orthotropic plate theory and are shown in Table 3. The static displacement in the Table 3 is obtained by assuming the vehicle is moving at 5 mph (8 km/hr). The impact factor for the vertical deflection is in the range of 36.81% to 43.96% in the Table 3, whereas the impact factor given by the AASHTO formula for the bridge is $\frac{50}{112.5+125} = 21.05\%$. Thus the AASHTO formula underestimates the impact factor.

Table 3. Maximum vertical displacements at the center of the bridge deck

Speed mph (km/hr)	Vertical displacement in. (mm)	Static vertical displacement in. (mm)	Impact %
40 (64)	0.299 (7.595)	0.218 (5.537)	36.81
45 (72)	0.314 (7.976)	0.218 (5.537)	43.96
50 (80)	0.305 (7.747)	0.218 (5.537)	39.56
55 (88)	0.301 (7.645)	0.218 (5.537)	37.91
60 (96)	0.306 (7.772)	0.218 (5.537)	40.11
65 (104)	0.304 (7.722)	0.218 (5.537)	39.01
70 (112)	0.299 (7.595)	0.218 (5.537)	36.81
75 (120)	0.302 (7.671)	0.218 (5.537)	38.46
80 (128)	0.301 (7.645)	0.218 (5.537)	37.91
85 (136)	0.308 (7.823)	0.218 (5.537)	41.21
90 (144)	0.312 (7.925)	0.218 (5.537)	42.86

CONCLUSIONS

- The road surface roughness of various types of highways ranging from very good roads on motorways to poor category on minor roads can be generated by using the power spectral density function.
- An AASHTO HS20-40 vehicle is modeled successfully as a 12 degree of freedom system to account for the effect of vehicle dynamics for calculating the dynamic force coming from the tires on the road surface.
- The solution of the equation of motion gives the vehicle spring suspension forces and the tire forces acting on the road. The impact of the tire forces varied from 24.72% for the trailer axle tires to 51.7% for the tractor axle tires when the speed of the vehicle is increased from 40 to 90 mph (64 to 144 km/hr).
- The cumulative effect of the road surface roughness, vehicle dynamics, weight and speed of the vehicle is found in the vertical deflection at the center of a simply supported T-Beam bridge deck by orthotropic plate theory. The impact factor varied from 38.81% to 43.96%, whereas the impact factor from ASSHTO formula is 21.05% for this bridge, which is an underestimation.
- It is recommended to further study the effect of number of vehicles traveling in different lanes and various speeds. In this study only one vehicle is traveling along the center line of the bridge deck.

ABSTRACT

There are, enormous number of, steel truss bridges in the U.S. and around the world. Elementary theory of structural analysis or linear elastic small displacement finite element method is typically used for analysis and design of these bridges. However, steel bridges may face large deflections and inelastic displacements due to unexpected live loads and/or unfavorable environmental conditions. Therefore, there is a need for the second- or higher-order elastic and/or inelastic analysis of these bridges. This article presents a methodology for the elastic large displacement analysis of plane trusses that are novel in bridge engineering practice.

Higher-order stiffness matrices and finite element procedure is used for the elastic nonlinear analysis of plane truss structures. The higher-order stiffness matrices are derived and formatted by using the updated Lagrangian description and the finite element concept. Then a numerical method, a modified Riks-Wempner approach, is used for the solution of geometric nonlinear plane truss problems. First, background on nonlinear truss analysis, the scope of this work, and the assumptions pertinent to this research are given. Second, the stiffness matrices, for nonlinear elastic plane truss analysis, are presented by using the incremental equation of equilibrium that is derived from first variation of increment of total potential energy. Third, a modified Riks-Wempner method is used for programming and software development. Numerical examples and results are presented next. The accuracy of the software developed is checked by comparing the results of numerical examples with theoretical results and examples published by other authors. In this research, the concept of Object-Oriented technology and C++ programming language are used for coding and software developed.

INTRODUCTION

To reflect the real behavior of structures under ultimate or abnormal loading conditions, nonlinear analysis should be adopted instead of linear analysis, since most structures exhibit some nonlinear behavior before reaching their limits of resistance. In the analysis of structural systems, two different types of structural nonlinearities have been identified. They are material nonlinearity and geometric nonlinearity. In this work, geometric nonlinearity for plane trusses is considered and the load-deflection paths of several trusses are traced and compared to existing literature and benchmark problems.

Nonlinear analysis of truss structures has been widely investigated by many researchers during the last four decades. However, because of the space limitation a literature review is not provided in this article.

SCOPE AND OBJECTIVES

The purposes of this research are: (1) to present the finite element formulation and derivation of higher-order nonlinear stiffness matrices that may be used for the analysis of plane truss systems under large strain conditions, (2) to apply a numerical procedure that is a variation of the modified Riks-Wempner method with higher-order nonlinear stiffness matrices for solving geometric nonlinear plane truss problems, (3) to develop a software package using C++ language capable of providing geometric nonlinear analysis for plane trusses, and

(4) to check the accuracy and reliability of the theoretical developments and software developed in this study by comparison of the results from two examples presented in this work with published literature.

ASSUMPTIONS

The following assumptions are made in order to solve the problems more effectively: (1) The members of the structures are straight, free of residual stress and imperfections. The longitudinal axis of each member is collinear with the centroidal axis of the cross-sections, (2) The nodes of each truss element are assumed to be hinged. The truss elements can resist axial force, but not bending moment or shear force, (3) Only deformations occurring in the plane of the truss structure are considered; local buckling is not taken into account, (4) The cross sections of members are symmetric about the plane of the truss (x-y plane), and are always normal to the x-axis of the members during deformation of the members, and (5) The cross-sections of members always stay in the plane of the truss, and large strains are allowed.

COORDINATE SYSTEMS

Lagrangian formulation is recommended in the analysis of solids and structures since it may represent a more natural and effective analytical approach than an Eulerian formulation. An Eulerian formulation is generally adopted in the analysis of fluid mechanics problems focused on the motion of the material through a stationary control volume. However, if problems arise with the use of a free surface analysis, an arbitrary Lagrangian-Eulerian formulation provides an effective solution because it allows the modeling of general free surfaces and interactions between fluid flows and structures (Bathe 1996).

There are two primary types of Lagrangian descriptions in geometric nonlinear analysis. They are *total* and *updated* Lagrangian descriptions. In the *total* Lagrangian description, all quantities are referred to the initial configuration of the element, *i.e.,* the initial configuration is selected as the reference configuration. Fig. 1 shows this initial configuration, which is called C_0. Although this type of description is easy to apply, a major disadvantage is that it leads to incorrect description of the equilibrium path when large deflections exist.

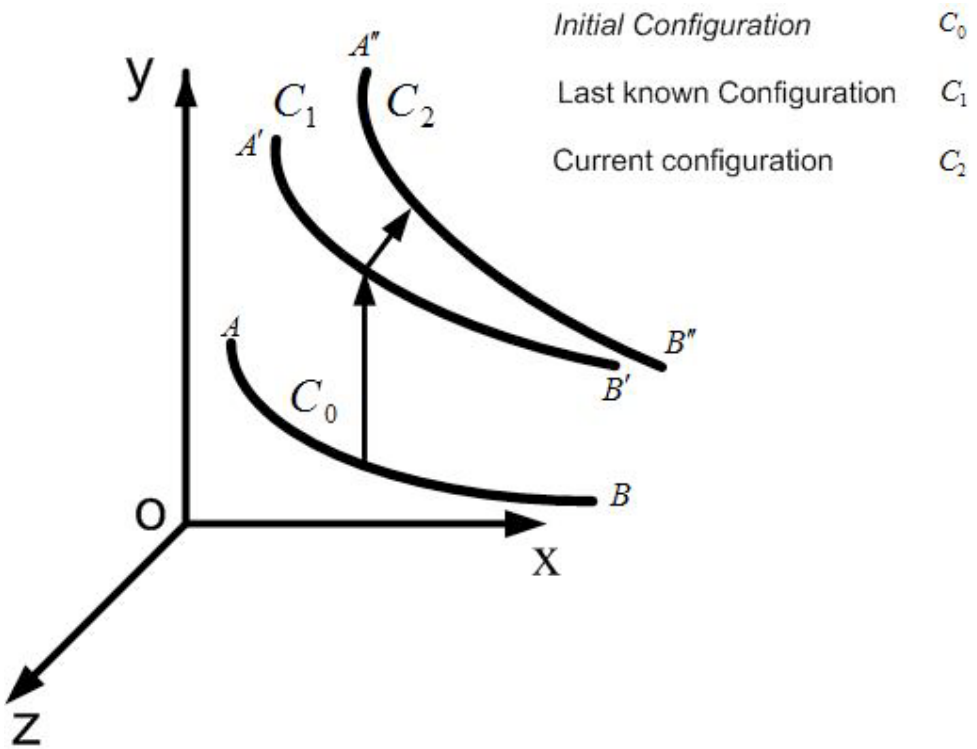

Fig. 1: Displacement of a Continuous Media from C_0 to C_2

In the *updated* Lagrangian description, all quantities are referred to the last configuration of the element, *i.e.,* the last configuration is chosen as the reference configuration (called C_1, see Fig. 1). This method generates a more accurate result than the first one. In the present study, this method is adopted, since its efficiency in dealing with the numerical computation is proven as compared to the total Lagrangian description (Torkamani and Sonmez 2001, Yang *et al*. 2007).

GENERAL FORMULATION

The elementary theory of structural analysis has been widely used for the calculation of internal forces, displacements, stresses, and strains of structures in order to select the proper member sizes for such systems. The shortcoming of elementary theory is its inability to represent the real behavior of the structures. For instance, the elastic behavior of cable nets, the calculation of the buckling load of a steel structure, and the nonlinear material behavior of a concrete building all fall in this category. In addition, it should be noted that the results obtained on the basis of elementary theory are questioned for many cases because the elementary theory of structures uses the most simple way to describe the behavior of structures. Moreover, in the elementary theory, the effects of the large deformations are ignored when considering the equations of equilibrium or motion.

Updated Lagrangian Formulation

In the updated Lagrangian formulation, the description of the continuous media up to the C_1 configuration is calculated (see Fig. 1). Furthermore, the media is in equilibrium at C_1 configuration. The deformation from the C_0 to C_1 is large. By increasing the external load, the continuous media deforms from the C_1 to C_2 configuration.

The incremental equilibrium equation is derived by applying the principle of minimum of increment of total potential energy. The increment of total potential energy from C_1 to C_2 configuration, considering C_1 configuration as the reference point, is given by

$$ {}^{2}_{1}\Delta\pi = \int_{{}_1V} ({}^{1}_{1}\tau_{ij} + \frac{1}{2}\,{}_1\tau_{ij})\,{}_1\varepsilon_{ij}\,{}^{1}dV - \int_{{}_1V} ({}^{1}_{1}f_i + \frac{1}{2}\,{}_1f_i)\,{}_1u_i\,{}^{1}dV - \int_{{}_1S} ({}^{1}_{1}t_i + \frac{1}{2}\,{}_1t_i)\,{}_1u_i\,{}^{1}dS \tag{1} $$

The stress, body force, surface traction, finite strain and displacement increments of a point P from C_1 to C_2 are written as:

$$ {}^{2}_{1}\tau_{ij} = {}^{1}_{1}\tau_{ij} + {}_1\tau_{ij} \tag{2} $$

$$ {}^{2}_{1}f_{ij} = {}^{1}_{1}f_{ij} + {}_1f_{ij} \tag{3} $$

$$ {}^{2}_{1}t_i = {}^{1}_{1}t_i + {}_1t_i \tag{4} $$

$$ {}^{2}_{1}\varepsilon_{ij} = {}^{1}_{1}\varepsilon_{ij} + {}_1\varepsilon_{ij} \tag{5} $$

and

$$ {}^{2}_{1}u_i = {}^{1}_{1}u_i + {}_1u_i \tag{6} $$

where ${}^{2}_{1}\tau_{ij}$ denotes the stresses, ${}^{2}_{1}f_{ij}$ the body forces, ${}^{2}_{1}t_i$ the surface tractions, ${}^{2}_{1}\varepsilon_{ij}$ the finite strains, and ${}^{2}_{1}u_i$ the displacements. All of these terms are at the C_2 configuration with respect to the C_1 reference configuration. In this study, a left superscript denotes the configuration of occurrence, and a left subscript the configuration of reference. The strain increments ${}_1\varepsilon_{ij}$ may be decomposed into linear and nonlinear parts:

$$ {}_1\varepsilon_{ij} = {}_1e_{ij} + {}_1\mu_{ij} \tag{7} $$

where ${}_1\varepsilon_{ij}$ denotes the increment of finite strain from configuration C_1 to C_2 with respect to the C_1 reference configuration and the linear part of strain increment ${}_1e_{ij}$ is defined as

$${}_1e_{ij} = \frac{1}{2}\left(\frac{\partial\ {}_1u_i}{\partial\ {}^1x_j} + \frac{\partial\ {}_1u_j}{\partial\ {}^1x_i} \right) \tag{8}$$

The nonlinear part ${}_1\mu_{ij}$ is expressed as

$${}_1\mu_{ij} = \frac{1}{2}\left(\frac{\partial\ {}_1u_k}{\partial\ {}^1x_i}\ \frac{\partial\ {}_1u_k}{\partial\ {}^1x_j} \right) \tag{9}$$

If one expands Eq. (1), takes the first variation of the expended equation, and sets the first variation of the increment of the total potential energy equal to zero, one would have $\delta\ {}^2_1\Delta\ \pi = 0$. On the other hand, the first variation of Eq. (7) may be written as:

$$\delta\ {}_1\varepsilon_{ij} = \delta\ {}_1e_{ij} + \delta\ {}_1\mu_{ij} \tag{10}$$

Substituting Eq. (10) in $\delta\ {}^2_1\Delta\ \pi = 0$ and taking advantage of virtual work equalities, one has the following incremental equilibrium equation

$$\int_{{}_1V} C_{ijkl}\ {}_1e_{kl}\ \delta\ {}_1e_{ij}\ {}^1dV + \int_{{}_1V} C_{ijkl}\ {}_1\mu_{kl}\ \delta\ {}_1e_{ij}\ {}^1dV + \int_{{}_1V} C_{ijkl}\ {}_1e_{kl}\ \delta\ {}_1\mu_{ij}\ {}^1dV$$

$$+ \int_{{}_1V} C_{ijkl}\ {}_1\mu_{kl}\ \delta\ {}_1\mu_{ij}\ {}^1dV + \int_{{}_1V} {}^1_1\tau_{ij}\ \delta\ {}_1\mu_{ij}\ {}^1dV + {}^1_1R = {}^2_1R \tag{11}$$

where ${}^2_1R$ and ${}^1_1R$ denote the virtual works done by the external loads acting on the continuous media at the C_2 and C_1 configuration, respectively.

Since all of the terms in Eq. (11) refer to the last calculated configuration, C_1, the left subscript 1 for e_{ij} , μ_{ij}, C_{ijkl}, ${}^1R$, ${}^2R$, and the left superscript 1 for V are dropped to simplify the equation as presented in the following forms

$$\int_V C_{ijkl}\, e_{kl}\, \delta e_{ij}\, dV + \int_V C_{ijkl}\, \mu_{kl}\, \delta e_{ij}\, dV + \int_V C_{ijkl}\, e_{kl}\, \delta \mu_{ij}\, dV$$

$$+ \int_V C_{ijkl}\, \mu_{kl}\, \delta \mu_{ij}\, dV + \int_V {}^1\tau_{ij}\, \delta \mu_{ij}\, dV + {}^1R = {}^2R \tag{12}$$

Finite Element Model

First, the stiffness matrices for a geometrically nonlinear elastic plane truss element suitable for updated-Lagrangian analysis using the incremental equations of equilibrium given by Eq. (12) is derived.

Considering the nodal displacements defined in Fig. 2, the displacements *u(x)* and *v(x)* may be written as the following forms

$$u(x) = [N_u]\{d\} \tag{13}$$

$$v(x) = [N_v]\{d\} \tag{14}$$

where

$$[N_u] = \left[1 - \frac{x}{L},\ 0,\ \frac{x}{L},\ 0 \right] \tag{15}$$

$$[N_u] = \left[\ 0,\ 1-\frac{x}{L},\ 0,\ \frac{x}{L}\ \right] \tag{16}$$

$$\{d\}^T = \{u_1, v_1, u_2, v_2\} \tag{17}$$

In Eqs. (15) and (16), $[N_u]$ and $[N_v]$ are vectors of shape functions for axial and lateral displacement of a truss element with length L. Note that the element force vector corresponding to the element nodal displacement vector, Eq. (17), is written as

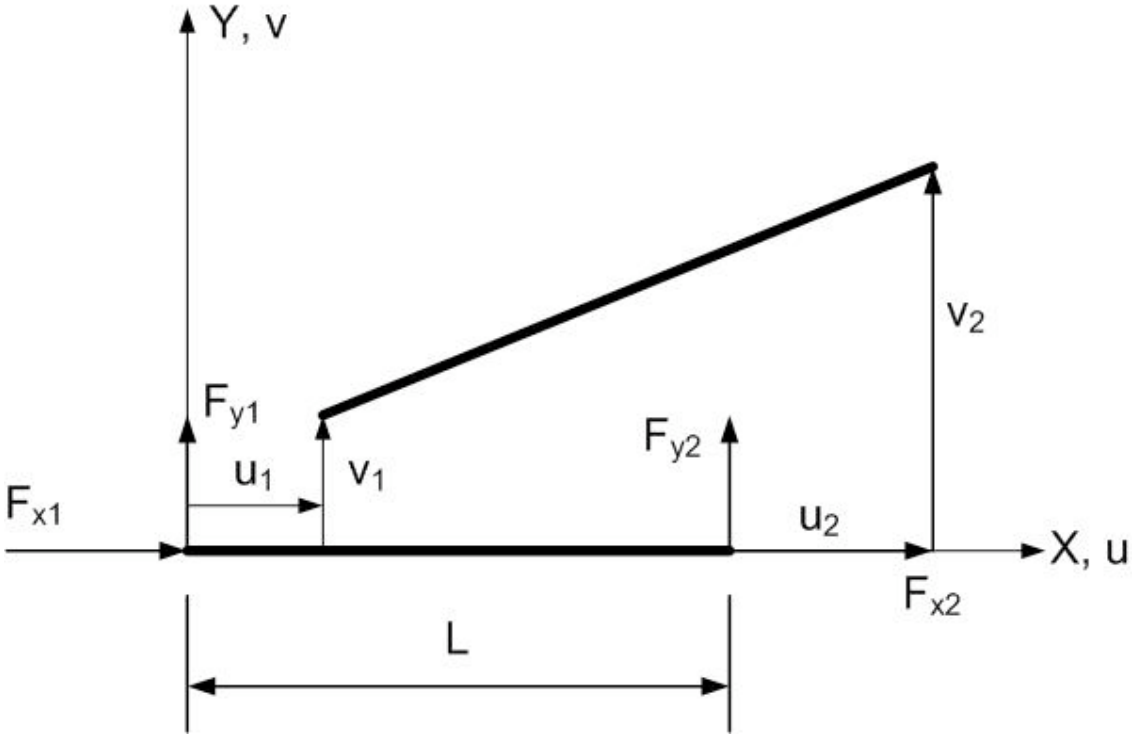

Fig. 2: Coordinate Systems of a Plane Truss Element

$$\{f\}^T = \{F_{x1}, F_{y1}, F_{x2}, F_{y2}\} \tag{18}$$

See Fig. 2 for notations used in this article.

Equilibrium Equations for Truss Element

The incremental equation of equilibrium, Eq. (12), is now applied to a truss element. A truss element is a special case of a continuous media, therefore; C_{ijkl} becomes E and ε_{ij}, e_{ij}, μ_{ij} and ${}^1\tau_{xx}$ are given by Eqs. (19) to (22):

$$\varepsilon_{ij} = \varepsilon_{xx} \tag{19}$$

$$e_{ij} = e_{xx} \tag{20}$$

$$\mu_{ij} = \mu_{xx} \tag{21}$$

$${}^1\tau_{xx} = \sigma_0 \tag{22}$$

where E is the modulus of elasticity of the material. According to Eqs. (19) to (22), Eq. (12) is then given by

$$\begin{aligned}&\int_V E e_{xx}\delta e_{xx}\,dV+\int_V E\mu_{xx}\delta e_{xx}\,dV+\int_V E e_{xx}\delta\mu_{xx}\,dV\\&\int_V E\mu_{xx}\delta\mu_{xx}\,dV+\int_V {}^1\tau_{xx}\delta\mu_{xx}\,dV+{}^1R={}^2R\end{aligned}\tag{23}$$

Furthermore, based on Eqs. (13) and (14), Eqs. (7) to (9) may be written as

$$e_{xx}=\frac{\partial u}{\partial x}=[N_u']\{d\}\tag{24}$$

$$\mu_{xx}=\frac{1}{2}\left[\left(\frac{\partial u}{\partial x}\right)^2+\left(\frac{\partial v}{\partial x}\right)^2\right]=\frac{1}{2}\left(\{d\}^T[N_u']^T[N_u']\{d\}+\{d\}^T[N_v']^T[N_v']\{d\}\right)\tag{25}$$

$$\varepsilon_{xx}=e_{xx}+\mu_{xx}=\frac{\partial u}{\partial x}+\frac{1}{2}\left[\left(\frac{\partial u}{\partial x}\right)^2+\left(\frac{\partial v}{\partial x}\right)^2\right]\tag{26}$$

$$\varepsilon_{xx}=[N_u']\{d\}+\frac{1}{2}\left(\{d\}^T[N_u']^T[N_u']\{d\}+\{d\}^T[N_v']^T[N_v']\{d\}\right)\tag{27}$$

The first variation of Eq. (24) and Eq. (25) is expressed, respectively, as

$$\delta e_{xx}=\{\delta d\}^T[N_u']^T\tag{28}$$

and

$$\delta\mu_{xx}=\{\delta d\}^T[N_u']^T[N_u']\{d\}+\{\delta d\}^T[N_v']^T[N_v']\{d\}\tag{29}$$

where $[N']=\frac{dN}{dx}$.

Substituting Eqs. (24) to (29) into Eq. (23) and, rearranging the results, yields

$$\begin{aligned}&\{\delta d\}^T\int_V E[N_u']^T[N_u']\{d\}\,dV\\&+\{\delta d\}^T\int_V\frac{E}{2}[N_u']^T\left(\{d\}^T[N_u']^T[N_u']+\{d\}^T[N_v']^T[N_v']\right)\{d\}\,dV\\&+\{\delta d\}^T\int_V E\left([N_u']^T[N_u']+[N_v']^T[N_v']\right)\{d\}[N_u']\{d\}\,dV\\&+\{\delta d\}^T\int_V\frac{E}{2}\left([N_u']^T[N_u']+[N_v']^T[N_v']\right)\{d\}\{d\}^T\left([N_u']^T[N_u']+[N_v']^T[N_v']\right)\{d\}\,dV\\&+\{\delta d\}^T\int_V\sigma_0\left([N_u']^T[N_u']+[N_v']^T[N_v']\right)\{d\}\,dV\\&+\{\delta d\}^T\{{}^1f\}=\{\delta d\}^T\{{}^2f\}\end{aligned}\tag{30}$$

Nonlinear Incremental Stiffness Matrices

Canceling out the term $\{\delta d\}^T$, and extracting the term $\{d\}$ from the integrals of the first variation of the increment of total potential energy, Eq. (30), and integrating yields

$$\left([k_0]+[k_p]+[k_1]+[k_2]+[k_3]\right)\{d\}=\{{}^2f\}-\{{}^1f\}\tag{31}$$

where

$$[k_0] = \int_L E\,A\,[N_u']^T\,[N_u']\,dx \tag{32}$$

$$[k_p] = P\int_L \left([N_u']^T\,[N_u'] + [N_v']^T\,[N_v']\right)dx \tag{33}$$

$$[k_1] = \int_L \frac{E\,A}{2}\,[N_u']^T\left(\{d\}^T[N_u']^T\,[N_u'] + \{d\}^T[N_v']^T\,[N_v']\right)dx \tag{34}$$

$$[k_2] = \int_L E\,A\left([N_u']^T\,[N_u'] + [N_v']^T\,[N_v']\right)\{d\}[N_u']\;dx \tag{35}$$

$$[k_3] = \int_V \frac{E\,A}{2}\left([N_u']^T\,[N_u'] + [N_v']^T\,[N_v']\right)\{d\}\{d\}^T\left([N_u']^T\,[N_u'] + [N_v']^T\,[N_v']\right)dx \tag{36}$$

Rewriting Eq. (31) leads to the following desired incremental force-displacement relationship:

$$[k_I]\{d\} = \{f\} \tag{37}$$

where

$$[k_I] = [k_0] + [k_p] + [k_1] + [k_2] + [k_3] \tag{38}$$

and

$$\{f\} = \{^2f\} - \{^1f\} \tag{39}$$

The incremental-stiffness matrix $[k_I]$ consists of five matrices that connect the incremental-element displacement $\{d\}$ to the corresponding incremental element force $\{f\}$.

Each term of the incremental stiffness matrix $[k_I]$, as given in Eq. (38), is presented in matrix form in Appendix A.

The first matrix $[k_0]$ is the conventional linear stiffness matrix for uncoupled axial behavior and is constant. The second matrix $[k_p]$ is the initial stiffness matrix which depends on the axial force *P* presented at the beginning of each incremental load step.

Considering the other three terms of Eq. (38), it is noted that the elements of the matrices $[k_1]$ and $[k_2]$ are the linear function of the incremental element displacements. The last matrix $[k_3]$ is a quadratic function of the incremental element displacements. This matrix is symmetric.

SOLUTION OF NONLINEAR EQUILIBRIUM EQUATIONS

In order to obtain the non-linear incremental equilibrium equations, the global stiffness matrix must be assembled from the incremental element stiffness matrices after they are transformed to the global coordinate system by using the transformation matrix. The non-linear incremental equilibrium equation may then be written as

$$\{F\} = [K]\{D\} \tag{40}$$

where $[K]$ denotes the global nonlinear stiffness matrix, $\{D\}$ represents the vectors of the incremental nodal displacements, and $\{F\}$ represents the vectors of the incremental nodal forces. In general there are three primary procedures for the solution of nonlinear structural analysis. They are the pure (linear) incremental method, the nonlinear incremental method (incremental-iterative procedure), and the direct method. Among these, the linear incremental method is the easiest procedure to implement, but its results are not accurate for problems involving large displacements and rotations, because of the large errors which accumulate in each incremental step. Therefore, this method is not popular and will not be discussed further.

The most effective methods for the solution of the Eq. (40) are the incremental-iterative methods, since iterations are performed at each incremental step during the solution procedure, thus; the accumulation of errors is small. Depending on the efficiency and accuracy of the solution desired, there are five various types of nonlinear solution approaches. They are the Newton-Raphson method, displacement control method, generalized displacement control method, work control method, and arc-length method. Each of these methods has its own advantages or disadvantages and also distinctive variations. More extensive information on evaluating these methods can be found in Wong and Tin-Loi (1990), Yang and Kuo (1994), and Torkamani and Sonmez (2008).

In the direct method, the deformation corresponding to any load along the load deformation curve can be obtained by applying the total load in one step and iterating to convergence. The secant stiffness matrix is used in this method.

Since the incremental-iterative methods can solve the nonlinear problem in a step-by-step fashion, equilibrium of the nodal points is achieved at each increment or step through an iterative process. For most problems, the incremental-iterative methods would be preferred. In this work, one is interested in not only load-deflection curves of geometrically nonlinear problems, but also the buckling load and post-buckling behavior of a structural system. Therefore, the arc-length method, an incremental-iterative method, is recommended and used to solve the post-buckling problems and is adopted in this research. To calculate the variation of the nonlinearity of the structure, the arc-length method adds an extra constraint equation to control the step size for each incremental load. One version of the arc-length method, called the modified Riks approach, was proposed by Tsai and Palazotto (1990) to analyze the shell structures. Later, Xu and Mirmiran (1997) combined a co-rotational finite element and a modified version of the Riks-Wempner method to analyze prestressed arches. This study uses the modified Riks-Wempner method with variable stiffness matrix to solve nonlinear plane truss problems.

NUMERICAL EXAMPLES AND RESULTS

To test the efficiency, accuracy and validity of the theory and the software package that are developed in this study, 2 plane truss problems are examined and presented in this article. The results of these examples are compared to the theoretical solutions, if available, or the results of the other theories that are published in the literature. Problems that are presented in this section are considered to have large deflections and to behave elastically and be geometrically-nonlinear.

Example No. 1 - Shallow Truss

This example is a two member truss that was previously analyzed by Papadrakakis (1983). Because of its low aspect ratio, this is considered a shallow truss. The theoretical solution of this benchmark problem is derived and presented in Eq. (41).

$$P = \frac{2EA}{L}(h-u)\left[\left(1+\left(\frac{u}{L}\right)^2-\frac{2uh}{L^2}\right)^{-\frac{1}{2}}-1\right] \tag{41}$$

In Eq. (41), u is the vertical displacement of node B and h is the total height of the truss before application of any load. Fig. 3 shows the undeformed configuration of the truss with solid lines with the applied load P acting at node B.

The following data are used in this example: the modulus of elasticity E = 2.06 × 10^8 kN/m^2 (29,870 ksi), the length of each member L = 11 m (36 ft 1.08 in), members have a circular cross-section with an area A = 0.00169 m^2 (26.2 in^2), and the rise angle $\alpha = 3.326^\circ$. Member and local buckling effects are disregarded in this example.

The results of Example No.1 that are obtained in this study using modified Riks-Wempner method are compared to the theoretical solution given by Eq. (41). Fig. 3 shows the relations between the applied load P and the displacement of node B; the theoretical solution and numerical results have very good agreement. This

example demonstrates a typical snap-through phenomenon. The load-deflection curves (Fig. 3) indicate that at 338.04 kN (75,991.4 lb) applied load, a limit-point load is reached. This limit-point load is referred to as the system buckling load. When the applied load is zero and the vertical displacement of point *B* is 0.695 m (2 ft 3.36 in), the structure becomes flat. In an experimental case, the structure snaps through such a deflection and reaches the point of zero applied load and the vertical displacement of 1.4 m (4 ft 7.12 in). At this point the structure hangs down below the horizontal level without any applied load.

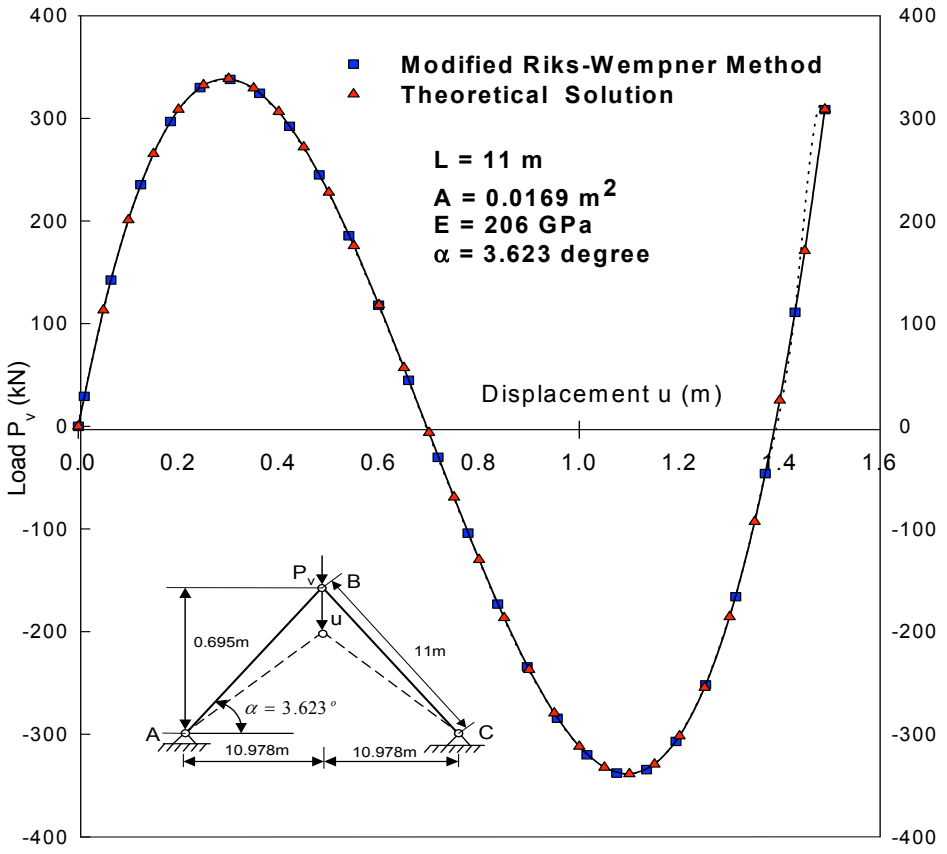

Fig. 3: Load-Displacement Relation for Shallow Truss

Example No. 2 - Strut Structure

Thompson and Hunt (1973) analyzed this structure for imperfection-sensitivity in the buckling of a reticulated or triangulated column. Later, Rosen and Schmit (1979) investigated the influence of local imperfections on the behavior of the global structure, and Kondoh and Atluri (1985) studied the relation between local buckling and global instability.

The configuration of this structure is shown in Figs. 4 and 5. This structure is composed of 35 members, all of which have a circular cross-section, and an identical modulus of elasticity of $E = 68.964 \times 10^6$ kN/m^2 (10,000.72 ksi). The influence of member and local buckling are not considered in the nonlinear analysis of this example. Table 1 lists the cross-sectional areas for all of the members. It is noted that this strut structure is not strictly symmetric with respect to the X axis (see Fig. 4), therefore, the effective neutral axis of the strut is slightly above the horizontal axis passing through nodes 1 and 19 (Kondoh and Atluri 1985).

Table 1: Cross-section of area for each member of Thompson's strut structure from Kondoh and Atluri (1985).

Member's Number	Cross-sectional area for each member cm^2
1-13, 17-21	54.84
14-16	54.84
22-35	51.61

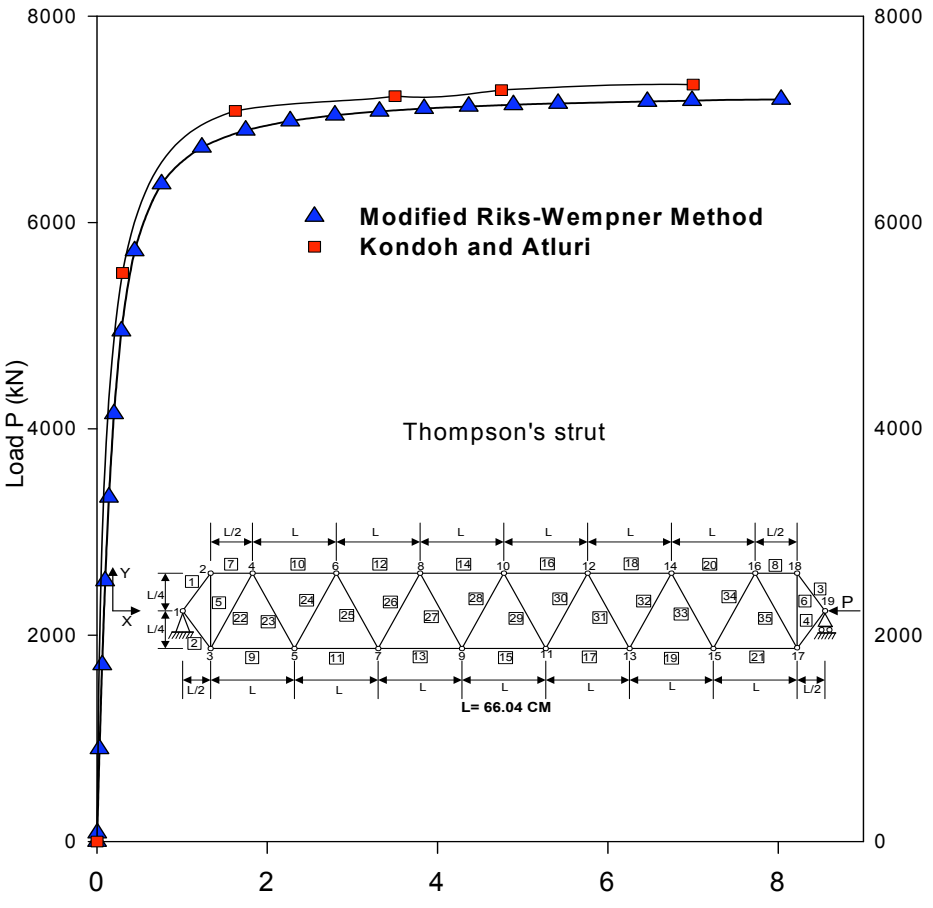

Fig. 4: Load-Displacement Relation for Thompson's Strut Truss, Node 10

The purpose of this example is to track the load-deflection curves for the displacement of node 10 in the vertical direction, and node 19 in the horizontal direction corresponding to the compressive load *P* applied at node 19. Figs. 4 and 5 show the load-deflection curves for node 10 and 19, respectively. It is observed that the structure exhibits global buckling behavior at a load of about 6,915.88 kN (1,556,143.46 lb). After this point, the stiffness of the structure is approaching zero, and the equilibrium path remains stable. The solutions obtained in the present work appear to be close in agreement compared to those of Kondoh and Atluri (1985).

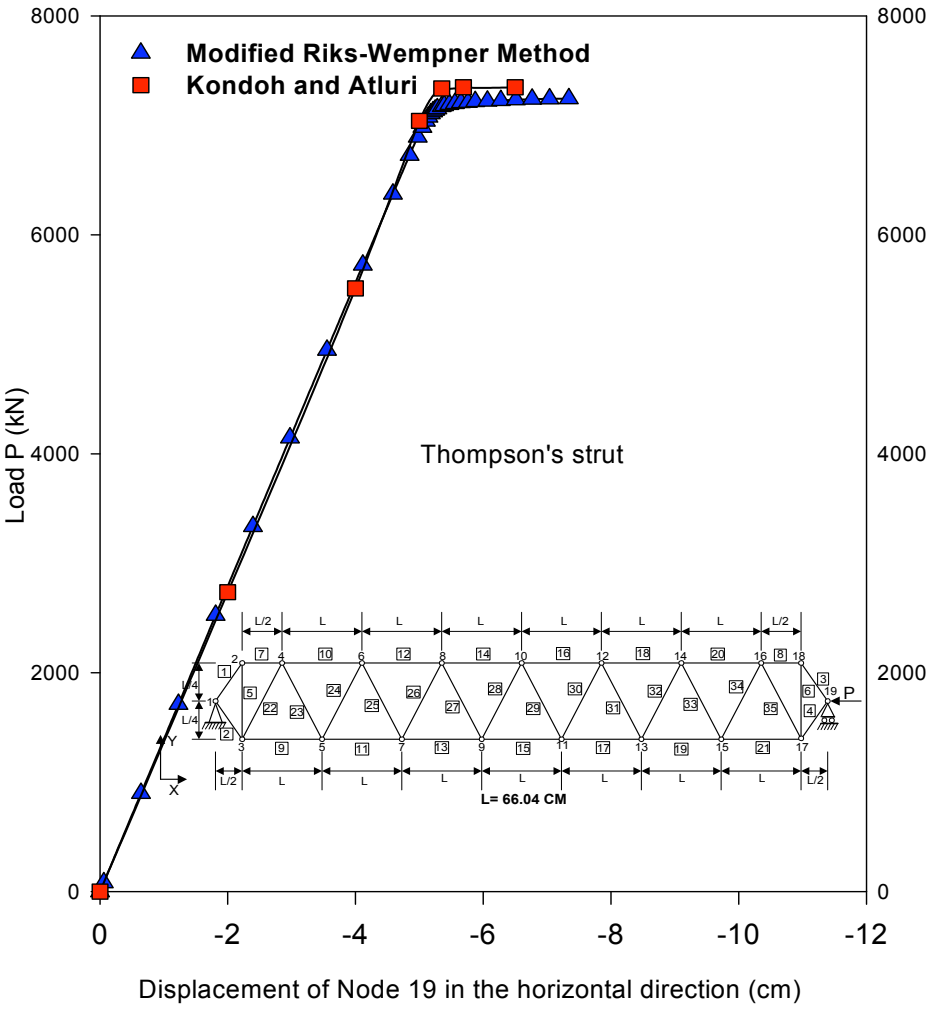

Fig. 5: Load-Displacement Relation for Thompson's Strut Truss, Node 19

SUMMARY AND CONCLUSIONS

The strain-displacement relation with the consideration of large or finite strain for plane trusses is considered in this work. Based on this relation, the incremental stiffness matrices for the higher-order analysis of elastic plane trusses were derived using the minimization of incremental total potential energy and variational principle. In addition, a nonlinear analysis procedure for predicting the load-displacement of plane truss structures subjected to geometric nonlinearity and elastic behavior has been developed and implemented in a computer package.

An algorithm for the modified Riks-Wempner method with variable stiffness matrix has been applied to finite element analysis to trace the full load-deflection path of two examples. Some modification was added in the modified Riks-Wempner method in order to let the load-deflection curve pass the limit points.

The presented numerical examples confirm that the results obtained by developed software are in agreement with the theoretical solution and examples published by other authors.

The first example is shallow two member truss subjected to a vertical concentrated load *P*. This problem is used as benchmark to examine the accuracy of the software. The results of the first example are identical to those given by the theoretical solution. The second example is the strut structure previously analyzed by Kondoh and Atluri (1985). As presented here, the result of this example also demonstrate a reasonable agreement compared to Kondoh and Atluri's work.

In conclusion, the reliability of the model and the software package that are developed during the course of this research are examined through two numerical examples showing reasonable accuracy. The methodology developed in this work provide the bases for further research and development; further research is focused on the problems of inelastic post-buckling analysis. In addition, more rigorous investigations on the stress-strain, force-deflection relationship for the truss systems must be done.

APPENDIX A - INCREMENTAL STIFFNESS MATRICES

The elastic stiffness matrix [k_0], the geometric stiffness matrix [k_p], and the stiffness matrices [k_1], [k_2], and [k_3] are given as:

Matrix: [k_0]

$$[k_0] = \frac{EA}{L}\begin{bmatrix} 1 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \\ -1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{42}$$

Matrix: [k_p]

$$[k_p] = \frac{P}{L}\begin{bmatrix} 1 & 0 & -1 & 0 \\ 0 & 1 & 0 & -1 \\ -1 & 0 & 1 & 0 \\ 0 & -1 & 0 & 1 \end{bmatrix} \tag{43}$$

Matrix: [k_1]

$$[k_1] = \frac{EA}{2L^2}\begin{bmatrix} \Delta u & \Delta v & -\Delta u & -\Delta v \\ 0 & 0 & 0 & 0 \\ -\Delta u & -\Delta v & \Delta u & \Delta v \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{44}$$

where, $\Delta u = u_2 - u_1$ and $\Delta v = v_2 - v_1$.

Matrix: [k_2]

$$[k_2] = \frac{EA}{2L^2}\begin{bmatrix} 2\,\Delta u & 0 & -2\Delta u & 0 \\ 2\,\Delta v & 0 & -2\Delta v & 0 \\ -2\,\Delta u & 0 & 2\Delta u & 0 \\ -2\,\Delta v & 0 & 2\Delta v & 0 \end{bmatrix} \tag{45}$$

Matrix: [k_3]

$$[k_3] = \frac{EA}{2L^3}\begin{bmatrix} \Delta u^2 & \Delta u\Delta v & -\Delta u^2 & -\Delta u\,\Delta v \\ \Delta u\,\Delta v & \Delta v^2 & -\Delta u\,\Delta v & -\Delta v^2 \\ -\Delta u^2 & -\Delta u\,\Delta v & \Delta u^2 & \Delta u\Delta v \\ -\Delta u\,\Delta v & -\Delta v^2 & \Delta u\,\Delta v & \Delta v^2 \end{bmatrix} \tag{46}$$

ABSTRACT

This study presents an inelastic non-linear three dimensional (3-D) beam element with axial, bending, shear force and torsion interaction for seismic analysis of Reinforced Concrete (RC) bridge columns. As a result of these load combinations the structural performances of RC bridge columns defer in strength, deformation capacity and failure modes. The shear mechanism along the beam is modeled by using Timoshenko beam approach with curved 3-D frame elements. The values of the concrete strength in principal directions 1, 2 and 3 are affected by the strain state in the other directions. The problem consists in solving a system of equations by combining the equilibrium conditions, compatibility conditions and constitutive laws of materials at section and structural level. The model is validated with the experimental tests subjected to real time earthquake motions.

INTRODUCTION

The behavior of the earthquake on the reinforced concrete (RC) structures is dependant on time, frequency of occurrence, and intensity. It is well known that RC structures are subjected to multi-directional loadings under earthquake ground motion. The multi-directional loading conditions are caused by multi-dimensional earthquake motions and structural configurations like spandrel beams, skewed bridges, curved bridges and bridges with outrigger beams (Figure 1). The analytical modeling of the behavior of structures under bending, shear and axial force interaction has received considerable attention in recent years because the shear failure in bridges is sudden and brittle and can potentially fail at lower ductility under the gravity loads. The establishment of nonlinear constitutive models for RC elements under combined loadings and the development of corresponding nonlinear finite element models are essential to predict the correct behavior of RC structures. The past three decades saw new constitutive models in an effort to improve the general performance of the structures and elements. In these models, the equilibrium equations assume the stresses in the concrete struts and steel bars to be smeared. Similarly, the strains of steel and concrete are also smeared, and are obtained by

averaging the strains along a steel bar that crosses several cracks. The constitutive laws of concrete and steel bars were developed through large-scale panel testing, and relate the smeared stresses to the smeared strains of the element (Hsu and Zhu 2002). In this current research Softened Membrane Model (SMM) was implemented (Mullapudi, 2010). In this model, the tension stiffening effect of concrete was taken into account with a shear stress contribution along the crack direction. This model was further extended by developing the Hsu/Zhu ratios (Poisson effect) (Zhu and Hsu 2002), which can help to predict accurately the entire response of the specimen, including both the pre and post-peak responses.

An RC element with combined loading including torsion is a more sensitive problem than shear because it is a three dimensional (3-D) problem, which is the combination of the two dimensional shear problem and an additional shear caused by torsion (Figure 2). The equilibrium and compatibility of the 3-D element with the warping of the tube wall causes additional bending in the concrete struts. Vecchio and Selby (1991) have developed a finite element program for 3-D analysis with an eight node regular hexahedral element. In their constitutive material model they have used the Modified Compression Field Theory. In this research a generalized 3-D frame element with the Softened Membrane Model is implemented. Every section of the frame element is subdivided into different regions to account for 1-D, 2-D and 3-D material responses.

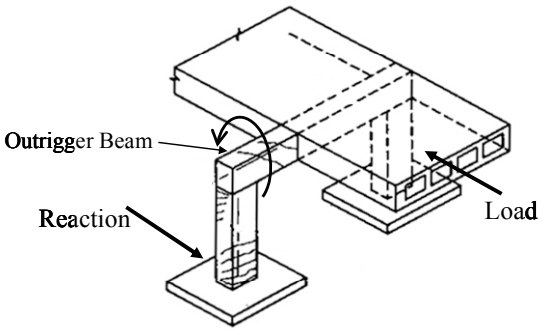

Figure 1. Torsion in outrigger beam

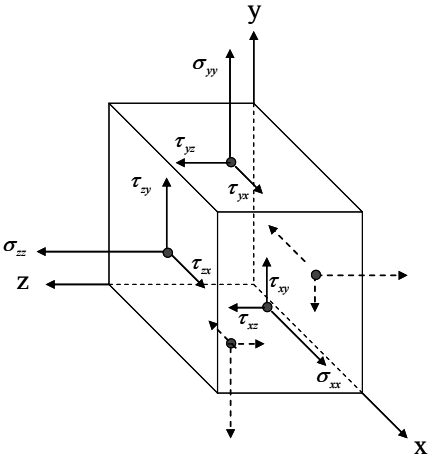

Figure 2. 3-D Stress distribution

FINITE ELEMENT FORMULATION

The finite element model is based on the recently developed force method of analysis (Spacone et al. 1996). The force-based formulation proved to overcome most of the difficulties associated with the standard displacement approach and generally has superior robustness and requires lower number of model degrees of freedom for comparable accuracy when dealing with RC members. This model was developed based on the Timoshenko type force formulation with the assumption that plane sections remain plane. The element comprises two node frame element which follows a directrix line between nodes 1 and 2 (Figure 3). Each element is divided into several

sections along the length of the element and also into several fibers across the cross section of the member. The response at each fiber is calculated from the response at the directrix with the help of plane sections which remain plane.

The general 3-D beam element with rigid body modes is shown in (Figure 4) and; without rigid body modes in shown in (Figure 5).

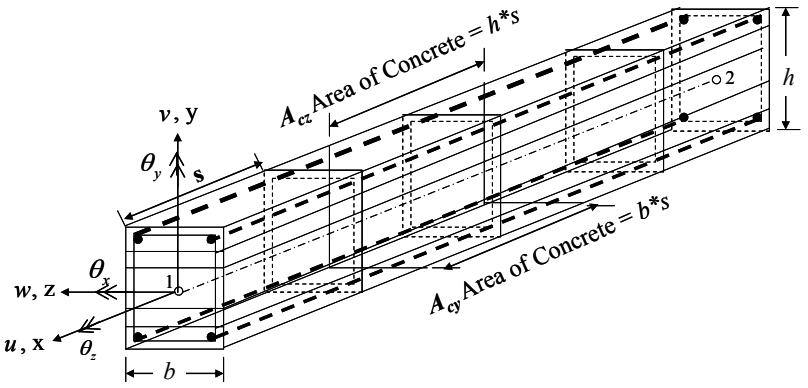

Figure 3. 3-D Fiber element formulation

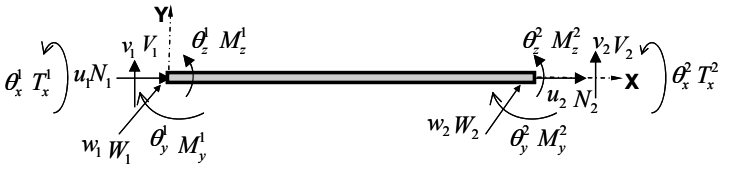

Figure 4. Displacements and forces with rigid body modes

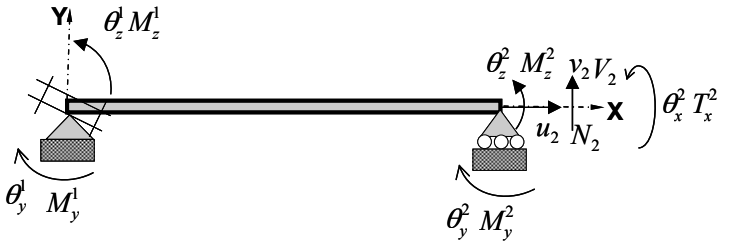

Figure 5. Displacements and forces without rigid body modes

The section behavior is evaluated through fiber discretization with appropriate material constitutive models. The constitutive behavior of the concrete fibers is described in subsequent sections. To account for dynamic effects, the Newmark method is adopted and is briefly described in the next section. The model was developed using the finite element program FEAPpv (Taylor 2005).

DYNAMIC BEHAVIOR FORMULATION

The nonlinear dynamic behavior is analyzed following the well known Newmark method (Newmark 1959). Accordingly, the following equilibrium equation

is solved for:

$$\hat{k}_j \Delta d_j = \Delta \hat{F}_j \tag{1}$$

where Δd_j is the displacement increment at time step j, and the dynamic stiffness $\hat{k}_j$ is evaluated as

$$\hat{k}_j = k_j + \frac{\gamma}{\beta \Delta t} c + \frac{1}{\beta (\Delta t)^2} m \tag{2}$$

whereas the k_j is the static stiffness, m is the mass matrix, c is the Rayleigh damping matrix, and Δt represents the time increment from steps j to $j+1$. In the current model the coefficients $\gamma = 0.5$ and $\beta = 0.25$ were selected for considering the average acceleration method, which is unconditionally stable.

The dynamic residual load increment $\Delta \hat{F}_j$ is evaluated as

$$\Delta \hat{F}_j = \Delta F_j + \left(\frac{1}{\beta \Delta t} m + \frac{\gamma}{\beta} c \right) \dot{d}_j + \left[\frac{1}{2\beta} m + \Delta t \left(\frac{\gamma}{2\beta} - 1 \right) c \right] \ddot{d}_j \tag{3}$$

where $\dot{d}_j$ and $\ddot{d}_j$ are the velocity and acceleration respectively at time step j.

The damping matrix is determined based on the Rayleigh-type formulation expressed as a linear combination of the mass matrix m and the stiffness matrix k as

$$c = \alpha_m m + \beta_k k \tag{4}$$

whereas the parameters α_m and β_k are calculated based on the natural frequencies of the first modes and their damping ratios. For a nonlinear system, the incremental procedure described in Equation. 1 needs to be accomplished using an iterative procedure.

Reyleigh damping with first five modes were considered in the analysis. Three damping ratios were used in the analysis based on the condition of the member. A damping ratio of 2% was used when the structure was in the elastic stage and only slight cracking was observed. A damping ratio of 4% was used when the considerable cracking was observed. A damping ratio of 8% was used when the reinforcement of the member yielded until the failure. A time step of 0.01 sec has been used in the earthquake analysis.

CONCRETE CONSTITUTIVE MODEL

Constitutive laws depend upon the type of region of the cross section in which the material model is used. A smeared stress-strain curve with smearing behavior is used for the response of the reinforcing bar. The cross section is divided into a number of sub divisions based on the appealing three stress state. They are 1-D, 2-D and 3-D regions (Figure 6). 1-D regions are subjected only to normal stresses, 2-D regions are subjected to normal and transverse stress in one direction, and 3-D regions are subjected to normal stress and transverse stress in two directions.

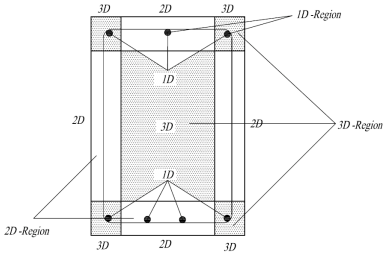

Figure 6. Sectional regions definition

3-D regions have six stresses $\{\sigma_{3D}\}$ and corresponding strains $\{\varepsilon_{3D}\}$; however the current beam formulation only considers three stress $\{\sigma\}$ and strain $\{\varepsilon\}$ components while the other three stress and strain components are derived by solving the equilibrium conditions.

$$\{\sigma_{3D}\}=\begin{bmatrix}\sigma_x & \sigma_y & \sigma_z & \tau_{xy} & \tau_{yz} & \tau_{xz}\end{bmatrix}^T \quad \{\varepsilon_{3D}\}=\begin{bmatrix}\varepsilon_x & \varepsilon_y & \varepsilon_z & \gamma_{xy} & \gamma_{yz} & \gamma_{xz}\end{bmatrix}^T \quad (5)$$

$$\{\sigma_{UN}\}=\begin{bmatrix}\sigma_y & \sigma_z & \tau_{yz}\end{bmatrix}^T \qquad \{\varepsilon_{UN}\}=\begin{bmatrix}\varepsilon_y & \varepsilon_z & \gamma_{yz}\end{bmatrix}^T \quad (6)$$

The unknown stress components σ_{UN} should be zero to satisfy the internal equilibrium between the reinforcing steel and concrete, which will result in the corresponding three unknown strain values ε_{UN}. Since the constraint condition is nonlinear, the determination of the corresponding strains requires an iterative solution procedure.

Concrete strains ε_{3D} were used to calculate the principal strains, or Eigen values, and principal strain directions, or Eigen vectors, with the Jacobi method.

To rotate the stress and strain vectors from global x-y-z co-ordinate system to 1-2-3 co-ordinate system with an angle of $[\alpha_1]$:

$$[R(\alpha_1)]=\begin{bmatrix} l_1^2 & m_1^2 & \mathrm{n}_1^2 & l_1m_1 & m_1n_1 & n_1l_1 \\ l_2^2 & m_2^2 & \mathrm{n}_2^2 & l_2m_2 & m_2n_2 & n_2l_2 \\ l_3^2 & m_3^2 & \mathrm{n}_3^2 & l_3m_3 & m_3n_3 & n_3l_3 \\ 2l_1l_2 & 2m_1m_2 & 2n_1n_2 & l_1m_2+l_2m_1 & m_1n_2+m_2n_1 & n_1l_2+n_2l_1 \\ 2l_2l_3 & 2m_2m_3 & 2n_2n_3 & l_2m_3+l_3m_2 & m_2n_3+m_3n_2 & n_2l_3+n_3l_2 \\ 2l_3l_1 & 2m_3m_1 & 2n_3n_1 & l_3m_1+l_1m_3 & m_3n_1+m_1n_3 & n_3l_1+n_1l_3 \end{bmatrix} \quad (7)$$

In a fiber-based element formulation, the process of the state determination at the fiber level requires the calculation of the fiber stresses $\begin{bmatrix}\sigma_x & \sigma_y & \sigma_z & \tau_{xy} & \tau_{yz} & \tau_{xz}\end{bmatrix}^T$ from the strain state $\begin{bmatrix}\varepsilon_x & \varepsilon_y & \varepsilon_z & \gamma_{xy} & \gamma_{yz} & \gamma_{xz}\end{bmatrix}^T$. Because the SMM has been implemented in a Timoshenko-type beam element, the values of ε_x, γ_{xy}, γ_{xz} are typically known, while the lateral strain ε_y, ε_z values must be evaluated from the equilibrium. Due to the nonlinear behavior of the concrete and

steel, an iterative procedure is needed to determine the lateral strain ε_y and ε_z.

STRESS STATE DETERMINATION

The constitutive equations depend on the strain state and the region of the cross section. The principal strains ε_1, ε_2 and ε_3 are found from the global strains using the Jacobi method and the equivalent uniaxial strains $\bar{\varepsilon}_1, \bar{\varepsilon}_2$ and $\bar{\varepsilon}_3$ are derived based on Hsu/Zhu ratios (Jeng and Hsu, 2009). Local concrete material stiffness is derived based on the material Young's Modulus and the Hsu/Zhu ratio. The global stiffness in Cartesian direction is calculated by transforming the local stiffness to global direction. The global stiffness in *y*, *z* and *yz* direction are condensed in the element formulation and, during this process the stresses in axial, flexure and shear direction are coupled together.

The values of the concrete uniaxial strains in principal directions 1, 2 and 3 have eight cases, namely 1-Tension, 3-Compression; 1-Tension, 3-Tension; 1-Compression, 3- Compression; 1- Compression, 3-Tension; 1-Tension, 2-Compression; 1-Tension, 2-Tension; 1-Compression, 2- Compression and 1-Compression, 2-Tension. The strength in one direction is affected by the strain state in the other direction. Because of the lateral tensile strain, principal compressive strength of the concrete reduces or softens.

For the first case, the equivalent uniaxial strain of concrete $\bar{\varepsilon}_1$ in principal direction 1 is in tension, and the equivalent uniaxial strain $\bar{\varepsilon}_3$ in principal direction 3 is in compression. The equation for compressive strength and strain reduction factor ζ is given by (Hsu and Zhu 2002):

$$\zeta = \left(\frac{5.8}{\sqrt{f_c^{'}(MPa)}} \le 0.9 \right) \left(\frac{1}{\sqrt{1+400\bar{\varepsilon}_1}} \right) \left(1 - \frac{|\beta|}{24^{\circ}} \right) \tag{8}$$

$$\beta = 0.5 \tan^{-1} \left(\frac{\gamma_{13}}{\varepsilon_1 - \varepsilon_3} \right) \tag{9}$$

The ultimate stress in the orthogonal directions is therefore $\zeta f_c^{'}$ at a softened strain $\zeta\varepsilon_0$, where ζ is the softening coefficient, β is the deviation angle in degrees which is the difference between the applied stress angle α_1 and the rotating angle α_r, $\bar{\varepsilon}_1$ is the lateral tensile strain and γ_{13} is the shear strain in 1-3 direction. Similar relations were applied in remaining seven cases.

NUMERICAL CORRELATIONS WITH EXPERIMENTAL RESULTS

SIMULATION OF PRAKASH et al. (2010) COLUMN H/D(6)-T/M(0.2)

The 3-D model was used to simulate the behavior of a reinforced concrete bridge column (Column H/D(6)-T/M(0.2)) tested by Prakash et al. (2010) at the

Missouri S&T. Column was analyzed with an applied torsion to moment (T/M) ratio of 0.2. The aspect ratio height to diameter (H/D) of the column is 6 and the spiral reinforcement ratio of 0.73% and longitudinal reinforcement ratio of 2.1% with a concrete compressive strength of 41.2 MPa (6.0 ksi) was used in the analysis. Yield strength of longitudinal steel of value 490 MPa (71.0 ksi) and yield strength of transverse reinforcement of value 525 MPa (76.1 ksi) were used.

Flexural cracks first appeared near the bottom of the column and their angle became more inclined at increasing heights above the top of the footing. The appearance of the cracks increased with an increase in applied loading. The longitudinal bars yielded at about 38 inches from the base of the column. The model failed by yielding of the longitudinal and transverse reinforcement followed by core degradation. The load-displacement curve matched well with the experiment (Figure 7).

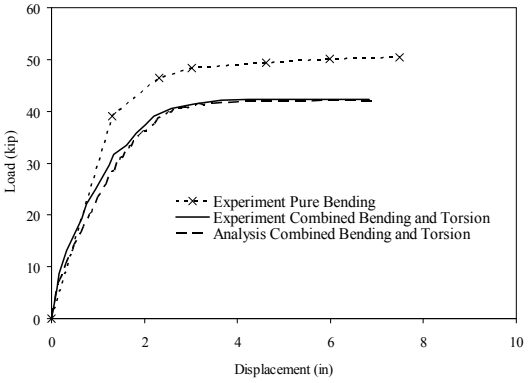

Figure 7. Monotonic load-displacement curve

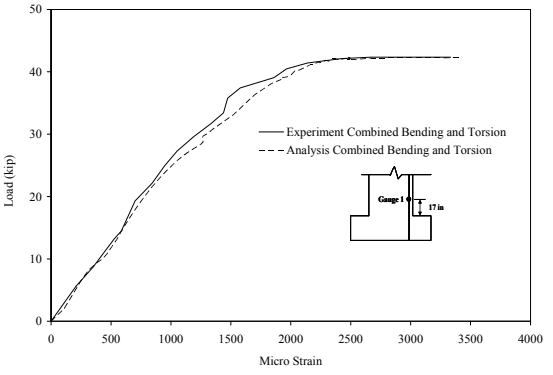

Figure 8. Longitudinal steel strain distribution

Figure 7 shows the comparison of the column performance with pure bending ((T/M =0) and combined loading (T/M =0.2). Because of the induced torsion the bending strength and stiffness have been reduced considerably.

Figure 8 shows the longitudinal steel strain distribution at 17 inches above the foundation. The longitudinal strain increased with the increase of the lateral load on the column. The experimental strain gauge readings matched well with the analytical results and the current model captured the yielding rather well.

SIMULATION OF LAPLACE et al. (2001) COLUMN 9F1 UNDER SHAKE TABLE TESTING

The model was used to simulate the behavior of the circular RC bridge column 9F1 subjected to the real time 1940 Imperial Valley (El Centro) earthquake excitation tested by Laplace et al. (2001) at the University of Nevada, Reno. An axial load of 356 kN (80 kip) was applied constantly to the column. The column is loaded in single curvature. The actual test specimen has a 406.44 mm (16 in) diameter and is 1.83 m (72 in) long from the top of the footing to the centerline of the applied load. The reinforcement consisted of twenty No. 4 longitudinal bars, and 6.5 mm (0.25 in) spiral transverse reinforcement spaced at 38.1 mm (1.5 in). A concrete compressive strength of $f_c^{'}$=37.4 MPa (5.4 ksi) and tensile strength of f_t=2.0 MPa (0.3ksi) are used to analyze the reinforced concrete column. A yield stress of longitudinal and transverse reinforcement of f_y=458.2 MPa (65.0 ksi) and f_y=397.4 MPa (57.6 ksi) respectively are used in the analysis. The Young's modulus of concrete and steel are E_c = 37500 MPa (5440 ksi) and E_s = 200,000 MPa (29000 ksi) respectively.

9F1 Column was analyzed with the 2.5xEl Centro earthquake motions and the comparisons of the experimental results with the flexural element and the currently developed shear element are presented in Figure 9 - Figure 14. At 2.5xEl Centro earthquake motion the flexural element is unable to predict accurately the displacement amplitude and the resisting load capacity (Figure 9 and Figure 11) but the shear element is able to predict well (Figure 10 and Figure 12). At this El Centro motion longitudinal bar has yielded more than 2 times the 1.0xEl Centro earthquake motion at gauge 1 location and is fairly accurate compared to experimental values (Figure 13). Transverse steel bar at gauge 2 location as shown in Figure 14 is not yielded and agreed well with the experimental results.

SIMULATION OF ARIAS-ACOSTA AND SANDERS (2010) COLUMN C1 UNDER SHAKE TABLE TESTING

Arias-Acosta and Sanders (2010) have conducted bidirectional shake table testing's of bridge columns under combined effect of axial, shear, bending and torsion at University of Nevada, Reno (UNR). The 3-D model was used to simulate the behavior of the circular RC bridge columns C1 subjected to the real time bidirectional 1992 Petrolia at Mendocino earthquake excitations.

The column is tested under cantilever type loading. The actual test specimen has a 406.44 mm (16 in) diameter and is 1.83 m (72 in) long from the top of the footing to the centerline of the applied load. The reinforcement consisted of twenty No. 4 deformed longitudinal bars, and 6.5 mm (0.25 in) spiral transverse reinforcement spaced at 38.1 mm (1.5 in). A concrete compressive strength of $f_c^{'}$=30.0 MPa (4.5 ksi) and tensile strength of f_t=1.7 MPa (0.2ksi) are used to analyze the reinforced concrete column. A Yield stress of longitudinal and transverse reinforcement of f_y=447.0 MPa (64.0 ksi) and f_y=420.0 MPa (60.0 ksi) respectively

are used in the analysis. The Young's modulus of concrete and steel are E_c = 30000 MPa (4350 ksi) and E_s = 200,000 MPa (29000 ksi) respectively.

A unique inertial loading system named Bidirectional Mass Rig (BMR) was developed for shake table testing of single column under biaxial motions (Figure 15). The purpose of this setup is to distribute the mass on BMR (Figure 16) such that the mass center and stiffness center of the loading frame differs from each other and induces torsion on column under bidirectional earthquake excitation.

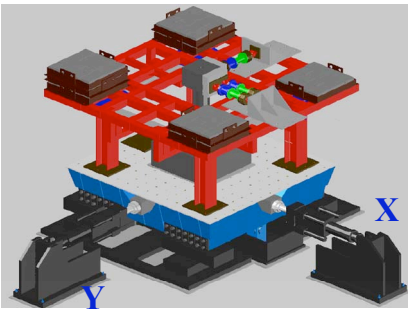

Figure 15. Bidirectional Mass Rig (BMR)

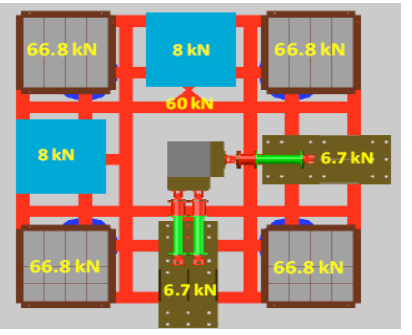

Figure 16. Mass distribution on BMR

The C1 Column was analyzed with the 0.6 x Petrolia earthquake motions in X and Y directions (Figure 15). The ground motion is considered as near fault ground record with asymmetric peak velocity pulses along X and Y directions. The comparison of the experimental results with the currently developed shear element is presented in Figure 17 and Figure 18. At 0.6 x Petrolia motion, shear element is fairly accurate to predict the load - displacement behavior in X –direction (Figure 17) and in Y – Direction (Figure 18). The behavior of the specimen was controlled by biaxial effect of bending including the induced torsion. The longitudinal bar yielding was observer after 0.6 x Petrolia motion and agreed well with the experimental results.

CONCLUSIONS

This work represents a new approach for the dynamic analysis of structures made up of non-linear materials under combined loadings including torsion. A Fiber based 3-D beam element was developed to analyze reinforced concrete structures with the incorporation of mechanisms of shear deformation and strength. The section deformations are determined from the strain state using the classical plane section hypothesis. The proposed model is able to capture the interaction between axial, flexural, shear and torsional responses. The results of a numerical correlation with the experimental data of bridge piers show that the model is able to capture the failure mechanism and provides accurate results.

Abstract

Seismic analysis results of typical post-tensioned concrete bridges are presented considering the nonlinear behavior of transverse abutment shear. Current Caltrans and AASHTO bridge design criteria present overly general assumptions for the boundary conditions provided by abutment shear keys. This work uses a suite of ground acceleration time histories to compare the code specified assumptions to a more rigorous abutment shear key model that includes the lateral gap between the superstructure and the keys as well as the non-linear material response of the key itself. With the exception of the abutment shear key elements, the bridges are modeled using linear-elastic frame elements, as is typical in practice. Results of a sensitivity analysis are presented for typical parameters, including: record variability, bridge skew, bridge length, and bent heights. The analysis results precede a discussion which demonstrates the necessity for experimental work on this topic to verify the adequacy of the existing design code.

Introduction

Bridges are critical structures in the network of highways and roadways connecting cities, towns, businesses and communities. Extensive earthquake damage to bridges creates a lasting effect on local and state economies as well as public confidence in the general infrastructure of the transportation system. The resulting economic losses and disruption of earthquakes are neither acceptable to the public nor cost-effective from a repair perspective. Understanding the effects of earthquakes on bridges has been a focus of the research and design communities, resulting in novel analysis techniques and improved design provisions. A somewhat recent thrust has been to accurately model bridge end conditions, including the effects of the abutment and soil behavior (Romstad et al, 1995, Goel and Chopra, 1997, Shamsabadi et al, 2005, Huang et al, 2008) on the longitudinal stiffness and strength of the structure.

Conversely, modern Californian seismic design codes include the lateral stiffness, strength and damping effects of bridge end abutments in the analysis of the overall structure, albeit in a more simplified manner by assigning a stiffness to the abutment shear keys in proportion to the lateral stiffness of the bridge bents. While the current design methodology may be appropriate for ordinary configurations, little research has verified these lateral stiffness values. Moreover, the shear keys are viewed more as a brittle fuse during the seismic response of the structure, rather than a ductile, energy dissipating element. Thus, not only is there a need to investigate the lateral elastic stiffness of shear keys, which will influence the distribution of seismic forces, but there is also an opportunity to develop an energy dissipating element from the shear key response. The latter requires examining the nonlinear response of these elements designed with modern practices while also developing innovative reinforcement details to improve the ductility of the shear keys.

The paper begins by introducing the motivation for the current study, including common geometries and loading on bridge abutment components. Next, it presents the analytical modeling approach and associated ground motions along with results from a parametric study of several bridge geometries. Finally, the results are discussed in the context of current code-based modeling assumptions and the need for future experimental and analytical work.

Background and Motivation

Abutment shear keys, shown schematically in Figure 1, are typically designed as brittle elements if the abutment is supported on piles, with the assumption that they will lose strength capacity during a large seismic event. In the case of spread footing conditions, the keys are still considered brittle elements, albeit with a larger strength capacity so as to ensure they remain intact. Current editions of the Caltrans Seismic Design Criteria (SDC) provide a complete set of seismic design guidelines for post-tensioned reinforced concrete bridges.

Regardless of foundation type, however, the lateral stiffness of the component is taken as 50% of the total stiffness of the adjacent bent or pier group. Thus, the transverse abutment stiffness is currently modeled in an ad-hoc manner by using the stiffness of adjacent bents rather than the physical size, reinforcing details and other parameters associated with the abutment keys. Considering this, there is a need to investigate the appropriateness of using pier and bent stiffnesses to inform geometrically-unlike abutment key rigidities. Furthermore, regardless of the accuracy of current Caltrans Criteria, within a performance based engineering perspective, it would be valuable to develop a rational procedure for the design and analysis of the transverse behavior of the superstructure at the abutment.

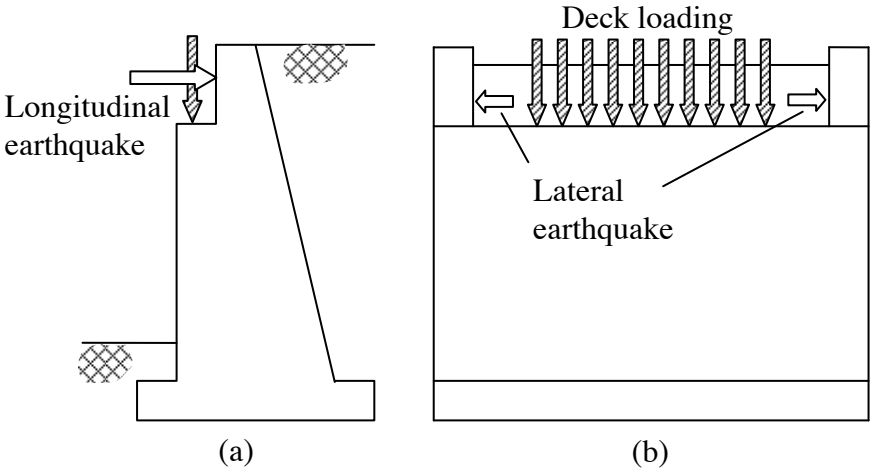

Figure 1: Typical (a) Longitudinal and (b) Lateral abutment and shear key details and loading

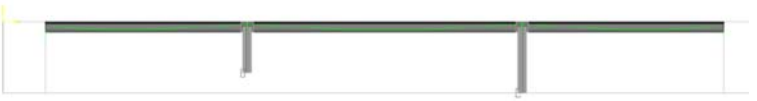
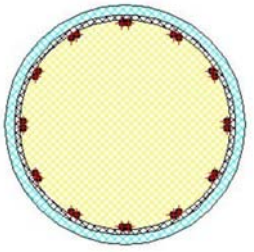
The current procedure to calculate lateral earthquake design loads for California bridges is dependent on a site-specific, elastic spectral acceleration demand (i.e., site-specific hazard curves found in Appendix B of the SDC). In considering the elastic stiffness of a typical bridge system, a large degree of uncertainty is associated with the abutment shear keys in the case of moderate to severe earthquake events. While the stiffness of the bridge bent and abutment stiffness in the longitudinal (or normal) direction are considered less variable due to a large amount of research conducted on each respective subassembly, the lateral behavior of abutments have not been rigorously investigated. Thus, the current seismic design criterion assumes that the lateral abutment stiffness is 50% as stiff as the nearest bents (section 7.8.2 in the SDC). This assumption is driven by the fact that end conditions (typically a shear key) will soften considerably at the Maximum Credible Earthquake (MCE) level, while, on the other hand, provide significant elastic rigidity during low and moderate level seismic events. In this light, an advancement of bridge design methodologies would be to incorporate a lateral stiffness model into the seismic design criterion for abutments, similar in form to the longitudinal model proposed by Romstad et al, (1995).

Archetype Bridge Geometry

Post-tensioned box girder concrete bridge geometry can be adapted to meet a wide variety of physical constraints. Thus, it is difficult to capture the behavior of all concrete bridges with the parametric study presented in this paper. Rather, the current investigation is meant to query key geometrical features that, when coupled with the boundary conditions at the abutments, may influence the overall response of the structure. This may inform future analytical studies with a wider range of geometric, material and loading scenarios.

An archetype bridge geometry (Geometry A) was designed for a high seismic risk site in Riverside, CA. For simplicity, the structure is considered to be on a tangent in both the horizontal and vertical directions. It is a relatively short, three span structure, such that modifications to the abutment boundary conditions will have a noticeable effect on the overall structure response. Key properties of the archetype structure are listed in Table 1. An elevation view of the bridge is shown in Figure 2, while the cross-sections of the columns and bridge superstructure are shown in Figure 3.





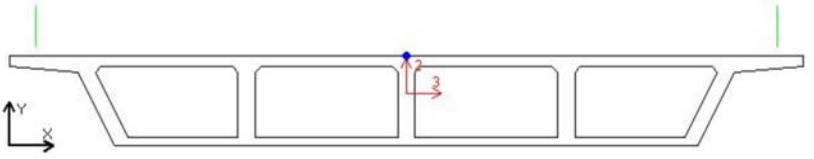


Figure 2 – Elevation View of Bridge Geometry "A"

Three dissimilar bridge configurations were analyzed, each representing a change to a key geometric feature likely to influence the structural response. Geometry B modifies Geometry A with a large (45 degree) skew at the bents and abutments. Geometry C modifies Geometry A by substantially decreasing the length of the end spans of the bridge. Geometry D modifies Geometry A by doubling the length of the bridge columns.

Modeling Approach and Development

Dynamic Model

The bridge was modeled using a refined mesh of one dimensional elements, including linear elastic frame elements (for the bridge superstructure and columns), linear elastic truss elements (for the abutment springs), and special non-linear shear key elements (discussed later in this section). See Figure 4. The model was constructed in compliance with all applicable SDC recommendations and requirements.

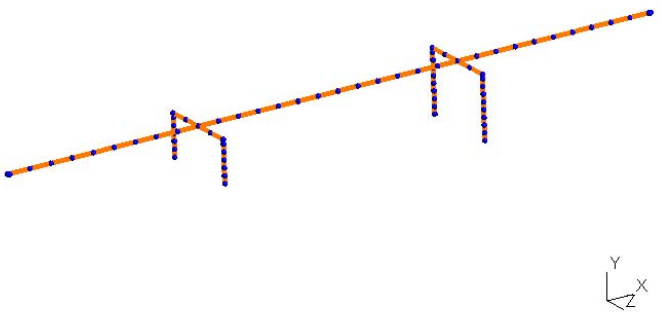

Figure 4 – Bridge Mesh

The equation of motion for a linear elastic system subjected to a ground acceleration is described by the differential equation $\mathbf{ma} + \mathbf{cv} + \mathbf{ku} = -\mathbf{ma}_g$, where $\mathbf{m}$ is the mass matrix (lumped, for this work), $\mathbf{c}$ is the viscous damping matrix, $\mathbf{k}$ is the stiffness matrix, $\mathbf{a}$ is the vector of nodal accelerations, $\mathbf{v}$ is the vector of relative nodal

velocities, $\mathbf{u}$ is the vector of relative nodal displacements, and $\mathbf{a}_g$ is a vector associated with the ground accelerations. In design practice, the analysis is commonly performed with modal design response spectrum, as opposed to a suite of ground acceleration time histories.

To utilize a non-linear shear key, the differential equation must first be recast in the more general form: $\mathbf{ma} + \mathbf{cv} + \mathbf{f}_s(\mathbf{u}) = -\mathbf{ma}_g$. Here, the stiffness term $\mathbf{ku}$ has been replaced with the nonlinear displacement response $\mathbf{f}_s(\mathbf{u})$. It is also necessary to abandon the direct use of a response spectrum, as the use of a response spectrum explicitly assumes a linear elastic system. Instead, a suite of ground acceleration time histories such that the non-linear differential equation is solved at each time step. For this work, the unconditionally stable constant average acceleration time integration technique was used.

Finally, it should be noted that developing the viscous damping matrix $\mathbf{c}$ is somewhat challenging. For a linear modal analysis, an appropriate damping ratio can be specified for each mode (typically 5% of critical damping). For the non-linear time history used here, the damping matrix must be constructed directly. For simplicity, a mass-proportional matrix was used that corresponds to a 5% damping ratio for the first mode of vibration.

Time History

The time histories used for the analyses have been selected from a suite of ground motions produced for the PEER Transportation Research Program (TRP) for broad-band ground motions. For the TRP study, the broad-band ground motions were selected for relatively generic structures, and sites with M = 7, R = 10 km, and a soil site (Jayaram, N. and Baker J.W., 2010). Considering that this is a preliminary study, 7 pairs of ground motions were selected from the 40 pairs created for the larger TRP program. It is expected, however, that future analyses will use the entire package of ground motions. The ground motions were scaled to an appropriate Caltrans Acceleration Response Spectrum at the first mode period of 1.3 seconds. See Figure 5.

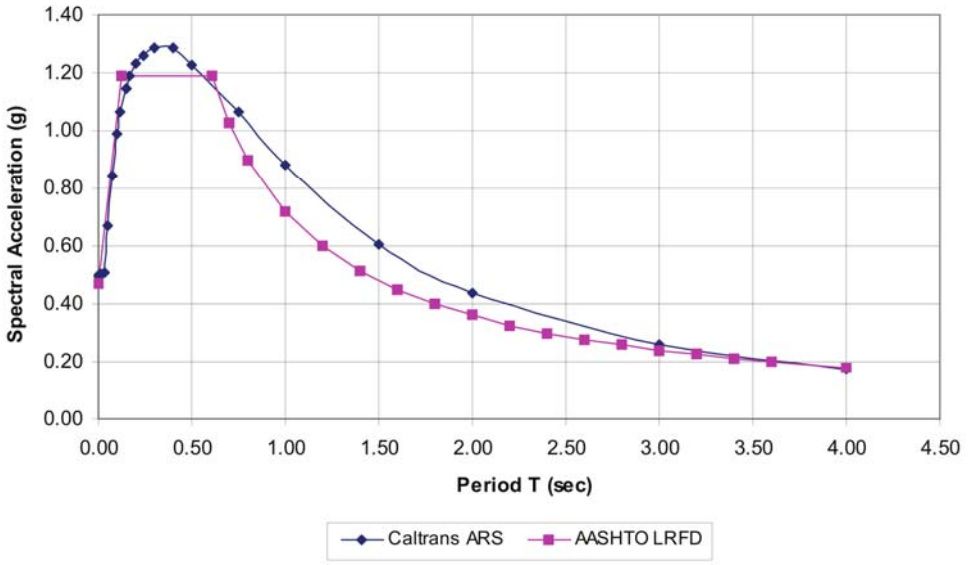

Figure 5 – Caltrans Acceleration Response Spectrum

Constitutive Model

Standard constitutive models, consistent with the latest version of the Caltrans SDC, were used for most of the bridge model. Gross section properties were used to represent the post-tensioned superstructure and cracked section properties were used to model the substructure. Moduli of elasticity for members were calculated using the concrete compressive strength according to the relation $E_c = 57{,}000\sqrt{f_c'}$.

Longitudinal springs were placed at the abutments, consistent with the requirements of the SDC, Section 7.8.1, "Longitudinal Abutment Response." For the linear elastic model, transverse springs were placed at the abutments, consistent with the requirement of SDC, Section 7.8.2, "Transverse Abutment Response." The effects of compliant soils at foundations were not considered for this analysis. Therefore, foundation supports were assumed to be rigid.

For the non-linear model, a rate-independent force-deformation model is assumed for each of the two shear keys at each abutment. The model includes a gap between the bridge superstructure and the shear keys, a short, stiff, linear portion as the key itself deforms elastically, and a perfectly plastic portion to represent the post failure behavior of the key. See Figure 6.

The model requires three parameters: an initial gap size (typically one inch), an ultimate shear key force, and the stiffness of the shear key. The shear key force and shear key stiffness remain unchanged throughout the analysis. The gap size is allowed to increase, however, as the shear key fuses and deforms plastically. A portion of a single load cycle resulting in an increased gap is shown in Figure 6.

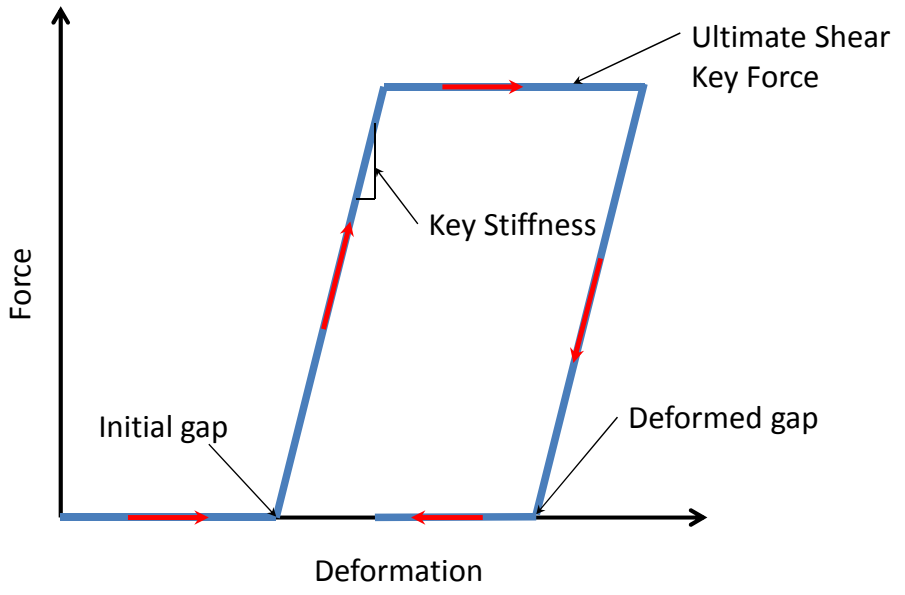

Figure 6 – Nonlinear Shear Key Constitutive Model

The ultimate shear key force is determined from the theoretical capacity of the key itself, typically using the shear friction method ($F_{key} = \mu A_s f_y$), where A_s is the cross sectional area of the reinforcing steel crossing the shear key failure plane and $f_y$is the yield strength of that steel (typically 60 ksi). The value of μ depends on the construction details (e.g. monolithic construction versus the use of construction joints). For the bridge analyzed in this study, it is assumed that $\mu = 1.0$ and $F_{key} = 237$ kips.

The key stiffness will be quite high relative to the rest of the model. For this analysis, a plane stress finite element model was used, resulting in a key stiffness of approximately 108,000 kips per inch. See Figure 7.

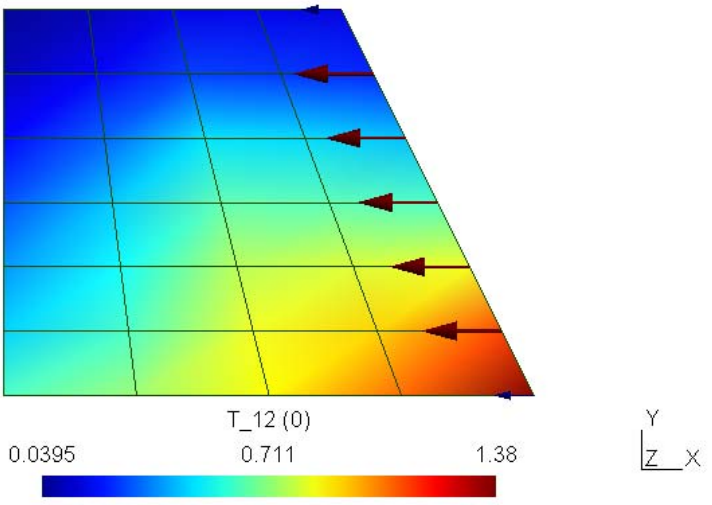

Figure 7 – Shear Key Finite Element Element Model

Analytical Results

For each of the four bridge configuration, two cases were considered for the time history analyses: 1) a standard linear elastic representation of the transverse shear keys, and 2) the nonlinear shear key model discussed in the previous section. For each time history analysis, the maximum lateral displacement of the columns was recorded. Results for each time history are shown in Table 2. A summary of all results are shown in Table 3

Table 2 – Max Column Displacements (inches)

The results associated with the linear analyses are surprisingly similar to the results associated with the nonlinear analyses. In fact, the linear analyses yield results that are more conservative than their nonlinear counterparts (as explicitly assumed in the SDC) and produce a wider range of displacements across the suite of ground motions.

This by no means implies that the standard linear elastic methodology accurately represents the nonlinear abutment response. Rather, it suggests that the existing methodology may not spoil the overall structural response for normal ordinary bridges. The large observed displacement standard deviation associated with the linear model for a bridge with unusually long columns suggests the need for additional investigations into bridges with highly flexible substructures.

Summary and Future Work

While several investigations have examined the longitudinal stiffness of bridge abutments (Romstad et al, 1995, Goel and Chopra, 1997, Shamsabadi et al, 2005, Huang et al, 2008) there has not been a rigorous experimental study on the lateral abutment stiffness. Goel and Chopra (1997) reported field data from the instrumented US 101/Painter Street Overpass and partly investigated this stiffness; however, only two ground motions are discussed while only one produced significant inelastic response.

Therefore, combined with the results from this study, a more rigorous and complete analytical and experimental study may be warranted. The fundamental objective will be to develop and validate new seismic design procedures for bridge structures including accurate models of bridge abutment keys. As the earthquake engineering community moves more towards performance based design criteria, sophisticated models will become a valuable tool in accurately assessing the behavior of bridges under extreme loading events. Medium and large-scale experimental investigations should be included, supported by several analytical research thrusts including non-linear dynamic analyses using a larger set of ground motions than presented here and elastic modeling approaches to inform modifications to design procedures.

ABSTRACT

Computational systems analyses are described for bridge systems that employ quasi-isolation by using a set of fixed bearings in addition to isolation bearings such as elastomeric bearings with an elastomer-concrete sliding interface or elastomeric bearings with a PTFE (Teflon) to stainless steel sliding interface. The system uses stiffened L-shaped retainer brackets that limit transverse displacement of elastomeric bearings and the bridge is intended to respond predictably, reliably, and elastically under service loading (including small seismic events), but for larger seismic events, certain bridge bearing components are intended to "fuse" and experience nonlinear behaviors that can allow for passive quasi-isolation of the bridge superstructure. To facilitate the computational modeling, experimental findings from ongoing research are being used to formulate phenomenological element models that simulate nonlinear fusing behaviors in the bridge bearings and auxiliary components. Furthermore the substructure pier elements, the bridge foundations and the abutment backwalls were modeled as they can exhibit nonlinear behaviors under large loadings. A parametric study is being carried out to investigate the effectiveness of the isolation system for various bridge structures and bearing combinations, and the findings will provide guidance for confirmation and further development of quasi-isolation design strategies.

INTRODUCTION

The concept of a quasi-isolation system for bridges has come from ongoing research to calibrate and refine the Earthquake Resisting System (ERS) methodology currently in use by the Illinois Department of Transportation (IDOT). The project

which is a joint effort of the Illinois Center for Transportation (ICT) and IDOT, is investigating a system of prescribed sequential "fusing" (i.e., exceeding ultimate capacity) of specific components such that more critical components remain in service after an earthquake, and structural collapse is prevented (Tobias et al., 2008). The core of this proposed ERS is an extension of a common bridge design methodology employed in high seismic regions of the United States, where the substructure and superstructure should remain elastic while a fusing mechanism is implemented at the interface between the two (AASHTO 2000, AASHTO 2009). The central objective of the IDOT study, is to observe the progression of damage in common bridge configurations when subjected to large seismic motions and the concomitant quasi-isolated response of the global bridge system as various components transition from elastic behavior to alternate forms of response.

The ongoing experimental work at the University of Illinois (Filipov et al. 2010), is aimed at investigating the nonlinear behavior of: (1) IDOT Type I bearings fabricated using an elastomer reinforced with steel shims placed directly on a concrete substructure, allowing for the possibility of sliding during an earthquake; (2) IDOT Type II bearings that consist of a bottom steel plate connected to the substructure and vulcanized to an elastomer, a steel reinforced elastomeric bearing, a top plate vulcanized to the elastomer and coated on the top side with PTFE, and a stainless steel plate carrying the girded load directly on to the PTFE surface; (3) low-profile fixed bearings with anchor bolts and pintles that prevent movement during ordinary service operations, but are designed to fail at higher earthquake loads; and finally (4) L shaped retainers that are designed as fuse components to fracture the attached anchor bolt during a seismic event. Preliminary experimental results documented in (Steelman et al. 2011) are being followed by a comprehensive component analysis using Abaqus (Abaqus FEA 2010), and the findings will be used to finalize the models for simulating the bearings and ancillary components.

The base global bridge system described herein, incorporates nonlinearities in the bearing components, substructures, foundations and abutment backwalls, and is being be used to study the effectiveness of quasi-quasi isolated systems. A study by (Bignell and LaFave 2009) has shown the seismic fragility of bridges in Southern Illinois and it is believed that isolation would be a cost effective solution to provide safer infrastructure. Dynamic nonlinear analyses with different ground motions will be completed for various IDOT bridges that differ in superstructure girder type and length, intermediate sub-structure type and height, and the type of isolation bearings installed.

MODELING OF A BASIC BRIDGE PROTOTYPE

The global system models are being analyzed using the open source, nonlinear seismic analysis program Open System for Earthquake Engineering Simulation (OpenSees 2006). The system models incorporate linear elastic behavior for all elements in the bridge superstructure, such as the beams, cross-bracing, deck, and parapets. The girders are modeled as linear beam-column elements based on the specified section properties, and the deck is modeled using four-node shell elements with linear elastic behavior. Low-profile fixed bearings are implemented at one of

the intermediate piers, while Type I or Type II elastomeric expansion bearings are used at the other pier and the abutments. Figure 1 shows the finite element mesh for the basic prototype bridge which has three 15.2m (50') spans bridge with 4.6m (15') tall multi-column piers. The rendering shows the scaled deflection of the bridge when the superstructure is loaded in the longitudinal direction. The right pier experiences a larger deflection than the left, since it is equipped with fixed bearings. The prototype bridge deck is 12.8m (42') wide, which allows for two lanes of traffic, it has six W27x84 Gr. 50 composite girders and a 20.3cm (8") concrete deck.

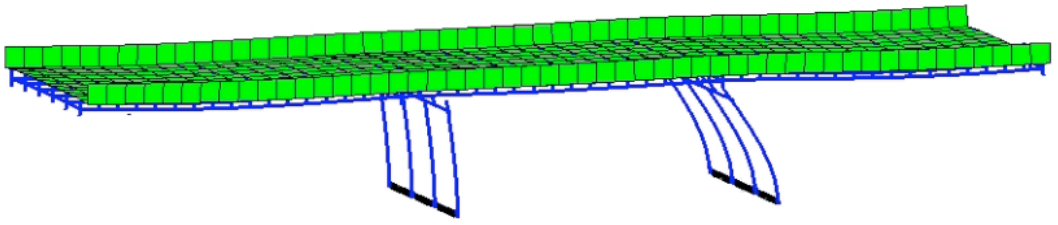

Figure 1. Basic bridge prototype model created using OpenSees

To formulate the parametric study, the basic bridge will be modified as shown in Table 1. Variations will include using a different type and length of superstructure and also different substructure types and heights; further modeling the bridge with Type I or Type II bearings will result in a total of 24 distinct bridge model configurations. Each model variation will be subjected to several suites and intensities of ground motions, and the behavior will be investigated in both the longitudinal and transverse directions.

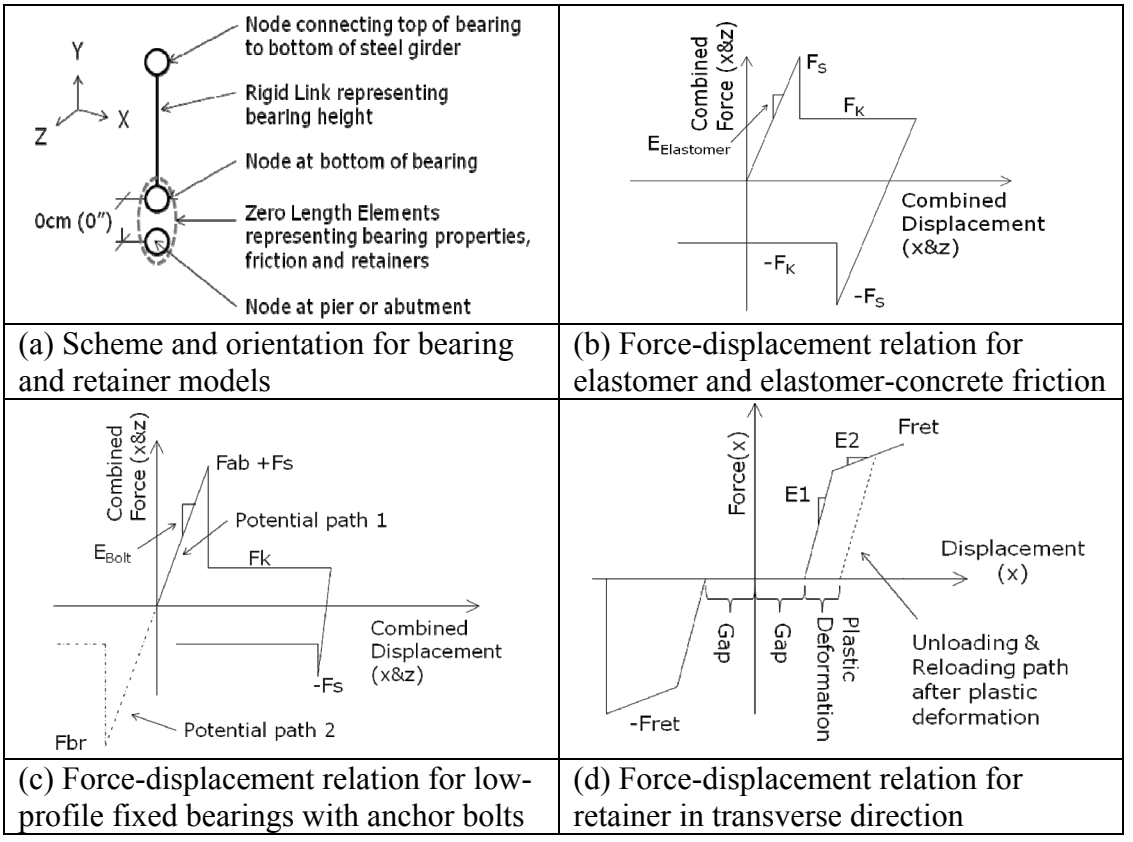
Bearings and ancillary components

The OpenSees program allows for the implementation of user defined materials and elements that can be modified to exhibit specific behaviors. C++ programming was used to create models that augment the capabilities of OpenSees, and thus allow for modeling of complex nonlinear behaviors such as the sliding of elastomeric bearings and PTFE bearings, and the plastic deformation and failure of the retainers and fixed bearings. The bearing models are still in a preliminary

development phase, but have been formulated based on similar studies in literature and the ongoing experimental testing by (Steelman et al. 2011). The bearing and component behaviors will be updated and refined as the experimental test are completed in the near future.



A zero-length bi-directional element was created to combine the force-displacement definitions for the *x* and *z* translation DOFs, so that the force in these directions is governed by their combined displacement. This allows a user to capture phenomenon such as friction break off, as it occurs simultaneously in both the x and z directions. Figure 2 (a) shows the general orientation under which the zero length bi-directional element is to be used. Four uniaxial materials (preferably linear elastic) can be used to define the element's translation in the y direction, as well as rotations about the *x*, *y* and *z* axes. In contrast to the bearings, the retainer models are created to act only in the transverse direction of the bridge.

Elastomer and Elastomer-Concrete/PTFE-Stainless Steel Friction: This element combines the effects of the elastomer along with the stick-slip friction behavior experienced either at an elastomer-concrete interface (for Type I bearings), or a PTFE-stainless steel interface (for Type II bearings). Initially the nonlinear friction response at a bearing is modeled through a "static configuration" with an elastic response, which is effective until the static friction break-off force (*Fs*) is reached at the elastomer-concrete interface. At this point slip occurs and the model enters a "kinetic configuration" where the force at the elastomer-concrete interface is reduced to the kinetic friction force (*Fk*) as shown in the force-displacement relation in Figure 2 (b). This kinetic configuration is maintained until the elastomer force falls below the kinetic friction force, in which case the bottom of the bearing comes to a stop relative to the concrete below and the model returns to the "static configuration". The static and kinetic forces (*Fs* and *Fk)* are governed by the applied axial force on the bearing(N), multiplied by the coefficients of friction at the interface surface (μ_S and μ_K respectively). Therefore, different static and kinetic forces may be expected at each substructure depending on the carried axial load and bearing type. At this time coefficients of static and kinetic friction (μ_S and μ_K) have been set constant at 0.35 and 0.15, however recently completed experiments shown that these coefficients could be dependent on the applied axial load, and could have a broad range of values.

Low-Profile Fixed Bearings with Anchor Bolts: As shown in Figure 2 (c) these bearings are initially modeled as elastic until the horizontal force exceeds the combined anchor bolt shear failure force (*Fab*) plus the static friction break-off force at the steel plate-concrete (*Fs*) interaction surface. This would cause anchor bolt failure and sliding, and the fixed bearing model will thereafter be governed only by a friction behavior similar to that described in the text above. At this time coefficients of static and kinetic friction (μ_S and μ_K) for the steel bearing plate to concrete substructure interface, have been set constant at 0.62 and 0.40 based on previous literature.

Retainers: The phenomenological retainer component has an initial gap that must be closed by the bearing's top plate before the retainer is engaged and force is observed.

Once this initial gap is closed, the force-displacement behavior of the retainer is modeled as elastic, up until plastic deformation begins, as shown by the backbone force-deformation relationship in Figure 2 (d). At this stage the component model experiences linear strain hardening until it reaches a peak breaking force (*Fret*). As plastic deformation is accumulated by the retainer assembly model, the retainer contact point is moved away from its initial configuration, and the gap between the initial position of the bearing top plate and the retainer increases. Furthermore, it is important to note that the positive and negative force-displacement curves are used to separately model the two retainers, therefore the incremental plastic deformations are specific to each retainer and once the breaking force is reached in a retainer, its effects are entirely removed from the model. This initial retainer model is based on the assumption of tension-shear failure in the anchorbolt that holds the retainer to the concrete substructure. Recent experimental testing has shown that although this model seems to provide a reasonable approximation of the force-displacement behavior, the actual capacity of the retainer assembly may be significantly higher than was initially calculated.

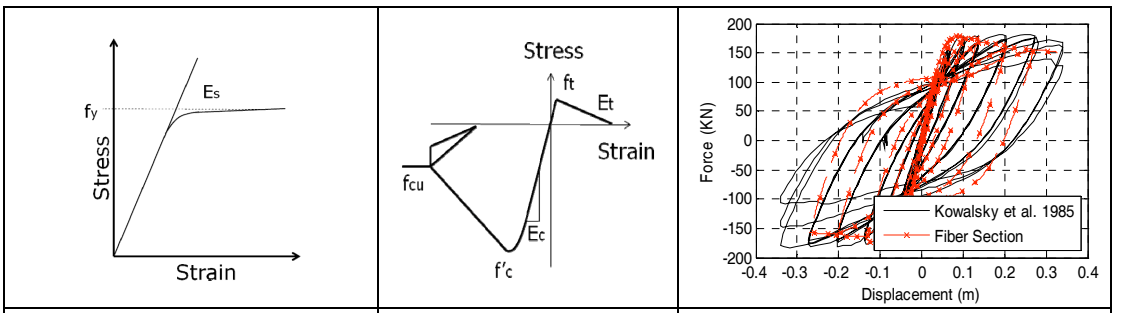
Substructures

The substructure layout is shown in Figure 3 (a) the pier and pile caps are relatively stiff compared to the columns or wall, and are thus modeled as linear elastic elements. The column and wall piers can however experience nonlinear phenomena



such as cracking and flexural yielding when subjected to high lateral loads. Different elements, element discretizations and fiber sections were investigated to find an appropriate method for modeling a single cantilever, and dual curvature columns. The lumped plasticity model proposed by (Scott and Fenves 2006) was used, as it presents a higher curvature at the plastic hinge regions as shown in Figure 3 (b), which well matches concrete column behavior. The plastic hinge length is defined per (Berry et al. 2008), as $l_p = 0.05L + 0.1 f_y d_b / \sqrt{f_c'}$ in MPa ($l_p = 0.05L + 0.008 f_y d_b / \sqrt{f_c'}$ in psi) is used, where L is distance from the critical section to the point of contraflexure, *fy* is the longitudinal rebar yield strength, *db* is the longitudinal rebar diameter, and *fc'* is the concrete strength.

A fiber section, Figure 3 (c), was used to model the nonlinear material behavior in the plastic hinge regions of the column. To provide consistently reliable results the section was discretized to have 15 fiber wedges, 15 fiber rings of confined concrete, 5 fiber rings of un-confined concrete and the necessary number of fibers to simulate each rebar individually. The reinforcement was modeled by using the OpenSees Steel 02 - material (Figure 3 (d)), while the un-confined and confined concrete were modeled using the OpenSees Concrete 02 material (Figure 3 (e)). Some constants used in the column analysis include using 1.25 for the confined to un-confined concrete ratio, $ft = -0.12 f_c'$ for the concrete tensile capacity and $E_C = 4730\sqrt{f_c'}$ in MPa ($E_C = 57,000\sqrt{f_c'}$ in psi) for the concrete modulus of elasticity.

Modifying the material properties, as well as column and section geometries, it was possible to validate the lumped plasticity model against experimental findings from (Ang et al. 1989), (Chai et al. 1991), and (Kowalsky et al. 1999). A sample cyclic force-displacement validation of the (Kowalsky et al. 1999) test FL 3 is shown in Figure 3 (f) with the analytical results based on the described fiber model. The wall substructures are modeled in the same fashion for out-of-plane loading, where a rectangular fiber section is used in a beam-column element with hinges. For in-plane behavior of the wall a spring is used to model shear deformations and a linear elastic member is used to model flexural deformation of a cracked section of the wall. The wall capacity and stiffness are significantly less in the out-of-plane direction, thus this direction is also more important, and the model is validated against experiments from (Haroun et al. 1993) and (Abo-Shadi et al. 1999) for the out-of-plane loading. Both the column piers and wall piers have significantly higher shear capacities than the bearings' fuse capacities so shear failure is not expected to occur.

Figure 3. Definitions and validation for pier column substructure

For the parametric study it was important to define the limit states of concrete piers, so cracking, and steel yielding effects are carefully monitored. Figure 4 shows a force-displacement hysteresis for a typical IDOT cantilever column that would be used for a short bridge structure. The analyzed column is 4.6m (15') tall from base to point of load application, it has a 0.91m (3') diameter, 24.12MPa (3500psi) normal weight concrete, and eleven #9 longitudinal bars with 3.81cm (1.5") clear cover.

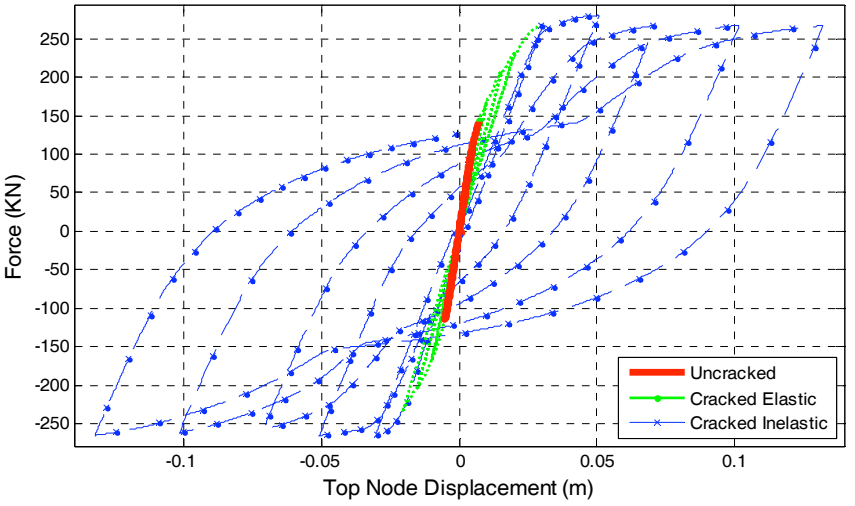

Figure 4. Limit states for typical IDOT column in force-displacement

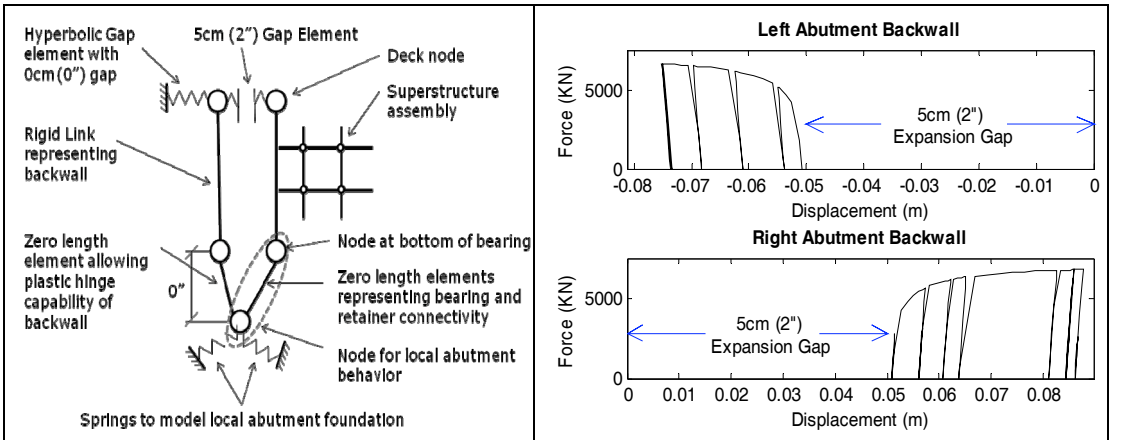

Foundations

Intermediate substructure and abutment foundation response is included in the system models based on a separate study of the bridge foundations and soils that was carried out with a geotechnical pile group analysis program. The typical abutment foundation for bridges in Illinois is defined as (11) HP12x63 piles at a 13.7m (45') depth, with a 1.2m x 1.8m x 12.8m (4'x6'x42') concrete pile cap. A row of four piles is battered towards the superstructure at a 1 to 3 slope, a row of five piles is placed straight and two piles are placed in the wing walls. The typical foundation for the intermediate substructure has three rows of four HP12x63 piles at a 13.7m (45')

depth, with a 0.76m x 3.7m x 10.7m (2.5'x12'x35') pile cap, and all piles being straight. Soil types were modeled as (i) a stiff rocky soil modeled as a fixed base, (ii) stiff clay or medium stiff sand, modeled with 0.072–0.096MPa (1500–2000psf) shear strength, and (iii) a soft clay or loamy soil, modeled with a 0.014-0.024MPa (300–500psf) shear strength. The soil-foundation interaction behavior was calculated for the foundations and different soil types as curvilinear force-displacement relations. The foundation is then simulated in OpenSees as a zero-length element that restrains the bottom node of each substructure using springs for lateral and rotational stiffness as per (Finn 2005).

Abutment backwalls

Abutment backwalls are placed at a distance from the bridge deck, allowing for an expansion gap, and are a very important component of the bridge seismic behavior. When subject to longitudinal movement, the bridge is reasonably flexible and as soon as the 5cm (2") gap is closed the superstructure contacts the backwall and experiences nonlinear behaviors both from the structural concrete backwall as well as the soil backfill behind the abutment elements. As shown in Figure 5 (a), the backwall structural element is modeled using a rigid link connected to a bilinear zero length element that simulates the flexural stiffness and capacity of a 0.61m (2') concrete wall with a reinforcement ration of 0.11%. The nonlinear soil behavior is defined as per (Shamsabadi et al. 2007), and is modeled using the OpenSees hyperbolic gap material assuming the backfill is a compacted, dense sand with an ultimate passive resistance of 262.7KN per meter (18 kips per foot) of backwall, similar to what can be expected for typical Illinois bridges. The backwall and backfill system produces the force-displacement behavior as shown in Figure 5 (b), when the prototype bridge is subjected to a 975 year return period longitudinal earthquake ground motion. The backwall can have a substantial effect on the bridge response as described in the design recommendations from (AASHTO 2009), both for longitudinal and transverse bridge loading, since twisting about the vertical axis of the superstructure could lead to substantial deck to backwall interactions.

PRELIMINARY BRIDGE ANALYSES

Transient nonlinear dynamic modeling is carried out using the OpenSees program. Due to the high degree of nonlinearity an adaptive algorithm was created, such that when non-convergence was encountered the time-stepping solution algorithm, and the integrator were altered in an attempt come to an acceptable solution for the system displacement. The base bridge model (bridge #1 with bearings Type I per Table 1) was simulated using a synthetic earthquake record with a 975 year return period, generated for Paducah, KY (Fernandez and Rix 2006), where the seismic hazard is dominated by large magnitude, but infrequent, seismic events in the New Madrid seismic zone. Figure 6 shows the bearing forces and residual displacement (distance from initial bearing seat location to the new location where the bearing is seated) vs. time plots for an intermediate bearing (bearing carrying girder #3), at each of the four substructures.

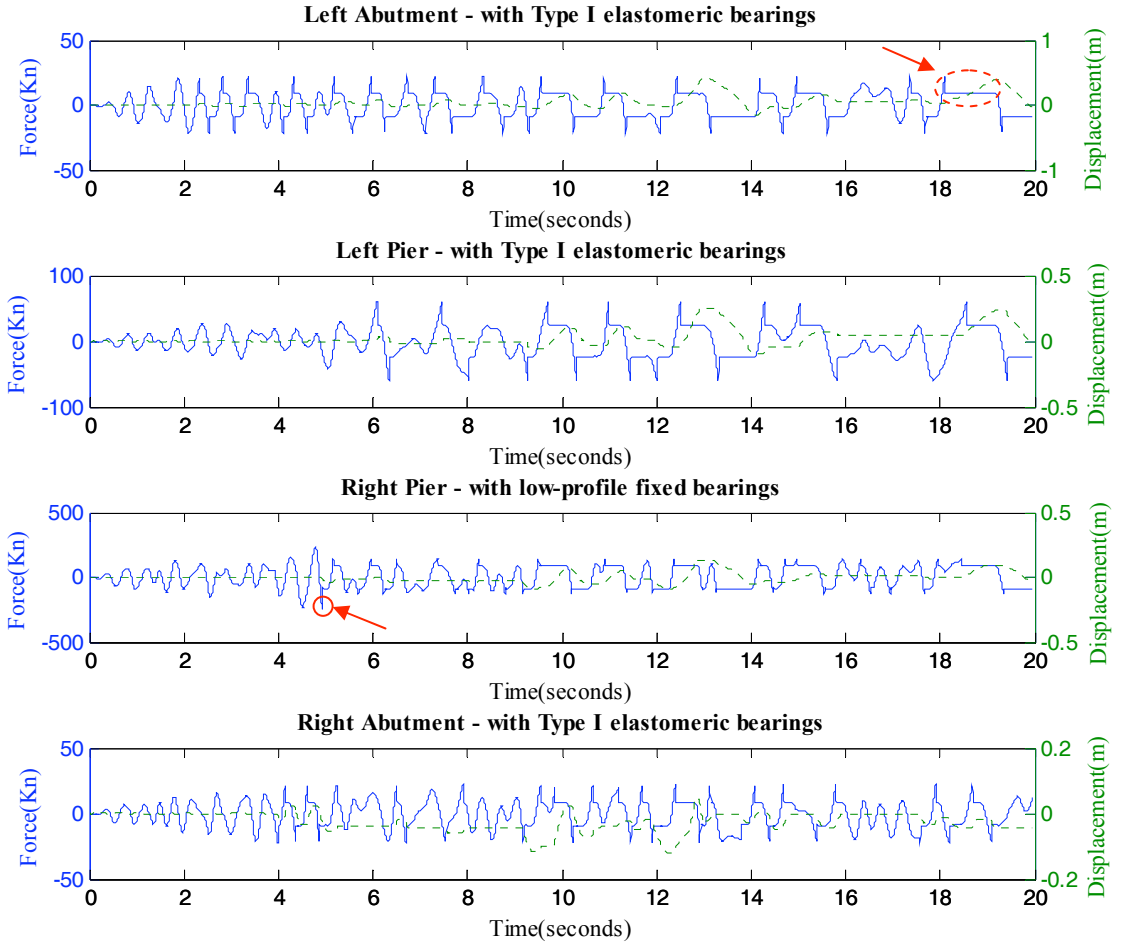

Figure 6. Force (solid) and relative displacement (dashed) at bearing locations vs. time step

Since the intermediate pier bearings have a larger tributary area and carry a larger load, the break-off friction forces for the intermediate piers are significantly higher than those for the abutments. Furthermore it is also interesting to see that since

the right pier has the fixed bearing, it also experiences an interesting response that incorporates a pintle failure at about the 4.8 seconds in the dynamic analysis. At that time the bearing experiences a maximum force of 251KN (56.4kips), and thereafter the forces in the bearing are significantly smaller since the anchorbolt is no longer in place. The sliding behavior of the bearings can easily be observed as pointed out in the left abutment plot between 18 and 19.4 seconds. When the static friction force is reached in the bearing, the force drops down to the kinetic friction force and the bearing slides from a 0.04m to a 0.39m residual displacement. Notice that since the fixed bearings have a higher initial break-off force as well as higher coefficients of friction, they tend to experience less sliding and residual displacement than the rest of the bearings. This leads the superstructure to twist about the vertical axis located at the right pier as it is sliding in the transverse direction. Testing in the longitudinal direction exhibits similar sliding behavior as in Figure 6, however since the bridge is symmetric, there is no twisting behavior, and the bearing displacements are greatly limited by the backwall.

To carry out the parametric study, the different bridge models will be analyzed for varying earthquake hazards. A number of factors affect the response of a bridge including the magnitude of the earthquake, the source mechanism, the distance from the epicenter to the bridge site, the attenuation of the seismic motions with distance, the soil type at the bridge site, and the bridge configuration. For the bulk system analysis it was decided to use suites of (10) 975 year return period synthetic ground motions for each Cape Girardeau, MO, and Paducah, KY provided by (Fernandez and Rix 2006). These ground motions are then scaled to match different degrees of earthquake intensity by using the procedure from the (Sommerville et al. 1997) SAC report where the weighted sum of the squared error between the average spectrum and the target design spectrum is minimized.

To study the three dimensional behavior of the bearings and the full bridge system, the models will all be analyzed for longitudinal, transverse and bi-directional loading application. This will permit for the investigation of the bearing assemblies to different loading directions and will also employ the use of the retainers and backwall as necessary. Bi-directional loading and twisting due to the bridges' asymmetries will also give valuable information about torsional loading of the substructures and the global three dimensional behavior. Although vertical ground motions will not be used for preliminary analysis, since the bearing behaviors are greatly governed by axial load it would be useful to perform research for near-field loadings where vertical accelerations could be significant (Elgamal and He 2004).

A baseline set of analyses has been completed using strong ground motions in the transverse direction to show that the computational approach is effective. Figure 7 shows the same bridge as defined before, subjected to a suite of truncated ground motions that have been scaled to different intensities. The graphs show that with higher intensity shaking there would be higher displacement as expected, and there would also be a larger standard deviation of the data for stronger ground motions. The graphs in Figure 7 also show that the displacements at the right pier are smaller than those at the abutments or left pier. This is to be expected, since the preliminary values for coefficients of friction for the fixed bearings at the right pier are high and there is also the initial capacity of the anchorbolt.

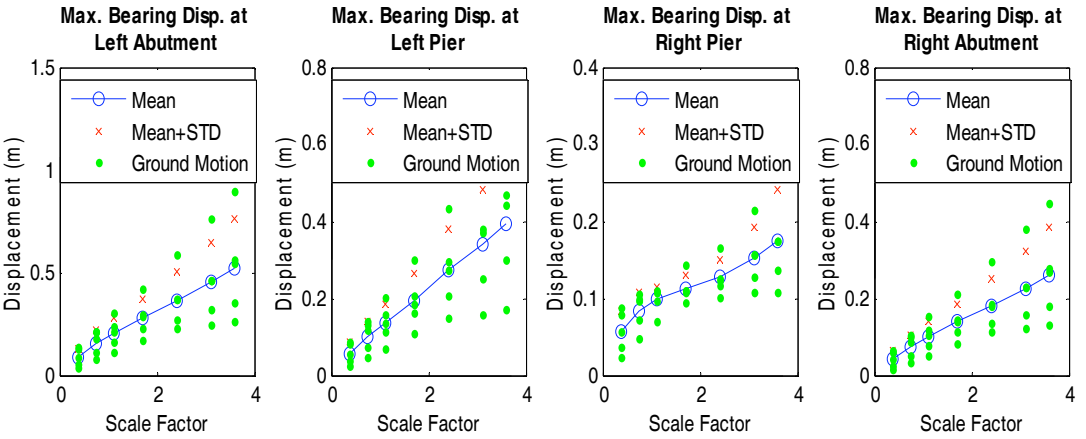

Figure 7. Maximum displacement for a middle bearing at each substructure, when bridge is subject to transverse ground motion loading

SUMMARY AND CONCLUSIONS

The computational models are currently based on preliminary assumptions about the bearing and fuse behaviors. Information in the literature, computational component analysis data, and future experimental results are all expected to provide valuable additional input on how to appropriately model the bearing and ancillary component fusing behaviors. Using well calibrated and validated bearing models, the computational analysis will provide valuable insight about the performance of different bride elements in the global structural response. Typical bridge substructures, foundations and abutment backwalls have been studied, and the bridge model has been built to account for a variety of nonlinear behaviors that can occur as a result of strong ground motions. Initial results have shown that the bearing friction force has a large influence of the superstructure displacement in the transverse direction, and the abutment backwall tends to limit longitudinal displacements. A baseline set of analyses incorporating a suite of ground motions have been completed and current research is aimed at performing parametric studies to investigate the performance of quasi-isolation systems for different bridge structures.

ABSTRACT

Integral abutment bridges are jointless bridges in which the deck is continuous and connected monolithically with the abutment walls supported typically by a single row of piles. Part of the research results from an ongoing project is presented in this paper, which focuses on the effects of two major parameters on the seismic behavior of an integral abutment bridge in Tennessee by considering soil-structure interaction around the piles and in back of the abutments: (1) clay stiffness (medium vs. hard) around the piles, and (2) level of compaction (loose vs. dense) of the abutment wall backfilling. Modal and nonlinear time history analyses were performed on a three dimensional detailed bridge model using the commercial software SAP2000, which clearly showed that (1) compacting the backfilling of the abutment wall will increase the bridge dominant longitudinal natural frequency considerably more than increasing the clay stiffness around the piles; (2) the maximum deflection and bending moment in the piles under seismic loading will happen at the pile-abutment interface; (3) under seismic loading, densely-compacted backfilling of the abutment wall is generally recommended since it will reduce the pile deflection, the abutment displacement, the moments in the steel girder, and particularly the pile moments; (4) under seismic loading, when the piles are located in firmer clay, although the pile deflection, the abutment displacement, and the maximum girder moment at the pier and the mid-span will decrease, the maximum pile moment and the maximum girder moment at the abutment will increase.

INTRODUCTION

Integral abutment bridges are jointless bridges in which the deck is continuous and connected monolithically with the abutment walls supported typically by a single row of piles. A typical integral abutment bridge is illustrated in Figure 1.

The advantages of these bridges include reduced maintenance costs compared to jointed bridges with expansion joints and abutment bearings, reduced corrosion and material degradation at the joints (FHWA, 1986), increased structural capacity during seismic events (Hassiotis et al, 2006), the elimination of uplift due to dead loads (Wasserman and Walker, 1996), the provision of reserve live load capacity by distributing the loads along the continuous and full depth diaphragm at bridge ends,

as well as faster and simpler construction. (Wasserman and Walker, 1996; Hopper and Gomes , 1996)

During the analysis and design of integral abutment bridges, the biggest uncertainties generally lie in the nonlinear soil-abutment and soil-pile interactions, since the magnitude and nature of the soil and structural deformations and stresses are interdependent (Faraji *et al, 2001).* Therefore, it is meaningful to investigate the nonlinear soil-abutment and soil-pile interactions during seismic events, and identify the main factors affecting bridge behavior.

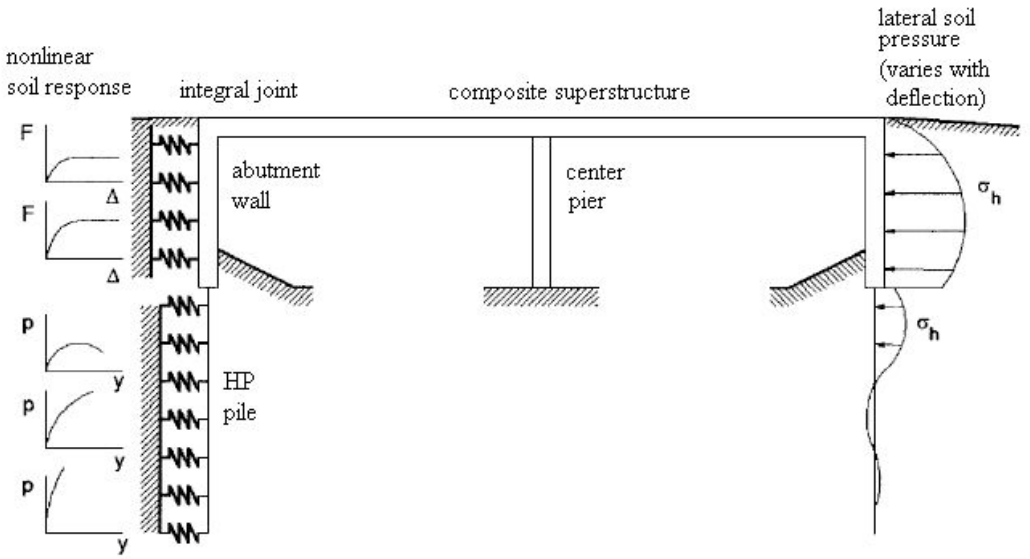

Figure 1 Typical integral abutment bridge

BACKGROUND

Behavior of integral abutment piles under realistic soil constraints

Burdette et al. investigated experimentally the response of integral abutments supported by steel H-piles and prestressed concrete piles, respectively. It was found that a pile embedment length of 305 mm into the abutment was sufficient to assure pile-abutment integrity, when the pile deflection did not exceed the design limit of 25.4 mm specified by the Tennessee Department of Transportation (TDOT). Beyond this limit, some cracking of the pile-abutment interface was observed, which was more extensive in stiffer soils but still did not cause the loss of integrity at significantly larger displacements, even in extremely stiff soils (Burdette et al, 2000). It was also found that the prestressed concrete pile cracked just below the pile-abutment interface when the deflection at the ground surface approached 25.4 mm, which significantly reduced the section stiffness but did not greatly affect the overall behavior. It was then concluded that the current deflection limit was conservative and a value of 38 mm would appear to be reasonable (Burdette et al, 2007)

Soil-structure interaction of integral abutment bridges under thermal loading

Many researchers have studied the soil-pile and soil-abutment interaction in integral abutment bridges, the first dealing with thermal analysis. Faraji et al. presented a

thermal analysis of an integral abutment bridge which explicitly incorporated nonlinear springs for cohesionless soil behind the abutment walls and adjacent to the supporting piles. A parametric study was conducted on the compaction effects, where it turned out that soil compaction behind the abutment wall would double the peak axial forces and moments in the deck, while reducing the peak pile moments by half. Also, soil compaction adjacent to the piles affected the moments in the HP piles, without any significant influence on the abutment wall or bridge deck. (Faraji et al, 2001).

Khodair and Hassiotis studied soil-pile interaction in integral abutments under thermal loading experimentally and numerically, and found that the influence of lateral loads imposed by the superstructure on the piles was confined within a small volume of soil around the piles. (Khodair and Hassiotis, 2005)

Civjan et al. studied effects of backfill properties and soil restraints on integral abutment piles with regard to bridge distortions, and maximum moments developed in the piles caused by thermal loading. It was found that the bridge expansion was predominantly affected by the backfill conditions, whereas the bridge contraction was influenced by the pile restraint conditions. It was also shown that the pile moments were minimized when denser backfill and smaller pile restraint were provided (Civjan et al , 2007)

Seismic response of integral abutment bridges

Several researchers have also investigated seismic response of integral abutment bridges (e.g. (Goel, 1997), (Dehne and Hassiotis, 2003) and (Spyrakos and Loannidis, 2003). Goel studied earthquake characteristics of integral abutment bridges, in which he measured the dynamic properties of a two-span concrete bridge from motions recorded during an actual earthquake, and indicated that the vibration period elongated and the damping ratio increased by a factor of more than two as the intensity of the ground motion increased. (Goel, 1997)

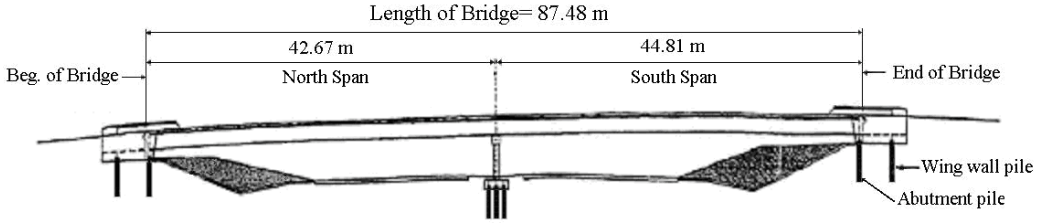
Dehne and Hassiotis conducted seismic analysis on an integral abutment bridge, through which it turned out that accurate modeling of the soil-structure interaction was required to evaluate the effects of longitudinal and transverse earthquake excitation on the response of integral abutment bridges. It was concluded that an integral abutment bridge system with the dense compacted soil behind the abutment wall and loose sand around the piles would have the best performance characteristics. (Dehne and Hassiotis, 2003)

Spyrakos and Loannidis studied seismic behavior of a single-span post-tensioned integral abutment bridge including soil-structure interaction, in which they assessed the significance of soil-structure interaction on the mode shapes and seismic response of the bridge. Sensitivity studies were conducted to investigate the effect of foundation stiffness on the overall dynamic and seismic response of the bridge system. It turned out that the vibration frequencies changed about 20 percent in extreme cases, and the foundation stiffness did not affect significantly the seismic response of the bridge. They also found that the existence of backfill had a significant effect on the dynamic characteristics and seismic response of the bridge. (Spyrakos and Loannidis, 2003)

ANALYSIS OF AN INTEGRAL ABUTMENT BRIDGE IN TENNESSEE

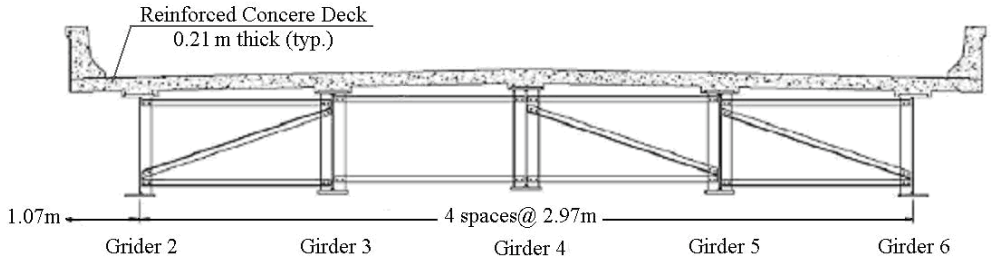
This paper focuses on the seismic behavior of a two-span integral abutment steel bridge in the State of Tennessee, with an emphasis and sensitivity study on the effects of the levels of sand compaction in back of the abutments and clay stiffness around the piles. Clay is the common type of soil in most locations in Tennessee, which has not been studied enough on seismic response of integral abutment bridges yet. A 3-D model of an integral abutment bridge was constructed with seismic soil springs around the piles and behind the abutments. The commercial design/analysis software SAP2000 is used for convenience of application of research results for the design engineers.

1) BRIDGE MODEL



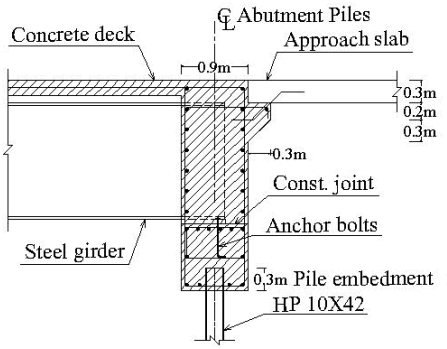
The bridge is located on Massman Drive across I-40 in Nashville, Tennessee, with a north span of 42.67 m and a south span of 44.81 m. The bridge superstructure consists of five steel plate girders with a height of 1.63 m and center to center spacing of 2.97 m, supporting a 0.21 m thick concrete deck above. The bridge substructure consists of two 2.87 m height and 0.91 m thick integral abutments supported each by ten HP10×42 steel piles oriented in the strong axis bending. Views of the bridge and also its abutment details are shown in Figure 2.

2) FINITE ELEMENT MODEL



A 3-D finite element model (FEM) of the bridge was constructed using SAP2000 software. The deck, abutments and pile caps are modeled as shell elements while the steel plate girders, piers, bent cap and piles are modeled as beam elements. To account for the composite action of the superstructure, rigid link elements are inserted between the deck nodes and the girder nodes. A rigid connection is assumed at the conjunction of the steel girders and the abutments, as well as between the piles and the abutments, reflecting the fact that the steel girders and piles were cast rigidly in the concrete there. Nonlinear link elements are used to model the nonlinear soil reactions around the piles and in back of the abutments. For the analyses, a damping coefficient of 0.05 is considered in the bridge model. The 3-D finite element model of the bridge is shown in Figure 3.

3) NONLINEAR SOIL SPRINGS



The soil around the piles is considered clay, which is common in most locations in Tennessee. Properties of medium clay and hard clay are selected from the geotechnical reference (Coduto, 1999) in order to represent soil characteristics in Tennessee. The abutment wall backfilling is cohesionless clean sand with properties based on experimental test data obtained at Brigham Young University (Cummins, 2009) for both the loosely and densely-compacted cases. Therefore, four different soil cases are defined for the sensitivity study, as shown in Table 1.

Table 1 Soil properties for the sensitivity study

Case	Soil around piles	Abutment backfill
1	Medium Clay ($c_u = 37.5\,kPa, \gamma = 14.61\,kN/m^3$)	Loosely-compacted clean Sand ($\phi = 37^o, c = 0, \gamma = 16.50\,kN/m^3$)
2	Medium Clay ($c_u = 37.5\,kPa, \gamma = 14.61\,kN/m^3$)	Densely-compacted clean Sand ($\phi = 40.5^o, c = 0, \gamma = 18.30\,kN/m^3$)
3	Hard Clay ($c_u = 200\,kPa, \gamma = 18.14\,kN/m^3$)	Loosely-compacted clean Sand ($\phi = 37^o, c = 0, \gamma = 16.50\,kN/m^3$)
4	Hard Clay ($c_u = 200\,kPa, \gamma = 18.14 kN/m^3$)	Densely-compacted clean Sand ($\phi = 40.5^o, c = 0, \gamma = 18.30\,kN/m^3$)

c_u = undrained shear strength of undisturbed clay; γ = effective soil density

Nonlinear soil springs around the piles

The procedures given in the American Petroleum Institute (API) are followed to define the p-y curves for clay material and model the nonlinear soil springs around the piles (American Petroleum Institute, 1993). The ultimate unit lateral bearing capacity of clay p_u is shown by EQ (1):

$$p_u = \begin{cases} 3c_u + \gamma X + J\dfrac{c_u X}{D} & for\ X < X_R \\ 9c_u & for\ X \geq X_R \end{cases} \quad (1)$$

Where p_u= ultimate resistance, *kPa* (psi), c_u = undrained shear strength, *kPa* (psi), D= pile diameter, *mm* (in.), γ = effective soil density, MN/m^3 (lb/in^3), *J*= dimensionless empirical constant, X = depth below soil surface, *mm* (in.), X_R = depth below soil surface to bottom of reduced resistance zone, *mm* (in.) and determined by EQ (2):

$$X_R = \frac{6D}{\dfrac{\gamma D}{c_u} + J} \quad (2)$$

After determining p_u, the *p-y* (load vs. deflection) curves for soil springs along the pile length are generated from Table 2. Note that $y_c = 2.5\varepsilon_c D$, where ε_c is the strain at 50% of soil ultimate resistance from undrained compression tests of undisturbed soil samples. For $c_u = 37.5$ and 200 kPa used in the analyses, corresponding ε_c values of 0.01 and 0.005 are selected. 0) For the different soil springs along the pile length shown in Figure 3 as Pile SP1, Pile SP2… the *p-y* curves are determined as shown in Figure 4 for the hard clay, in which *y* is the lateral displacement of the pile.

Table 2 Load-deflection curves for clay soil under cyclic loading (API, 1993)

$X > X_R$		$X < X_R$	
p / p_u	y / y_c	p / p_u	y / y_c
0	0	0	0
0.5	1.0	0.5	1.0
0.72	3.0	0.72	3.0
0.72	∞	$0.72\,X / X_R$	15.0
------	------	$0.72\,X / X_R$	∞

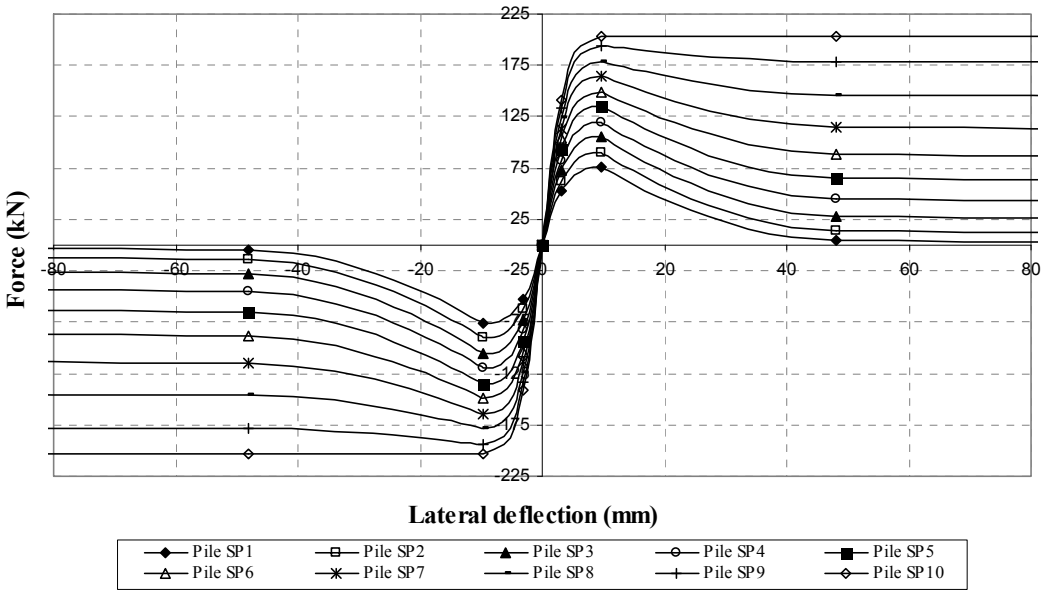

Figure 4 Force-deflection curves of pile springs under cyclic loading for hard clay

Nonlinear soil springs in back of the abutments

Based on a comprehensive study on nonlinear soil-abutment interaction for seismic design of bridges by Shamsabadi et al. (2007), a simplified hyperbolic force-displacement relation was proposed by EQ (3) and shown in Figure 5.

$$F(y_i) = \frac{F_{ult}(2Ky_{\max} - F_{ult})y_i}{F_{ult}y_{\max} + 2(Ky_{\max} - F_{ult})y_i} \tag{3}$$

where y = lateral displacement of the abutment, K= average soil stiffness as shown in Figure 5, F_{ult} = maximum abutment force (per unit length of the wall) developed at a maximum displacement of $y_{\max}$. For cohesionless soil backfilling F_{ult} can be determined by

$$F_{ult} = 0.5K_{pe}\gamma h^2 \tag{4}$$

where K_{pe}= seismic passive earth pressure coefficient, γ = soil density and h = height of the wall.

To determine the seismic passive earth pressure coefficient, a log spiral procedure is used following Shamsabadi et al. (2007) or NCHRP 12-70 (2008). Based on the location of the bridge, peak ground acceleration (PGA) and horizontal seismic coefficient (K_h) are determined. Then, a log spiral procedure using the NCHRP Figures is used to obtain K_{pe} for different abutment backfilling soils.

Based on the experimental test results obtained at Brigham Young University (Cummins, 2009), $y_{\max} = 0.024H$ for loosely-compacted clean sand backfilling and $y_{\max} = 0.03H$ for densely-compacted clean sand backfilling where H was the height of the pile cap. Moreover, considering the test results two values of K = 120 kN/cm/m and K = 180 kN/cm/m have been selected for loosely-compacted clean sand backfilling and densely-compacted clean sand backfilling, respectively. These K values are then adjusted for the 2.87 m wall height according to the Caltrans specifications (Caltrans, 2006) and K = 120(2.87m)/1.68m = 205 kN/cm/m and K = 180(2.87m)/(1.68m) = 307.5 kN/cm/m were assigned for loosely-compacted backfilling and densely-compacted backfilling, respectively.

Following the approach above, as shown in Figure 6, force displacement relations for unit length of the wall for two different cases of loosely-compacted and densely-compacted sand backfilling are determined and modeled by nonlinear link elements in the bridge model.

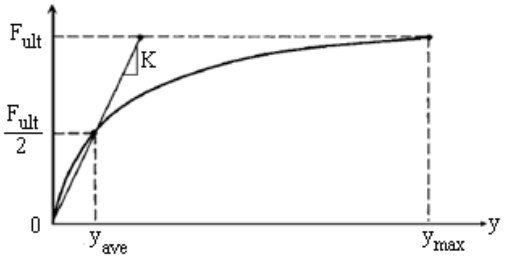

Figure 5 Hyperbolic force-displacement formulation

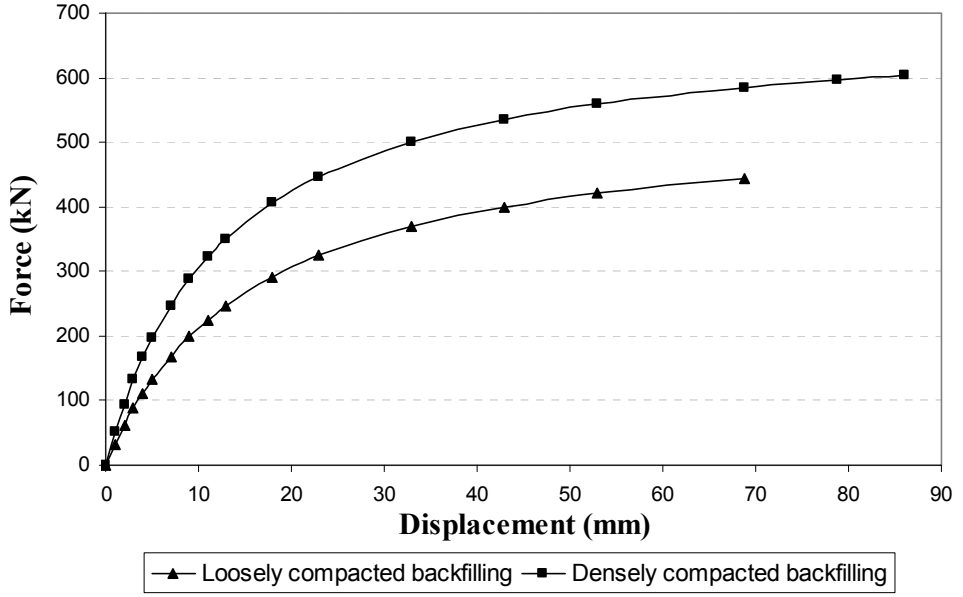

Figure 6 Force displacement relations for abutment backfilling

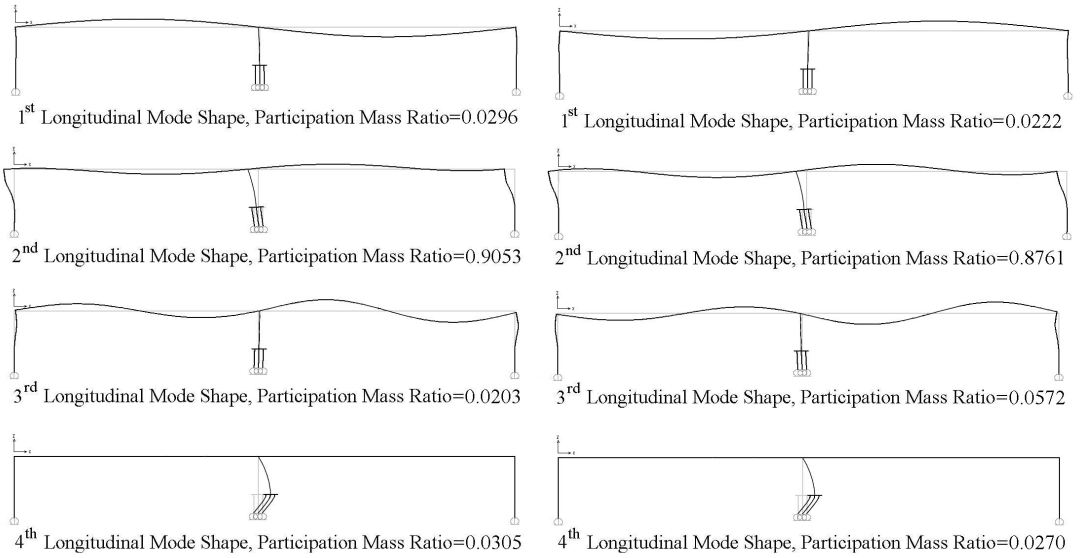
4) MODAL ANALYSIS AND SENSITIVITY STUDIES

In order to evaluate the effect of different clay materials around the piles and different levels of soil compaction in back of the abutments on dynamic properties of the integral abutment bridge, modal analysis is performed using the three dimensional finite element model of the bridge for the 4 cases defined in Table 1. The results of the modal analyses include different mode shapes in all three directions, but in this paper, since the focus was to investigate the effect of soil material around the piles and the levels of soil compaction in back of the abutments, only the longitudinal mode shapes are presented and discussed, which are numbered only considering the longitudinal direction modes instead of all the modes. These longitudinal mode shapes, for two different cases of piles in medium clay and hard clay, are shown in Figures 7 and 8, respectively, and the corresponding natural frequencies are shown in Table 3.

Table 3 Natural frequencies of Massman Drive Bridge for longitudinal modes (Hz)

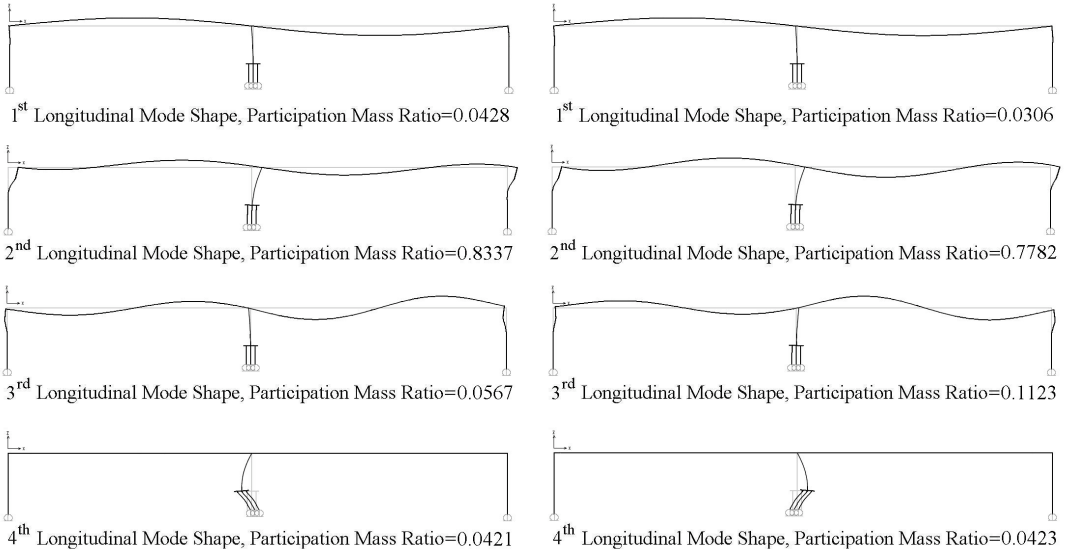
Longitudinal Mode #	Case 1	Case 2	Case 3	Case 4	Case 1&2	Case 3&4	Case 1&3	Case 2&4
	Medium clay Loose backfill	Medium clay Dense backfill	Hard clay Loose backfill	Hard clay Dense backfill	Diff %	Diff %	Diff %	Diff %
1	2.07	2.09	2.10	2.14	1	2	2	2
2	4.67	5.54	5.17	5.83	19	13	11	5
3	7.61	7.70	7.83	7.94	1	1	3	3
4	9.24	9.24	19.66	19.66	0	0	113	113



**Positive means increasing*

As shown in Figures 7 and 8, the longitudinal mode which contributes the most to the seismic analysis is primarily the second mode with frequency shown in Table 3. From Table 3, it is clear that the dominant frequency increases by about 19% and 13% for the piles in medium clay and hard clay respectively, when the sand backfilling varies from loosely to densely compacted. The dominant frequency increases by about 11% and 5% for loosely-compacted sand backfilling and densely-compacted sand backfilling respectively, when the clay around the piles varies from medium to hard. Therefore, the bridge dominant longitudinal natural frequency will increase considerably by compacting the sand backfilling of the abutment wall.

5) SEISMIC ANALYSIS AND SENSITIVITY STUDIES



The Massman Drive Bridge is located in Nashville, Tennessee, which is in a low seismic region with peak ground acceleration (PGA) equal to 0.086g. In order to obtain a better understanding of the seismic response of integral abutment bridges in Tennessee, the Memphis region is considered instead with peak ground acceleration equal to 0.39g. The bridge is studied using the IMPVALL/I-ELC180 component of El Centro earthquake (Imperial Valley, 1940) scaled to the PGA of 0.39g. Nonlinear time history analyses are performed using the scaled component of El Centro earthquake applied in the longitudinal direction of the bridge. The same four cases defined in Table 1 are considered here, similar to the modal analyses, to investigate

the effect of clay stiffness around the piles and the levels of sand compaction in back of the abutments on seismic behavior of the bridge. The results of the nonlinear time history analyses are presented in Figures 9 and 10 for maximum pile deflections and maximum pile moments, and in Tables 4 and 5 for maximum abutment displacement and maximum girder moments.

(a)Loosely-compacted backfilling (b) Densely-compacted backfilling

Figure 7 Longitudinal mode shapes of bridge model for piles in medium clay

(a) Loosely-compacted backfilling (b) Densely-compacted backfilling

Figure 8 Longitudinal mode shapes of bridge model for piles in hard clay

Maximum pile deflection and abutment displacement

The maximum lateral deflections of the piles during the time-history analysis were compared, and the most critical pile was identified. The maximum deflection along the height of this pile is plotted in Figure 9 for all four cases, where it is obvious that the maximum lateral deflection of the pile along the length is always located at the pile-abutment interface. The maximum value of this deflection from all cases is 19.7 mm for **case 1**, with medium clay around the piles and loosely-compacted sand backfilling behind the abutments, a value less than the limiting value of 25.4 mm proposed by the Tennessee Department of Transportation (TDOT). The minimum value from all cases was 8.6 mm for **case 4**, with hard clay around the piles and densely-compacted sand backfilling behind the abutments. Therefore, it is clear that the pile deflection is affected by the soil stiffness both behind the abutment and around the piles, and the pile deflection will decrease when the soil stiffness increases, in other words, when the abutment backfilling is compacted or the piles are located in firmer clay, or both.

The maximum lateral displacements at the top and the bottom of the abutment walls during the time-history analysis are shown in Table 4 for all four cases. The maximum wall lateral displacements are generally larger at the bottom and match well with the pile deflection.

Maximum moments along abutment piles

The maximum moments along the piles during the time-history analysis were compared and the most critical pile was also identified. The maximum moment along the height of this pile during the time-history analysis is plotted in Figure 10 for all four cases, where it is obvious that the maximum moment is always located at the pile-abutment interface. The maximum value of this maximum moment from all cases is 240.99 kN.m for **case 3**, with hard clay around the piles and loosely-compacted sand backfilling behind the abutments. The minimum value from all cases is 129.40 kN.m for **case 2**, with medium clay around the piles and densely-compacted sand backfilling behind the abutments.

Therefore, it is clear that the pile moment is affected by the stiffness of the soil behind the abutment and around the piles in a different way from pile deflection. It is clear that the maximum pile moment will decrease when the abutment backfilling is compacted and increase when the piles are located in firmer clay. The maximum pile moment will be reduced about 25% and 18% by densely compacting the abutment backfilling, when the piles are in medium and hard clay, respectively.

Maximum moments in steel girders

The maximum positive and negative moments in steel girders during the time-history analysis are shown in Table 5 for all the cases. The maximum positive girder moment is generally located at the middle of the longer south span (44.81 m), and the maximum negative girder moments are generally located at the pier and the abutments.

For the steel girder moments at the middle of south span and at the pier, the maximum values happen in **case 1**, with medium clay around the piles and loosely-compacted sand backfilling behind the abutments, while the minimum values happen

in **case 4**, with hard clay around the piles and densely-compacted sand backfilling behind the abutments. For the steel girder moments at the abutments, the maximum value happens in **case 3**, with hard clay around the piles and loosely-compacted sand backfilling behind the abutments, while the minimum value happens in **case 2**, with medium clay around the piles and densely-compacted sand backfilling behind the abutments.

Therefore, it seems that the steel girder moments along the bridge, i.e., inside the span and at the pier will generally decrease with the soil stiffness both behind the abutment and around the piles, similar to the pile deflection and abutment displacement. On the other hand, the maximum steel girder moments at the abutment will decrease when the abutment backfilling is compacted and increase when the piles are located in firmer clay, similar to the pile moment, since these two moments are closely related.

Based on the analyses results, it is recommended to compact the backfilling behind the abutments densely for the integral abutment bridges in clay soil, in order to control the pile deflection, the abutment displacements, the maximum bending moments in the pile as well as the maximum bending moments in the steel girders.

**Positive means increasing; Negative means decreasing*

CONCLUSION

For the bridge discussed in this paper located in the State of Tennessee, the following conclusions can be drawn from the dynamic and seismic analyses:

(1) Compacting the sand backfilling behind the abutment wall will increase the dominant longitudinal frequency of the bridge considerably more than increasing the clay stiffness around the piles.

(2) Under seismic loading, the maximum pile deflection and the maximum abutment wall displacement are both at the pile-abutment interface. This deflection is affected by the soil stiffness both behind the abutment and around the piles, and will decrease when the abutment backfilling is compacted or the piles are located in firmer clay, or both.

(3) Under seismic loading, the maximum moment in the pile is at the pile-abutment interface. The pile moment will decrease when the abutment backfilling is compacted and increase when the piles are located in firmer clay. Therefore, this

moment is maximum for the case with piles in hard clay and loosely-compacted backfilling, and minimum for the case with piles in medium clay and densely-compacted backfilling.

(4) The maximum steel girder moments at the pier and the mid-span will generally will decrease when the abutment backfilling is compacted or the piles are located in firmer clay, similar to the pile deflection and abutment displacement. However, the maximum steel girder moments at the abutments will decrease when the abutment backfilling is compacted and increase when the piles are located in firmer clay, similar to the pile moment.

(5) When the piles are located in firmer clay, although the pile deflection, the abutment displacement, and the maximum girder moment at the pier and the mid-span will decrease, the maximum pile moment and the maximum girder moment at the abutment will increase.

(6) Densely-compacted backfilling behind the abutments is generally recommended, since it will reduce the pile deflection, the abutment wall displacement, the steel girder moments, and particularly the pile moment.

ACKNOWLEDGEMENT

The research presented in this paper is funded by the Tennessee Department of Transportation (TDOT) and the Federal Highway Administration. Their financial support is gratefully acknowledged. The authors would also like to thank Mr. Ed Wassermann and Mr. Tim Huff for providing resources and technical help during the research activities. Any opinions, findings or conclusions expressed in this paper are those of authors and do not necessarily reflect the view of the sponsoring agencies.

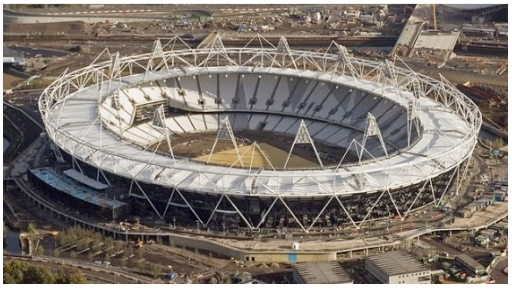
ABSTRACT

Designed by Populous (architects) and Buro Happold (structural engineers) and fabricated and erected by Watson Steel Structures Ltd, the roof over the London 2012 Olympic Stadium covers an area of more than 24,500m^2. The construction of the cable net roof posed many complex engineering problems, culminating in the erection of the 14 lighting towers, perched on the leading edge of the roof and supported by a secondary cable net. The entire main cable net, including access gantries, was lifted in one operation involving the simultaneous operation of 28 pairs of strand jacks to lift and pre-stress the cable net roof structure. The design of the staged lifting procedure meant that no additional strand jacks were required for the connection of other cables. An innovative method of lifting the lighting towers into position, using a single crane, was developed to save time and avoid the use of a second crane in a tight location.

This paper covers the fabrication of the roof elements, the staged erection and pre-stressing of the main cable net and also the erection of the stadium's signature lighting towers.

INTRODUCTION



a)  b) 

Figure 1 – London Olympic Stadium ((a) Photographer: Phil Wright)

The roof over the 80,000 capacity London 2012 Olympic Stadium (Figure 1) forms the crown over a highly efficient stadium design, incorporating only 10,000t of steelwork for the entire stadium structure. The form of the roof is commonly known as a 'Bicycle wheel' cable net roof, as shown in Figure 2, and was first used for stadium roof designs in the early 1980's. As with a bicycle wheel, the radial cables are pre-stressed between the compression ring (rim) and tension ring (hub) to avoid any slack cables under extreme load cases and provide the strength and stiffness required to span over the seats below. The pre-stress also serves to provide geometric stiffness to the compression truss and resists global buckling of the truss.

Stadium roof statistics:

- The roof covers an area of approximately 20,000m^2.
- There are over 14,000m of spiral strand cables ranging from 80mm diameter to 25mm diameter.
- The compression truss weighs approximately 2500t.
- Each of the 14 lighting towers contains up to 45 lights that were installed and operational prior to erection of the towers.
- Lifting equipment with a total capacity of 6800t was required to pre-stress the 600t primary roof cable net.
- The largest crane used on site was a 1350t capacity, Liebherr LR11350 crawler crane, the largest in the UK at the time.

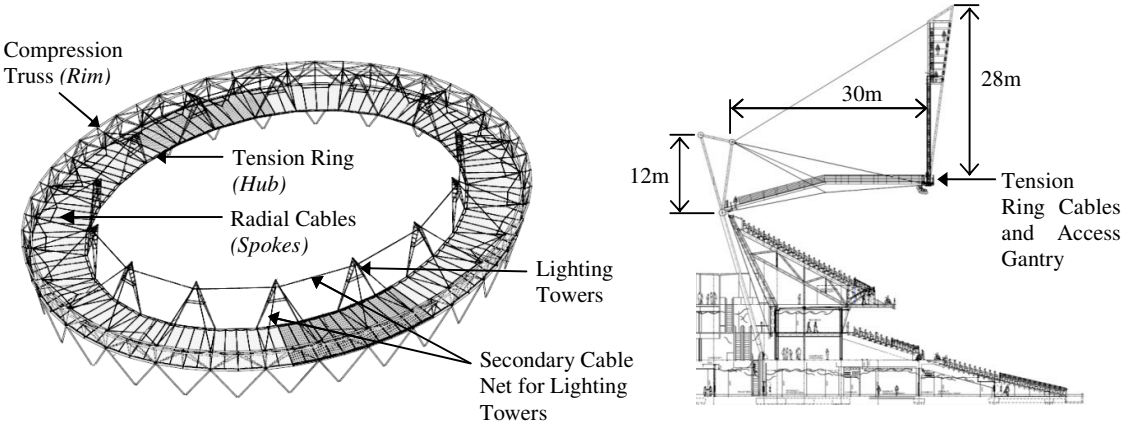


Figure 2 – Roof structure definitions **(Images: Buro Happold, Populous)**

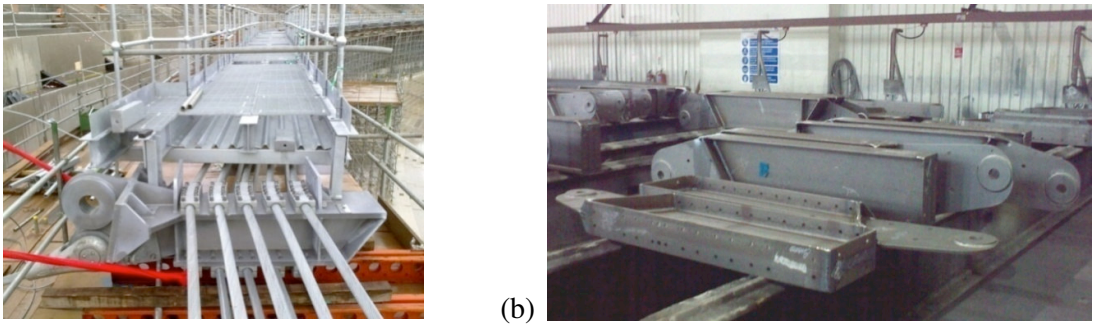
The cable net roof consists of 28 'major' radial gridlines forming the main roof support, with an additional 84 'minor' gridlines for the support of the PVC coated polyester fabric covering. This divides the roof into 112 gridlines at approximately 6m spacing at the leading edge of the roof. The tension ring consists of ten 60mm diameter cables that are connected to steel 'nodes' (Figure 4) that also support the access gantry and the lighting tower bases.

Throughout the design and construction of the 2012 Olympic Stadium roof 'demountability' was a key consideration. It is intended that the stadium will be converted for use on a smaller scale following the 2012 Olympics, which will most likely involve the removal of the current roof for replacement with a smaller permanent roof.

FABRICATION

Compression Truss

The final forces developed in the cable net are a direct result of the accuracy that the compression truss has been fabricated and built to and, as a result, tight tolerance requirements were specified for the length of individual members and the angle of the end plates. The chord members were fabricated in a continuous run in the workshop (Figure 3a), with each segment being fabricated slightly oversize and the 'pipe flange' bearing connections machined to fit with the previous segment, following a survey of the previous end plate. The first fabricated segment was kept in the factory and used for the fabrication of the last segment to ensure correct fit up of all pieces. This method ensured that the final piece could be installed with minimal adjustments to the adjacent temporary truss supports and to a high degree of accuracy.



(a) (b) (c)

Figure 3 – Compression truss (a) Chords fabricated in factory to provide exact fit up; (b) Site assembled 'bay' (36m) being lifted out of site erection jig; (c) Final piece of compression truss being installed

Surveys of the compression truss were continuously taken during construction to check the tolerances. However, with over 40mm radial expansion of the truss due to the winter-summer temperature variation and a 6 month construction program, the steelwork temperature had to be measured at the time of each survey and used to alter the theoretical model for comparison with the survey.

Nodes

Typically, the tension ring/ radial cables for roofs of this form are connected by cast steel nodes, incorporating all cable connections and clamping details. For the 2012 Olympic Stadium, it was found that significant material and cost savings could be made by fabricating the nodes from a combination of plate material for the major nodes and standard beam sections for the minor nodes (Figure 4). Cable clamps were manufactured separately as cast items and bolted to the nodes on site. An additional feature of the design of the nodes was the incorporation of permanent fabricated plates for the connection of the temporary strand jack cables during erection. These can be seen at the rear of the top flanges of the nodes and are mostly concealed by the gantries and fabric roof covering when complete (Figure 4a and Figure 11). These permanent connection points simplified the erection and will also aid the deconstruction in several years time.

(a) (b)

Figure 4 – (a) Major node showing cables connected with clamps and gantry installed (b) Minor nodes during fabrication

Cable Clamps

The design of the cast cable clamps was rationalised to allow a single clamp mould to be used for all major nodes and a second mould for the minor nodes. These moulds had tapered cable grooves to accommodate the full range of cable kink angles around the oval roof shape. The clamps were installed with aluminium sleeves wrapped around the cables to reduce localised bearing stresses on the surface of the cable strands.

Following the requirements of EC3 1-11, a test rig, mimicking the final condition of the clamps was built in the steel fabricators workshop and a piece of test cable and two cable clamps were tested (Figure 5). The tests were carried out at varying axial loads in the cable to measure any effect of the reduction in cable diameter, due to Poisson's ratio, that may reduce the clamping force. The ultimate clamp slip resistance was measured for each load condition and it was found that the variation in load had negligible effect on the overall slip resistance.

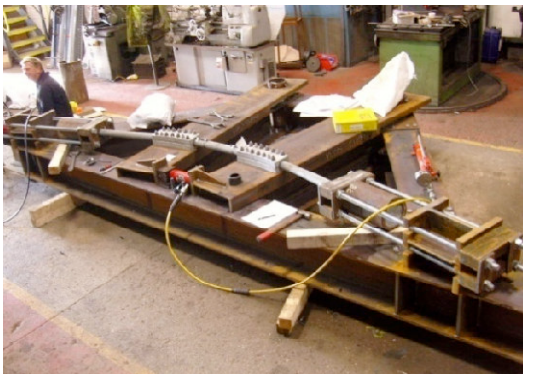


Figure 5 – Cable clamp test rig in steel fabricators workshop

PREPARING FOR THE BIG LIFT

Following completion of the precast terracing and compression truss, a scaffold was erected on the terrace, directly below the final position of the tension ring. The tension ring cables and nodes were laid out onto the temporary scaffold and connected, followed by the access gantry which is connected to the top of the nodes. The gantry, running the entire length of the tension ring, was lifted with the cable net to avoid the 112 additional lifts that would have been required for its installation in the air. An added advantage of lifting the gantries with the cable net was that it provided instant access to the roof and strand jacks as soon as the roof was lifted. Each gantry segment was, therefore, designed to allow a large range of movement in all axes to avoid any damage to the units during the lift operation.

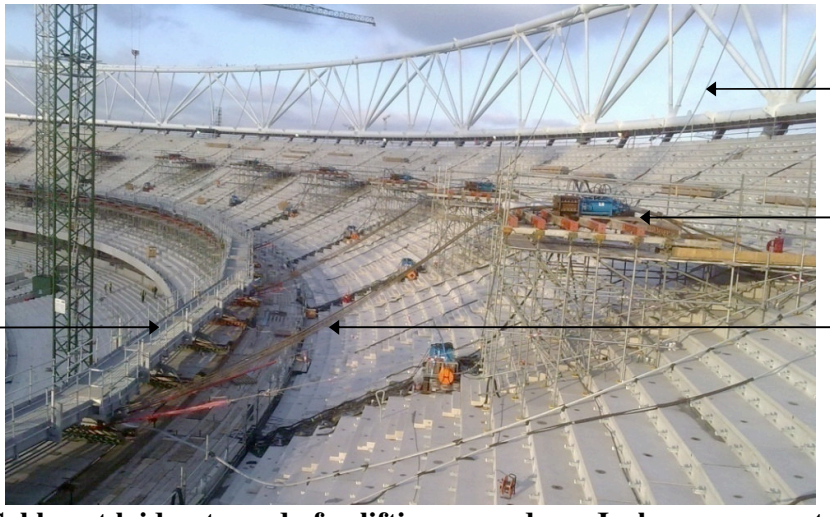

Figure 6 – Cable net laid out, ready for lifting procedure. Jacks are connected to the 28 main suspension cables.

The 112 lower radial cables were connected directly to the tension ring nodes and laid across the terrace, whilst the 28 main suspension cables were hung from the top chord of the compression truss and connected to pairs of strand jacks midway up the terrace. The jacks were connected to each other, and to the suspension cables, via bespoke jacking beams (Figure 7) and the temporary steel strands linked the jacks to the strand termination plates on the major nodes. The strand jacks, supplied by Fagioli Ltd, varied in capacity between 100t and 180t and were required to pre-stress the most highly loaded cables up to 2600kN, giving a total lifting capacity in excess of 6800t.

Figure 7 - Strand jack arrangement

LIFTING OPERATION

Due to the hierarchy of major and minor cables, it was only necessary to pull from the 28 major gridlines using pairs of linked strand jacks. Each strand jack is an electronically operated hydraulic ram that uses a system of mechanical grips to climb along the temporary jacking strands. The jacking operation used 'flying jacks' (Figure 7 and Figure 8) to pull the free ends of suspension cables towards the tension ring until the final connection could be made. The use of flying jacks simplified the temporary works that would have been required for the more standard system of jacks mounted on the compression truss as they used the permanent load paths without imposing any additional temporary loads on the structure.

The jacking process involved the simultaneous operation of all 56 jacks, controlled from the main control cabin on the ground. The operation of the jacks was carried out to a tightly prescribed routine that had been developed from the simulation in the analysis model. The position of each of the 28 major nodes was monitored at regular intervals using pre-programmed survey instruments and compared with the theoretical positions from the analysis model. In addition, each jack gave a continuous load readout which was also recorded and compared to the model results throughout the operation. This combined force/ geometric surveying allowed any small deviations from the intended lifting procedure to be corrected quickly.

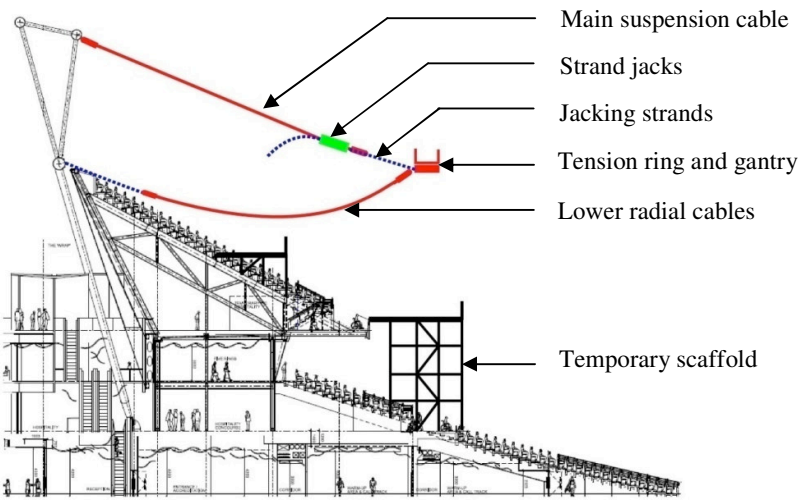

Figure 8 - Diagram showing intermediate jacking stage

The lift operation was conducted in several stages that had been analysed in detail previously:

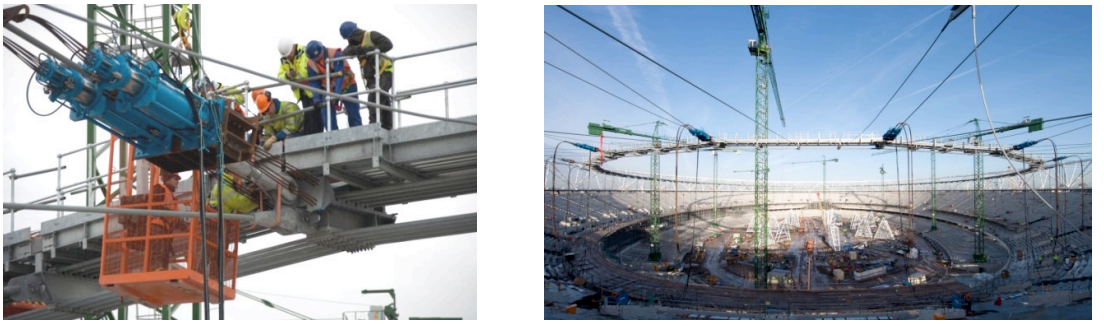
1. Lift jacks from platforms individually and operate until they are suspended
2. Operate jacks until full tension ring lifts off
3. Operate jacks until tension ring reaches intermediate height (Figure 8).
4. Connect lower cables to compression truss
5. Complete jacking to full height, pre-stress cable net and insert pins in upper cables

Figure 9 - Initial lift off of tension ring

It was critical that the tension ring lifted off vertically from the scaffold platform as there was only a small allowance for horizontal movement on the surface of the scaffold (Figure 9). This was further complicated by the fact that, due to the oval shape of the stadium, the natural shape of the tension ring is in the form of a saddle under its self weight and the forces in the suspension cables vary around the stadium. This resulted in the North and South ends of the tension ring raising 7.5m clear of the scaffold before the East and West sides lifted off (Figure 10).

Figure 10 – Saddle shape of tension ring at the point of lift off

It took one day to lift the entire tension ring clear of the scaffold platform with a further day to raise the cable net 10m to the level of the bottom chord of the compression truss. This position was selected as the shortest distance between the tension ring and the bottom chord of the compression truss to reduce the lower cable connection loads. In this position, all the lower cables could be connected using either manually operated tirfors (pulling wires) or small manually operated hydraulic jacks. Once all the cables had been connected, the final lift and pre-stressing operations took a further day. The whole operation from the start of the lift to insertion of the last pin (Figure 11) was completed in less than 4 weeks and met both the positional and force tolerances that had been set on the cable net structure.



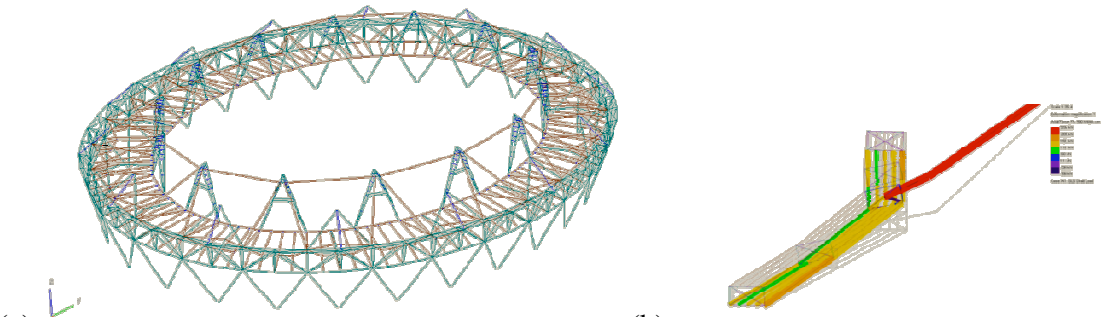


Figure 11 - Insertion of pins following final pre-stressing (Photographer: Adam Wilson)

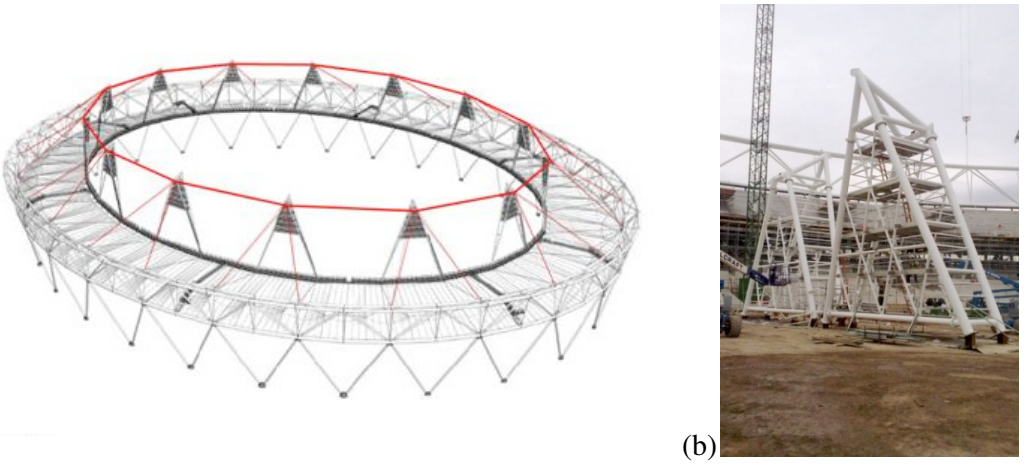
ERECTION ANALYSIS

The roof erection analysis was carried out by the steelwork fabricator and was independently checked by the consultant engineers. The roof erection process involves a vertical range of movement in excess of 20m, during which time the cable net is highly flexible. For this reason, GSA, dynamic relaxation, analysis software was used for the analysis due to its ability to solve highly non linear problems.

Some additional software was written to solve the particular geometric requirements at each of the jacking stages. This calculated the distribution of cable forces to allow a perfectly vertical lift off of each tension ring node without affecting the plan position of the remaining nodes. It also minimised the forces required to connect the lower radial cables allowing connections to be made using hand operated equipment rather than high capacity jacks. These results were then inputted back into the main analysis model for confirmation.



(a) (b)

Figure 12 – (a) Full roof analysis model (b) Localised twist on tension ring cables at lift off

Localised effects on the gantries and cables, as the tension ring lifted off, were analysed (Figure 12) and the results used to detail the connections to allow for adequate movement in all directions.

LIGHTING TOWERS

The 14 lighting towers sit on the tension ring major nodes and are supported by a secondary cable net. The secondary cable net functions in a similar manner to the primary net, with an upper tension ring, made up of 2 cables, spanning between the tops of the towers pulling the towers towards the centre of the field of play and radial backstay cables that are pre-stressed back to the compression truss (Figure 13).

(a) (b)

Figure 13 – (a) Lighting tower cable net (b) Construction of lighting towers at ground level

The stability system of this form of cable net is such that none of the 14 towers are stable until the final cable has been connected and pre-stressed. Several options were explored for the temporary stability of the towers and the final scheme saw them erected with a 40m long temporary strut connecting each tower back to the compression truss (Figure 14).

The tops of the lighting towers were constructed at ground level (Figure 13) and were fully fitted out with lights and electrical connections prior to lifting up onto the roof.

Each lighting tower weighed less than 35t but, due to the length of the reach over the tension ring, the main lift was completed using a 600t crawler crane fitted with a 30m luffing jib and 90t of superlift ballast (Figure 14). An innovative solution was developed to lift in the 6t temporary strut, to avoid the use of a second crane in a congested work area. This involved using two independent hooks from the same crane, an operation rarely done on this scale. The main hook supported the lighting tower itself, whilst a second hook, from the luffing jib, carried the temporary strut and could be operated, independently, to lower the strut into position.

Figure 14 - Lighting tower supported from main hook with temporary strut hung from luffing jib

For the erection of the lighting towers a staged analysis was performed for the addition of each tower. In each analysis stage the towers were checked for the 1 in 5 year wind load to ensure that the permanent design loads would not be exceeded in the temporary condition. This analysis included each stage of the lift on the crawler crane under an operational wind speed of 20m/s.

As for the main cable net lift, the erection of the lighting towers had been extensively analysed and was conducted with positional monitors on the tension ring and all lighting towers and force monitoring equipment on several members relaying data to be compared with the analysis results.

Figure 15 – Lighting towers supported on temporary struts prior to installation of lighting tower support cables

Following installation of all 14 towers on their temporary supports, the secondary cables were lifted into position and pre-stressed using small hollow ram hydraulic jacks. Before the temporary struts could be removed, it had to be verified that the cables had been pre-stressed to the required load and that the stability of the lighting towers had been transferred to the cable net system. A survey of the cable forces showed that in some locations the forces deviated significantly from the required values.

The analysis model was updated to reflect the surveyed geometry of the compression truss and lighting towers and it became apparent that small out of tolerances of the top chord of the compression truss resulted in large out of tolerances in the lighting tower cable forces due to the geometry of the backstay cables. To rectify the problem, the original cable net form finding process was repeated with the new model to provide new lighting tower cable lengths. These lengths were then used to provide adjustments for the adjustable turnbuckles, located on every backstay cable. Following the adjustments, the cable forces were re-surveyed and, to the relief of the engineers, had been corrected to the theoretical values.
The final erected geometry of the roof and lighting towers was verified by the main contractor using a full 3D laser scan of the entire stadium structure. The cable net pre-stress forces were also independently checked by a team from Porto University in Portugal using cable vibration measurements to calculate the natural frequencies and forces in the cables.

CONCLUSION

The detailed analysis results that had been prepared prior to the lift operations ensured quick checking of how the structure was behaving and gave the design and construction team added confidence in what was a technically challenging procedure. The lighting towers, perched on the roof edge in an apparent permanent state of instability, are testament to the challenges tackled by the construction team in realising a cutting edge design.

The successful completion of this complex engineering structure relied on the close coordination between consultants and contractors for every stage of the works to ensure that the project would be constructed safely as it was well outside the envelope of standard construction works.

ABSTRACT-

BC Place Stadium in Vancouver, BC opened in 1983 as the first domed stadium in Canada covered by the largest air-supported roof in the world. As part of a major revitalization project the stadium dome is being replaced with a new retractable roof structure. The new roof, designed and engineered by an international team, is under construction with completion scheduled in late 2011. The new roof, designed for the 1 in 100 year snow and wind loads and current seismic requirements, is supported by the original stadium superstructure. The new roof structure is a post-tensioned radial cable truss, clad with tensile membrane with a center retracting pneumatic membrane.

The paper presents features of the new roof and addresses some of the unique challenges encountered in this unprecedented project. While the challenges overcome in the roof construction, now nearing completion, are worthy and manifold, this paper is limited to roof design due to required brevity. The roof construction will hopefully merit future publication.

INTRODUCTION-

BC Place Stadium is located in downtown Vancouver along the North Shore of False Creek. The original construction was undertaken on a relatively open site in what was then an industrial enclave at the fringe of the Vancouver urban center. The stadium development was a catalyst in the transformation of the False Creek eastern basin to a vibrant mixed use urban area. Indeed this success provided the first of many significant challenges to the revitalization of the stadium as construction access to the site had become highly constrained. What had been a relatively open site in the early 1980's is now a high trafficked urban site. Moreover, the greatest asset of the facility is its location and the surrounding land. These conditions were key in the decision to revitalize the existing stadium rather than to pursue a new build to respond to the increased demands and expectations for multi-purpose stadium facilities. Not coincidently, with consideration of a general refurbishment of the facility was consideration of the future of the stadium's air-supported roof; which had reached the end of its originally anticipated service life. Moreover in replacing the

roof the Owner hoped to transform the image of the venue. Consequently, the roof replacement became a major driver of the facility revitalization.

An initial feasibility study of roof replacement identified the key challenges. Site constraints and the facility's configuration all but necessitated supporting a new roof on the existing stadium superstructure. Evolution of the Building Code of British Columbia, based upon the National Building Code of Canada, was such that any new passive roof structure is subject to much greater snow loads and seismic demands. Moreover, the primary virtue of the active air-supported roof structure is its extremely minimal mass and its nearly 'invisible' dynamic demand on the supporting structure, it was likely that any passive structure with the capacity to carry the very significant design roof snow load of 2.2 kPa would create undue demands on the existing stadium superstructure. Site constraints also limited access for construction and erection. The primary objectives in design were to meet the Owner's desire to create a dramatic change in the building architecture and to minimize lost use of the venue.

The roof structure developed by the roof design team, Geiger Engineers with Schlaich Bergermann and Partner, Tensys and RWDI, responded to these and other significant challenges.

BC PLACE NEW ROOF STRUCTURE-

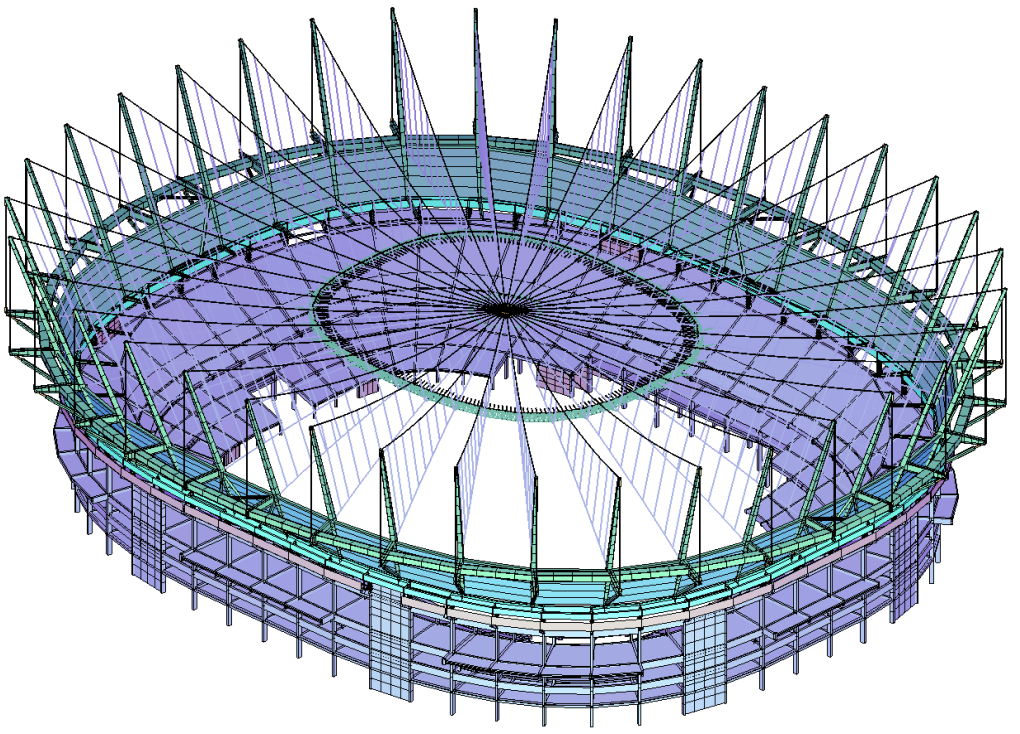

Figure 1. Stadium Superstructure with Primary Roof Structure, Membrane and All Cladding Removed

The new roof, developed to meet these criteria, is a tensioned membrane clad radial cable truss structure with a retractable center. The roof membrane is supported at the bottom radial cable chords.

The primary structural system is comprised of 36 structural steel masts supporting the radial cable truss, post-tensioned within a steel compression ring. The system is illustrated in Figures 1 & 2. The primary structure is exposed and featured architecturally realizing the desire of the Owner to transform the image of the stadium in its revitalization.

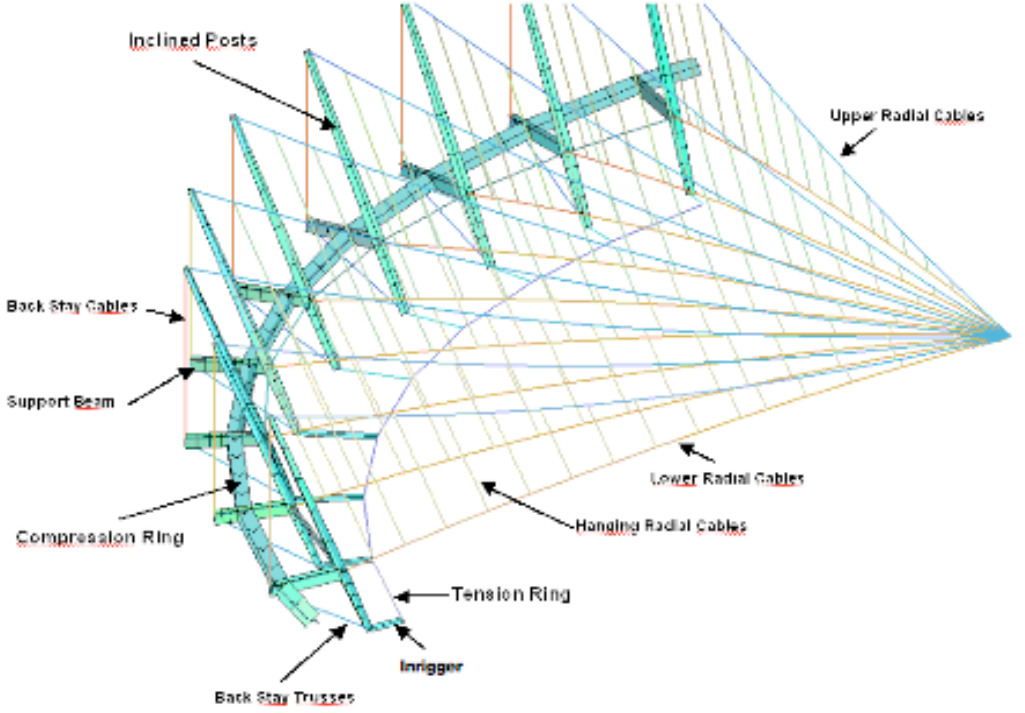

Figure 2. One Quarter of Primary Roof Structure, All Cladding Removed

To minimize the demand on the supporting structure the new roof structure is a 'closed system' (as was the original air-supported roof), equilibrating horizontal forces of the cable truss internally and only relying on the existing stadium superstructure for vertical support and to resist applied lateral loads. The tangential horizontal moment on a mast assembly resulting from the upper radial cables is resisted by the vertical separation of the tension and compression rings. The former is at the base of the roof and the latter nominally 12.5 m above this elevation. As the stadium plan and the original ring geometry was developed as a super-ellipse to equilibrate the air-supported roof's skew-symmetric cable layout the 36 sided polygons of the new rings would not follow this form, but rather were form-found with the cable truss prestress to provide a funicular equilibration of the cable forces. This resulted in the distinct architecture of the system with the exterior compression ring and interior tension ring nested in plan. The configuration concentrates structural material at the perimeter where it is easiest to erect and allowing the roof span to be solely cables. See Figure 3.

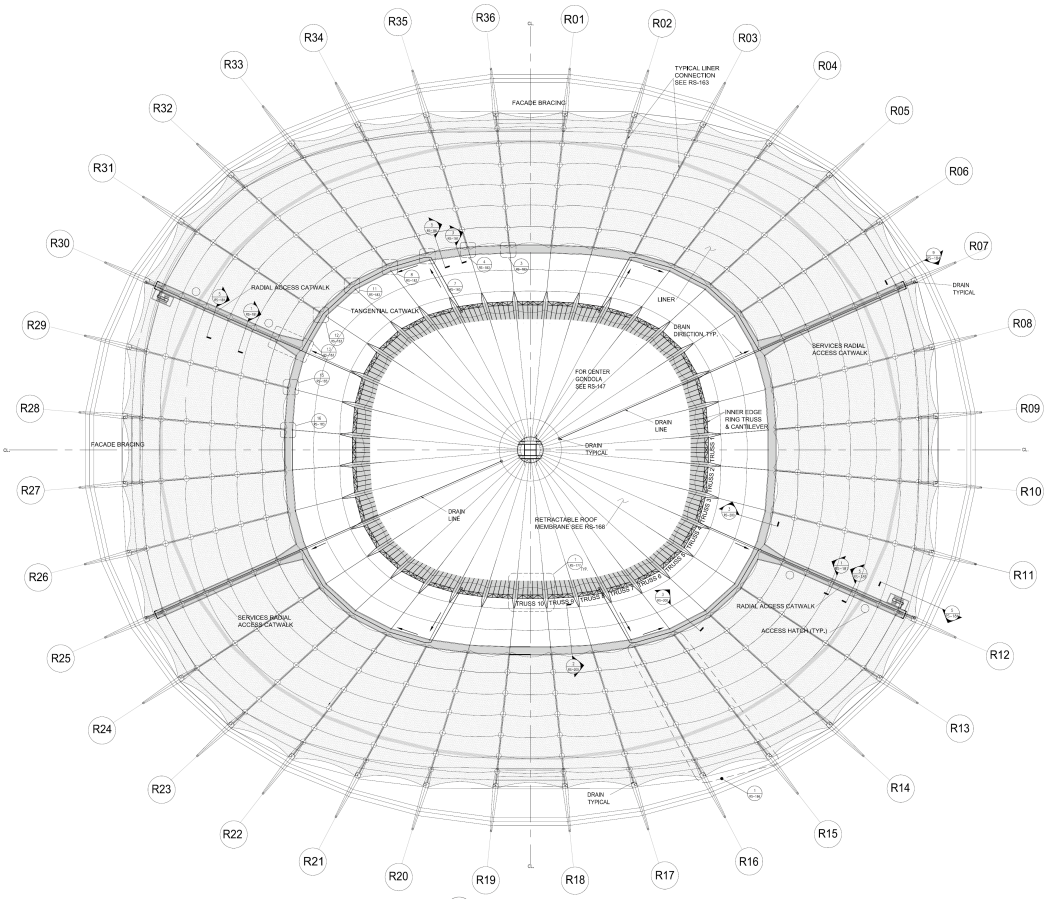

Figure 3. Stadium Reflected Ceiling Plan

The roof cladding consists of three systems, chosen for their low mass, functionality, serviceability, and suitability: 1) A retractable membrane roof over the field comprised of fluorocarbon composite fabric. 2) The fixed roof canopy, covering the balance of the roof, comprised of ptfe coated fiberglass roof membrane supported by steel arched ribs that span between radial bottom chord cables and 3) The clerestory façade comprised of ETFE film membrane panels and louvers.

RETRACTABLE ROOF-

The retractable roof, covering nominally 7,500 m^2, is comprised of pneumatically inflated cushions, which span between radial bottom chord cables. The interior space between the top and bottom membranes of the cushions is pressurized by compressors in the roof's center house. Internal operating pressure of the cushions is 500 Pa and is increased to a maximum of 2,000 Pa when the design snow load is present. (For reference, the operating pressure of the original air-supported roof was 270 Pa with a maximum of 700Pa.)

The retractable roof is a prefabricated membrane assembly supported by trolleys that ride on the radial bottom chord cables. When retracted, the membrane cushions are deflated and collected to the center node where they are stowed in a 20 m diameter receptacle for protection from weather. The roof is intended to be closed (fabric deployed) through the winter season and retracted during appropriate weather in the summer season. The deployed roof laps over a 'shelf' at the perimeter of the fixed canopy roof and seals to it by means of a pneumatic cushion.

FIXED ROOF CANOPY-

The fixed roof canopy is a ptfe-coated fiberglass fabric membrane supported on tied steel arch ribs. The ribs span between the radial bottom cable chords of the primary roof structure. The roof membrane is the same generic material as the existing air-roof. An acoustic liner is provided covering nominally 50% of the roof area.

At the inside edge of the fixed roof canopy is a glazed ring, cantilevered from the inner ring girder truss providing a "shelf" for retractable roof overlap. The glazed shelf is pitched to drain to a continuous gutter around the edge girder truss, which is drained via radial pipes to the roof perimeter. A personnel access walkway is provided on top of the ring to service retractable roof winches, seals, gutters and drains.

The outer roof perimeter is supported by built-up steel hollow members with trapezoidal cross-section spanning between masts. The top of the edge beams is a perimeter walkway. A continuous steel perimeter gutter is attached to the inside of edge beam below the fabric panel clamp-line.

ROOF SUPPORT AND MAST BEARING SYSTEM-

The primary structure is supported upon a new cast-in-place concrete transfer girder built within the original air-supported roof's precast compression ring. Additional steel columns were added parallel to the upper deck's outer column line to support the transfer structure and the new roof loads. See Figure 4. This work was completed in the Phase 1 of the project in 2009, while the facility remained in use. As the existing ringbeam was used as the air-supported roof's snow melt air distribution plenum, alternative snow melt air ducting was required for the winter of 2009-2010 during which time the facility was the host venue for the 2010 Olympic Winter Games Opening and Closing Ceremonies.

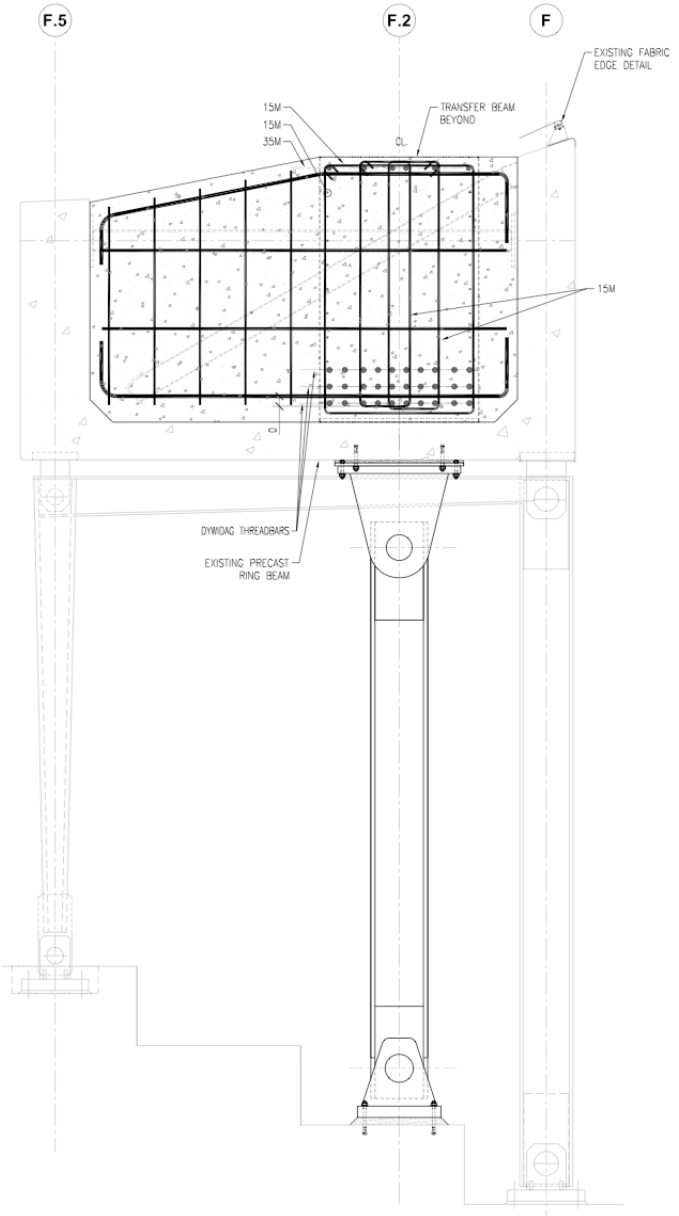

Figure 4. Section thru Existing Ring Beam and Transfer @ Support, Phase 1

The roof system is supported on 36 radially-guided slide & rotation bearings and laterally supported in the tangent direction at four braced bays at the cardinal points in plan. This uncoupling of the roof from the supporting structure allows for the relatively large deformations of the rings necessary to resist various load conditions without transfer of lateral loads to the existing supporting superstructure. However these large deformations, as much as 450mm, created challenges in supporting the mast bearings throughout their range of motion and in detailing the secondary façade clerestory structure. See Figure 5.

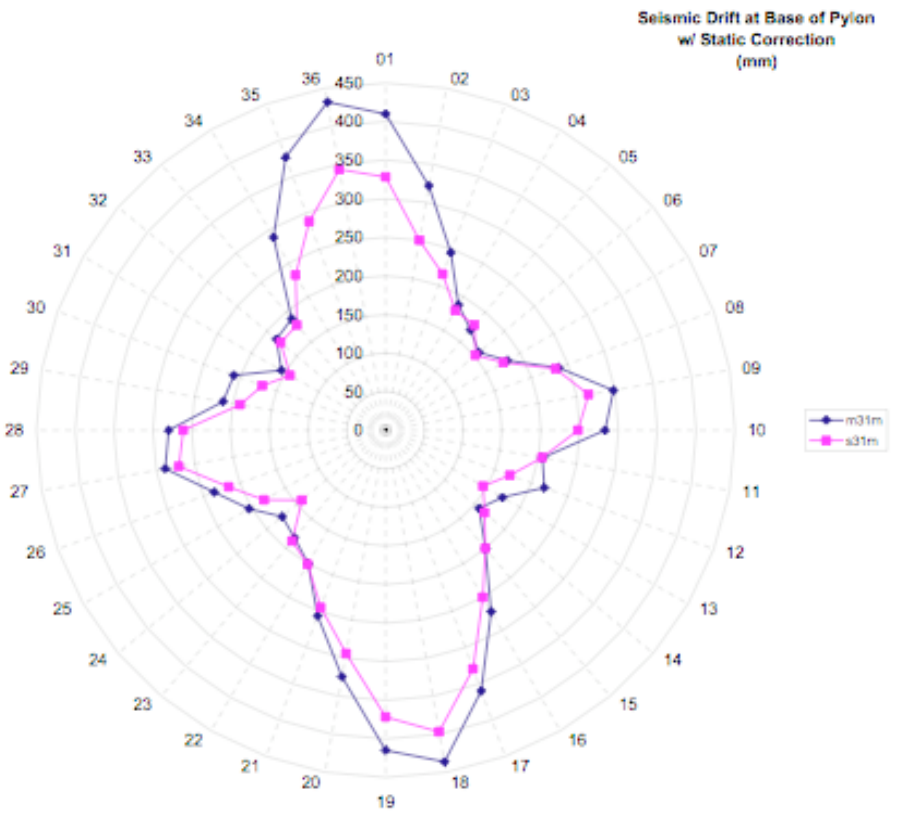

Figure 5. Radar Chart Unsigned Maxima of Seismic Drift at Mast Base Supports.

FAÇADE CLERESTORY-

The façade clerestory is composed of five horizontal panels; the panel immediately above the original precast ringbeam is a series of operable louvers for ventilation. See Figure 6. The primary elements of the façade are structural steel HSS girts spanning nominally 20 m between masts and panelized single skin ETFE foil membrane with vertical aluminum ribs. The connection of the girts to the masts must accommodate tangential expansion/contraction from zero at head to the maximum at foot of the façade. This was achieved by pinning one end of each girt and allowing a cuff at the other to slide on a horizontal 80 or 120mm spigot. This allows the foot of the façade to "float" with the masts.

Additionally, the geometry of the roof system is such that the masts are not oriented radially. Therefore the behavior of the girts is not symmetric about the mast and is unique in each location. The drainage system from the main roof, which is mounted on the masts, must also accommodate this same range of movement. A flexible membrane connects the vertical edge members of the façade to the masts thereby sealing the entire system.

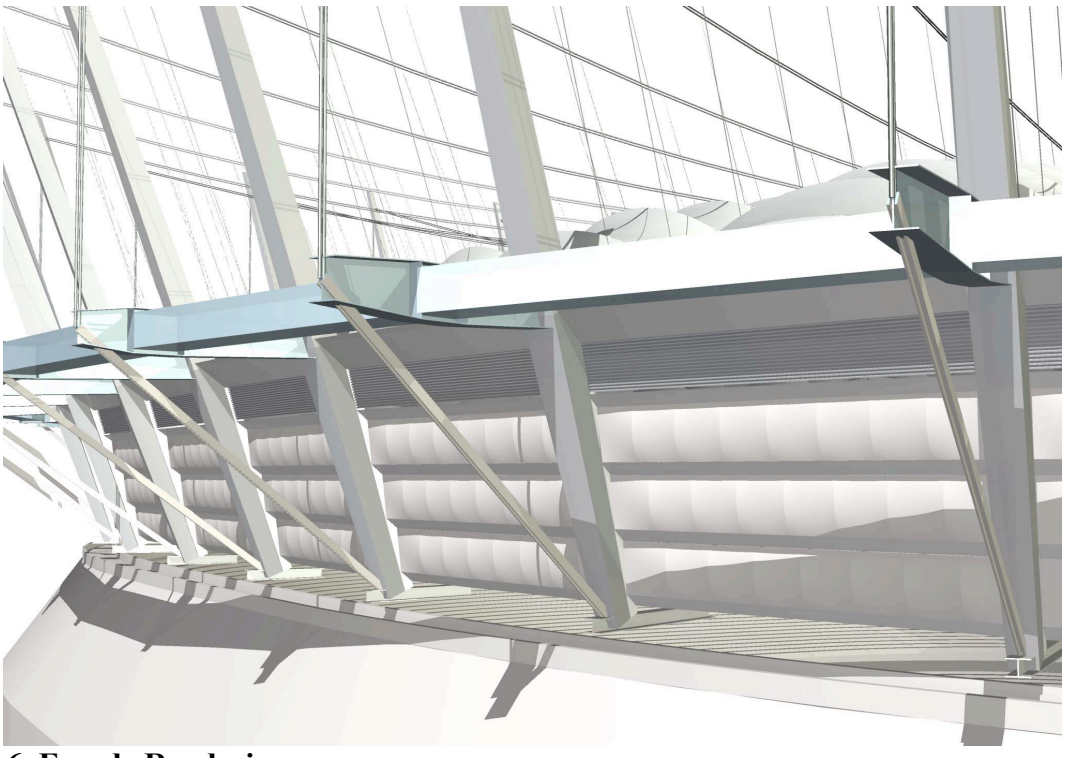

Figure 6. Façade Rendering.

LATERAL FORCE RESISTING SYSTEM-

The existing stadium superstructure is comprised of eight nominally independent reinforced concrete structures with lateral force resisting systems comprised of shear walls in the circumferential direction and moment fames in the radial direction. The new roof, as well as the original roof, is a single integrated structure supported on these eight structures. The dynamic characteristics of the roof system are intentionally quite different from that of the supporting stadium superstructure. A response spectrum analysis was performed modeling the existing stadium superstructure with the new roof. In final design, seismic demand governed some of the roof members, the roof's eccentrically braced frames, the travel of the mast bearings, and necessitated stiffening of the storey between the top of the reinforced concrete structure and the transfer girder at the original ring beam level.

The original roof's ring was supported on intentionally flexible moment frames therefore radial lateral stiffening frames were added to control drift (Hamilton, 1987). See Figure 7. The RSA indicated that the new roof and transfer structure contributed to approximately 10% of the overall base shear of the stadium. Evaluation of the existing stadium by Genivar, the structural engineer for the base structure, indicated the necessity of reinforcing the upper stadium columns supporting the roof as well as a general upgrade to the stadium's seismic force resisting systems, mostly as a consequence of the changes in code from the time of original construction. These innovative structural upgrades were designed by Genivar and, while of interest, are beyond the purview of the limited scope of this paper.

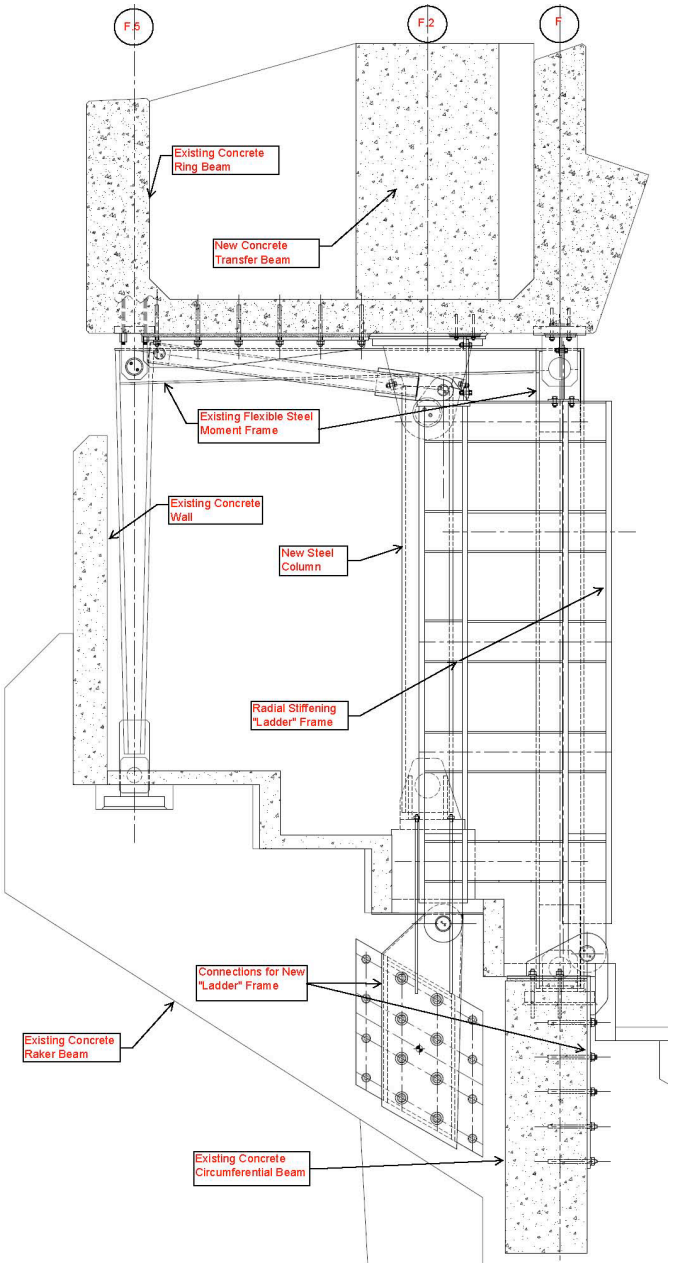

Figure 7. Section thru Existing Ring Beam and Transfer @ Support with Ladder Frames

The transfer of lateral load from the four braced bays to the existing shear walls presented some challenges as the roof's braced bays do not coincide with the shear wall locations. In plan, the two systems are more than two bays (28.6m) apart and the vertical distance from the new bearings, on top of the ringbeam, to the shear wall is 3.5m. During Phase 1, a built-up steel section was cast into the new concrete transfer beam and rigidly connected at the existing column lines. In order to allow movement of the mast and simultaneously transfer lateral load, a pivot strut was connected from the base of the mast at the braced bay to the Phase 1 embed. Below

the ringbeam, another beam was welded to the underside of the embed and bolted to the shear wall system. This series of beams, which in addition to the elevation change has two changes in plan orientation, resists the lateral load from half of the roof.

CONCLUSION-

The renovated BC Place Stadium is nearing completion. Roof construction, more challenging than it's design, is scheduled for completion in the Fall of 2011. The revitalized stadium presents a new image inside and out for sports and for exhibitions with its new retractable roof. The facility was closed for renovations for nominally 16 months.

ABSTRACT

When the Florida Marlins began planning for a new baseball-only facility, the presence of a retractable roof was essential. The team owner had a vision for a modern structure different than many of the recently-constructed retro-ballparks. That vision included a retractable roof that was foreseen as more than an umbrella for field and fans. Armed with this direction, the design team embarked on devising a roof structure that could survive major hurricanes economically, while still satisfying the architectural and operational demands of the ballpark.

The new ballpark, currently under construction and moving towards an opening day in April 2012, is situated near downtown Miami, Florida. On the one hand, the design team was challenged to support an architecture that did not overwhelm the surrounding residential neighborhood. On the other hand, traditional approaches to resisting hurricane-force winds forecast the need for either a potentially obtrusive or more costly structure.

To resolve this dilemma, the roof team implemented an innovative storm preparation strategy to survive major tropical events. Leveraging the experience gained from previous collaboration on several retractable roofs, the team approached their design holistically, with each consultant balancing the efficiency and cost associated with their scope against the roof as a whole. The engineers also collaborated heavily with the project wind consultant to determine cost-effective operating parameters. Because of its unconventional functionality, the resulting three-panel roof, with spans up to 560 feet, exemplifies a new generation of retractable roof design. This session will present the challenges encountered, and solutions provided, by the structural team in charge of designing this new type of roof.

OWNER REQUIREMENTS

Early in the project the design team was made aware of certain key parameters that ultimately would influence the roof design significantly. First, the look of the ballpark ought to be a notable departure from the focus on nostalgic features of other recently-completed ballparks. This directive harmonized with the owner's interest in work from 20th artisans specializing in surrealism and abstract art, as well as Miami's own vibrant art deco culture. In response to this interest, the design team expressed the entire stadium with bold, sculpted shapes.

Second, there was a strong interest in having a roof with increased functionality versus other baseball venues. Many Major League Baseball stadiums are designed to function only in two positions: open and closed. As such, their only purpose is that of shelter from precipitation.

However for the Marlins Ballpark, the team added a new function: variable shade positioning. This new capability would place the new stadium squarely in a new generation of sport venue – one that could adjust fan and player comfort in real-time. This implied more frequent use than roofs on other baseball stadiums.

Finally, in response to the design team's recommendation, ownership explicitly included in the project the provision that the stadium would not be used as a hurricane shelter. Unlike most design parameters that typically constrain a design team, this allowed the team to incorporate an innovative feature, discussed later in this paper, into the stadium's function that saved roof steel tonnage and construction cost.

SITE CONSTRAINTS

External Site Constraints

The Marlins Ballpark is located in the Little Havana district of Miami, on a site that was home to the now-demolished Orange Bowl. The urban setting, coupled with the requirement for a retractable roof, required a relatively compact stadium. Seating will be limited to approximately 37,000 patrons – one of the smallest venues in Major League Baseball. Parking garages flank the stadium on the north and south sides, leaving the west side of the site available for storing the roof. Furthermore, the plan area facilitated a tri-panel, telescoping retractable roof, which is a design used successfully at other baseball stadiums. Fewer panels would have required more real estate or perhaps dictated less roof movement, both of which were undesirable options.

Additionally, the surrounding buildings in Little Havana are mostly one or two-story residential and commercial structures. Throughout the design process, the team remained sensitive to the possibility that the ballpark could "overpower" its surroundings. To guard against this possibility, the roof's profile needed to be kept to a feasible minimum.

Finally, the design team selected an orientation for the track supporting the retractable roof based on the fact that downtown Miami is located east of the stadium and the moveable glass wall in the outfield would expose a view of downtown. To provide unobstructed views of Miami through the outfield wall, the track is oriented in the East-West direction, which requires the roof to span in the North-South direction.

Internal Operations

The usage of the ballpark within the stadium influenced the design of the retractable roof as well. The primary need is the ability to span across the playing field. Typical baseball fields inscribe a square area roughly 350 feet on a side. Add to this dimension the necessary plan distance for seating and concourses, and the minimum span for a roof usually will surpass 500 feet.

Another parameter establishing the geometry of the roof is the height required to clear batted balls. There seem to be few, if any, objective criteria for establishing the minimum

volume required to play baseball without obstructions from above. Major League Baseball publishes detailed ground rules for how to call certain plays when the ball strikes an overhead structure, but does not publish criteria on how to build the structure to avoid batted balls in the first place. Nevertheless, the design team was conscious of the nuisance of obstructed flight paths for both players and fans alike, and worked to minimize the probability that this could occur.

There has been some research in determining optimum parameters for baseball flight. (Sawicki, et al, 2003). Using parameters from this research, typical ambient conditions in Miami during baseball season, and the general flight equations including drag effects, a volume was constructed representing the maximum reasonable boundary of expected baseball flight at Marlins Ballpark. The resulting volume could be used to evaluate the impact of various panel shapes and elevations on a comparative basis, and help the designers understand specifically where trouble spots might occur.

ENVIRONMENTAL CONDITIONS

The stadium happens to be situated where one environmental condition, wind, dominates the structural design over many others. South Florida is subject to some of the highest design wind speeds in the United States, while other environmental conditions such as seismic or snow load are inconsequential. Interestingly, this afforded the design team the chance to focus on minimizing the effect of wind load, without being constrained significantly by other environmental conditions that might otherwise blunt the effectiveness of wind mitigation solutions.

As prescribed by the Florida Building Code, the design wind speed (3-second gust) for Miami - Dade County is 146 mph. Of the five other Major League Baseball stadiums that have retractable roofs, Minute Maid Park (Houston, TX) is subjected to the next-highest design wind speed of 110 mph. Since wind pressure is related to the square of velocity, a comparable roof in Miami would have experienced wind pressures 76% higher than Houston.

MECHANIZATION INTEGRATION

A variety of mechanization systems have been employed, with varying amounts of success, for North American sports venues with retractable roofs. The ability of the roof to function as specified depends in large part on the integration of the roof mechanization system with the roof structure, and the ability of the entire design team to understand how the roof behaves as a whole.

For this project, the mechanization consultant selected a traction drive system, due to considerations of cost, loading, operating frequency, and other variables. The system consists of a series of independently-driven transporters, utilizing steel wheels riding on a heavy-duty steel rail. The roof structure bears on the transporters, which in turn provide a load path for all roof reactions down to the concrete track beam.

Although cost-effective, the mechanization imposed certain demands on the roof structure above. First, quite unlike a typical building structure, where the foundation simply can be sized for whatever loads the superstructure imposes on it, here the "foundation" system worked only for a certain range of roof loads. In fact, three different configurations are evaluated: Operating (associated with a maximum wind speed of 40 mph), Parked (maximum wind speed of 95 mph), and Secured (50-year wind speed of 146 mph). Any significant deviation from preliminary estimates of wheel reactions would require a change to an entirely different, much more costly, mechanization system. The cost of the foundation for the roof structure can be represented by a step-function: an incremental increase in roof loading is accompanied potentially by a dramatic increase in mechanization cost.

Secondly, the relative stiffness in the vertical direction of the roof, mechanization, and supporting concrete track structure all contribute to the reactions on the wheels as the panels move along the track. Unlike certain systems used in the design of other ballparks, the mechanization system for the Marlins Ballpark would not have any kind of spring system. Thus, it would not be able to accommodate either appreciable deflections of the track structure (even deflections meeting code requirements) or excessive vertical stiffness of the roof.

Finally, due to its nature as a moveable structure, the retractable roof is subject to certain dynamic loads. For the rare case of a panel that may have lost the ability to brake using the transporters, bumpers are installed at the end of each rail. Therefore, each panel needs to be able to withstand the loading associated with a rapid deceleration parallel to the rail. This deceleration typically is a small fraction of the acceleration of gravity.

Another unusual load case occurs if a panel hits an obstruction on one of its rails, but the transporters on the other rail continue traveling. The time required to notify the transporters on the still-moving end of the panel is such that one end of the panel could move beyond the other end. In essence, this arrangement "racks" the panel beyond its design geometry.

STRUCTURAL SOLUTIONS

Roof Basics

The roof is comprised of three structurally independent roof panels: two "low" panels that can nest beneath an "upper" panel when the roof is in the open position. The panels travel in an east-west direction, supported by post-tensioned concrete track beams on concrete supercolumns. In the closed position, the roof is sealed between panels and also at the interface of the panels and the fixed roof. Each panel consists of planar trusses spanning over 500 feet from south track to north track, with three trusses per lower panel, and six trusses in the upper panel. Trusses are linked together, perpendicular to their span, with sway bracing in the vertical plane. In the bottom plane of the panels, bracing links the trusses together to resist horizontal loads. Each panel behaves essentially as a large beam, with a pin support at one end, and a roller support at the opposite end. The trusses are parallel to the first base line, resulting in a 6 3/7 degree plan skew relative to a line perpendicular to the concrete track beams.

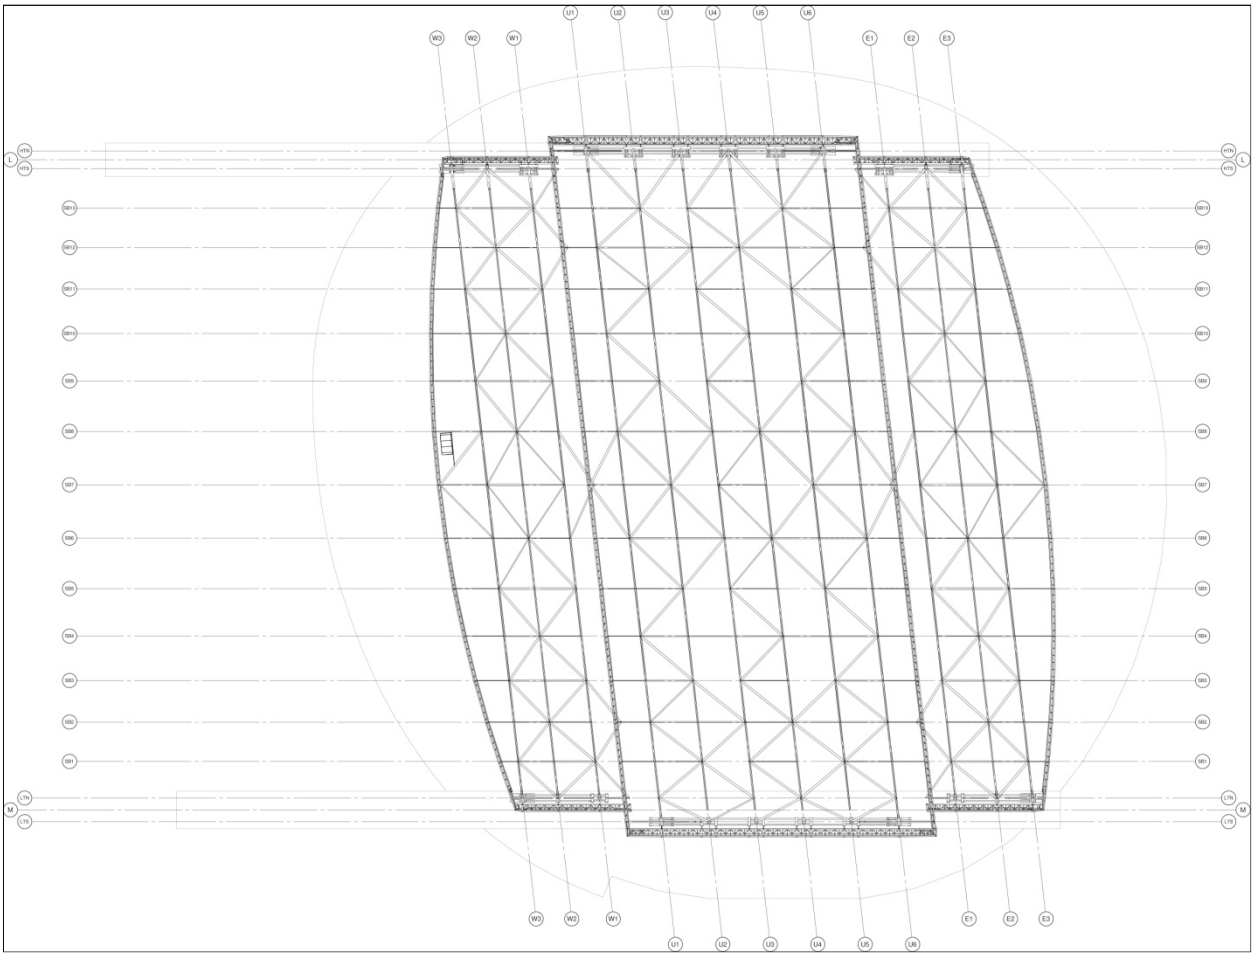

Figure 1. Plan view at bottom plane of roof panels

Walter P Moore collaborated with Populous to establish the overall shape of the roof, aiming for a sculpted, sleek look. The structure was set as high as possible to miss batted balls, but low enough on the outside to not overpower little Havana. Further, the structure had to be deep enough to span effectively and stay within preliminary tonnage estimates: the low panels are 42.5 feet deep at midspan, and the upper panel is 45 feet deep at midspan.

Once the bottom of the structure was set, and the truss height determined at midspan, there were a few options available to the design team to control the look of the roof. First, the panels were tapered towards their ends to minimize height. Second, sloping cantilevers were provided on the east and west sides of the panels beyond the last trusses to prevent the look of a boxed shape. Finally, the roller support was placed at the lower, south track, again to minimize height.

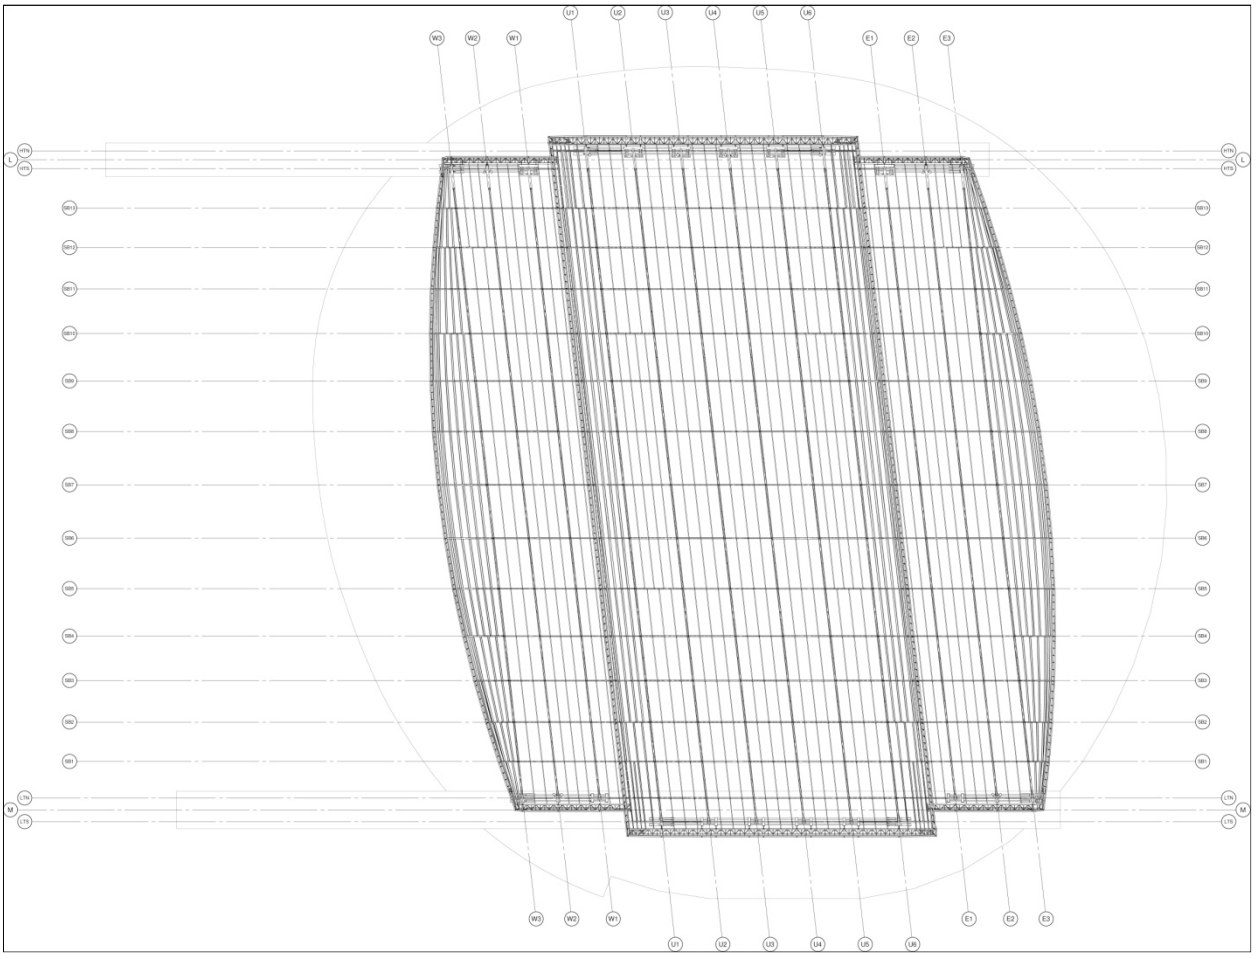

Figure 2. Plan view at top plane of roof panels

What does what

The planar trusses are a modified Pratt type, comprised of W14 web horizontal sections (ASTM A913, Grade 65) for the chords, and W12 (ASTM A992 or ASTM A572, Grade 50) web horizontal web members. The top chords are braced out of plane at panel points by W30 (ASTM A992 or ASTM A572, Grade 50) members that support purlins. The bottom chords are braced out of plane at panel points by square HSS (ASTM A500, Grade B, Fy = 46ksi) and pipe (API 5L X52, Fy = 52ksi) members. The chords are braced in-plane at panel points by the W12 web members. Within certain panels, the chords also are braced at panel half-points by sub-vertical and sub-diagonal W12 members (ASTM A992 or ASTM A572, Grade 50). The trusses are the primary load path for all vertical loads and lateral loads in the north-south direction.

To resist lateral loads in the east-west direction, a horizontal truss is formed in the bottom plane of each roof panel. Square HSS and pipe members constitute the tension and compression diagonals of the horizontal truss, and the aforementioned W14 members comprise the tension and compression chords. This arrangement is efficient from a tonnage standpoint because any compression created in the chords of the horizontal truss due to lateral loads is counteracted by

the tension in these same members resulting from resisting vertical loads. For downforce load combinations, there is compounding tension within certain members (tension due to vertical loads and lateral loads), but there is no compounding compression, as there would be if the lateral system was in the top plane of the roof panel. There is also a benefit of simplifying fabrication and erection by placing the horizontal braces in the bottom plane of the roof panel. Were these placed in the top plane of the roof panel, they would subdivide the purlins, necessitating many more purlin pieces, associated connections, and crane time.

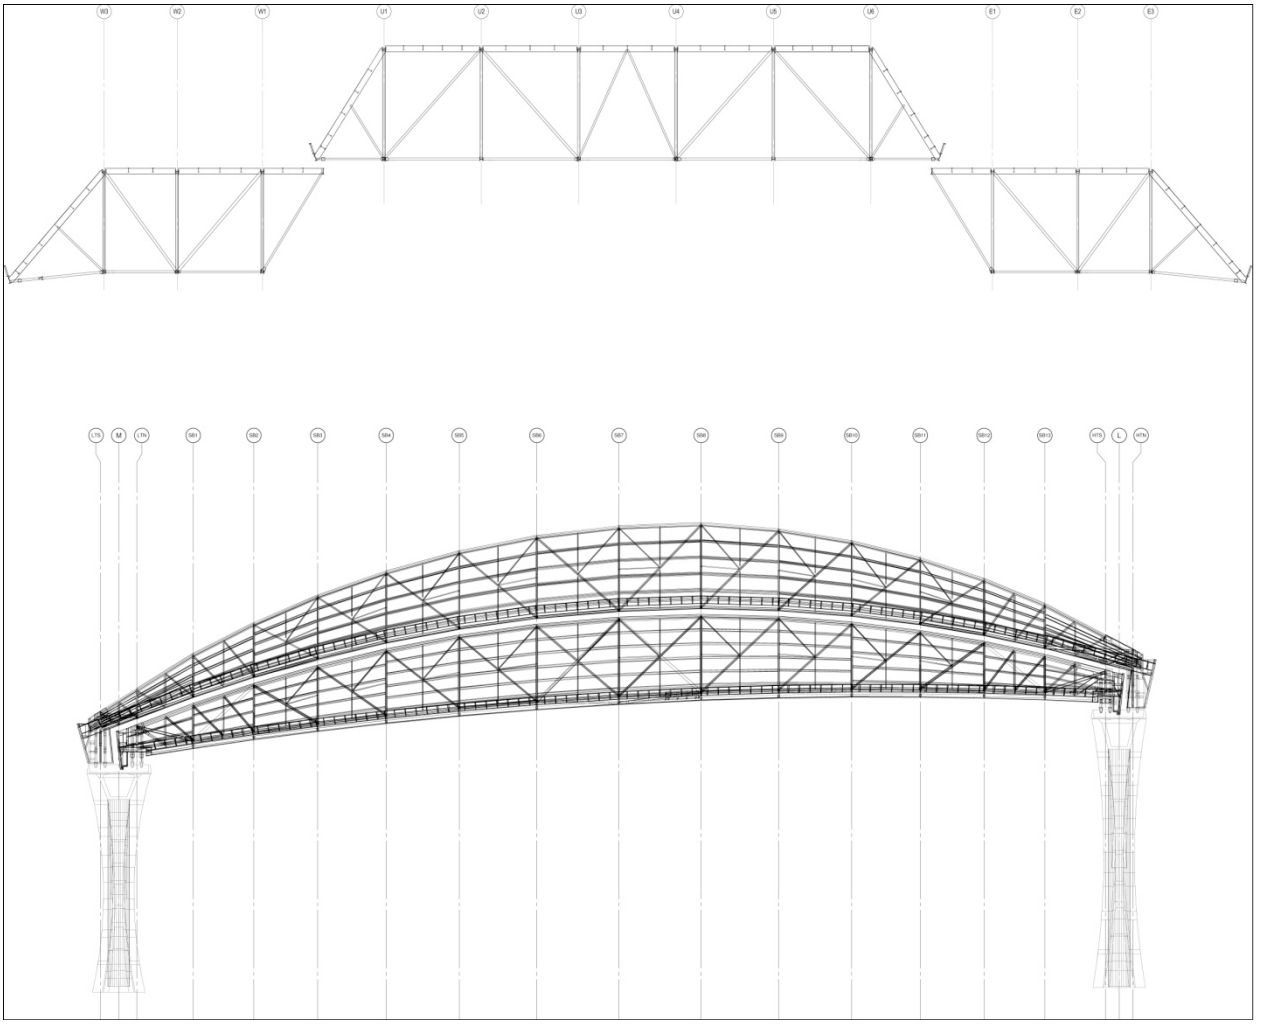

Figure 3. Section perpendicular and section parallel to roof span

Maximum cladding uplift pressures of approximately 150 psf (for 10 square feet of tributary area) are resisted by 3" steel deck (18 or 20 gage, depending on location) supported by steel beam purlins (ASTM A992 or ASTM A572, Grade 50). Purlins span to, and brace, the aforementioned W30 members. End support and sidelap fastening, although necessary only to resist uplift pressures, resulted in a certain diaphragm capacity as well. The diaphragm contributed to the resistance of lateral loads such as wind and deceleration forces. Consequently, each panel behaves like a tube for lateral loads and torque parallel to the main span. It was not prudent to ignore the deck's diaphragm stiffness, as the design team could not assume sufficient

ductility existed at the deck to steel connection to instantiate the desired behavior of uplift resistance only. Therefore, deck support and sidelap fastening has been designed not only for uplift pressures, but also for diaphragm shear.

Getting Load Down to the Track

Although the panels are shaped like arches, they cannot be allowed to act as such. From a mechanization standpoint, arch behavior is deeply undesirable, because the associated thrust loads require a more complex, more costly support system. To resist the lateral component of thrust, it is almost certain that another rail and set of wheels would be required. This in turn would necessitate a wider, probably more heavily reinforced, track structure. Also, the track structure, which is supported by concrete columns cantilevering over 100 feet above the ground, would have to resist a much larger lateral load. This would require larger, more heavily reinforced columns, and larger foundations.

Furthermore, from the perspective of the retractable roof, an arch is an indeterminate system. As such, it provides a load path that is more sensitive to relative stiffnesses of the roof structure, mechanization, and track structure. It is critical to the reliable function of the roof that the loads on the transporters are known with a reasonably high degree of confidence, and an indeterminate roof structure adds undesirable uncertainty to this estimate.

For these reasons, arching action would not be used. But how does one create a roller, and make each roof panel act as a beam? One solution to this problem is a four-bar linkage (refer to Figure 4). Imagine a rectangle (the four sides representing the four "bars") located in a vertical plane that is perpendicular to the direction of the rail. The rectangle has two long vertical sides, and two short horizontal sides. The vertical sides are structural steel W14 columns, the bottom horizontal side is represented by the transporter, and the top horizontal side is represented by the connection collecting the top and bottom truss chords at a single work point. The connections at each of the four corners are released for moment, which is accomplished by using spherical hinges.

Placed beneath one end of a roof truss, such an arrangement permits the truss end to move perpendicular to the rail, thus relieving any arch action. This release comes at the cost of horizontal reactions developing in the four-bar linkage as the linkage becomes a parallelogram to accommodate lateral movements. To minimize these horizontal thrust reactions (i.e., prevent the acute angle of the parallelogram from becoming too small), the mechanization requires 10 units of height to the rectangle for every unit of lateral displacement. Therefore, the lateral movements must be known to a high degree of accuracy before setting the final roof geometry. The resulting height required for the four-bar linkage was approximately 16 feet for the low panels, and 20 feet for the upper panel.

The layout of the bowl permitted the elevation of the south track (near right field, where there could be relatively fewer seats than near the bases) to be 30 feet lower than the north track (which is parallel to the third base line). The design team elected to place four-bar linkages at the south end of the roof, at the low track. This way, even though extra height was required at

the south end, the roof profile at the low track need not be any higher than the profile at the high track (i.e., the north end of the panel).

Figure 4. Four-bar linkage during low panel construction

As a standalone structure, the linkage is not stable. Therefore, the top horizontal bar of the linkage is attached rigidly to the truss support above the south track, and serves two purposes. First, because the connection of the panel to the north track still retains stiffness in the north-south direction, the truss becomes a tension tie for the transmission of the stabilizing shear reaction from the south track to the north track. Second, because the bar is attached rigidly to the truss, a stabilizing moment can develop to keep the transporters vertical. Thus the stability of the panel as a whole is assured, even while providing a release of the arching tendency of the panel.

Letting in the Wind

Preliminary studies performed by the wind tunnel consultant on an enclosed structure indicated maximum uplift pressures of approximately 90 psf, and maximum downforce pressures of approximately 60 psf, including the effects of internal pressure. But the design team had to consider the effects of a seal breaking between panels, and the structure undergoing an enclosure classification change from “Enclosed” to “Partially Enclosed”. In effect, the result of a seal breaking would be to change the GC_{pi} value in ASCE 7 from +/-0.18 to +/-0.55. Given that the q_z was approximately 82 psf, this meant that were the seal to break, internal pressures could

increase from about +/-15 psf to +/-45 psf. The design team had to account for this contingency in the design if the roof was to remain in a closed position during the maximum wind event, but this came with an associated cost premium to the project.

However, because the stadium would not be used as a hurricane shelter, there was no need to keep the stadium weatherproof during this extreme wind event. Therefore, the team studied the effect of maintaining a gap between panels and between panels and the fixed roof – the wind tunnel consultant explicitly incorporated the gapped position into its testing regime. The results of the wind tunnel study were encouraging: in some locations on the roof, wind pressures were reduced by as much as 70% simply by providing this gap. Regardless of wind direction, internal pressures stayed very low when the roof was configured in the gapped position. Net wind pressures typically were less than initial estimates. Use of the gapped position reduced the total roof weight by approximately 5%-10%. Also, mechanization costs were saved by reducing the need for as many transporter tiedowns to resist uplift and lateral loads.

The gapped position also acted as an insurance policy against the unexpected, but still possible, occurrence of a breach in the east wall. Were this wall to break, and were the roof in a conventional closed position, significant internal pressures (estimated to be at least 45psf, but potentially as high as 80psf) would develop, causing major uplift on the roof. Rather than face the decision of designing for this possibility (and incurring cost premiums as a result), the team could rely on the fact that even if the east wall is breached, the internal pressures change very little on account of the gapped roof.

Maintaining Stability

The roof panels were designed using the Direct Analysis Method described in AISC Specification Appendix 7. The fundamental requirements for this method are:

1. A second-order analysis that accounts for P-δ and P-Δ effects
2. Notional loads to account for geometric imperfections, or the inclusion of the geometric imperfections directly
3. Reduced stiffness of all members contributing to the stability of the structure

All three requirements were met in the design of the roof panels. In summary, the process for implementing this method was to determine notional loads that could be applied to a model with the completed, theoretical geometry and unreduced stiffness such that the resulting forces within the members closely matched the forces resulting from an analysis of a structure with initial deformations and reduced stiffness.

Appendix 7 of AISC 360-05 does not prescribe specifically how to account for the effects of geometric imperfections and inelasticity on the lateral framing system for a long-span roof structure. Building and maintaining many analysis models would be required to directly incorporate these geometric imperfections into the design. Given the infeasibility of this approach, an externally-applied set of notional loads that indirectly imposes these effects on the lateral framing system was derived and applied to a single analysis model. The notional loads

were combined appropriately with gravity and lateral loads for the design of the system. Notional loads were applied on the flat portions of the Upper and East roof panels in the North, South, East, and West directions. The effect of the notional loads on the member forces was compared to the effect of the deformed starting geometry and reduced stiffness, and then adjusted appropriately.

Several types of starting geometries were considered to represent imperfections in the roof structure: buckled shapes in the North, South, East, and West directions; purely translational parabolic shapes in the East and West directions; and purely translational shapes in the North and South directions. The imperfect starting geometries were determined from an eigenvalue buckling analysis, and then scaled to 2" of initial imperfection in the North and South directions, and 4" in the East and West directions. The purely translational parabolic shapes were determined from a parabola equation at coordinates that fall on truss panel points, and linearly interpolated for coordinates between these points. For the purely translational North and South shapes, the entire roof structure supported by the four-bar moment frames was simply shifted to the North or South by 2", and the coordinates on the four-bar linkage members were interpolated linearly down to a shift of zero at the wheels.

A reduced flexural stiffness of 0.8*EI and a reduced axial stiffness of 0.8*EA were applied to all members that contributed to the lateral stability of the panels. The magnitude of reduced stiffness was in general accordance with Appendix 7 of AISC 360-05. Conservatively, the stiffness of the deck was not considered.

The resulting notional loads generated by this study were combined as appropriate in gravity-only and gravity-plus-lateral load combinations. In general, the effect of implementing the Direct Analysis Method was to increase the demand by a few percent on members contributing to the lateral stability of the structure. The increased demand was larger for members comprising the moment frame directly above the north track. This is to be expected for at least a couple of reasons: the arch shape of each panel is asymmetric: the slope at the south track is greater than at the north. Thus, the panels naturally will tend to move in that direction under self-weight alone, even if there are no geometric imperfections. Also, these moment frames are the only restraint for any load in the north-south direction.

Achieving the Right Wheel Reactions

Sets of either two or four W14 columns, centered below each of the trusses, carry vertical loads down to the transporters. The transporters transmit compression to the wheels, which then bear directly on the rail. The transporters transmit tension to a combination of rail clamps and uplift clips, both of which hold the rail. For lateral load in the north-south direction, at the north end only, these same columns are linked together with beams to create a moment frame. Lateral loads also are carried down through the transporters, and are transmitted to the track structure through either the wheels bearing on the rails, or tie-downs connecting the transporters to the track beam.

All lateral loading is delivered at the truss work points, which are in excess of 20 feet above the wheel / rail interface. In the east-west direction, a robust load path obviously is

required to get this shear (typically several hundred kips) down to the rails. Structurally, the most efficient way to do this is to have a simple braced frame, perhaps using the aforementioned columns as boundary elements.

But a braced frame presents a problem for the retractable roof panels: it is too efficient. More specifically, a braced frame provides so much vertical stiffness relative to its strength that it severely overloads the wheels beneath its boundary elements. The result is an inefficient use of the mechanization: not enough wheels contribute to resisting lateral load. The vertical stiffness presents a second problem. As the panel moves along the rail, the individual wheels encounter "hard" and "soft" points along the track, depending on whether they are above a track column or track center span, respectively. Wheels on top of hard points tend to accumulate roof load, and wheels on top of soft points tend to shed roof load. The two main contributors to this phenomenon are the roof framing directly over the rail, and the track framing supporting the rail.

Given the size and span of the concrete track beams, it was not feasible to increase their stiffness sufficiently to use braced frames in the roof structure directly over the rail. Instead, the problem had to be solved within the roof framing. What followed was an iterative process with the following objectives: tune the stiffness to mitigate the load-sharing phenomenon and engage all the transporter wheels to resist the overturning moment, while still providing a sufficiently strong load path for the several hundred kips of shear that needed to migrate down to the rail.

The solution chosen was a set of moment frames in the east-west direction to transmit shear down to the track beam. The columns are linked together typically with heavy W18 sections. In this way, a fraction of the total shear is carried down through each subassemblage, until it is resolved as a small tension / compression couple with the two transporter wheels. At the last subassemblage, the beam to column connections are pinned, otherwise the wheels in these transporters would be overloaded.

Holistic Analysis

For the roof to function over the long term, the effects of track and roof stiffness, plus creep on the track beam, need to be understood. Creep will impact the long-term shape of the track beam, and therefore will also influence the wheel reactions. To better understand these effects, an integrated analysis model of all three roof panels plus the track and bowl structure was created.

The ratio of creep strain to initial strain was calculated, in accordance with ACI 209, to be approximately 0.93. This is the factor to apply to the sustained dead load to simulate creep-only deflections. The post-tensioning in the track structure was designed to counteract the self weight of the track. Therefore, only the dead load of the roof is effective in contributing to creep effects on the track. To simulate creep effects in the analysis model, line loads (hereinafter referred to as the "creep load") equal to the creep factor multiplied by the distributed wheel reactions due to roof weight plus superimposed dead load on the roof were applied to the rail.

Unless the dead load is constant and sustained for the same amount of time over the entire length of the rail, then the track will not experience uniform creep over its entire length.

Consequently, it would not be reasonable to apply a single case of creep load over the entire length of the rail. Moreover, it is possible that certain wheel reactions could be governed by creep occurring over only a limited length of rail. For these reasons, the following different cases of creep load were analyzed. In each case, creep load is applied on the rail only at the position specified:

- Open position
- Closed position
- Hurricane position
- 100% of creep load applied at the Open and Closed positions, and 75% percent of creep load applied along the rail between these positions
- No creep anywhere along the rail

After an initial review of the effects of creep on wheel reactions, the design team concluded that rail camber would be required to offset the adverse impact that creep would have on the wheels. The general procedure for determining the amount of camber consisted in tuning an upward-directed load that approximately balanced the deflection due to creep. The final cambered shape approximately equaled the inverse of the instantaneous deflected shape due to roof panel dead load.

Such variables result in a large number of possible results per wheel. For each roof position, the total effect is comprised of:

Total Effect = Effect of Gravity and/or Wind + Effect of Camber + Effect of Creep

For each position, and each wheel, the maximum and minimum vertical and north-south reactions were gathered from the variable combinations indicated by the above equation. This process was repeated for each wind condition. This allowed for comparison of the entire range of wheel reactions to the acceptable limits provided by the mechanization consultant.

CONCLUSION

As of January 2011, the roof of the new Florida Marlins Ballpark is under construction, with its three panels at different stages of completion, from the assembly of the Upper Panel on shoring towers, to installing steel roof deck on the lower panels. The ballpark is on track to bring a new environment for enjoying baseball to the fans of south Florida beginning in April 2012. As part of that experience, players and fans alike will be exposed to the next generation of retractable roofs for stadiums.

Evaluation of wind-induced torsional loads on buildings by North American and European codes and standards

M. Elsharawy, T. Stathopoulos, and K. Galal

Faculty of Engineering and Computer Science, Concordia University, Montréal, Québec, Canada H3G 1M8

ABSTRACT

The common characteristics of wind-induced loads on building envelopes always vary in temporal and spatial dimensions. The variation of local wind pressures on building claddings and the total effective wind forces (base shear/overturning moment) on the main structural building systems have been investigated in the past few decades. However, very limited studies examined wind-induced torsional loads on the main resisting structural systems of buildings. This paper reviews these past studies and proceeds with a comparison of torsion provisions in three national wind loading standards, namely the American Society of Civil Engineers standard (ASCE/SEI 7-10), the National Building Code of Canada (NBCC 2010), and the European code (European 2004). Three low buildings located in an open terrain, in addition to three tall buildings located in suburban terrain were considered for this comparison. The low and tall building dimensions were selected to cover three different aspect ratios (length/width) varying from 1 to 3. The results demonstrated significant discrepancies among the provisions of these wind standards in evaluating torsional wind loads on buildings.

1. INTRODUCTION

Wind-induced torsional loads on buildings have been of concern to wind engineering researchers, structural engineers as well as code committees. An extensive literature survey demonstrates that the simplified methods introduced in the current wind load standards to evaluate wind load effects on buildings cover the effective base wind shear and overturning moment. However, more work is required to ensure that these provisions are adequate to assess wind-induced torsion, which is mainly generated as a result of non-uniform horizontal distribution of wind forces on the main wind force resisting system. Although wind-induced torsional loads on buildings may not be always the dominant load case for building design, overlooking the accurate representation of wind-induced torsional loads may lead to unrealistic spatial distribution for wind design loads. Such unrealistic loads may be conservative in certain design situations and detrimental in others. Clearly, a realistic evaluation of wind-induced design torsional loads has a significant effect on the serviceability and survivability of buildings.

This paper presents a review of the wind-induced torsional loads studies on low and tall buildings. In addition, it presents a comparison of the provisions of three well-known wind loading standards: the American Society of Civil Engineers standard (ASCE/SEI 7-10), the National Building Code of Canada (NBCC 2010), and the European code (European 2004). Three low buildings in open terrain exposure and three tall buildings in suburban terrain exposure are analyzed using the three standards. All analytical approaches provided

in these standards for the evaluation of wind loads on the buildings considered are applied and results are compared.

2. WIND-INDUCED TORSIONAL LOADS ON BUILDINGS

The majority of residential and commercial buildings worldwide are categorized as low-rise buildings. Moreover, low-rise buildings are prone to excessive damage in wind disaster events. Very limited studies examined wind-induced torsional loads on low-rise buildings as shown clearly in the comprehensive reviews by Holmes (1983), Stathopoulos (1984) and Krishna (1995). A major contribution in the development of provisions for the evaluation of wind loads on low-rise buildings was based on the research carried out at the University of Western Ontario (UWO) in the late 70's. An extensive experimental program in a boundary layer wind tunnel examined a variety of rectangular low buildings with different dimensions, roof slopes and upstream terrain exposures but wind-induced torsional loads were not examined in detail. However, wind-induced torsion has been examined in the wind tunnel for three low-rise buildings with different aspect ratios by Isyumov and Case (2000). The study recommended that applying partial wind loads similar to those implemented for the design of tall buildings will improve the design of low buildings. This study, which was the only one carried out to examine wind-induced torsional loads on low buildings, concluded that more information is essential to improve the evaluation of wind-induced torsional loads on low buildings.

Wind-induced torsional loads on tall buildings have received more attention compared to low buildings, since more complex interactions between the fluctuating wind forces and main wind force resisting systems may result in significant dynamic wind torsion for tall buildings. Moreover, any rotational motion of a building could be a reason for disturbance and for causing discomfort to building habitants. Wind tunnel studies are recognized as a reliable source of information for engineers to design such buildings. Ten multi-degree-of-freedom aeroelastic models have been tested in the wind tunnel by Greig (1980) to measure the mean and the dynamic torsional wind-induced moments. This is the first study that introduced an empirical formula for predicting the torsional wind moment on tall buildings, although this was an empirical formula based on a finite data set; indeed, to be used as a general estimator, this formula must be validated and improved through performing additional wind tunnel tests.

Isyumov and Poole (1983) tested buildings with square and rectangular cross-sections in the wind tunnel by using the weighted pneumatic averaging technique to measure the mean and dynamic torque components. This study was trying to overcome the limitation of the pressure instrumentation to measure simultaneously the wind pressure over the building surfaces. It was shown that the pressure fluctuation on the back face induced by vortex shedding has a significant contribution to the dynamic torsional moment in the studied buildings. Also, the study showed that the quasi-static assumptions can provide reasonable estimates of the dynamic torque. A comparison between measuring the base torque using a force balance method in wind tunnel and the integration of the pressures measured on the sides of the model has been published by Tallin (1985) where it was shown that although the force balance technique requires smaller computational effort, it over-estimates the torsional moment. Lythe et al. (1990) conducted a wind tunnel study, in which torsional wind loads for different building shapes (simple, complex symmetrical, and complex non-

symmetrical) were measured in detail. Instrumentation and computational limitations at the time restrained the study to only examine the mean torsional wind loads.

As a kind of simplicity and by using two dimensionless factors, the equivalent eccentricity, e, and the load reduction factor, r, the magnitudes of torsional wind loads were investigated in wind tunnel for several tall buildings with respect to horizontal loads, as reported by Xie et al. (2000). In general, it was illustrated that for most buildings the overall equivalent eccentricities are found to be more than 10% (20% for torsional sensitive buildings). Some real-life tall buildings have been tested through wind tunnel tests and results presented by Boggs et al. (2000). In general, the equivalent eccentricity for these buildings might reach up to 30% of the building width and the wind-induced torsion effects cannot be eliminated but can possibly be minimized by changing the building geometry or the structural properties of the tall buildings. The tests also showed the effects of the structural properties on the elimination the coupling between the torsional and sway vibrations.

Zhou et al. (2000) introduced a gust load factor (GLF) formulation to estimate the torsional wind response for tall buildings. This was based on data collected from High Frequency Force Balance (HFFB) wind tunnel tests. The study discussed the effect of a nonuniform mode shape on the HFFB results since the rigid model used allowed only for linear mode building shape. This GLF procedure can be used in the preliminary design stages prior to the detailed wind tunnel tests. This procedure requires also more validations, possibly through aeroelastic model testing in the wind tunnel, to become a generalized approach. More recently, the development of the solid state switching technology has allowed the use of the High Frequency Pressure Integration (HFPI) method to determine the overall wind loads on tall buildings. The effectiveness of using this method has been studied by Ho et al (1999) who compared the traditional HFFB with HFPI method. The results collected from testing two tall building models in the wind tunnel demonstrated that wind tunnel testing with HFPI method is capable of providing improved information on the overall wind-induced building forces and torsional moments.

3. WIND-INDUCED TORSION IN WIND CODES AND STANDARDS

The instantaneous variation of wind-induced forces on building envelope in both temporal and spatial dimensions may introduce significant instantaneous torsional moments about the vertical building axis. This wind-induced torsion should be accounted for during building design process. Generally, there are two main approaches in the wind loading standards for the evaluation of the actual effects of wind-induced torsional loads on buildings. The first approach is implemented by applying reduced uniform wind loads on building surfaces with additional equivalent eccentricity from the building dimensions (used in ASCE/SEI 7-10), while the other way is by applying non-uniform wind loads (used in NBCC 2010, and European 2004). The non-uniform wind loads can be simulated by either increasing the wind pressure on the building corners, by using partial wind load acting on one part of the building face, or by applying a triangular wind load on the building surfaces. Table 1 summarizes the different procedures proposed in the current issues of the wind loading codes and standards for estimating the torsional moments acting on buildings due to wind. These procedures lack the full details required for describing the torsional wind load cases. The following sections describe the different approaches used to calculate the wind-induced torsional loads in the American, the Canadian and the European wind code / standards:

Table 1: Analytical approaches provided in the current standards

ASCE/SEI 7-10	NBCC 2010	European 2004
• **Simplified(Envelope) method** (for low-rise buildings) Load cases: - Transverse direction - Longitudinal direction - Torsional case	• **Simplified (Static) method** (for low-rise buildings) Load cases: - Transverse direction - Longitudinal direction	• **Detailed method** (for all building heights) Load cases: - Transverse direction - Longitudinal direction - Torsional case (triangular load)
• **Detailed(Directional) method** (for all building heights) Four load cases using: - Reduction factor - Equivalent eccentricity	• **Detailed (Dynamic) method** (for all building heights) Four load cases using: - Partial Loads - Reduction Factors.	

3.1 American Society of Civil Engineers (ASCE/SEI 7-10)

Wind load provisions in ASCE/SEI 7-10 include two analytical methods to estimate wind forces on the main wind force resisting system (MWFRS): the simplified (envelope) method, which is applicable for low-rise (h<60 ft) buildings and the detailed (directional) method, which can be used for designing buildings of all heights. The simplified method has three main load cases, namely; transverse (perpendicular to ridge) load case, longitudinal (parallel to ridge) load case, and torsional load case. The description of the three load cases is given in ASCE/SEI 7-10 in chapter 28, Figure 28.4-1. In the third case, the torsional effects have been taken into account by applying only 25% of the full design wind pressure on half of the building faces. Exceptionally, one-storey buildings with h<30 ft and two-story buildings framed with light frame construction or designed with flexible diaphragms need not be designed for the torsional load cases. On the other hand, the detailed method has four load cases described in ASCE/SEI 7-10, chapter 27, Figure 27.4-8. In the first and third cases uniform wind loads are applied without any torsional loads. Torsional wind loads are specified in cases 2 and 4 by introducing two non-dimensional parameters, 15% equivalent eccentricity of the building dimension and 0.75 and 0.563 reduction factors respectively for the equivalent static wind pressure. Specific exemptions are provided in Appendix D of the Commentary of ASCE/SEI 7-10. Finally, it is also quoted in the Commentary that

> *"Although this is more in line with wind tunnel experience on square and rectangular buildings with aspect ratios up to about 2.5, it may not cover all cases, even for symmetric and common building shapes where larger torsions have been observed"* (C27.4.6)

3.2 National Building Code of Canada (NBCC 2010):

Among the national building codes and standards, the NBCC was the first to include in its provisions the effects of wind-induced torsional loads on buildings. In fact, there are two analytical methods stated in NBCC 2010 to predict wind-induced torsional moments on

buildings. The simplified (static) method is appropriate for low-rise buildings, while the detailed (dynamic) method is specified for all building heights. Two wind direction ranges are considered in the simplified method, i.e. the transverse (perpendicular to ridge) and the longitudinal (parallel to ridge). In this method, the external peak (gust) pressure coefficients (C_pC_g) provided for low rise buildings implicitly account for torsional loads. Based on the concept of partial loads acting on building envelope, the detailed procedure has four load cases. In Cases A and C symmetric uniform loads are considered, in order to estimate the maximum base shears and overturning moments. On the other hand, partial wind loads are recommended to create equivalent torsional building loads in Case B and Case D. Nevertheless, the choice of partial loads could be difficult for designer engineers as can be seen from the code statements quoted below:

> *"In case B, the full wind pressure should be applied only to parts of the wall faces so that the wind-induced torsion is maximized"* (note (2) to figure I-16); and
> *"… the influence of removing 50% of the case C loads from parts of the face areas that maximizes torsion, as shown in figure I-16, case D, should be investigated"* (Commentary I, 37).

3.3 European 2004: Actions on structures - General actions - Part 1-4: wind actions

The Eurocode defines one unified analytical method that can be used for predicting the wind forces on all building types regardless of height. Wind pressure and force coefficients are described in Eurocode part 4 section 7. Torsional effects are taken into account by applying non-uniform pressures and forces, as shown in European 2004, Figure 7.1. A triangular wind load is applied on the windward surface with a rectangular load on the leeward face of the building. Limited information regarding wind-induced torsional loads and only for rectangular buildings can be found in this code. In addition, European 2004 includes a rather difficult to apply statement regarding the torsional wind load case:

> *"For other cases an allowance for asymmetry of loading should be made by complete removing the design wind action from those parts of the structure where its action will produce a beneficial effect".* (Section 7.1.2 – note (b))

4. WIND-INDUCED TORSION COMPARISONS: CASE STUDIES

In this section, different building configurations were analyzed using the three codes/standards. Three low-rise buildings (gabled roof slope 4:12, width (B =16 m), and height (h = 6 m) with horizontal aspect ratios (L/B =1, 2, and 3) located in an open terrain; and three tall buildings (B = 30 m, h = 60 m) with horizontal aspect ratios (L/B =1, 2, and 3) located in suburban terrain have been analyzed for this comparison. Both simplified and detailed methods described in the ASCE/SEI 7-10 and NBCC 2010 has been applied for the three low-rise buildings, in addition to the detailed method available in European 2004. For tall buildings, the detailed method in the three codes/standards has been used to estimate wind loads. In the simplified method (ASCE/SEI 7-10), the external pressure coefficients (GC_{pf}) on building envelope are estimated for low-rise buildings using Figure 28.4-1. In the detailed method (ASCE/SEI 7-10), the roof and side wall external wind pressure (GC_{pf}) are estimated according to Figure 27.4-1. In the simplified method (NBCC 2010), external peak pressure coefficients (C_gC_p) are provided for low-rise buildings, in Figure I-7, Commentary I. The external pressure estimation by the detailed method (NBCC 2010) is taken from

Figure I-15, Commentary I. Likewise for European 2004, external pressure coefficients for vertical walls of rectangular plan buildings are calculated using Figure 7.5 and Table 7.1 available in section 7, while for the external pressure of duo pitch roofs, values are provided in the same section (Figure 7.8 and Table 7.4a). The assessment of torsional moment should be done with respect to the corresponding applied wind forces. For this reason, two load cases, maximum torsional moment with the corresponding shear force and maximum shear force with the corresponding torsional moment, were presented in this study. The wind velocity was adjusted by using Durst curve given in the ASCE/ESI 7-10 Commentary, Figure C26.5.1. This was to alleviate the effect of using the 3-sec reference wind speed in ASCE/SEI 7-10, as opposed to the mean hourly and 10-minute wind speed in NBCC 2010 and European 2004 respectively. The results are presented in terms of shear force and equivalent eccentricity. The shear coefficients and equivalent eccentricities in transverse direction were estimated as per Eq. 1 and 2 respectively.

$$C_V = \frac{\text{Base shear}}{0.5\ \rho\ V_h^2\ B\ h} \tag{1}$$

$$e\ \% = \frac{\text{Base torsional moment}}{L\ *\ \text{Base shear}} *\ 100 \tag{2}$$

It is also important to compare the magnitude of the torsional moment estimated for the three low buildings based on the application of the wind load patterns introduced (simplified and detailed methods) in the standards considered with the past wind tunnel results. The estimated torsional moment is normalized to get the torsional coefficient according to Eq. 3.

$$C_T = \frac{\text{Base torsional moment}}{0.5\ \rho\ V_h^2\ B\ L\ h} \tag{3}$$

Details of the calculation procedure are provided in Appendix I for one building configuration.

5. COMPARISON RESULTS AND DISCUSSION

Comparisons among ASCE/SEI 7-10, NBCC 2010 and European 2004 for three low-rise buildings are presented in Figure 1. The results are introduced in terms of shear coefficients and equivalent eccentricities for the load case representing the maximum torsional moment and the corresponding horizontal shear force. As clearly shown, significant differences are found among the three national codes/standards in evaluating the torsional moment, whereas smaller differences are found in evaluating shear forces. The results show that ASCE/SEI 7-10 estimates torsional loads three times higher than those of NBCC 2010 and more than twice the torsional loads calculated by the European 2004. This is attributed to the different methodologies adopted by different codes/standards in representing the actual wind distribution by an equivalent wind static load. In Figure 2, comparisons among the three codes/standards using the detailed analytical procedure for the same buildings are presented. Although significant differences of equivalent eccentricities have been found among the codes/standards, different values of shear coefficients compensate and produce more comparable torsional moments. For example, NBCC 2010 introduces the highest equivalent eccentricity value, which is equal to 25% of the building length but it also has

the smallest value for shear coefficient. Thus, it appears the detailed method fixes an appropriate equivalent eccentricity depending on the value of shear coefficient in order to produce comparable torsional moments for all cases. For instance, the detailed method (ASCE/SEI 7-10) estimated torsional coefficients for the three low buildings equal to 0.24, 0.48 and 0.73. Likewise, torsional coefficients for the same buildings evaluated by the detailed method (NBCC 2010) are 0.24, 0.45 and 0.70. Clearly, the magnitude of the torsional moments produced by the detailed method is almost the same in the two standards. However, the total wind loads required to be applied in the torsional load case by using the detailed method in the two standards and resulting from adding the shear forces and the forces resulted from the torsion are different given that ASCE/SEI 7-10 requires applying 75% of the full wind loads while NBCCE 2010 requires applying 50% of the total wind loads. This needs deeper assessment and investigation.

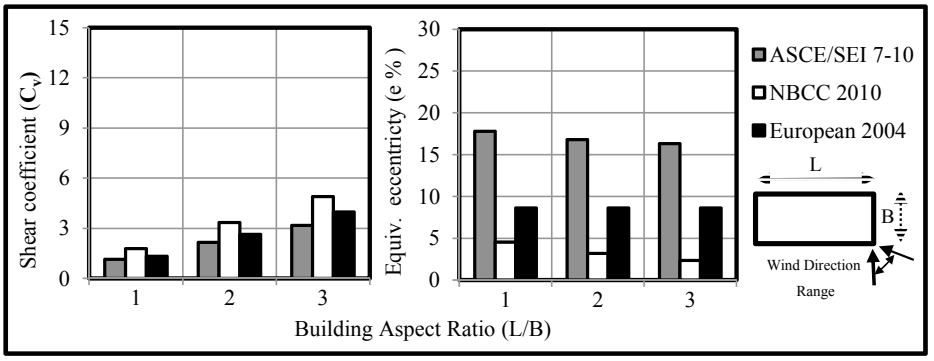

Figure 1. Simplified method - low buildings - partial wind load case (max. torsion and corresponding shear)

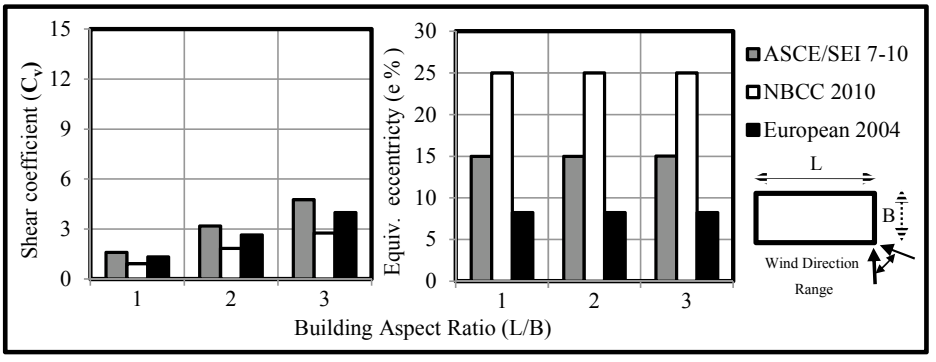

Figure 2. Detailed method - low buildings – partial wind load case (max. torsion and corresponding shear)

It is also of interest to compare the wind-induced torsion between the simplified method and the detailed method proposed in the same building code. Comparing the simplified method with the detailed method proposed by ASCE/SEI 7-10 for low-rise buildings shows a decrease of the equivalent eccentricity by about 18% and an increase of the shear coefficient by 40%. Therefore, using the simplified or detailed method of ASCE/SEI 7-10 for estimating wind design values for the main frame elements for low-rise buildings would result in similar loads. In NBCC 2010, the shear coefficient values estimated by the detailed method have smaller values compared to the simplified approach by 45%; on the other hand, the equivalent eccentricity in the detailed approach have more than four times higher

values compared to the simplified method. This is another point that requires further research to fill the gap between the detailed and the simplified method in NBCC.

As previous studies focused on estimating the effective horizontal wind loads for low rise buildings (i.e. maximum base shear) regardless of the horizontal distribution of the real wind loads (i.e. leading to maximum torsion), the current comparison shows that the three codes are successful in yielding similar values for maximum base shear loads, as can be seen in Figure 3. The values for the shear coefficients are estimated based on the full wind load cases in the simplified and the detailed method. Figure 4 presents peak torsional moment coefficients estimated by the simplified and the detailed method in the three codes/standards with the peak torsional coefficient measured in past wind tunnel tests. It can be seen that the detailed method proposed in ASCE/SEI 7-10 and NBCC 2010 succeeded to predict the wind-induced torsional moment on low buildings, particularly for small aspect ratios. However, significant difference has been found between the simplified method of ASCE/SEI 7-10 and NBCC 2010 when compared with the wind tunnel test results. The simplified method in both standards underestimates the torsional moment due to wind on low-rise buildings. However, the simplified method (ASCE/SEI 7-10) appears closer to the wind tunnel results. European 2004 underestimates the torsional moment due to wind on low-rise buildings by almost 50%.

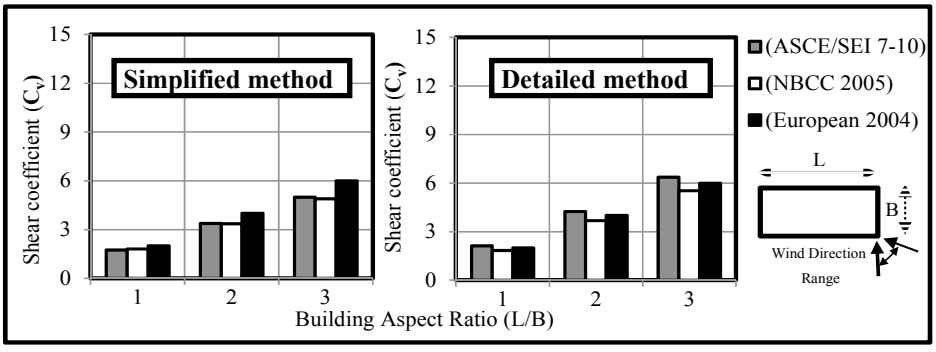

Figure 3. Simplified and detailed methods - low buildings – full wind load case (maximum shear force)

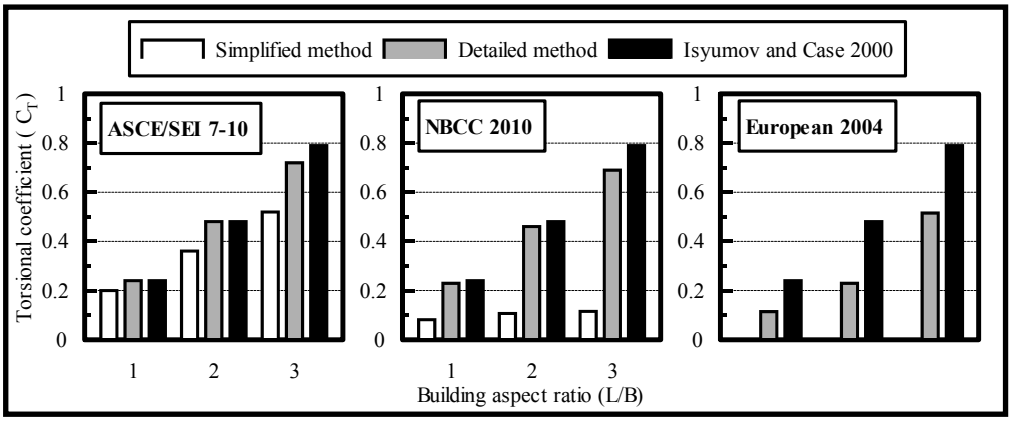

Figure 4. Peak torsional coefficients for three low buildings evaluated by the three codes/standards compared with wind tunnel results by Isyumov and Case 2000.

For tall buildings, only one analytical approach is proposed for calculating the wind loads on the main resisting frame in the three standards – see Table 1. Figure 5 presents the comparison among the provisions for the three tall buildings examined. Shear coefficients and the equivalent eccentricities are presented for the torsional load case (maximum torsion and corresponding shear force). It has been noticed that higher eccentricities are associated with lower shear coefficients. This is in line with what has been found in the low-rise building cases, (see Figure 2). For instance, the detailed method in ASCE/SEI 7-10 estimates torsional coefficients equal to 0.27, 0.54 and 0.85 for the three tall buildings considered. In a similar manner, torsional coefficients for the same buildings evaluated by the detailed method of NBCC 2010 are found equal to 0.30, 0.60 and 1.0. As previously mentioned, the magnitude of the torsional moments produced by the detailed method is almost the same in the two standards. However, the total wind loads due to shear, as well as those forces resulting from torsion, are different given that ASCE/SEI 7-10 requires applying 75% of the full wind loads while NBCC 2010 requires applying only 50% of the full wind loads. On the other hand, the European standard estimates torsional coefficients equal to 0.18, 0.39, and 0.60 for the three tall buildings. However, this is about 35% less than the other two standards; the European code requires wind loading for torsional case 40% higher than the other two codes/standards. These discrepancies need to be investigated to assess their effects on tall building design. Figure 6 illustrates the variation of the maximum base shear created by wind loads over the three tall buildings proposed by the three codes/standards, similar to Figure 3. ASCE/SEI 7-10 and NBCC 2010 show good agreement while the European 2004 provides almost 15% higher shear coefficient values.

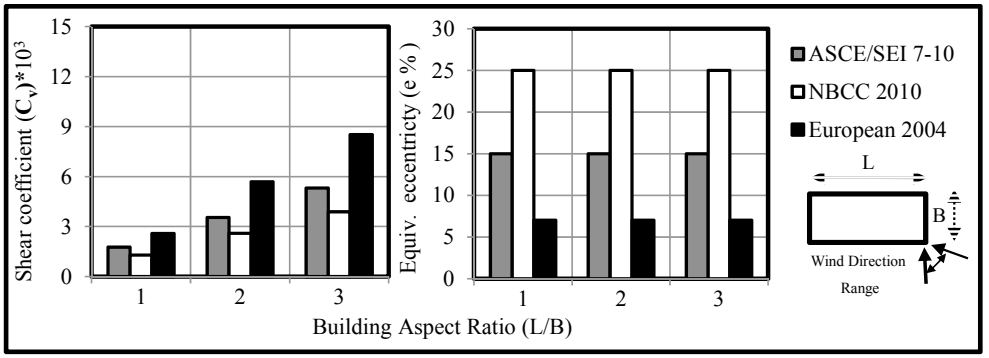

Figure 5. Detailed method – tall buildings – partial wind load case (max. torsion and corresponding shear)

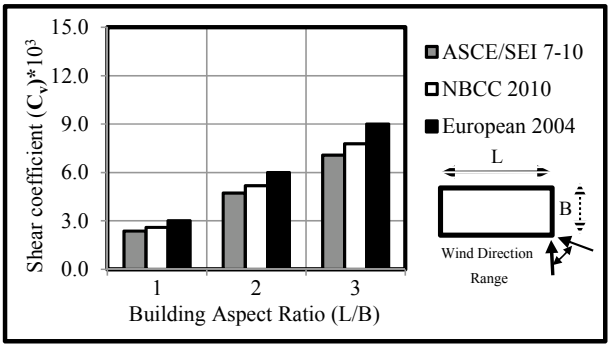

Figure 6. Detailed method – tall buildings – full wind load case (maximum shear force)

6. SUMMARY AND CONCLUSIONS

This paper reviews past studies on wind-induced torsional loads for low and tall buildings. In addition, it discusses and compares the provisions for wind-induced torsion in the Canadian, American and European wind codes/standards along with the previous wind tunnel studies. Both simplified and detailed methods provided in these codes/standards for the evaluation of wind-induced torsional loads on buildings have been used. The comparison results demonstrate the following:

a- For low buildings:
- The simplified method in ASCE/SEI 7-10 estimates torsional moments more than three times those of NBCC 2010 while twice those of the European 2004 provisions.
- Compared to the previous wind tunnel measurements, the simplified method for torsional moment in ASCE/SEI 7-10 works well for the square building; less so for buildings with higher aspect ratios. On the other hand, the simplified method in NBCC 2010 underestimates the measured torsional moment significantly.
- The detailed methods in both ASCE/SEI 7-10 and NBCC 2010 show good agreement with the torsional moment measured while the European code seems to underestimate these torsional moments for all building geometries.
- The detailed methods in both ASCE/SEI 7-10 and NBCC 2010 yield torsional moments of comparable magnitudes. However, the total wind loads due to shear forces, as well as those forces resulting from torsion are different.
- Good agreement is noticed for estimating wind-induced torsion by the simplified and the detailed method in ASCE/SEI 7-10 for low building aspect ratios; for higher aspect ratios the simplified method yields lower torsional moments.
- NBCC 2010 simplified and detailed method yields similar maximum base shear forces but very different maximum torsional loads.

b- For tall buildings:
- ASCE/SEI 7-10 estimates the maximum torsion by applying 0.75 of the maximum wind load with additional equivalent eccentricity 15% of building dimensions, while NBCC 2010 applies 0.5 of the maximum wind load with additional equivalent eccentricity of 25%. On the other hand, the European code applies 0.70 of the maximum wind load with an eccentricity of 7%. In general, these yield comparable torsional moments; however the total effective loads resulting from adding the shear force and additional force due to the torsional moment are different.
- Eurocode estimates maximum base shear somewhat higher than ASCE/SEI 7-10 and NBCC 2010.

More experimental data are required for a reliable assessment of wind-induced torsion on low-rise and tall buildings.

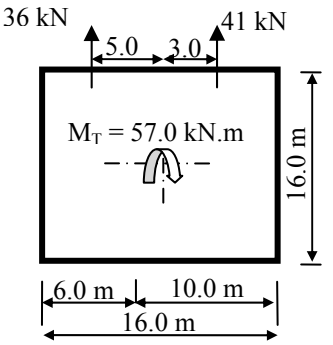
APPENDIX I

Building 1: Note that the magnitude of the wind velocity does not have an effect on the results since all the values are normalized with respect to it.

A) AMERICAN SOCIETY OF CIVIL ENGINEERS (ASCE/SEI 7-10):

3-second guest wind speed = 40.2 m/s
The velocity wind pressures are computed using:
$q_z = 0.613\ k_z\ k_{zt}\ k_d\ V^2\ I = 0.613\ (0.932)(1)(0.85)(40.2)^2 =$
$= 760\ N/m^2 = 0.76\ kN/m^2$
Design pressures for the MWFRS:
$P = q_z\ [(GC_{pf}) - (GC_{pi})]$
(GC_{pf} values are taken from the table in figure (28.4-1),
Transverse direction $\theta = 18.4^o$
Width of end zone surface: a = 3.2 m.



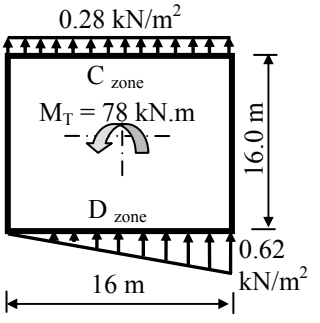
Torsional load case - transverse direction:

$$C_V = \frac{(48.65 * 10^3)}{0.5 * 1.25 * 26.645^2 * 16 * 6} = 1.14$$

$$e\% = \frac{1}{16} * \frac{138.2}{48.65} * 100 = 17.8\%$$

B) NATIONAL BUILDING CODE OF CANADA (NBCC 2010):

The equivalent hourly mean wind speed = 26.645 m/s
Calculation of wind velocity pressure q (kN/m^2):
$q = (V_{10})^2/39.2^2 = 0.462$ kN/m^2
Take the important factor =1
Calculate the exposure factor related to open terrain
$Ce = (Z/10)^{0.2} \geq 0.9$ $Ce = (7.333/10)^{0.2} = 0.94 \geq 0.9$, then Ce = 0.94
Calculation of end zones:
$y^{(6)} = 6.0$ m
Wind pressure over building surface:
$p = 1 * 0.462 * 0.94 * C_gC_p = 0.434 * C_gC_p$ (kN/m^2)
C_gC_p values obtained from figure I-7
(Commentary I, page I-13):
For $\theta = 18.4^o$



Torsional load case - transverse direction:

$$C_V = \frac{(77.0 * 10^3)}{0.5 * 1.25 * 26.645^2 * 16 * 6} = 1.8$$

$$e\% = \frac{1}{16} * \frac{57.0}{77.0} * 100 = 4.6\%$$

C) EUROPEAN 2004

The equivalent 10-minute reference wind speed = 28.2 m/s
Calculation of Wind velocity pressure:-
Fundamental basic wind speed
$V_{b,o}$= 28.20 m/s (terrain category II)
Basic wind speed $V_b = C_{dir}\, C_{season}\, V_{b,o}$ (m/s)
Mean wind $V_m(z) = 5.3542 \ln (z/0.05)$
Peak velocity pressure q (kN/m^2)
$q_b(z) = [1 + 7 * 1/\ln (z/0.05)] * 1/2 * 1.25 * V_m^2(z) = 1.0$ kN/m^2
Wind pressure on surface
$W_e = q_p(z_e) * C_p * 0.85 = 850 * C_p$ (N/m^2)
$C_{P\,(D\ zone)} = 0.72$ and $C_{P\,(C\ zone)} = 0.333$

Torsional load case- transverse direction:

$$C_V = \frac{(56.45 * 10^3)}{0.5 * 1.25 * 26.645^2 * 16 * 6} = 1.325$$

$$e\% = \frac{1}{16} * \frac{78.0}{56.45} * 100 = 8.64\%$$

Wind-induced torsional loads on low-rise buildings

M. Elsharawy, K. Galal and T. Stathopoulos

Faculty of Engineering and Computer Science, Concordia University, Montréal, Québec, Canada H3G 1M8

1. ABSTRACT

This paper presents a set of wind tunnel tests that are carried out to examine wind-induced torsional loads on low-rise buildings. Three low-rise buildings were tested in the Building Aerodynamics Laboratory located in the Engineering Complex at Concordia University, Montreal, Canada. Two low-rise buildings (scale 1:400) with a flat and 4:12 gabled roof slope (having the same dimensions) were examined in open and urban terrain exposures for a half wind direction cycle (every 15^o). In addition, a model (scale 1:200) of an actual low-rise building in Fredericton, New Brunswick, Canada and its surroundings has been tested in three wind tunnel tests. Two of latter set of tests were conducted for the building model with a complete simulation of its surroundings in open and urban terrain exposures for a complete cycle by 10^o increments. The building was also tested in an open terrain exposure without any surroundings. Peak, mean, and minimum base torsion and shear force for each azimuth were evaluated for all tests. In general, the measured results indicated that the maximum torsional moment on low-rise buildings could be simulated by applying 75% of the full wind loads (maximum shear) with additional 15% equivalent eccentricity of the facing building dimension.

2. INTRODUCTION

The majority of buildings worldwide are categorized as low-rise buildings. Low-rise buildings are prone to excessive damages in wind disastrous events. The proper design for such building depends significantly on the sufficient evaluation of the instantaneous temporal and spatial variation of wind-induced loads on building envelopes. These variations of wind-induced loads may result in significant torsion/torque about the vertical building axis. Even though for symmetric building shapes wind-induced torsional moment are found. Several studies have been carried out to evaluate the variation of local wind pressures on building claddings and the total effective wind forces (base shear/overturning moment) on the main structural building systems. However, very limited studies examined wind-induced torsional loads on low-rise buildings, as shown clearly in the comprehensive reviews by Holmes (1983), Stathopoulos (1984) and Krishna (1995). The major contribution in the development of North American provisions for the evaluation of wind loads on low-rise buildings was based on the research carried out at the University of Western Ontario (UWO) in the late 70's. An extensive experimental program in a boundary layer wind tunnel examined a variety of rectangular low buildings with different dimensions, roof slopes and upstream terrain exposures. However, wind-induced torsional loads were not examined in detail. Isyumov and Case (2000) studied wind-induced torsion

by conducting wind tunnel tests for three low-rise buildings with different aspect ratios. The study suggested (till more data are developed) that applying partial wind loads similar to those implemented for the design of tall buildings will improve the design of low buildings. This study was the only are addressing wind-induced torsional loads on low buildings. Clearly, more information is essential to improve the evaluation of wind-induced torsional loads on low buildings.

This paper presents a set of wind tunnel tests that are carried out to examine wind-induced torsional loads on low-rise buildings. One of the targets for this study is to quantify the effect of the different building geometrical parameters, as well as the effect of different terrain exposures and the surroundings on the wind-induced torsion. Thus, three low-rise buildings were tested in different terrain exposures. Two similar buildings with different roof slopes were tested in open and urban terrain exposures. In addition, a model of an actual low-rise building in Fredericton, New Brunswick, Canada and its surroundings has been tested.

3. CURRENT STATE IN BUILDING CODES

In this section, a summary of a comparison is conducted by Elsharawy et al. (2011) for peak torsional coefficient, C_T, as estimated by the application of the load patterns stated in three building standards/codes namely; the American Society of Civil Engineers standard (ASCE/SEI 7-10), National Building Code of Canada (NBCC 2010), and European code (European 2004) versus wind tunnel results reported by Isyumov and Case (2000) (see Figure 1). Three 4:12 roof-gabled low buildings with different aspect ratios, namely; L/B =1, 2, and 3 were tested by Isyumov and Case (2000) in an open terrain exposure. The simplified (envelope/static) and the detailed (directional/dynamic) methods stated in the ASCE/SEI 7-10 and NBCC 2010 as well as the detailed method available in Eurocode 2004 have been applied for their analysis. The wind velocity was adjusted by the Durst curve given in the commentary part of ASCE/ESI 7-10 in figure C26.5.1. This was to alleviate the effect of using the 3-sec reference wind speed used in ASCE/SEI 7-10 instead of the mean hourly and 10-minute wind speed used in NBCC 2010 and Eurocode 2004, respectively. The peak torsional coefficient, C_T, was calculated using the following equation:

$$C_T = \frac{\text{Peak Torsional Moment}}{0.5\ \rho\ V_h^{\,2}\ B\ H\ L} \tag{1}$$

where ρ = air density (kg/m^3), V_h = reference mean hourly wind velocity (m/s).

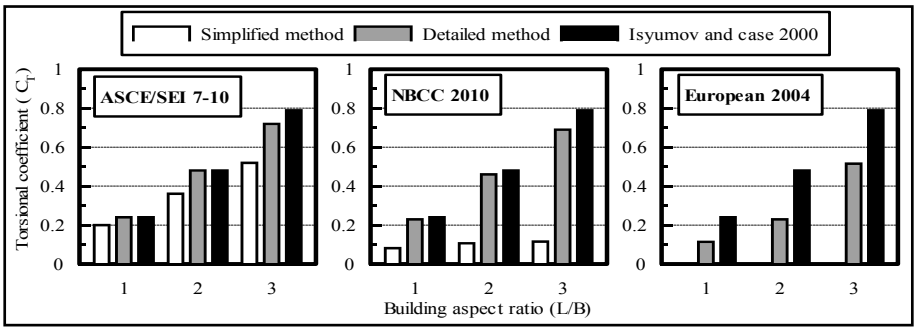


Figure 1. Comparison of torsional coefficients for three low-rise buildings with the wind tunnel tests conducted by Isyumov and case (2000), Elsharawy et al. (2011)

The comparison presented in Figure 1 demonstrates the following:

- The simplified method in ASCE/SEI 7-10 estimates torsional moments more than three times those of NBCC 2010 while twice those of the European 2004 provisions.
- Compared to the previous wind tunnel measurements, the simplified method for torsional moment in ASCE/SEI 7-10 works well for the square building; less so for buildings with higher aspect ratios. On the other hand, the simplified method in NBCC 2010 underestimates the measured torsional moment significantly.
- The detailed methods in both ASCE/SEI 7-10 and NBCC 2010 show good agreement with the torsional moment measured while the European code seems to underestimate these torsional moments for all building geometries.
- The detailed methods in both ASCE/SEI 7-10 and NBCC 2010 yield torsional moments of comparable magnitudes. However, the total wind loads due to shear forces, as well as those forces resulting from torsion are different.
- Good agreement is noticed for estimating wind-induced torsion by the simplified and the detailed method in ASCE/SEI 7-10 for low building aspect ratios; for higher aspect ratios the simplified method yields lower torsional moments.
- NBCC 2010 simplified and detailed method yields similar maximum base shear forces but very different maximum torsional loads.

The literature survey showed that the study conducted by Isyumov and Case (2000) is the only available study that addresses wind-induced torsional loads on low-rise buildings. Therefore, there is still a need to conduct more wind tunnel studies in order to enhance the understanding and modeling of wind-induced torsional loads acting on low-rise buildings. This highlights the need for the current study.

4. WIND TUNNEL TESTS

Three low-rise buildings were tested in the Building Aerodynamics Laboratory of Concordia University. Two models of low-rise buildings (scale 1:400) that have external dimensions of 152.5 mm (length) by 9.75 mm (width) and eave's height of 30 mm were constructed and tested in the wind tunnel. The first building model noted by "building I" has a flat roof while the other noted by "Building II" has a 4:12 gabled roof slope. The buildings with a flat and 4:12 roof slopes are equipped by 76 and 128 pressure taps, respectively. For "Building I" which has a flat roof, the pressure tapes are located on the side walls only since the uplift pressure on the top surface will not contribute to the base shear force and the torsional moment about the vertical building axis. "Building I" and "Building II" were tested in an open and urban terrain exposures for a half wind direction cycle (every 15^{o}). In addition, a model of a low-rise building noted by "Building III" in Fredericton, New Brunswick and its surroundings has been tested in the wind tunnel (see Figure 2). Taking into consideration the size of the full-scale building and the surrounding structures, as well as the simulation conditions of the boundary layer wind tunnel of Concordia University, a geometric scale of 1:200 was selected for the wind tunnel study. The model has external dimensions of 86.5 mm (length) by 42.5 mm (width) and a total height of 24.35 mm. The gabled roof has a slope $\theta=22.5^{o}$. The model called "Building III", is equipped with 128 pressure taps located on the wall and roof surfaces. Two tests were conducted for the building model with a complete simulation of its surroundings in open

and urban terrain exposures for a complete cycle by 10^o increments (36 wind directions). The building model was also tested in an open terrain exposure without any surroundings.

The wind velocity and turbulence intensity profile were measured using the 4-hole Cobra probe (TFI) and sampling rate of 1000 Hz. The velocity profile and the turbulence intensity simulated in the wind tunnel for open and urban terrain exposures are shown in Figure 3. The gradient wind velocities are measured as 13.2 m/s and 12.4 m/s for open and urban terrain exposures respectively. The power law exponent for the wind velocity profile simulated in these tests was 0.17 and 0.29, whereas the turbulence intensity at the mean roof height was 20.2% and 30.2% for open and urban terrain exposure, respectively. The pressure measurements on the models were conducted using a system of miniature pressure scanners from Scanivalve (ZOC33/64Px) and the digital service module DSM 3400.

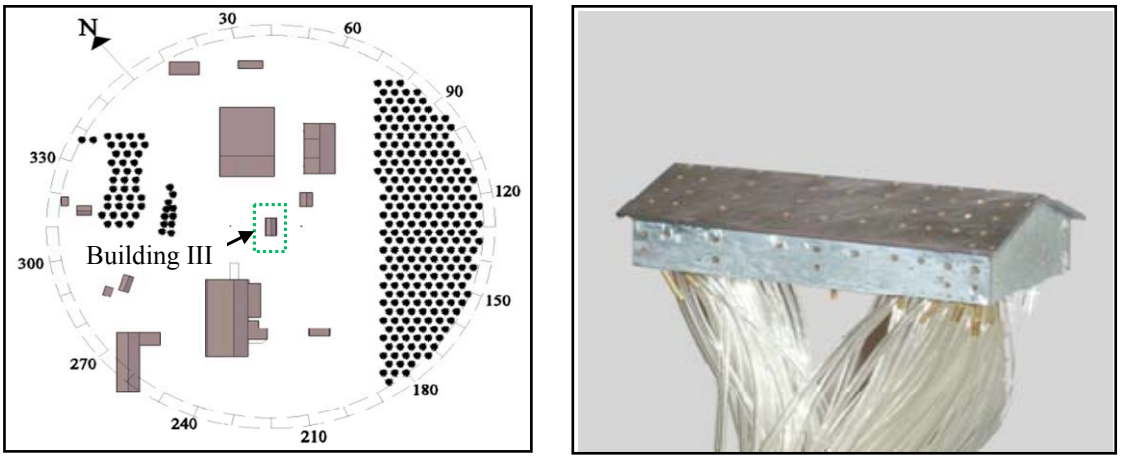

Figure 2. a) A plan of the model "Building III" with its surroundings tested in wind tunnel
b) Wind tunnel model "Building III" and location of pressure taps (Zisis and Stathopoulos (2010))

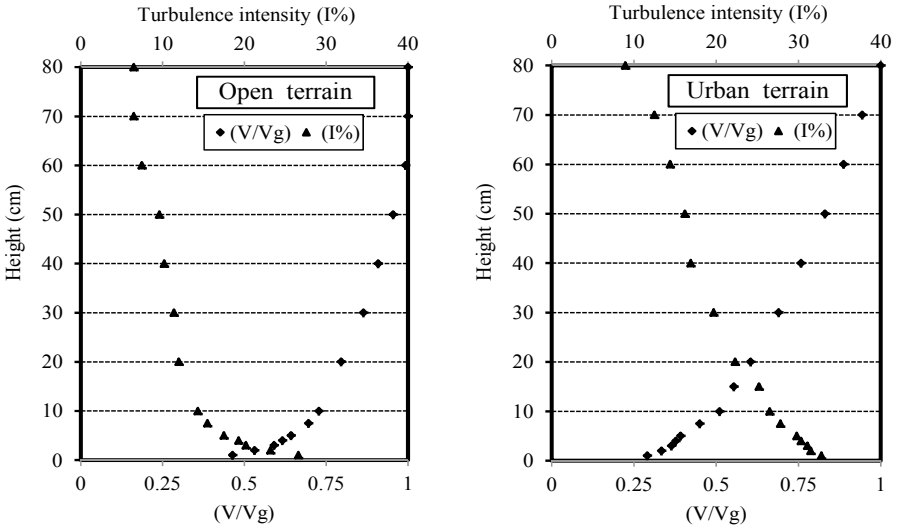

Figure 3. Wind velocity profile and the turbulence intensity simulated in wind tunnel for open and urban terrain exposure

The results of the wind tunnel tests were analysed. The measured pressures on the model surfaces are represented as differential pressure with respect to the atmospheric pressure. The wind pressure coefficient for each tap are estimated using

$$C_P = \frac{P - P_a}{0.5\ \rho\ V_h^2} \tag{2}$$

where P is wind pressure (kN/m^2), P_a is atmospheric pressure, ρ is air density (1.25 Kg/m^3) and V_h is the velocity at the mean roof building height (m/s).The instantaneous wind force corresponding to each tap is estimated by integrating the pressure coefficient over the effective area ($A_{effective}$) and multiplying it by the wind velocity pressure q_h

$$f_{tap} = C_p\ A_{effective}\ q_h \tag{3}$$

Since the vertical component (up-lift) of the force does not affect the torsional moment, the horizontal components of the wind forces acting on the inclined gable roof, in addition to the side wall forces, have been considered. The total instantaneous horizontal shear forces are calculated for each direction. The resultant shear force is estimated and normalized by using Eq. 4 below. The torsional coefficients were also estimated by normalizing the instantaneous torque according to Eq. 1. Maximum and minimum shear and torsional coefficients are estimated by applying extreme value analysis for each wind azimuth.

$$C_V = \frac{\text{Base Shear Force}}{0.5\ \rho\ V_h^2\ B\ h} \tag{4}$$

4.1 Experimental results

Three low-rise buildings are tested in the boundary layer wind tunnel. Four wind tunnel tests have been conducted for “Building I” and “Building II” with a flat and 4:12 gabled roof slopes in open and urban terrain exposures. In addition to that, three wind tunnel tests for “building III” ($\theta = 22.5^o$). The first two tests are for the building with the completed simulated surroundings in open and urban terrain exposure. To evaluate the effect of the surrounding on the wind loads, “Building III” was also tested in an open terrain exposure without any surroundings. The instantaneous base shear and torsional moment coefficients are estimated for each azimuth. Furthermore, the peaks are estimated based on extreme value analysis.

4.2 Effect of changing roof slope

Figure 4 shows the variation of peaks and means for shear and torsional coefficients with wind direction for “Building I” and “Building II” in open and urban terrain exposure. In fact, as it is well established in building codes that increasing the roof slope results in increasing the shear forces and consequently the overturning moments, similarly, the torsional moment should also be expected to increase. The test results demonstrate that increasing roof slope angle from flat to 4:12 led to an increase of the wind forces and torsional moment. The magnitude of shear and torsion for the building with 4:12 roof slope is higher by about 25% in open than urban terrain exposures.

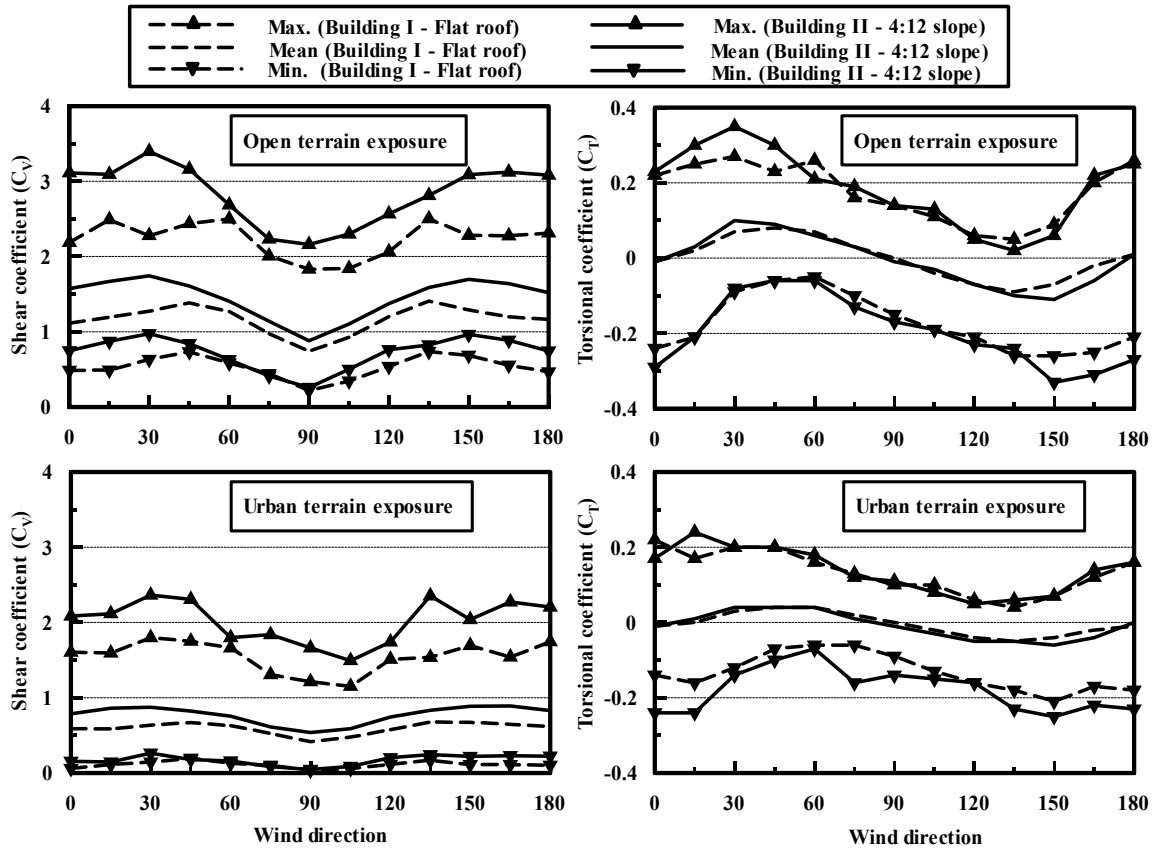

Figure 4. The variation of shear and torsional coefficients with wind direction for buildings I and II in open and urban terrain exposure

4.3 Effect of terrain exposure on base shear and torsional moment

The results for the first two buildings (flat and 4:12 roof slope) are presented in Figure 4. It can be seen that the base shear and torsional moment have been reduced in the urban terrain exposure for the same building by about 30%. Thus, the reduction in wind standards adopted for the maximum shear and overturning moment load cases should be also implemented for the torsional load case. On the other hand, the third building was tested with a complete simulation for the surroundings (local elements) in open and urban terrain exposures. The variation of peak and mean torsional coefficients for thirty six wind directions is presented in Figure 5. The results show that the effect of the terrain exposure on the torsional coefficient, C_T, is insignificant. The variation of peak base shear force with wind direction is presented in Figure 6. In general, it is expected to have a reduction in wind loads when considering the two different terrain exposures. In the current tests, the reduction of the mean wind velocity pressure in urban terrain exposure is counteracted by the effect of the high turbulence in wind flow due to the surroundings. This could be the reason of having almost the same peak torsional moment due to wind in the two terrains. This implies that there is a need to investigate the effect of the terrain exposure and the interaction with the surroundings in detail.

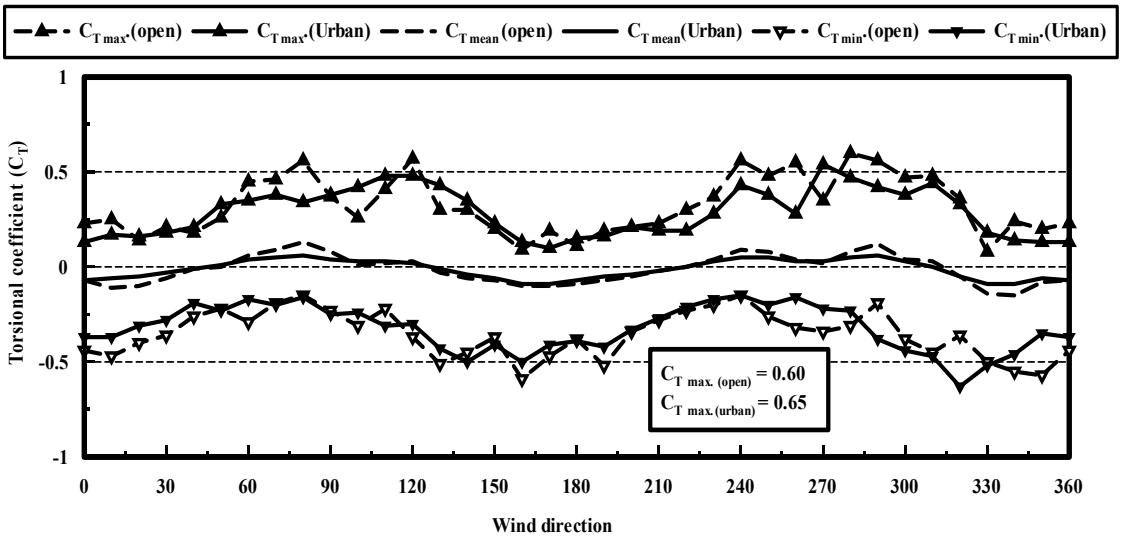

Figure 5. The variation of torsional coefficients with wind direction for building III in open and urban terrain exposures

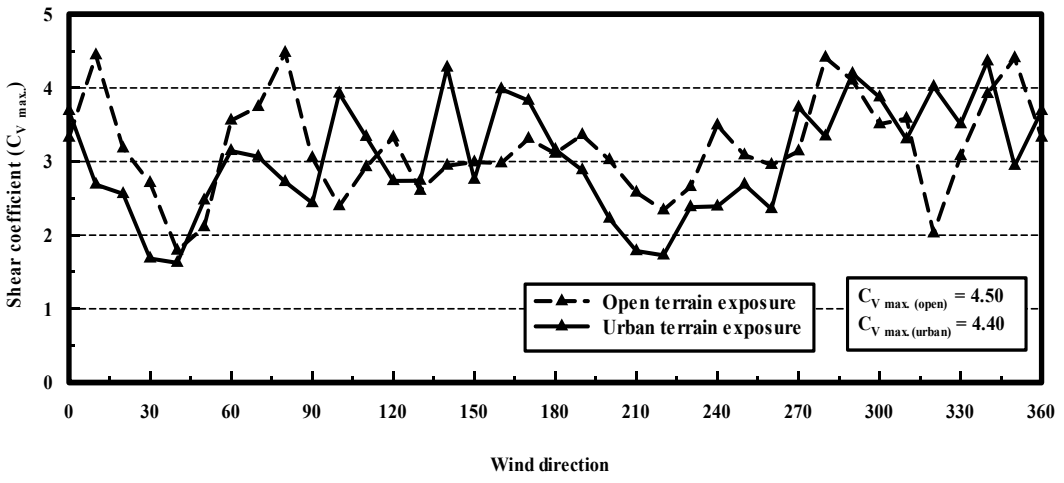

Figure 6. The variation of shear coefficient with wind direction for building III in open, and urban terrain exposure

4.4 The effect of surroundings on base shear and torsional moment

Two cases for "Building III" were investigated in the wind tunnel in open terrain exposure. The first case was the building with a complete simulation of the surroundings (scale 1:200), whereas the second case was for the building without any surroundings. In the latter case, due to the symmetry in the building's shape and the free space around the building model in wind tunnel, the data was measured only for the buildings in wind directions varying from 130^o to 220^o (every 10^o). The maximum and minimum torsional coefficients for the two cases were presented in Figure 7. It can be observed that the surroundings reduce the maximum torsional loads by about 20%.

It is also noticed that Building III in open terrain without the surroundings will gain higher base shear. The surroundings as obstacles facing the wind flow reduce the base shear by 30% for this particular building model. In general, it can be concluded that the surroundings will most likely help decrease the wind loads on buildings.

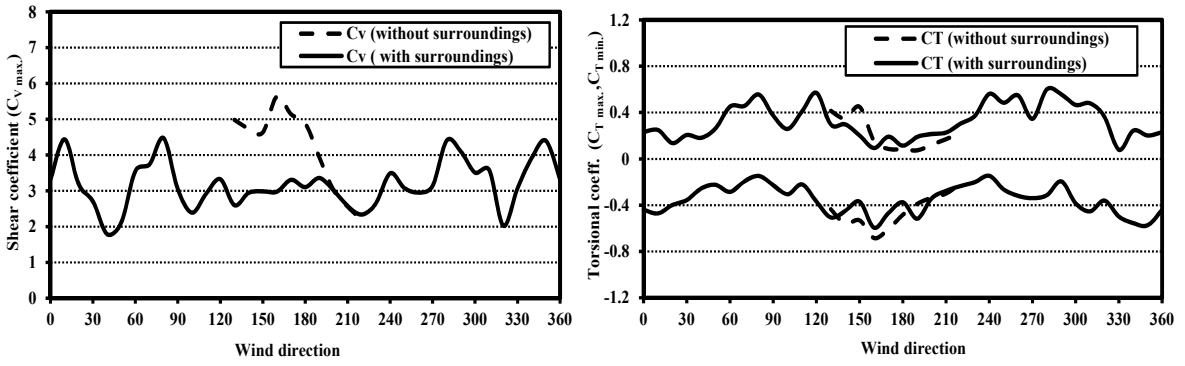

Figure 7. The effect of the surroundings on shear and torsional coefficients in an open terrain exposure

5. COMPARISON WITH STANDARDS

The wind tunnel test results for the three buildings are compared with the proposed values for base shear force and torsional moment stated by two currently updated building codes and standards, ASCE/SEI 7-10 and the NBCC 2010. The shear and torsional peaks for all tested wind directions in open terrain exposure are plotted in Figure 7 along with the result evaluated by the application of wind load patterns proposed in the codes/ standards considered. For the first two buildings (flat and 4:12 roof slope), the absolute maximum shear and torsional coefficients for thirteen wind directions are presented, whereas the peak shear and torsional coefficient are presented for thirty-six azimuths for Building III. The experimental results are compared with the provisions of the simplified (envelope/static) method and the detailed (directional/dynamic) method in the two building codes. For the simplified method calculations in ASCE/SEI 7-10, figure 28.4-1 is used to get the external pressure coefficients (GC_{pf}). The basic (transverse) and torsional load cases presented in figure 28.4-1 of ASCE/SEI 7-10 are used to estimate the maximum torsional moment and base shear for the buildings. For the detailed method calculation in ASCE/SEI 7-10, Figure 27.4-1 is used to get the external pressure coefficient, C_p, on the side walls and the roofs. The simplified method calculations in NBCC 2010 for the torsional and shear coefficients were derived based on figure I-7 where the external peak composite-gust pressures (C_pC_g) are provided for low-rise buildings. The external pressure estimation by the detailed method of NBCC 2010 follows the flowchart of figure I-15 in Commentary I. ASCE/SEI 7-10 and NBCC 2010 calculations were carried out considering the open terrain exposure C, and terrain category II, respectively.

From Figure 8, the following can be observed:

- There is a good agreement in evaluating the base shear force by the simplified and the detailed method in both standards.

- The application of the wind load patterns proposed in the detailed (directional/dynamic) method in ASCE/SEI 7-10 and NBCC 2010 is sufficient to evaluate and predict the torsional moments for all cases considered.
- The simplified (Static) method of NBCC 2010 underestimates the torsional moment in all studies cases.
- In general, the simplified method of ASCE/SEI 7-10 works well for the torsional moment, yet it becomes problematic to account for surroundings and other local elements.

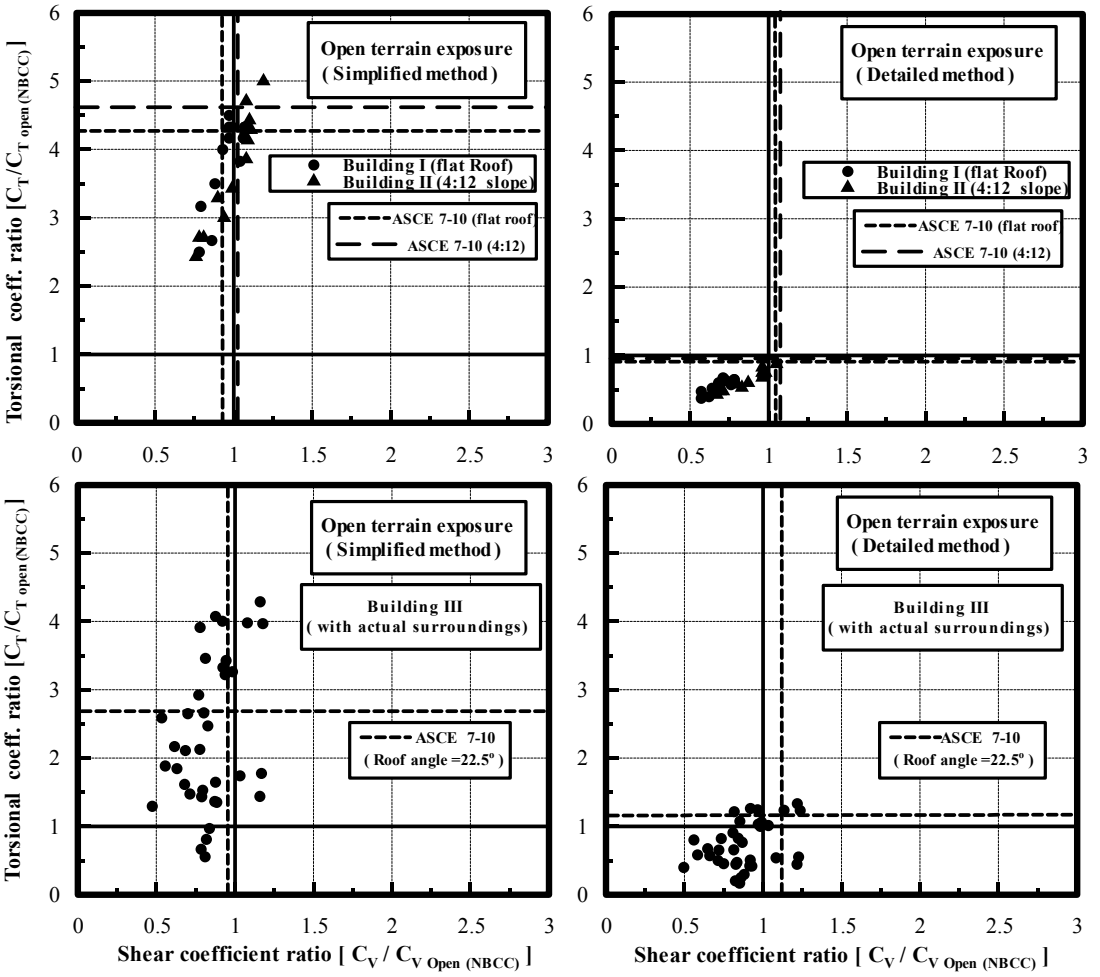

Figure 8. Comparison of wind tunnel shear (C_V) and torsional coefficients (C_T) with the values proposed in the North American codes/standards for open terrain exposure

The horizontal distribution of the instantaneous wind loads on the main wind resisting building system always causes torsional moment about the vertical building axis. The magnitude of this torsion significantly depends on the magnitude of the wind resultant and the deviation (eccentricity) ever existing between the aeroelastic wind resultant force and the building center of rigidity. The torsional load design case is generally simulated by applying reduced wind loading on parts of the building envelope generating additional equivalent eccentricity. Table 1 presents a summary for the peak shear and torsional coefficients based on the application of two North American wind standards (ASCE/SEI 7-

10 and NBCC 2010) and the results of previous and present wind tunnel tests. The shear load case is presented in a form of shear coefficient ($C_{V\ max.}$), whereas the torsional load case is described by using three parameters, namely peak torsional coefficient "C_{Tmax}", peak equivalent eccentricity "e %", and the percentage of the full wind load "Load %" required to get the maximum torsional moment. The equivalent eccentricity "e %" is calculated as

$$e\ \% = \frac{\text{Base torsional moment}}{L\ *\ \text{Base shear}} *\ 100 \qquad (5)$$

where L = building dimension facing the wind,

Table 1: Wind tunnel measurements of peak torsional moment on low buildings and comparisons with building codes and standards

Information source	Building I (flat roof) (B = 39, L = 61, H =12) m				Building II (θ = 18.4°) (B = 39, L = 61, H = 12) m				Building III (θ = 22.5°) (B = 8.5, L = 17, H =3.1) m (with surroundings)			
	Shear case	Torsional case			Shear case	Torsional case			Shear case	Torsional case		
	$C_{v\ max}$	$C_{T\ max}$	e_{max}%	Load %	$C_{v\ max}$	$C_{T\ max}$	e_{max}%	load %	$C_{v\ max}$	$C_{T\ max}$	e_{max}%	load %
Simplified ASCE/SEI 7-10	2.28	0.26	17.6	65	2.90	0.33	17.5	65	3.42	0.38	17.25	65
Detailed ASCE/SEI 7-10	3.35	0.38	15	75	3.45	0.39	15	75	4.52	0.51	15	75
Simplified NBCC 2010	2.34	0.06	2.6	100	2.86	0.07	2.5	100	3.8	0.14	3.95	100
Detailed NBCC 2010	3.22	0.4	25	50	3.22	0.4	25	50	3.62	0.45	25	50
Isyumov and Case. 2000 (B = 9.75, L=19.5, H = 4.88) m	-	-	-	-	-	0.48	-	-	-	-	-	-
Wind tunnel (open terrain)	2.5	0.27	15.20	70%	3.40	0.35	15.50	65%	4.5	0.60	15.24	87%
Wind tunnel (urban terrain)	1.8	0.20	14.82	75%	2.36	0.25	15.30	70%	4.36	0.65	14.8	84%
Reduction percent (open / urban)%	28%	26%			30%	32%			3%	10%		

The main observation from the values presented in Table 1 is that the maximum torsional loads can be produced by applying 75% from the total wind load (maximum base shear) with additional equivalent eccentricity 15% from the perpendicular building dimension to wind load.

6. SUMMARY AND CONCLUSIONS

This paper examines wind-induced torsional loads on low-rise buildings. A set of wind tunnel tests are presented. Two buildings scaled at 1:400 have the same dimensions, but "Building I" has a flat roof while "Building II" has a 4:12 gabled roof. These two buildings were tested in open and urban terrain exposure. "Building III" was scaled at 1:200 and simulates a building in Fredericton, New Brunswick with its surroundings. Three tests were conducted for the building model with a complete simulation of its surroundings in open, suburban and urban terrain exposures for a complete cycle of wind

directions by 10^o increments. This building was also tested in an open terrain exposure without any surroundings. Peak, mean, and minimum base torsion and shear force coefficients for each azimuth were evaluated. The results indicate the following:

- Changing the roof from flat to a 4:12 slope results in an increase of 30% in the total shear force and an increase of 25% in the torsional moment due to wind.
- The buildings located in urban terrain exposure are subjected to less wind loads (shear forces and torsional moments) by about 30% than those located in open terrain exposure.
- The simplified (envelope) method in ASCE/SEI 7-10 and the simplified (static) method in NBCC 2010 require more attention to account for the surrounding effects on torsional moment.
- The maximum torsional loads can be produced by applying 75% from the total wind load (maximum base shear) with additional equivalent eccentricity 15% from the perpendicular building dimension to wind load.

It should be noted that the above conclusions are drawn based on a limited number of tests with specific conditions. More data is required to develop better wind load patterns accounting for wind-induced torsional loads on low-rise buildings.

ABSTRACT

Recently developed steel-framed floor systems utilizing long-span metal deck have the potential of providing large column free areas with overall floor thicknesses approximately equal to concrete flat plates while typically imposing less dead load on the structure. The vibration serviceability of such floor systems is investigated in this paper. Two laboratory specimens, a full-scale mockup, and 13 in-situ floors were tested to measure their natural modes and responses to walking excitations. Natural modes were determined using experimental modal analysis techniques or heel-drop test results. Response to walking was determined by measuring the maximum peak acceleration due to individual walkers traversing the floor. The natural frequencies for the laboratory specimens and mockup were in the range of those measured for typical composite framing systems whereas all in-situ floors are high-frequency floors. The measured accelerations due to walking and subjective evaluations indicate that such floors will generally have adequate resistance to vibrations due to walking.

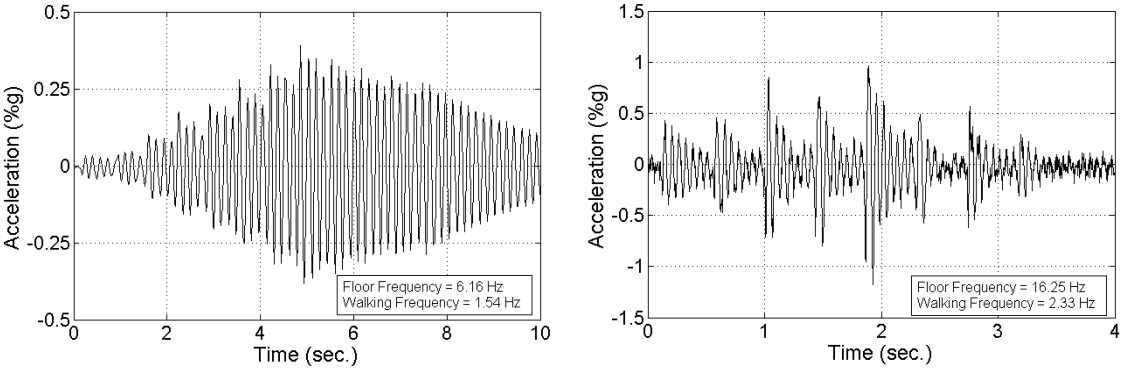
INTRODUCTION

Steel-framed floors offer several advantages compared to cast-in-place concrete floor systems, including speed of construction, economy, and flexibility for future remodeling. However, they usually require larger floor-to-floor heights than those required for concrete flat plate floors, which is the primary reason that flat plate floor systems are more commonly used in high-rise residential structures such as hotels and condominiums. Steel-framed floor systems are also perceived by the engineering community to be more vulnerable to vibration serviceability problems due to humans walking on the floor.

Very recently, new steel-framed floor systems have been developed that decrease or eliminate the floor-to-floor height disadvantage. The systems use long-span composite deck (LSCD) to span up to 9.14 m (30 ft) without interior beams, to create large column-free areas with relatively high ceilings. When used for spans approaching 9.14 m (30 ft), the composite slabs are 200 mm to 250 mm (8 in. to 10

in.) deep and use fairly deep—nominally 115 mm (4.5 in.) and deeper—composite deck that is shored during construction. The resulting UL D951 fire rated assembly achieves a two hour rating without sprayed-on fire protection while UL D501 provides a two hour rating with a gypsum board ceiling. The slabs are supported at the column lines by steel beams with the top flange either flush with the bottom of the deck or embedded in the slab to minimize the total system depth. The slab edges parallel to the deck are sometimes constructed without spandrel members to minimize the floor depth at the cladding. Other variations in the use of these floors include supporting the slab directly on CMU or steel stud walls. This construction system used in low-rise residential buildings eliminates the need of supporting beams, so the total floor depth is the slab thickness.

Intuitively, one might assume that a composite slab spanning 9.14 m (30 ft) would be subject to disturbing vibrations due to walking and, unfortunately, there is no current standard method in North America for evaluating LSCD systems for vibration serviceability. The lack of experience with such systems would undoubtedly deter some engineers from using them. Therefore, the objective of the study described herein is to investigate the floor vibration performance of LSCD systems. Experimental results and subjective evaluations from a laboratory floor specimen, a floor mock-up, a laboratory footbridge, and in-situ tests of thirteen floors of buildings currently in service are used to assess the vibration behavior of these systems.



CATEGORIZATION OF FLOORS BY NATURAL FREQUENCY

Human perception of vibrations depends on the vibration frequency and therefore the natural frequency of the floor. Vibrations of floors with frequencies below about 10 Hz are much more likely to cause discomfort of the occupants than in floors with frequencies above 10 Hz (Murray et al., 1997; Smith et al., 2007). Based on this limit, floors can be classified as low-frequency or high-frequency.

The type of response to walking also depends on the natural frequency of the floor. In low-frequency floors, a walking force harmonic frequency (integer multiple of the step frequency) can match a natural frequency, resulting in a resonant response. Figure 1(a) shows an example of the typical response of these floors. The plot is the acceleration trace measured in a floor with a natural frequency of 6.16 Hz, while walking at 1.54 Hz, the fourth sub-harmonic (integer division) of the floor frequency. Therefore the fourth harmonic of the walking force matched the natural frequency. The figure shows that the response builds up with every step which causes the high acceleration response to last for several seconds.

In high-frequency floors, the acceleration response is a series of impulse responses that experience a fast decay after each step and therefore no resonant build-up. Figure 1(b) shows the trace measured in a floor with a natural frequency of 16.25 Hz, while walking at the seventh sub-harmonic of the floor frequency, 2.33 Hz. The accelerations in this floor are a sequence of short transient responses that die out before the next step. (The increased response near 2 sec. is due to the walker being nearer to midspan, not due to a resonant build-up.) An important characteristic of these systems is that generally the accelerations are not perceived by floor occupants because the vibrations decay so rapidly and because they occur at frequencies that are

outside the range in which humans are most sensitive to vertical vibrations, 4 Hz to 8 Hz (Murray et al., 1997; Smith et al., 2007). Therefore, in some cases the peak accelerations that result from each step may be larger than in low-frequency floors, however, they are not perceived by the occupants.

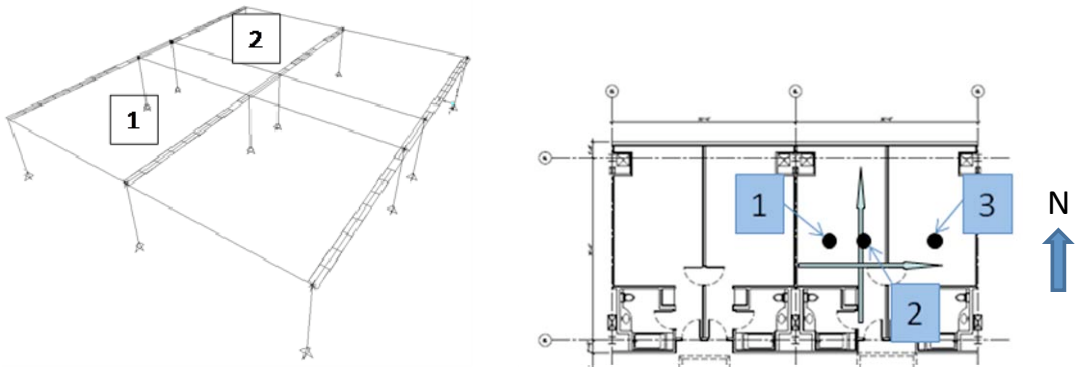
EXPERIMENTAL PROGRAM

Floor descriptions. The program included investigations of a laboratory floor, a floor mockup, a laboratory footbridge, and thirteen floors in residential buildings.

The laboratory floor, Figure 2, was a single 9.14 m by 9.14 m (30 ft by 30 ft) bay constructed and tested at the Virginia Tech Thomas M. Murray Structural Engineering Laboratory in 2006. The 222 mm (8-3/4 in.) composite slab consisted of a 117 mm (4-5/8 in.) steel deck covered with 105 mm (4-1/8 in.) of 24 MPa (nominal 3.5 ksi) normal weight concrete. The floor was supported only at the perimeter with W530x66 (W21x44) girders and W360x32.9 (W14x22) beams which framed into W310x60 (W12x40) steel stub columns. Temporary shoring was provided at the third points of the slab to limit the dead load deflections during the concrete placement. The slab supported no nonstructural elements such as cladding or partitions.



(a) Photograph. **(b) Section.**

Figure 2. Laboratory floor specimen.

The 18.5 m by 22.6 m (61 ft by 74 ft) full-scale floor mockup, located in Las Vegas, Nevada, was tested in January 2008 and again August 2008. The slab was supported by perimeter beams and interior girders to simulate a four bay (separated

by a corridor) portion of a hotel wing with 9.14 m by 9.14 m (30 ft by 30 ft) areas free of columns and beams. Figure 3(a) is an image of the mockup configuration. The mockup was constructed using a similar LSCD system described above for the four main bays and a 133 mm (5-1/4 in.) total thickness composite slab on 51 mm (2 in.) deck for the corridor. It was tested in the stages that are summarized in Table 1. During Stages 1 through 4, cladding and partitions (see Figure 3(b)) were installed below and on the slab in Bay 1 and the adjacent main bay. The partitions and cladding were constructed of light-gage steel studs with one sheet of drywall on each side. Bay 2 and its adjacent main bay were bare slabs during all stages. During Stage 4, the main north-south partitions below and above the slab in the middle of Bay 1 were removed to create a partition layout similar to that in a condominium "great room."

(a) Configuration including bay numbers.

(b) Partition locations, accelerometer locations, and walking paths.

Figure 3. Floor mockup.

Table 1. Summary of stages – floor mockup.

Stage	Partitions	Cladding	Shaker locations
0	None	None	Centers of Bay 1 and Bay 2
1	Hotel Rooms	Slip Connected to Slab	Bay 1, 7.5 ft west of center
2	Hotel Rooms	None	Bay 1, 7.5 ft west of center
3	Hotel Rooms	Supported by Slab	Bay 1, 7.5 ft west of center
4	Great Room	Supported by Slab	Center of Bay 1

The 2.13 m (7 ft) wide by 9.14 m (30 ft) long laboratory footbridge was built and tested in three stages at the Virginia Tech Thomas M. Murray Structural Engineering Laboratory during 2007 and 2008. The slab was 222 mm (8-3/4 in.) thick and consisted of a 117 mm (4-5/8 in.) deep deck and 105 mm (4-1/8 in.) of concrete topping. The slab was supported by nominally 200 mm (8 in.) CMU walls and the connections between the slab and the CMU walls were detailed to perform as moment connections. Figure 4 shows a photograph of the laboratory footbridge. Figure 5 shows the testing stages which were designed to determine the effect of different amounts of restraint being provided by the CMU walls.

Figure 4. Laboratory footbridge.

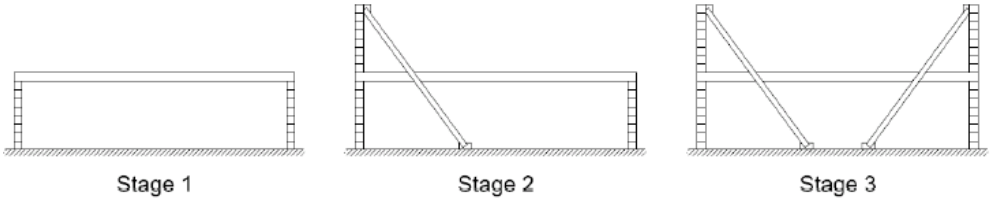


Figure 5. Laboratory footbridge stages.

In-situ tests of 13 floors in six buildings were conducted to investigate the performance of LSCD in residential structures constructed with CMU and stud walls. The buildings were under construction at the time of testing and most of the floors did not have partitions. Table 2 contains descriptions of the tested floors.

Table 2. Descriptions of in-situ floors.

Floor bay number	Bay width x span	Slab thickness mm (in.)	Concrete strength MPa (ksi)	Deck height mm (in.)	Floor support
1	6.15 m x 6.92 m (20.2 ft x 22.7 ft)	152 (6.0)	28 (4)	51 (2.0)	Stud wall - Steel beam
2					Stud wall - Stud wall
3	8.13 m x 4.48 m (26.7 ft x 14.7 ft)	152 (6.0)	28 (4)	51 (2.0)	Stud wall - Stud wall
4	4.19 m x 7.16 m (13.75 ft x 23.5 ft)	152 (6.0)	28 (4)	51 (2.0)	CMU - Concrete beam
5	9.28 m x 6.61 m (30.5 ft x 21.7 ft)	152 (6.0)	21 (3)	51 (2.0)	Stud wall - Stud wall
6	9.75 m x 7.01 m (32 ft x 23 ft)	171 (6.75)	28 (4)	51 (2.0)	CMU wall - CMU wall
7	8.96 m x 4.27 m (29.4 ft x 14 ft)	140 (5.5)	28 (4)	51 (2.0)	CMU wall - CMU wall
8	5.39 m x 6.71 m (17.7 ft x 22 ft)	152 (6.0)	28 (4)	51 (2.0)	Concrete beam – CMU
9	5.39 m x 7.52 m (17.7 ft x 24.7 ft)	152 (6.0)	28 (4)	51 (2.0)	Concrete beam – CMU
10	8.92 m x 5.11 m (29.3 ft x 16.8 ft)	152 (6.0)	28 (4)	51 (2.0)	Steel beam - Steel beam
11	6.05 m x 5.92 m (19.8 ft x19.4 ft)	152 (6.0)	21 (3)	51 (2.0)	Stud wall - Stud wall

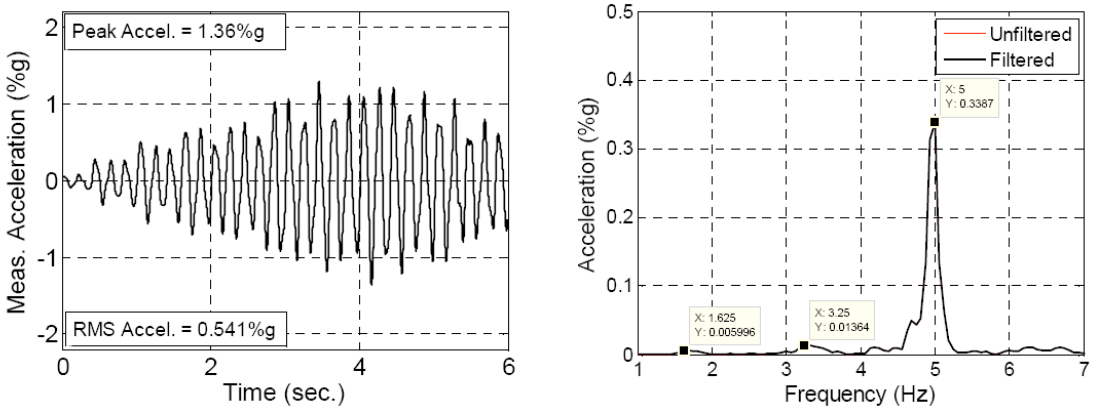
Experimental methods. For other than the in-situ floors, experimental modal analyses (EMA) were performed by applying a measured dynamic force to the floors while simultaneously measuring the acceleration response at numerous locations. The measurement results were post-processed to estimate the frequency response function (FRF) which gives detailed information on the natural modes. An electrodynamic shaker was used to provide excitation because it provides higher quality FRF estimates than those obtained using other forms of excitation (Pavic and Reynolds, 1999; Reynolds and Pavic, 2000a; Reynolds and Pavic, 2000b; Hanagan et al., 2003). Dynamic forces were applied at the center of the laboratory floor and at the mockup locations indicated in Table 1. During the laboratory footbridge tests, the shaker was positioned 0.914 m (3 ft) away from one support wall. It was determined that at this location, the force drop-offs due to shaker-structure interaction were insignificant. Burst chirp (sinusoidal) force input was applied by the shaker and measured using a custom-built force transducer placed between the slab and the shaker during tests on the laboratory floor and laboratory footbridge and using an armature accelerometer during tests on the mockup. Burst chirps were used because they provide a very controlled level of force input—selected to result in accelerations approximately equal to those expected from walking, 0.5%g to 2%g—over a bandwidth including natural frequencies of interest.

Accelerations were measured at various locations on the laboratory and mockup slabs and the footbridge. The measured force and accelerometer time domain signals were converted from volts to engineering units and used to estimate the accelerance FRFs for excitation and response at various locations on the slabs. Natural frequencies were detected by visual observation of the FRF magnitude and imaginary part plots and damping ratios were determined by FRF curve fitting using ME'ScopeVES Version 3.0 (Vibrant Technology, 2001). The basic concept of FRF curve-fitting is to match a parametric mathematical model of the FRFs to the ones estimated (measured) using the FRF estimator. Natural frequencies and modal damping ratios are primary parameters of the model. If a set of natural frequencies and damping ratios is selected such that the parametric model matches the estimated FRF, then the selected natural frequencies and damping ratios are presumably good approximations of the actual values.

For the floors tested in-situ, the modal properties of the slabs were determined using unmeasured heel-drops as the input force. A single heel-drop provides a broadband force excitation with significant energy between approximately 0.5 Hz and 20 Hz. The time domain acceleration signal is transformed to the frequency domain using a fast Fourier transform (FFT) and peaks in the resulting spectrum indicate natural frequencies. However, mode shapes and damping cannot be directly inferred from unmeasured heel-drop test results.

Experiments were also performed to determine the acceleration response to walking excitation for each floor. The general approach was to first determine the natural frequencies using EMA or heeldrop tests, and where available, use the FRF magnitude to determine which mode or modes will provide the highest accelerations. A walker then attempted to walk at specific frequencies to determine the maximum acceleration response that can be reasonably expected in the bay. Walking paths were



through the middle of the laboratory floor, the footbridge, the in-situ bays, and along the two paths indicated in Figure 3(b) for the mockup. Acceleration responses were measured at the middle of the laboratory floor and at eleven different locations on the laboratory footbridge, including midspan. During the mockup Stage 0 tests, the accelerations were measured at the centers of Bays 1 and 2—see Figure 3(a). During the other stages, accelerations were measured at the locations shown in Figure 3(b). Researchers also stood near mid-bay or midspan on each floor during several walking tests and offered subjective evaluations of vibration severity.

In all cases with EMA results available, one mode had a significantly larger FRF peak magnitude, indicating that it provides much higher accelerations than the other modes. Such a mode is referred to as the dominant mode. All dominant modal frequencies were far outside the range of reasonable walking frequencies (approximately 1.6 Hz to 2.2 Hz per Murray et al., 1997). However, as described previously, it is also possible to cause resonance using a harmonic of the walking force. Therefore, the walker carried a metronome and attempted to walk at a subharmonic (integer division) of the dominant frequency. Numerous walking tests were performed at the chosen subharmonic of the dominant frequency in an effort to determine the maximum acceleration due to walking that can be reasonably expected. Multiple individual walkers were used where possible. Single trips across the tested bay were performed in all cases rather than walking back and forth.

The acceleration waveforms collected from the two laboratory specimens and the mockup floor were filtered to exclude frequency content below 1 Hz to eliminate any DC offset and above 15 Hz to eliminate high frequency vibrations which are of no interest in assessing floor vibration serviceability. For the in-situ building tests, the recorded measurements where filtered to only include frequencies between 1 Hz and 35 Hz. The upper limit was increased for these floors because in many cases, the floor responses included significant contributions from modes with frequencies higher than 15 Hz.

EXPERIMENTAL RESULTS

Laboratory floor. The measured natural frequency of the laboratory floor was 4.98 Hz which is within the range of natural frequencies for low-frequency steel-framed floor systems. The measured damping ratio was 0.44% of critical damping. The measured walking acceleration waveform and spectrum for the test conducted while walking at 1.66 Hz (the third subharmonic of the natural frequency) are shown in Figure 6. The maximum peak acceleration in the time domain was 1.36%g which exceeds the 0.5%g limit for residences. However, subjective evaluators judged the floor to not have objectionable vibrations. Also note that in a real floor with the same dimensions as this laboratory specimen, the floor performance would be significantly improved with the addition of nonstructural elements, people, partition walls, and adjacent slab spans.

(a) Waveform. **(b) Spectrum.**

Figure 6. Measured acceleration response of the laboratory floor to walking.

Floor mockup. Table 3 shows the measured natural frequencies for the mockup. Interestingly, the natural frequencies only increased slightly with the addition of partitions, which indicates that the partitions added some stiffness corresponding to the added mass. However, the damping increased substantially from 0.5% of critical to 2.2% for Stages 3 and 4. As was the case for the laboratory floor, the natural frequencies are in the typical range of natural frequencies for low-frequency steel-framed floors. The table also shows the peak accelerations due to walking that were measured for all five of the mockup stages. The peak accelerations exceed the 0.5%g limit for residences, but by only a small margin in Stages 1 through 4 which most closely represent actual service conditions. Note that with additional damping from more nonstructural components, people, and connection of the partitions to the floor above, the Stage 1 through 4 responses would not exceed 0.5%g. Subjective evaluators during each stage indicated that the floor did not undergo objectionable vibrations, with most being described as "barely perceptible" or "slightly perceptible."

Table 3. Mockup measured natural frequencies, damping ratios, and accelerations due to walking.

Stage	Natural frequency (Hz)	Damping ratio (% critical)	Peak acceleration (%g)
0, Bay 1	5.55	0.5	0.768
0, Bay 2	6.00	0.5	0.966
1, Bay 1	6.35	1.3	0.626
2, Bay 1	5.93	1.3	0.559
3, Bay 1	6.03	2.2	0.527
4, Bay 1	5.72	2.2	0.599

Laboratory footbridge. Figure 7 shows the measured FRF for the three stages and Table 4 shows the natural frequencies which place each stage into the low frequency floor category. Interestingly, the natural frequencies barely changed with the addition of restraining CMU during Stages 2 and 3, probably indicating that the tops of the CMU walls moved laterally very slightly as the slab moved vertically.

The FRF peak magnitude decreased substantially, however, most likely due to the additional vibrating mass provided by the CMU walls. The peak acceleration due to walking was less than the 0.5%g limit during tests at all three Stages. Subjective evaluators indicated that the vibrations were slightly perceptible, but would not be severe enough to cause complaints. The vibration response would be further improved by the addition of nonstructural components.

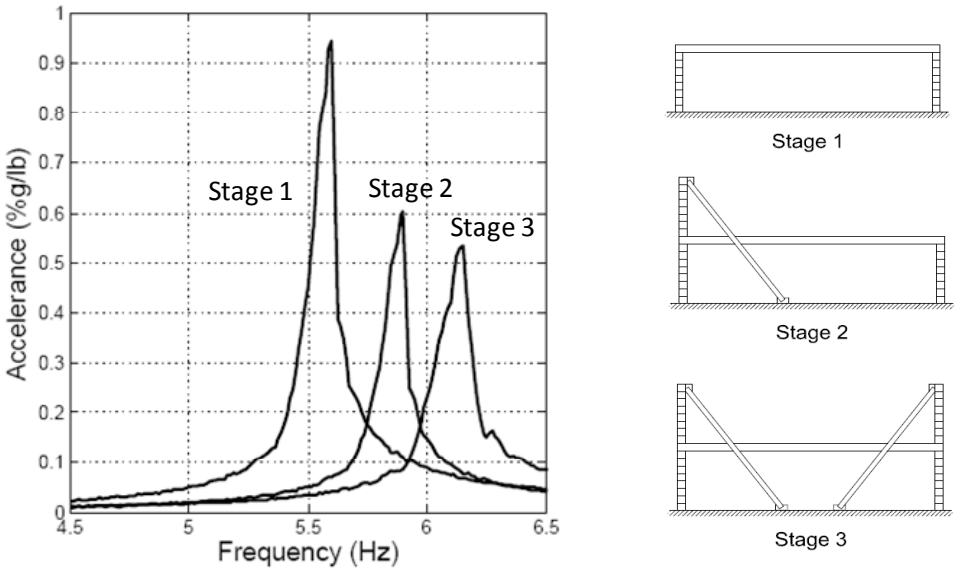


Figure 7. Measured FRFs for the laboratory footbridge (all three stages).

Table 4. Laboratory footbridge measured natural frequencies, damping ratios, and accelerations due to walking.			
Stage	**Natural frequency (Hz)**	**Damping ratio (% critical)**	**Peak acceleration (%g)**
Stage 1	5.73	1.0	0.35
Stage 2	5.89	1.3	0.39
Stage 3	6.14	1.3	0.45

In-situ tests of residential buildings. Measured natural frequencies and peak acceleration from walking tests at several subharmonics of the measured frequencies are summarized in Table 5. The accelerations shown in the table correspond to the maximum values measured in the walking tests. Except for Bays 3 and 9, partitions were not in place at the time of testing. In these two bays, the partition walls significantly increased the floor system. For these floors, the peak accelerations were less than 0.1%g during the walking tests. As shown in Table 5, all the tested floors had frequencies above the 10 Hz, meaning LSCD behave as high-frequency floors when they bear on rigid supports, as is the case of the structural walls. Because the floor frequencies are above 10 Hz, the previously mentioned 0.5%g acceleration limit for residual floors does not apply. Subjective evaluators indicated that the vibrations were imperceptible during all walking tests.

Table 5. In-situ building floors measured natural frequencies and accelerations due to walking.		
Bay number	**Natural frequency (Hz)**	**Peak acceleration (%g)**
1	13.30	1.41
2	16.80	1.32
3	26.00	< 0.1
4	11.80	1.05
5	13.50	0.60
6	14.50	0.84
7	27.80	0.94
8	11.50	1.73
9	20.50	< 0.1
10	13.50	0.38
11	13.00	2.57
12	10.50	0.78
13	10.75	0.84

The frequency results obtained from the in-situ tests are quite interesting because even though the spans are long (Table 2), the floors are very stiff. Apparently, the typical slab-to-supporting wall connection provides flexural fixity, which significantly increases the floor natural frequency. This behavior is contrary to the expected performance in steel-framed floors, where the beams and girders behave as simply supported elements with pinned connections (Murray et al., 1997; Smith et al., 2007).

DISCUSSION AND CONCLUSIONS

The laboratory floor, floor mockup, and laboratory footbridge tests indicate that LSCD have very good resistance to floor vibrations due to walking. The floors had natural frequencies that are in the range of those measured for composite slab and composite beam floor systems and far above the 3 Hz limit to avoid vandal jumping. Measured peak accelerations due to walking exceeded the 0.5%g limit for residences in most bays, but tests represent a scenario more severe than expected in service. The in-service responses should be less than 0.5%g due to the presence of nonstructural elements, people, partition walls, and partition connections to the floor above. Also, the tests were conducted with walkers traversing the least favorable path (directly through the middle of the bay) and the accelerations were measured at mid-bay, which is the location of maximum response. Subjective evaluators indicated that the responses were not severe enough to cause complaints. Therefore, it is concluded that LSCD systems have very good potential to be constructed to spans of 9.14 m (30 ft) without annoying vibrations due to human activities in residential structures. It should be emphasized, however, that LSCD designs must be evaluated during the project design phases.

The in-situ tests show that floor vibration performance is very satisfactory when the LSCD are supported by steel stud or CMU walls. For these cases, the systems

behave as high-frequency floors, with natural frequencies that in many cases well above the 10 Hz limit. Subjective evaluators indicated that the vibrations due to walking were imperceptible on these floors. Hence, it is concluded that slab and wall combinations similar to those described in this research have very good potential to be used without vibration problems. Again, it is emphasized that LSCD designs must be evaluated during the project design phases.

ACKNOWLEDGEMENTS

ABSTRACT

Laboratory and manufacturing facilities are frequently located in areas that experience high-frequency (greater than 30 Hz) environmental vibration. Such vibrations are a concern for the proper functioning of sensitive laboratory devices, precision manufacturing equipment as well as human comfort. A simple method to accurately predict the magnitude of high-frequency floor vibrations would allow detailed vibration assessment during the conceptual design phase, and provide physical insight useful for developing vibration mitigation approaches. This paper discusses a methodology for prediction of train-induced floor vibrations in buildings using a wave propagation technique. The data obtained from an experiment carried out at Tufts University on a scale model laboratory building have been used to validate the predictions. The proposed wave propagation method successfully predicted the measured velocities and impedances of the scale model building.

INTRODUCTION

Many facilities are located in environments with substantial ambient vibration. The vibration may be from highway vehicles, trains, or other sources. Floor vibrations are of concern for precision manufacturing facilities and for laboratories where sensitive experiment is carried out. Examples of sensitive manufacturing processes include fabrication of laser devices, electronic microscopes, surgical devices, and semiconductor integrated cores. As technologies continue to evolve and become more complex, the demands on manufacturing are expected to become more rigorous. These vibrations also may be of concern for human comfort in residential settings.

This paper focuses on the experimental validation of a simple wave propagation based modeling approach for the prediction of train-induced floor vibrations. This approach can be used during the conceptual design phase of projects where owners

are concerned about environmentally induced floor vibrations—with the potential to save millions of dollars in construction costs and hundreds of thousands of dollars detailed finite element studies whose accuracy is not guaranteed in the high frequency range.

BACKGROUND

Problems associated with floor vibrations are not new. The first known study was reported almost 70 years ago (Hunaidi et al., 1997). Numerous studies have been carried out to contribute to the understanding of the problem of floor vibrations.

Bahrekazemi (2004) reported that the techniques used for vibration mitigation are location dependent. These locations are either at the vibration source, in the path, or at the structure. Ju et al. (2004), Adam et al. (2005), and Wang et al. (2003) applied these various mitigation methods for the reduction of train induced vibrations. Mitigation methods selected were based on the location including soil improvement under the embankment and construction of concrete slabs, construction of open as well as in-filled trenches and isolation of the building foundation from the ground using elastic support system. Site conditions also play a dominant role in deciding the most appropriate mitigation method.

For successful mitigation of floor vibrations, it is necessary to have accurate and efficient prediction methods. In order to predict building vibration induced by nearby trains, various approaches have been adopted. Some of these approaches include finite element modeling, numerical model based approach, utilization of transfer functions and impedance based models. Each of these methods is characterized by its own efficiency, accuracy, ease of use in application, time consumption and limitations.

Ju (2007) developed an integrated finite element model for a bridge, nearby building, soil, and train for vibration prediction. Gupta et al. (2008) developed a coupled periodic finite element and boundary element model. It was used for prediction and assessment of subway induced vibrations with respect to studying the performance of different track structures in tunnels. With et al., (2007) used transfer functions for the prediction of floor vibrations in a building. Trochides (1991) predicted excitation levels due to ground borne vibrations in buildings near subways based on the approximate impedance formulae for the tunnel and the structure and energy considerations.

In the present paper, an approach for floor vibration prediction based on impedance modeling has been used. The authors developed an analytical model based on their previous research published by Sanayei et al. (2008), Hughes et al. (2008), and Zhao et al. (2010) to predict the velocity response of the structure. Experiments using a shaker on a scale model building have been carried out to simulate train-induced vibrations. The measured floor velocities have been used to validate the wave propagation model predictions. This paper also explains the efficiency and applicability of this approach in predicting floor vibrations in buildings.

MATHEMATICAL MODEL FOR IMPEDANCE BASED APPROACH

Train-induced vibrations propagate through soil in the form of waves that are transmitted to buildings at the foundation level. The vibrations are predominantly vertical although horizontal components exist (Li et al.2009; Yanmei et al. 2010). The interaction between the ground borne vibration and the vibration induced in the building foundation is complicated. In the present paper, it is assumed that the dominant mode of transmission into the upper floors in buildings is from longitudinal waves (dilatation) in the columns, bending wave transmission is more readily blocked at the lower floors. In the mathematical model, the vibrating force is assumed to be applied only in the vertical direction at the base of the columns (Conroy, 2008). Floor plates attached to the columns radiate energy as transverse bending waves. Longitudinal waves transmitted in columns are less affected by floors of typical weights and are more importantly responsible for the transmission into the upper floors.

Modeling of Column. The partial differential equation for free vibration of a column subjected to longitudinal waves (see Figure 1) is given by (deSilva, 2000)

Figure 1. Simple bar element representing column

$$\rho A(x)\frac{\partial^2 u(x,t)}{\partial t^2}-\frac{\partial}{\partial x}[E_c A(x)\frac{\partial u(x,t)}{\partial x}]=0 \tag{1}$$

where ρ, A and E are density, cross-sectional area and modulus of elasticity, respectively. E_c is the complex modulus of elasticity representing energy dissipation as $E_c = E(1+j\eta)$ with η denotes the structural loss factor.

The steady state response is given by:

$$u(x,t)=u(x)e^{j\omega t} \tag{2}$$

By substituting (2) into (1), the spatial equation of motion thus obtained is,

$$-\rho A(x)\omega^2 u(x)-\frac{\partial}{\partial x}[E_c A(x)\frac{\partial u(x)}{\partial x}]=0 \tag{3}$$

Furthermore, for a prismatic bar element, (3) can be written as,

$$\frac{\partial^2 u(x)}{\partial x^2}+\beta^2 u(x)=0 \tag{1}$$

where

$$\beta=\omega\sqrt{\frac{\rho}{E_c}}=\frac{\omega}{c_L} \tag{5}$$

$$c_L=\sqrt{\frac{E_c}{\rho}} \tag{6}$$

β is called as wavenumber (Cremer et al., 1988), which is a measure of the phase change per unit distance of a propagating wave, and c_L is the constant axial wave velocity.

The homogeneous solution for partial differential equation is,

$$u(x) = C_1 \sin(\beta x) + C_2 \cos(\beta x) \tag{7}$$

The element stiffness matrix is computed using the stiffness method, assuming linear spring behavior $\left(\{f\} = [k_{col}]\{u\}\right)$, by first applying a unit axial displacement to the left end of the rod, and then to the right. By fixing the right end of the rod and applying a unit displacement to the left end, the coefficients C_1 and C_2 can be solved,

$$C_1 = -\frac{\cos(\beta L)}{\sin(\beta L)} \text{ and } C_2 = 1 \tag{8}$$

Therefore, the steady state displacement field for a rod fixed at one end and free at the other, similar to a founded structural column, is,

$$u(x) = -\frac{\cos(\beta L)}{\sin(\beta L)}\sin(\beta x) + \cos(\beta x) \tag{9}$$

and the corresponding force field is,

$$f(x) = -E_c A\beta\left[\frac{\cos(\beta L)}{\sin(\beta L)}\cos(\beta x) + \sin(\beta x)\right] \tag{10}$$

By fixing the left end of the rod and applying a unit displacement to the right end, the coefficients are calculated (Brett 2007),

$$C_1 = \frac{1}{\sin(\beta L)} \text{ and } C_2 = 0 \tag{2}$$

The corresponding steady state displacement field and the force field are:

$$u(x) = \frac{\sin(\beta x)}{\sin(\beta L)} \tag{3}$$

$$f(x) = E_c A\beta\frac{\cos(\beta x)}{\sin(\beta L)} \tag{4}$$

The reactions at each end, related to each displacement, are the elements of the dynamic stiffness matrix of a single column acting as a bar element, and can be written as,

$$[k_{col}] = \frac{E_c A\beta}{\sin(\beta L)}\begin{bmatrix} \cos(\beta L) & -1 \\ -1 & \cos(\beta L) \end{bmatrix} \tag{14}$$

Modeling of Floor Slab. Floors attached to the columns can be modeled as energy dissipating floors slabs. The bending theory used to describe the response of the floor is thin plate theory. Thin infinite plates are totally resistive in the sense that they carry energy away from driving point (the column). This resistance is called point force impedance and is given as:

$$Z = 8\sqrt{D}\sqrt{\rho h} \tag{15}$$

where D is the bending stiffness of a plate of thickness h

$$D = \frac{Eh^3}{12\left(1-\nu^2\right)} \tag{16}$$

In general terms, impedance is the ratio of the applied force f to the response velocity v,

$$Z = \frac{f}{v} \tag{17}$$

Thus using Newton's second law and eq. (17),

$$f = m_{eff}\ a = Z\ v \tag{18}$$

The dynamic effective mass of the plate (m_{eff}) which is dependent on the driving frequency, is given by,

$$m_{eff} = \frac{Z}{j\omega} = -\frac{j}{\omega} 8\sqrt{D}\sqrt{\rho h} \tag{19}$$

Assembly of System of Equations. The dynamic stiffness matrix of the column elements, $\left[k_{col}\right]$ and the dynamic floor participation, $\left[m_{eff}\right]$ are assembled into global system matrices $\left[K_{col}\right]$ and $\left[M_{slab}\right]$, to be used in the steady state response, $\{U\}$, of a building column subjected to a harmonic loading, $\{F\}$.

$$\left[K_{col}\right]\{U\} - \omega^2\left[M_{slab}\right]\{U\} = \{F\} \tag{20}$$

Note that the stiffness and mass matrices are both frequency dependent in that the elements change based on the driving frequency.

The frequency dependent steady state response for all the floors becomes,

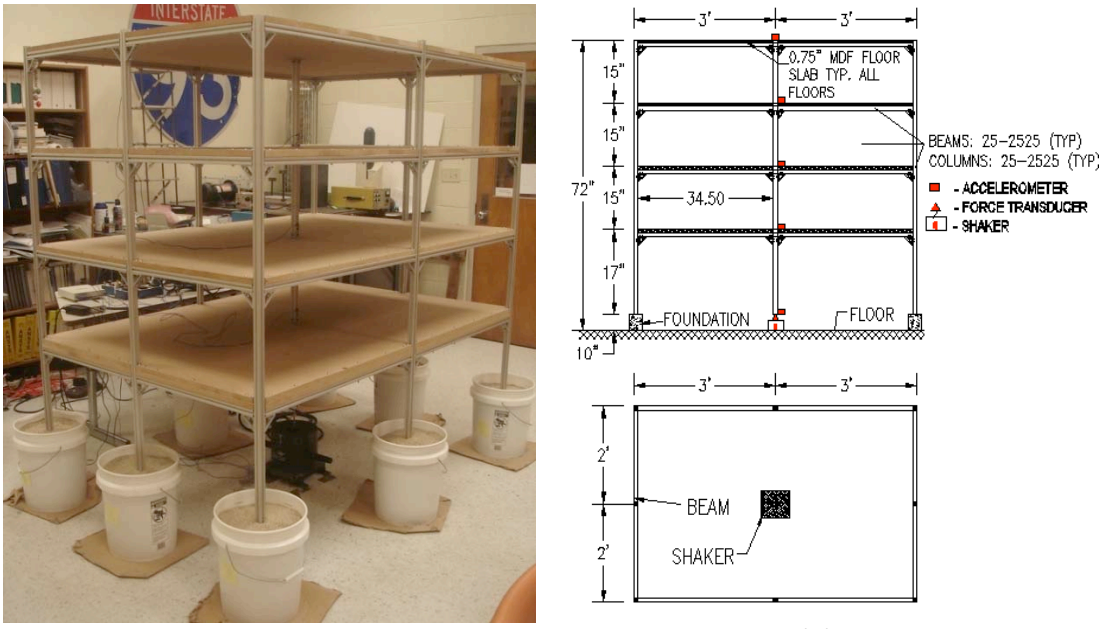
$$\{U\} = \left[K_{col} - \omega^2 M_{slab}\right]^{-1}\{F\} \tag{21}$$

and the velocity is given as,

$$\{V\} = i\omega\{U\} \tag{22}$$

The vibration velocity response level at all floors is given in VdB scale as,

$$VdB = 20\log_{10}\frac{v}{v_{ref}} \tag{23}$$



where,

$$v_{ref} = 1\times 10^{-8}\ \text{m/s} \tag{24}$$

Note that only the center column is considered in the mathematical model in (20). Therefore the sizes of the above system matrices are 5 x 5 (one for modeling of the column excitation at the base and four for the point impedances of the four floors).

EXPERIMENTATION OF SCALE MODEL BUILDING

Zhao (2009) designed and constructed a scale model building including base and 4 floors (see Figure 2). The scale model building (6' x 4' x 72") has a floor height of 17" at the base and 15" for all other floors. The model consists of 9 columns in total and 4 floor slabs. Aluminum alloy of 6105-T5 strips were used for the column while the floor slabs were constructed from medium density fiberboard (MDF).

(a) (b)

Figure 2. Scale model building with MDF floors (all dimensions in inches)

The material properties for columns and floors are summarized in Table 1.

Table 1. Materials used and its properties

Properties	Column	Floor
Material	Aluminum (6105-T5) Alloy	Medium Density Fiberboard
Young's Modulus (E)	70.3 GPa	3.15 GPa
Density (ρ)	2691 kg/m^3	700 kg/m^3
Poisson's Ratio (υ)	0.33	0.18
Loss Factor (η)	0.002	0.02

A Bruel & Kjaer Permanent Magnetic Vibration exciter type 4808 with a force rating of 112 N was used to excite the model at the base on one column. A Bruel & Kjaer force gauge type 8230 was used at the base of the column to measure the excitation force. PCB accelerometers type 352C65 were used to measure the vibrations on the floors at the center column.

The scale model building in Figure 2 consisted of base and 4 floors with accelerometers attached at each level. A Brüel & Kjær Permanent Magnetic Vibration Exciter Type 4808 was connected to the base of the center column. In order to measure the force applied to the structure, a load cell was mounted at the base of the center column. The shaker was supported by four neoprene base isolators to minimize flanking excitation to other columns. The eight (side and corner) columns that were not excited were buried in sand-filled buckets.

The scale model building in Figure 2 consisted of base and 4 floors with accelerometers attached at each level. A Brüel & Kjær Permanent Magnetic Vibration Exciter Type 4808 was connected to the base of the center column. In order to

measure the force applied to the structure, a load cell was mounted at the base of the center column. The shaker was supported by four neoprene base isolators to minimize flanking excitation to other columns. The eight (side and corner) columns that were not excited were buried in sand-filled buckets.

The scale model building was excited axially at the base of the center column for the purpose of testing and modeling the vertical propagation of structure-borne vibrations. A white noise signal was generated as the excitation source with a 50 kHz sampling rate and a sampling block of 50,000 data points. The length of each set of data was 1 second and the frequency resolution was 1 Hz. A Hanning window was applied to each set of one-second measured data in the time domain. The measured acceleration was transformed to the frequency domain using FFT function in Matlab.

Figure 3 shows the measured excitation force after taking moving average over 201points.The horizontal axis shows the range of frequency from 10 to 5000 Hz while the vertical axis shows the measured input force in N. A moving 201 point average was used to smooth the results.

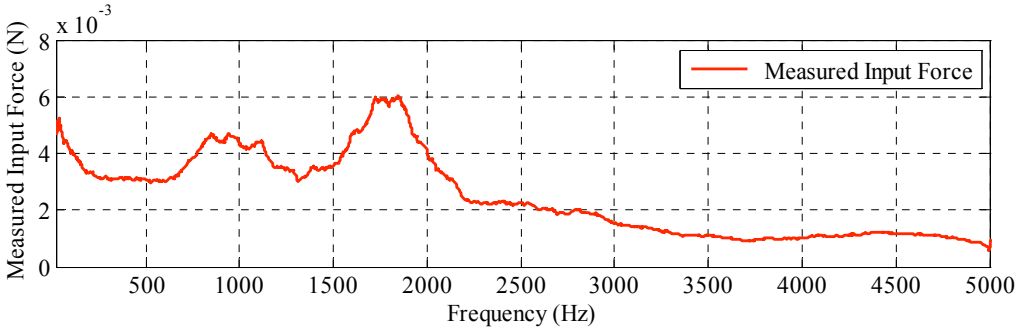


Figure 3. Force Spectrum

Acceleration measurements were made in the vertical direction on the center column at each floor, as well as at the column base. The measured data obtained from the load cell gives the measurement of the applied force at the base through shaker at the corresponding frequency. These readings were used to calculate and predict the velocity response at each level using the analytical model. The measured acceleration data were used to calculate the velocity at each floor. A moving 201 point average was used to smoothen the results. The plot comparing the predicted and measured velocity response is thus obtained. Figure 4 shows that the predicted and measured velocity response at each floor and the base of the building in the same frequency range after taking the moving average over 201 points. The vertical axis shows the velocities in VdB with a reference velocity of 10^{-8} m/s.

The ratio of measured input force to the velocity of the floor is defined as the impedance of that floor slab. If the velocity response is at the point of excitation, it is called the driving point impedance. If the response is measured at other locations within the building, it is called the transfer impedance. The data obtained through this experiment was further used to compare the predicted impedance to the impedance measured experimentally. Figure 5 shows the predicted and measured impedances at each floor and the base of the building. The vertical axis shows impedances in dB reference to 1 N-s/m.

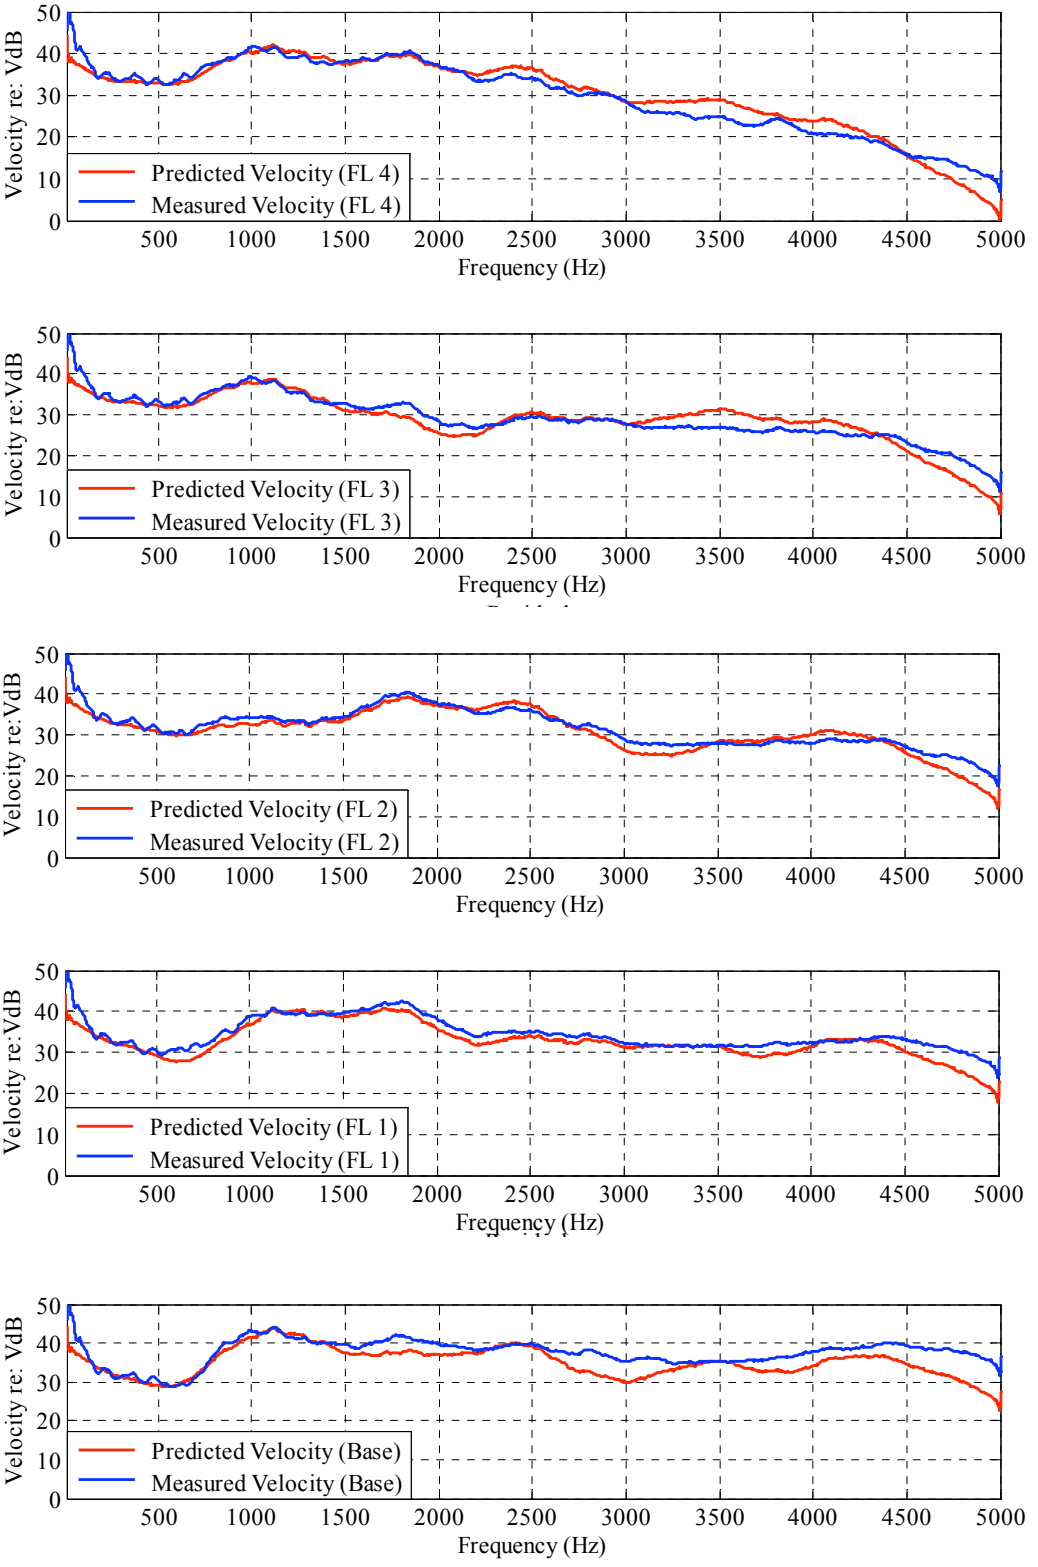

Figure 4. Predicted and Measured Velocity Response for Each Floor

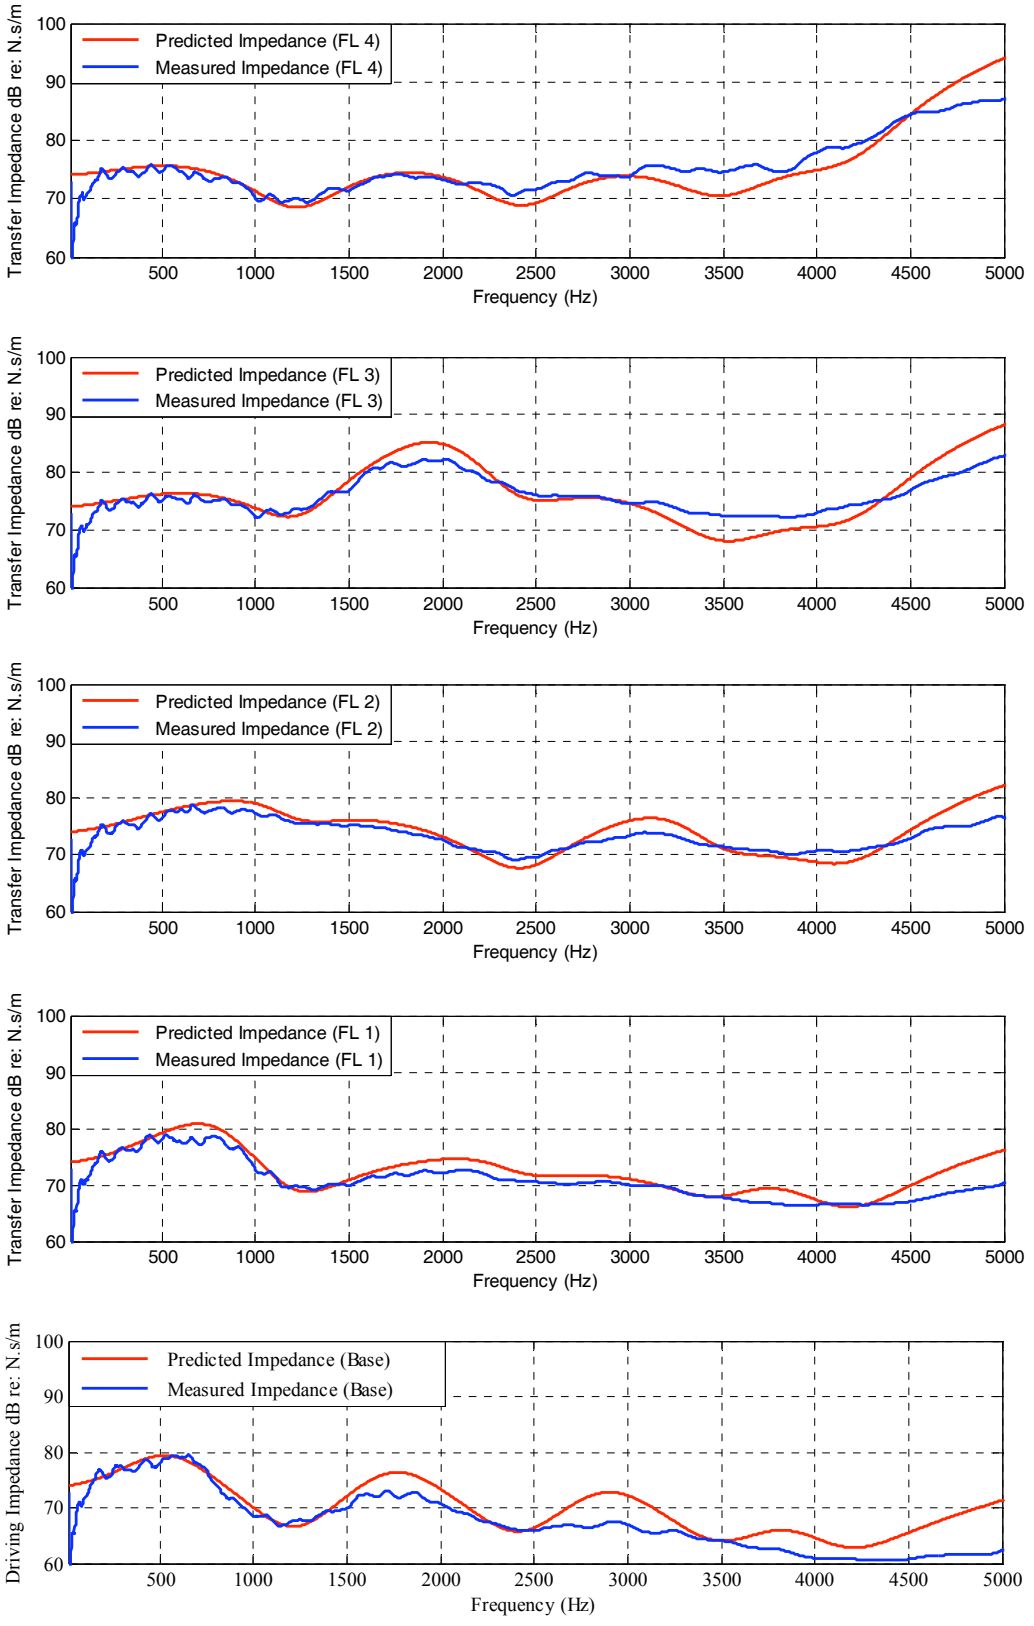

Figure 5. Predicted and Measured Impedance for Each Floor

Observations. As it can be observed from the plots (Figures 4 and 5), the predicted velocities and impedances are very good predictors of the measured values. However, there are some discrepancies found in the high frequency region. Also it can be inferred from these plots that the accuracy in the prediction of velocity and impedance is better for higher floors.

Sources of errors. The probable reason for the deviation at the higher frequency may be due shear softening of the floor slabs at higher frequencies. The predictions are expected to roll off at higher frequencies if a thick infinite plate model (Mindlin model) was used instead of a thin plate bending theory. Mindlin model accounts for shear deformation of the cross-section of the floor. Another source of error may be due to the bending phenomena that can be present in the column.

Impedance based model: advantages and limitations. The impedance based model, compared to the other approaches like finite element approach (which requires many more DOF at higher frequencies with greater cost and time to characterize an extended building structure), is simple, efficient, and provides a fast way to estimate the effects of vibrations induced by passing trains or other environmental sources.

In its present form however, the impedance based model cannot be used to predict the vibration induced in a building containing a staircase or opening in the floor slab or other kind of discontinuities and irregularities.

CONCLUSIONS AND FUTURE WORK

The impedance based model developed was verified with experimental results from a scale model building for longitudinal excitation of a building column. From the results and the observations, it can be concluded that:

1. The impedance-based model successfully predicted the velocity response of the scale model building at column locations.
2. These predictions are more accurate in the lower frequency region as compared to the high frequency region.
3. This method can be applied accurately to special cases where the train induced vibrations are mainly vertical in transmission to building columns.
4. Impedance-based modeling was used for prediction of train-induced vibrations in buildings.
5. Wave propagation models are highly efficient in terms of computation time required.

In the future, use Mindlin thick plate theory to improve modeling of the floor behavior. This model is expected to improve the accuracy of the predictions in the high frequency region. Shear deformations need to be included in the response in addition to bending deformations. Furthermore, full scale testing of a building will be performed for validations of the presented wave propagation method.

Future work also includes plans to test a full scale building during various stages of construction and fit-out. It is well known that non-structural elements can affect vibration measurements significantly. In fact, the inability to correlate basic models with real buildings at a level of acceptable accuracy, led to this study. This completed model study, will have a significant impact on future work in real buildings, helping to direct methods of measurement, and helping to discern the different effects of structural and non-structural elements.

ACKNOWLEDGEMENTS

The authors would like to thank Acentech Inc. for their volunteering time, expertise and equipment in every stage of this research. Thanks to Professor Babak Moaveni at Civil Engineering department at Tufts University for his advice and concern in this research. Also thanks to Tufts Faculty Research Awards Committee (FRAC) for their funding for this research.

Abstract

Floor vibration serviceability has become an area of interest over recent years. Lightweight electronic offices, especially those with slender architectural forms, and high-technology buildings with low vibration environments can often have excessive floor vibration due to human walking. This can result in a floor which is not fit-for-purpose. There exist a number of design guides which offer simplified formulae to analyse these floors. However, the simplistic methods are often shown in be inaccurate and inappropriate. The alternative, finite element analysis (FEA), which is often considered more accurate, can be expensive to implement and time consuming. In addition, modelling techniques required for dynamic analyses are different to that required for static analysis. This is often overlooked, resulting in poor inaccurate models. An accurate, simplistic, method is required which is suitable for everyday design.

This paper examines the current simplified methods of predicting floor response to a single human walking. The inaccuracies are highlighted, as well as where the methodology is inappropriate. The paper also introduces new techniques and ideas to improve design guides in the future.

Introduction

Vibration performance of floors subject to human walking is a relatively modern concern resulting from two main factors. Firstly, throughout the last century, modern advances in construction technology have allowed for floors in new constructions to become more slender, which leads to more economical, aesthetically pleasing, designs. In offices in particular, the increased slenderness is coupled with a reduction in mass applied to the floor due to a move from a heavy traditional office to a light-weight electronic paperless office, making the floors more susceptible to excessive vibration from walking. Secondly, advances in technology have resulted in increased use of high-technology electronic devices becoming common in our

everyday lives. Components in these computers and measurement devices (e.g. in hospitals) often have sensitive vibration criteria. Thus from the standpoint of both design, vibration serviceability often governs the design of floors, influencing the member sizes and structural layout more than strength requirements.

Currently, the most accurate and efficient method for determining the response of a proposed floor design is by extracting the modal properties using finite element (FE) analysis, and calculating the response with a characteristic force model or measured walking force. However, this process is time consuming and costly. It is desirable for a cost effective method of quickly and economically assessing the floor's vibration performance to human induced walking. A number of design guides have been published which use simplified procedures to calculate the response to walking based on the response of a single vibration mode.

Unfortunately, these guides tend not to be clear in their application and are not flexible in their methods. For example, if the structure is not a simple design with a uniform structural plan, the simple rules become complex, abstract and difficult to use. Moreover, they often prove to be inaccurate, predicting responses differing widely from those obtained using finite element analysis or from direct measurement in situ.

This paper focuses on application of and problems with using the AISC design guide. It begins by briefly describing how the guide recommends calculating the modal properties. It then continues to examine the force models recommended. One of the examples within the AISC design guide is then examined by comparing it with FE analysis and with a novel method of obtaining modal mass. At each stage, any inaccuracies in the guidance are highlighted, and where possible avenues of improvement are suggested.

Current design guides

There exist a number of design guides to aid in assessing a floors performance. The most recent ones in Europe and America are:

- AISC design guide 11: Floor vibrations due to human activity (USA) (Murray, Allen, & Ungar, 1997)
- ATC design guide 1: Minimizing floor vibration (USA) (ATC, 1999)
- SCI P354: Design of floors for vibration: a new approach (UK) (Smith, Hicks, & Devine, 2009)
- CC CCIP-016: A design guide for footfall induced vibration of structures (UK) (Willford & Young, 2006)
- Hivoss: Vibration design of floors (Europe) (Hivoss, 2007)

Each guide is similar in approach: calculate modal properties, apply a force and evaluate the response; however, there are small differences in the calculation methods, which can cause large differences in the calculated responses. Due to their similarities, the areas in which errors are introduced are common across the design guides.

AISC design guide 11

The design guide is split into a number of parts. It starts by giving an overview of vibration terminology and principles and continues to discuss acceptance criteria, which are beyond the scope of this paper. The guide recommends determining the fundamental modal properties for analysis and offers methods in their calculation. For walking excitation, there are then two methods of calculation, depending on the occupancy of the floor: design for walking excitation and design for sensitive equipment. There is also a section on rhythmic excitation and the guide finishes with remedial measures for vibration problems, both of which are not within the scope of this paper.

Mode shape and modal mass

Throughout the AISC design guide, first a floor mode must be determined before any modal property is calculated. An understanding of the assumed mode shapes is essential. In addition, as modal mass is defined by:

$$M = \int_{xmin}^{xmax} \int_{ymin}^{ymax} \phi(x,y)^2 m \, dydx \qquad \textbf{Equation 1}$$

where ϕ is a mode shape function in x and y, and m is a mass distribution function, modal mass is directly linked to the mode shape, and are therefore discussed together.

In the design guide it is recommended that there is likely to be a mode governed by the floor joists (left plot of Figure 1), a mode governed by the floor girders (right plot of Figure 1) or a combination of the two.

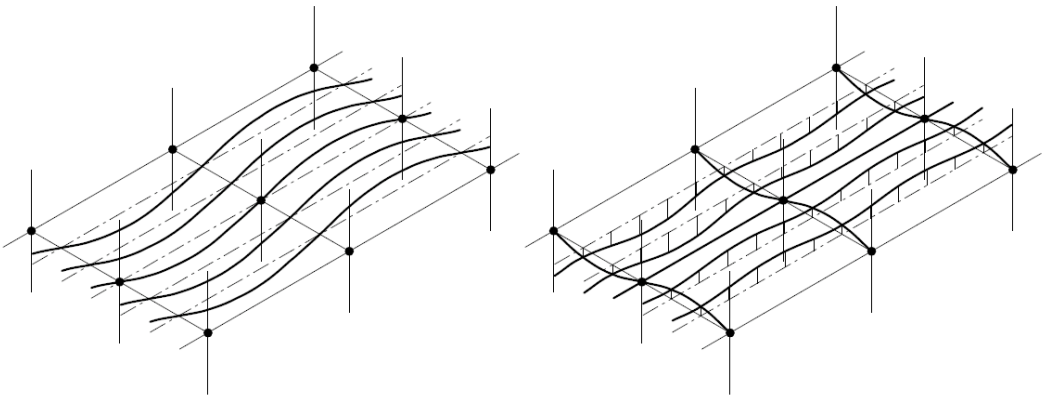

Figure 1: Joist (left) and girder (right) floor modes, illustration from SCI P354 (Smith, Hicks, & Devine, 2009).

One of the key assumptions in the AISC design guide is that partitions and non-structural elements will confine dynamic response to a localised region; i.e. only one floor bay needs to be considered and it will act as a two way slab. Finite element (FE) modal analysis of the whole empty structure, with many uniformly spaced bays, results in many closely spaced modes spanning the whole structure. The design guide recommends its simplified single panel approach over the FE analysis as it implies it is unlikely for the FE modes to exist. As this assumption would dramatically change the shape and area of a mode shape, this would also have a significant effect on the modal mass of the assumed mode. It is crucial to accurately determine the area of the floor participating in the response to calculate the modal mass.

Measured modal properties of a structure which includes partitions can be used to investigate the assumption the partitions constrain modes shapes. The left plot of Figure 2 shows the floor plan of an experimentally measured structure. The partition layout is clear, with the highlighted area showing the test area. In this case, most of the partitions are substantial heavy brick partitions. The right plot shows the first and third vibration modes, which span the whole test area and beyond. It is clear that the partitions do not break up these modes. There were also more localised modes, but a number of these also spanned partition lines. The localised modes contributed to the response more, but the global modes response was still significant enough to require consideration.

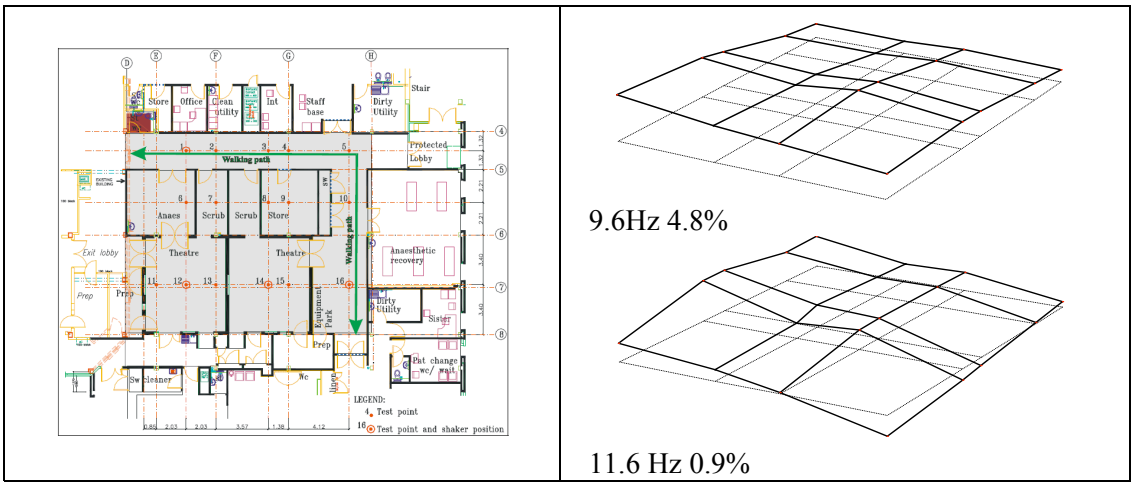

Figure 2: Partition layout (left) and the 1st and 3rd vibration modes (right) from a measured structure with brick partition walls.

The influence of partitions is not understood and is under-researched. Falati, in his PhD thesis (Falati, 1999), examined the contribution of partitions. He discovered:

- Contribution depends on if they are full height or cantilever.
- Contribution depends on their geometrical position to the mode shape.
- Full height partition acts as a flexible vertical support.

In addition to this, it would be possible to add some common sense assumptions:

- Lightweight partitions would have less influence than massive partitions
- Stiff partitions would have more influence than flexible partitions

Even trying to model partitions with finite elements is difficult due to the variability in stiffness of the connections as they are not structural. In the author's experience, partitions generally reduce the response, but to what extent is very situation-dependant. As it is difficult to predict how partitions will affect modes shapes, and in turn modal masses, it should be recommended that they are not included in the analysis, resulting in a slightly conservative response estimation.

In the AISC design guide, the modal mass is expressed as an effective panel weight:

$$W = wBL \qquad \textbf{Equation 2}$$

Where w is the distributed weight per m^2, L is the panel length and B is the effective panel width. This equation is common in all design guides, but generally it is expressed with mass, not weight. However, there are various methods of calculating B and L, but the origin of the methods is never clear or referenced. In the UK design guides it seems to be based on the beam frequency equation, empirically altered with parametric studies. In the AISC design guide it is based on a relationship between

relative stiffnesses of the structural members, but how this has been developed is not clear. It is commonly known that increasing the number of floor bays in the structure reduces the response. The AISC design guide includes this by stating: if there is an adjoining bay with a span 0.7 times this span the mass may be increased by 50%. It has been shown many times that modal mass estimations using the simplified methods are very inaccurate and are the biggest source of error in the design guides (Middleton & Brownjohn, 2007) (Middleton & Brownjohn, 2010).

Equivalent modal mass estimation

To facilitate improving the modal mass estimation methods of the design guides, a new method has been developed. This method is based on using the actual deformed shape of the vibration response to calculate a participating mass using Equation 1.

If a single bay is considered in both directions, there is generally only a single mode that needs to be considered in the analysis. As such, the shape of the response is the same as the mode shape, and this shape is very similar to the static deflection of the floor to a point load at the centre. If the static deflection is used in Equation 1, a participating mass can be found that is very similar to the modal mass.

The same idea can be applied to multiple bays. The top row of Figure 3 shows the first three modes shapes of a 3 bay structure. Each one of these modes pertains to the fundamental mode of a 1 bay structure, and as such have very closely spaced modal frequencies; in this case they are all within 0.5 Hz of each other. The bottom left plot of Figure 3 shows the initial dynamic response to an impulse applied in the centre of the middle bay. If this was animated it could be seen that this shape is preserved for a significant number of oscillations before the damping and geometrical distribution of the response effects it. It is clear that this shape is a combination of all three mode shapes, and as their frequency is closely spaced, they stay pretty much in phase for a significant number of oscillations. Due to this, it may be possible to approximate the response of the three modes using a single equivalent mode, with an equivalent modal mass. The bottom right plot of Figure 3 shows the static deflection to a point load applied to the centre of the middle bay. Again this deflected shape is very similar to the shape in the bottom left of Figure 3 and it may be used to approximate a modal mass for the equivalent mode.

For this structure the response seems to be confined to 3 bays. This is true even if the number of bays is increased and the mode shapes span the whole structure due to the way the modes sum. As such, with this structure increasing the number of bays further would not have a significant influence on the response. Interestingly, this agrees with the AISC design guides assumption that the response will be localised – but not due to non-structural elements and partitions, this is due to the support

conditions. It is likely that this is case specific and depends on the structural layout and member properties – the number of bays to consider would not always be 3.

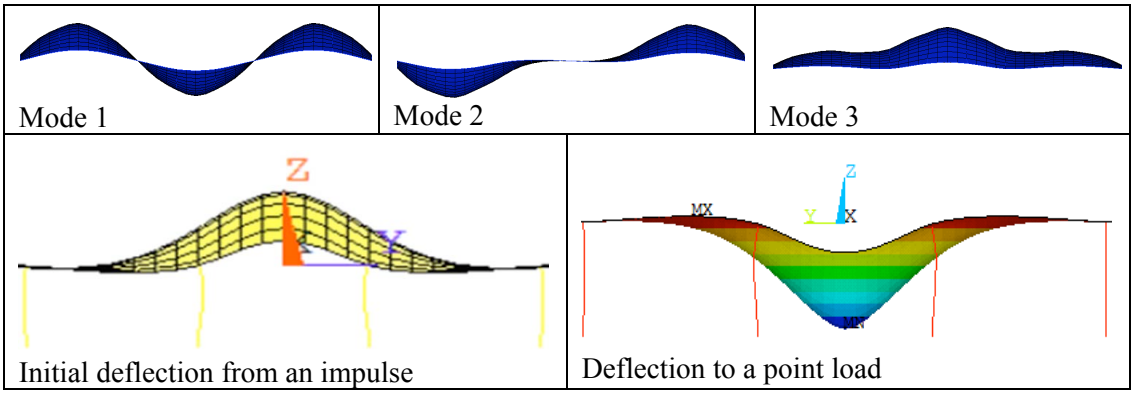

Figure 3: First 3 modes of a 3 bay floor structure (top row), the initial dynamic response to an impulse (bottom left) and the displacement to a point load at the centre of the middle bay (bottom right).

Fundamental frequency

The AISC design guide describes the fundamental natural frequency as the most important parameter in estimating the response and recommends its simplified procedure over modal analysis. The method presented is based on the two mode system shown in Figure 1; the frequency is calculated for the beam and girder mode separately, then a combined mode and the fundamental frequency is the lowest of the three.

The frequency is estimated from the static deflection due to self-weight plus any permanent live loads. In these calculations the design guide recommends increasing the static Young's modulus by a factor 1.35 due to small strains and to assume full composite action between beams and the slab. Although written in a slightly different form in the guidance, the natural frequency calculations are built up by first assuming the fundamental natural frequency of a beam as:

$$f_1 = \frac{\pi}{2}\sqrt{\frac{EI}{mL^4}} \qquad \textbf{Equation 3}$$

where is the Young's modulus, is the second moment of area, is mass per unit length . The deflection of the beam to a UDL is defined by:

$$\Delta = \frac{5}{384}\frac{mgL^4}{EI} \qquad \textbf{Equation 4}$$

where is acceleration due to gravity. Equation 4 can be substituted into Equation 3 to express the fundamental frequency in terms of deflection:

$$f_1 = \frac{17.75}{\sqrt{\Delta}}$$ **Equation 5**

which can be approximated by:

$$f_1 \approx \frac{18}{\sqrt{\Delta}}$$ **Equation 6**

where Δ is deflection in millimetres and can be defined as $\Delta = \Delta_j + \Delta_g$, where the subscripts j and g represent the joist and girder respectively. Each deflection can be considered separately to find the frequency of each mode, or both together to find the frequency of a combined mode.

The accuracy of the frequency estimate using this displacement approach depends on how well the static displacement matches the mode shape. This can be illustrated simply with a spring and mass system where the fundamental natural frequency can be defined as:

$$f_1 = \frac{1}{2\pi}\sqrt{\frac{k}{m}}$$ **Equation 7**

where k is the spring stiffness and m is its mass. The deflection of a spring to a load is defined by:

$$\Delta = \frac{mg}{k}$$ **Equation 8**

which can be substituted into Equation 8 to express the fundamental natural frequency in terms of displacement:

$$f_1 = \frac{1}{2\pi}\sqrt{\frac{g}{\Delta}}$$ **Equation 9**

Assuming a spring mass system with two masses in series, with equal masses and equal stiffnesses, the deflection can be defined as:

$$\Delta = \frac{2mg}{k} + \frac{mg}{k} = \frac{3mg}{k}$$ **Equation 10**

which, if substituted into Equation 7 to express the fundamental natural frequency in terms of displacement gives:

$$f_1 = \frac{0.5774}{2\pi}\sqrt{\frac{g}{\Delta}}$$ **Equation 11**

and the corresponding mode shape would be $x_1 = 1, x_2 = 1.5$. However, this is different from an exact analysis of a double spring mass system in series, which can be defined as:

$$f_1 = \frac{0.6180}{2\pi}\sqrt{\frac{g}{\Delta}} \qquad \textbf{Equation 12}$$

and the corresponding mode shape would be $x_1 = 1, x_2 = 1.618$. The discrepancy in result due to assuming the Equation 9 Is also suitable for a double spring mass system in series gives an error in frequency of approximately 6.5% due to the mismatch in mode shape assumption. If the spring approximation was used for a beam and plate the error would be approximately 11% and 22% respectively. The same calculation can be performed starting with the beam frequency equation and calculating the error for spring mass system and a plate, but it is not so clear to present. If the calculation is performed the error found is approximately 11% for both cases. This means that if the modal frequency is estimated using Equation 6, but the mode of vibration is predominantly a plate mode, an error of up to 11% may be introduced.

Modal damping

The AISC design guides states that until recently damping determined from filtered heel drop tests. The test were performed by performing heal drop, filtering out high frequency modes and estimating damping using logarithmic decrement. This method generally overestimated the modal damping and values ranging from 4-12% we reported. The over estimation was due to the contribution of closely spaced modes of vibration, which cause geometric dispersion of the response. When the response was filtered a number of closely spaced modes can still contribute to the response, but the separate contributions are not distinguishable in the time history response. Estimating the corresponding damping for each mode requires more sophisticated modal analysis techniques.

Damping cannot be modelled as easily as mass and stiffness; it is not related to the material properties of the structure, but derives from frictional forces in joint, connections and not structural elements (Jeary, 1985). As such, guidelines can be given for typical structures but these must be used with engineering judgement and the analyst's experience and are also amplitude-dependent. The AISC design guide recommends 2-5% for offices, 2% for shopping malls and 1% for footbridges. The large range for offices depends on its type (open plan, many partitions, traditional of electronic, etc.)

Force Modelling

For typical floors (e.g. office floors), the AISC design guide uses harmonic amplitudes from footfall forces:

$$F_i = P\alpha_i \cos(2\pi i f_p t) \qquad \textbf{Equation 13}$$

where P is the persons weight, α_i is the harmonic amplitude of the ith harmonic, f_p is the pace rathe in Hz and t is time. The values of α are given as 0.5, 0.2, 0.1 and 0.05 for the 1st, 2nd, 3rd and 4th harmonic respectively. The values of the harmonics reported in the literature vary significantly, and in any case are stochastic parameters that depending on pacing rate. A good overview is presented by Zivanovic (Zivanovic, Pavic, & Reynolds, 2005). Figure 4 shows the harmonic amplitudes for the first and second harmonic, each dot represents a different study. It is clear to see why the values have been disputed over the years. For the first harmonic, the amplitudes have a clear trend proportional with pace rate, although there is still a large degree of variation. For the second, and, although not shown, higher harmonics, the distribution is much more scattered and a line of best fit does not describe the data – it is clearly a random process. From Figure 4, one can conclude the AISC values are likely to be conservative. The problem with the harmonic method is that above the last significant harmonic (approximately the fourth harmonic) there is no force, so negligible response. As such, this method cannot be used to analyse modes above approximately 10 Hz

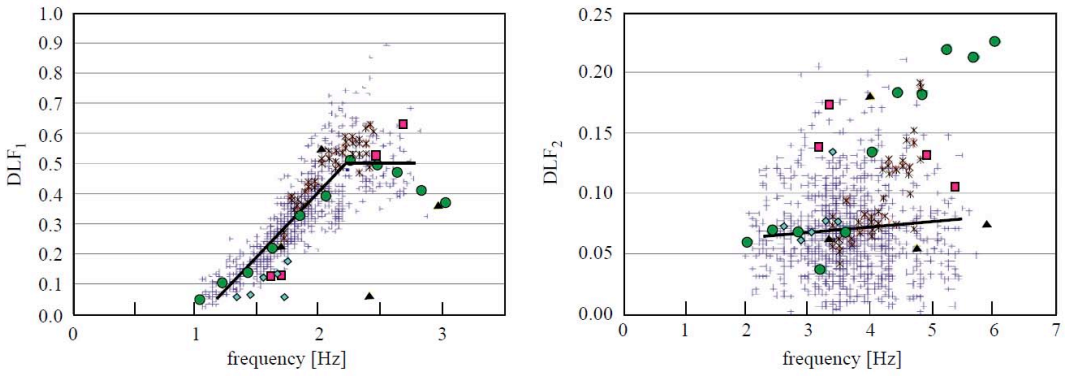

Figure 4: Harmonic amplitudes after Zivanovic (Zivanovic, Pavic, & Reynolds, 2005) for the first (left) and second (right) harmonic; each different type of dot is representing a different study. The solid line is a line of best fit.

For sensitive occupancies, the AISC design guide recommends using the kf method developed by Ungar (Ungar & White, 1979). The method is based on a pulse approximation of a footfall force, which is illustrated in Figure 5. It is assumed that disregarding the characteristic peaks and trough of a footfall force will only introduce minor errors.

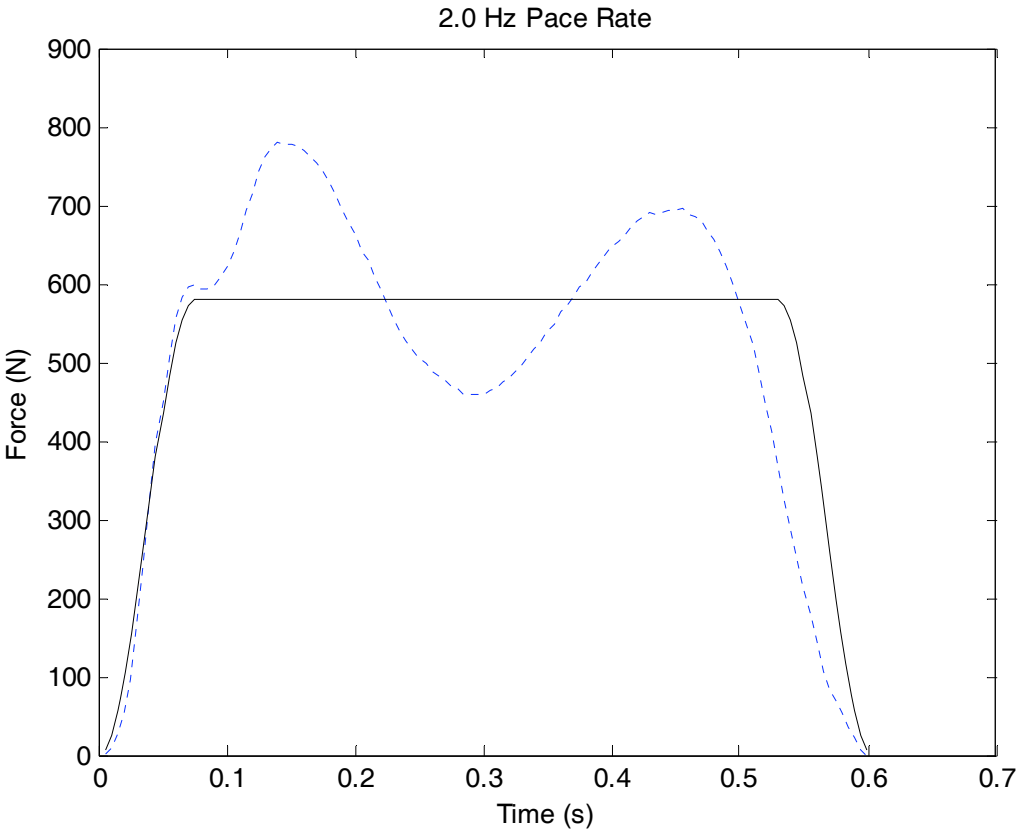

Figure 5: Measured footfall force (dotted line) with the idealised pulse over laid.

The analysis of the response is based on an amplification factor and static deflection. Although the presentation in the AISC design guide differs slightly, the velocity of the nth mode can be derived:

$$V = 2\pi f_n X_{max} \qquad \textbf{Equation 14}$$

where X_{max} is the maximum dynamic displacement and is given by:

$$X_{max} = \frac{F_m k f_0^2}{2 f_n^2} \qquad \textbf{Equation 15}$$

where F_m represents a person's dynamic force, k is the point stiffness of the floor and f_0 is related to a person's pace rate. If Equation 15 is substituted into Equation 14, the resulting velocity expression is:

$$V = \frac{\pi F_m k f_0^2}{f_n} \qquad \textbf{Equation 16}$$

which shows that an increase in the natural frequency will decrease the velocity. As frequency is related to stiffness and mass by:

$$f_n = \frac{1}{2\pi}\sqrt{\frac{k}{m}} \qquad \textbf{Equation 17}$$

reducing the mass, while the stiffness remains constant, will increase the frequency and reduce the response, which is intuitively incorrect. This method has often been shown to be inaccurate and non-representative of response to measured forces (Brownjohn & Middleton, 2008).

The reason for the inaccuracy with this method is shown in Figure 6. The kf method calculates the residual response considering no damping, i.e. the response after the duration of the pulse. The column on the left shows no damping with the top, middle and bottom row showing the force, velocity response of a 10 Hz oscillator and velocity response of a 15 Hz oscillator respectively. It can be seen that with the correct oscillator frequency, the residual response can be 0. This does not happen in the design guide as the exact amplification factor is fitted with a crude curve for the remainder of the calculation. The right column shows the response with 3% damping. It is clear that this considerably changes the response. In addition, Figure 7 shows the response of SDOF oscillators to a measured walking force. The response is clearly very different to that of the idealised pulse in Figure 6. The response of kf method does not represent the characteristic response from a walking force, and as the method disregards the response during the force (which is important in the response) it is recommended that this method is not used

The response of the 10 Hz oscillator is not intuitive and may require some further explanation. In this method the rise of the pulse is defined with a sine wave, and in this example the period of that sine wave (the rise time) matches the period of the oscillator. If displacement is considered, the oscillator would displace with exactly the same shape as the pulse force. It displacement increases with the rise and would halt at the plateau – there is no momentum and the restoring force is balanced by the static force of the pulse's plateau. The plot in Figure 6 is the velocity, which is simply the displacement response differentiated

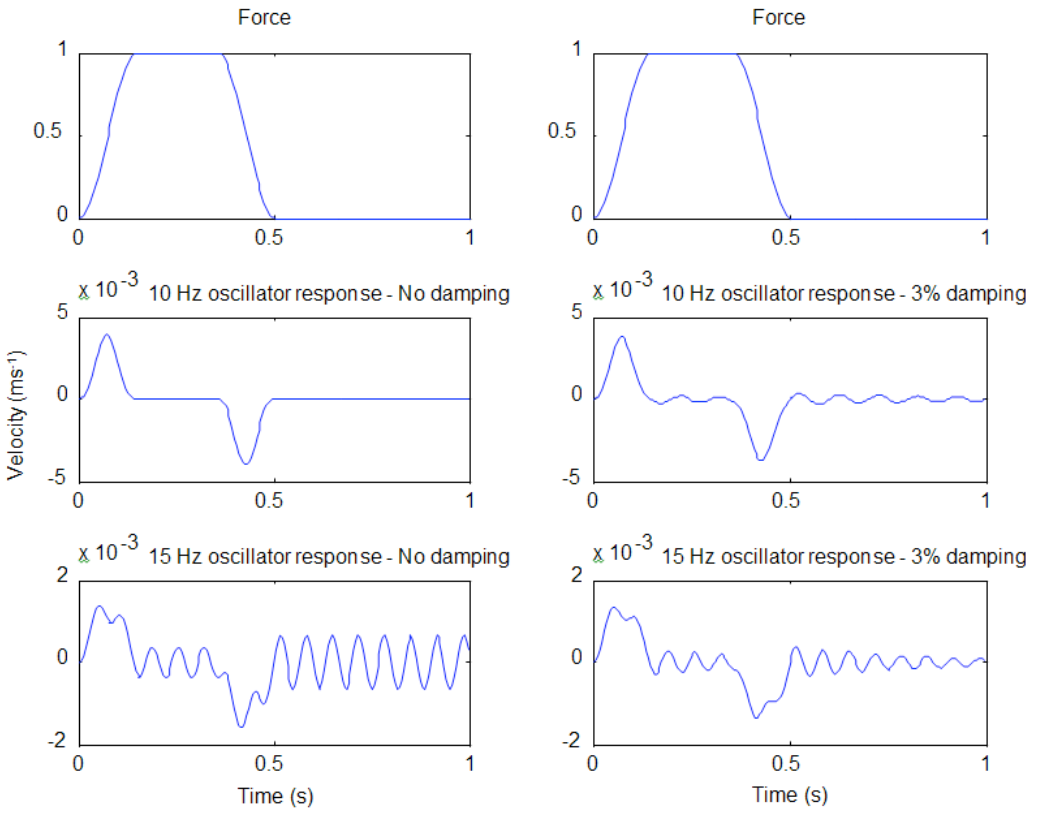

Figure 6: Velocity response of the idealised pulse. The left column is with no damping and the right column is with 3% damping. The top row is the force, the middle row is the response of a 10 Hz oscillator and the bottom row is the response to a 15 Hz oscillator.

The AISC design guide categorises floors by the occupancy. For office floors, it recommends using the harmonic method, which is only suitable for modes up to approximately 10 Hz. For sensitive floors it recommends the kf method for all frequencies. It does not make sense that there should be an overlap of frequencies, if the harmonic method is accurate below 10 Hz, then it should also be suitable for sensitive occupancies. Indeed, if a force model is accurate and characteristic of a walking force, it should be suitable for all cases.

As the response of a floor changes from a resonant response to a transient response (illustrated in Figure 7) after the fourth harmonic, a more logical step is to have a difference force model depending on floor frequency. This split is present in the UK guidance; floors are known as low frequency floors (LFFs) when the response with resonance to walking and high frequency floors (HFFs) when they response transiently. For high frequency floors, the force model used is the effective impulse developed by Arup (Willford, Field, & Young, 2006).

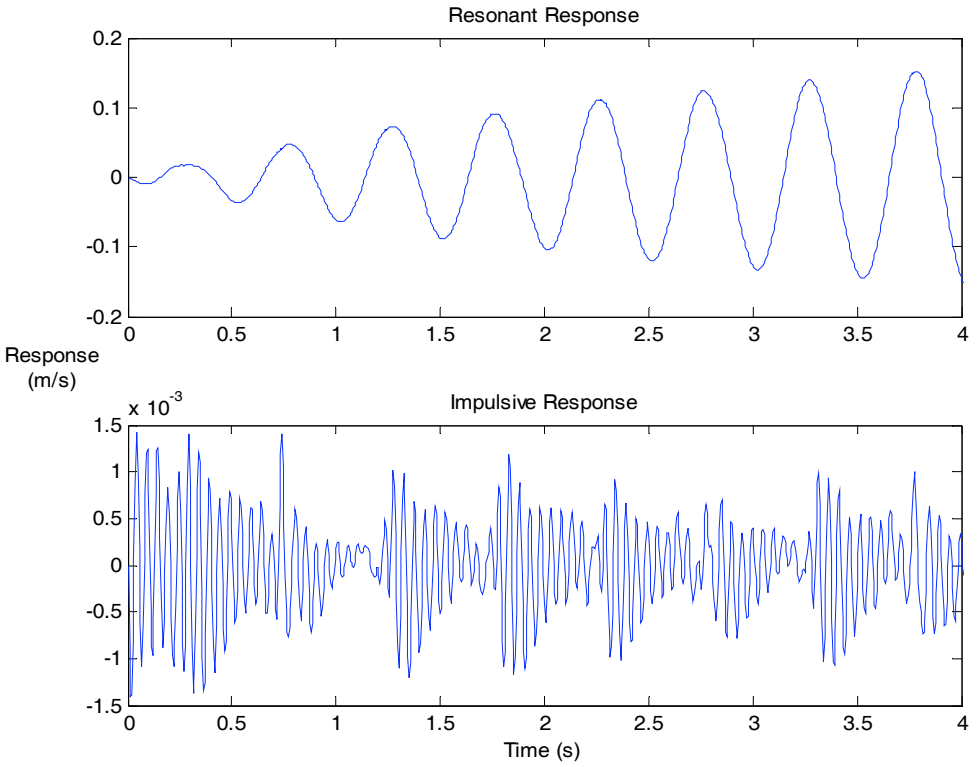

Figure 7: Low frequency (top) and high frequency (bottom) floor response to a measured force with a 2 Hz pace rate.

The effective impulse is based on the velocity response of a mass to a given impulse, which is defined as:

$$V = I/M \qquad \textbf{Equation 18}$$

where V is the velocity of a body, M is its mass and I is the impulse applied in Ns^{-1}. If the mass is set to 1, it can be seen that the resulting velocity is equal to its impulse. To obtain the effective impulse values in the design guides, measured walking forces were applied to a SDOF oscillator with a known frequency and unit mass. The resulting peak velocity is equal to an impulse that would give the same peak velocity, and is termed the effective impulse of the force. The procedure was repeated at different oscillator frequencies. As an impulse is representative of an instantaneous force, it is not suitable for resonance. Arup performed these analyses for a range of pace rates and oscillator frequencies and curve fitted the results. The empirical expression for the effective impulse with a 25% chance of exceedance is given by:

$$I_{eff} = 54 f_p^{1.43} / f_n^{1.3} \qquad \textbf{Equation 19}$$

This method has been shown to be reasonably accurate (Brownjohn & Middleton, 2008), and much more so than the kf method for HFFs. A simple test of the accuracy

can be obtained by comparing the response of an SDOF oscillator to the measured force against the response from the corresponding effective impulses.

Although Arup recommend analysing the response to just one pace, in reality there would be multiple paces. Multiple paces will be used in this example as it is more realistic. The left plot in Figure 8 shows the response of a 15 Hz SDOF oscillator to a measured walking force with a 2 Hz pace rate. This force was generated using an instrumented treadmill with metronome-prompted walking. This gives the most stable pacing rate possible, however variation does still exist. The middle plot shows the response to the corresponding curve fitted effective impulse, but with the pace rate variations kept. The characteristics of the response have been preserved, including the larger response towards the end of the signal. The plot on the right shows the response with the impulses at exactly 2 Hz, with no variation. In this case the characteristics of the response have been removed, and the peak response at the end of the signal has been eliminated. This demonstrates that not only does the force of an individual step need to be modelled appropriately, but so does the variation in timing between successive steps. This would also vary the harmonic amplitudes.

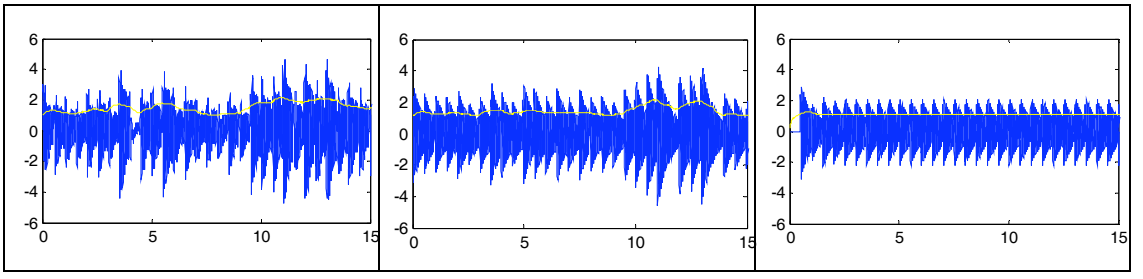

Figure 8: 15 Hz SDOF oscillator response to a measured walking force time history (left), effective impulse including pace rate variation (middle) and the effective impulse without pace rate variation (right).

With the two force models that depend on floor frequency, it is possible to calculate much more accurate responses, but as was shown, these force models are not perfect. In addition, having two models is not ideal. For lightweight floors there often exist low frequency global modes, and at high frequency, low mass local modes, with both contributing significantly to the response. Ideally, a universal force model would be appropriate, that includes variation in pace rate.

Comparison of FE analysis Vs. AISC design guide 11

To assess the accuracy of the AISC guide, example 4.3 presented in the guide will be analysed with FE analysis and with the modal mass from displacement of a point load. In the example only one bay is described, but it is implied that it is continuous over the supports. As such, the floor will be considered as 1x1 bay, 3x3 bay, 5x5 bay, 7x7 bay, 9x9 bay to see how the structural size changes response and modal

properties. Columns have not been modelled, but pinned supports have been applied, which is more in keeping with the design guides calculations, however it is commonly known that columns may have an influence on the response (Middleton & Brownjohn, Response of high frequency floors: A literature review, 2010). The 1x1, 3x3 and 5x5 bay models are shown in Figure 9.

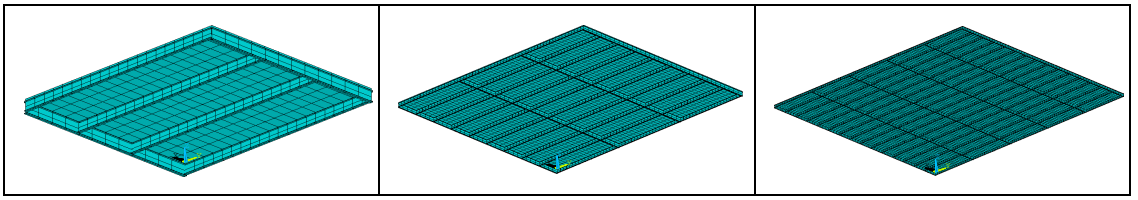

Figure 9: Underside of the FE model showing the beam locations for the 1x1 bay (left), 3x3 bays (middle) and 5x5 bays (right) models.

For each model, the FE model modal properties are extracted for the mode grouping that pertains to the first mode of a single bay. As this example is concerned with accuracy of the modal properties, not the force, the response is calculated with a unit impulse to remove any errors introduced by force assumptions in the guidance. This impulse is applied to the centre point of the middle bay and the response will be calculated assuming 3% damping.

Table 1 shows an overview of results for the 1x1 bay structure and Figure 10 shows the response time histories of the impulse excitation. It is clear that the frequencies are not too different, with a maximum of 0.75 Hz between the AISC design guide and FE analysis. However, when considering the modal mass the AISC design guide value is approximately 5 times more that from the FE analysis. This translates to the response being considerably underestimated. However, the modal mass calculated using the static deflection is very similar to value from the FEA modal analysis.

Table 1: Results comparisons for AISC design guide, FEA and modal properties from static deflection.

	AISC Example	FE with modal analysis	From static load deflection
Fundamental modal frequency (Hz)	4.15	4.9	4.6
Fundamental modal mass (kg)	46800	8500	8200
Peak velocity from 1N/s impulse (m/s)	0.23×10^{-4}	1.17×10^{-4}	1.23×10^{-4}

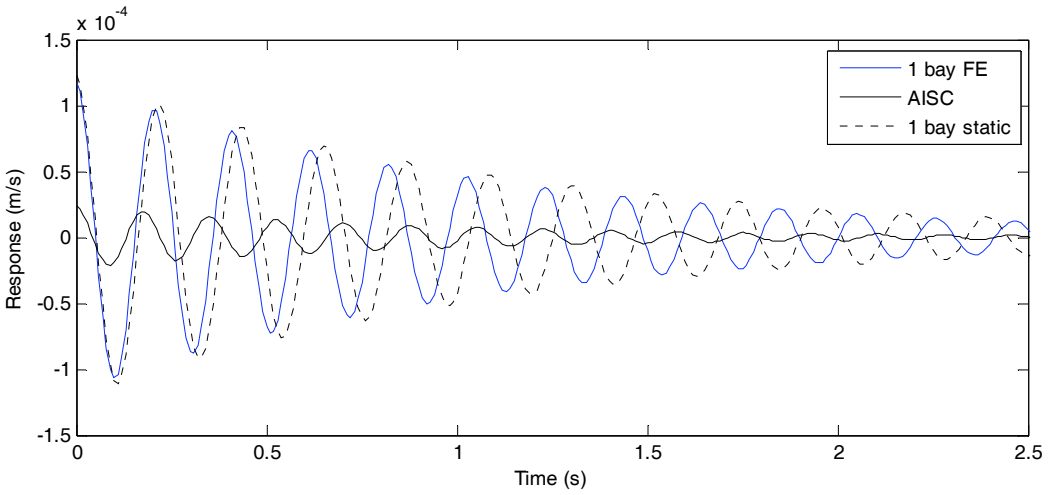

Figure 10: Time history response for the 1 bays structure for each analysis technique

The left plot in Figure 11 shows how the fundamental natural frequency changes with increasing bays using FE modal analysis and static deflection from the FE model. In both cases the frequency increases, but interestingly (although not shown here) if columns are modelled the frequency decreases. The right plot shows the % difference between the modal analysis frequency and the frequency calculated with deflection using Equation 6. Interestingly the maximum error is approximately 11 %, which is close to the maximum error when calculating natural frequency with the beam equation but using displacement from a slab. One example is not conclusive, but this indicates why there is a discrepancy in the frequency results.

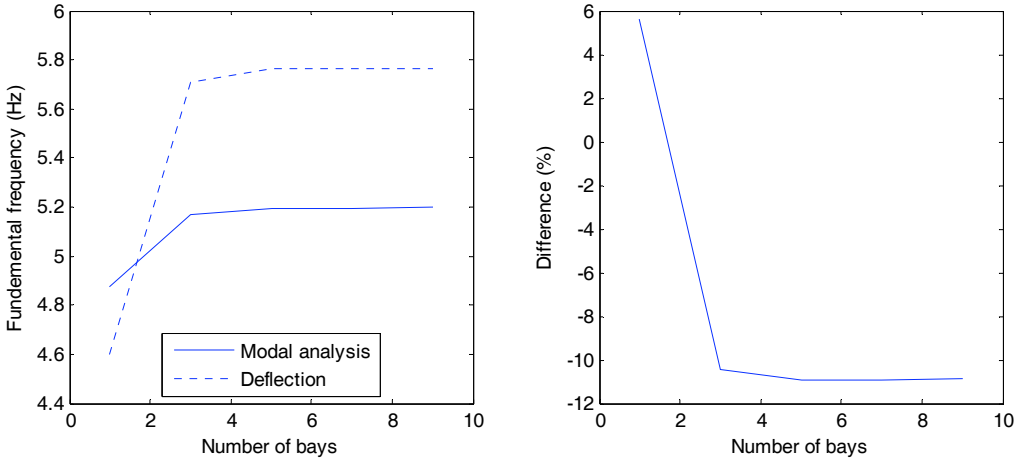

Figure 11: How fundamental natural frequency changes with increasing bays (left) and the difference in the calculation methods (right).

Figure 12 shows how the peak velocity changes due to the impulse with the number of increasing bays. In this case, the response approximately halves between 1 and 3 bays. As the response to an impulse is proportional to the mass, this means the mass participating in the response must approximately double – much more than the AISC design guide's 50% increase recommendation. In this case, after 3 bays there is no significant reduction in response with increasing the number of bays.

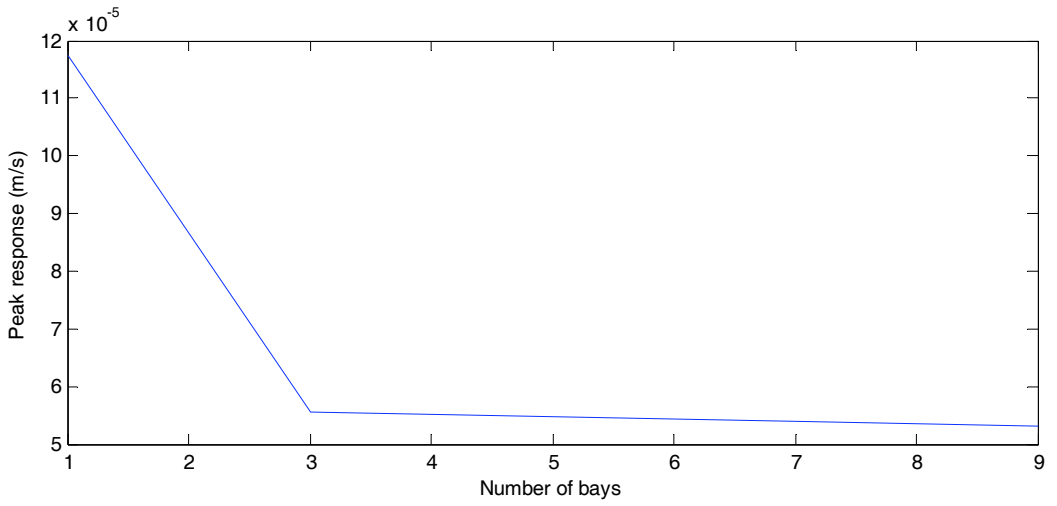

Figure 12: Peak velocity response from the unit impulse with increasing bays.

Figure 13 shows the time history response for the AISC and modal FE analysis overlaid. Due to such a large overestimation in mass, the AISC response is lower than all the FE responses, even for the largest structures. Another interesting point is that although there is a large number of closely spaced modes, the response of all the time histories appear to be dominated by one frequency. If the response of the 3x3, 7x7 and 9x9 bays are compared to the AISC design guide it is clear that they decay much quicker although they were all analysed with 3% damping. This is due to the geometrical spread of energy.

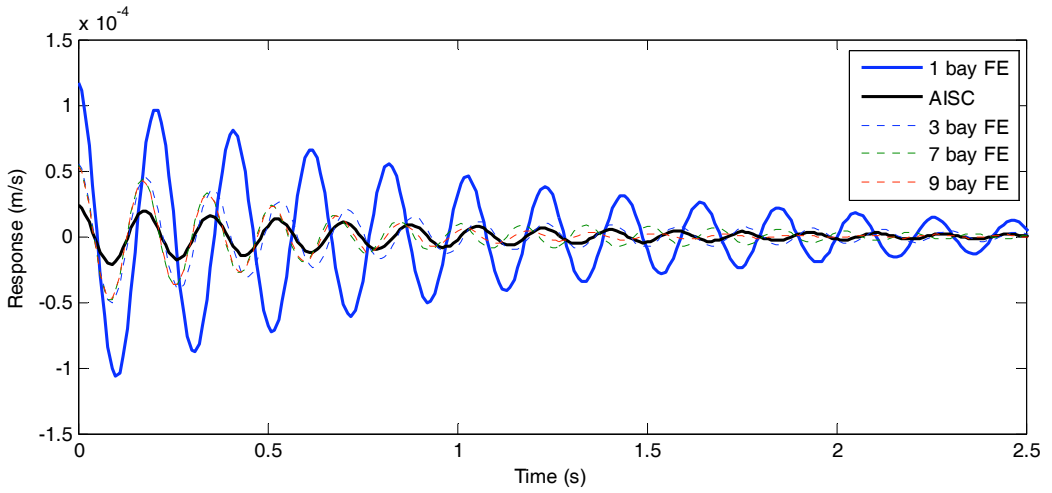

Figure 13: Time history response for the AISC and modal FE analysis overlaid. The lines for the 1 bay analyses are made thicker for clarity.

Discussion and conclusions

Although only AISC design guide was assessed in this study, all guides have similar inaccuracies in estimating modal properties, especially with modal mass. All design guides have similar procedures and calculations and it was shown that their methods are not always appropriate for assessing floor vibration response, especially for multi-bay structures.

The response of multi-bay structures is made up of many modes, but because the frequencies are closely spaced the total response appears to be dominated by one single frequency, but with a higher damping ratio due to the geometrical spread of energy. The individual closely spaced modes span the whole floor area, but the summed response results in a localised response. It appears that the combined response of all the modes is similar to a single localised mode. It seems plausible that the simplified method in the design guides based on a single mode of vibration may be able to represent accurately the response of large floors if a set of equivalent modal properties can accurately be determined. For this an equivalent mass, frequency and damping ratio is required. This paper has shown a possible method which provides a reliable equivalent mass and has shown where errors in frequency maybe introduced, although damping estimation has yet to be addressed. Past results from heel drop tests, which overestimated the damping ratios may actually be useful. Although the damping values do not match each individual mode found in a modal analysis, they may be appropriate in determining the response of an equivalent mode. Ideally, the reduction in response due to the geometric effects should be calculated and added to an appropriate damping value. Ironically, if the work within this paper is validated further, simplified floor design may do a full circle. Originally

(unintentionally) geometric damping was included in the analysis, this was then removed as it was not modal damping. One mode was always used in the response calculations, but recently the design guides have proved to be inaccurate and multi-modal analysis using FE was recommended. With the results in this paper, it may be possible to represent a number of closely spaced modes as a single mode, and if geometric dispersion is included in the damping ratio, the response is very similar to a multi-modal response. However, this time round, an appropriate equivalent modal mass is required.

Even if modal properties can be accurately determined, or if an equivalent mode can be obtained, the results are meaningless if there is not an accurate and appropriate force model. The current state-of-the-art is to have different force models for different floor frequencies. This indicates that neither model truly models the walking force. It is desirable to have a single model, which is suitable for all floors, and all structures subject to human walking.

A floor should not have a binary pass or fail, the very nature of the analysis is stochastic and should be reflected in the guidance. There is a large degree of randomness of a walking force, not only between different people, but with each step of the same person. In addition, the modal properties of the floor are not fixed. Modal analysis gives a linear fit of a non-linear structure. All structures have amplitude dependant frequency and damping. Finally, classifying a floor with a maximum response may not be characteristic of the floor. If that response is only for 5% of the floor area, it may still be acceptable.

The aim of this paper was to highlight common inaccuracies in all design guides, and to suggest possible avenues for improvements. In addition, the whole procedure of analysis and classification of the floor was discussed. Although the study presented here is large enough to be conclusive, it should serve as an indicator for future research.

ABSTRACT

Improved design methods have led to the use of more slender structural elements in the construction of many newly built structures, especially office floors. These floors satisfy ultimate limit state criteria but can attract complaints arising from excessive human-induced vibrations. Active vibration control is a technology that has been shown to significantly reduce the level of response in this situation. This paper investigates the potential increases in slenderness and associated materials savings that can be realised whilst adhering to the vibration serviceability limits through the implementation of an active vibration control system. The decentralised control setup used was found to realise significant material savings whilst still achieving desirable vibration performance.

INTRODUCTION

Floor vibrations in structures such as offices can cause disturbance and annoyance to occupants if they are sufficiently large (Hanagan, 1994; Hanagan et al., 2003; Setareh and Hanson, 1992). Advances in structural design methods have permitted more slender elements to span long distances in office structures, while meeting ultimate limit state (ULS) and deflection requirements. Furthermore, there has been a trend of employing more open-plan office layouts which have inherently less damping than traditional compartmentalised offices with full height partitions (Díaz et al., 2009; Hanagan, 1994). Consequently, these slender and open-plan structures tend to be more prone to excessive vibrations resulting from human activity. Previously, this has typically meant that floors must be designed stiffer and more

massive than ULS requirements require or that the column/beam layout must be modified to correct this problem.

Active vibration control (AVC) has been shown to have great potential for reducing the level of vibration in floor structures (Hanagan, 1994; Nyawako and Reynolds, 2009; Díaz and Reynolds, 2009, 2010). It is proposed in this paper that AVC can be incorporated at the design stage to avoid the increases in member sizes that would otherwise be required to meet vibration performance criteria.

This paper begins with an analysis of the vibration performance of a range of composite steel/concrete floor systems of differing slab thicknesses and a comparison against vibration serviceability criteria. Following on from this, the effect of utilising an AVC system on each floor system is examined. The results from this are then presented and conclusions drawn.

STRUCTURAL MODEL

A Finite Element (FE) model of a typical office floor has been developed using the commercially available software ANSYS (ANSYS, 2000). The layout of this steel-concrete composite structure has overall dimensions of 45m x 24m, based on a column grid of 15m x 6m, as shown in Figure 1. Primary beams span 6m between columns and secondary beams span 15m between columns and primary beams. A composite steel/concrete slab spans 3m between the secondary beams.

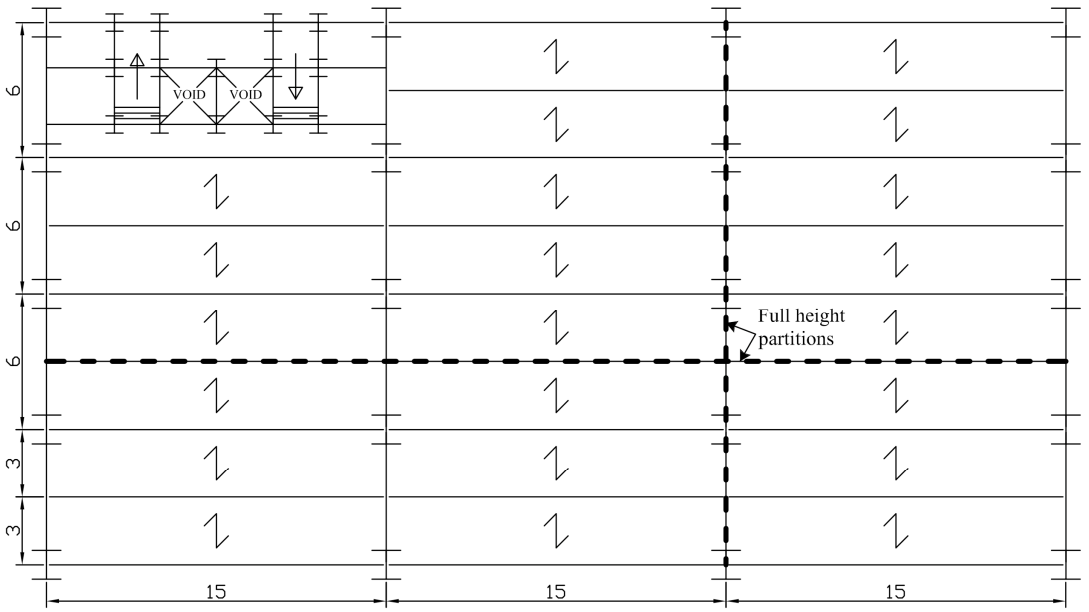

Figure 1 - Structural layout for FE model

This type of regular bay structure tends to have modes that involve movement throughout the whole floor plate. This feature yields modes with large modal mass which reduces the amplitudes of vibration. Real structures tend to have irregularities

that break up this regular grid and so have more localised modes. A lift shaft and staircase have been incorporated into the structural model to simulate this. Additionally, 2 full-height glass partitions physically connected to the floor and ceiling above have been modelled to further break up the global modes into more localised modes to make the modes more realistic for a building of this size (indicated as thick dashed line on Figure 1).

Asymmetric cellular beams were used as long-span beams because of the long distance these relatively light members can span. This is a typical feature of many modern office floors. Initial member sizes were designed through ULS and deflection requirements using a 130mm slab depth. This resulted in a secondary beams size of 748 x 152/210 x 72.2 ACB and primary beams size of 457 x 191 x 74 UB. These beam elements were modelled using BEAM44 elements so that the connection with the floor slab could be simulated through an offset (Smith et al., 2007). BEAM44 elements are uniaxial with tension, compression, bending and torsion capabilities (ANSYS, 2000). The floor slab itself was modelled using orthotropic SHELL63 elements; the change in thickness of the profiled slab was modelled by reducing the Young's modulus in the weaker direction while maintaining a constant slab thickness and (reduced) density. All connections were assumed to be fixed, an assumption that is generally valid because the vibrations caused by human excitation result in only small deflections that are not sufficient to cause significant rotation at joints (Pavić and Willford, 2005). SHELL63 elements were used to model the staircase floor and lift shaft walls, assuming concrete plates of thickness 300mm and 150mm respectively. The partitions were represented as a series of 1m long vertical BEAM4 elements with only axial stiffness of 1.0×10^8 N/m per m width (Miskovic et al., 2009). The resulting FE model is shown in Figure 2.

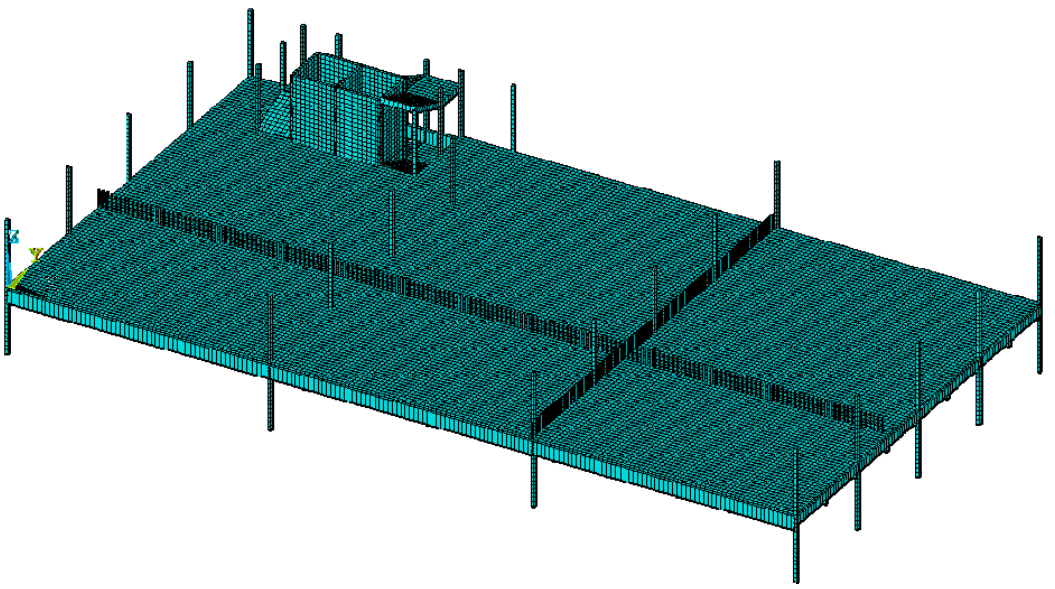

Figure 2 - FE model of structure

RESPONSE PREDICTION

The vibration performance of this structure was predicted and compared against typical vibration limits placed on office floors. Here, the Response factor, R, is used to quantify the level of vibration in the structure – this is a scalar multiple of a baseline response of 0.005m/s^2, which is close to the threshold of human perception. For quiet offices, an R factor limit of 4 is often recommended (Smith et al., 2007).

The response factor was calculated using real walking force time histories at pacing frequencies between 1.6Hz and 2.2Hz. The structural properties were modelled using the modal data extracted from the FE model with assumed modal damping of 2.5% for every mode. This damping value lies within the range recommended by the SCI P354 guidelines (Smith et al., 2007) of 1.1% for floors with only a small amount of furnishings and 3.0% for fully fitted out floors. The large areas of uninterrupted office space present here mean that the floor system is unlikely to develop modal damping as if fully fitted out, hence the slightly reduced value of 2.5% damping has been used. All modes up to 30Hz were considered even though the lowest mode had a natural frequency of 5Hz. This is a considerably higher cut-off than current guidance (Pavić and Willford, 2005; Willford and Young, 2006; Smith et al., 2007) recommends, since recent research (Živanović and Pavić, 2009; Middleton and Brownjohn, 2010) has shown that the division of floors into "low frequency" and "high frequency" can lead to a significant loss of accuracy by omitting the important contributions from some modes. The response analysis was performed using a modal superposition method to calculate the modal forces from pedestrian and the control system at different physical locations, as discussed by Hudson and Reynolds (2010).

The response factor was calculated over a 2.5m x 1m grid encompassing the whole floor structure, with the stationary pedestrian force applied and the response evaluated at each grid point. The results of this calculation for the initial floor system (with slab depth of 130mm) are shown in Figure 3a. Note that a non-linear colour mapping has been used here – the lighter areas indicate areas where $R<4$, while the darker areas indicate areas where $R\geq4$. The shading has been generated through interpolation from the response at the grid points.

It is observed that the response for this initial floor exceeds the limit of R=4 in many areas, so the floor design must be modified. A larger slab thickness was modelled because this makes the structure more massive which tends to reduce the amplitude of vibration. Furthermore, the increase in lateral stiffness acts to increase the global nature of the modes, further increasing the modal mass. The depth of the slab was therefore increased in 20mm increments in an attempt to reduce the response. The steel beam sizes were not increased, both for simplicity and because a preliminary ULS and deflection check indicated that the increase in composite action due to the increased slab depth was sufficient to cover the increased loading. The response factor results for these floor systems are indicated in Figure 3b-e and in Table 1.

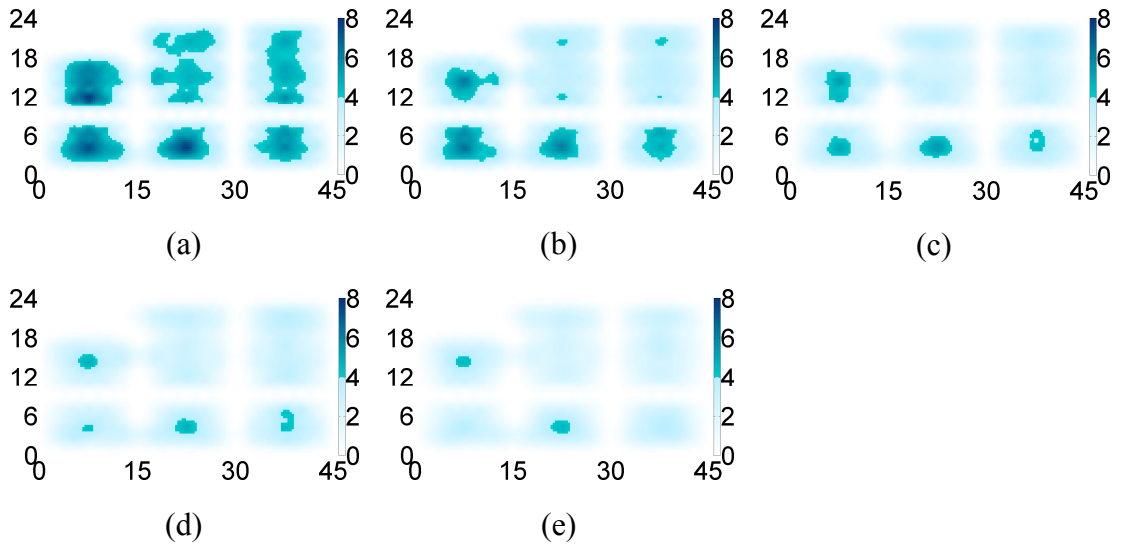

Figure 3 - Response of uncontrolled floor subject to human excitation with varying slab depth: (a) 130mm, (b) 150mm, (c) 170mm, (d) 190mm, (e) 210mm

The response of the floor only becomes acceptable in the majority of locations when the slab is increased to 210mm depth, and even at this depth there are still areas that exceed the R factor limit. However, as the R factor does not exceed 4 by a large amount or over large areas of the floor, it is considered unlikely that this would result in adverse comment.

Table 1 - Increases in R factor for various slab depths

Slab depth (mm)	Maximum R factor	Percentage of floor exceeding R=4 (%)
130	7.6	22.7
150	6.5	9.1
170	5.5	2.9
190	4.7	1.5
210	4.5	0.8

CONTROL SYSTEM

The AVC system comprises of 3 key components as shown in Figure 4: accelerometers to measure the response of the floor; actuators to apply a control force to the floor; and a controller to generate the input voltage to the actuators as a function of the response measured. The accelerometers and actuators are often collocated to avoid instability complications arising from additional phase-lags introduced in non-collocated implementations (Preumont, 2002).

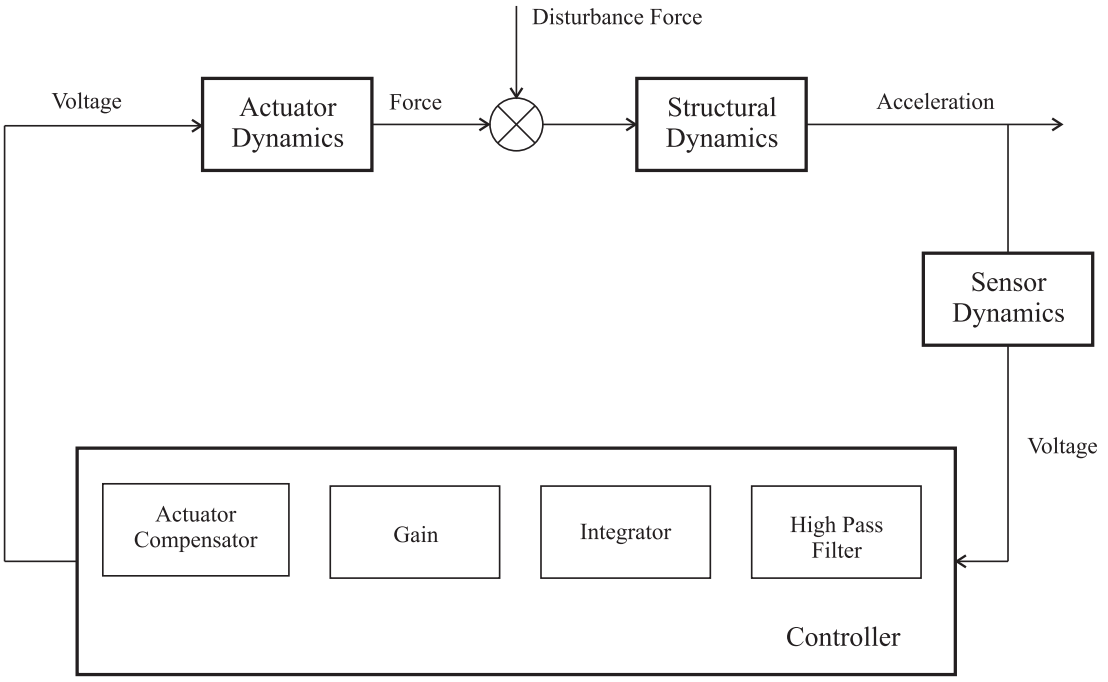

Figure 4 - Active control schematic

The actuators modelled in this study were the APS Dynamics Model 400 electrodynamic shakers that have been used in previous AVC experiments (Nyawako and Reynolds, 2009). The dynamics of the actuator have a significant effect on the performance of the AVC system; indeed, it is often one of the poles relating to the actuator dynamics that first becomes unstable as the feedback gain is increased. These dynamics were modelled by a third order transfer function – a combination of a second order spring-mass-damper model and a first order lag term that is caused by virtue of working the amplifier in 'voltage mode'. The resulting transfer function was thus approximated as (Nyawako and Reynolds, 2009):

$$\frac{F(s)}{V_{in}(s)} = \frac{-ws^2}{s^2+2\zeta_a\omega_a s+\omega_a^2 s} \cdot \frac{1}{s+\epsilon}$$

where: $F(s)$ is the force output from the actuator, $V_{in}(s)$ is the voltage input to the actuator, w is the force voltage characteristic for the actuator, s is the laplace

operator, ω_a is the natural frequency of the actuator, ζ_a is the damping ratio of the actuator and ϵ is a constant representing the lag in the voltage mode.

Direct velocity feedback with a compensator to account for the actuator dynamics was used as the control law in this study. The response of the structure was measured in terms of acceleration so the signal required integration to yield velocity. The accelerometers used in experimental work often have an offset due to the earth's gravitational field or signal conditioning electronics, hence a high pass filter is required to remove this constant before integration. This filter was modelled as a 2nd order high-pass Butterworth filter with a cut-off frequency of 1Hz. In addition, a compensator was designed to limit the detrimental dynamics introduced by the actuator.

This floor system has many modes of vibration that are locally spatially distributed. This means that there is no single point that can control and observe the vibration resulting from all the modes that are excited by human excitation. One possible solution to this problem is to use several actuators distributed across the structure, each acting independently to reduce the response at that location – a decentralised controller (Skogestad and Morari, 1989) – as shown in Figure 5. Whilst this cannot offer the capability of a 'full MIMO' (multiple input – multiple output) configuration, where the actuator voltages are computed as functions of the response at multiple locations, it does have the advantage of a simpler and more intuitive design process as well as being easier to make failure tolerant (Skogestad and Morari, 1989).

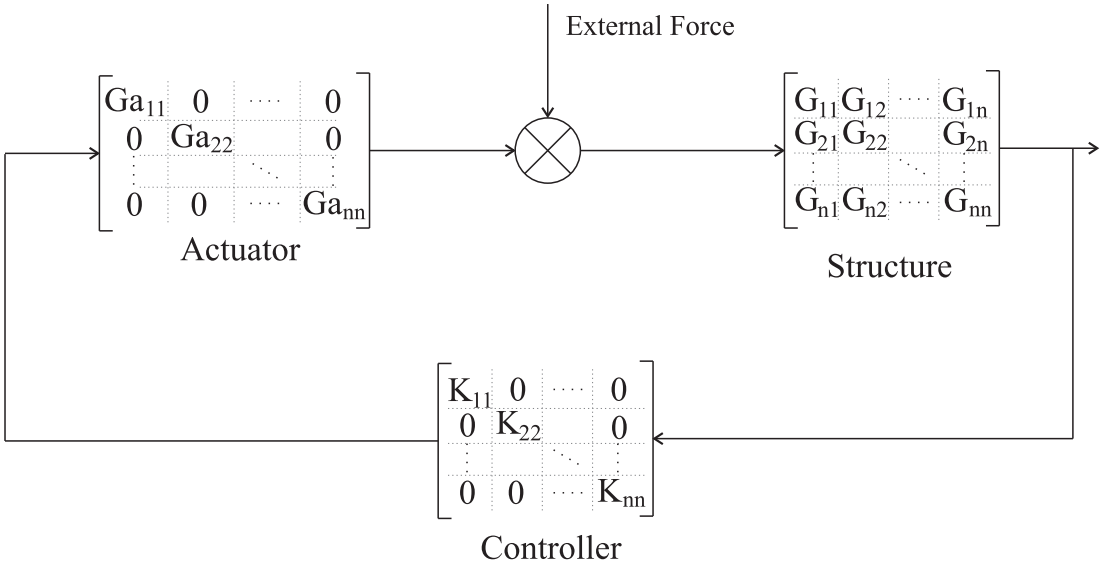

Figure 5 - Decentralised control setup

The design of a decentralised controller involves two main steps – 1) the choice of input/output pairings and 2) the design of each SISO (single input, single output) controller (Skogestad and Morari, 1989). Here, the input output pairings are intuitively chosen as the collocated actuator and sensors. With regards to the second

step – it is important to note that stability of the individual SISO loops does not guarantee stability of the overall system because of the interaction with off-diagonal terms in the structural system (Vaes et al., 2005). This means that a MIMO stability check is required; the generalised Nyquist criterion (Skogestad and Postlethwaite, 2005) was used here. Ensuring failure tolerance within the system was beyond the scope of this paper, thus the design process was simplified to one of ensuring stability while considering all control loops. Here, optimal gains for each SISO collocated actuator sensor setup were chosen to be the maximum gains that ensure at least 6dB gain margin and 30° phase margin. When combined in the MIMO setup the gains for all loops were modified by an equal percentage until the same stability margins were met in the MIMO case.

The difference in modal properties for each of the 5 floor systems means that the suitable locations of actuators and sensors differ. For this reason an actuator placement study was performed for each of the floors, the results of which are shown in Figure 6.

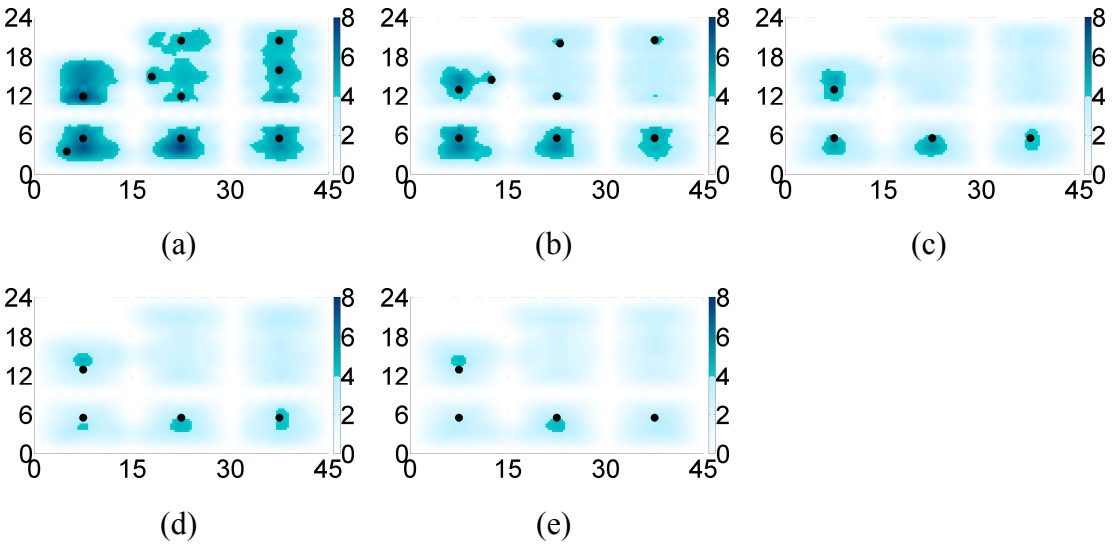

Figure 6 - Actuator locations (shown as black dots) with uncontrolled response shown as shaded

It is interesting to observe that floor system (e) required 4 actuators while the uncontrolled response was high in only 2 locations. The reason for this is that when only 2 actuators were used at the locations of large response an increase in the response at the other locations was observed. This is likely due to the off-diagonal terms in the structural system; these have an unquantified effect on the control system because they were neglected during the design of each SISO controller. Whilst the MIMO system was checked for stability, crucially, it was not checked for performance improvements. The μ-interaction measure (Grosdidier and Morari, 1986) could be used to ensure nominal performance. However, for simplicity in this paper the extra actuators were utilised as shown in Figure 6e.

RESULTS

The response factor was calculated for all 5 floor systems with AVC applied as described earlier, with the results shown in Figure 7.

The maximum response for all floors is greatly reduced. Some of the floors had small areas whose response was slightly greater than R=4. However, these small areas could be unlikely to cause adverse comment, as was also the case for the best-case uncontrolled floor. Indeed, the maximum response for the 130mm controlled structure was less than the maximum response for the 210mm uncontrolled structure at R=4.3 compared with R=4.5. The envelopes of maximum response when viewed along lines parallel to the X-axis are shown in Figure 8.

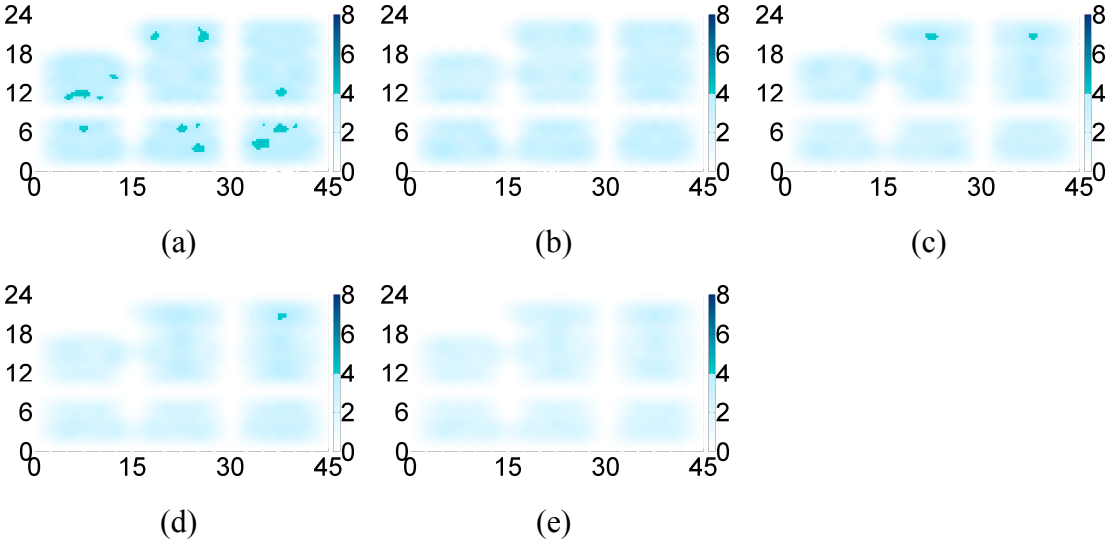

Figure 7 - Response of controlled floor subject to human excitation with varying slab depth: (a) 130mm, (b) 150mm, (c) 170mm, (d) 190mm, (e) 210mm

It is observed that for all 5 floors the response factor was reduced along the cross section by introducing AVC. While increasing the slab thicknesses tended to reduce the whole response globally, AVC targeted only the locations at which the response was greatest. In terms of dynamic performance this leads to a more efficient floor system where the response is not unnecessarily low at some locations.

It can be seen in Figure 8c that the response of the controlled floor around 18m actually exceeded that of the uncontrolled floor. This again was a consequence of using the decentralised controller without ensuring nominal performance – only nominal stability. Given that the response was predominantly reduced to below R=4 the controller can be deemed as performing suitably well.

The impact of AVC is shown even more clearly in Figure 9 which plots the maximum response factor for each floor system. Here, it is apparent that the maximum response measured for the thickest uncontrolled floor was actually greater than the maximum response for the thinnest controlled floor.

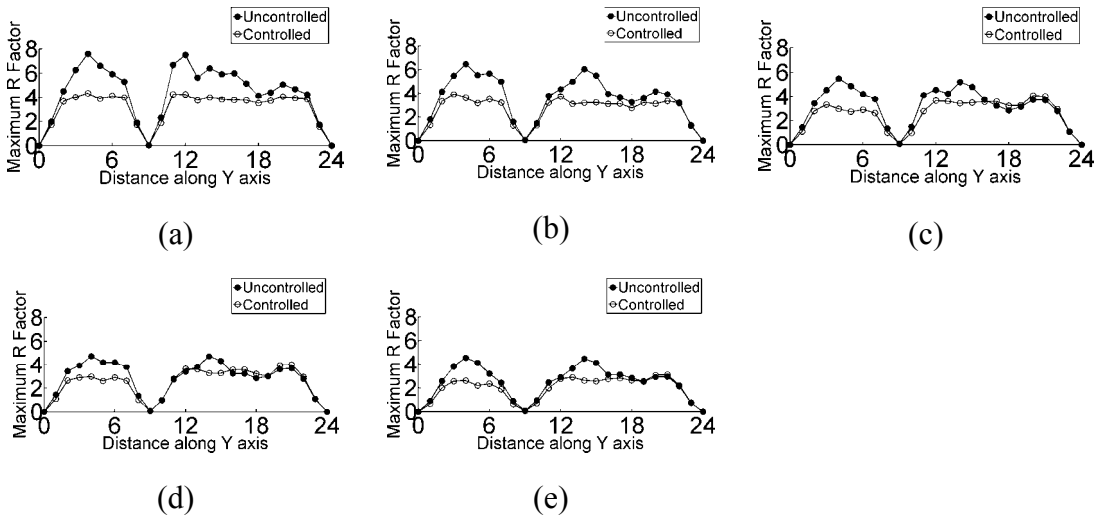

Figure 8 – Envelope of reduction in response due to AVC

This difference in slab depth for equivalently performing floors is equivalent to a 46% reduction in concrete required for the slab. The embodied energy and embodied carbon that could be saved through this reduction can be calculated by using the data provided by Hammond and Jones (2008). Here, RC40 concrete was assumed and thus it was calculated that approximately 243GJ and 35tonnes of CO_2 would be saved from the concrete not used on this floor alone.

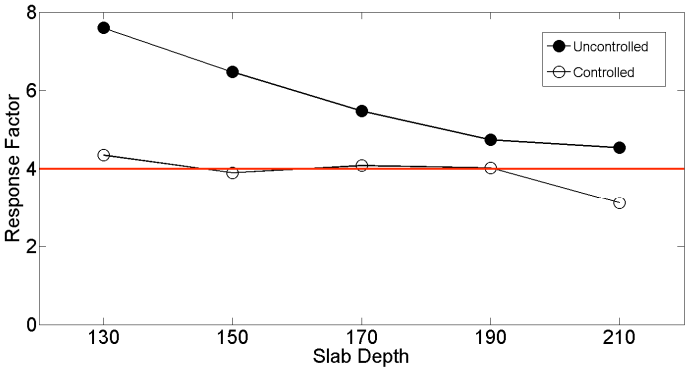

Figure 9 - Summary of response factor changes

CONCLUSIONS

This paper has demonstrated a possible application for active vibration control, utilising its ability to reduce the response of a structural floor system subject to human-induced excitation. Here, the design of a floor that performs poorly from a vibration serviceability perspective has been brought in line with recommended

limits through two distinct methods – 1) by increases to slab depth and 2) by the introduction of an AVC system. It has been shown that by using an AVC system significant material savings can be realised, amounting to 46% for the concrete in the slab.

The additional stiffness introduced through the use of partitions caused the mode shapes to become significantly localised. This actually made controlling the response a more difficult task due to controllability and observability issues. Where more global modes are involved, e.g. in smaller floor systems where it is possible that the whole floor is open-plan, it is expected that fewer actuators would be needed to achieve desirable performance improvements. On the other hand, research is currently working towards improving the performance and cost of the actuators used for AVC in floor structures. This may make it a more desirable option to use many actuators distributed across the floor system even when the modes are fairly global in nature.

This work could be extended by considering the effect of the coupling between each actuator – a result of the off-diagonal terms in the structural system. This could be achieved through the use of the μ-interaction measure or by using a full MIMO scheme with a model-based controller such as LQR, IMSC or H_∞. Also, the additional costs that the use of AVC incurs, both operational and embodied, should be quantified to permit a thorough evaluation of the benefits of including AVC in the design of new floor structures.

ABSTRACT

The strength and stability of connections in a floor system is an integral part of a building structure. A connection is subjected to large compressive and tensile forces during heating and cooling phase of a fire, respectively. Since shear connections are only designed for gravity loads that produce shear, their behavior in a floor assembly at elevated temperatures needs to be investigated. This paper compares the behavior of three types of shear connections (single plate, single angle and double angle) under fire conditions using the finite element software ABAQUS. The single plate shear connection was validated by a full-scale building fire tested in Cardington. Adopting Eurocode and AISC provisions on the shear connection design, the Cardington connection was redesigned using the single and double angles. While the single plate connections can provide substantial rotational ductility and tensile strength, it could fail during cooling phase of a fire by bolt-hole bearing or bolt shear. The bolted double angle connections are generally more ductile in tension which is advantageous during cooling phase; however they are prone to develop prying forces which could cause the failure of the bolts. In all of the connection models, the beam near the connection experiences local buckling at elevated temperatures.

INTRODUCTION

Structural floor systems undergo significant geometric changes due to thermal expansion of steel during a fire event. Additionally, the strength and stiffness of steel reduce dramatically at elevated temperatures. Hence, connections become an integral part of building construction because they could be subjected to large axial forces, moments and strain reversal during cooling period of a fire [Ramli-Sulong et al 2007]. Current design codes [AISC 2005 and ECCS 2001] are based on isolated member tests subjected to standard fire conditions. Such tests do not reflect the behaviour of a complete building under either normal temperature or fire conditions [Wald F. et al. 2006]. The complex interaction of structural components such as

angles, plates, bolts and supporting members can be accurately captured by conducting large scale experiments or utilizing three-dimensional finite element models. The finite element modeling of the three different types of shear connections (single angle, double angle and single plate) under the same boundary conditions, loading and natural fire scenarios enables us to compare the strength, ductility and failure modes of these connections and their effect on the global behavior of the floor subassembly. This paper uses the finite element software ABAQUS [Simulia 2008]. The single plate shear connection was validated by a full-scale building fire tested in Cardington [Garlock and Selamet 2010; Wald, F. et al 2006]. Adopting AISC provisions on the shear connection design at ambient temperature, the Cardington connection was redesigned using the single and double angles.

Previously, Ramli-Sulong et al. [2007] used the component based method to estimate the axial force and moment capacity of double angle connections. However, the method was limited in capturing the ductility of the connection. Liu et al. [2002] conducted several furnace experiments with axially restrained unprotected beam with a double angle connection. He found that there were clear indications that the bolt holes in the beam web had been elongated as a result of the large bearing forces. The connections, although designed to carry only shear, developed significant moment because of the high rotations and the contact between the lower beam flange and the column. The combination of high connection moment and axial compression force causes lower flange buckling in the beam near the connection. The connection then loses its moment resistance. This paper aims to observe and compare the behavior of the three types of shear connections under a natural fire, which has not been studied previously.

SINGLE PLATE CONNECTION IN A SUBASSEMBLY

Geometry

We previously modeled a subassembly of the Cardington building test using the finite element software ABAQUS. The geometric details are given in Figure 1. The connection between the secondary beam and the girder is a single plate connection, which is designed according to Eurocode provisions [ECCS 2001] at ambient temperature. We modeled only half of the bay and used necessary boundary conditions and loading for symmetry. Further, the thermal and structural effect of the composite slab in the experiment is taken into account by applying a three-sided fire boundary on the beam and by using *Connector elements in ABAQUS, respectively. The use of *Connector elements to represent the additional flexural stiffness provided by the slab is explained thoroughly in Garlock and Selamet [2010].

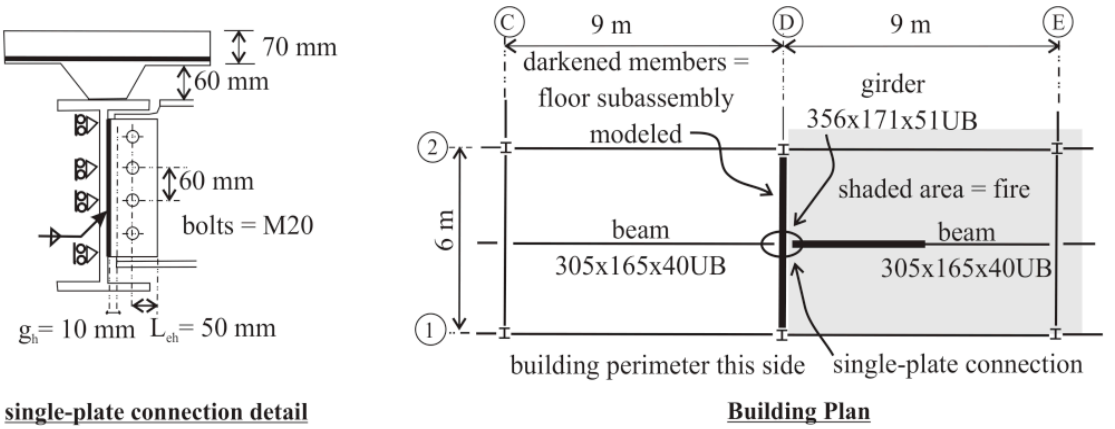

Figure 1: Details of Cardington [Wald, F. et al 2006] (a) single plate connection and (b) the building compartment and the subassembly (illustrated with thick lines).

Fire Scenario

In Cardington, a moderate fire scenario is used with the fire load of 40 kg/m^2 with wooden cribs covering the compartment floor area. In our model, the secondary beam is heated on three-sides with the average (recorded) thermocouple readings at the beam midspan taken from the Cardington test. The range of the beam midspan (structural) temperature and the gas (fire) temperature history is shown in Figure 2. The intensity of fire is slightly reduced near the connection region due to local massitivity.

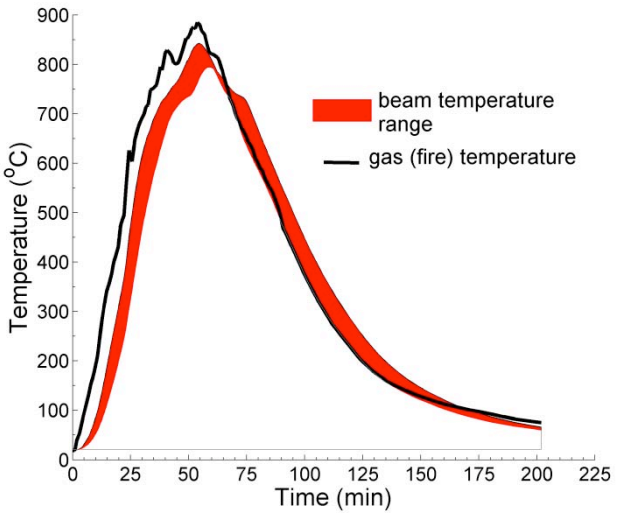

Figure 2: The temperature history of the recorded compartment fire and the range (min-max) of beam (305x165x40UB) temperature in Cardington building test.

Material Properties

In the finite element model, the steel properties of the plate, bolts, beam and girder are taken directly from the measured values at ambient temperature in the Cardington building test. Young's modulus *E* of steel is taken as 207GPa for all components. The strength and stiffness of hot-rolled steel are reduced according to Eurocode

provisions [ECCS 2001]. The elevated temperature properties of quench-tempered bolts are applied using Kirby [1995]. The steel plasticity is modeled using 'von Mises' yield criteria with isotropic strain hardening. No material softening (decreasing branch of the stress-strain curve) is included as this would greatly decrease the convergence character of the problem. Table 1 shows the ambient temperature yield and ultimate (strain hardening) strength of the subassembly components. The single plate, single angle and double angles are modeled using Grade 43 strength. Figure 3 shows the (engineering) stress-strain curve of four components at ambient temperature and 600 °C. These curves are converted to true stress and strain for the finite element analysis.

Table 1: Steel properties at ambient temperature.

Materials	**S275** (beam)	**S355** (girder)	**Grade 43** (plate/angle)	**Grade 8.8** (bolt)
yield strength (MPa)	303	396	275	695
ultimate strength (MPa)	469	544	430	869

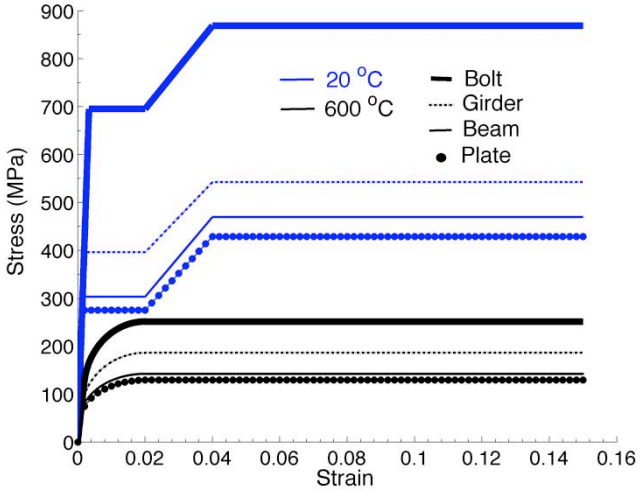

Figure 3: Eurocode steel stress-strain curves with strain hardening for plate/angle, bolts, 305x165x40UB (beam) and 356x171x51UB (girder) at 20 °C and 600 °C.

DESIGN OF SINGLE AND DOUBLE ANGLE CONNECTIONS

The single and double connections are designed for ambient temperature conditions for the Cardington building scenario using AISC provisions [AISC 2005]. The geometric details of the three connections are illustrated in Figure 4. As seen in Table 2, the connections are designed with similar shear and tensile strength according to AISC provisions. All three connections have beam web bolt-bearing as the governing limit state in shear and tension as stated in Equation J3-6a in Steel Construction Manual [AISC 2005]. The single plate and single angle connections have four bolts and are almost identical in geometry. The double angle connection has a smaller angle thickness (6 mm) and has 3 bolts centered in the beam web. Further, the bolt end distance (L_{eh}) is 50 mm in the beam web. Such geometric change is necessary to

keep the ambient temperature shear and tensile strength of the double angle connection similar to the strength of the single plate and single angle models.

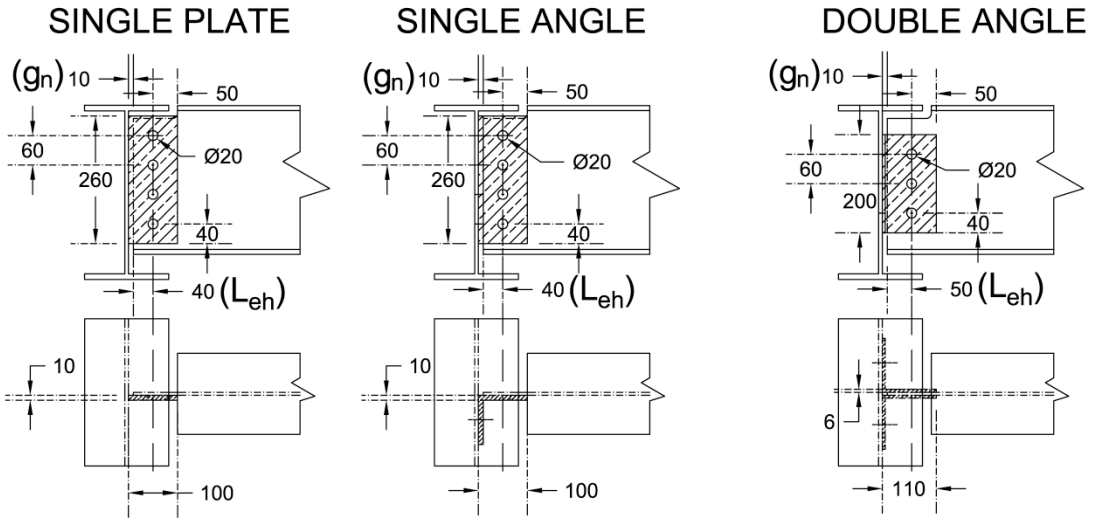

Figure 4: Geometric details of the three shear connection types (dimensions are in millimeters).

Table 2: Shear and tensile strength of single plate, single angle and double angle connections at ambient temperature.

dimensions in mm	**Shear strength (kN)**	**Tensile strength (kN)**
Single Plate (P10-260x100)	349	294
Single Angle (L10-100x100)	349	294
Double Angle (2L6-110x110)	294	296

Neither of the angle models are designed considering the prying action because the expected tensile force in the beam is not known apriori. Figure 5 shows the prying action of an angle. Here, *T* is the maximum expected tensile force in the angle (per bolt), *Q* is the prying force (per bolt) and *B* is the allowed tensile force in the bolt. The geometric parameters are *a'*, *b'* and *p* (tributary length per bolt).

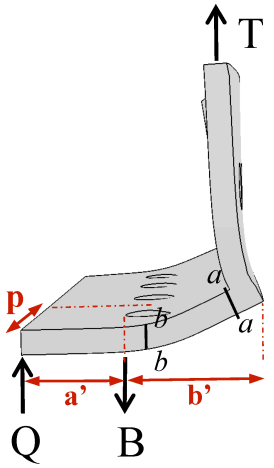

Figure 5: Prying action and illustration of forces *T*, *Q* and *B* in an angle.

The general formula for the minimum angle thickness t_{min} to avoid failure due to prying action is stated by Thornton [1985] in Equation 1.

$$t_{\min} = \sqrt{\frac{8Tb'}{pF_y(1+\delta\alpha)}} \qquad \text{Eq. 1}$$

Here, F_y is the yield strength of the angle and δ is the ratio of the net area at section *b-b* and the gross area at section *a-a* (both shown in Figure 5). The coefficient α is the ratio between the moment per unit width at section *b-b* and the moment per unit width at section *a-a*. For the single angle model; if we assume that T is equal to 400kN (:= 100kN per bolt) and B is the ultimate tensile capacity of Grade 8.8 bolts, the equation suggests that t_{min} should be about 25 mm (~1 inch) with $\alpha = 1$ and $\delta = 1$. Similarly, t_{min} = 28 mm (~1.1 inch) for the double angle model. Hence, both the single angle (t = 10 mm) and the double angle thickness (t = 6 mm) used in the model suggest that the prying action will likely occur due to large tensile forces in the beam during fire.

THE FINITE ELEMENT MODEL

Meshing

Several convergence studies for the three-dimensional finite element connection models were implemented previously by the authors [Selamet and Garlock 2010]. For the bolts and the bolt-hole regions, 20 elements are found to be sufficient to accurately represent the shear and tension capacity of the region. Further, minimum of 3 elements through the angle/plate thickness is necessary to capture the bending behavior of the angles or the plate. Generally, finer meshes are utilized around the connection region, where large concentration of forces and instabilities such as the local buckling are expected. Fully integrated (C3D8) and incompatible (C3D8I) hexagonal elements are used near connection region and at contact areas, whereas reduced integrated (C3D8R) elements are used for the rest of the subassembly.

Imperfection Study

Due to the eccentricity of single plate and single angle connections, no imperfection is introduced prior to static analysis since deformations will inherently develop as the beam starts to expand at elevated temperatures due to the unsymmetrical nature of the connection. For double angle connections, however, imperfections need to be introduced, because of the perfect symmetry at the beginning of the analysis. The imperfection geometry is found using the eigenvalue extraction method by ABAQUS. The eigenmode of the subassembly is scaled to 1% and introduced to the general static analysis.

Analysis

An uncoupled thermo-mechanical analysis is performed since the heat transfer is independent of the structural response of the subassembly. The creep property of steel is not considered; hence an uncoupled thermal and structural analysis is computationally efficient. For gravity and fire loading, a purely static analysis is

performed, where several stabilization techniques are utilized in order to establish convergence especially at the onset of the beam web and lower flange buckling at the connection.

OBSERVATIONS AND RESULTS

Out of the three subassemblies, only the single plate model failed by bolt bearing in the beam web at 123 minutes into the fire as seen in Figure 6. Both the single angle model and the double angle model (see Figure 7 and Figure 8) survived the entire fire duration without significant deformation in the beam but with excessive bending and significant plastic deformation in the angle due to the large tension in the beam. Additional details of observations are listed in Table 3.

Table 3: Response details of finite element models

PARAMETERS	SINGLE PLATE	SINGLE ANGLE	DOUBLE ANGLE
time @ analysis end (min)	123	202	202
temperature @ analysis end (°C)*	231	62	62
$P_{c,max}$ (compression-kN)**	745	750	750
$P_{t,\,max}$ (tension-kN)**	395	305	280
connection limit state	beam web bolt bearing	excessive angle bending, but no failure	excessive angle bending, but no failure
web buckling (time)	yes (@12 min)	yes (@ 11.5 min)	no
lower flange buckling (time)	yes (@ 20 min)	yes (@ 20 min)	yes but minimal (@ 20 min)
girder contact (time)	yes (@ 14 min)	yes (@ 14 min)	yes (@ 15 min)
other observations	n/a	girder top flange buckling near connection	girder top flange buckling near connection

* average beam midspan temperature
** at beam midspan

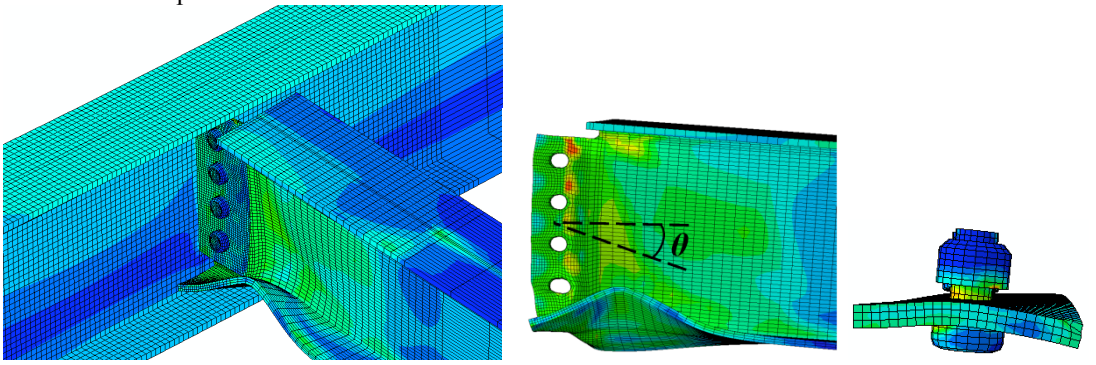

Figure 6: Mises contours and deformations of single plate connection subassembly at the end of analysis (123 minutes). θ represents the connection rotation angle.

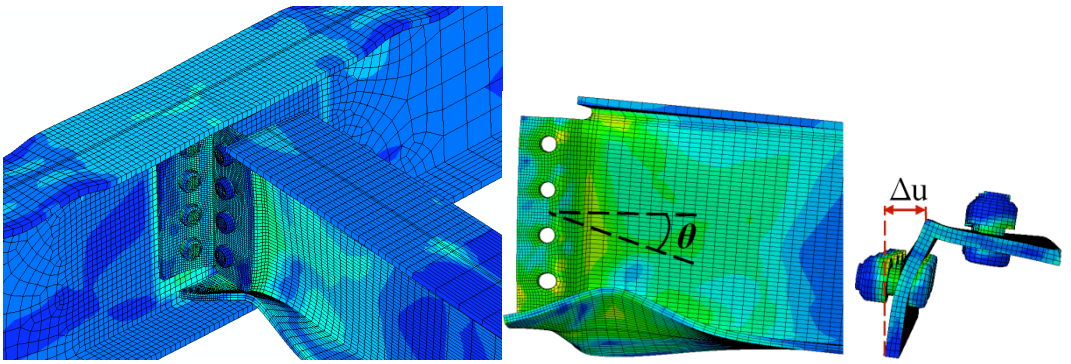

Figure 7: Mises contours and deformations of single angle connection subassembly at the end of analysis (202 minutes). Δu represents the horizontal uplift of the angle heel. θ represents the connection rotation angle.

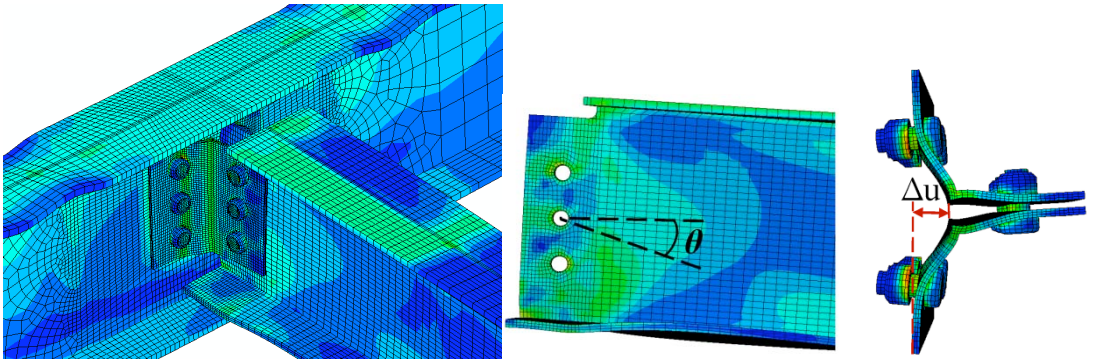

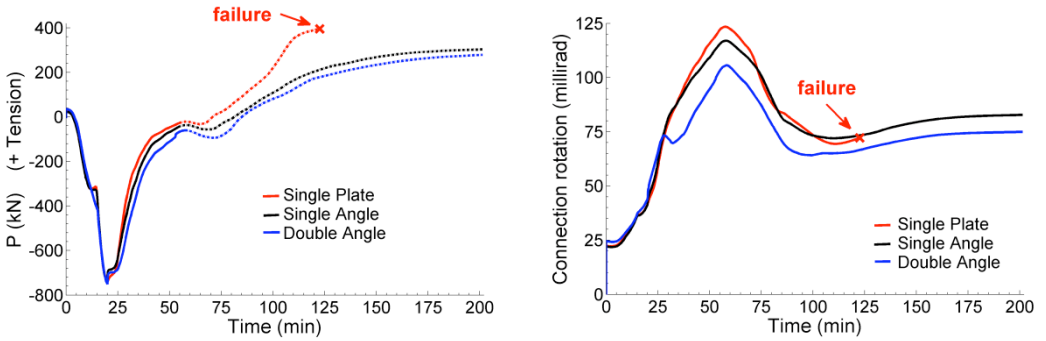

Figure 8: Mises contours and deformations of double angle connection subassembly at the end of analysis (202 minutes). Δu represents the horizontal uplift of the angle heel. θ represents the connection rotation angle.

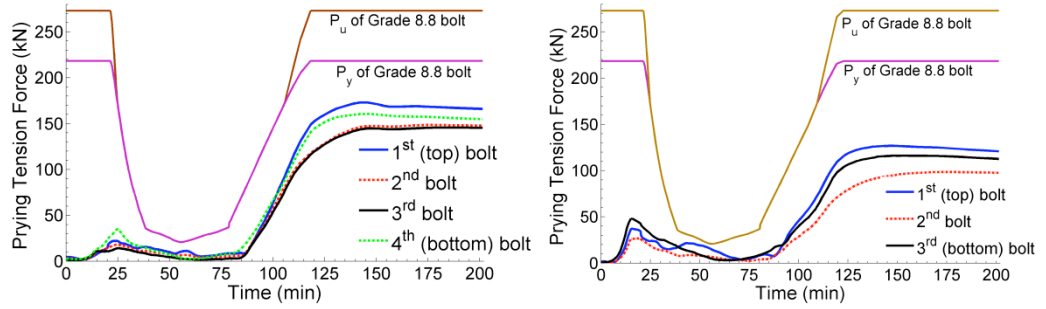
The axial force time history in Figure 9 illustrates the differences in structural fire behavior between the angles and the plate as a shear connection. In previous papers [Selamet and Garlock 2010], we have shown that the maximum compression in the beam during heating phase of a fire was governed by the buckling capacity of the beam web and lower flange near the shear connections. The single and double angle shear connections also exhibit this behavior. All of the three subassemblies have the same axial capacity in compression which is governed by the beam lower flange buckling. The single plate and single angle connections do not provide enough lateral resistance to the beam web; hence the web buckling occurs in early stages of fire. The double angles provide significant resistance to the beam web, and we observe no web buckling in this model. The extent of lower flange buckling is similar for single plate and single angle models, but it is much less severe for the double angle because it is not preceded by the web buckling.

As seen in Figure 9, the tensile strength capacity of both the single angle and double angles is lower than that of the single plate connection. Although the maximum tensile strength of angle connections is lower, the angles exhibit ductile behavior and survive the fire. As the beam contracts during the cooling phase, the tensile resistance



of the single plate itself (ignoring the other connection parts) is governed by the gross yielding of the plate, whereas the tensile resistance of the angles itself is governed by the bending capacity of the angle leg. The additional deformation provided by the angle leg significantly decreases the beam tensile force because it adds flexibility to the connection. Hence, the subassembly with the single angle connection survives the fire and the beam does not fail by the bolt-bearing limit state. On the other hand, the double angle connection has thinner angles (6 mm) and thus a smaller bending resistance. This model survives the fire, but experiences significant plastic deformation (see Figure 8) whereas the beam bolt region does not deform.

(a) (b)

Figure 9: (a) Axial force time history in the beam (dashed lines represent the cooling of fire) and (b) connection rotation θ (clockwise is positive, see Figures 6, 7 and 8).

All three shear connections exhibit similar moment time history (although not shown). This indicates that the moment at a shear connection is dependent mostly on the slab (composite deck) behavior and the gap distance (g_n) between the beam and girder, and it does not necessarily depend on the type of the shear connection. Since the gap distance (see Figure 5) and the *Connector resistance representing the slab structural behavior are kept the same for all models, the beam moment time history as well as the connection rotation (shown in Figure 9b) are similar for all three shear connection designs.

(a) (b)

Figure 10: Bolt tension (due to prying action) for (a) the single angle and (b) the double angle connections (due to symmetry, only 3 bolts on one angle are shown). P_u and P_y represent the ultimate and yield bolt strength, respectively.

Figure 10 plots the tension in the bolts (*B* in Figure 5), which includes the prying action for (a) the single angle and (b) double angle connections. Figure 10a shows that the bolts in the single angle exhibit significant tensile forces; however they do not reach their yield or ultimate tensile strength. The three bolts in the double angle model (Figure 10b) exhibit smaller tensile forces as expected because the tension in the beam is split evenly into two angles.

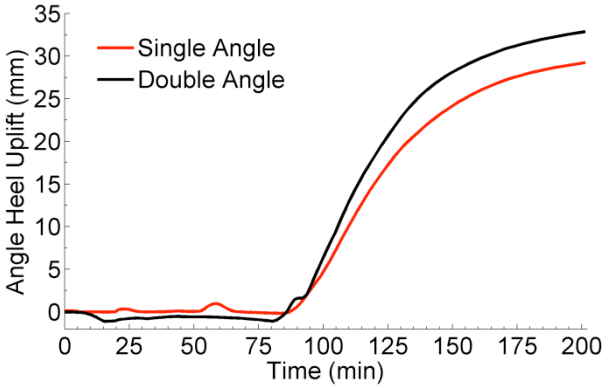


Figure 11: Angle heel uplift or relative displacement Δu (see Figure 7 and 8) for the single and double angle connections.

Figure 11 shows the uplift of the angle heel (at the top) for both models. The double angle connection experiences a larger uplift (Δu) because of its thinner angles. Since both angle models have a large Δu (~30-35 mm), we can assume that such deformation absorbs some of the beam contraction during cooling phase of the fire. Such flexibility in the connection prevents the beam web from failing by bolt-bearing limit state.

CONCLUSION

In this paper, we designed and modeled single and double angle connections using the same boundary, loading and fire scenario of the single plate connection subassembly which is adopted from the Cardington building test. The finite element models are able to capture the large deformation and the change of contact conditions accurately for the duration of fire. Our observations suggest that the angle connections have a more ductile fire response compared to the single plate although their maximum tensile strength is lower. Both the single and double angle connections survive the natural fire with significant plastic deformation in the angle legs whereas the single plate connection fails by bolt bearing in the beam web. Using different type of shear connections did not change the overall response of the subassembly during heating, but had significant influence on the overall response during cooling. We can confirm this by looking at the beam axial force diagram where the onset of the lower flange buckling and the maximum beam compression for all three connection models are almost identical. Further, the models exhibit similar connection rotation and beam midspan deflection behavior. During cooling, the shear connections have different responses in terms of failure limit state, deflection and maximum tensile strength.

During the heating phase of fire, all connections experience local buckling in the beam lower flange when the gap distance (g_n) closes and the girder-beam contact is established. The lower flange buckling also marks the maximum compression in the beam. The beam web buckling occurs in the coped beam only for connections with plates/angles on one side of the beam web (single plate and single angle).

As the beam contracts during the cooling phase of fire, the bending of the angle legs due to large tensile force in the beam creates the phenomenon called 'prying action'. The use of high strength bolts eliminates the possibility of a bolt failure in tension; however the bolt tensile forces get close to the bolt yielding capacity. The angle connections provide additional flexibility that the single plate connections do not have. The use of thin angles for the double angle connection creates significant plastic deformation in the angle, and it is recommended to use caution when selecting the angle thickness. In conclusion, we see a significant benefit using the angle connections for a more robust fire connection design.

Effects of Thermal Expansion and Support Restraints on Performance of Composite Floors in Fire

H. Mostafaei[1], F. Alfawakhiri[2]

ABSTRACT

This paper presents results of a numerical study on the effects of thermal expansion and support restraint conditions on the performance of composite floors in fire. Previously, two full-scale composite floor specimens were tested to investigate factors, such as the supports restraint conditions, that affected the failure of the World Trade Center buildings' floors. Although higher fire resistance was expected for the restrained floors, the test results showed higher fire resistance rating for the unrestrained floor specimen. The purpose of this research was to understand the rationale behind these results numerically. The structural analysis software SAFIR was employed to evaluate the response of the composite floor specimens in fire, such as strain and stress distributions and floor deflection. The results show that the concrete spalling during the first hour of the test for the restrained specimen would have been due to concrete compression failure caused by the restraint condition and thermal expansion.

INTRODUCTION

Since the 9/11 disaster, various studies have been carried out to investigate the performance and collapse simulation of the World Trade Center (WTC) buildings subjected to the impact of the aircrafts and the following fire. Significant efforts have been extended to investigate performance of the WTC's building structures in the fire (NIST, 2005). Although damage from the impacts could have had considerable effects on the structural response of the two towers, the WTC's towers had not collapsed in fire shortly after the impacts. In fact, the WTC's north tower burned for 102 minutes, after it was hit by the aircraft, before it collapsed. As for the WTC south tower, the collapse of the structure occurred after burning for 56 minutes in fire. Therefore, fire was considered as a major factor in the collapse of the two towers.

One of the experimental studies was carried out by the National Institute of Standards and Technology (NIST) on the fire resistance and performance of the WTC's towers composite floors (Gross et al., 2005). A main objective of this experimental study was to explore "why and how WTC towers collapsed following the initial impacts of the aircraft and to determine factors that most influenced the buildings' composite floors failure". Two full-scale composite floors were tested by NIST at the Underwriters Laboratories of Canada fire testing facility in Toronto (ULC). In order to investigate the support restraining effects on fire performance of the floors, one specimen was tested with restrained supports and the other - with unrestrained supports conditions. Although higher fire resistance was expected for the restrained floors, the test results showed higher

fire resistance for the unrestrained full-scale floor specimen compared to the restrained floor. Observations during the two tests indicated more damage and spalling of concrete for the restrained floor specimen compared to the unrestrained specimen.

This paper provides results of a numerical study for the two floor test assemblies. The main objective is to investigate and understand the failure mechanism of these two full-scale specimens, which simulate the WTC's towers composite floors. The analysis was done using the SAFIR structural analysis package (Franssen, 2007). Furthermore, a post-processor was developed to generate stress and strain profiles on the cross-sections of the floors' elements.

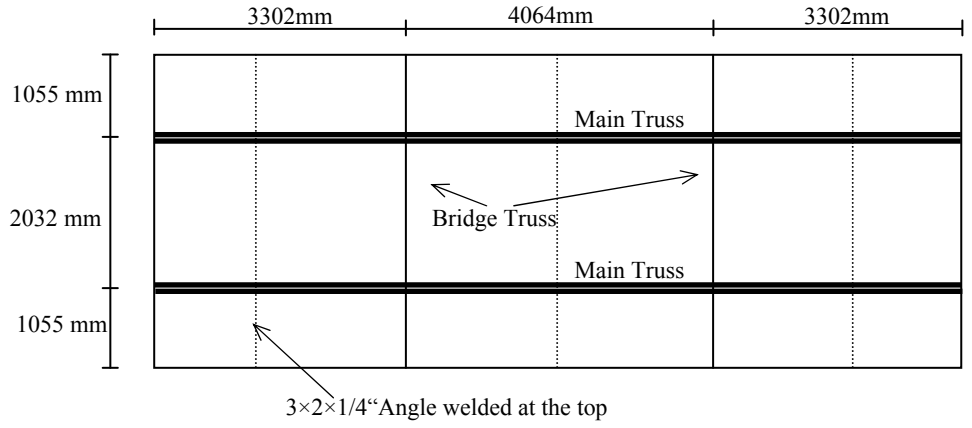
FLOOR SYSTEM OF THE WTC TOWERS

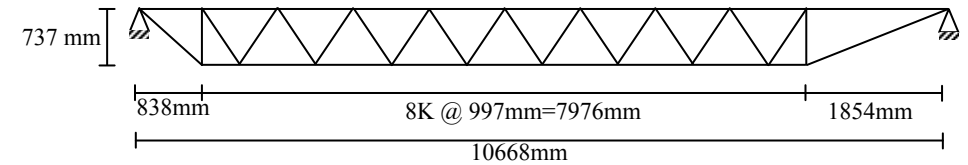
The World Trade Center towers had a steel/concrete composite floor system. It consisted of a concrete slab and steel trusses supported at the two truss ends between the building's core columns and exterior wall columns. The steel trusses were installed in pairs with 2.0 m spacing, on center, with a nominal clear span of either 18.3m or 10.7m. Both top and bottom chords were made of double steel angles. Double round bars were used as the diagonal members of the trusses. The diagonal bars were extended beyond the top chord, in form of a "knuckle", to play the role of the shear connectors for the composite floor. In addition, bridging trusses were used, perpendicular to main trusses, in the floor system, to transfer the applied loads to the main trusses, spaced 4.0 m on center (Gross et al., 2005).

The Cafco Type D was used as the Spray-Applied Fire-Resistive Materials (SFRM) for fire protection of the WTC's floor truss steel elements. The two full-scale floors test assemblies, selected for the purpose of numerical studies in this paper, have been designed to simulate the performance of the WTC's towers composite floors in fire. Results of the numerical studies are provided in the following sections.

FLOOR TEST ASSEMBLIES

Two floor specimens were tested by the NIST at the ULC Toronto based on the ASTM E119 standard, one with restrained and one with unrestrained supports. The floor specimen configuration and dimensions are provided in Figure 1. The floor main truss, for specimen No. 1 with restrained support, the main truss for specimen No. 2 with unrestrained support and the details of the bridging truss are plotted in Figure 2.





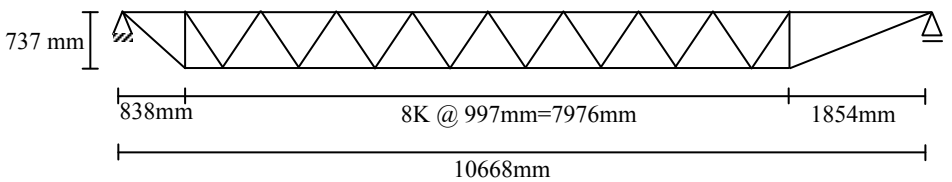


Figure 1. Configuration of the full-scale floor specimens.

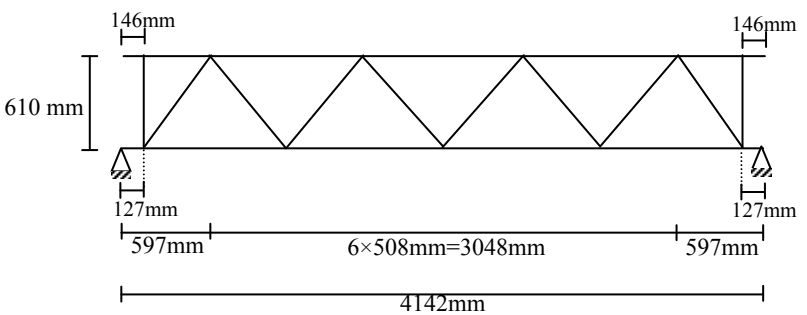

Figure 3 identifies types of the steel sections for the top and bottom chords and the diagonal members of the truss specimens. A cross-section for the truss system, including the entire steel truss section and the concrete slab, is provided in Figure 4. Top and bottom chords and diagonal elements of the main and bridging trusses were coated by 19.05 mm thickness of the available SFRM (BLAZE-SHIELD DC/F by Isolatek International). Further details of the specimens can be found in the test report by Gross et al. (2005).

NUMERICAL MODELING

Geometry and configuration

The floor specimens were modeled using the SAFIR software (Franssen, 2007), which is a program for analysis of structures for both structural and fire loads. Based on the support details shown in Figure 2-c, the bridging trusses have less stiffness than the main truss and would not be capable of transferring high shear force to the supports.

Therefore, it was assumed that the main structural elements transferring the applied load to the test frame would be the main trusses. The concrete slab was assumed acting as a one-way slab in the direction of the main trusses, and compositely with the main trusses. These assumptions simplified the analysis to model only the main trusses with the concrete slab, and to ignore the bridging trusses. In addition, due to the symmetrical geometry only half of the floor specimen was modeled.

Figure 5 shows the model of the main truss for specimen No. 2, with unrestrained supports and the applied load. The geometry and the element sections for restrained specimen No.1 are similar to that of specimen No. 2. Except that for specimen No. 1 the truss's right end support is restrained for horizontal displacement.

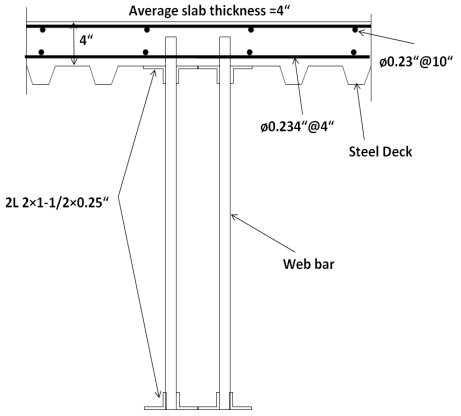

Figure 4. Cross-section of the floor system at the main truss location.

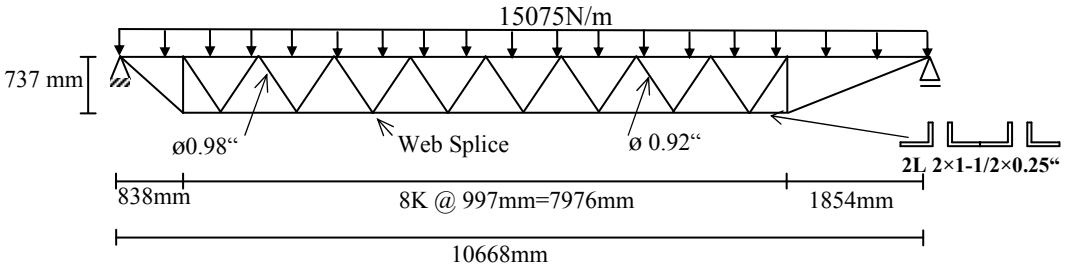

Figure 5. The main truss model for analysis of unstrained specimen No. 2.

Material mechanical properties

Bottom chord angles of the truss were made of 2 L2×1-1/2×0.25", as shown in Figure 4, with A572 steel and yield strength of f_y= 425.5 MPa. Round bars with two different diameters, 0.92" and 0.98" were used as the diagonal elements for the truss. Figure 5 shows the web splice where the diagonal round bars changed from 0.98" to 0.92" section through the truss. The yield strength for bar 0.92" is f_y= 402 MPa and for bar 0.98" is f_y= 372 MPa. The concrete slab reinforcement of the floor consists of two layers of welded wire fabric 254mm × 102mm (10 in. by 4 in.), as shown in Figure 4. W4.2 wires with a diameter of 5.8mm (0.23"), a yield strength of 492 MPa and spacing of 254mm were placed in the longitudinal direction. W4.3 wires with a diameter of 5.9mm (0.234"), a yield strength of 498 MPa and spacing of 102 mm were located in the transverse direction. For the purpose of this study only longitudinal bars were included in the analysis, based on the assumption that the floor would act as a one-way slab structure. The above steel material properties were derived from the individual material property

tests reported by Gross et al. (2005), and applied to both specimens No. 1 and No. 2. The concrete slabs of the specimens were made of lightweight concrete. Mechanical properties of the concrete are provided in Table 1 for both specimens. The concrete compression strengths were taken from the test reports and the tensile strength of concrete were estimated according to equation (1) proposed by Vecchio in Wong and Vecchio (2002).

$$f_t' = 0.33\sqrt{f_c'} \quad (1)$$

where, f_t' is the tensile strength in MPa and f_c' is the concrete compression strength at 56 days in MPa.

Table 1. Mechanical properties of the floor lightweight concrete of specimens.

Specimen	Compressive Strength at 28 Days (MPa)	Compressive Strength at 56 Days (MPa)	Tensile Strength* (MPa)
No.1	28.8	32.6	1.9
No.2	20.2	26.8	1.7

* estimated according to equation (1).

Applied loads

The total uniform load for each floor specimen consists of two load cases: the uniform self weight construction load of 2298 N/m^2 (48 psf) and an additional superimposed load of 4981 N/m^2 (104 psf). Hence, the total applied uniform load on the floor is 7279 N/m^2 (152psf). Since only one truss is modeled, due to the floors symmetrical geometry and loading, the linear uniform load on each truss is determined with multiplying the total uniform load by half of the floors' width; uniform load (per unit length) = 7279N/m^2 × 4.142 m / 2 =15075N/m, as shown in Figure 5.

Material thermal properties

In both floor specimens, the BLAZE-SHIELD DC/F was used as the SFRM in multiple coats with an average thickness of 0.75", to protect elements of the main and bridging trusses. The test report indicated that no attempt was made to control overspray of material onto the deck of the test assemblies. Thermal properties of the SFRM were obtained at different temperatures based on the test repot by Carino et al. (2005). Thermal conductivity of the SFRM changes from 0.046 W/(m.K) at 25 ^{o}C to 0.53 W/(m.K) at 1200 ^{o}C. Specific heat for the SFRM starts with 826 J/(kg.K) at 25 ^{o}C and increases up to 1392 J/(kg.K) at 1200 ^{o}C. The density of the SFRM was considered variable for the analysis from 236 (kg/m^3) at 25 ^{o}C to 432 (kg/m^3) at 1200 ^{o}C, Carino et al. (2005).

For all steel elements of the truss, STEELEC3 material model of the SAFIR was used for both thermal and material properties. As for concrete, thermal properties were derived from the study results reported by Prasad and Baum (2005). Appendix A of the report provides these properties at different temperatures for the lightweight concrete. For concrete thermal conductivity the value is varied from 1.5 W/(m.K) at 25 ^{o}C to 1.00 W/(m.K) at 1200 ^{o}C and for specific heats it is from 880 J/(kg.K) at 25 ^{o}C to 1500 J/(kg.K) at 1200 ^{o}C. The lightweight concrete of the two specimens was designed for a density of 1600 kg/m^3 (100 pcf) at ambient temperature, which is different from that of the concrete reported by Prasad and Baum (2005). Therefore, for this analysis, the

concrete density was reduced from 1600 kg/m^3 at 20 ^{o}C to 1300 kg/m^3 for 1200 ^{o}C. The reduction function was selected as those of the lightweight concrete used by Prasad and Baum (2005). Moisture content of concrete was obtained as 51 kg/m^3, based on the reported 70% relative humidity, 0.23 chemically bound water, 237 kg (522lb) cement, and concrete water mix of 127 kg (281 lb).

Heat transfer analysis

Due to the round shape cross section, finite element (FE) meshes with triangle elements were generated to model cross sections of the diagonal elements of the truss assemblies. Figure 6 shows the FE mesh for these elements. Elements with a darker color represent the steel bars and elements with a lighter color form the SFRM materials. Using SAFIR, the heat transfer analysis was carried out for the web elements while they were exposed to standard fire, ASTM E 119. The results for the temperature distributions on the cross sections at the time = 3600 seconds are plotted in Figure 7. Figure 8 shows the comparison between analysis and test results for the temperature at the surface of the web elements at different time steps.

Figure 6. FE mesh for the double bar web elements, each with diameter of 0.98".

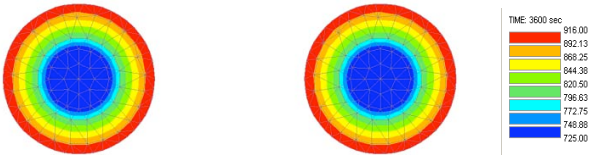

Figure 7. Temperature distribution on sections of the web elements at time = 3600 sec.

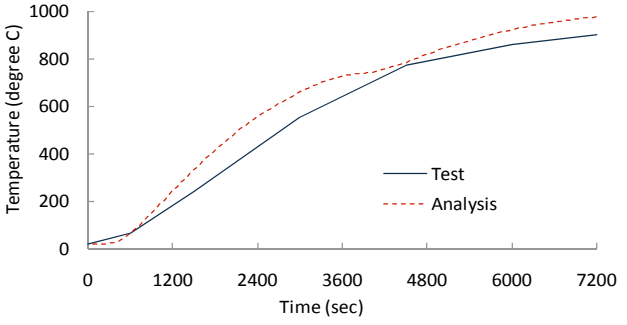

Figure 8. Temperatures on the surface of the bar, web elements, for specimen No. 1.

In this figure, although the test results show a little lower temperature profile than that of the analysis, they are in close correlation. For the structural analysis, the temperature results of the test were employed.

FE meshes with rectangular elements were assigned to both concrete and steel angles of the truss's top and bottom chords of the assemblies. Based on the total cross-section area of the longitudinal steel reinforcement wires, two fiber elements on the top and two on the bottom of the slab cross-section were assigned as the slab steel reinforcement, with each fiber away from the slab top and bottom edges in accordance with the cover concrete thicknesses. Since BEAM element, a fiber model, of the SAFIR package was used for modeling the cross sections, this lumping of reinforcement wires

into a limited number of fibers would have no effect on the results. Figure 9 shows the mesh generated for the top chord of the truss, concrete slab and steel angels. The steel deck was modeled for heat transfer analysis; however it was not included in the structural analysis as there would be no shear interaction between the deck and the concrete. The test observations for both assemblies indicated separation of the steel deck at the very early stage of the tests.

Figure 9. FE mesh for the top chord steel elements and the concrete slab.

In the initial thermal analysis, SFRM overspray was ignored, so the lower face of the floor was exposed directly to the assigned furnace temperature profile. First, the metal deck and the protected steel truss top chord angles were exposed to the furnace temperatures measured in test and the analysis was carried out. In order to impose the exact test temperatures to the angles and the metal deck, large values were assigned to the convection coefficient on hot surfaces, convection coefficient on cold surfaces and relative emissivity of the steel deck in the SAFIR input file. This would accelerate the heat transfer through the slab frontiers by convection and radiation.

In this initial analysis, the analytical results showed considerably higher temperatures, at the unexposed side of the slab, compared to that of the test data. This could be due to the separation of the metal deck from concrete, reported during the test. The gap between the concrete slab and the steel deck, which was not modeled in the initial analysis, could act as an additional insulation layer delaying the heat transfer to/through the slab. Therefore, the second analytical approach was to expose the slab directly to the measured concrete temperature profiles. However, no measurement was reported from the tests for temperatures on the bottom surface of the concrete. Therefore, an attempt was made to determine such temperatures for the bottom surface of the concrete slab. Figure 10 illustrates the developed temperature histories for both specimens. The concrete slabs were then exposed to the developed temperature histories for the heat transfer analysis.

The top chord steel angles of the specimens were subjected directly to the test temperatures, since the measurements were available. Figure 11 verifies that the temperatures on the top chord angles, measured during the test, are in exact agreement with those of the top chord mesh, determined from the analysis. The same verifications were obtained for the web elements and the bottom chords.

Figure 12 illustrates the results for temperatures at the unexposed surface of the floor assemblies. It indicates a consistent correlation between the test and the analytical results. The calculated temperature distribution in the concrete slab and top chord angles of the truss assembly No. 1 are illustrated in Figure 13.

Structural analysis

Structural analysis of the two truss assemblies were carried out using the same software package, SAFIR, by employing the defined material properties for each section and the calculated temperature distributions from the heat transfer analysis. In the

structural analysis, the metal deck of the floor was not simulated since, as mentioned earlier, there was no shear interaction between the slab and the steel deck. The temperature distributions and material properties of the structural elements had minor differences in the two specimens. Hence, practically, the main difference between the two specimens was the restrained conditions of the truss end supports; that is being restrained for assembly No. 1 and unrestrained for assembly No. 2. Figure 14 shows the truss deflection, for specimen No. 1, generated by the SAFIR post-processor software, before and after fire exposure. Figures 15 and 16 compare analytical and experimental results for deflections in specimen No. 1 and No. 2, and indicate a consistent agreement between the analysis and the test results.

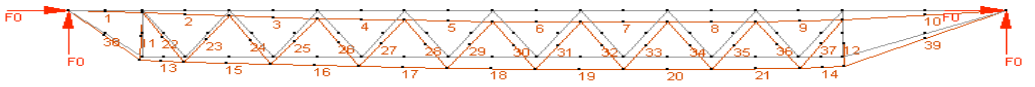

Figure 14. Truss specimen No. 1 with restrained ends before and after fire exposure.

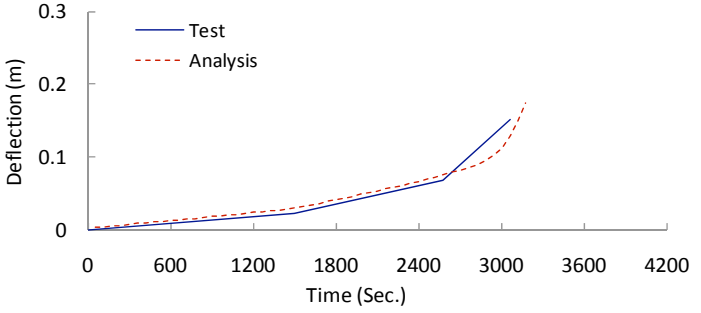

Figure 15. Deflections histories for specimen No. 1: analysis and experimental results.

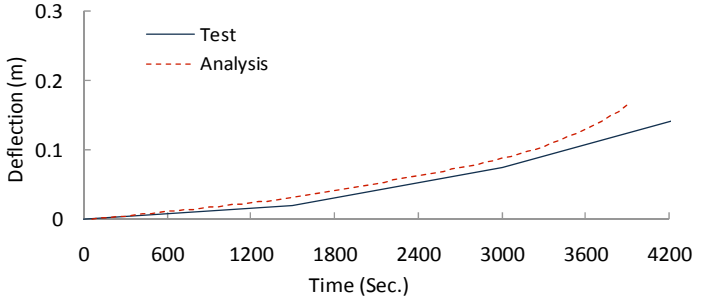

Figure 16. Deflections histories for specimen No. 2: analysis and experimental results.

The floor assemblies were able to last significantly longer in the tests, compared to the analytical results shown in Figures 15 and 16. That was because the SAFIR software would fail to converge when the structure suffered certain level of damage; which was compression failure of the top fibers/layers of the slab for this analysis. However, during the tests, the floors can sustain higher levels of damage and deformation. Observations from the test indicate significant spalling of the concrete in specimen No. 1, at both ends of the floor. This spalling occurred at about the same time as the convergence failure obtained from the analysis, preceded by sharp acceleration of deformations, as shown in Figure 15.

Figure 17 shows the total axial load in element #10 of the truss in Figure 14, for both the restrained specimen No. 1, and the unrestrained specimen No. 2. These analytical results indicate a difference of about 15 times between the restrained and unrestrained specimen axial loads, which show the considerable effects of supports restraint conditions on the structural response. The results convey the fact that the significant spalling observed during the test for specimen No. 1 would be the result of compression failure of the top fibers/layers of the concrete slab.

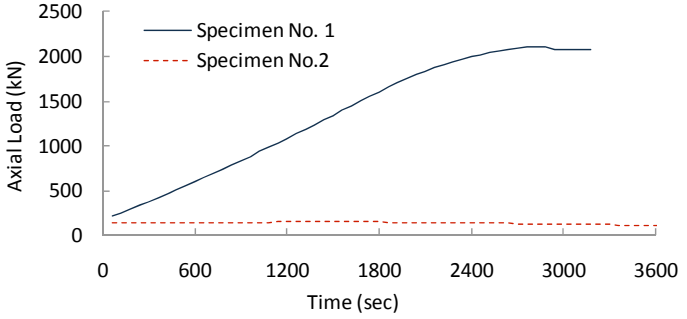

Figure 17. Axial load in element 10 of both restrained, specimen No. 1, and unrestrained specimen No. 2, assemblies (see Figure 14 for elements number).

In addition to the deformation and load response, strain and stress results for the concrete were investigated. Figure 18 and Figure 19 provide stress and strain distributions on the cross section of the concrete slab for element #10 of the restrained truss, specimen No. 1, at the time of failure. Figure 19 provides mechanical strains on the section, which is determined by SAFIR by subtraction of the thermal expansion strain from the total strain. Both results indicate that at this time step, the extreme top fibers of the concrete, cover concrete, fail in compression when concrete compression stress reaches 32 MPa or concrete compression strain achieved 0.002.

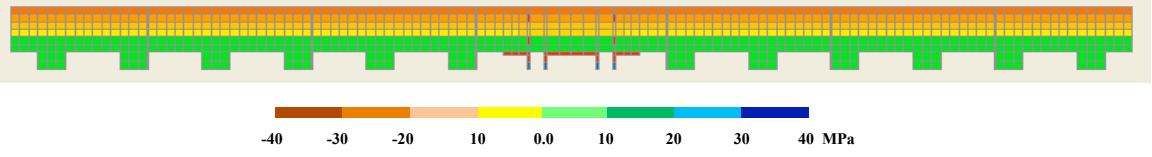

Figure 18. Stress distribution on the top chord of specimen No. 1 for element #10 of the truss at the time of concrete failure.

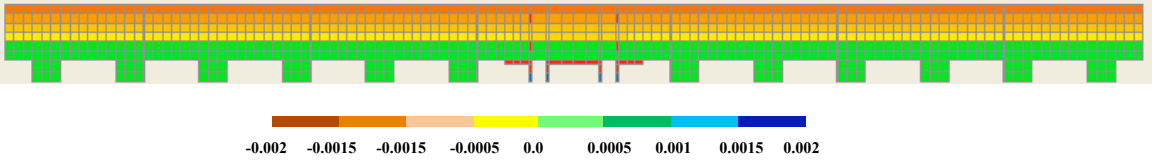

Figure 19. Mechanical strain distribution on the top chord of specimen No. 1 for element #10 of the truss at the time of concrete failure.

To study the stress and strain development, stress and strain distributions of the concrete slab were obtained for the vertical center line section of the slab at different time steps. Figures 20 through 23 illustrate the stresses and curvatures for both specimens. The analytical results clearly indicate that the stress and strain are considerably higher in the case of restrained specimen compared to that of the unrestrained assembly. It can also

be pointed out that the section experienced significantly larger curvature at the time of failure compared to that of the ambient temperature, which could be the result of large thermal expansion of the truss.

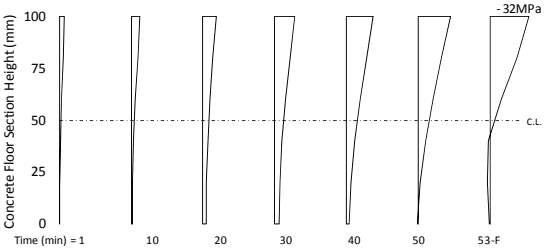

Figure 20. Stress profile at the vertical center line of the concrete slab section for specimen No. 1 at different time steps.

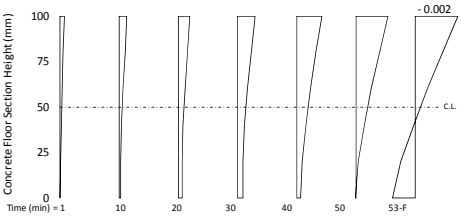

Figure 21. Mechanical Strain profile at the vertical center line of the concrete slab section for specimen No. 1 at different time steps.

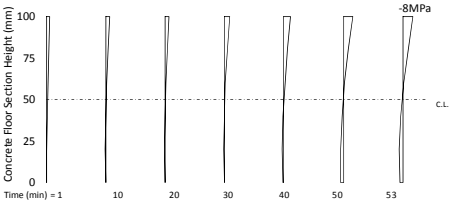

Figure 22. Stress profile at the vertical center line of the concrete slab section for specimen No. 2 at different time steps.

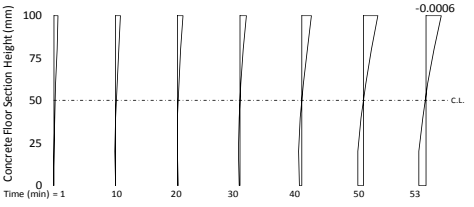

Figure 23. Mechanical Strain profile at the vertical center line of the concrete slab section for specimen No. 2 at different time steps.

Results from this numerical study and the two test assemblies indicated that overall performance of unrestrained floor specimen was better than the restrained specimen. Future comparative tests of restrained vs. unrestrained floor assemblies would be suggested to confirm if unrestrained floors perform better in other comparative tests.

In this study, no damage to the fireproofing materials of the truss, due to the initial impact and jet fuel explosion, is considered. In the 9/11 fire, the WTC towers' floors were exposed to a hydrocarbon fire load, however, in this investigation the composite floors were exposed to a standard fire, ASTM E119. In addition, the horizontal support

restraint condition for the test assembly No. 1 was only in compression. The floor specimen was free to displace in tension. However, in practice such restraint conditions would be imposed both in compression and tension.

Future studies would be recommended to investigate the above mentioned deficiencies in different scenarios.

CONCLUSIONS

A numerical study was carried out to investigate failure mechanism of the World Trade Center composite floors. The results from the analysis and the comparisons with the test results of the two full-scale floor assemblies, suggested the following conclusions:

Separation of the metal deck from the concrete slab during the fire would have decreased the heat transfer to the concrete slab.

The significant spalling of concrete and large deformation of specimen No. 1 at about 50 minutes would have been due to the thermal expansion of the truss resulting in compression failure of the top fibers of the concrete slab.

The axial load in the restrained truss assembly was significantly (about 15 times) higher than that of the unrestrained specimen.

ACKNOWLEDGMENT

Acknowledgements are extended to Mr. Joe Hum from NRC Fire Research Program for developing a post-processor software to simulate the stress and strain diagrams and his contribution in this study.

ABSTRACT

RC bearing walls are one of the most common primary lateral and gravity load carrying systems in U.S. building practice. Severe exposure to fire can compromise the out-of-plane stability of these walls under service-level gravity loads, causing catastrophic overall or disproportionately large failure of the structure. Considering these issues, the authors are conducting a project with the overall objective of developing experimental and analytical evidence to demonstrate the structural design and performance of RC walls under fire. Eight full scale wall fire tests are scheduled to be completed as part of this project. This paper describes the finite element modeling of the full scale concrete wall structures, and initial pilot experiments conducted to validate the modeling approaches. The results of the finite element simulations will be paired with the experimental results of full scale walls to develop a predictive fire-resistant structural design procedure for the walls.

INTRODUCTION

The response of reinforced concrete (RC) structures to fire is a complex coupled phenomenon. Current building codes in the U.S. are based on prescriptive fire resistant design provisions for the individual components of a structure. For example, according to ACI 216.1 (ACI 2007), the fire endurance of a RC wall is governed by its ability to confine a fire over a specified period of time (rather than by its structural strength or stability) and the fire endurance for a wall can be determined similar to a RC slab. The International Building Code (ICC 2009) requires a standard "fire resistance rating" of 2 to 3 hours (depending on structure height) for exterior and interior bearing walls. While a significant amount of previous research has been conducted to establish relative fire resistance ratings for different types of structural components, the results from these efforts do not provide knowledge on the structural load bearing capacity under fire. Rational performance-based design methods and analysis tools (as an alternative to the current prescriptive methods) are needed (NIST 2005) to enable the evaluation of the structural performance of a building component under a prescribed fire loading, similar to structures under other types of loads.

This ongoing project has the following three specific objectives involving basic research on the fire resistant behavior and design of load-bearing RC wall structures: (1) to investigate the out-of-plane axial-load-moment-curvature-temperature (P-M-φ-T) behavior of RC wall cross sections under elevated temperatures; (2) to evaluate the effects of geometric, material, reinforcement, and loading parameters on the behavior of RC wall structures under fire; and (3) to develop a rational, predictive fire-resistant structural design procedure based on the research results. The current paper describes the finite element modeling of full scale concrete wall structures, and initial pilot experiments conducted to validate the modeling approaches. The results of the finite element simulations will be paired with the experimental results of full scale walls to develop a predictive fire-resistant structural design procedure for the walls.

BACKGROUND

Most of the previous experimental research on RC structures under fire is based on the ASTM E119 standard test method (ASTM 2009), which requires that the fire endurance of a building component be determined by subjecting it to increasing temperatures that vary with time as shown in Figure 1. The tests are conducted by placing the specimen inside a specially-built furnace designed to follow the ASTM E119 time-temperature (t-T) curve.

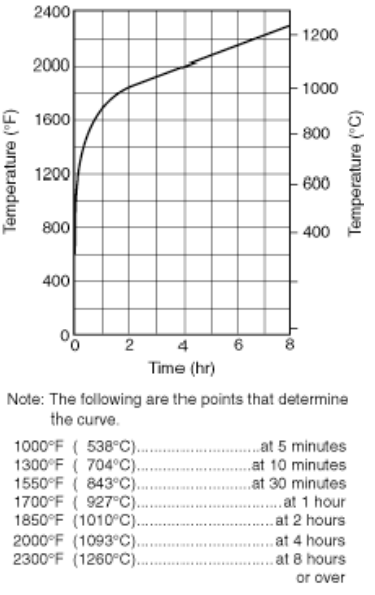

Figure 1. ASTM E119 time-temperature curve

In comparison with RC beam, column, and slab members, the previous fire engineering research on RC wall structures is limited (Lie 1972; Gustaferro and Abrams 1975; Plecnik et al. 1982; Crozier and Sanjayan 2000). The experiments conducted by Crozier and Sanjayan (2000) in Australia form the single most relevant research for the current project. A total of eighteen slender RC wall specimens were subjected to eccentric gravity loads and out-of-plane lateral loading, and then heated on one side following the ASTM E119 t-T curve using a gas-fired furnace. The wall specimens were 1.2 m (4 ft) long and 3.66 m (12 ft) high with uniform thicknesses of 75, 100 and 150 mm (3, 4, and 6 in), corresponding to wall height-to-thickness slenderness ratios of 48, 36, and 24, respectively. Concrete strengths of 48 MPa (7 ksi) and 69 MPa (10 ksi) were used with 0.25% steel reinforcement in the form of deformed wire mesh and reinforcing bars. The gravity and lateral loads were kept constant and the specimens were heated until collapse or other failure criteria (e.g., excessive deflections or deflection rates) were reached. It was found that: (1) out-of-plane thermal bowing due to one-sided fire exposure results in a significant reduction in the gravity load capacity of the walls; (2) flexural cracking allows the pore vapor pressure inside the heated concrete to be released; and thus, walls with little or no flexural cracking (i.e., with smaller M/P ratio) are more likely to experience explosive spalling than walls with significant flexural cracking; (3) higher strength concrete walls experience smaller out-of-plane thermal bowing due to higher thermal

conductivity and lower thermal expansion of higher strength concrete; and (4) the thickness of the concrete cover over the steel reinforcement has a significant effect on the load carrying capacity of the walls. These results indicate that in addition to material properties and reinforcement details (e.g., concrete cover), the dehydration of concrete and its relationships with temperature and deformation (e.g., cracking and spalling) play an important role on the behavior of RC walls under fire.

The parameters to be varied in the experimental program are: (1) wall axial load level; (2) concrete strength; (3) concrete cover to reinforcement; and (4) reinforcing details. A total of 8 specimens will be tested as shown in Table 1. Each specimen will first be subjected to a constant axial load (both low and moderate load levels will be considered as shown in Table 1), representing service gravity conditions. Then, the temperatures on the heated surface will be increased based on a pre-determined t-T curve. The application of out-of-plane bending moments will include both initial and increasing moments. Moments that subject the fire-exposed surface to flexural tension as well as flexural compression will be considered.

Table 1: Test Matrix

Specimen Number	Type of Design	Axial Load Level	Concrete Strength MPa (ksi)	Clear Cover cm (in.)	Wall Thickness cm (in.)
1	NSB	$0.10P_0$	31 (4.5)	1.9 (0.75)	38 (15)
2	NSB	$0.20P_0$	31 (4.5)	1.9 (0.75)	38 (15)
3	NSB	$0.20P_0$	31 (4.5)	3.8 (1.50)	38 (15)
4	W	$0.20P_0$	31 (4.5)	1.9 (0.75)	38 (15)
5	SB	$0.20P_0$	31 (4.5)	3.8 (1.50)	38 (15)
6	NSB	$0.20P_0$	31 (4.5)	1.9 (0.75)	38 (15)
7	NSB	$0.10P_0$	62 (9.0)	1.9 (0.75)	38 (15)
8	NSB	$0.10P_0$	62 (9.0)	3.8 (1.50)	38 (15)

NSB = Non-Seismic Boundary
W = Web
SB = Seismic Boundary
P_0=concentric axial compression strength of section at room temperature.

The test specimens represent seismic boundary regions, non-seismic boundary (i.e., end) regions, and web regions from the prototype wall designs. As described below, the web (W) region specimens have distributed reinforcement in the vertical and horizontal directions of the structure, the non-seismic boundary (NSB) region specimens have nominally spaced closed hoops, and the seismic boundary (SB) region specimens have a larger amount of hoop reinforcement in addition to the flexural steel. The finite element models described

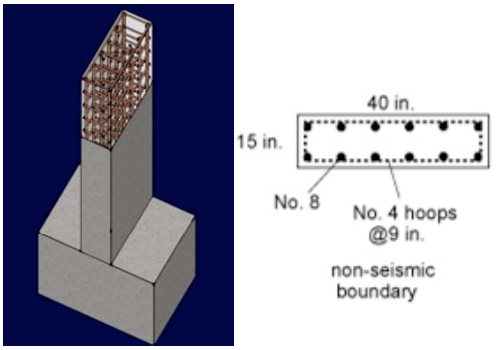

Figure 2. Full scale wall experimental details

in this paper are for the wall detailed for non-seismic applications. Since the research focuses on the out-of-plane response of RC walls under fire, the wall properties in the thickness direction are the most important. Thus, the wall thickness and reinforcement details (including concrete cover) are modeled at full scale. The test specimens model, at full-scale, a 1.0 m (40 in) long strip from the first story [3.05 m (10 ft) high] of a wall. Each specimen has a uniform thickness and uniform reinforcement details along its length and height. This will permit the tests to focus on the most important parameters (i.e., parameters in the thickness direction) affecting the wall response.

FINITE ELEMENT MODELING

Wall Model Description

A finite element model in ABAQUS (2009) was created for the pre-test analyses of the wall specimens. Prior to the laboratory experiments, these models are being used to determine the expected performance of the test specimens so that structures with the highest potential benefit to the current state of knowledge can be tested. Validation and refinement of the analytical models will be based on comparisons between the experimental data and the analytical predictions. Ultimately, the validated models will provide information beyond what could be measured in the laboratory. Furthermore, since only a limited number of structure configurations, designs, and loading histories can be tested, analytical parameter studies are conducted to extend the test data.

The current model utilizes a sequential analysis where the service level gravity load is applied to the wall first followed by a heat transfer analysis to determine the thermal effects. Other loads such as out-of-plane (i.e., in the weak direction of the wall cross-section) lateral forces and moments as well as increased axial forces can be added to the procedure.

The ABAQUS model uses standard 8-node linear brick elements for the wall concrete and 2-node truss elements for the reinforcing bars. The mechanical properties of the concrete were taken from Knaack et al. (2010a,b). This recent research at the University of Notre Dame took all of the available experimental data on North American unreinforced concrete properties under elevated temperatures and performed a statistical analysis to obtain best fit regression lines. The thermal properties of the concrete and the thermal and mechanical properties of the reinforcing steel were taken from Eurocode 2 (2005). Since the thermal conductivity and specific heat vary with temperature, multiple data points were specified in ABAQUS.

The service-level axial load was applied through a stiff steel plate rigidly connected to the top of the wall model to ensure uniform axial stresses on the concrete below. The fire load was applied through radiation and convection coefficients applied with a heat sink corresponding to the appropriate fire load over a 1.83 m (6 ft) height of the wall base. For the pre-test investigation, the thermal analysis was conducted for the full 8-hour ASTM E119 exposure so that extreme limits can be determined beforehand. To reduce the computational run time, the analyses were conducted on a 0.46 m (18 in.) wide wall model [as compared with the

1.0 m (40 in.) wide test specimens]. Similar to the full-scale walls, the base of each model was rigidly connected to a foundation block, which had fixed boundary conditions at the bottom. The temperatures were applied to one face of the wall above the foundation block at the base. Radiation and convection were considered at the back face of the wall since ambient air temperature is assumed in both the test setup and the real building scenario. The two side faces of the wall were modeled with adiabatic boundary conditions because the specimen is a "slice" from a much longer wall. This means that the temperature distribution along the length of the wall is assumed to remain relatively constant.

To validate these models for use in designing test specimens, a fire test of a simpler, smaller concrete wall panel was conducted. This validation effort is described in the next section.

Validation Experiment Description

The validation experiment consisted of testing a simple un-reinforced concrete wall panel under compression loading and simulated fire conditions similar to the fire time temperature curve specified by ASTM E119. Figure 3(a) shows a photograph of the experimental specimen that was tested. The specimen is 1.2 m (4 ft) tall, 0.91 m (3 ft) wide and 0.014 m (5.5 in) thick. The pattern of lines on the face of the specimen was used as part of the deformation measurement technique applied during the testing (digital image correlation) which is described later in this paper. The validation wall was loaded by post-tensioning (PT) bars that were placed within 65 mm diameter ducts that pass through the specimen. The load in the hydraulic jacks was held at a constant 400 kN (90 kips), simulating a service load stress in the validation wall of 6.9 MPA (1 ksi). Figure 3(b) shows a close-up of the load application region of the specimen with the 6.4 mm (0.25 in) thick steel load redistribution plates that were used to spread the load from the jacks. The validation wall was free to expand in the vertical direction.

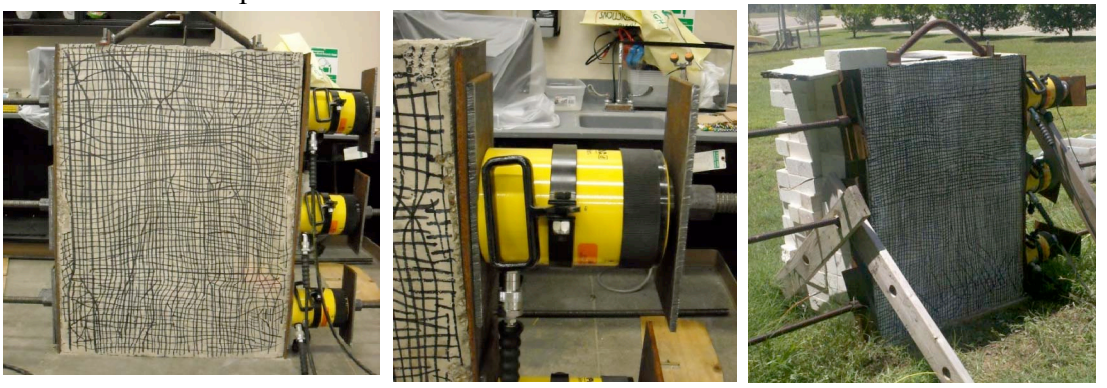

Figure 3. Validation test specimen: (a) specimen; (b) load region; (c) fire test set-up

The validation wall was comprised of concrete with f'_c equal to approximately 41 MPa (6 ksi) and was tested at an age of approximately 12 months from the casting date. The wall was stored exposed to the exterior relative humidity conditions in Tyler, TX during its aging and curing time period from July 2009 to July 2010. The curing conditions influenced the moisture movement documented during the validation test and are discussed more fully later in this paper.

Figure 3(c) shows a photograph of the test set-up for the validation wall. The fire load was applied with a venturi style burner that was outfitted with a simple baffle to spread the heated gasses across the back surface of the concrete specimen. The hot burner gasses were contained within an insulated enclosure with approximate dimensions of 1.2x0.91x0.6 m (4x3x2 ft) constructed of dry fitted refractory bricks. Figure 4 shows the time-temperature curve applied in the validation wall test. The curve plotted is the average of readings from 5 thermocouples that were distributed through the insulated enclosure behind the validation wall. Although similar to ASTM E119, the applied temperatures represent a fire with growth, free burning, and decay phases.

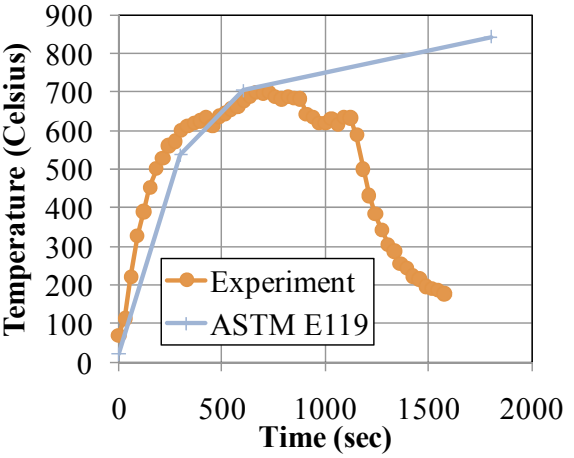

Figure 4. Validation experiment time-temperature curve

A secondary consideration in the validation experiment was to validate new approaches for data collection during fire testing. In the validation experiment, deformations (displacements and strains) were measured with 3D digital image correlation (DIC). 3D-DIC has been used to capture deformations in many civil engineering applications (e.g., Orteu 2009; McGinnis et al. 2005), including those in concrete structures (Corr et al. 2007). In this method, a stochastic pattern is applied to the surface of an object and stereo pairs of photographs of the object are captured before and after load events. The captured digital images are divided into regions that are several pixels across, called facets. Then, these facets are tracked through an image series using pattern recognition and photogrammetric triangulation principles, thus yielding essentially full-field, 3D surface displacements and strains of the view area. The accuracy of 3D-DIC scales somewhat linearly with the field of view (FOV). For the FOV used herein (approximately 1.3 m vertical by 1 m horizontal (51x40 in.), the in-plane accuracy for displacements is conservatively stated as +/-30 microns (0.0011 in). As noted, the pattern used for 3D DIC is visible in the photographs shown in Figure 3.

The full-field of temperatures on the unheated face of the specimen were measured using infrared thermography. The FLIR T400 used is capable of measuring temperatures from -20 to 1200 °C with an accuracy of ±2°C or ±2% of the reading.

Validation Model Description

Details of the validation model were selected to closely match those for the full scale walls. In particular, the material properties, heat transfer and heat input properties (radiation, convection and conduction), element type and approximate element size were similar. The geometry, boundary conditions, and loading matched the validation experiment, and the temperature loading was specified as shown in Figure 4.

Validation Results

Figure 5(a) shows the measured out-of-plane displacements of the validation wall at a time of approximately 500 seconds, and Figure 5(b) shows the output from the validation wall finite element (FE) analysis. The figures show results for approximately the upper 0.99 m (39 in) of the wall – the DIC technique did not record results for the lower 0.23 m (9 in) of the wall. It is clear that the validation wall experienced significant thermally-induced bending during the experimental test that is well captured in the FE model.

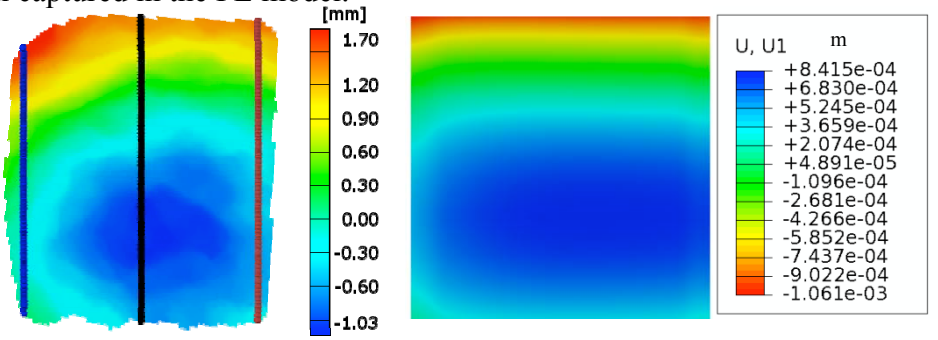

Figure 5. Out of plane displacements in validation experiment: (a) DIC; (b) ABAQUS

Figure 6 shows a comparison of the center out-of-plane displacement of the wall as measured by DIC and as calculated in the FE model. The FE model appears to be capturing the global deformation behavior well.

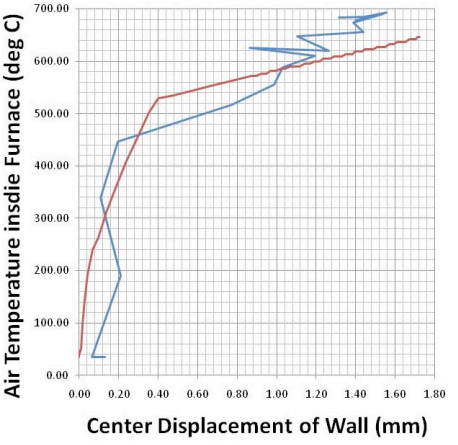

Figure 6. Comparison of center out-of-plane displacement in validation experiment

Figure 7(a) shows the vertical (i.e., y-direction) strains as measured by DIC at a fire time of 80 seconds. The figure shows that the validation wall has cracked at the location of the upper and lower PT ducts at this relatively short fire duration. The validation wall is un-reinforced and relatively thin at the duct locations, resulting in this early cracking. Figure 7(b) shows strain results from the FE model for comparison. The FE model exhibits the same cracking phenomena, albeit at a slightly later time (280 seconds). Within the first several minutes of fire loading, the model is particularly sensitive to the values used for the convection coefficient of the wall, but this dependence drops rapidly at later times when radiation dominates the heat transfer. For realistic concrete walls, the time

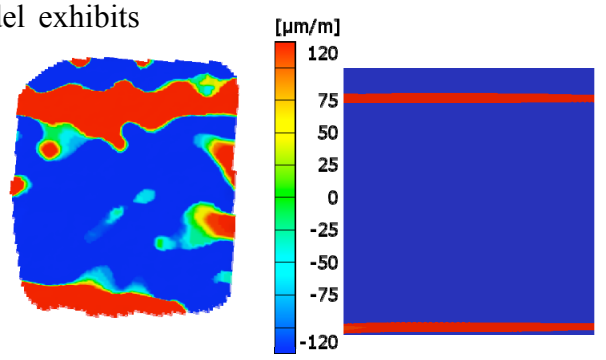

Figure 7. Y-direction strains in validation experiment: (a) DIC, (b) ABAQUS

durations will be considerably longer than in this simple validation test. Good agreement is shown between the experimentally measured values and those from the ABAQUS model.

Finally, the temperatures measured with the thermal imaging system in the validation test are compared with those computed in the FE model (Figure 8). Temperatures are shown for the unheated face at the end of the validation test. The test is for a relatively short fire duration (25 minutes, including the cool-down phase), and thus for this 14 cm (5.5 in.) thick wall, the temperatures of the unheated face do not change significantly from the ambient air temperatures (35 degrees Celsius). Good agreement is noted between measured and modeled results.

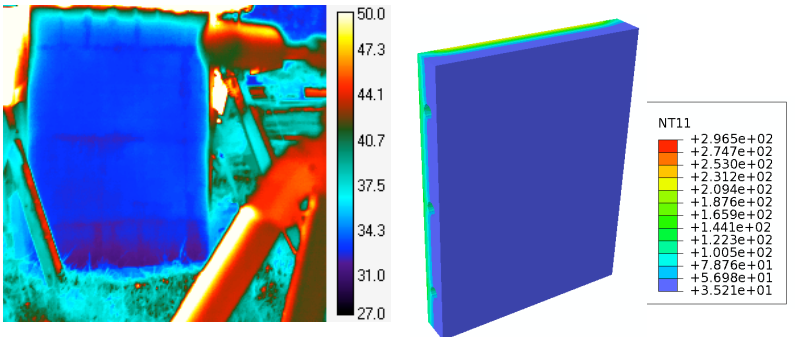

Figure 8. Cold face temperature in validation experiment: (a) measured; (b) ABAQUS

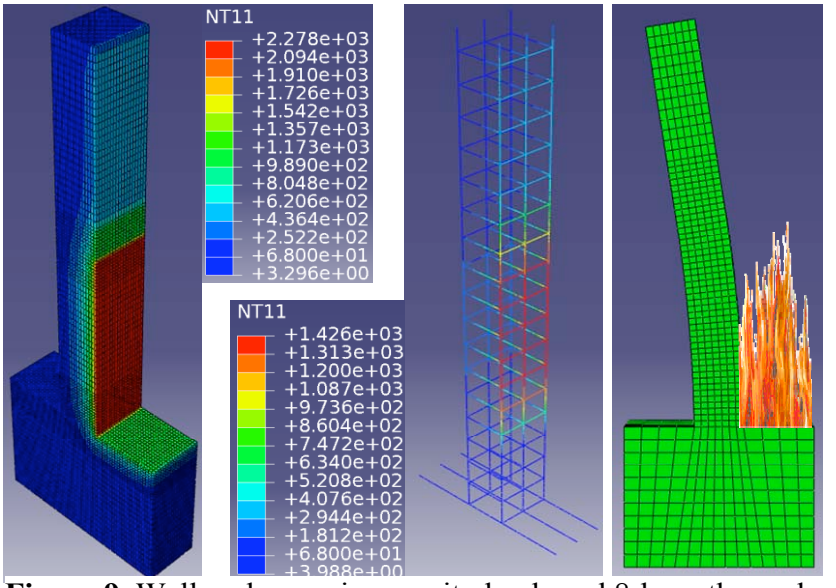

Figure 9. Wall under service gravity loads and 8-hour thermal exposure: (a) concrete temperatures; (b) steel temperatures; (c) wall deflected shape

FULL SCALE WALL MODEL RESULTS

The resulting predicted temperature distribution and deflected shape for one of the full scale wall test specimens is shown in Figure 9. In this analysis, the top of the wall was assumed free to rotate and displace laterally. Additional analyses with different boundary conditions for the wall top will be investigated in the future (e.g., fixed or partially-fixed conditions).

Figure 10. Spalling observed at the end of the validation experiment

Figure 11. Moisture leakage through wall in validation experiment

In the validation tests, spalling (see Figure 10) was observed after only a few minutes of fire exposure. This was expected, as noted, the validation specimen was stored in a high relative humidity environment and thus was at a high internal moisture state. Figure 11 shows the unheated face of the validation specimen at the completion of the test and shows significant water has migrated to the cold surface, driven by the internal temperature changes occurring in the wall. The significant role of moisture movement in spalling phenomena is well known (Consolazio 1998). It is intended that this project will include moisture movement effects in future modeling efforts. Additionally, moisture profiles through the depth of concrete walls will be captured in the experiments using a nuclear magnetic resonance imaging probe (NMR) (Beyea et al. 1997, Prado 2003, Manz et al. 2006, van der Heijden 2007).

Since the accurate modeling of this behavior is difficult in ABAQUS, two extreme models were created to investigate the possible effects of spalling. In the first model (Figure 10), it was assumed that the wall cross section remained unchanged throughout the heat transfer analysis considering no spalling. The second model assumed full spalling from the start of the analysis by removing all of the concrete cover and running the same gravity plus heat transfer analysis on a wall with reduced thickness over the complete heated region. The results from these two models bound the expected actual behavior. The maximum and minimum principal stresses of the concrete from the spalled wall model are shown in Figure 12. The pilot experiment highlighted the challenges in FE convergence after concrete cracking, and these issues as well as the others raised in this paper will receive further study as part of this ongoing project.

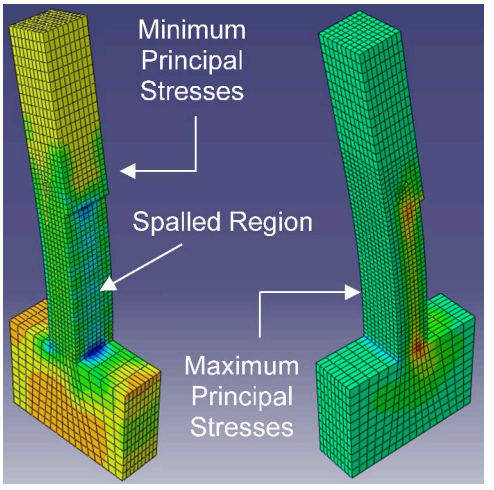

Figure 12. Maximum and minimum principle stresses of wall concrete under service gravity loads and 8-hour ASTM E119 thermal exposure (spalled model)

SUMMARY AND CONCLUSIONS

This paper presents an ongoing research effort on the behavior of reinforced concrete bearing walls under elevated temperatures from fire. General features of a series of wall test specimens are given and a preliminary finite element analysis model for the walls is described. To validate these models for use in designing the test

specimens, a fire test of a simpler, smaller concrete wall panel was conducted. A secondary consideration in the validation experiment was to explore the use of 3D digital image correlation and infrared thermography for data collection during fire testing. The measured and predicted behaviors from this pilot test are compared in the paper. Based on the results, the modeling approach appears appropriate for use in designing the experimental parameters; however, further analytical development is needed, especially on the effects of concrete spalling as well as the behavior after cracking. It is shown that the combination of full-field measurement techniques strengthens the confidence in the validity of experimental and analytical approaches.

ACKNOWLEDGEMENTS

This research is being funded by the National Science Foundation (NSF) under Grant No. CMMI 0800356. An EAGER extension to the project is also funded by the NSF under Grant No. CMMI 1049577. The support of the NSF Program Director Dr. M. P. Singh is gratefully acknowledged. In addition, the authors recognize the technical support provided by Dr. T. D. Lin, President of Lintek International, Inc. The following engineers contributed RC building design details to the project and their help is gratefully acknowledged: Thomas A. Sabol – Englekirk and Sabol; Paul J. Brienen – PCS Structural Solutions; Brian G. Morgen – Magnusson Klemencic Associates; Michael G. Allen and James O. Malley – Degenkolb Engineers; and Rashid Ahmad – Walker Parking Consultants. Strain gauges used in two of the wall specimens were donated by Hitec Products, Inc. The authors are also grateful to StresCore Incorporated, South Bend, Indiana, for allowing the casting of three of the wall specimens in their facility. The opinions, findings, and conclusions expressed in the paper are those of the authors and do not necessarily reflect the views of the NSF or the individuals/organizations acknowledged above.

ABSTRACT

Composite action in floor systems plays an important role in enhancing load carrying capacity. Fire resistance of composite floors however remains an uncertain issue. As such, the fire response of composite floor assemblies during fire resistance tests is presented in this paper. Three composite floor slab assemblies were tested under different fire scenarios, connection configurations and fire protection schemes in the beam. It was observed that the concrete slab plays a major role in transferring forces from one part of the slab assembly to the other. Data from these fire resistance tests are being used to develop and validate numerical models for tracing the fire response of floor slabs.

INTRODUCTION

Composite floor assemblies are predominantly used in the construction of buildings due to the numerous advantages they offer over other floor systems. Composite floors have reduced construction costs, higher load-carrying capacity, and better fire resistance properties. The steel deck present on the top of steel framing system, acts as formwork during concrete casting, eliminating the need for external formwork and thus leads to reduced construction costs. The savings in the construction costs can be significant for multi-storey buildings. Once concrete attains its design strength, the concrete slab acts compositely with the steel beam in carrying the applied loads.

The behavior of composite floor assemblies under fire conditions is different from that at ambient temperature and extremely complex. It was observed in the Cardington test (British Steel, 1998) that the load carrying capacity of the composite floor assemblies under fire conditions was different from that obtained from the consideration of flexural theory. Hence a clear understanding of the fire behavior of the composite floor assemblies is necessary for developing rational design approaches under performance based design environment.

To develop a better understanding of the behavior of composite floor systems under fire conditions, an experimental program was undertaken at the Center for Structural Fire Engineering and Diagnostics at Michigan State University (MSU) in collaboration with Purdue University. As part of the study, fire resistance tests were conducted on three composite floor slab systems. Results of these fire tests are presented in this paper and utilized to quantify the effect of parameters such as fire scenario, fire insulation and connection type on the fire behavior of composite floor systems.

RESEARCH SIGNIFICANCE

There is lack of understanding and data on the behavior of composite floor systems, with unprotected secondary beams, under fire conditions. Previous fire resistance experiments (Bailey et.al (2000), Gillie et.al (2001), Martin Gillie et.al (2001), Gillie et.al (2002), Bailey (2004), Martin Gillie et.al (2004), Wang (2005) and Lamont et.al (2007)) have shown that real structures demonstrate higher fire resistance than predicted by element level fire resistance tests. These studies have indicated that the enhanced fire resistance can be attributed to the composite action in floor systems, and the development of tensile membrane action. During later stages of fire exposure, tensile membrane action helps in transferring forces from fire weakened steel beams to the slab and other cooler parts of the structure. Thus, overall load carrying capacity of the composite floor assembly is maintained for a longer duration. To quantify this effect there has been significant interests in recent years to develop a better understanding on the behavior of floor systems specifically with unprotected secondary beams.

There is however still a lack of understanding on the interaction between fire induced internal forces (such as tension and compression) and composite construction. To gain a better understanding into the effect of internal forces on the behavior of composite floor slab assembly, experiments were undertaken to study the fire response of composite floor systems. Results from these studies, as presented in this paper, can be used to illustrate the typical behavior of composite floor systems under fire exposure.

FIRE RESISTANCE TESTS

To overcome current knowledge gaps about understanding the enhanced fire resistance of composite floor slab assemblies, three composite floor slab assemblies were tested. The test parameters include, fire exposure, connection configuration and fire protection schemes. The experimental program and conclusions are presented in detail elsewhere (Wellman et al. 2010), and are presented briefly in the following sections.

Test specimens: The experimental program consisted of fire resistance tests on three composite floor slab assemblies designated as “Slab1”, “Slab 2” and “Slab 3”. The floor systems were 4.57m long and 3.96m wide, supported on a composite steel beam and girder framework which was 3.96m long and 2.13m wide. As shown in Fig 1 the framework was made with ASTM A992 steel and consisted of W10X15 beams and W12X16 girders. The beams were connected to the girders via shear tab connections

in Slabs 1 and 2 as shown in Fig 2, while they were connected using double angle connections for Slab 3 as shown in Fig 3. The detailing of the assembly including the design of the connections was done as per AISC specifications for structural steel buildings (AISC, 2005).

The girders in all three floor assemblies and the beam in Slab 1 were provided with 14.3 mm of Carboline Type 5GP fire protection in order to achieve a 1-hour fire resistance rating. For all insulated members fire protection thickness was measured at several locations to assure a uniform thickness. In Slabs 2 and 3, the beams were left entire unprotected.

The concrete was cast atop of Vulcraft 1.5VLR composite decking. The deck was arranged such that the ribs are oriented parallel to the girders and perpendicular to the beams. The slab had a maximum thickness of 101.6mm and a minimum thickness of 63.5mm above the ribs of the deck. The slab was provided with 6x6-W1.4xW1.4 welded wire fabric shrinkage reinforcement at a distance of 38.1mm from the top surface of the slab. The beam and girder framework was connected to the slab using 76.2mm (3 inch) long, 15.9 mm (5/8 inch) diameter shear studs with a spacing of 406.4 mm along the girder and 152.4 mm along the beam, as shown in Fig 4. The shear studs are welded to the beam and girder framework and are protruded into the slab through the steel deck by cutting holes of appropriate size in the steel deck.

The concrete on these floor assemblies was placed in two batches. Slabs 1 and 2 were cast from the same batch of concrete while Slab 3 was cast from a different batch of concrete. Light weight concrete was supplied from a local concrete batch mix plant. After placing the concrete, the test specimens were covered with a vapor proof barrier and allowed to cure at ambient conditions until achieving a constant relative humidity. The concrete was designed for a compressive strength of 28 MPa with an actual strength at testing of 42 MPa for all three Slabs.

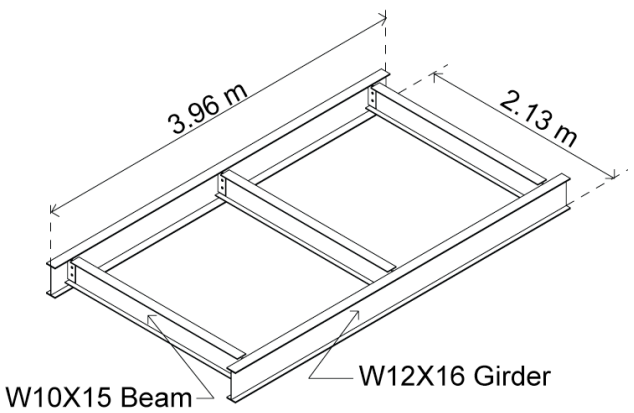

FIGURE 1 – STEEL BEAM AND GIRDER FRAMEWORK USING IN THE COMPOSITE SLAB ASSEMBLIES

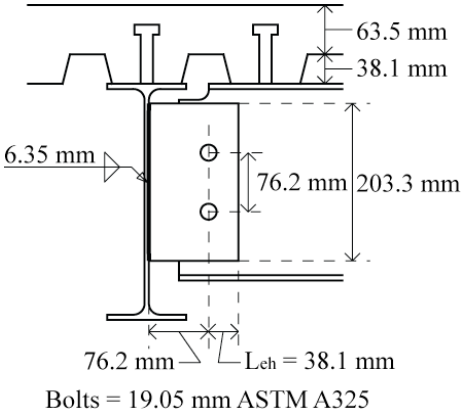

FIGURE 2 – SHEAR TAB CONNECTION USED IN FLOOR SLABS (SLAB 1 AND SLAB 2)

Test Apparatus: The fire resistance tests on the composite floor systems were carried out using the structural fire testing facility at Michigan State University. The test furnace, as shown in Fig.5, has the capacity to simultaneously apply both thermal and structural loading to the test specimen, to simulate that experienced in a real structure.

The furnace consists of a heating chamber that is 2.44 m wide, 3.05 long, and 1.78 m high. The maximum heat power the furnace can produce is 2.5 MW. Six gas burners located within the furnace provide the thermal energy, while six thermocouples, distributed throughout the test chamber, monitor the furnace temperature during a fire test. To facilitate the visual observation of the fire exposed specimen during the course of the fire test, two small view ports are provided on either side of the furnace wall.

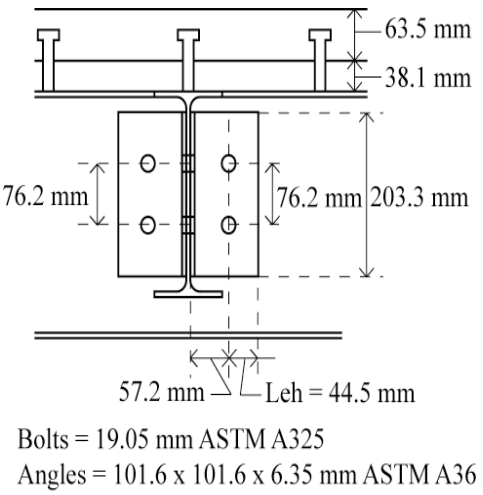

FIGURE 3 – ALL BOLTED DOUBLE ANGLE CONNECTION USED IN FLOOR SLAB 3

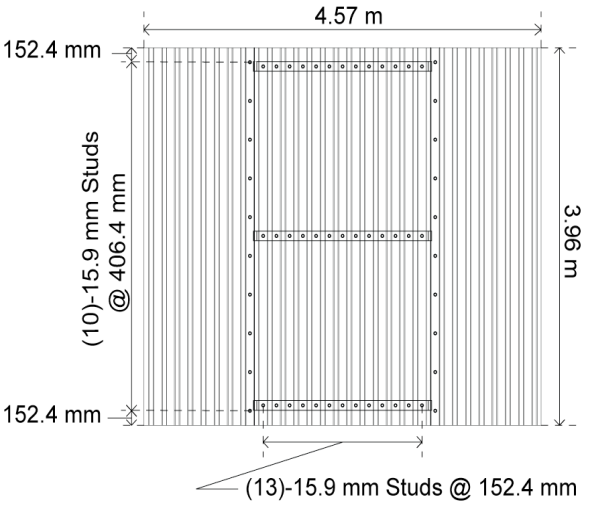

FIGURE 4 – LAYOUT OF SHEAR STUDS IN THE COMPOSITE FLOOR ASSEMBLIES

FIGURE 5 – STRUCTURAL FIRE TESTING FACILITY AT MICHIGAN STATE UNIVERSITY

Test Conditions and Procedure: The slab systems were placed on the furnace in such a way that the middle W10x15 beam was completely inside the furnace, while the ends of W12x16 girders were resting on external supports. Both the external W10x15 beams were completely outside the heating chamber of the furnace.

Loading on the slab systems was applied as five point loads, two along each external girder, and a single concentrated load at the mid-span of the interior beam. The point

loads on the girder were separated by a distance of 870 mm. Loading on the slab assemblies were computed using the ambient temperature ultimate moment capacities of the members assuming equal dead and live load then reduced for fire exposure. The calculated load value at the mid-span of beam was 133.4 kN for Slab 1 and 111.2 kN for Slab 2 and 3 while that on the girders was 22.2 kN applied at 432 mm on either side of the girder mid-span. The loading was applied 30 minutes prior to the start of the test to ensure that the deflections reached a steady state before the start of fire.

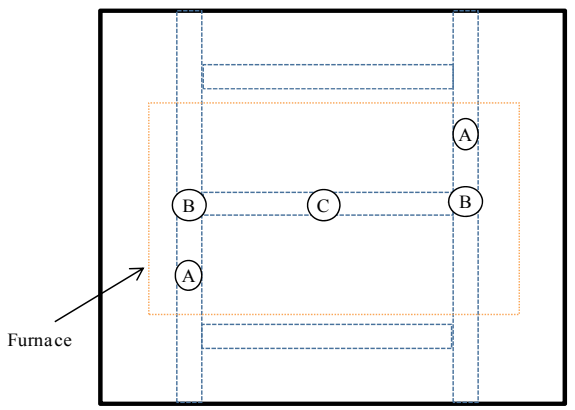
After 30 minutes of load application, Slab 1 was exposed to ASTM E119 standard fire. The load on the beam was applied and continued until the beam failed. Then the concentrated load on the beam was removed and magnitude of two point loads on each girder was increased to 44.5 kN (applied at a distance of 432 mm on either side of girder mid-span). This increased value of concentrated loads on each girder created the same moment at the girders mid-span as that experienced during the initial loading (two point loads of 22.2 kN on each girder and a load of 133.4 kN at beam mid-span). Loading was intended to continue until failure was reached in the girders; however the actuators reached their full extension and the loading value was no longer able to be maintained. At this time all loading was removed and the test ended.

Failure criteria in all the slabs was defined using the criteria recommended by BS-476 (CEN,1987), where failure is defined to be either deflection or rate of deflection. The first failure criterion corresponds to a maximum deflection greater than L/20. The second failure criterion corresponds a deflection greater than L/30 and a rate of deflection greater than $L^2/9000d$.

Slabs 2 and 3 were exposed to design fire with the initial five points loading as described above. This loading was maintained until failure was reached in the beam. Loading on the beam was removed and two point loads on each of the girders were increased to 44.5 kN. Loading was intended to continue until failure was reached in the girders, after which all loading was to be removed and the cooling curve phase initiated. However, in the case of Slab 2, the actuators reached their full extension and the loading value was no longer able to be maintained. In Slab 3, failure was reached in the girders.

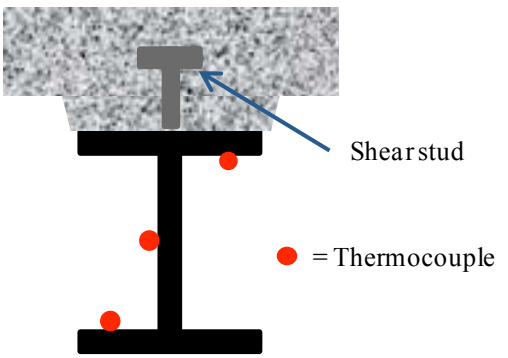
The design fire used for Slab 2 and Slab 3 consisted of ASTM E119 standard fire (ASTM, 2008) for the first 110 minutes for Slab 2, and 85 minutes for Slab 3. This was followed by a decay phase with a cooling rate of 12.2 °C/minute. A summary of test parameters considered in this study are shown in Table 1.

TABLE 1: TEST PARAMETERS USED IN THE CURRENT STUDY FOR COMPOSITE SLABS



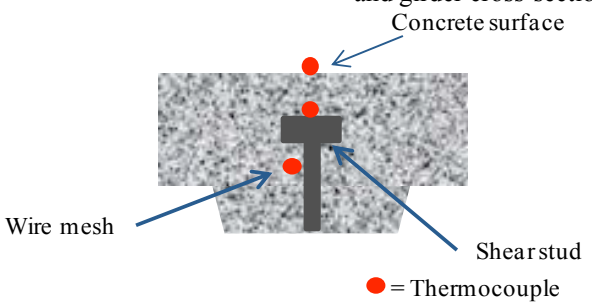
Specimen	Fire Protection (Beam, Girder)	Fire Scenario	Connection	Loading (Beam, Girders)
Slab 1	1 hour, 1 hour	ASTM E119	Shear Tab	133.4 kN, 22.2 kN
Slab 2	None, 1 hour	Design fire 1	Shear Tab	111.2 kN, 22.2 kN
Slab 3	None, 1 hour	Design fire 2	Double Angle	111.2 kN, 22.2 kN

Instrumentation: The instrumentation in the composite floor assemblies included thermocouples, strain gauges, and displacement transducers to monitor thermal and structural response of the floor assemblies. Type-K chromel-alumel thermocouples of



0.91 mm thick were placed on the lower and upper flanges as well as on the web of the steel beams and girders at different locations along the length. Additionally, thermocouples were placed on the ribs of the deck, shear studs and on the surface of the concrete slab. The thermocouples were placed at five different sections (labeled A,B and C) in the slab assembly. Section A is located at the quarter-span of the girder; section B is located at the intersection of beam and girder while section C is located at the mid-span of the beam. Location of thermocouples in the slab assembly along with the thermocouple layout in beam and concrete section are shown in Fig 6. Also, the furnace temperature was measured using six thermocouples distributed spatially inside the furnace in accordance with the ASTM E119 test procedures.

The vertical displacements of the slab were measured using linear varying displacement transducers (LVDT's) connected to the top surface of the slab. Also strain on the top surface of the slab was measured using strain gauges located at three locations on the slab. Location of the displacement transducers and strain gauges are shown in Fig 7.



Data from the instrumentation network was recorded at five second intervals via a central data acquisition system. Also, the pressure in the vertical actuators of the furnace was also recorded as a measure of applied load. Additionally, visual observations were made to record any important events (beam buckling, insulation fall off) or at five minute intervals throughout the duration of the test.

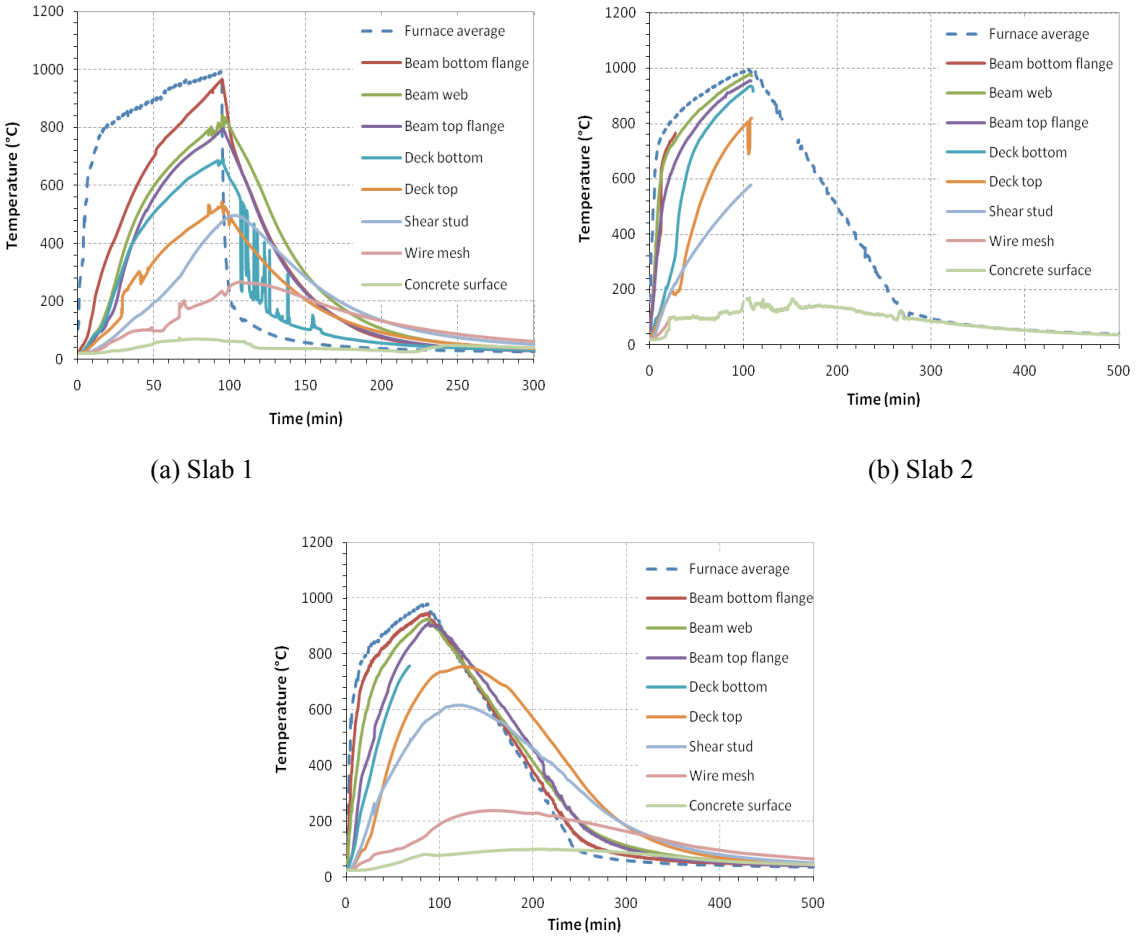
EXPERIMENTAL RESULTS

Data generated from the above fire tests can be used to study thermal and structural response of the composite slab floor assemblies under fire exposure. Thermal response, structural response, and failure patterns are presented in the following sections to illustrate the response of the assemblies to fire.



Thermal Response: Fig 8 shows the recorded temperatures at mid-span of the beam for Slabs 1, 2 and 3 during the fire test. As expected, the temperature of the unprotected beam closely followed the fire temperature, and in general, is higher than the other slab components. The maximum temperature recorded at various locations along the beam cross-section decrease from beam bottom flange to the concrete surface. This is on the expected lines because the beam is subjected to maximum fire exposure as it is closer to the fire zone and the temperatures decrease with increased distances from fire zone.

The temperatures in the deck (bottom and top) follow that of the fire, though the temperatures themselves are lower. These lower temperatures observed in the deck are due to large thermal capacity of the concrete slab, while the similarity in the temperature trends is because the bottom of the deck is directly exposed to the fire. Also the maximum temperature in the shear stud and wire mesh are lower than that of steel beam and deck because of the fact that they are located in the concrete and far from the fire zone. Also the thermal conductivity of concrete is lower as compared to steel. However the trend in the temperature variation is similar to that of the average temperature recorded in the furnace.

Structural Response: The structural response of the composite slab can be gauged through deflection time history of the slabs as seen in Fig 10. Fig 9 shows the labeling of displacement transducers used in the displacement plots. It can be seen in Fig 10 that the displacements in the beam and girders gradually increase with increasing fire

temperatures. Then the displacements start to decrease in the cooling phase of the fire (Slabs 2 and 3). The increase in deflections is caused due to the loss in stiffness of steel and thermal expansion of steel with increasing temperature. The free thermal expansion of the beam is restrained by the presence of surrounding girders. The restraint provided by the girders induces additional compressive forces in the beam. The reduced strength of the beam and restraint provided from the protected girders results in an increase in deflection.

As soon as the decay phase of the fire starts, the temperatures in the beam as well as the entire slab assembly start to decrease, allowing it to regain part of their initial strength and stiffness as well as an increase in thermal contraction. This increased strength and thermal contractions results in the decreased deflections in the entire slab assembly.

(a) Slab 1

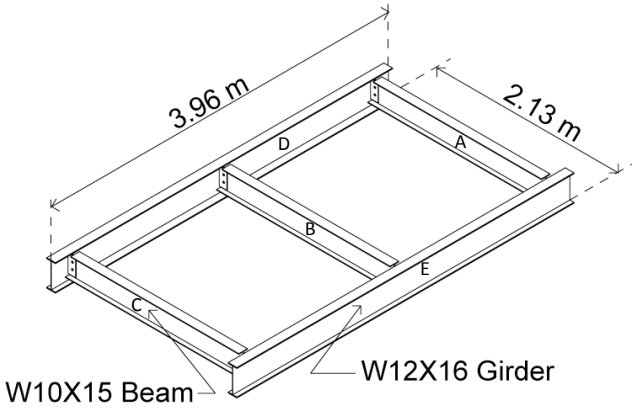
(b) Slab 2

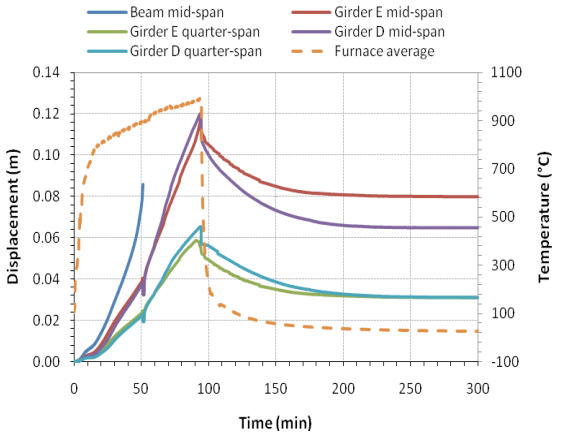
(c) Slab 3

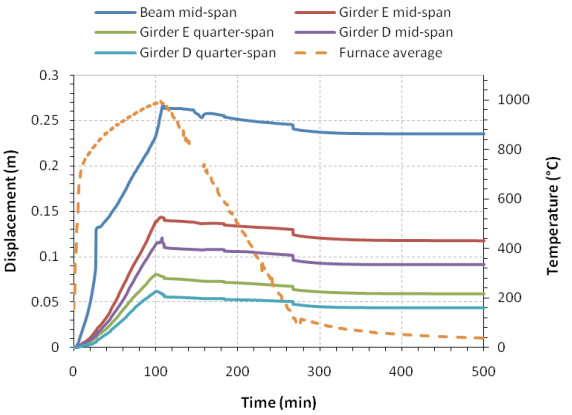
FIGURE 8 – RECORDED TEMPERATURES AT MID-SPAN OF BEAM AS A FUNCTION OF FIRE EXPOSURE TIME

It can be seen from the figures that the maximum displacement occurs at the beam mid-span. Also, the deflections at the beam mid-span increase rapidly during the growth phase of the fire. This is expected because as the fire temperatures increase, the beam undergoes an increased thermal expansion as well as rapid loss in stiffness

in comparison to the protected girders. The girder mid-span deflection is slightly higher for slab with unprotected beam in comparison to the one with protected beam. This indicates that the reduction in deflection due to fire proofing the beams is not significant and leaving the beam unprotected might not significantly influence the overall behavior of slab.







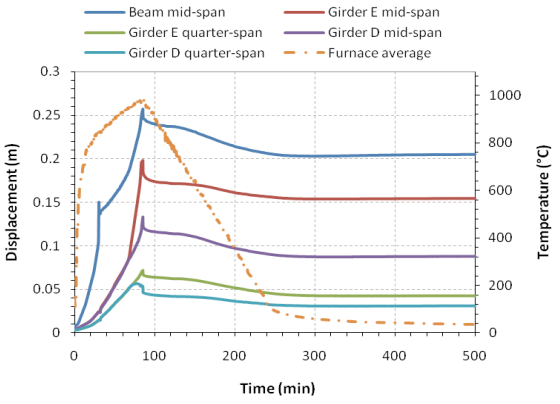


FIGURE 9 – LABELING OF BEAMS AND GIRDER IN THE SLAB ASSEMBLY USED IN DISPLACEMENT PLOTS

(a) Slab 1

(b) Slab 2

(c) Slab 3

FIGURE 10 – DEFLECTIONS RECORDED AS A FUNCTION OF FIRE EXPOSURE TIME AT DIFFERENT SECTIONS FOR THE SLAB ASSEMBLIES

A comparison of deflections of slab with shear tab connection and double angle connection shows that the deflection of girders with double angle connection is greater than that with shear tab connection. Also the rate of deflection for double angle connections is higher than that of shear tab connection. These observations indicate that the double angle connections have more flexibility in comparison to shear tab connections.

Cracking and failure patterns: In addition to the thermal and structural responses recorded through the instrumentation, visual observations were taken during the course of each fire test to note important events. For Slab 1, initial cracking was observed in the concrete slab over the beam and girders. These cracks were followed by the development of diagonal cracks from the girder and exterior beam joints with steam and boiling water emitted from the cracks. At about 51 minutes in to fire exposure, the concrete under the central load actuator failed to the concentration of forces, thus the load had to be removed. At 94 minutes in to the test, deflections in the girders accelerated and the actuators could not maintain loading, thus the test was ended at this time.

For Slab 2, cracking occurred initially in an ovular shape, in the slab, with steam and boiling water emitted from the cracks. At 27 minutes, the deflection failure criterion for the beam was reached. Beam loading was then removed and the girder loading increased. Testing then continued until 110 minutes when the actuators reached their full extension and no further loading could be applied. The cooling phase was then entered and maintained until 270 minutes when the furnace reached its ambient state. When the specimen was removed from the furnace, visible rotational deformations were present in the shear connections, along with bearing deformations of both the beam web and the plate, as well as deformations of the bolt shank.

Initial cracking of Slab 3 was over the beam, parallel to the member, as well as in ovular shape around the loading point. At 31 minutes, the maximum deflection in the beam was reached. Beam loading was then removed and girder loading increased. Testing continued until 85 minutes, when one of the girders reached its deflection failure criteria. The girder failure resulted in the development of a huge crack along the length of the girder. The cooling phase of the heating curve was entered and maintained until 265 minutes when the furnace reached its ambient temperature. When the specimen was removed from the furnace, small but visible rotational deformations were present in the shear connections.

In all three slab assemblies, cracks started forming in ovular pattern with steam emitting from the cracks. As the test progressed, cracks began to form at different locations in the slabs with initial cracks widening. At the end of the tests, all slabs had ovular cracking patterns with all the cracks present in the region between the two girders. The crack development and concentration indicates the development of tensile membrane action (tensile ring in the concrete surrounded by a compressive ring) where in the concrete slab started to carry load from the fire affected steel section and transfer it to unaffected steel sections.

CONCLUSIONS

Based on the results from the presented experimental study, the following conclusions can be drawn:

- Application of fire protection to the beams helps in reducing the heating rate of the beam as well as its deflections.
- No failure was observed in the fire exposed beam to girder connections though these connections underwent permanent deformations.
- In composite beam slab assemblies the deflection in girders are slightly higher when beams are unprotected than those with protected beams. This indicates that leaving the beams unprotected might not significantly affect the overall slab behavior.
- In composite beam slab assemblies double angle connections are more flexible than shear tab connections under fire conditions.
- Unique data generated from these floor tests can be used to validate numerical models for tracing the fire behavior of floor systems and connections under fire conditions.

ABSTRACT

This paper presents the behavior of A992 wide flange steel columns under fire loading. Experimental tests were conducted to investigate the structural-thermal response of steel columns subjected to axial loads and elevated temperatures. Two identical W14X53 specimens were tested under (i) non-standard fire loading to determine the axial load capacity at elevated temperature and (ii) standard fire loading to determine the buckling temperature of the axially loaded steel column. For the non-standard fire test (Test I), the monotonically increasing axial load was imposed on the steel column under steady-state heating condition. For the standard fire test (Test II), the steel column carrying the sustained axial load was tested under transient heating condition. The structural-thermal responses of steel columns observed in Test I and Test II were compared including column end rotations, lateral and axial displacements, and steel temperatures. The measured column buckling behaviors were also compared to those obtained by 3D finite element analyses. The results indicated that the end rotations and displacements of the steel column before buckling were affected by the sequence of applied loading. Both Test I and Test II provided the similar prediction of axial load capacity and buckling temperature of the steel columns.

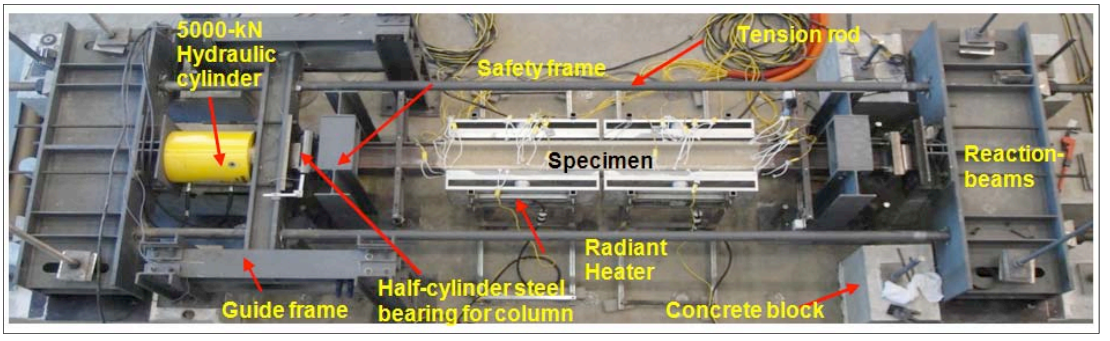
INTRODUCTION

In U.S., prescriptive fire ratings of building components have been obtained from ASTM E119 (2010) standard fire test or standard calculation methods based on the results of prior E119 fire tests. However, most column tests have been conducted without applying service loads. This is because the standard fire tests on the mechanically loaded steel columns are expensive and there are only a handful of column testing furnaces in the world. As a result, there is a lack of knowledge regarding fire behavior of the structural steel columns in service. This knowledge must be supported by experimental data regarding the structural-thermal responses of steel columns subjected to combined axial loads and elevated temperatures. Theses experimental test results are essential to develop structural performance-based design guidelines for steel building structures under realistic fire loading effects. The

behavior of steel building structures under fire loading depends significantly on the elevated temperature performance of the steel columns (Varma et al. 2008).

This paper presents experimental test program to investigate the inelastic behavior of A992 wide flange steel columns subjected to elevated temperatures from standard and non-standard fire loading. The 3D finite element models were also developed to predict the fire behavior of steel column prior to the tests. The experimental results can be a benchmark to validate any existing column design curves that account for the effects of surface temperatures, thermal gradients, and restraints at the columns ends.

TEST PROGRAM



The experimental tests were conducted to determine the fundamental behavior and stability of wide flange steel columns subjected to combined axial loads and thermal loading. Test program consisted of Test I and Test II by imposing two different loading conditions including non-standard fire and standard fire, respectively. Test I was conducted such that the steel column was tested under steady-state heating condition. Note that the steel column was exposed to uniform temperature throughout the test. Test II was conducted such that the axially loaded steel column was exposed to increasing temperatures until column buckled. To do this, ASTM E119 temperature-time (T-t) relationship was used for determining the rate of heating to the specimen. Test results included: (i) axial load-displacement (P-δ), (ii) axial load-lateral displacement (P-Δ), (iii) axial load-end rotation (P-θ), (iv) temperature-axial displacement (T-δ), (v) temperature-end rotation (T-θ), and (vi) temperature-lateral displacement (T-Δ) responses. In addition, these measured responses obtained from Test I and Test II were compared.

The specimens were A992 W14X53 columns with the length of 3.45 m. They were simply supported bare steel columns with slenderness ratio (L/r_y) of 71. Mechanical properties of W14X53 columns were: yield strength of 406 MPa, ultimate tensile strength of 530 MPa, and elongation (with 8 in-gauge length) of 24.5%. Figure 1 (a) shows the self-reacting test frame that was designed for conducting the column tests, which could allow (a) easy access to install the voltage-based displacement and rotation transducers and (b) axial loads up to 4000 kN. Four concrete blocks supported the entire setup. Machine greased steel plates (A572) were placed on the blocks to minimize the friction effect on the measured axial loads. Half-cylinder steel bearings and matching saddles were used to avoid the undesired bending of tension rods.

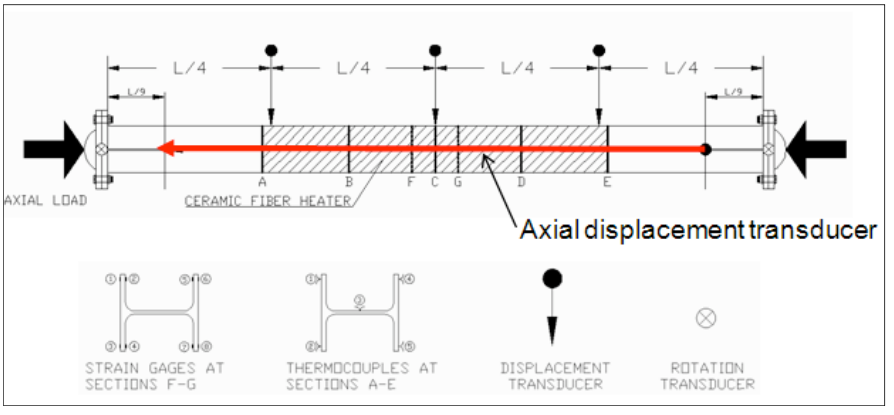


Figure 1 (a) shows the location of ceramic radiant heaters. The column was exposed to radiant heating with surface dimensions equal to 400 mm x 1000 mm. The column length subjected to high temperature during the test was 1800 mm. These heaters were placed as close as 1 cm from each side of the specimen. Namely, the flanges in the mid-portion of specimen were directly exposed to radiant heating. Figure 1 (b) shows the instrumentation layout. Three linear displacement transducers along the specimen length measured the lateral displacements. Two rotation transducers were mounted at the column ends. Two string potentiometers were

installed toward the column ends to measure the axial displacement. K-type thermocouples covered with insulation cement patch measured the steel temperatures during the test. Ceramic insulation blankets were placed on top of the steel specimen where radiant heating was not directly applied.

In Test I, the steel column was exposed to the target steel temperature of 500 ^{o}C, which maintained throughout the test. Once target temperature was achieved, axial loading was applied monotonically until the column buckling occurred. In Test II, the specimen carrying the constant axial load (60 % of ambient axial load capacity) was exposed to increasing temperatures until column buckled. The heating rate used in Test II was obtained from 2D heat transfer analysis using the standard E119 T-t relationship. For both Test I and Test II, axial load of 133 kN was applied initially to align the specimens and to ensure the concentricity of loading.

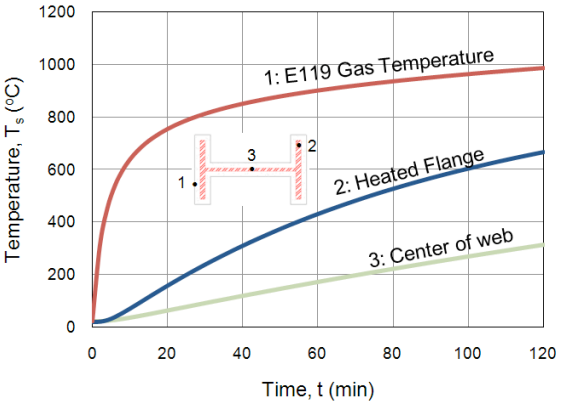
Steel Temperature Profile

In order to determine the heating rate used in Test II, ASTM E119 (2010) gas temperature-time (T-t) relation was considered. Using the ceramic radiant heaters, this standard gas temperature could not be directly applied to the specimen; instead,

the pre-determined steel surface temperature profile was required to operate the heaters. The applied steel temperature profile was determined before the testing, the procedure was as follows: (1) thickness of fire protection (e.g. SFRM) was assumed to be 20 mm (3/4 in.). This fire protection provided the design fire resistance rating of 1 hour for W14X53 steel column. The building code, IBC (2008) was used for the design of fire protection. (2) 2-D heat transfer analysis was conducted to obtain the steel temperatures when the specimen subjected to the standard E119 fire for 2 hours. The material properties of steel and spray fire resistant materials (SFRM) were considered as specified in Eurocode-3 (ECS 2005).

Figure 2 shows the prediction of steel temperature profile that was used for thermal loading to the W14 specimen in Test II. As shown below, when the W14X53 column with SFRM coating (with design fire rating of 1hr) is subjected to the standard E119 fire, the heated steel temperature is increased almost linearly with the rate of 6 ^{o}C/min. In Figure 2, gray and red lines represent the SFRM coating and the cross section of W14X53, respectively. Note that the flanges were exposed to the E119 fire but the web remained at ambient. Web temperature was increased by thermal conduction. The same heating condition was used in Test II.



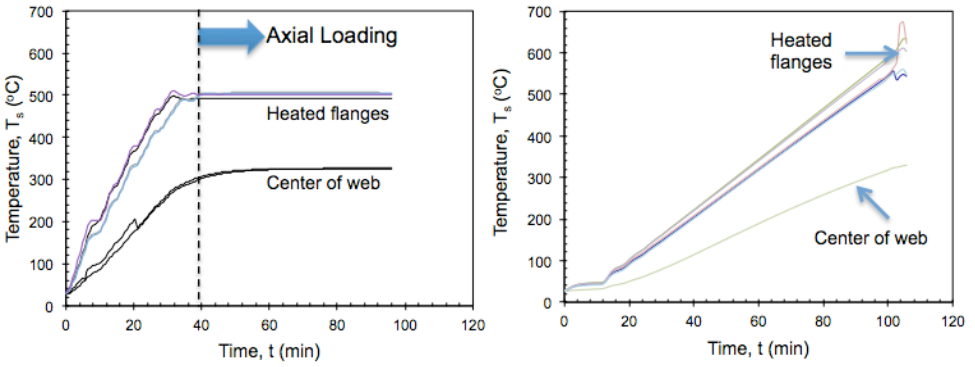


Figure 2 Temperature-time (T-t) relations obtained from 2-D heat transfer analysis

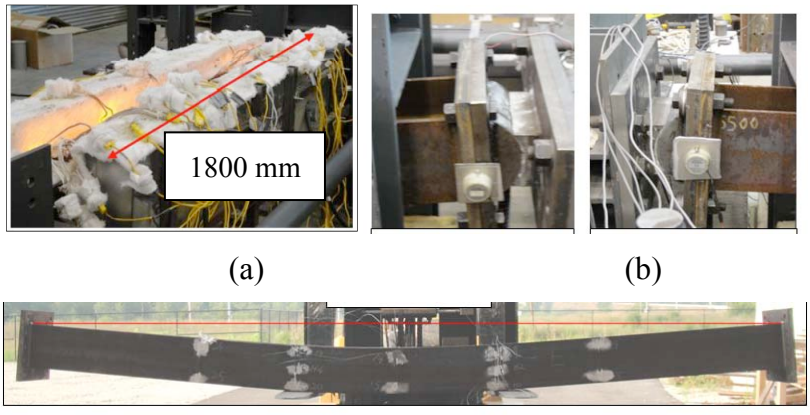
TEST RESULTS

Temperature Measurement and Loading Procedure

Figures 3 (a)-(b) show the steel temperatures of W14X53 specimens measured in Test I and Test II, respectively. In Test I, it took about 40 minutes to reach the exposed steel temperature of 500 ^{o}C followed by increasing axial loading under steady-state heating condition. In Test II, the identical W14X53 specimen was also tested under transient heating condition. As shown in Figure 3 (b), the steel

temperature was increased with the approximate rate of 6 ^{o}C/min obtained from 2-D heat transfer analysis. To compare the column behavior under two different heating conditions, the specimen used in Test II was subjected to axial load of 1450 kN, which was the maximum axial load measured in Test I.

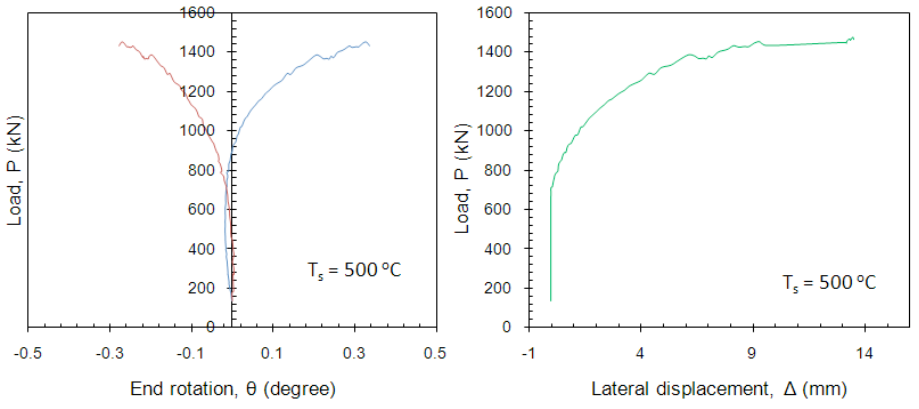


(a) (b)

Figure 3 Steel temperatures of W14X53 columns measured in (a) Test I and (b) Test II

Observation from Test I

Figures 4 (a)-(c) show photographs of W14X53 column during testing, the final end rotations, and final deflected shape, respectively. Increasing axial load slowly developed the global buckling at the steel temperature of 500 ^{o}C. When axial load reached to 1450 kN (about 60% of ambient axial load capacity), the column instability was accelerated with developing large lateral displacement. No local buckling was observed.



(a) (b)

(c)

Figure 4 (a) The specimen during the test, (b) final end rotations, and (c) final deflected shape obtained from Test I

Figures 5 (a)-(b) show the measured axial load-end rotation (P-θ) and the axial load-lateral displacement (P-Δ) response of W14X53 column when exposed to steel temperature of 500 °C, respectively. In Figure 5 (a), positive values indicate the rotations (θ) measured near the hydraulic cylinder; negative values indicate the far end rotation. It was observed that the magnitude of end rotation increased remarkably after the axial load was about 1450 kN. This result was also reflected in the measured lateral displacement response as shown in Figure 5 (b). Very small end rotations and lateral displacements were observed at the axial load less than 800 kN.

(a) (b)

Figure 5 (a) Axial load-end rotation (P-θ) and (b) axial load-lateral displacement (P-Δ) response obtained from Test I

Observation from Test II

Figure 6 (a)-(b) show the measured steel temperature-end rotation (T-θ) response and the measured steel temperature-lateral displacement (T-Δ) response of W14X53 column subjected to constant axial load of 1450 kN. This magnitude of axial load was the maximum axial load measured in Test I. Compared with Figures 5 (a)-(b), the specimen behavior in Test I was different from Test II. The column behavior was controlled by the sequence of loading.

As illustrated in Figures 6 (a)-(b), the W14X53 column in Test II was deflected upward at the initial stage of thermal loading (up to 250 °C), and then changed the direction. This is probably because of the temperature gradient through the cross-section that was not avoidable due to the heater layout shown in Figure 1 (a). Also, ceramic insulation blankets were placed top of the specimen only to protect the thermocouples as shown in Figure 4 (a). It was observed that the exposed temperature of top flanges were 20% higher than the bottom flanges. When the column was under transient heating condition, the temperature gradient across the cross section had a significant effect on the column behavior. Further investigation on the cause of this thermal bowing is still undergoing.

Figures 6 (a)-(b) also indicate that end rotations and lateral displacements are increased significantly in the temperature range from 500 to 550 °C. After the

exposed steel temperatures reached to 550 ^{o}C, the noticeable global buckling was observed. At that point, the hydraulic cylinder and controller could not hold the specified axial load (=1450 kN) anymore. The final deflected shape of the specimen was similar to that of the specimen observed from Test I. No local flange distortion was observed.

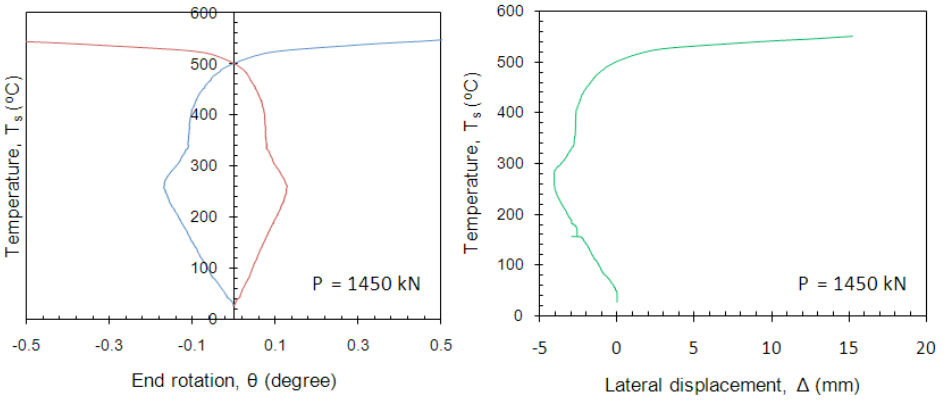


Figure 6 (a) Axial load-end rotation (P-θ) and (b) axial load-lateral displacement (P-Δ) response obtained from Test II

3D FEM PREDICTIONS AND COMPARISONS

Prior to each experimental test, three-dimensional finite element models (3D FEMs) were developed to predict the expected specimen behavior. Test I and Test II were simulated using finite element based software, ABAQUS ver. 6.10-1 (ABAQUS 2010). The modeling approaches were based on the methodology developed by Agarwal et al. (2009) and summarized in Choe et al. (2010). Eurocode-3 (ECS 2005) temperature dependent elastic, plastic, and thermal material properties of steel (i.e., σ-ε-T and α-T, where σ = stress in MPa; ε = strain; T = temperature in ^{o}C; and α =thermal expansion coefficient in $^{o}C^{-1}$) were used in the finite element models. Figure 7 (a) shows comparisons of the measured and numerically predicted axial load-displacement (P-δ) response of the W14X53 column in Test I. Similarly, Figure 7 (b) presents the exposed.

As shown in Figure 7 (a), the column specimen in Test I axially shortened with increasing axial load. The load-displacement response was similar to the column buckling at ambient temperature, but the steel stiffness and yield strength at elevated temperatures were degraded significantly. The measured axial capacity was 1450 kN (about 60% of axial capacity at ambient). In contrast, the column specimen in Test II elongated until the column was not able to maintain the sustained axial load of 1450 kN as shown in Figure 7 (b). The exposed steel temperature at column buckling was 550 ^{o}C. The specimens in Test I and Test II had a different behavior (i.e, shortening vs. elongation), but provided the similar prediction of axial capacity and buckling

temperature. Also, the comparisons in Figures 7 (a)-(b) show that the 3D finite element models reasonably predict the experimental behavior of the tested column specimens.

Figure 7 (b) shows there is slight discrepancy between the measured and calculated steel temperature-displacement (T-δ) response of the W14X53 column in Test II. This is probably due to the temperature gradient across the cross section in experiment. Temperature measured at the bottom of specimen was lower than 500 ^{o}C because of the heater layout and insulation used in Test II as described earlier. No temperature gradient was included in finite element model, and column buckling temperature was more conservative than the measured buckling temperature.

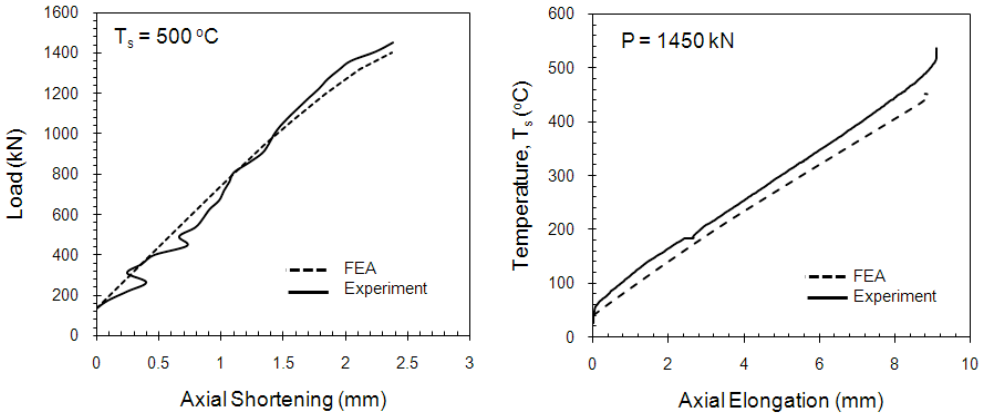

Figure 7 (a) Axial load-displacement (P-δ) in Test I and (b) Temperature-displacement (P- δ) response in Test II

SUMMARY AND CONCLUSION

This paper has presented the structural-thermal response of structural steel columns subjected to elevated temperatures. Experiments were conducted to compare the column behavior under two different heating conditions. In Test I, the W14X53 column was subjected to 500 ^{o}C and increasing axial loading until column buckling occurred. In Test II, the pre-determined steel surface temperature profile (obtained from heat transfer analysis) was used to apply thermal loading to the specimen subjected to sustained axial load (about 60% of axial load capacity). The overall behavior including end rotations, lateral displacements, and axial displacements were dissimilar between Test I and Test II. This is because the column behavior was controlled by the loading sequences. Initial thermal bowing was observed in Test II. This was because the effect of temperature gradient across the cross section in the heated region was more significant on the column behavior under transient heating condition. Test I and Test II resulted in different column axial displacements (i.e, shortening vs. elongation) before buckling, but provided the similar prediction of axial capacity and buckling temperature.

ACKNOWLEDGMENT

The research presented in this paper was funded by the National Science Foundation (Grant No. SMM-0825506 and 0825338). The project is titled " Structural Mechanics of Steel columns and Beam-Columns under Fire Loading". Experimental data, findings, and conclusions or recommendations are those of the authors only.

INTRODUCTION

The contribution of carbon emissions to the increase in the global average temperature is well established. It is nearly universally accepted that significant decreases in carbon dioxide and other greenhouse gas emissions must be realized in the near future, or the global community will face very troublesome and possibly even catastrophic climate-related impacts. Civil engineers have a professional duty to abide by the code of ethics adopted by ASCE. The first principle states "Engineers uphold and advance the integrity, honor and dignity of the engineering profession by: a) using their knowledge and skill for the enhancement of human welfare and the environment." The first canon instructs us that "Engineers shall hold paramount the safety, health and welfare of the public and shall strive to comply with the principles of sustainable development in the performance of their professional duties" (ASCE, 2009). To these ends, structural engineers are tasked with finding ways to reduce the climate impacts of structures. This paper provides information on the currently available data pertaining to the carbon impacts of concrete and steel. The focus is on how to use the available data to make informed choices to minimize the climate impact of the material aspects of structural design. The first step is to understand the

impacts, their relative intensities, and a little bit about climate science. The Carbon Working Group is dedicated to making this information available and usable.

BACKGROUND

The term "greenhouse effect" is used to describe how carbon and other heat-trapping gases in our atmosphere warm the Earth and its lower atmosphere. These gases allow visible light to enter, but obstruct escaping heat. Sunlight imparts energy to the Earth. When the Earth radiates this solar energy back out in the form of infrared radiation (heat), greenhouse gases (GHGs) reflect this heat in all directions, including down toward the Earth. Ice core data shows that for all of human history—roughly 200,000 years—the amount of CO_2 in the atmosphere ranged from about 190 to 290 parts per million (ppm) (Petit 1999). Most recent temperature and carbon concentration data sets show rapid increases over the past 100 years. Currently the concentration of atmospheric CO_2 is about 390 ppm and is increasing at a rate of about 2 ppm/year (ESRL 2011). Between 1910 and 2005, the global average temperature rose by 0.9 degrees Celsius, with over 60% of the rise occurring since 1970 (IPCC 2007). The scientific community is nearly unanimous that these increases are due to human activities.

While CO_2 is not the most potent GHG, it is the most abundant and therefore has the largest cumulative effect. Greenhouse gases persist in the atmosphere. Each gas has a different rate of decay. One-fifth of the CO_2 we emit today will remain in the atmosphere in the year 3011. The carbon we "spend" today will continue warming the earth for thousands of years, and so it follows that the carbon we spend tomorrow doesn't replace today's carbon, but rather is added to it, resulting in carbon build-up. The decay rate of GHGs is therefore a fundamental part of determining its global warming potential (GWP).

Many gasses contribute to the greenhouse effect, but the warming potency of the gasses varies widely. By far the most abundant greenhouse gas is carbon dioxide (CO_2), but nitrous oxide (N_2O) and methane (CH_4) are present in significant amounts and are more potent warmers. The GWP of any gas is a measure of how much it contributes to global warming compared to how much the same mass of carbon dioxide contributes. Thus, by definition, the GWP of carbon dioxide is 1. GWP depends on how well a gas absorbs infrared radiation (radiative forcing) and how quickly it decays from the atmosphere. Therefore, the GWP depends on what time-span is being considered, for example the next 10, 100 or 500 years. The 100-year time-frame is most common. At 100 years, the GWP of methane is 25 and that of nitrous oxide is 298 (IPCC4 2007).

Carbon Dioxide Equivalency (CO_2e) represents the global warming potential of a mixture of gasses in known amounts as an equivalent amount of CO_2. To convert non-CO_2 emissions into CO_2e, the mass of each gas is multiplied by its GWP and added together to find a mass of CO_2e. It is important that all the GWP values used are from the same time-scale or the result is meaningless. References to "carbon" emissions in this paper refer to CO_2e unless otherwise noted.

The relatively sudden rise in temperature caused by increasing CO_2 emissions is destabilizing the earth's weather systems, leading to more frequent and severe storms, new rainfall and drought patterns, and altered temperature patterns that will

make some areas of the planet significantly colder and some areas much warmer. The warming of the arctic regions will melt ice sheets, causing a rise in sea level, and putting low-lying coastal areas and some island nations under water.

SOURCES OF CARBON EMISSIONS

Fossil fuel use is the largest contributor to carbon emissions. The U.S. Environmental Protection Agency (EPA) reports that in 2008 the U.S. emitted about 6,960 million metric tons (Tg) of CO_2e, about 85% of which was due to fossil fuel combustion (EPA 2010). Figure 1 shows the breakdown of these fossil fuel emissions.

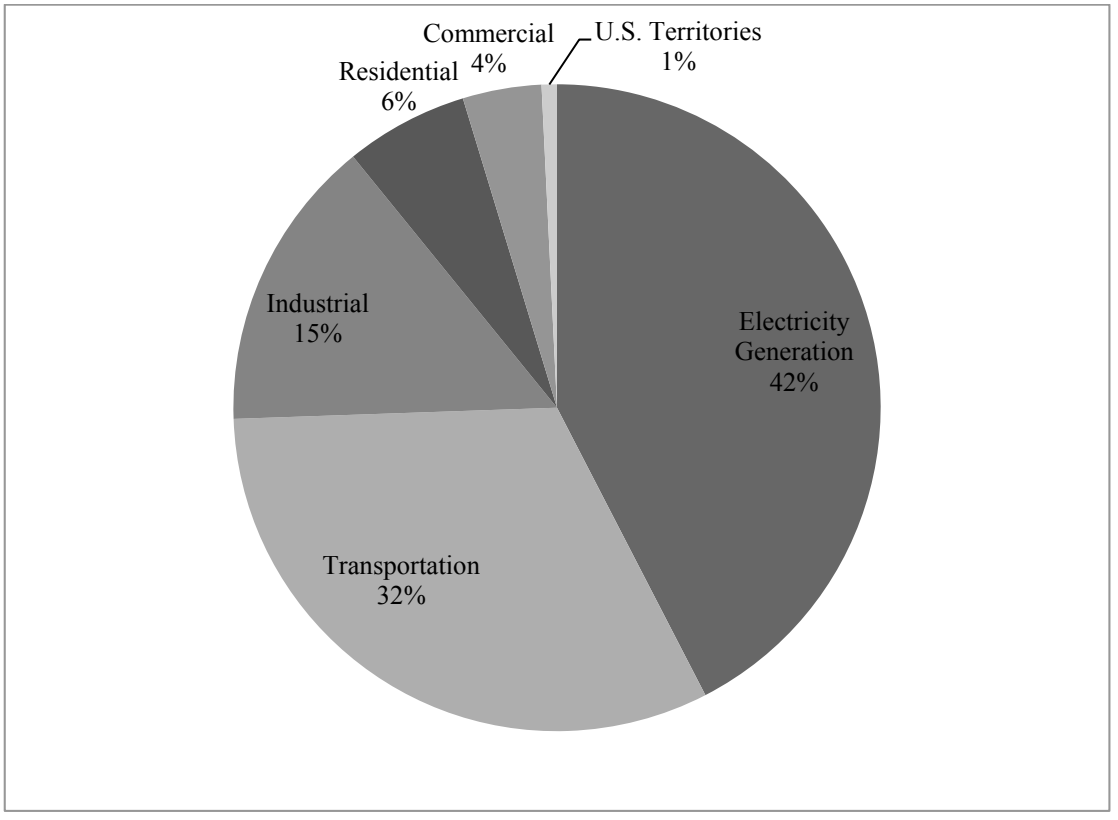

Figure 1: U.S. Carbon Emissions Due to Fossil Fuel Consumption (EPA 2010)

In addition to fossil fuel combustion, certain industrial sectors produce significant quantities of carbon emissions due to process-related chemical reactions. Iron and steel production and metallurgical coke production accounted for 69 Tg CO_2e in 2010 and cement production for 41 Tg.

RELEVANCE OF BUILDING STRUCTURE

Building structure primarily contributes to a building's carbon emissions in two ways: embodied carbon and use-phase carbon.

Embodied carbon is the sum of all carbon emissions generated during the extraction, manufacturing, fabrication, and erection of the structural system.

Sometimes end-of-life emissions are also included, such as the emissions due to building demolition and disposal of materials. Emissions due to the transport of materials from extraction to erection and also at end-of-life are typically included in the calculation for embodied carbon.

During the use-phase of a building, i.e. occupancy, carbon emissions result primarily from the consumption of on-site energy and water. The structural design of a building can impact the building's energy efficiency. For example, if strategically located, the thermal mass of concrete and masonry can help temper swings in exterior temperature, thereby reducing energy use. Another example is thermal bridging. When structural components such as steel outriggers and concrete cantilevered decks pass through the building's thermal envelope, breaking the insulation layer, significant thermal losses can occur, increasing the building's energy consumption.

Assuming a 50-year life, the global warming potential associated with the embodied impacts of a building's structural system can vary from about 1 to 16 percent of the building's total life-cycle GWP (Webster 2004). The type of construction, energy sources, and the energy efficiency of the building systems are important factors in determining the structural contribution to the impact. As buildings become more energy efficient and electricity production transitions towards renewable sources, the relative impact of building structure will increase even further.

CARBON IMPACTS OF CONCRETE AND STEEL

This interim report addresses only concrete and steel. The CWG is also studying wood, FRP, and masonry and plans to address these materials as well in its forthcoming white paper.

Concrete

Concrete's primary carbon impacts derive from cement and steel reinforcement. Reinforcement is addressed in the steel discussion below. In a typical concrete mix, the cement accounts for 12% or less of the concrete mix by weight, but represents about 95% of the carbon emissions (Kestner 2009).

Portland cement is produced in manufacturing facilities where raw materials (lime, iron, silica, and alumina, most commonly in the form of limestone and clay) are heated in a kiln to high temperatures (reaching 1450ºC) causing a chemical reaction called calcination. Calcination produces approximately 0.51 metric tons of carbon dioxide (CO_2) per metric ton of clinker produced. Ordinary portland cement is about 95% clinker and 5% gypsum. The fuel required to heat the kiln to such high temperatures contributes another 0.43 metric tons of CO_2 per metric ton of clinker produced (van Oss 2005). Using van Oss's figures, 54% of emissions are due to calcination and 46% are due to thermal or primary energy uses. It is important to note that electricity—which typically account for between 7% and 10% of total energy—is not accounted for. The carbon impact of electricity used to grind and process cement is difficult to quantify; it varies from very low for electricity from hydro power to very high for coal-based power.

The EPA reports that cement manufacturing produces roughly 1.5% of total GHGs in the United States, while the construction industry produces 6% of all U.S. GHGs (EPA 2008). These numbers are lower than the global average simply because

the U.S. is such a big consumer of energy; it is not an indication of superior performance by U.S. cement plants (Meryman, 2010). For close to a decade the cement sector has conceded to contributing around 5% of global anthropogenic CO_2 emissions. This number has been up for debate, especially considering the continued growth in cement demand. Using 2007 data from the Carbon Dioxide Information Analysis Center (CDIAC) for total fossil fuel and cement-based CO_2 emissions (30,675 million tons), cement calcination emissions (1,977 million tons), and the emissions breakdown provided above by van Oss, we can generate a more current estimate (CDIAC 2010). Globally, GHG emissions due to cement manufacturing account for over 6.4% of the major anthropogenic CO_2 emissions.

Concrete's carbon impacts can be reduced by replacing portland cement with complementary cementing materials such as fly ash and slag. As post-industrial "waste" materials, fly ash and slag have very low carbon emissions. The carbon emitted during their production does not contribute to their embodied carbon because it is attributed to the primary product, such as the electricity generated by a coal-fired power plant that produces fly ash as a waste product.

BEES 4.0, is a free life-cycle assessment program developed by the National Institute of Standards and Technologies (NIST) that can provide useful insight into the climate impact of materials. BEES includes carbon figures for a number of different concrete mixes used in a number of different types of structural elements. BEES reports figures only for assemblies of reinforced concrete elements that include assumed quantities of reinforcement and formwork. According to BEES, a reinforced concrete beam constructed with 4 ksi concrete using only portland cement as a binder has a CO_2e of 14.1 kg/ft^3. The same element using a concrete mix with 50% cement replacement with slag has a CO_2e of 10.4 kg/ft^3. Even though the reinforcement and formwork impacts are identical for both options, the carbon impact for the slag mix is 26% lower. The carbon impact of concrete alone is very much controlled by the cement content; replacing 1 ton of cement with fly ash or slag reduces the carbon impact of concrete by about 0.84 to 0.9 tons, per the following calculation:

> (0.51 tons (CO_2 from calcination) + 0.43 tons (CO_2 from thermal energy)) x 0.95 (emission factor attributed to the cement portion of concrete) x 0.95 (clinker factor)) = 0.84 tons.

Since electricity is not included in the energy emissions, this is a minimum value.

Steel

Structural steel is produced primarily in electric arc furnaces (EAFs) or basic oxygen furnaces (BOFs). According to the Steel Recycling Institute (SRI 2009), steel produced in EAFs has a total recycled content of about 90%, compared to 33% for steel produced in BOFs. In part due to its recycled content, EAFs produce fewer carbon emissions per ton of production than do BOFs.

All hot-rolled shapes produced in the United States are from EAFs (AISC 2008). HSS is currently manufactured using steel from both EAFs and BOFs. In 2008, more than half of the coil steel used to produce HSS came from BOFs (AISC 2008-1).

Most of the structural steel used for buildings in the United States is produced domestically. AISC estimates that only 9% of domestic consumption is imported (AISC 2010).

Steel deck and cold-formed framing are typically produced from the same stock material—cold-rolled sheet—and is often galvanized. Most of this steel is produced domestically in BOFs. Reinforcing steel used in masonry and concrete construction is typically produced domestically in EAFs.

The primary life-cycle stages of structural steel production are:

1. Extraction of raw materials. Raw materials include iron ore, coal, and limestone. Collection of steel scrap, another primary raw material, is included in this life-cycle stage. About 80% of post-consumer steel is recycled into new steel (World Steel 2008).
2. Steel production, including rolling and forming.
3. Shop fabrication.
4. Transportation between life-cycle stages.
5. Construction.
6. End-of-Life. Most steel removed from buildings is recycled into new steel.

Of these six life-cycle stages, the steel production stage produces the most CO_2e. EAF production produces less than half as much CO_2e as BOF production. The Steel Manufacturer's Association (SMA) estimates that EAF production emits 0.74 tons of CO_2/ton of product, while BOF production emits 1.91 tons CO_2/ton of product (SMA 2007).

AISC publishes a "carbon footprint" for domestically produced rolled shapes, all of which are produced in EAFs, of 0.73 to 0.89 tons of CO_2 per ton of steel (AISC 2010), based on the SMA study as well as a study AISC commissioned from a life-cycle assessment consulting firm. These figures assume a recycling rate of 98% and exclude fabrication. AISC's life-cycle assessment consultant recently completed a study of the fabrication of structural steel. The study found that fabrication adds about 0.19 to 0.26 tons of CO_2e per ton of steel (Weisenberger 2010). Summing the production and fabrication figures gives a range of 0.92 to 1.15 tons of CO_2e per ton of fabricated steel.

HSS sections are produced in both EAFs and BOFs, so their production emits more CO_2e than hot-rolled shapes. AISC does not publish carbon impact estimates for HSS sections. The Athena Institute, an independent life-cycle assessment consulting firm, published production and transport emissions values of CO_2 and methane for HSS sections produced in combined U.S. steel mills (Athena 2002). Unfortunately the reports do not include nitrous oxide (N_2O) emissions. Applying a GWP factor of 25 for methane, the total CO_2e for HSS amounts to 1.76 tons/ton of production.

Steel reinforcement is produced primarily in EAFs. Again using the Athena inventory data and the same approach we used for the HSS calculations, we find that the CO_2e figure for U.S. reinforcement is 0.59 tons/ton.

Athena also addressed galvanized steel deck and welded wire mesh. For these products the CO_2e figures are 1.79 and 1.35 tons/ton, respectively.

DESIGNING TO REDUCE CARBON IMPACTS

Once the structural designer understands the carbon impacts of available materials, he or she can implement carbon-reduction strategies. For most buildings, the choice of concrete or steel construction will depend upon factors other than carbon emissions. Assuming this is the case, the designer's task is to reduce the impacts of the given material.

For both concrete and steel structures, material optimization will generally reduce carbon impacts.

For steel, optimization strategies might include the following:

- Using more labor-intensive (and potentially more expensive) options such as lighter columns with continuity plates at joints rather than larger columns sized to minimize fabrication.
- Selecting braced frames for lateral-load resisting systems in place of moment-resisting frames, which use substantially greater quantities of steel. A study by Simpson Gumpertz & Heger, Inc. found that, for a representative 9-story building in Los Angeles, designing a braced-frame lateral system in place of a moment-resisting frame reduced the structural steel quantity by 37%, with a commensurate reduction in GWP.
- Designing with castellated beams rather than conventional wide flanges.
- Investigating catenary structures in place of trusses for long-span roofs.

For concrete, optimization might include:

- Strategically introducing air voids into concrete elements, such as those employed in the BubbleDeck® system.
- Investigating thin-shell arched or folded-plate structures in place of linear and planar elements.

Concrete offers additional opportunities to reduce carbon impacts by specifying material improvements, such as the replacement of cement with complementary cementing materials such as fly ash and slag. Other ways to reduce the carbon-intensive cement content include:

- Avoiding over-specifying concrete strength and designing and specifying for f'c at 56 days where feasible.
- Using larger-sized aggregates to reduce the paste volume.

Finally, steel reinforcement quantities can be reduced where it is not required. For example, reinforcement in slabs-on-grade can be eliminated by using more closely spaced control joints. Use of 75 ksi reinforcement in place of Grade 60 reinforcement can also reduce carbon impacts by reducing the reinforcement tonnage.

CARBON CALCULATION EXAMPLE

Until standardized methods of carbon impact are fully developed and implemented, we cannot be certain that carbon figures obtained from different

sources, and perhaps even from the same sources, are directly comparable. The International Standards Organization (ISO) has developed and is continuing work on standards for performing life-cycle assessments such as those used to determine carbon emissions. Carbon accounting is still in its infancy, and, although we see enough consistency in the figures developed by different organizations that we believe some convergence is underway, we realize that the figures may still vary by 50% or more depending on the assumptions and methodologies used. One problem is that the assumptions used to build the data set are usually not well explained, so it is difficult to know if it is an apples-to-apples comparison. Currently, comparisons between options using similar materials are more accurate than comparisons between different materials. For these reasons, the following exercise is intended for demonstration purposes only and is not intended to provide a definitive conclusion regarding the relative carbon impacts of the two systems.

The example shown in Tables 1 and 2 compares two alternatives for a 30-foot span in a typical office building, with loads including self weight, 10 psf for MEP and finishes, 20 psf for partitions, and 50 psf live load. The structural proportions were selected to provide a 2-hour fire rating without the need for additional fireproofing on the steel deck. Note that it is a component comparison, so does not account for possible differences in the building systems beyond the boundaries of the beams, such as girder and column differences and fireproofing materials.

Option 1: Steel Composite Beam

- W14x22 beams @ 8'-4" o.c.with 10 shear studs per beam
- 20 ga. 2-inch steel deck
- 2 inches plus 4.5 inches for a total thickness of 6.5 inches of normal-weight, 3,500 psi concrete with 25% of cement replaced by Class C fly ash
- 6x6-W2.1xW2.1 steel mesh

Table 1. Carbon account for Option 1.

Item	Unit	Quantity per Square Foot	Carbon Intensity (lb/lb or lb/cy)	Carbon (psf)	% of Total
W 14x22	22 plf	2.64 psf	1.04	2.7	22%
Deck		1.97 psf	1.79	3.5	29%
Mesh		0.29 psf	1.35	0.4	3%
Studs		0.03 psf	1.04	0	0%
Concrete	5.5 in	0.02 cy/sf	332	5.6	46%
Total				**12.3**	**100%**

Option 2: Concrete pan-formed beams

- 5-inch normal-weight 4,000 psi concrete with 25% of cement replaced by Class C fly ash

- pan-formed beams 6-inch wide by 16-inch deep (below slab) @ 72 inches o.c. (total system thickness of 21 inches)
- 1.65 psf of beam reinforcing

Table 2. Carbon account for Option 2.

Item	Unit	Quantity per Square Foot		Carbon Intensity (lb/lb or lb/cy)	Carbon (psf)	% of Total
Slab Steel		0.3	psf	0.59	0.2	2%
Beam reinf.		1.65	psf	0.59	1.0	11%
Concrete	6.64 in	0.02	cy/sf	376	7.7	87%
Total					**8.9**	**100%**

While this comparison shows that the concrete option has a lower embodied carbon impact per square foot of floor area, it addresses only an element and does not account for the full structural system. It also does not consider impacts due to the construction process or those from material transportation. However, it serves as a starting point for those who want to perform this type of calculation in their practice. A complete example would need to address the girders, vertical and lateral framing elements, as well as foundations to make an actionable assessment of the relative merits of the two systems. For even more accuracy, differences in non-structural systems, such as any additional fire-proofing required for the steel-framed option, would need to be included.

Additionally, this example is based on publicly available carbon data developed by different organizations at different times using different assumptions. Our hope is that practitioners will soon have at their disposal more reliable and comparable figures for carbon intensity that will give more credence to calculations such as these. The National Renewable Energy Laboratory is compiling a U.S. Life Cycle Inventory Database (http://www.nrel.gov/lci/) that may eventually fulfill this need. Additionally, the World Resource Institute is developing product-specific carbon footprint standards and ASTM is developing "product category rule" standards which aim to enable more accurate comparisons between products and assemblies. With supply-chain-specific product carbon footprints, designers could specify carbon as a performance metric to motivate and reward lower impact/higher efficiency manufacturing methods.

CONCLUSIONS

Structural engineers have an important role to play in reducing the carbon impact of the built environment. The structural system accounts for a significant portion of a building's life-cycle carbon impacts. Understanding the environmental impact of the structures we design is the first step in cultivating our ability to reduce and mitigate these impacts. Using currently available data is appropriate as structural engineers work to define methods to account for and report the carbon footprint of

structures. The accuracy of these analyses will improve as better LCA data becomes available. With an understanding of material carbon emissions and the limitations of current data, the structural engineer can effectively use simple calculations to make rough comparisons between options and can apply carbon-reduction strategies to reduce the structural system's carbon impacts. As the data improves and structural engineers develop their own tools to utilize it, we can look forward to having a more valued voice in the discussion of the climate impacts of materials, and improved capability to design projects to minimize those impacts.

ABSTRACT

Life cycle assessment is a means of calculating the environmental impact of processes. The ATHENA® Impact Estimator for Buildings was developed by the Athena Sustainable Materials Institute and software collaborator, Morrison Hershfield as a means of applying life cycle assessment to the construction of buildings. The Impact Estimator measures the environmental impact of the new construction of a building in the areas of: Primary Energy, Global Warming Potential, Human Health Respiratory Effects, Ozone Depletion, Weighted Resource Use, Water Pollution, and Air Pollution. It is the intent of this paper to use the software to evaluate a four story office building for four proposed structural framing systems currently under construction in Chicago. The building was designed with the intent of achieving LEED® Platinum certification. The results of the four life cycle assessments will be compared. During this comparison, the authors intend to examine the software to determine its validity as a tool for making sustainable design decisions based upon structural systems.

INTRODUCTION

Sustainable development, defined in *Our Common Future* as "development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (World Commission on Environment and Development, 1987), has been gaining more attention in the past few decades. In many industries, environmental consequences are now given consideration alongside economic and social consequences. One of the challenges in the sustainable development movement has been developing metrics that more effectively aid in making decisions based on how these decisions will affect the environment. One way the building industry measures sustainability is by using a technique call life cycle assessment.

Life cycle assessment (LCA) is a study of the consequences that certain products, processes, or services will have on the environment based on the byproducts, energy

and resources that they require throughout their lifespan. LCA is a relatively new tool for rating the sustainability of buildings but its use is being encouraged by the incorporation of LCA into the LEED® and Green Globes® rating systems.

It is the purpose of this paper to compare four life cycle assessments based on structural system options (S1-S4) for a four story office building constructed in Chicago using ATHENA® Impact Estimator. The results of the Impact Estimator output will be will be considered in several ways:

- Program accuracy
- Embodied vs. operating impacts
- Environmental metrics
  - Embodied Energy Consumption
  - Global Warming Potential - CO_2 equivalence
  - Smog Potential - NO_x equivalence
  - Human Respiratory Effects - PM2.5 equivalence

Program Accuracy
The Impact Estimator allows data to be inputted in two different ways: by identifying assembly type, providing geometry and live loads, which the program then uses to calculate a bill of materials ('A' models), and by input of material quantities directly ('B' models). ATHENA® Impact Estimator for Buildings V3.03 Software and Database Overview claims that these values should be within +/- 10% of a detailed manual take-down. It is the intention of the authors to investigate this claim.

Embodied vs. Operating Energy
Previous research (Hsu 2010) has shown that the embodied energy of a building is only a fraction of the operating energy. The authors intend to quantify this difference and check it against previous research.

Environmental Impacts
Through a comparison of the environmental impacts, it will be determined whether the structural system that was chosen for the office building is the most environmentally sustainable.

By comparing the above results for the four structural systems, the authors will examine the software to determine its validity as a tool for making sustainable design decisions based upon structural systems.

LIFE CYCLE ASSESSMENT FOR BUILDINGS

A building's energy use and its associated emissions have an extensive impact on the environment. In the United States, the building industry accounts for approximately 40% of the country's primary energy use (US DOE 2009). Though a majority of this is operating energy, the materials used to construct a new building have an inherent environmental cost (Johnson 2006). This cost is associated with the extraction,

manufacturing, transportation, construction and end of life disposal of the building materials and is referred to as embodied environmental impacts.

Structural elements have a greater environmental impact than many of the other building elements such as finishes, flooring, and roofing, because they are the greatest percentage of the total building material. The decision on how to structurally frame a building can therefore have a great impact in the building's environmental impact. Though this energy is only a fraction of what is used to power the building over its lifetime, as building envelope and HVAC systems become more efficient and the amount of energy required to heat, cool, and light a building decreases, the environmental impacts associated with the manufacturing and construction phases will make up an increased percentage of the total impact.

While the gathering and evaluation of the data for all of the processes involved in the extraction, manufacturing, construction and end of life disposal associated with structural components is very rigorous, new advances in LCA have made it possible for a structural engineer to compare how particular structural framing schemes will impact the environment. Programs like ATHENA® Impact Estimator for Buildings allows the design team to perform a desktop LCA of several options during the schematic design phase so that environmental impacts can be considered at the beginning of the design process when major system decisions are being made.

ATHENA® IMPACT ESTIMATOR FOR BUILDINGS

Athena Sustainable Materials Institute, a non-profit organization based in Ontario, Canada developed the ATHENA® Impact Estimator for Buildings. The Institute's mission is to promote sustainability in the built environment through the use of Life Cycle Assessment in North America. They offer two products in the United States, the Impact Estimator for Buildings and EcoCalculator for Assemblies. The EcoCalculator supplies more accessible results based on predefined calculations made with the Impact Estimator. This paper focuses on the use of the Impact Estimator to analyze a low rise office building constructed in Chicago.

The Impact Estimator was developed as a support tool to aid in the decision making process at the conceptual design stage. The software provides a cradle-to-grave (extraction through end of life disposal) life cycle assessment for a building design. It allows us to compare up to five design scenarios in terms of the following environmental impact categories set forth by the US Environmental Protection Agency for LCA in accordance with ISO 14040:

- Primary energy consumption
- Acidification (Air) Potential - moles of H^+ ions equivalent mass
- Global warming potential – $C0_2$ equivalent mass
- Human Health Respiratory Effects Potential - PM2.5 equivalent mass
- Ozone Depletion Potential – CFC 11 equivalent
- Photochemical Smog Potential - NO_x equivalent mass
- Eutrophication Potential - N equivalent mass

- Weighted Raw Resource Use

(ATHENA® Impact Estimator for Buildings, Overview)

The impact estimator takes into account any or all of the following building characteristics and life-cycle factors to measure the impact in each of the metrics listed above:

- Material manufacturing, including resource extraction and recycled content
- Related transportation
- On-site construction
- Regional variation in energy use, transportation and other factors
- Building type and lifespan
- Maintenance and replacement effects
- Demolition and disposal

(ATHENA® Impact Estimator for Buildings, Overview)

The user enters the city which best represents the location of the project (currently only seven US cities are included as options), the expected life span of the project, and the material assemblies of the project. The project location determines the electrical grid, transportation mode and travel distances for each material, as well as product manufacturing technologies. The life span of the project will affect the maintenance and replacement cost for building assemblies. For example, any assembly that has a service life, based on regional data, less than that of the whole building will have increased environmental costs associated with repair and replacement and any assembly with a service life greater than that of the structure will be credited with the environmental impact of the difference in lifespan. The material take-off can be determined in two different ways: a "deterministic" method where the model completes a quantity take-off calculation based statistical data and a "prescriptive" method where the user directly enters quantities. The bill of materials is used in conjunction with recognized material databases to determine the environmental impacts of the materials. A table of the databases and their vintage is available on the Athena Institute's website at www.athenasmi.org.

PROJECT DESCRIPTION

The building under consideration is a four story (125,000sf) owner occupied office building on the north side of Chicago, Illinois. The building has open floor plates, a semi-circular training room and an atrium acting as lobby and connector, built close to the Chicago River. To simplify the analysis, only the 79,800sf, four story, main office building will be considered and the atrium, lobby and other interstitial space will be omitted. All options share a common foundation system and are clad with a glass curtain wall which was assumed to be 80% glass and 20% spandrel with 6" of insulation. Due of the nature of the work being done in the building a live load of 80psf plus a 20psf partition load for a total of 100psf live load was used in the Athena model. At the roof level the authors also used a 100psf live load as an average of the plaza area, mechanical units and green roof. A detailed description of the foundation and structural options follow and a sketch of a typical floor layout for the office

building can be found in Appendix A. For this study, the building was assumed to have a 50yr lifespan.

Foundation System

The foundation system for this building consists of belled caissons down to stiff clay at approximately 32 feet below grade. Grade beams were installed at the perimeter of the building to accommodate frost requirements of the building location, support the first floor of the building façade, and assist with thermal insulation at the perimeter of the building. A few isolated grade beams were also installed at bays that contained steel cross-bracing. In options that have a concrete shear wall lateral system, a mat foundation was considered under the elevator cores and stairwells to support the shear walls.

Option S1: Structural Steel Framing

The framing for this scheme consists of rolled steel W shaped beams, columns and braces. The gravity floor framing system consists of 3" concrete slab on 3" steel deck supported by W18x50 floor beams (typical) acting compositely with the deck/slab. Beams are supported by W21x55 girders or frame directly into columns, depending on their location. The lateral load resisting system consists of steel cross-bracing located around the elevator shafts, stairwells and washrooms.

Option S2: Reinforced Concrete Option

The framing for this scheme consists of reinforced concrete band beams, one-way slabs, columns and shear walls. The gravity floor framing system consists of reinforced concrete band beams 8'-0" wide on 30'-0" centers (i.e. at column lines). The beams are 28" deep for the 45'-0" spans and 16" deep elsewhere. An 8" thick reinforced concrete slab (whose depth is integral with the beams) spans one-way between these beams. In the exterior bay at each end of the building, the depth of the one-way slab must be increased to 12" in order to ensure that long-term deflections in these areas fall within the limits set by the design codes. In all other locations, the 8" slab suffices. The presence of framing in adjacent bays provides additional stiffness due to the continuity of construction. Columns are typically 26" in diameter. In this scheme, the spandrel beams support only the cladding. There are no girders. The lateral load resisting system consists of 10" thick reinforced concrete shear walls around the elevator cores and stairwells.

Option S3: Post-Tensioned Option

The framing for this scheme consists of post-tensioned concrete band beams and reinforced concrete one-way slabs, columns and shear walls. The gravity floor framing consists of post-tensioned concrete band beams 8'-0" wide on 30'-0" centers (i.e. at the column lines). The floor slab is not post-tensioned. The depth of the typical floor slab is 8", and 12" at end spans, the same as for the reinforced concrete option. The beams are 24" deep for 45'-0" spans and 16" deep elsewhere. Except for the post-tensioning of the beams, this scheme is similar in arrangement and general characteristics to the reinforced concrete scheme. The use of post-tensioning allows

the depth of the beams that span 45'-0" to be reduced from 28" to 24". This depth would also be required in the middle 20'-0" span due to construction and continuity issues associated with the post-tensioning. All spandrel beams are reinforced concrete 24" deep, and mildly reinforced. The lateral load resisting system consists of 10" thick reinforced concrete shear walls around the elevator cores and stairwells, exactly as in option S2.

Option S4: Hollow Core Plank Option

The framing for this scheme consists of pre-cast hollow core concrete slabs supported on structural steel beams and columns together with steel braced frames at the building core. The gravity floor framing system consists of 14" and 10" thick hollow core slabs supported by W24 or W27 girders. The 14" thick hollow core slabs are required for the 45'-0" spans under the specified loads. The 10" thick slabs are adequate elsewhere. Columns are typically W14 sections. A 2" thick topping is required over all slabs to ensure that the floor diaphragm is capable of transferring lateral loads from wind to the braced frames. This topping must be supplemented with additional reinforcement and detailing. To increase the floor to ceiling height additional steel is added so that top of hollow core is 2" below the top of steel elevation (see Figure 1). The lateral load resisting system duplicates that of option S1.

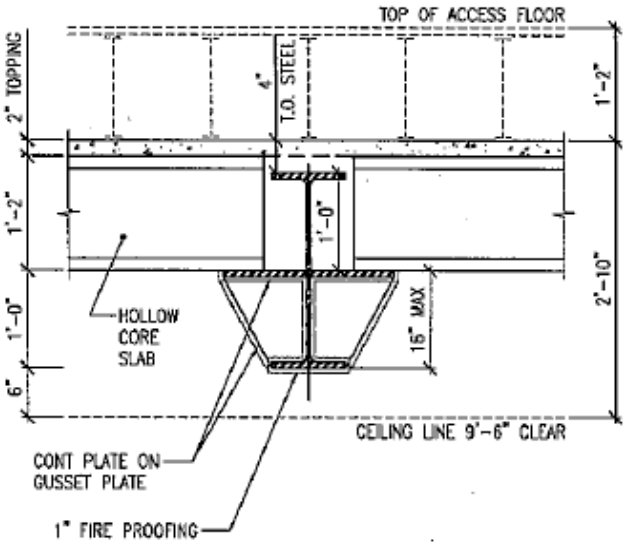

Figure 1: Option S4 connection of hollow core to floor beams (section elevation)

RESULTS

Program Accuracy

The take-off quantities resulting from Athena's assumptions ('A' models) vs. those calculated by a manual take-off ('B' models) are shown in Table 1. The Impact Estimator does not include many of the assemblies that were used in the four structural system options including: composite slab on deck, deep foundations, one-

way concrete slabs, lateral steel bracing, mat foundations, post-tensioned beams, and grade beams. Because of this it was necessary to do a manual take-off for these items, or to 'fake' them in as other assemblies which, by engineering judgment, would give approximately the same material quantities. Quantities added to the Impact Estimator because assembly options weren't available are identical in both 'A' and 'B' models. The manual take-off performed by the authors did not account for construction materials such as formwork or the curtain wall assembly, so these quantities were taken from Athena.

Table 1: Athena material quantities (A) vs. manual take-off quantities (B)

Matl	Units	S1A	S1B	A/B (%)	S2A	S2B	A/B (%)	S3A	S3B	A/B (%)	S4A	S4B	A/B (%)
Aluminum	Tons	44	44	---	44	44	---	44	44	---	44	44	---
Batt. Fiberglass	sf(1")	83009	83009	---	83009	83009	---	83009	83009	---	83009	83009	---
Concrete (total)	yd³	2410	2519	96%	7382	6295	117%	7382	6237	118%	3610	3773	96%
EPDM membrane (black, 60 mil)	lbs	4818	4818	---	4818	4818	---	4818	4818	---	4818	4818	---
Galvanized Decking	Tons	114	114	---	0	0	---	0	0	---	0	0	---
Galvanized Sheet	Tons	5	5	---	5	5	---	5	5	---	5	5	---
Galvanized Studs	Tons	4	4	---	0	0	---	0	0	---	0	0	---
Glazing Panel	Tons	248	248	---	248	248	---	248	248	---	248	248	---
Rebar, Rod, Light Sections	Tons	16	20	78%	638	295	216%	714	259	275%	77	65	119%
Screws Nuts and Bolts	Tons	25	7	373%	1	1	100%	1	1	100%	25	6	439%
Welded Wire Mesh/Ladder Wire	Tons	9	14	67%	2	6	30%	2	6	31%	16	6	261%
Wide Flange Sections	Tons	493	454	109%	0	0	---	0	0	---	491	423	116%

It can be seen in Table 1 that there are some discrepancies between the 'A' and 'B' models that are outside the +/-10% margin of error described by the Institute. In particular, the quantity of nuts and bolts that the program estimated for steel framing was an order of magnitude higher than the manual takeoff. Also the concrete volume and reinforcing quantities are significantly different for the concrete framing options from the 'A' to 'B' models. These differences affect the calculated impacts and should be kept in mind when reviewing the impact comparisons to follow.

Figure 2 shows the primary energy and global warming potential (GWP) associated with several systems. In the case of the concrete option S2, the lateral and foundation systems account for around 20% of both impacts. These systems are not inherently included in the Impact Estimator. The design team should be advised to consider the impacts that these additional structural systems can add to the gravity framing output that can be generated with ATHENA® Impact Estimator.

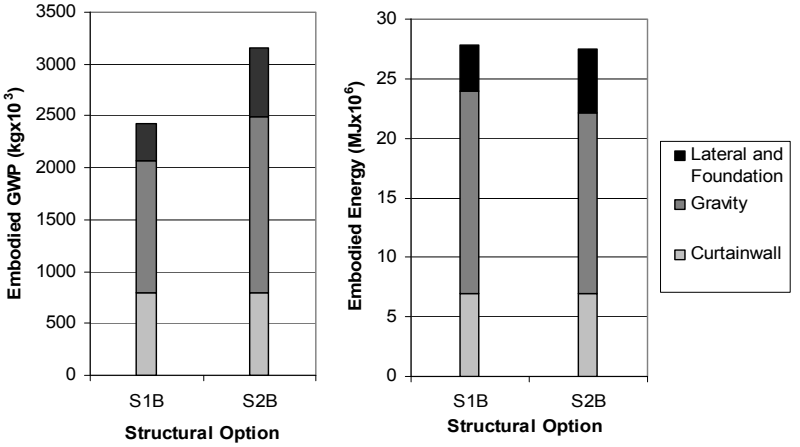

Figure 2: Primary energy and GWP impacts associated with various building systems

Embodied vs. Operating Impacts

The embodied impacts are those associated with the manufacturing of the building components, their construction on-site, and their disassembly and disposal at the end of the life of the structure. For primary energy analysis of the structural options, a majority of the embodied impact was a result of the manufacturing process (see Figure 4). Similar results were encountered for the other impacts in the study.

An energy study was performed separately with all inputs assumed equal for all options. The primary energy required to operate the building far outweighs the embodied energy of the materials used to construct the building. In all of the structural options for this office building primary energy required for operation is over ten times greater than the material embodied energy (see Figure 3), which accounted for anywhere from 6-9% of the total energy.

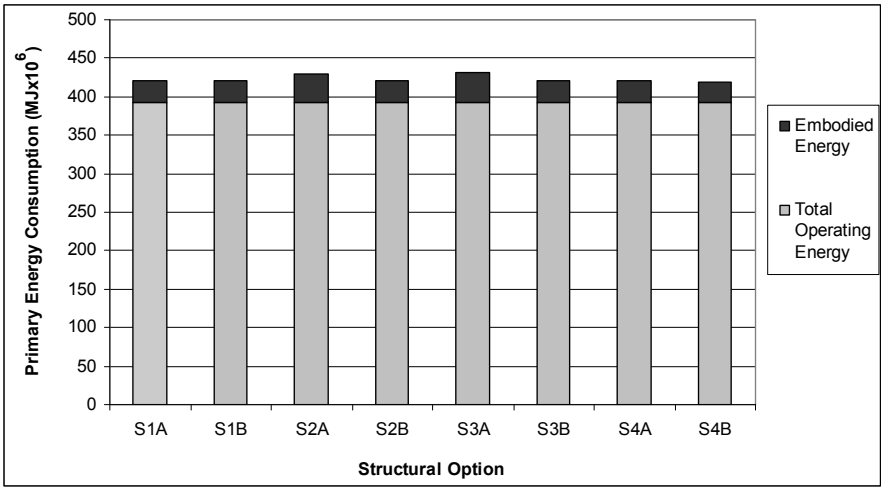

Figure 3: Embodied vs. operating primary energy consumption

When other environmental metrics are observed, the embodied impacts comprise a greater portion of the overall impact: 8-13% of the global warming potential is

associated with embodied processes as well as 19-24% of the human health respiratory effect potential (HHresp). When smog potential is considered, the embodied impacts make up a majority (60-72%) of the overall impact.

Environmental Metrics

Primary Energy Consumption

Though the energy associated with the operation of the building (roughly 90% of the total cradle-to-grave energy) is assumed equal for all of the structural options, there is variation of the embodied energy associated with each. The prescriptive or engineer determined ('B') structural options have approximately the same primary energy consumption (see Figure 4). None of them deviate more than 3% from their average. However, the embodied energy values for the 'deterministic' or program-determined ('A') concrete options, S2A and S3A, are roughly 40% higher than this average. This is consistent with the discrepancies in quantities noted earlier.

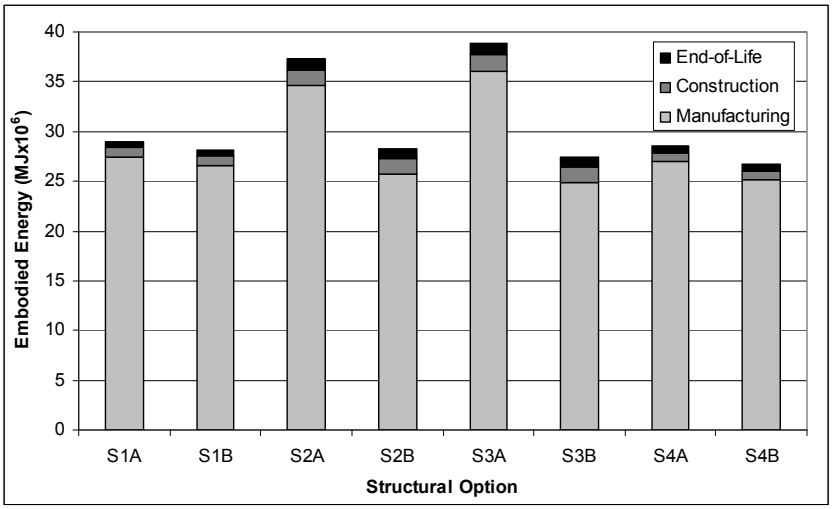

Figure 4: Embodied energy consumption

Global Warming Potential

If global warming potential is considered, the two structural steel options (S1 and S4) perform better than the concrete (S2 and S3) options (see Figure 5). This is consistent with previous LCA studies (Guggemos and Horvath 2005). Once again, the impact measurements for the deterministic concrete options are statistical outliers for reasons discussed previously.

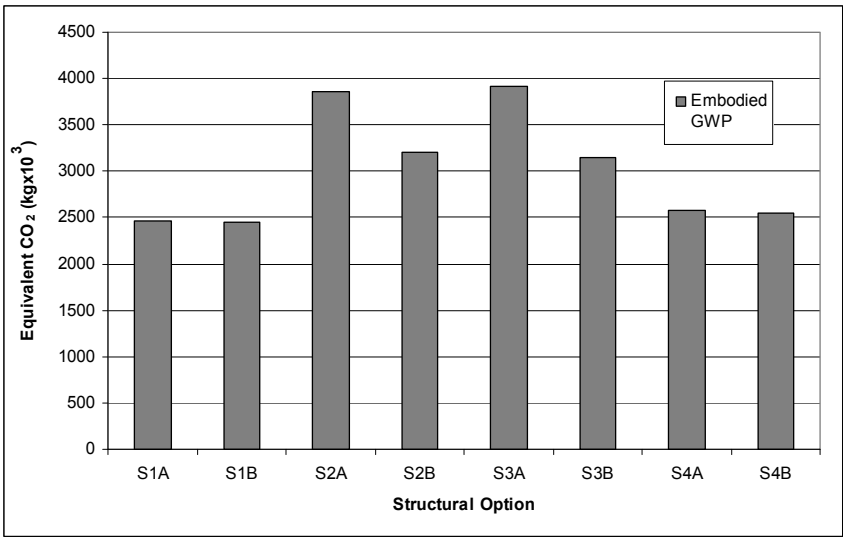

Figure 5: Comparison of global warming potential

Smog potential

Similarly to the global warming potential, the smog potential was greatest with the concrete options (S2 & S3) and least with the composite deck and steel framing option (S1) (see Figure 6).

Human health respiratory effects

Like the previous metrics, the concrete options contained the largest human health respiratory effects potential with S1 option containing the least (see Figure 6). Figure 6 also gives a comparison of embodied vs. operating impacts.

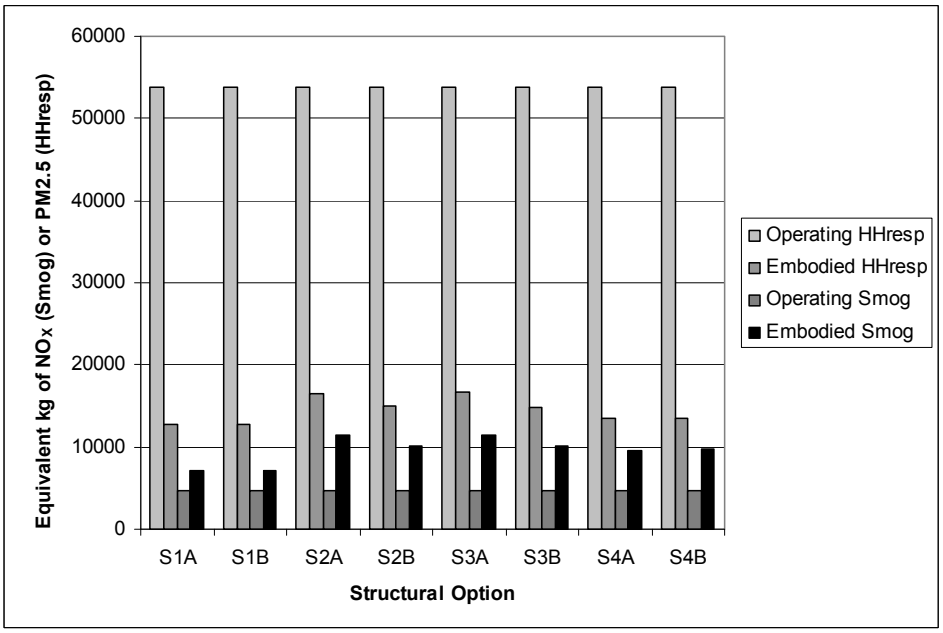

Figure 6: Comparison of human health respiratory effects potential

CONCLUSION

It is the purpose of this paper to examine the ATHENA® Impact Estimator for Buildings LCA software to determine its validity as a tool for making sustainable design decisions based upon structural systems. The intention of the authors is to view the results of the Impact Estimator output in several ways: the accuracy of the program's engineering assumptions, embodied vs. operating energy consumption, and environmental metrics. It is the conclusion of the authors that ATHENA® Impact Estimator has some inherent inaccuracies in estimating material quantities. The overestimate of the concrete volume and possibly the reinforcing quantities had the greatest influence, because it was the concrete options (S2 & S3) in the models where the quantities were determined from Athena ('A' models), that have a greater negative impact than the models where quantities were determined by the authors ('B' models). In regards to the embodied vs. operating energy, it is the conclusion that the embodied energy of the structural components comprises less than 10% of the total primary energy consumption, and in the embodied energy the extraction and manufacturing phases dominate over the construction and end of life phases. When comparing the four structural options in terms of primary energy, global warming potential, smog potential, and human respiratory effects, it is the author's conclusion that the option chosen, composite slab on deck with steel framing and cross-bracing (S1), was the best choice environmentally (see Figure 7). In conclusion, with an awareness of the limitations, ATHENA® Impact Estimator is workable tool for the comparison of structural systems at the schematic level but more work needs to be done to include a broader range of structural assemblies that are commonly used in the Chicago market.

Integrating Life Cycle and Carbon Assessments: What Life Cycle Assessment Can Teach Structural Engineers about Design and Specification

Frances Yang, P.E., LEED® AP[1]

ABSTRACT

Life-Cycle Assessment (LCA) is the method which most fully accounts for the environmental impacts of structures. The method provides feedback for our engineering design and specification choices. Three case studies will demonstrate how LCA was used in different ways to answer different questions structural engineers had in the desire to reduce the environmental impacts of their projects. One uses Athena® EcoCalculator for an existing building while the other two studies employ LCA outside of currently available software models for new structures.

INTRODUCTION

Life-Cycle Assessment (LCA) is the method which considers a range of environmental impacts of a product over a span of its life cycle stages. When used for a building, it most fully accounts for the environmental impacts of structures from the material extraction, processing and manufacture, construction, use, end of life, and transport of materials between these activities in these phases. A comprehensive set of environmental impacts includes energy use, resource depletion, toxicity to air and water, global warming potential, and ozone depletion, to name a few. Although the data needed gather such information is vast, tools in the US exist to make an LCA-based evaluation relatively simple for building designers. The way in which the structural engineer uses these tools depends on what questions they are asking.

Environmental Impacts Embodied in an Existing Building

The first study asked how much in environmental resources was already invested in the original structure and its multiple retrofits. The client sought to preserve not only the aspects of the original structure, but also the evidence that told its story as the region's first example of adaptive reuse. Reuse of existing structure is one of the most significant ways to reduce the embodied environmental impacts of construction. Structural elements of The Cannery dated back to 1967. Most structures only last 35-60 years, particularly in a region concerned with seismic safety.

Athena® EcoCalculator was chosen for this exercise because of how well the building construction materials matched the assembly choices. The simplicity of the spreadsheet-based tool also aligned with the limited time and budget, and the understanding that the client only desired a rough estimate, in only a few widely

understood metrics. Embodied energy, embodied carbon, and waste metrics were chosen to best represent the environmental concerns at hand.

Using EcoCalculator was feasible due to the availability and legibility of existing drawings documenting original construction and multiple retrofits. EcoCalculator merely required one to input total area of each assembly type. The Cannery was of typical historic brick wall and steel frame construction later retrofit with shotcrete and rigid diaphragm floors. Thus area of masonry walls, steel joist floors, steel columns, and concrete walls were the primary inputs. Sometimes the elements were found under a different assembly category than where they were found in the actual building, e.g. masonry walls were in "Interior Walls" in the EcoCalculator. The pad foundation and shotcrete were not found under the standard assemblies offered by EcoCalculator. After consulting with Athena® technical support, we felt comfortable with adding in an additional area of concrete floor equivalent to the volume of concrete foundation and using 6" cast-in-place to represent shotcrete.

Figure 1: Snapshot of Athena® EcoCalcutor v2.2. Input required under "Square footage" column heading. Environmental outputs in upper right hand corner.

EcoCalculator output was converted into metrics more easily understood by the client and other stakeholders. This resulted in stating that preservation of The Cannery's structure was on the scale of:

- saving enough energy to power 500 homes for one year,
- saving the amount of carbon it would take nearly 380,000 trees over 10 yrs to sequester, and
- avoiding an amount of waste that would fill 2.2 football fields

The first two conversions used the EPA Greenhouse Gas Equivalencies Calculator and the third used data from Arup's waste group regarding typical construction waste density and assumed landfilling to 3 feet high.

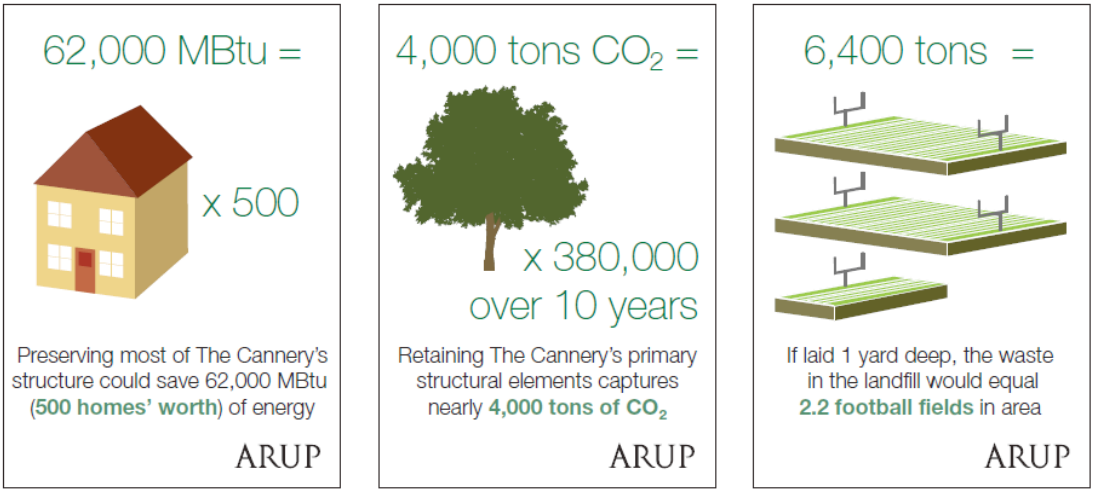

Figure 2: Representations of environmental resources invested in existing Cannery building

These results added quantitatively to the environmental piece of the preservation story the client had in mind for The Cannery building. Surveys of historic structures show the longer a building is conserved and adapted for future use, the more others will come to admire and care for it, and the more value people will find in investing future efforts to sustain its legacy (Brand 1994). The Cannery had reached its time horizon for expected replacement of the structure. However, by choosing to preserve the primary elements --masonry walls, steel framed floors with concrete slab, and foundation – it effectively reduced the embodied impacts on the environment over its lifespan. Design for enhanced seismic safety will further prolong its service life beyond the life that has repeatedly been preserved.

Embodied Carbon of Different Structural Schemes

In the second case, the study sought to answer several questions long held by structural engineers wanting to know how their role matters in sustainable design. SE's often ask themselves:

- What is the relative impact of: the choice of framing scheme, cement content in concrete mix, recycled content of steel?

- What is the relative impact of structure compared to transport, construction, and architectural components of the buildings?
- Do results change for different building types?
- With so much variation in LCA calculations, can what I do really make a difference to results?

The study chose to focus on embodied carbon from cradle to site for the sake of common language with the client and due to foreseen limitations in data for other environmental metrics. LCA then guided the quantification and comparison of three buildings that represent typical design and construction of commercial, school, and hospital structures. The bills of quantities were already available from a cost study published by The Concrete Centre in 2007.

Six different framing schemes were compared, plus two long span options for the commercial building only, for a total of 20 different structural solutions across the three building types. For each of the three building types the only variations were directly attributable to the choice of structural scheme. Thus, facade height, soffit area, and foundation differences changes were solely due to the framing option.

Figure 3: Framing options considered in study. Long span options not in hospital or school.

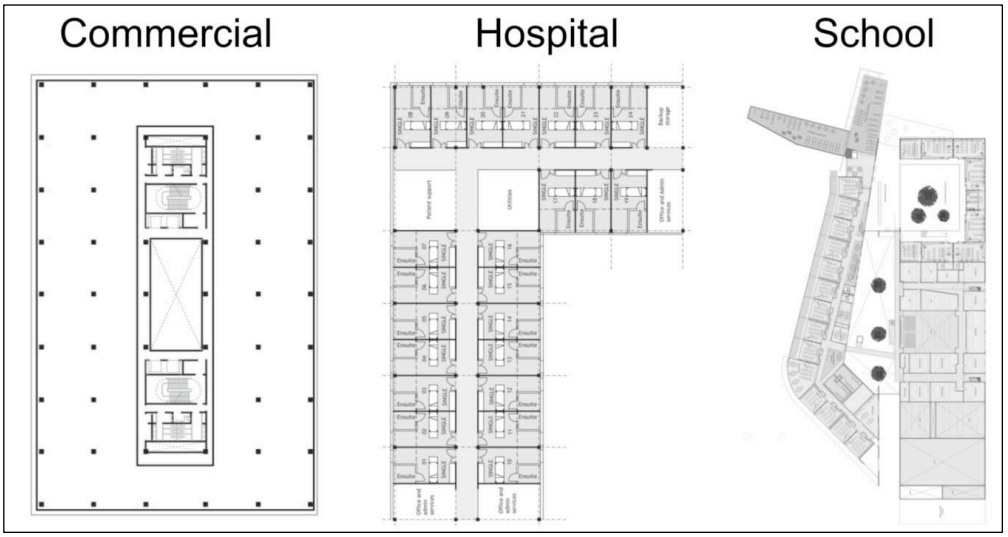

Figure 4: Plans of the three buildings studied

TABLE 1: Key characteristics of the case study buildings

	Measurement	Office	Hospital	School
Primary Parameters	Gross Floor Area (m^2)	16480	10752	13500
	Façade area / floor area	~40%	~60%	~65%
	Number of floors	6	2	2-3
	Basement?	No	No	No
	Foundations	Piles	Pads	Pads
	Number of schemes	8	6	6
	Construction impacts	12%	21%	16%
	Structure (% of total)	60%	50%	50%

Embodied CO_2 factors came from industry published figures when available (CISCF 2009). When not available, they were obtained directly from manufacturers or from life-cycle inventories (LCI) through LCA software (GaBi 2003). Development and accessibility of LCI data for construction materials has progressed much further in the UK than in the US (ICE 2008).

Results show that structure, including foundations, represented 50% or more of the whole building embodied CO_2. This was consistent across all three building types. There was no clear advantage to choosing steel over concrete or vice versa, as no structural scheme gave the lowest impact consistently. What mattered more was what was done with the scheme chosen. The amount of concrete in all buildings provided significant potential to change the embodied CO_2 of a building through specification of low cement concrete.

On the other hand, the minimum depth steel solution was consistently the highest impact solution by a large margin that was not recovered by reduction in facade area. Facade height reduction was limited by MEP needs. Thus, the least materially efficient design structurally was also the least advantageous in embodied CO_2.

Embodied CO_2 of non-structural elements was not affected significantly by changes in the structural scheme. As a general rule the embodied CO_2 of the structure can be optimised without adversely affecting the whole building impact.

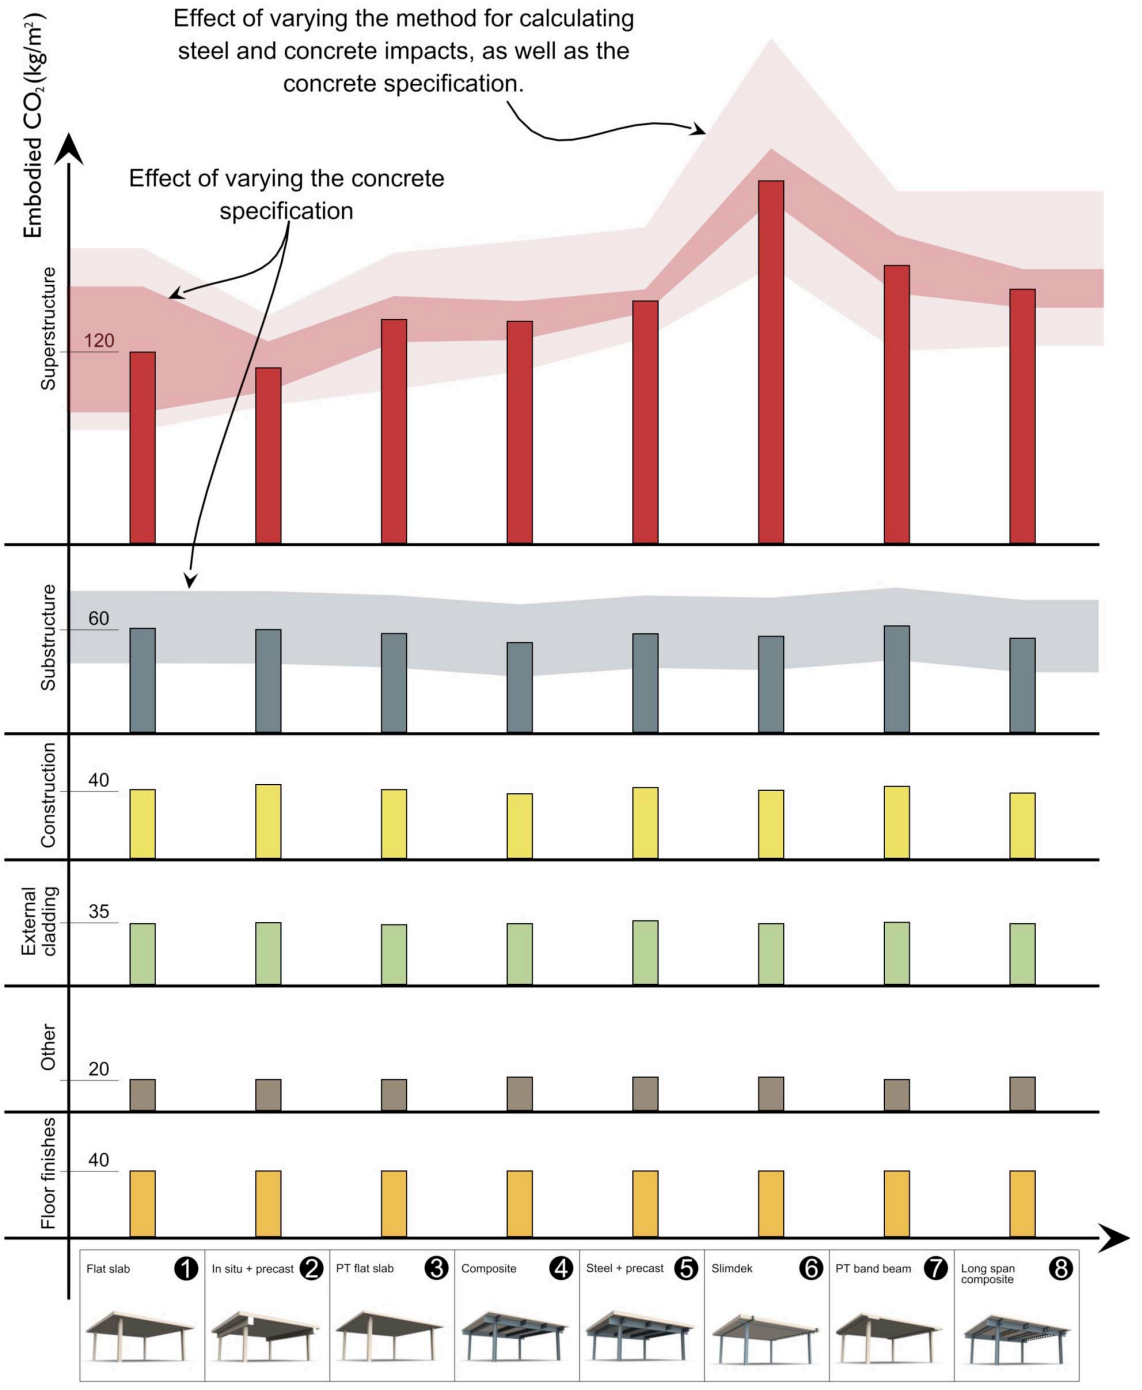

Figure 5: Breakdown of structural and non-structural elements for all framing scheme options (commercial building)

Standards such as ISO 14040 series allow broad flexibility in approach to the calculation of the materials impacts used in buildings. This has led to a range in embodied CO_2 factors that causes confusion when attempting to compare LCA results from different studies. The need for a standard methodology when evaluating buildings has been acknowledged and work has started, such as PAS 2050 in the UK

and CEN 350 in Europe. Still, the discrepancies have made some designers wonder if, until this flexibility is reigned in, attempts to quantify their efforts are futile. In this study, differences in method were separated from material specification choices to examine which design decisions, versus LCA methodology variations, will affect results.

Results showed that the real reductions to embodied carbon made through material specification and efficient design are just as great as reductions affected by changes in methodology. Thus, the role structural engineers have to play is significant to reducing climate change impacts of building construction.

Although operational and end-of-life impacts were not included in this study, the lower impact schemes would not preclude opportunities for reduction in operational impacts. Also excluded from the study are refurbishment and end of life scenarios. The potential variation introduced by these post-construction activities is very large. The design and detailing of the building can be reviewed in order to minimise operational impacts, maximise the life-span of the building elements and minimise end of life impacts.

Considering End-of-Life Options

The final study uses LCA principles to assess the effects of using framing designed for deconstruction for a parking structure. This required careful consideration of how to quantify end-of-life impacts.

The client requested an embodied carbon footprint comparison of eleven structural framing options for a parking structure in the United Arab Emirates (UAE). The comparison was based on supplied structural drawings, sample concrete mixes, and an understanding of end-of-life information and methodologies.

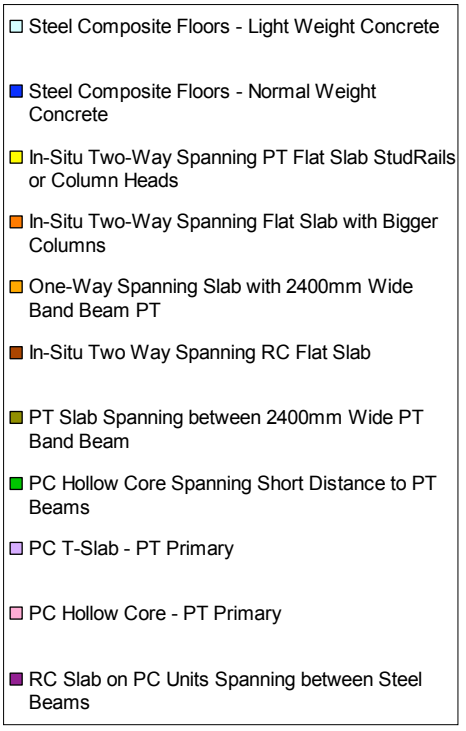

Figure 6: Eleven structural framing options under consideration

An inherent challenge for carbon footprinting projects in the Middle East region is a lack of region-specific carbon footprint data. Embodied carbon factors came from combining information for different concrete mixes and associated materials, based on UAE structural design and supply scenarios, with information provided by the Masdar project specifications manager and by regionalizing materials embodied carbon data in LCI databases.

The scope of the carbon footprint study included all material production activity including primary extraction activity, manufacture/production and transportation to site. End-of-life scenarios took into account current practice expected regionally for the different materials used in the structural design options proposed.

Recycling at end of life is based on a discounting methodology put forth by Eaton and Amato, adopted by CORUS. The formula takes into account the emissions from production of virgin steel discounted by emissions saved by future recycling. Use of this methodology reflects the likelihood of occurrence in current market conditions for rebar and structural steel sections. Other methods exist; this one seemed best suited for steel, which was the main material with an alternate end-of-life scenario in this study.

$$S_{ce} = (P_{ce} - R_{ce}) \times \frac{(1-r)}{(1-r^n)} + R_{ce}$$

Figure 7: Equation used in discounting method for taking into account materials recovery at end of life

Reuse at end of life could only realistically be applied to the precast slab on steel frame option. The other steel frame options support a composite concrete and metal deck. The metal studs that are welded onto the steel beams to achieve composite-action make reuse of the steel frame too difficult to have ever been done in practice. The most likely scenario for the steel sections in composite structures as currently constructed is demolition and recycling. The reuse of steel scenario assumed that the framing members would only be reused once, and that the concrete plank floors would be crushed and recycled as unbound aggregate, based on most likely current practice in the region.

Results from these comparisons showed that when only considering Cradle-to-Site, the deconstructable framing scheme performed the worst in carbon terms, whereas the concrete schemes performed best. All concrete on this job had aggressive cement replacement rates: 40% ground granulated blast furnace slag (GGBS) in precast, 50% GGBS in cast-in-place, and 70% GGBS in foundations. However, once the study expanded the life cycle boundary to include recycling of steel at end-of-life (and concrete crushed and used as base course), the steel schemes performed as well as the concrete schemes.

Finally, and somewhat surprisingly, when considering reuse of the steel frame, there was not enough sectional steel in the whole system to compensate for initial environmental burdens of more concrete and rebar to make it the best option in carbon terms. More concrete and rebar was needed for the less structurally efficient precast planks that do not act compositely with the steel frame.

These results points to several scenarios that would likely reap greater environmental benefit: reusing the precast planks, multiple reuse of the steel frame, using salvaged steel and using a deconstructable composite system. An example of the latter has been offered through a past Lifecycle Building Challenge (Webster, 2007). This study did not allow for investigating these scenarios, but based on current results, they emerge as logical next steps towards decreasing embodied carbon. Moreover, if an environmental impact metric besides embodied carbon was used for comparison, the ranking of schemes could have ended up quite different. For instance, steel manufacture tends to burden the environment in the category of toxicity to water much more heavily than concrete, so reuse of steel may exemplify a greater benefit if this impact were examined.

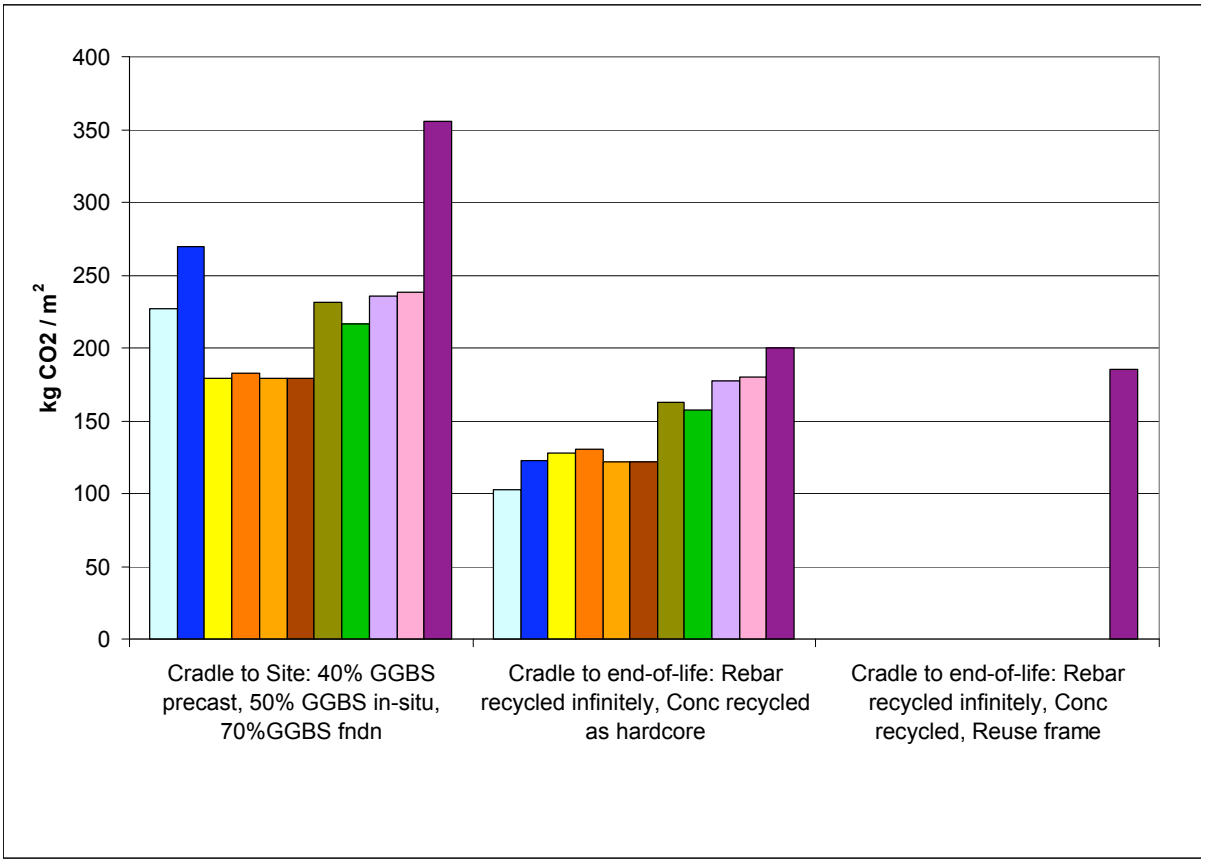

Figure 8: Comparison of framing options with and without end-of-life considerations

CONCLUSION

The first example showed that buildings embody vast repositories of energy and materials. The EcoCalculator was used to help quantify the resources tied up in a historic building. Turning these values into easily understood metrics helped the client add a layer of environmental stewardship to their value story in retrofit and preservation efforts.

In the second case, LCA principles are used to compare embodied CO_2 levels related to project choices within structural engineers' control, and bring to light the importance of their role in making more environmentally beneficial choices. Decisions in structural framing schemes, cement content in concrete mix, and recycled content were shown to have significant impact on whole building outcomes, in comparison to transport, construction, and architectural components of the buildings. Lessons learned were consistent across the three buildings that represent typical design and construction of commercial, school, and hospital structures.

The last example showed the importance of end-of-life considerations when designing for unconventional recovery of materials. The discounting methodology resulted in significant re-ranking of the environmental performance of design options. Results indicated that environmental benefits from deconstructable design has its

limits when it causes the need for more virgin material. Thus, an optimal solution would uphold both disassembly/reuse as well as optimal structural efficiency.

These varied studies show that structural engineers can use the principles and data from LCA in a variety of ways to make more informed design and specification choices. Methods should be tailored to the questions being asked. Having better understanding of LCA and using tools readily available, structural engineers have a large part to play in sustainable design.

Infrastructure Sustainability: Streamlining Life Cycle Assessment for Practicing Bridge Engineers

Extended Abstract

ABSTRACT

Life cycle assessment (LCA) can help bridge design engineers understand, measure, and evaluate the initial and long term environmental impacts of bridge projects, such as energy use and carbon dioxide (CO_2) emissions. LCA can be a helpful tool when comparing conventional construction materials with those that claim to be more environmentally sustainable because it provides the engineer with quantified information on impacts that cannot be identified by a typical bridge life cycle cost analysis (BLCCA).

This study investigates the life cycle environmental impacts for a small single span bridge project. A life cycle inventory is completed using the PaLATE v2.1 tool as modified for use with the Greenroads™ Rating System, and reports quantities for two key indicators of environmental impact for the project: energy use and CO_2. This research demonstrates that LCA tools can provide useful environmental information quickly and easily for structural engineers, but streamlined tools also require an understanding of the inherent limitations of their data sources and analysis methods.

INTRODUCTION

Whether designing a highway bridge, a building, a retaining wall or simple pedestrian overpass, structural engineers confront many decisions for which they follow a standardized method of accounting for those decisions, or they use a set of tools to put them to practice. Simple questions like *How long will the structure last? What loads will it carry? Is it safe? How will it perform in a natural hazard?* are only a few of the technical challenges and constraints faced by practicing engineers. Every project has a unique series of these challenges. In response, countless laboratory tests, decision-making tools and quality accounting methods have been developed and refined, and have ultimately transformed the standard of practice in bridge design to what it is currently.

Now, the infusion of sustainability in all aspects of resource management, manufacturing, land use, economic development, and social culture creates a new challenge: a need for additional tools to understand and quantify the broad range of environmental impacts caused by bridge projects in their lifetimes. But while use of life cycle assessment (LCA) as a decision-making tool is on the rise in the building industry, it has yet to appear in a structural engineer's typical toolbox for infrastructure construction projects. Due to the large footprint of transportation

infrastructure, LCA tools may have substantial and positive environmental influence if systematically implemented in the transportation industry as well.

What Life Cycle Assessment Is

At its heart, LCA is simply a method of environmental accounting. When completed correctly (meaning using best available data with reasonable assumptions, good faith and a standardized method), it can provide a quantified snapshot in time of any number of selected environmental impacts based on data from almost all industries. LCA data are widely available and well established in fields like product engineering, electronics, agriculture, resource extraction, and chemical processing, all of which influence bridge building in some respect. Thus, the main strengths and potential utility of LCA lie in the breadth of its existing literature as well as its standardized methodologies, such as process-based LCA, materials flow analysis (MFA) and economic input-output (EIO) LCA.

For construction projects, industry environmental emissions data is less prevalent, less accurate, less complete and often inaccessible except by academic researchers; consequently, this is LCA's main weakness. The lack of high quality data surely invites more assumptions and thus greater uncertainties into the final step of the LCA process, interpretation of the results. This weakness, however, does not distract from the overall utility of the process of measuring and tracking environmental emissions for a project.

This paper focuses on only the first steps in the LCA process: goal and scope definition and the life cycle inventory (LCI), where data collection is the key step. The inventory results in quantified impacts, such as megajoules of total energy consumed and kilograms of carbon dioxide emitted, but does not assign any weighting to these results. Valuations are also necessarily project-specific, so this focus is intended to limit the subjectivity of the reported results.

Because LCI results are heavily dependent on input data quality and availability, it is critical that the limitations of data used on a project LCI are well understood prior to acting on or interpreting the results. Importantly, and like any tool with built-in limitations, such as pile or beam design software, the lack of data or its uncertainty should not preclude an engineer from using the method so long as its limitations are clearly understood. Even the simplest LCI provides previously unmeasured perspectives by integrating environmental issues into everyday design choices, helping to weigh alternatives, and providing new insight on tradeoffs between those alternatives.

Life Cycle Assessment Is Not Engineering Economics

An important distinction must be made between LCA and life cycle cost analysis. LCA uses a decision-making process that is similar to life cycle cost analysis (LCCA), more commonly known as engineering economics or project finance. But, while both are decision-making tools that provide quantitative results, their purposes and scope are much different. A relationship between the two methods can be drawn by their overall usefulness when used in the decision-making process, but that is where the similarities end.

Since LCCA is also not widely adopted, as shown in Ozbay (2004), it is useful to mention that the majority of the life cycle oriented literature for bridge engineering is directed at optimization models in bridge management systems at the network and project level (Morcous, 2007; Frangopol & Liu, 2007; Estes & Frangopol, 2001; Frangopol, 2004; Hegazy, Elbeltagi, & El-Behairy, 2004), for preservation and maintenance (List, 2007; Strauss et al. 2007; Naus & Johnston, 2001), and reliability analysis under environmental stressors and hazards (Lee, Cho, & Cha, 2006; Hosser et al. 2008; Padgett, Dennemann, & Ghosh, 2010). Environmental costs are typically not considered in LCCA, but Ehlen (1999) provided a model using so-called "third-party costs," defined as environmental damages, though he used values of zero in his model for these costs. A case could be made for similar applications of life cycle assessment in each of these categories, with the primary goal of measuring environmental impacts instead of simple bottom-line cost impacts. Additionally, it is likely that current applications of LCCA can be expanded to include LCA, or perhaps new applications could be developed using similar algorithms.

Mathematically, LCCA allows a designer to understand the economic impact of their design choices and construction methods at any given point in time under the concept of time value of money. The National Cooperative Highway Research Program Report 483 (Hawk, 2003) provides the most comprehensive information on life cycle thinking for bridge projects. The report gives substantial detail about the utility and application of BLCCA, including examples, a guidance manual, and software tools, and a comprehensive summary of research work done using the LCCA method on bridge projects in the United States (until date of publication). Ehlen (1997) also provides an excellent explanation of the utility of BLCCA and relevant applications for engineers. It is notable there is no such manual or tools for LCA, and due to their similar nomenclature, this is perhaps why the methods are frequently confused.

However, there is government support for life cycle thinking. In 2005, the Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU) mandated that state departments of transportation (DOTs) use economic tools for decision-making in infrastructure design such as value engineering or LCCA for bridge projects valued at or above US$20 million or any federal aid project exceeding US$25 million (Federal Highway Administration, n.d). But, outside of compliance with this regulation, application of BLCCA is sparse. Thompson (2004) provides a discussion of LCCA tools for bridges and notes that it has not been applied in practice because adequate and accurate decision-support tools are still not widely available to the bridge engineering community for streamlining the process. Similar conclusions may be made about the adoption of life cycle assessment methods and tools.

According to Kendall et al (2005) and Keoleian et al. (2008), literature for bridge LCA is even less available, though some recent MFA and embodied energy work has been done in Japan (Itoh & Kitagawa, 2003), France (Le, Feraille-Fresnet, & Bouhaya, 2009) and the United Kingdom (Collings, 2006; Zhang, 2010). The most formative research projects in the United States have been process-based LCA comparisons of different concrete deck designs (Kendall et al., 2005, Keoleian et al., 2008) and the straightforward comparison of steel and concrete bridge alternatives

completed by Horvath and Hendrickson (1998) using an EIO-LCA model. Some authors have also attempted to use LCA software designed for buildings on infrastructure products (Reiner & Rens, 2006), which may not be advisable due to the different contexts of bridge and building projects. The variety of these studies makes comparing the results difficult because not only do the application regions differ, but so do the sources of data and methods or standards used. Additionally, there is currently no standardized tool that would allow results to be compared more easily.

Other groundbreaking work has been completed recently by Pacheco et. al (2010) on bridge construction processes and also for the general building construction process by Bilec, Ries and Matthews (2010). New studies on ground improvement methods are appearing from international researchers (Jefferson et al. 2010; Yee & Ooi, 2010). Possibly most relevant, Muench (2010) also provides a summary of 44 life cycle assessment models completed for roadways to date in order to determine average rules of thumb for different lifecycle stages. Unfortunately, a similar review of bridge LCAs would not be feasible considering the limited availability of results.

LCA differs substantially from LCCA in terms of its mathematical approach. For example, there is currently no consensus on the time value of environmental resources, like energy, or emissions, like CO_2, as there is a way to evaluate the time value of money: compound interest formulas. So, how inflation works, what its impacts are in the long and short term, and the economic conditions under which changes in inflation may occur, are well understood. Long range environmental consequences, on the other hand, such as the impacts of CO_2 on global warming or climate change, are not well understood and there is also great uncertainty in the availability of fossil energy reserves. These uncertainties do not reduce the importance of the LCA method, in fact, they reinforce its need. The complexity of LCA often comes from the idea that multiple criteria must be considered at the same time under the same conditions. A streamlined tool that can be applied in practical project contexts is needed.

SCOPE OF RESEARCH

This study provides preliminary results of streamlined life cycle inventory tool called PaLATE v2.1 as modified for use with the Greenroads™ Rating System. The goal of this study is to demonstrate that a tool is available that may be helpful for bridge engineers seeking to measure or include environmental criteria in their design process. The tool reports results of total energy consumed for the initial construction, materials production, future maintenance activities and transportation of materials to-and-from the site for a small single span bridge project. Results of this study will be presented at the Structural Engineers Institute Structures Congress in Las Vegas, NV, April 13-16, 2011.

Project Description

The Tonquin Avenue Bridge is located in Ocean Shores, WA and spans the 150-foot Lake Minard Canal (see Figure 1). It was built in 1970, deemed structurally deficient due to rotting of the timber superstructure and supporting piers in 2006, and was subsequently closed to traffic. This route is critical as for evacuation during a

tsunami for the community members and also provides crossing for several critical utilities such as electricity, water, and sewer.

Figure 1. Existing Tonquin Avenue timber bridge.
(Reproduced with permission courtesy of GeoEngineers, Inc.)

The new project calls for replacement of the bridge superstructure as a single span with five concrete WF58G prestressed concrete girders and cast-in-place concrete deck, abutments, piers and block retaining walls as well as new utilities (see Figure 2). The substructure is founded in beach soils and will require ground improvements, which will include dynamically placed stone columns. The bridge approaches on either side will also be removed and replaced to meet current design standards (AECOM USA, 2010).

ACKNOWLEDGEMENTS

The author would like to recognize the efforts of University of Washington colleague Craig Weiland, who helped develop and revise the PaLATE v2.1 software used in this study. Also, this work would not have been possible without the helpful collaboration of Michael Hutchinson, Lyle Stone and Bruce Stirling of GeoEngineers, Inc. Finally, the author is very grateful for the contributions of Kiva Lints and Vanessa Bacurin of AECOM USA, Inc., who were instrumental in providing the project data for this study.

Deflection Limits in Tall Buildings – Are they useful?

Rob Smith
Associate Principal, Arup, 12777 West Jefferson Blvd, Los Angeles, CA 90066, USA; PH +1 310 578 4598; email: rob-j.smith@arup.com

ABSTRACT

Serviceability criteria in the form of lateral deflection and acceleration limits under wind loading are often the governing structural issues for tall buildings. Whilst the basis for acceleration criteria has been the subject of research, rational refinement and consensus over recent years, deflection limits are still rather arbitrary. Current guidance on deflection limits in international design codes is very limited and is based primarily on experience with typical low and medium-rise buildings. The issues with lateral deflection in very tall buildings are different to those of low-rise buildings, and depend on structural form. Rational choice of deflection criteria for tall buildings therefore requires further consideration of the nature of the deformations and the effects they have on the functional aspects of the building.

This paper identifies the functional issues, the relevant deflection measures, and reviews current international practice. New design approaches are challenging previous design norms, and the paper describes a performance-based approach, which allows greater freedom in choosing appropriate constraints for structural and non-structural components. Whilst the subject matter is not new, the use of new design tools and processes leads us to re-examine rules of thumb previously used. The paper focuses primarily on wind events, but comparisons with seismic events are drawn.

INTRODUCTION

Lateral loading effects from wind and seismic sources usually dominates the structural design of tall buildings. As well as strength considerations, stiffness and its effect on deflection, is usually the governing criteria which determines structural element size and cost.

Structural design codes are generally written with conventional types of low-rise and medium-rise buildings in mind. High-rise buildings often have different structural forms such as outrigger systems, bundled tubes, megabracing etc. The nature of the deflection with these structural types often differs to that in low-rise buildings. At the time of writing there are a large number of buildings around the world being designed well above the height that has historically been fully considered when formulating code rules. In order to provide improved criteria for deflection performance of these buildings, it is essential to understand the nature of lateral deflections and effects on serviceability and strength.

The first part of this paper discusses the functional issues that are affected by deflections in high-rise buildings. The next part discusses factors that affect the predicted deflections. Finally, a review of recommended deflections and a design approach is given. This paper describes a performance-based approach for deflection limits, whereby the limit should be defined by consideration of the performance of all the associated non-structural and structural items.

PERFORMANCE CONSIDERATIONS RELATED TO DEFLECTION

Cladding and Facade

Cladding systems must be designed to accommodate the movements imposed upon them so as to maintain the functionality of weather-tightness, acoustic and thermal insulation and structural / mechanical integrity.

The movements of concern to cladding are local deformations, not overall deflections. The relevant local deformations are affected by the arrangement and types of fixing and the design of the joints, but may be categorised broadly as vertical compression/extension, in-plane shear, and warping.

All aspects of sources of deformation are of concern. These include

- Movements associated with continuing construction of the building after panels have been installed
- Long term (quasi-static) effects due to gravity loads, creep and shrinkage
- Medium term effects (e.g. thermal)
- Short term and dynamic effects (wind and earthquake)

Movements from all sources must be combined to determine the effect on individual panels. This is common practice amongst many specifiers of facade systems.

The movements tolerated by cladding panels are then limited by:

- Maximum movement joint size (limited by manufacturing or architectural preference)
- Size of panels
- Detailing of movement joints and connections
- Ductility of panels (which is typically low)

Interior fit-out : partition walls, architectural finishes etc

Broadly the same considerations apply to internal fit out as apply to cladding. However there may be additional racking deformations associated with:

- Relative vertical gravity and thermal shortening between internal and exterior cores, walls and columns
- Additional racking due to lateral deformation shapes of walls/cores and frames

It is common in seismic zones for partition walls to be designed for movement. For instance, soft layers can be placed at the end and head of walls, allowing in-plane movement, but restricting out-of-plane movement. Where brittle finishes are applied, and movement joints are not specified, the designer can assess shear drift for an appropriate panel size and limit drift based on guidance for low-rise buildings.

Lifts / Elevators

The considerations for lifts are different. Lifts are contained within shafts and are only sensitive to lateral movements due to wind (and earthquake). Lift cars and counterweights are laterally restrained by vertical rails within the shaft and systems can be designed to accommodate significant lateral ‘slope’. However, a major consideration is the profile of the cables and deflected lift shaft, and the need to

prevent the cables from snagging on fittings in the shaft. Cables respond dynamically to lateral vibration of the building and it is important to avoid significant resonance by ensuring the natural frequency of the cables is well separated from the natural frequencies of the building during significant building motions. This is often managed by parking the lifts during high winds so that the cable lengths are reduced to increase cable frequencies away from resonance.
The shaft size may need to be increased in order to provide adequate clearance between the cables and the shaft during strong winds, to accommodate the lateral curvature (related to deflection) of the lift shaft (and therefore building as a whole), and the sag and vibration of the cables. The geometry of the lift shaft and its deflected shape should be considered on a case by case basis and there is no single limiting value – the height is likely to be governed by the size and strength of cables. As lateral deflection limits are relaxed the sizes of lift shafts may have to increase, or other measures may be needed to reduce cable motions.

Occupant comfort

Occupant comfort is related to the perceived movement of buildings. In isolation from visual cues, humans cannot detect the quasi static lateral deflection of a tall building, sensing only the motion, normally quantified in terms of acceleration rather than displacement. Whilst there is no universally agreed limit for lateral accelerations, there are various guidelines in different design standards which are broadly similar.
Deflection checks are not adequate for assessing occupant comfort as these do not adequately cover the important dynamic factors affecting acceleration. For this reason the historic specification of a lateral 'deflection limit' (e.g. the Hong Kong concrete design code (2004) recommends a limit of H/500) as a means of guarding against excessive human perception of motion is at best indirect and empirical, and at worst could be either unsafe or uneconomic. For buildings with supplementary damping, it is possible to make a building more flexible and still achieve satisfactory accelerations.
In the case of a very tall or flexible building, the floor 'slope' might be noticed by the occupants. Perception might be might be triggered by a ball or marble starting to roll across a floor or table top, or a pendulum light fitting moving out of line with a 'vertical' feature. Criteria for such phenomena have not been developed, as traditionally it has been 'motion' (i.e. lateral accelerations) that has governed. However, this may not be the case in future for very tall buildings where human sensitivity to acceleration is lower and the floor slope becomes relatively more significant .

Acceptable damage

Normal design practice assumes that the structure will remain near-elastic for the ultimate (factored) wind load. It is also assumed that the non-structural elements will also remain largely undamaged for the unfactored wind load – typically 50 or 100 years. For seismic loading, more damage is acceptable. ASCE 41-06 (2006) provides guidance on how different shear drifts relate to different damage levels. The "immediate occupancy" damage category (typically relating to a 30-70 year seismic event) allows a small degree of damage, but the "service wind" (50 years) allows no

damage. The difference relates to the need to consider wind storms of lesser but still significant magnitude, and which remain a common occurrence.

CONSIDERATIONS IN THE PREDICTION OF DEFLECTIONS

Structural modelling of frame

Typically, structural modeling is performed with the intent of calculating force distribution within a building. A conservative approach is made which often over estimates deflections. Therefore realistic assumptions would need to made relating to items such as non-structural elements, P-delta effects, construction sequence, cracking of elements, short term elastic modulus, stiffness degradation, modelling of joints. While there are numerous text books written on this subject, there is little standardized guidance.

Loading and return period

Wind

Deflections under wind loading are normally taken at the "design wind speed". The design wind loading for tall buildings is usually taken as either 50 year (non-hurricane/cyclone/typhoon regions) or 100 year (in hurricane/cyclone/typhoon regions). Load factors used may also vary between codes and care should be taken when selecting a return period to take proper account of intended safety at the ULS limit.

For certain types of building, the peak wind loading may be associated with a lower wind speed. This occurs when the critical wind speed for vortex shedding is lower than the 50 year wind speed. In this case, the design should not only use the peak wind load for estimating deflections, but should also consider increasing this. The reason for the that the probability of the building experiencing this force is higher than for a building which does not see this vortex shedding peak.

Damping

Damping is a big factor in determining the dynamic response, which will often contribute a significant proportion of the overall deflections in wind. As discussed in Smith, Willford and Merello (2010) the values of damping conventionally recommended are typically too optimistic for very tall buildings, and appropriate values, based on improvements over the last 10 years or so in quality of understanding and measurement, should be adopted, especially where best-estimate wind speeds and responses are used for design.

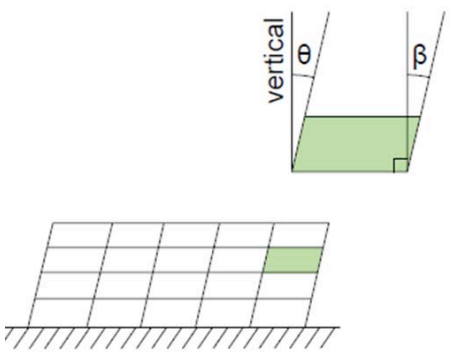
Seismic

Seismic response is usually based on either the 475 or 2475 year event. The nature of seismic loading is such that a much greater shear drift is seen within the building than in wind. Interstorey drift largely matches shear drift (racking deformation) in this case. See later for definitions of drift.

DEFINITIONS OF DEFORMATION UNDER WIND OR EARTHQUAKE

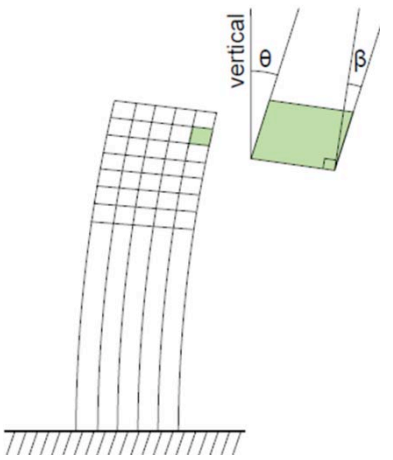
The following are useful definitions to describe how a building deforms.

Total building drift ratio is defined as the peak lateral deflection at the top of a building divided by the height of the building (excluding items such as masts etc) under the design wind load. This is a crude measure of assessing the stiffness of a building and its likely performance.



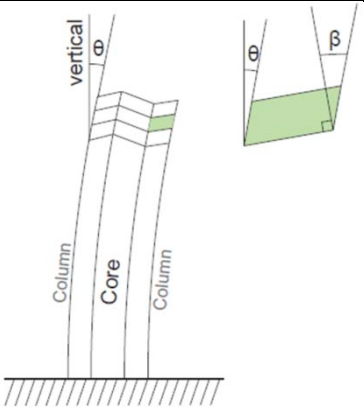
Interstorey drift is defined as the difference in horizontal displacement over one storey (floor) divided by the storey height. This is the most commonly used form of deformation criterion and many structural design standards refer to this. This can be seen as θ in Figure 1.

Floor Slope. In the context of building deflections, the slope can be defined as the average angle of the floor plate at the lower part of a panel that is considered. The slope may vary in each bay, depending on the relative vertical deflection of the columns or walls at each side of the bay. In Figure 1, this is θ – β and may vary from panel to panel.



Panel deformation is a measure of the in-plane shear deformation of a wall panel. It is the difference between the interstorey drift and the local floor slope. Whilst in framed perimeter structures the floor slope will generally mean the panel deformation is less than the interstorey drift, in some cases the effect of floor slope is additive (e.g. between a core and a perimeter structure). This is a measure of the deformation that would cause damage to non-structural elements. This is β in Figure1. If one compares figures b and c, it can be seen that panel deformation may vary across a storey. A famous example of a building with a high floor slope and high interstorey drift but no panel deformation is the leaning tower of Pisa. The deformation is almost entirely in the foundation.

Racking deformation can be defined as the average panel deformation over a storey.



Inclination may be defined as the slope of a nominally vertical element such as a lift shaft in wind. It is the same as interstorey drift.

a/ Low rise building – interstorey drift same as panel deformation

b/ Tubular building – interstorey drift higher than panel deformation

c/ Core building – interstorey drift can be lower than panel deformation

d/ Example of building with high interstorey drift and low panel deformation

Figure 1 - Definitions of drift - based on CTBUH (2008)

EXISTING CODES AND STANDARDS

The following data has been taken from various international design and loading codes. Many modern design codes do not apply limits on lateral deflection of buildings.

Table 1 - deflection limits in international standards

Standard/ Reference	Effect	Type	Inter-storey Drift Ratio Limit	Top Deflection Limit
Chinese Standard				
JGJ3-2002 Technical specification for concrete structures of tall building	Wind (H>250m)	Concrete/ Steel/ Composite	1/500	No guidance
	Seismic (50yrs) (H>250m)	Concrete/ Steel/Composite	1/500	No guidance
JGJ 99-98 Technical specification for steel structure of tall building	Wind	Steel Structure	1/400	No guidance
	Seismic (50yrs)	Steel Structure	1/250	No guidance
DG/TJ08-015-2004 Code for design of steel – concrete hybrid structures for high – rise buildings (Shanghai)	Wind (H>250m)	Composite	1/500	No guidance
	Seismic (50yrs) (H>250m)	Composite	1/500	No guidance
Hong Kong Code				
Code of practice on Wind Effects in Hong Kong 2004	Wind	RC/Steel	No guidance	No guidance
Code of Practice for Structural use of Concrete 2004	Wind	RC	No guidance	1/500
Code of Practice for Structural Use of Steel 2005	Wind	Steel	1/400	1/500
Eurocode				
Eurocode 3 ENV 1993-1-1:2005:	Wind	Steel	No guidance	No guidance
Eurocode 8 EN 1998-1-2004	Seismic (approx 95 year)	Steel / Concrete (limits depend on finishes)	1/200 – 1/100	No guidance
British Standards				
BS 5950 – structural steel in buildings	Wind	Steel	1/300	No guidance
BS 8110 – structural use of concrete ("limit applies unless partition, claddings have been specifically detailed ..")	Wind	Concrete	1/500	No guidance
American Standards				
ASCE 7-05 – Minimum design loads for buildings and other structures	Wind		No guidance	No guidance

Standard/ Reference	Effect	Type	Inter-storey Drift Ratio Limit	Top Deflection Limit
	Seismic (2/3 of 2475 event)	Steel / Concrete	1/100 – 1/200	No guidance
Los Angeles Tall Building Structural Design Council, An alternative procedure for Seismic analysis and design of Tall buildings located in the Los Angeles region (2008)	Seismic (MCE)	All	1/33	No guidance
Japanese Code				
Building Codes of Japan and Recommendations from the Special Approval Process by a Selected Expert Review Panel (applies to any building over 60m)	Seismic	Steel	Typically: (100yr): 1/200 (500yr): 1/75 - 1/100	No guidance
		Concrete	Typically: (100yr): 1/500 (500yr): 1/200	No guidance
Guidelines for the Evaluation of Habitability to Building Vibration	Wind	Steel	Same as above	No guidance

LITERATURE REVIEW

Interstorey drift

Recommendations for criteria on drift limits have been in existence for many years. For instance "The stability of tall buildings" (Wood, 1958) gives a table of racking tests. From this, it can be seen that typically first cracks in a masonry wall would occur at around H/400, although there is considerably more movement before ultimate load is reached.

Similarly, tests by Freeman (1977) on plasterboard partitions indicated that first cracks would occur around H/300 to H/400. The paper also discusses how partitions may affect the overall damping and stiffness of the building.

One of the most comprehensive reviews of the drifts is published by the Council of Tall Buildings and Urban Habitat (1980) includes a study of the state of the art in the 1970s. Limits for interstorey drift from literature range from H/333 to H/666. Note that the latter is based upon a wind pressure of 958 Pa (20 lb/ft2) at 30m height, rather than a specific return period. Most of the drift values in this book refer to those in common usage, but little mention is made of physical testing. A later study by ASCE (Ellingwood et al 1986) shown in table 3 compiled the results of various tests to ascertain the effect of drift on damage to non-structural components. As can be seen, the critical point where damage becomes visible would appear to be H/500 to H/300.

Galambos and Ellingwood (1986) suggest that the serviceability criteria based upon 50 year winds are too onerous and it would be more suitable to use a reliability method based around the 8 year period (8 years being a typical lease period in a tall building), such that the design deflections are not exceeded more than once in that period. We do not believe that this suggestion was ever taken up in building codes.

A further study by the ASCE (1988) conducted a survey of US structural engineering practices. The study focussed on engineers treatment of drift in tall buildings of the time. Typically (41% of respondents), engineers designed to H/400 interstorey drift for the 50 year wind. A number used different numbers between H/600 and H/200.

Of course, the above has focussed on determining a deflection limit for a defined wind event, ie a deterministic approach. Generally such approaches should be calibrated against probabilistic approaches, although such procedures are not practical in normal building design.

Reid and Turkstra (1981) reviewed such a process and concluded that the most important variable apart from loading was the damage limitation threshold (ie the drift limit!) The other conclusion that can be drawn from their work is rather simple – flexible buildings are more likely to suffer damage if not detailed correctly. This is a sliding scale and not based on a single number.

Examples of buildings which have been designed outside of "normal" drift limits are given in Taranth (2009) The SRZ tower in Dubai (265m high office building, designed by Lemessuirier Consultants) did not meet a limit of H/500 in design, and this requirement was relaxed owing to the nature of the deflection (bending rather than shear). The same argument was applied to the Al Bateen Towers in Dubai (204m). See table 4.

Another building designed (but not yet built) with high drifts is the 600m Chicago Spire. While the drifts are not reported publicly (Burns et al, 2008) the first natural period is – 18 seconds. This is an indication of a very flexible building which could not meet traditional deflection limits.

Total building drift

Much of the older literature (CTBUH, 1980) focused on total building drift limits, discussing occupant comfort and dynamics. At that time, the use of damping to control building dynamics was in its infancy, as was the understanding of the sensitivity of building occupants to lateral movement. A survey of engineers in Boston, Ma indicated that total building drifts used in the 1970s was between H/1000 and H/200, with the majority using a limit of H/400. Two companies reported that buildings designed with a limit of H/200 had performed adequately in the past, although no details are given.

A key point to note that in the 1970s US design practice, there was no fixed deflection criteria. This remains true in today's practice.

Table 2 - test data from Wood (1958)

Type of frame and infill	First visible crack : deflection / height	First crack deflection (inches)	Ultimate deflection (inches)
Frame type 1 Horizontal girders 10 in x 4.5 in (I25) Vertical stanchions 10 in x 8 in (I 55) (weak direction) 6 in x 3 in x 0.5 in bolted cleat connections to top and bottom flanges of each beam			
Open bare frame	n/a	1.0	6.0
Encased frame	1/100	1.0	2.3
Encased frame with 4.5 inch brick panel	1/350	0.3	2.5
(repeat test) with 4.5 inch brick panel	1/400	0.28	2.8
Brick on edge in filling	1/400	0.27	2.0
3 in hollow clinker block	1/450	0.25	0.8
(repeat test) 3 in clinker block	1/400	0.28	0.7
3 in hollow clay block	1/275	0.4	1.5
3.5 inch brick	1/425	0.26	0.6
4.5 inch brick with door opening	1/1000	0.11	2.1
Frame type 2 (stiffer) Horizontal girders 13 in x 5 in (I35) Vertical stanchions 10 in x 8 in (I 55) (strong direction) 6 in x 4 in x 3/8 in bolted cleat connections to top and bottom flanges of each beam			
Encased frame	1/100	1.0	2.2
4.5 inch brick infilling	1/400	0.28	1.5

Table 3 - Serviceability performance levels published by ASCE (Ellingwood 1986)

Deformation as a fraction of span or height	Visibility of deformation	Typical behavior
< 1/1000	Not visible	Cracking of brickwork
1/500	Not visible	Cracking of partition walls
1/300	Visible	General architectural damage Cracking in reinforced walls Cracking in secondary members Damage to ceiling and flooring Façade damage Cladding leakage
1/200 – 1/300	Visible	Visual annoyance Improper drainage
1/100 – 1/100	Visible	Damage to lightweight partitions, windows, finishes Impaired operation of moveable components such as doors, windows, sliding partitions

SAMPLE DATA FROM BUILDINGS

The following gives examples of tall building designs.

Table 4 - Design deflections

Name of building	Lctn	Source of data	Ht (m)	Structural System	Max Lateral Deflect	Max Interstorey Drift
Central Plaza	Hong Kong	Arup	374	perimeter tube core	H/785	
West Tower	Guangzhou	Arup	432	RC Core + CFT Diagrid	H/575	h/500
Jin Mao Tower	Shanghai	Taranath	421	RC Core + SRC Column frame	H/575 (Chinese code wind)	
International Commerce Centre	Hong Kong	Arup	480	RC Core + Outrigger + SRC Column frame	H/400	h/300
2IFC	Hong Kong	Arup	420	RC Core + Outrigger + SRC Column frame	H/466	h/315
Petronas Tower	Kuala Lumpur	Taranath	452	RC Core + Outrigger + SRC Column frame	H/560 (50 year wind)	
Elysian Hotel	Chicago	Taranath	208	RC Core + outrigger + RC Mega columns	H/800	
Pinnacle	London	Arup		Braced steel perimeter with viscous dampers		h/300
St Francis Towers	Manila	Arup	210	RC core, moment frame, Damped outrigger	H/230	h/250
Al Bateen Towers	Dubai	Taranath	204	Coupled shear wall		h/300 (reported as 10 year wind)
SRZ Tower	Dubai	Taranath	265	RC Core + outrigger + frame		Approx h/350 (10 year wind)

RECOMMENDATIONS

Stiffen building for the appropriate use and wind event

The degree of stiffening required for a building should consider the contents (brittle finishes, flexible panels etc) and also the nature of the climate (eg hurricane/typhoon/tropical cyclone, thunderstorm, or extra-tropical cyclone).

In a hurricane climate and with brittle finishes, it may be more appropriate to take a lower return period wind with tighter deflection criteria. This might be panel deformation of H/600 for a 10 or 20 year wind. The rationale is to concentrate on ensuring no damage in a more realistic service state. Although, in this case, the 50 or 100 year wind deflection may be high, the accumulated damage over the life of the building would be similar to that of a structure designed in a non-typhoon region.

For synoptic wind climates (non-typhoon), where detailing cannot accommodate higher deflections, panel deformations should be limited to between 1/300 and 1/500 in the 50 year wind.

Accommodate movements

In many case, non-structural items can be designed to accommodate deflections. Items which can be designed for this are cladding panels, partitions, lift cables, services etc. As has been discussed previously, overall deflection limits and interstorey drift limits can be a crude measure of the actual functional requirements, and specific 'performance based' approaches offer greater flexibility and make more sense particularly for very tall buildings. This is already common in seismic zones where construction details are modified to permit greater movement than normal with minimal damage to cladding and fit-out.

Use "panel" deformation as definition of movement

Deformations should be provided/specified for appropriate panel sizes and types to represent cladding panels or non-structural walls. Interstorey-drifts, even when considering the differing effects of shear and bending are fairly meaningless as they do not consider the internal deformation of the building.

Design for occupant comfort

Quantitative criteria for occupant comfort are expressed in terms of acceleration, not deflection, and traditional deflection limits are not a good way of attempting to satisfy comfort criteria.

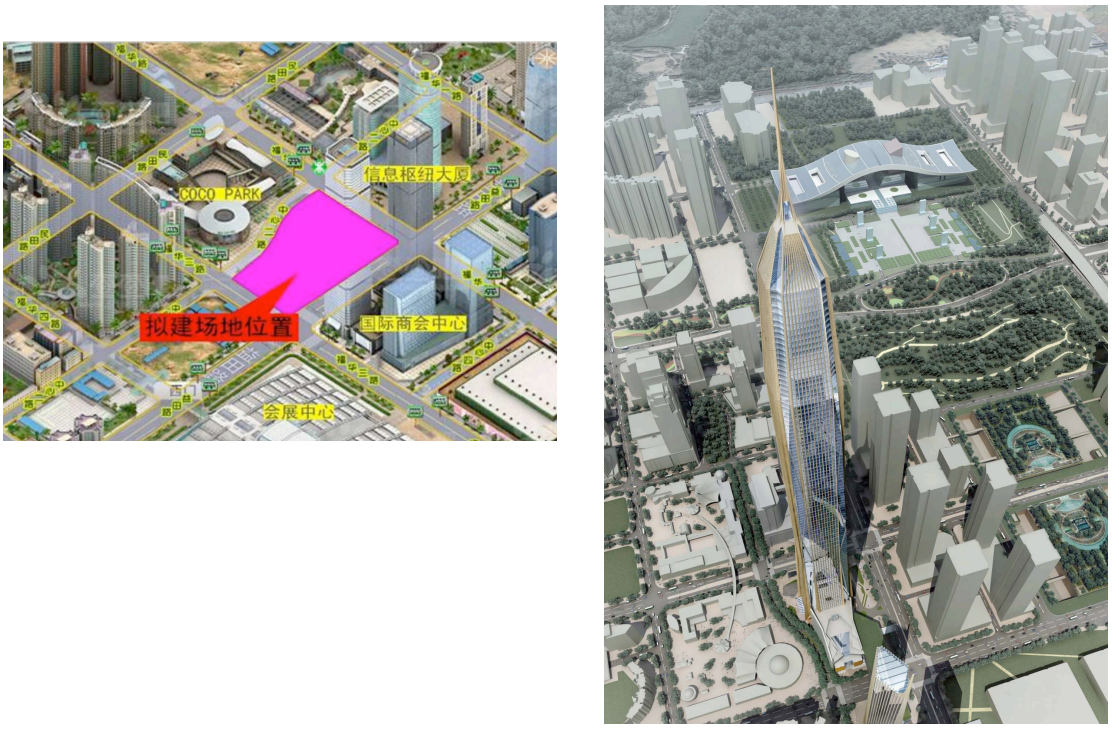
ABSTRACT

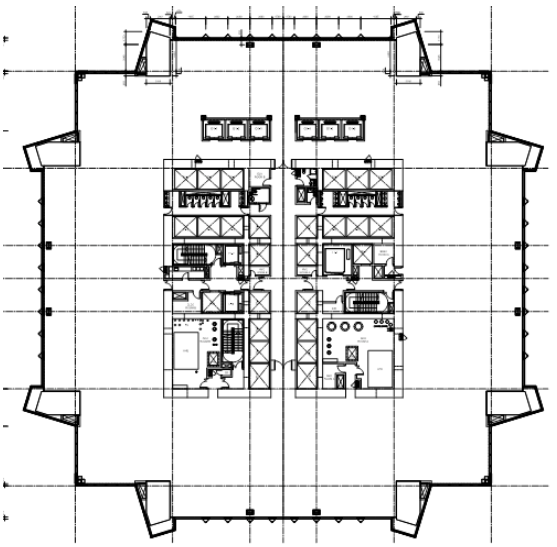
When completed the Ping An Tower will be the second tallest building in the world and the tallest in China. Its design was being developed at the same time as the latest cycle of revisions to the China Code were being proposed and considered. Expert panel reviewers familiar with upcoming code changes considered them when commenting on the design. As a result, the analysis and design challenges experienced on the Ping An Tower provide a preview of likely effects of the forthcoming China Code. The paper will discuss and summarize extensive analyses required to satisfy the new China Code standards. The impending provisions in the China Code will establish more stringent design requirements that go beyond current international building design standards.

PROJECT DESCRIPTION

At 660m of height, the Ping An Tower will be the centerpiece of the growing Shenzhen skyline located just a few minutes north of Hong Kong. It will be the tallest tower in China upon completion in 2014. Its skyward-pointing shape is reminiscent of classic skyscraper forms like the Empire State Building and Chrysler Building in New York City while using state-of-the-art technologies for design and construction. Implementing LEED requirements for design, construction and life cycle properties will set a new standard for China building design. In 115 stories the tower will accommodate high end Class A office space, trading floors, Skylobbies and sky restaurants as well as an observation deck. An 11 story podium will house entertainment venues, high end retail stores and cultural amenities. Its 5 story deep

basement includes spaces for mechanical, electrical and plumbing services as well as extensive parking areas. *See Figure 1.*
The development will occupy an area of 12,000m^2 with a total gross floor area (GFA) of 462,000m^2 (4.95 million ft^2) with 385,000m^2 above and 77,000m^2 below grade.





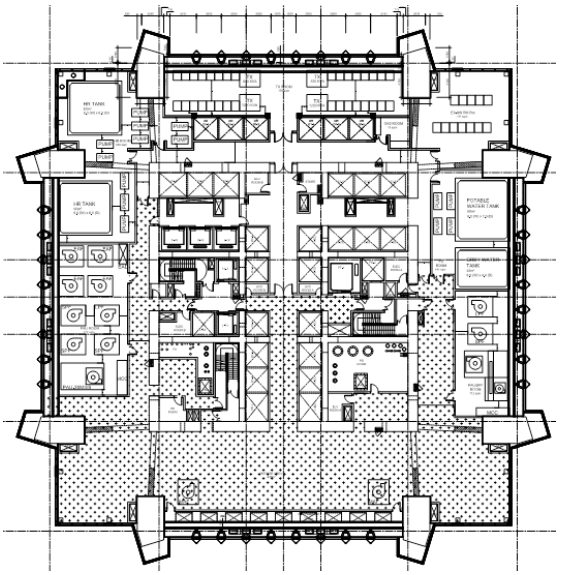


Figure 1 – Ping An Tower Site Plan and 3D Rendering
(Courtesy of KPF)

A stacked-zone approach was adopted for interior space planning. This design strategy is becoming more common for super tall structures since it provides efficiency in construction and ongoing building operation. Each zone, containing about 15 office floors, is separated from other zones by double height mechanical floors which are also designed as refuge floors in emergency events. The floor plates are square with recessed corners. Floor overall dimensions taper from the ground floor up to level 27 and then stay constant up to level 95 (while the four corners keep receding) From level 95 to 115 floor dimensions steadily reduce to produce a unique roof profile. Above the last floor a tapered structural steel frame will support a 60m tall mast (Figure 2).

Typical Office Floor Plan

Typical Mechanical Floor Plan

Figure 2 - Ping An Tower Elevation and Typical Floor Plans
(Floor Plans are Courtesy of KPF)

GEOTECHNICAL CONDITIONS AND TOWER FOUNDATION

Considering its coastal location, site subgrade conditions are fairly good: strata of clay, fine sand and coarse sand for 30m with at least 35m of decomposed rock below. The site is defined for seismic design as Type II to III. See Table *1* for typical soil strata and mechanical properties. The water table is high, just 2.2 to 4.9m below grade.

Table 1- Soil Profile

Soil Stratum Succession	Soil Stratum Name	Average Soil Stratum Thickness (m)	Average Distance to the Bottom of Stratum (m)	Saturated Undrained Internal Friction Angle (degree)	Saturated Undrained Cohesion (kPa)	Shear Wave velocity (m/s)
①	Backfill	5.45	5.45	-	-	190.3
②	Silty Clay	1.4	6.85	12.3	18.0	174.5
③-1	Clay	3	9.85	18.4	42.9	213.7
③-2	Med.Coarse Sand	2.3	12.15	-	-	245.4
③-3	Fine Sand	1.4	13.55	-	-	250.0
③-4	Silty Clay	3.15	16.7	14.8	34.9	243.4
③-5	Silty Clay	2.4	19.1	11.3	15.5	211.0
③-6	Coarse Sand	2.75	21.85			258.2
④	Grav. Clay	7.05	28.9	23.7	21.4	275.6
⑤-1	Fully Weathered Granite	5.85	34.75	26.0	16.5	336.6
⑤-2	Fully Weathered Granite	6.25	41	26.8	14.2	380.4
⑥-1	Severely Weathered Granite	14.55	55.55	-	-	458.4
⑥-2	Severely Weathered Granite	10.45	66	-	-	504.6
⑦-1	Medium Weathered Granite	6.25	72.25	-	-	663.9
⑦-2	Medium Weathered Granite	9.25	81.5	-	-	700.5
⑧-1	Slightly Weathered Granite	9.95	91.45	-	-	933.8

To support the heavy weight of the structure a bearing pile foundation was chosen. A single hand dug super caisson of approximately 9m diameter is located under each super column. It has a bearing capacity of about 543MN. Sixteen hand dug caissons of 7m diameter (bearing capacity 344MN) are located under the core. It is economical in the southern region of China to use hand dug caissons and a common practice. The caissons are about 30m long to bear on bedrock. The Ping An Tower mat is 5m thick beneath the main core and 3m thick in the surrounding area, using a concrete strength of C40 (f'c=4.9ksi). The advantage of locating large caissons under columns and core wall intersections is the direct load path from superstructure through mat to caissons and bedrock, minimizing mat thickness and excavation volume.

Figure 3a shows the pile layout and 3b the predicted mat settlement deformations.

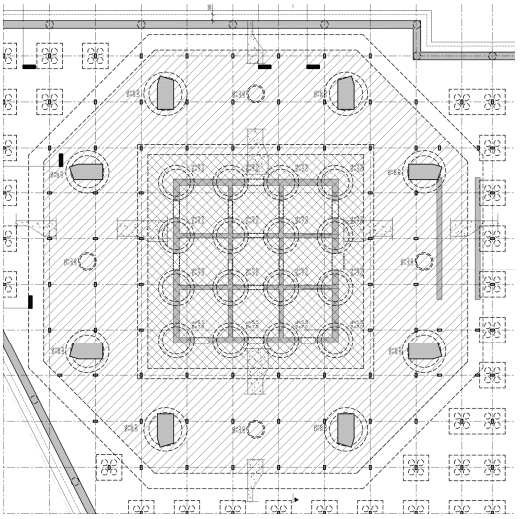

Figure 3a - Tower Mat

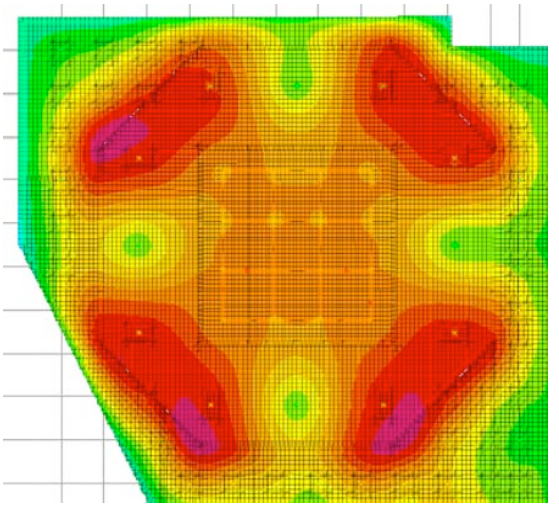

Figure 3b - Mat Settlement Contour

The anticipated settlement of the mat is greatest under super columns, at 20mm, followed by that under the core, at 14mm. To address the differential settlements between the podium and the tower mat, the design also includes delayed pour strips at basement levels, as well as recommendations for construction using specific stages and sequences.

LATERAL LOAD RESISTING SYSTEM

The eventual success of a super tall building design often hinges on selection of the most appropriate lateral load resisting system. Systems providing comparable strength and stiffness can differ by millions of dollars of construction cost, so various schemes were investigated at the beginning of the project. The goal was to find the most economical system using the least quantity of building material and weight that also provides the most efficient and flexible space layout. Among the options investigated were Tube-in-Tube, Mega Frames and various hybrid systems. The most efficient system is a "Core-Outriggers-Mega Frame" system with a reinforced concrete core, super composite columns and steel outrigger trusses. The final design uses a combination of a Core-Outriggers-Mega Frame and an Exterior Mega Frame formed by belt trusses and mega braces joining the super composite columns. The reason for that decision will be discussed later. *See Figure 4*

The two major criteria that need to be controlled for every super tall building are the limiting story drift and limiting acceleration (for comfort based on human perception). These two criteria can also be related to overturning moment and story shear.

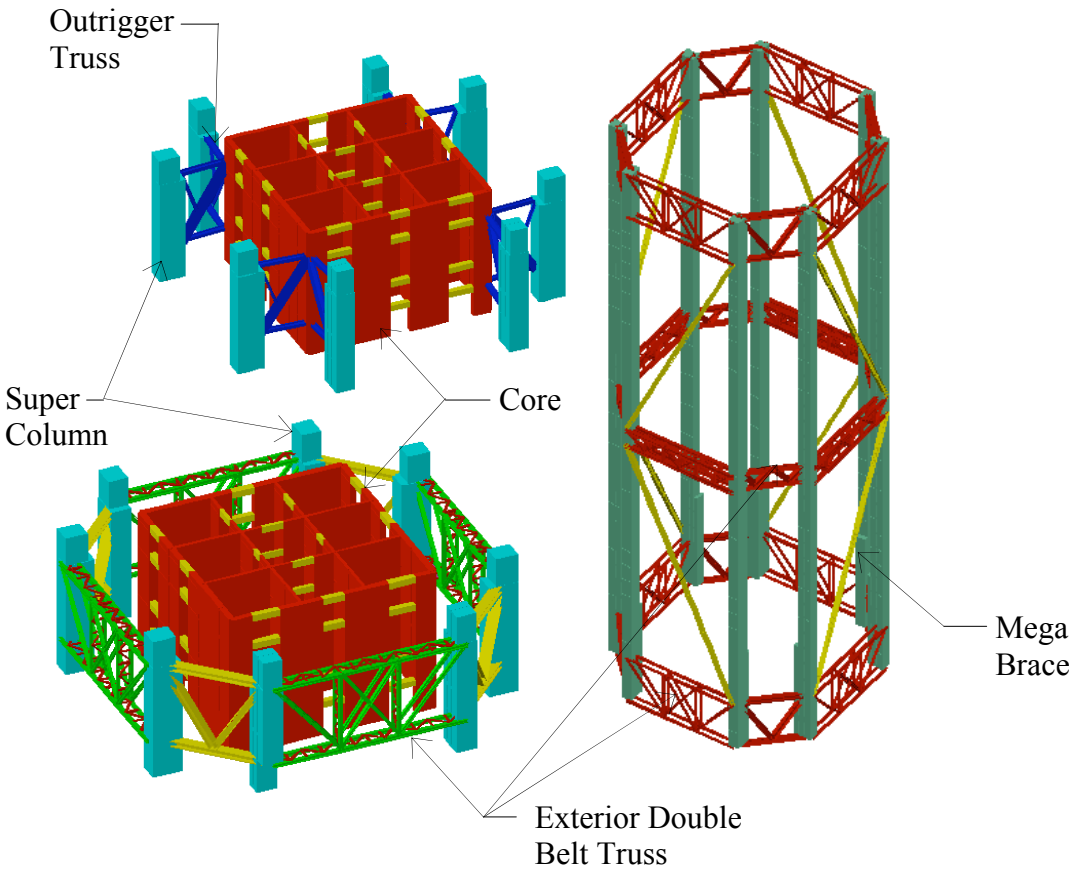

Figure 4 Lateral System Components

The concrete core is a nine-cell square in plan, 32m on each side from Zones 1 through 5. Starting with Zone 6, the four corner cells of the core are cut off to achieve an efficient office space layout. Above Level 112 parts of the south and north walls are also eliminated. See Figure 5. The flange (outermost) wall thickness varies from 1.5m at Zone 1 to 0.5m at Zone 8. Web (interior) walls vary from 0.8m to 0.4m thick. While it is unusual to change web wall thicknesses along elevator shafts, the changes address a specific seismic provision in the China code related to compression stress ratio in walls under gravity loads. Wide flange steel column shapes are embedded within boundary zones at the most highly stressed corners and ends of core walls. They serve to both strengthen the core and to provide a clear load path from outrigger forces into the core. The core walls play a critical role in resisting most of the gravity load and lateral load. To eliminate any concern about brittle shear failure when subject to a combination of high shear stress and axial stress, embedded steel plates are used to reinforce the core walls from foundation to level 12. The plates both enhance ductility and permit a reduced wall thickness.

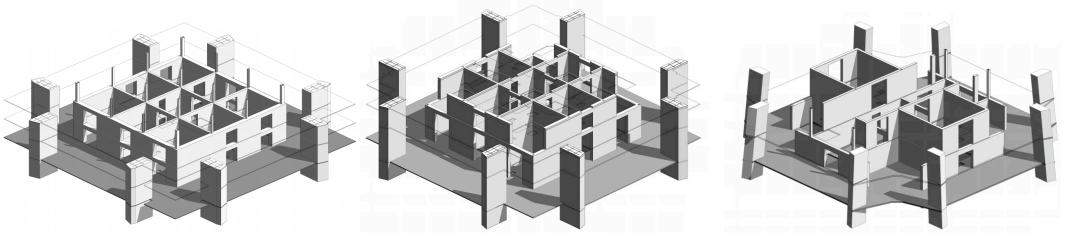

Figure 5a- zones 1~5 Figure 5b- zone 6 and above Figure 5c- above level 112

Figure 5 - Core Wall Layouts (scale varies)

It is impractical and inefficient to have a super tall tower core resist all overturning and provide all lateral stiffness by itself. The greater strength and stiffness of the whole building footprint is engaged by using outriggers at mechanical/refuge levels to tie the core to perimeter super columns. This creates a larger lever arm to resist overturning moment effects very efficiently. Their contribution to cantilever flexural stiffness can be expressed as $A*d^2$, where A is the area of the super columns and the d is the distance between them. As d gets bigger, the stiffness contributed by super columns increases dramatically. To achieve maximum outrigger effectiveness and to avoid secondary kink forces in slabs it is highly recommended to align outrigger trusses with main core wall planes. For the Ping An Tower outriggers are aligned with core flange walls. In plan, the super columns are generally rectangular, varying in size from approximately 6.0m by 3.2m at Zone 1 to 2.9m by 1.4m at Zone 8. To increase super column axial stiffness as well as axial and flexural strength, built up steel shapes are embedded within. Super columns are connected to the core through two story high steel outrigger trusses at four of the mechanical/refuge floors as shown in *Figure 6a*. Outrigger steel chords run continuously within the core walls. While this makes core wall construction more challenging, it avoids local stress concentrations from truss-to-wall transition details where outriggers and walls meet. The location and number of outrigger trusses was extensively studied and optimized. The outriggers at low zones are effective in

reducing the building fundamental period, while higher outriggers help control story drifts at upper zones.

Two-story high steel belt trusses exist at every mechanical/refuge level to connect all the super columns and form an "Exterior Mega Frame" system that provides additional lateral stiffness and strength to the overall lateral system of the tower (Figure 6a).

The current China code has a requirement similar to one in the IBC calling for a dual system approach for super tall structures. In the China code, that approach requires an exterior frame strong enough to resist 20% of the total seismic load on its own. During meetings with the China Seismic Expert Panel, this requirement was expanded based on current research and recent seismic events in China. In addition to the current strength requirement, to qualify as the second line of defense the exterior frame also must attract and resist at least 6% of the total story shear based on relative stiffness. In further meetings with the experts, the criteria became even more stringent: the secondary frame must attract and resist 6% of the total base shear (not story shear) at each level. As the comparison graphs in figure 6b show, meeting the stiffness requirement is difficult: most of the overturning moment is taken by the super columns, but most of the shear stays in the core.

A key strategy used to attract and maintain the required portion of base shear to the exterior frame was the addition of mega braces. The braces also provide additional load path redundancy and additional torsional stiffness. Another special design feature is the use of double belt trusses laced together, which were required to brace the super columns due to the eccentric alignment of the belt truss in plan with the super columns.

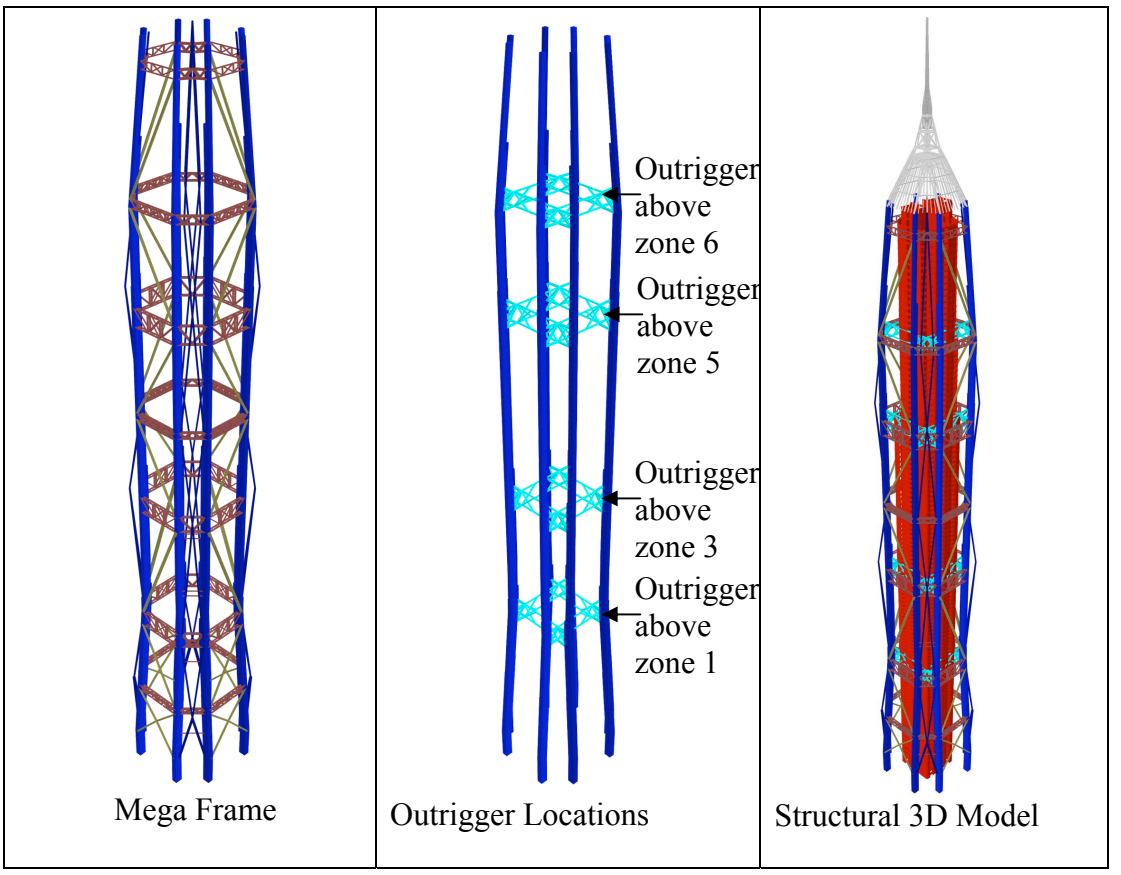

Figure 6a Exterior Mega Frame, Outriggers and Structural 3D Model

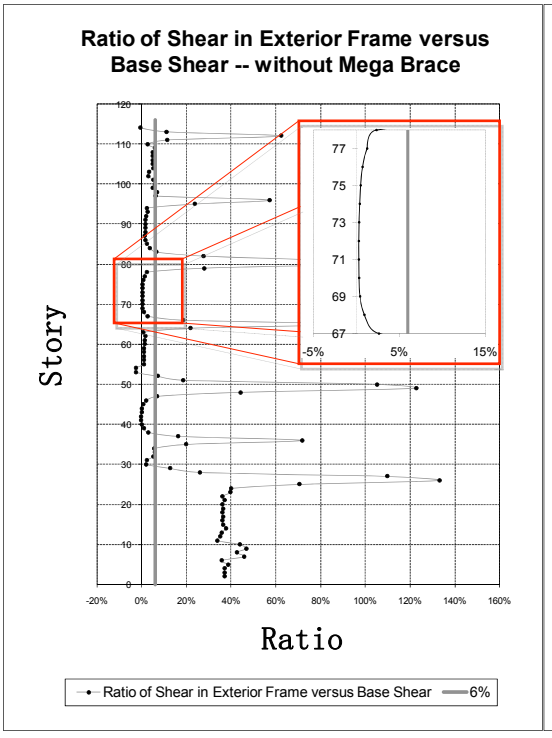

Figure 6b

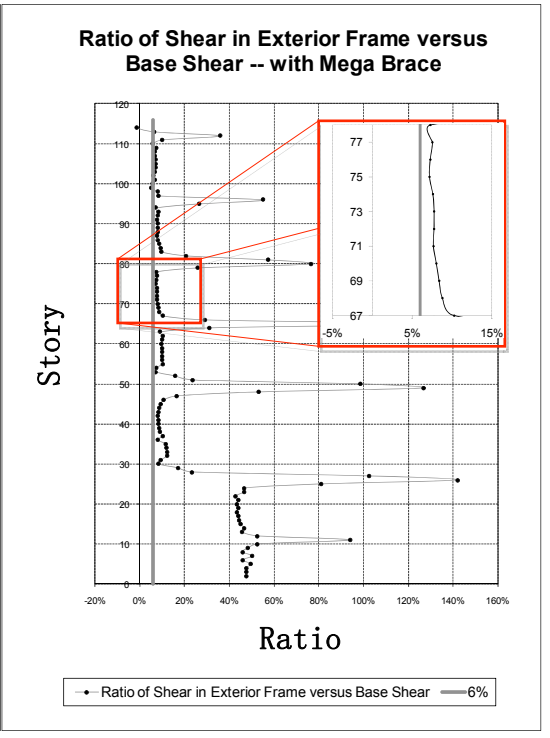

Figure 6c

Figure 6b and 6c show the ratio between the shear force in the exterior frame at every floor and the total base shear. Figure 6b corresponds to the structural system without mega braces and 6c with mega braces. As can be seen from the curves, the shear forces in Figure 6b is almost zero on typical levels, while in Figure 6c the shear forces increases to more than 6% of the base shear for most of the stories.

GRAVITY SYSTEM

The gravity supporting floor system of Ping An Tower consists of concrete filled composite metal deck slabs and steel beams composite with the slabs. Although in this region a composite slab and steel beam floor system is more expensive than a conventional reinforced concrete slab and beam system, composite framing was adopted to reduce form work, increase construction speed and reduce tower weight. Less tower weight reduces foundation costs and seismic loads. The composite slab design is controlled by gravity load bearing strength, stiffness, fire rating, diaphragm shear and acoustic requirements.

Typical office floors use a 125mm thick dovetail re-entrant composite floor deck (125mm thick concrete fill including dovetail ribs of metal deck) that provides a 2-hour fire rating according to laboratory tests. Typical mechanical/refuge levels use 180mm thick composite floor decks (180mm thick concrete fill including ribs of metal deck).

Typical office levels between mechanical levels have steel gravity perimeter columns that are continuous within one zone but stopped at mechanical levels, where the belt trusses transfer the column gravity loads into the super columns. *See Figure 7a.* This discontinuous gravity column scheme maximizes gravity loads in super columns to minimize tension forces from wind and seismic loads. It is crucial to keep the concrete super column in compression since even a small net tension force can result in a major loss of axial stiffness. By transferring column loads at every zone, perimeter steel gravity columns also have smaller column sizes that are more economical and aesthetically preferable.

The exterior mega braces large enough to attract significant shear forces also contribute to the gravity system, which poses some design challenges. First, single braces were arranged to create opposing forces upon application of gravity load (looking at any building corner elevation you see Xs or diamonds, as is shown in Figure 8a). If this had not been done, gravity would have caused the tower to twist. Second, the opposing forces required resolution for equilibrium. Kink forces in the belt truss levels (Figure 8b) must be considered in the floor system and core wall designs.

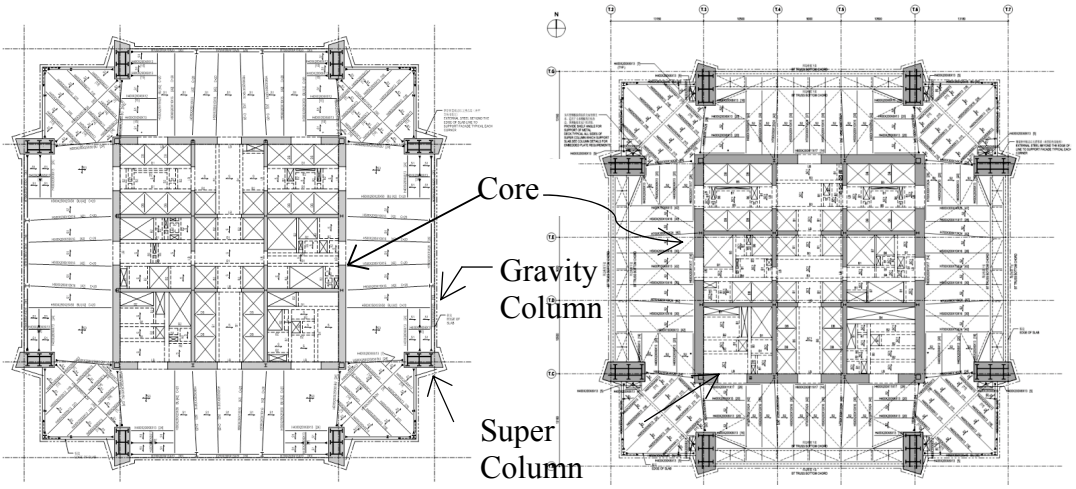

Figure 7a –Floor System at Office Level Figure 7b- Floor System at MEP Level

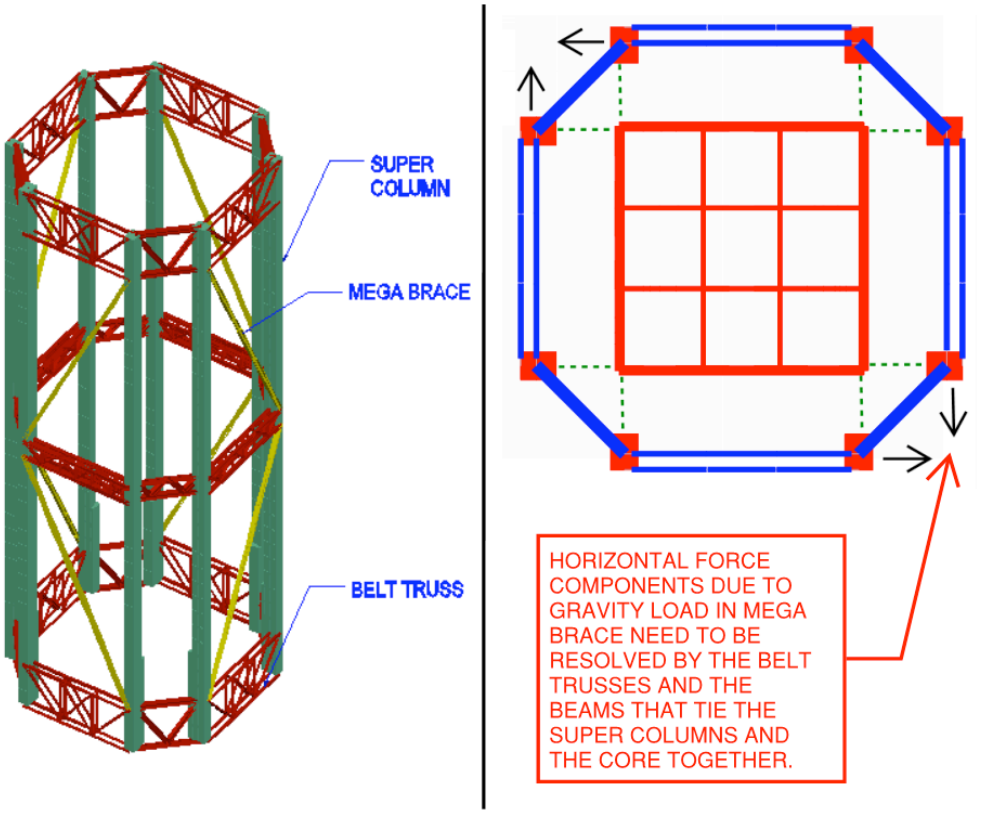

Figure 8a – Exterior Mega Brace Layout Figure 8b - Kink Force to Be Resolved

SPIRE STRUCTURE

The spire structure is located above level 115 and comprises a mast and its supporting structures, as is shown in Figure 9a.

The structural system of the spire is an industrial frame truss system, two frames in the north-south direction and two in the east-west direction, which is supported on the eight super columns (Figure 9b). Mast lateral support comes from its embedment within a steel braced socket. Overturning is resolved by a force couple through clamp mechanisms bearing against the top and bottom of the steel braced socket, which transfers the load into the steel spire support structure. The Building Maintenance Unit (window washing crane system) support structure carries the gravity load of the BMU as well as forces from the steel braced socket above.

CONCLUSION

Codes are based on research which relies on predictions, tests and experience. But these are limited to today's comprehension. Therefore engineers will constantly confront new challenges, either from unknowns or from situations and problems that are not covered by codes or other known publications. It is our responsibility to provide a product that satisfies all the requirements of public safety and that can only be achieved when research and design go hand in hand. The Ping An Tower is an example of a design that is ahead of standard conventions and meets requirements for both today and tomorrow through a unique design.

ACKNOWLEDGEMENT

We would like to thank Mr. Leonard Martin Joseph, P.E., S.E., Principal of Thornton Tomasetti, Inc, for comments and assistance during design of the structure as well as for enhancing this paper through his thoughtful suggestions.

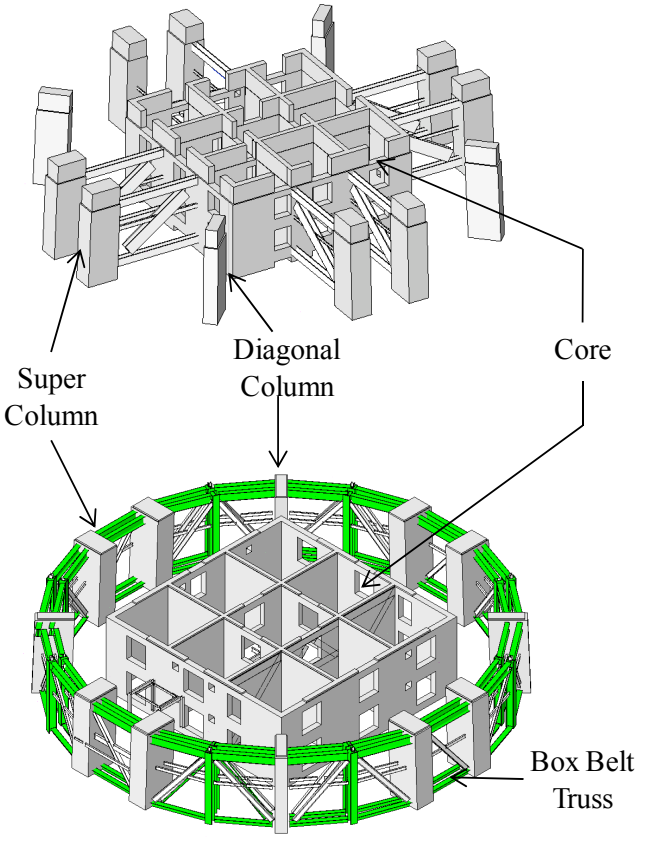
ABSTRACT:

Structural nonlinear performance of the 126-story, 632-meter tall Shanghai Tower has been studied for 2475-year return period seismic events through nonlinear time history analysis. Seven sets of ground motions were selected as representative of potential local seismic excitation and scaled to meet the provisions of China Seismic Code, GB50011-2001 (2008 version) and Shanghai Seismic Code, DGJ08-9-2003. A detailed and complex finite element model (FEM) of the structure was created within Perform 3D (2008), a widely used software program for nonlinear analysis and performance assessment of structures.

Global behavior of the structure was checked to meet serviceability requirement. For performance acceptance criteria at the individual structural element level, GB50011-2001 and ASCE 41-06 "Seismic Rehabilitation of Existing Buildings" (2006) were used as major references. The nonlinear time history analyses confirmed acceptable global and local performances of Shanghai Tower as designed.

INTRODUCTION



Shanghai Tower Complex, with 576,000 m^2 (6.2 million ft^2) of space and a total budget of US$2.2 billion, is a mixed-use development featuring world-class offices, luxury hotels, retail spaces, convention facilities and observation decks. Five story deep basement houses retail shops, mechanical rooms and parking spaces, as well as connections to the Shanghai Metro subway system. The 126-story, 632 meter (2,074 feet) tall tower is currently under construction and will be the world's second tallest building when completed in 2014.

The Shanghai Tower exterior facade, its most distinctive feature, is an outer skin based on a round-cornered triangle that gradually rotates in plan and reduces in size at upper levels. The tower interior spaces can be visualized as eight vertically stacked circular cylinders with gradually diminishing diameters, separated by larger two-level mechanical/refuge floors that extend to the outer skin. Figure 1 is a rendering of the Shanghai Tower Complex and surroundings.

(b)

Figure 1b - Lateral resisting System of Shanghai Tower

LATERAL SYSTEM

For supertall buildings such as Shanghai Tower, the structural lateral load resisting system must be very efficient and well integrated with the overall design. This tower uses a "Core-Outriggers-Mega Frame" system including a concrete core, outrigger trusses, super columns and an exterior mega frame using double belt trusses.

The square concrete core with 30m wide faces efficiently encloses numerous elevators and stairs needed to service tower occupants, but is not sufficient by itself to resist extreme overturning moments generated by lateral typhoon and seismic loads,

or to limit deflections to code-mandated values. The most economically feasible approach to resist overturning and improve stiffness is to engage outer columns to benefit from a bigger moment arm. So eight sets of two-story outrigger trusses aligned with inner 'web' core walls tie the core and exterior super columns together as seen in Figure 1b. In addition, the tower is wrapped by a mega frame consisting of double belt trusses at the mechanical/refuge levels linking the super columns together and transferring secondary column gravity loads to super columns. Core outer wall thickness varies from 1200mm to 600mm while inner 'web' wall thickness varies from 900mm to 500mm. Super columns slope very gradually to stay within the stacked cylinder diameters, and super column plan dimensions vary from 3.7m by 5.3m at the bottom to 1.9m by 2.4m at the roof.

PRESCRIBED CODE DESIGN

Seismic design of the Shanghai Tower followed the China Seismic Design Code , GB50011-2001 (2008 version) and Shanghai Seismic Code, DGJ08-9-2003, using a linear modal analysis procedure. Unlike some other international model code approaches, the China code defines three earthquake levels:

- Frequent Earthquake level with a return period of 50 years,
- Moderate Earthquake level with a return period of 475 years
- Severe Earthquake level with a return period of 2475 years.

The China Seismic Code only specifies simple performance goals for structures under these seismic levels as:

- " No damage" under Frequent Earthquake
- " Minor Damage, but Repairable" under Moderate Earthquake
- " No Collapse" under Severe Earthquake

Since Shanghai Tower height exceeds limits in the China code, it required a Non-Linear Time History Analysis. The structure was modeled and studied for different seismic stages by using both Abaqus and Perform 3D software. This paper presents Perform 3D results for the Severe Earthquake Level.

SELECTION OF GROUND MOTIONS

Seven sets of ground motions were selected, including two sets of synthetic seismic records. The other records were selected from earthquake events at locations that resemble the seismic characteristics of the Shanghai Tower site. All records were scaled to meet the requirements in China Seismic Code and Shanghai Seismic Code :

1. The peak ground motion in the major direction should be scaled to at least 200 gal and in the minor direction scaled to 170 gal.
2. The lowest base shear of the selected ground motion in the major direction shall be higher than 65% of the code spectrum base shear.

3. The average base shear of the selected ground motion in the major direction shall be higher than 80% of the code spectrum base shear.

Linear Time History Analysis was performed to determine the base shears of each set of ground motions and establish appropriate scale factors as shown in Table 1. Scaled ground motion records, and their response spectrum curves as generated by BiSpec (2009) are shown in Figure 2.

Table 1, Scale Factors for the Ground Motions

	Major Direction			Minor Direction

• Synthesized Records from CECS 160.

Response spectra of the records show similar behavior with the China code spectrum for periods above 1 second. This range is sufficient to capture the dynamic behavior of a 600 meter tall building since the first twelve periods of the tower, with cumulative mass participation approaching 90%, lay in this range.

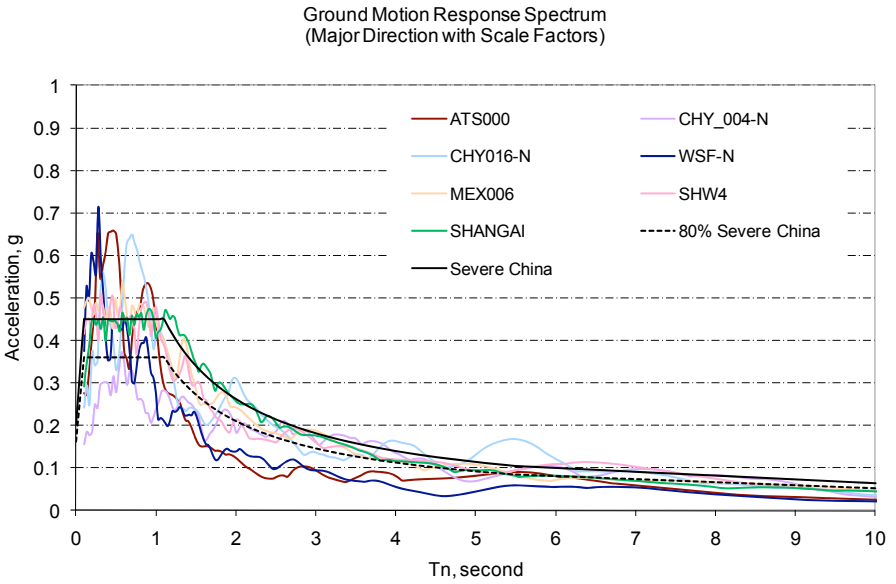

Figure 2, Ground Motion Response Spectra of the Selected Ground Motions

ANALYTICAL MODEL

General geometric and numerical modeling considerations for the nonlinear Perform 3D model were defined in the accordance with ASCE 41-06.

The components that contribute to the global lateral system were reflected in the model as shown in Figure 3. Core wall link beams, belt trusses and outrigger trusses were modeled with 2-noded frame elements that have 6 degrees of freedom at each end. Central core piers and super columns were modeled as 4-noded fiber wall elements which are analogous to shell elements in the analysis program ETABS; they have both in- and out-of-plane bending stiffness. Gravity loads were defined as line loads on core wall and super column elements. The translational and rotational mass at each level was assigned as a lumped mass at each story. All nodes at each level were connected with a rigid diaphragm. P-Δ effects were considered in the analysis. Nonlinear time history cases were run after the gravity load analysis was completed. Rayleigh damping varied between 1.5% and 2.0% for the first 10 modes of the structure. It was included to account for the energy dissipation contribution of non-structural components.

NONLINEAR BEHAVIOR

Conventional modeling techniques and assumptions vanish when the structural elements reach their nominal capacities. Engineers should strive to understand the global post-yield behavior of the structure rather than get lost in details of individual members and connections. The ASCE 41-06 document provides an important guide for challenging aspects of nonlinear modeling.

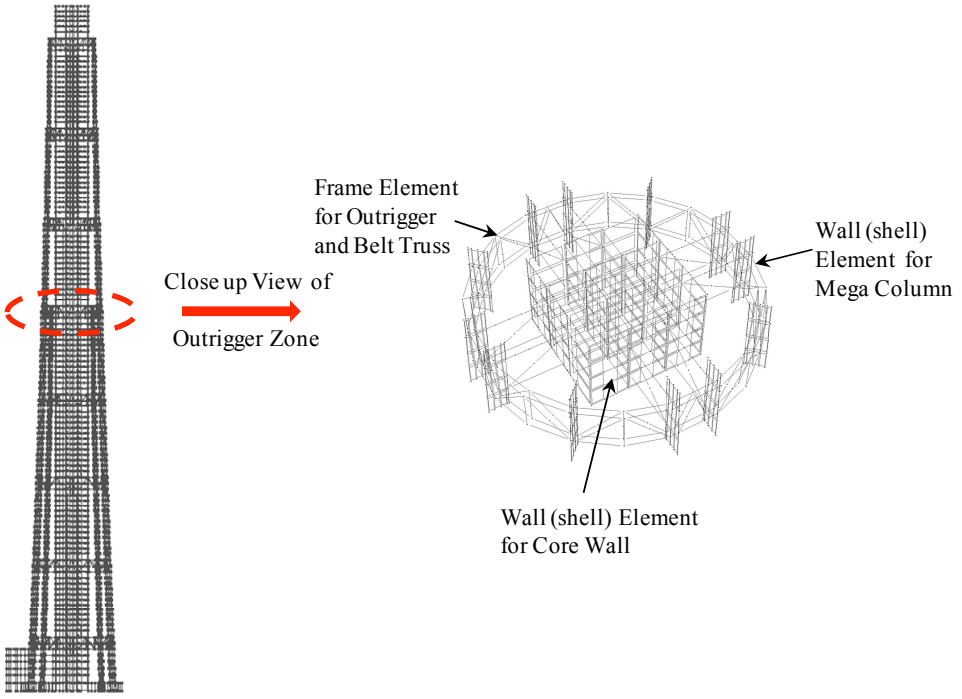

Figure 3, Shanghai Tower Analytical Model in Perform 3D

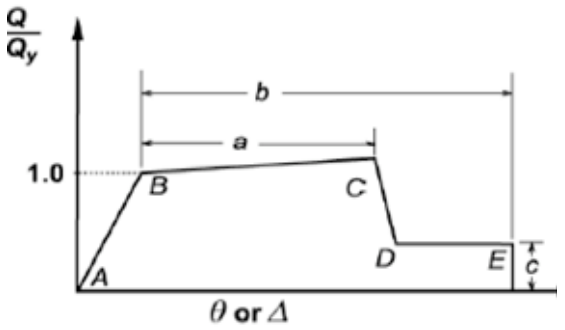
Moment-hinge methodology was used for defining nonlinearity of link beams, while fibers were used to model core walls and super (or mega) columns.



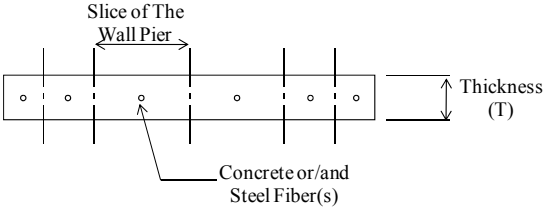


Figure 4, Generalized force-deformation curve by ASCE41-06.

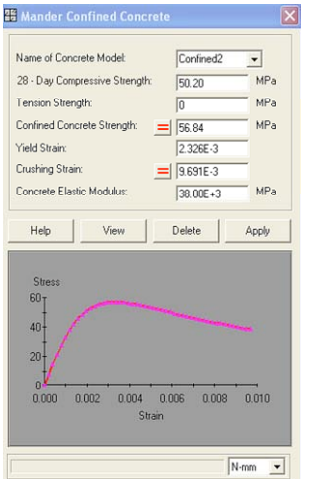

A generalized force-deformation curve proposed in ASCE 41-06 was used to model the behavior of reinforced concrete link beams. Parameters, denoted as 'a', 'b' and 'c' in Figure 4, were expressed in terms of end rotations and depended on the normalized shear stress and reinforcement type (diagonal or conventional). Following the specifications for beam members in ASCE 41-06, the designers used Perform 3D's built-in chord rotation function, which is based on moment-hinge theory, to model the nonlinearity of link beam.

For modeling the central core, we used Perform 3D fiber elements: wall slices as discrete 2D axial members with uniform nonlinearity throughout their length, as depicted in Figure 5a. These elements can be made of either steel or concrete, and their properties depend on the geometry and reinforcement ratio of the wall slice. The Mander Model (1988) was used to define the stress-strain relationship of confined and unconfined concrete. Figure 5(b) depicts the confined concrete stress-strain curve.

(a)

Figure 5a - Plane View of a Wall Pier defined with Fiber Elements

(b)

Figure 5b - Mander Model of Confined Concrete in XTRACT

Belt-truss and outrigger truss members were first defined with linear properties and were then checked to see if the demand exceeded the capacity. If so, those members were redefined with nonlinear properties.

PERFORMANCE LEVELS

Acceptance criteria specified in "Seismic Rehabilitation of Existing Buildings" (ASCE 41-06) were used. ASCE 41-06 classifies the performance of the structure into four levels. The conceptual definition for each building performance level is listed below:

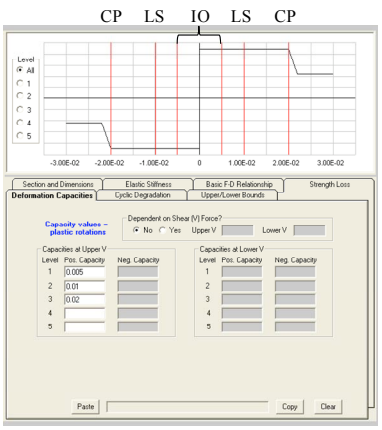

Figure 6, Definition of Performance Levels for Link Beams in Perform 3D

Operational Level (OL): Overall damage is very light and the structure almost behaves in the elastic range.

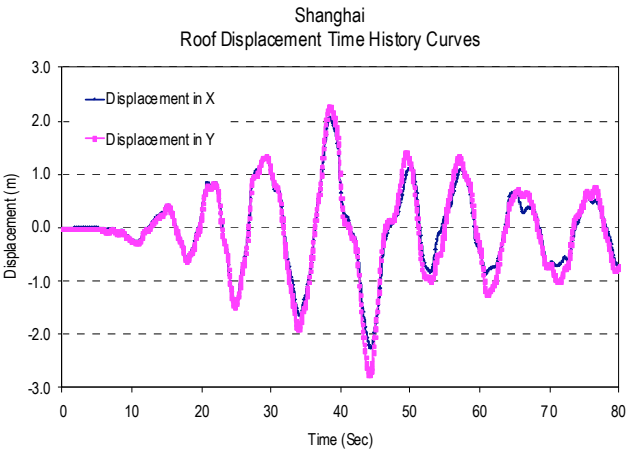
Immediate Occupancy (IO): Overall damage of the structure is light with no permanent drift. Structure retains its original strength.

Life Safety (LS): Moderate damage occurs with some permanent drift and strength loss.

Collapse Prevention (CP): Extensive damage with little residual stiffness and strength left. Structure is close to collapse.

The modeling parameters for beams, columns and coupled walls under each performance level are listed in ASCE 41-06 Tables 6-7, 6-8 and 6-18 respectively as related to plastic rotation. . These tables were used to assess the member performance of Shanghai Tower.

ANALYSIS RESULTS



Gravity analysis was performed first, followed by time history analyses in Perform 3D. Global behavior and individual member performance was then verified.

The behaviors of the structure were fairly similar under all ground motion records. Since the fundamental building period of the tower is relatively long (about 9 seconds), it took around 20 seconds for response to build up. At the floors above the 80th floor, the wall cracking and beam yielding behaviors were much more extensive than at lower floors. At first, core wall cracking was seen locally at higher floors, followed by link beam yielding. Under continued shaking, both wall cracking and beam yielding extended through the building height before the super columns started to crack. Super column reinforcement went into tension but did not yield. Core wall reinforcement did yield locally at outrigger zones. Peak roof displacement occurred after 30 seconds. Of all seven sets of ground motions, Shanghai synthetic records generated the largest roof lateral displacement, 2.75 meters, as shown in Figure 7.

The central core system dissipated inelastic energy through link beam yielding while outrigger trusses and belt-trusses remained elastic.

Earthquae	X Dir. (m)	Y Dir. (m)
ATS000	1.24	1.21
CHY004	1.89	1.84
CHY016	2.08	2.32
WSF-E	1.46	1.60
MEX006	2.17	2.35
SHW4	2.13	2.00
Shanghai	2.26	2.75

(a)

(b)

Figure 7 (a) Maximum Roof Displacements, (b) Roof Displacement vs Time Graph to Synthesized Shanghai Record

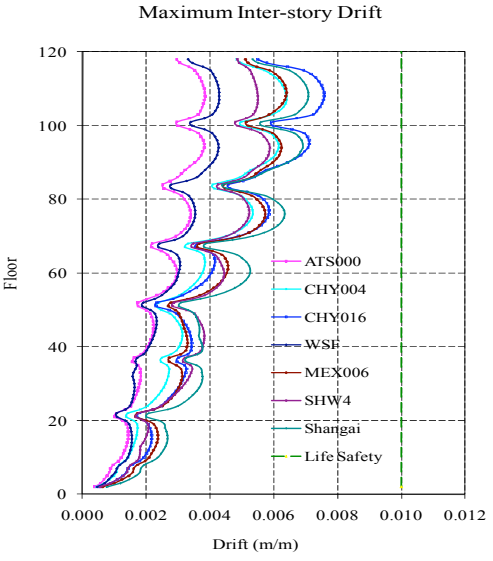


Figure 8, Story Drift Curves of Shanghai Tower

Maximum story drift curves for all ground motions are shown in Figure 8, **Story Drift Curves of Shanghai Tower**

The leftward (reduced) drift points indicate the presence of outriggers which significantly reduce story drifts. Maximum story drifts occur above 80th floor due to higher mode effects and range from approximately 0.004 to 0.008, within the acceptance limit of 0.01 set by the China Seismic Code.

A coupled wall system is composed of individual wall piers that are tied together by link beams. The link beams are the main structural elements that dissipate energy through hysteresis behavior. This is commonly seen in high rise structures, where beam deformation capability makes a significant contribution to overall ductility of the structure.

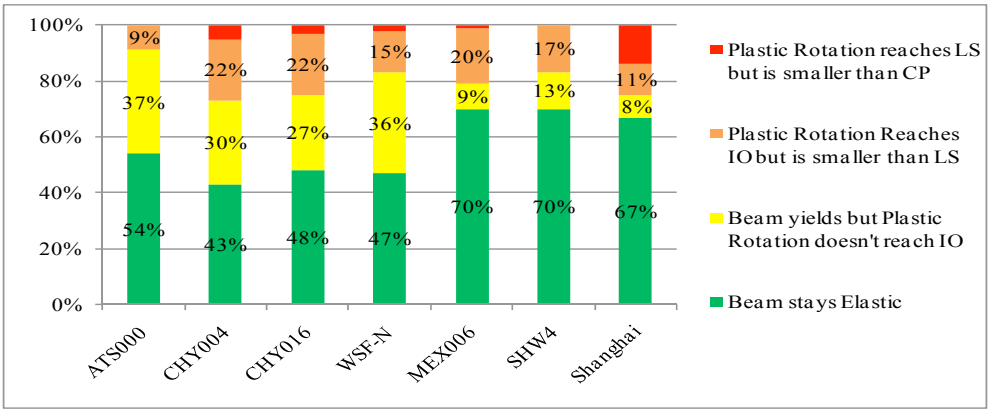

Figure 9, Performance Summary of Link Beams

Figure 9 summarizes performance of the Shanghai tower link beams. Approximately 30% to 60% of the link beams go into non-linear range, depending on the seismic event applied. Comparing maximum beam plastic rotation values to the limits given in ASCE 41-06, almost all link beams behave within LS level and none reaches the CP limit. Wall piers do crack throughout the tower but yielding of the vertical reinforcement is limited to outrigger zones only with plastic rotations being less than the IO level.

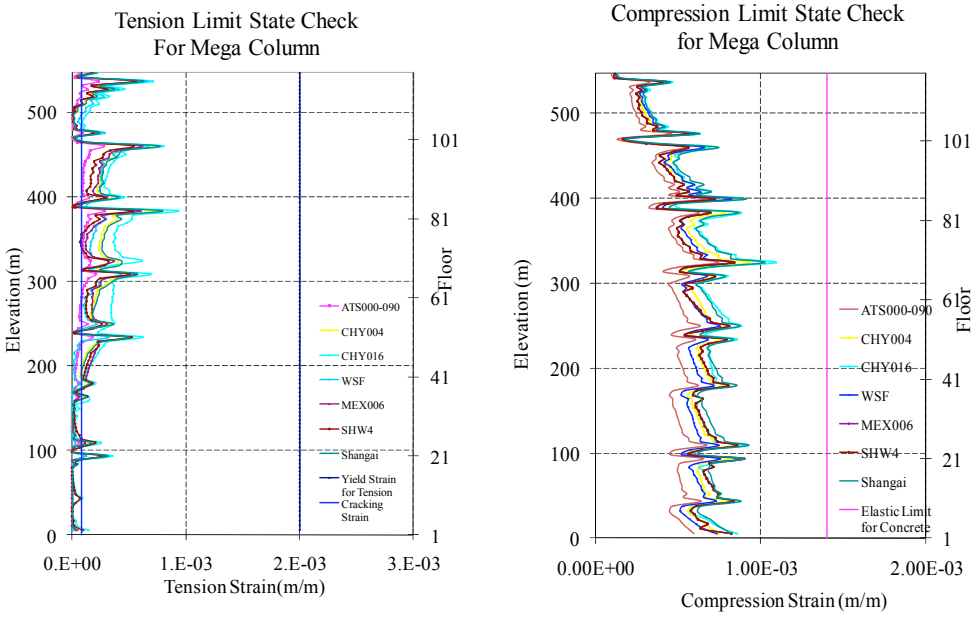

Figure 10, Maximum Tension and Compression Strains of Super Columns

Super column behavior was studied in detail as lateral stiffness of the structure heavily depends on it. These elements were mainly governed by axial forces as moments are relatively insignificant. Axial deformations were determined for each ground motion and reinforcement tension and concrete compression strains are graphed in Figure 10. Sudden changes in strain values occur at outrigger zones where forces can enter and exit the super columns via outrigger trusses. These columns

crack above the 35th floor due to relatively low gravity forces. Steel in super columns doesn't yield as maximum steel strain is determined to be around 0.001 m/m. Although axial compression forces in super column increase at lower levels, concrete compressive strains are generally 0.0005 to 0.001 because column sizes are getting larger. Overall, compression strains are not close to the crushing limit of confined concrete.

Belt trusses and outrigger trusses play important roles in terms of joining the core and super columns. These elements were assumed to stay elastic in the first run. Then maximum demands on these members were compared with their ultimate capacity. None of these members reach their buckling or yield point so inelastic behavior was not an issue.

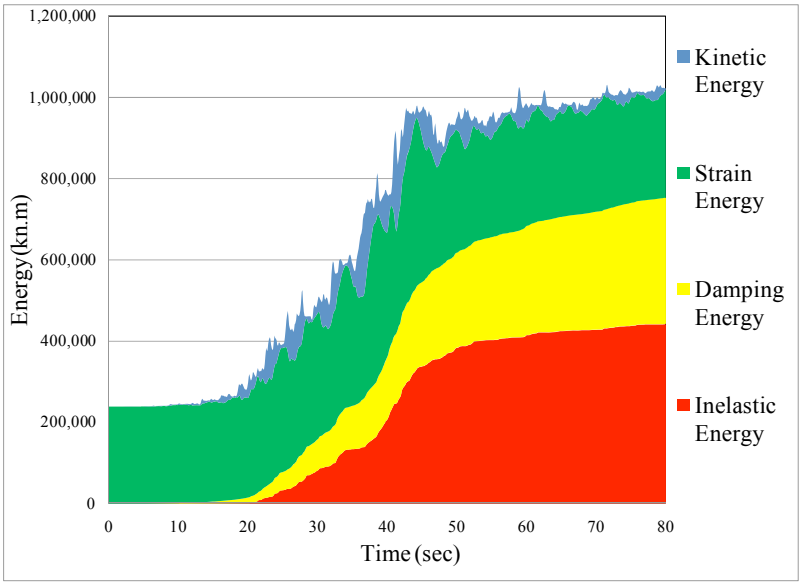

Figure 11, Energy Time Curve for Shanghai Synthesized Record

Energy generated under a seismic event is stored, absorbed, converted or dissipated by different behaviors such as kinetic, strain, damping and inelastic behavior. Energy time curves, as depicted in Figure 11 for a Shanghai synthetic record, are useful to understand its distribution. Approximately 40% to 50% of the total energy is dissipated by inelastic behavior.

CONCLUSION

Non-linear Time History Analysis of Shanghai Tower shows that this super tall structure provides an acceptable level of performance under a severe seismic event with a 2475 year return period. The maximum story drifts are within the code limit under all seven sets of ground motions. Link beams exhibit considerable yielding but plastic rotations are within the Immediate Occupancy level. Although wall piers and super columns are found to experience cracking, tension stresses in the reinforcement are below the steel yield point. Outrigger and belt-truss framing member demands are less than their ultimate capacities.

Effect of Stirrups on the Contribution of Concrete Compressive Strength and Tensile Steel to the Shear Strength of RC Beams Using Artificial Neural Networks

Hassan El-Chabib

Bradley University, Peoria, IL, 61625, Email: helchabib@bradley.edu

Abstract

Current shear design procedures calculate the nominal shear capacity, V_n of reinforced concrete (RC) slender beams with shear reinforcement (stirrups) by simply superimposing the shear capacity carried by concrete, V_c to that carried by stirrups, V_s. Previous studies concluded that current shear design equations do not only underestimate the resistance of concrete to shear, they also assume that the addition of stirrups does not alter the shear behaviour of RC slender beams. The addition of stirrups is known to provide confinement to concrete and therefore enhances the contribution of basic shear mechanisms to V_c. Current shear design provisions are yet to account for such enhancement and they simply calculate concrete contribution to V_n assuming that stirrups do not exist. In this paper, a previously developed artificial neural network (ANN) model trained on shear database of normal and high-strength concrete beams was used to investigate the effect of stirrups on the contribution of several basic shear design parameters to the overall shear capacity of RC beams. A sensitivity analysis was also carried out to evaluate the performance of several existing shear provisions in calculating the nominal shear capacity of reinforced concrete slender beams.

***Keywords**:* artificial intelligence, beam, slender, confinement, shear, strength.

INTRODUCTION

Most current shear design procedures and standards adopt semi-empirical and statistically derived techniques to calculate the nominal shear capacity, V_n of reinforce concrete (RC) slender beams. They simply superimpose concrete contribution, V_c (shear capacity of the beams not containing shear reinforcement) to that of stirrups, V_s. The shear capacity carried by stirrups, V_s is calculated based on the parallel truss model with 45^o diagonal shear cracks using the following equation:

$$V_s = \frac{A_v f_{yv} d}{s} = \rho_v f_{yv} b_w d \qquad (1)$$

where A_v = the cross-sectional area of stirrups, f_{yv} = yield strength of stirrups, b_w and d = the beam's effective depth and width respectively, s = spacing between stirrups, and ρ_v = ratio of shear reinforcement.

Whereas, the resistance of concrete to shear V_c, is determined based on the contribution of major shear transfer mechanisms in slender beams such as aggregate interlock, dual action, and the uncracked portion at the top of the concrete beam. It is usually calculated using semi-empirical equations, derived based on observations from experimental studies on RC beams with concrete compressive strength typically less than 40 MPa. Table 1 shows shear equations considered in this paper that are used in current shear provisions to calculate the nominal shear strength of RC slender beams.

Table 1- Shear expression of different methods

$V_n(N) = V_c + V_s = \left(0.158\sqrt{f_c'} + 17.2\rho_l\left(\frac{Vd}{M}\right)\right)b_w d + \frac{A_v f_{yv} d}{s}$ $V_c \le 0.3\sqrt{f_c'}\, b_w d \;\; ; \;\; V_s \le 0.06\sqrt{f_c'}\, b_w d \;\; and \;\; f_c' < 70 MPa$	(ACI, 11-5)*
$V_n(N) = V_c + V_s = 0.2\lambda\sqrt{f_c'}\, b_w d + \frac{A_v f_{yv} d}{s}$ $when \quad d \le 300\ mm$	(CSA, simplified method)*
$V_n(N) = V_c + V_s = \left(\frac{260}{1000+d}\right)\lambda\sqrt{f_c'}\, b_w d + \frac{A_v f_{yv} d}{s} \;\; ; \;\; V_c \le 0.1\lambda\sqrt{f_c'}\, b_w d$ $when \quad d > 300 mm$	(CSA, simplified method)*

*f_c' is the 28-day compressive strength of concrete cylinder (MPa), ρ_l is the longitudinal reinforcement ratio, V_c is the shear capacity at failure (N), and M and V are the moment and shear force, respectively at a critical section.

Such a practice assumes that the addition of stirrups does not affect the contribution of shear design parameters on V_c. Whereas, experimental studies (Mphonde, 1989 and Russo, 1997) reported that the addition of stirrups usually leads to a higher V_c than that determined for RC similar beams without shear reinforcement. Moreover, Ghana (1987) suggested that the shear failure mechanism of RC beams with shear reinforcement is fundamentally different from that of beams without shear reinforcement, and therefore V_c and V_s mutually influence each other. Furthermore, the shear fracture surface in high-strength concrete (HSC) slender members usually propagates through coarse aggregates rather than around them, and is therefore smoother than that in normal-strength concrete (NSC) members. This behavior tends to reduce shear resistance through aggregate interlock (a major shear transfer mechanism in RC beams not containing shear reinforcement), which may have serious implications in the shear design of such beams. Thus, empirical design equations, derived based on experimental data developed using NSC, needs to be cautiously evaluated for HSC.

Several studies (Mphonde, 1989, Kim, 1994, and Sarsam, 1992) also investigated the ability of various shear strength equations to predict the shear strength of reinforced concrete slender

beams with or without shear reinforcement. It was concluded that current shear design techniques are either very conservative or simply not applicable for RC beams made of HSC. This paper uses a neural network based model to investigate the performance of shear equations used by current provisions of the American Concrete Institute (ACI 318R-2008) and the simplified method of the Canadian Standards Association (CSA A23.3-05). A parametric study was also carried out to assess the ability of the above shear calculation/prediction techniques to quantitatively account for the effects of stirrups on the contribution of several basic shear resistance mechanisms to the shear strength of reinforced NSC and HSC slender beams.

ANN MODEL

Artificial neural networks (ANNs) are highly adaptive data-driven trainable systems capable of capturing hidden and complex behavior through learning from training examples. The multi-layer perceptron networks (MLP) are the most widely used ANNs in engineering applications due to their ability to implement non-linear transformations for functional approximation problems and to map given inputs into desired outputs (El-Chabib, 2006). The main objective in building an artificial neural network-based model is to train a specific network architecture using a comprehensive database to search for an optimum set of parameters for which the trained ANN can predict accurate values of outputs for a given set of inputs. Explaining the fundamental basis of ANNs is beyond the scope of this paper and details on how to build, train and simulate a neural network model can be found elsewhere [Haykin, 1994 and El-Chabib, 2005)]. A previously developed ANN model (El-Chabib, 2006) is used in this paper to investigate the effect of stirrups on the shear behavior of RC slender beams. The model was trained on shear strength results for 542 reinforced NSC and HSC slender beams with or without shear reinforcement. Results were collected from published literature and only simply supported beams with a shear span to depth ratio ($a/d \geq 2.4$) that exhibited shear failures were considered. Table 2 provides the range and average values of all parameters included in the database.

The network's architecture that was adopted consists of an input layer containing 6 variables representing the commonly known shear design parameters (d, b_w, a/d, $\rho_v f_{yv}$, ρ_l, and f'_c), an output layer with one unit representing the shear capacity (V_n), and a hidden layer of 10 processing units.

Table 2- Statistical data for shear design parameters and shear capacity of beams used in database

Parameters	Training data (542 beams)			Testing data (114 beams)		
	Minimum	Maximum	Average	Minimum	Maximum	Average
d (mm)	40.60	1097.28	332.56	95.00	930.00	366.85
b_w (mm)	38.10	457.00	196.71	38.10	457.00	215.61
a/d	2.40	6.05	3.26	2.40	5.00	3.12
ρ_l (%)	0.48	5.80	2.35	0.50	5.04	2.43
$\rho_v f_{yv}$ (MPa)	0.00	2.24	0.36	0.00	2.53	.46

PERFORMANCE OF SHEAR DESIGN METHODS

The performance of the ANN model as well as that of the shear equations considered in this paper was evaluated using shear results for 114 NSC and HSC slender beams. The predicted/calculated shear capacities were compared to the experimentally measured values using the average absolute error (*AAE*) and a performance factor (*PF*) calculated as follows:

$$AAE = \frac{1}{n}\sum \frac{\left|V_m - V_p\right|}{V_m} x\,100 \tag{2}$$

$$PF = \frac{V_m}{V_p} \tag{3}$$

where V_m and V_p are the measured and predicted/calculated shear capacity, respectively.

For NSC beams without shear reinforcement, the average absolute error (*AAE*) and the average of the performance factor (*PF*) for the ANN model were 11% and 1.02 compared to 25% and 1.29 for ACI (11-5) and 22% and 1.23 for the simplified method of CSA whereas those for HSC beams without shear reinforcement were, 13% and 1.02 for ANN, 33% and 1.23 for ACI (11-5), and 27% and 1.11 for the simplified method of CSA. On the other hand, the average absolute error (*AAE*) and the average of the performance factor (*PF*) for beams with shear reinforcement were as follows: 12% and 1.0 for ANN compared to 23% and 1.29 for ACI (11-5) and 19% and 1.64 for CSA-A23.3 (simplified method) in the case of NSC beams and 12% and 1.0 for ANN, 26% and 1.36 for ACI (11-5), and 22% and 1.28 for CSA-A23.3 (simplified method) in the case of HSC beams. The performance of ANN, ACI, and CSA in predicting/calculating the shear capacity of RC is shown in Figs. 1 and 2.

The figures show that the data points for the ANN model are the closest to the equity line, whereas those for ACI (11-5) and the simplified method of CSA-A23.3 are scattered over a relatively wider range, especially for beams having shear capacity values larger than 200 kN. It is also shown in the figures that ACI (11-5) and the simplified method of CSA are fairly conservative in predicting the shear capacity of RC slender beams as indicated by an *AAE* varying between 20% and 33% and an average *PF* reaching as high as 1.36 in the case of HSC beams with stirrups.

The conservative predictions provided by the CSA simplified method, and the more accurate equation of ACI-318 (11-5) for RC beams with stirrups are partially due to the fact that both methods assume that no interactions occur between stirrups and other shear transfer mechanisms, and simply calculate the shear capacity of RC beams containing stirrups by superimposing the contribution of stirrups to that of concrete. It is important to note herein that the data points located above the equity line for both ACI and CSA are for beams with either large effective depth, large amount of longitudinal and/or transverse reinforcement

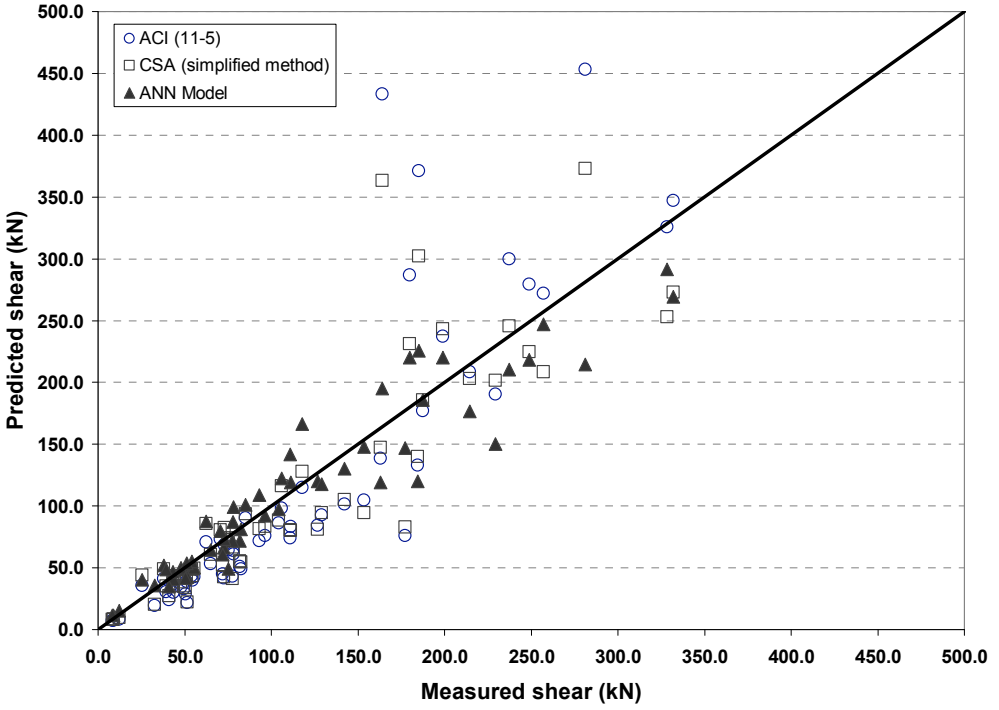

Fig. 1- Measured versus predicted shear capacity for beams without stirrups.

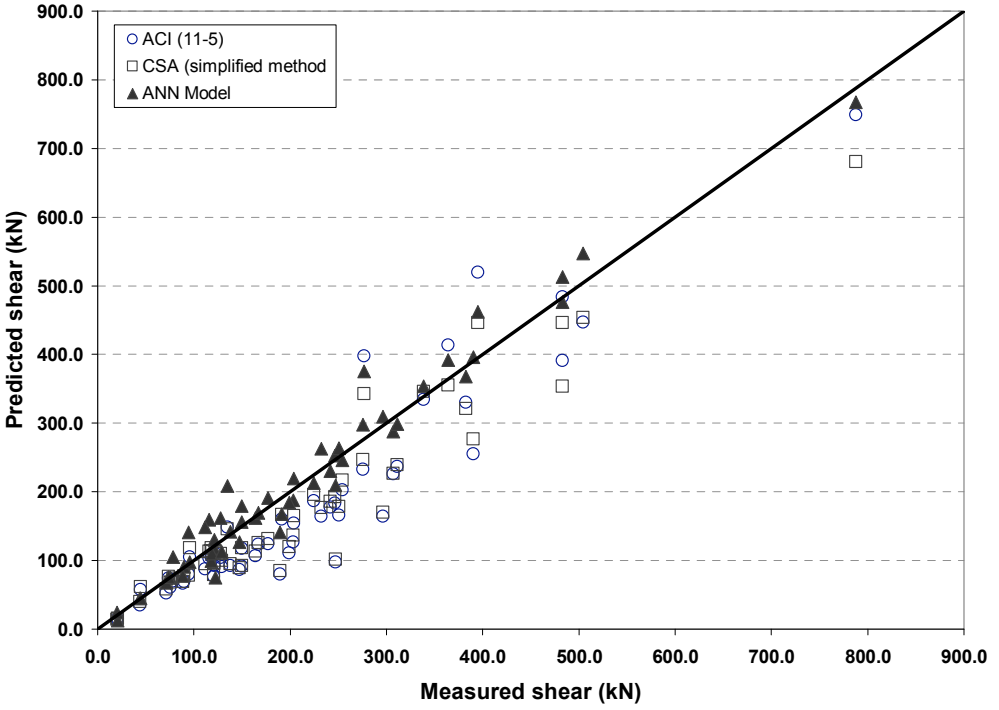

Fig.2- Measured versus predicted shear capacity for beams without stirrups.

EFFECT OF STIRRUPS ON THE CONTRIBUTION OF f'_c

The influence of stirrups on the contribution of f'_c to the shear strength of RC beams is illustrated in Fig. 3. The figure includes the shear strengths of three sets of beams as predicted by the ANN model. Beams in each set share the same properties except f'_c, and beams in different sets with similar f'_c share the same properties except for the amount of shear reinforcement, $\rho_v f_{yv}$. The first set represents the shear strength of RC beams without stirrups. The second and third sets show the shear strength of RC beams with stirrups capacity of $\rho_v f_{yv}$ = 0.344 and 1.034 respectively as predicted by ANN and as calculated by simply adding V_c and V_s. The figure clearly shows that the addition of stirrups contributes much more to the shear strength of RC beams than just the stirrups capacity of $\rho_v f_{yv}$. However, such effect decreases as the capacity of stirrups increases.

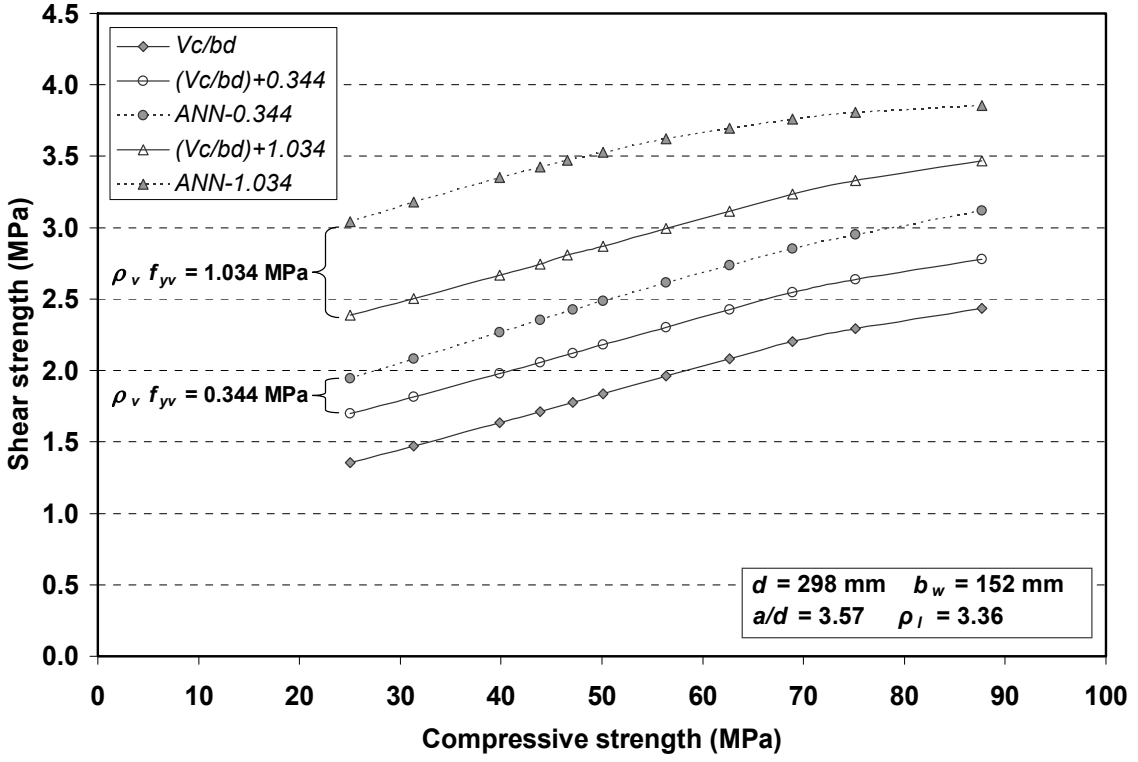

Fig. 3- Effect of stirrups on the contribution of f'_c to the shear strength of RC slender beams

EFFECT OF STIRRUPS ON THE CONTRIBUTION OF ρ_l

The influence of stirrups on the effect of longitudinal steel ratio ρ_l, is shown in Fig. 4. The figure illustrates the shear strength of three sets of beams versus ρ_l for different values of $\rho_v f_{yv}$. Beams in all three sets have similar properties except for ρ_l and $\rho_v f_{yv}$. Set # 1 contains beams without shear reinforcement ($\rho_v f_{yv}$ = 0.0), whereas sets #1 and #2 contain beams with $\rho_v f_{yv}$ = 0.754 and 1.14, respectively. The figure shows that the influence of stirrups on the contribution

of tensile steel to the shear strength of RC slender beams is independent of the stirrups capacity $\rho_v f_{yv}$. For a similar steel ratio, ρ_l and regardless of the amount of $\rho_v f_{yv}$, the addition of stirrups generates a constant increase to the shear strength of RC slender beams obtained using $V_s + V_c$. However, such increase is noticeably significant for $\rho_l > 2.5\%$. It is believed that stirrups help confining the longitudinal steel bars in place, thus preventing shear cracks from widening, and allowing an increase in dowel action.

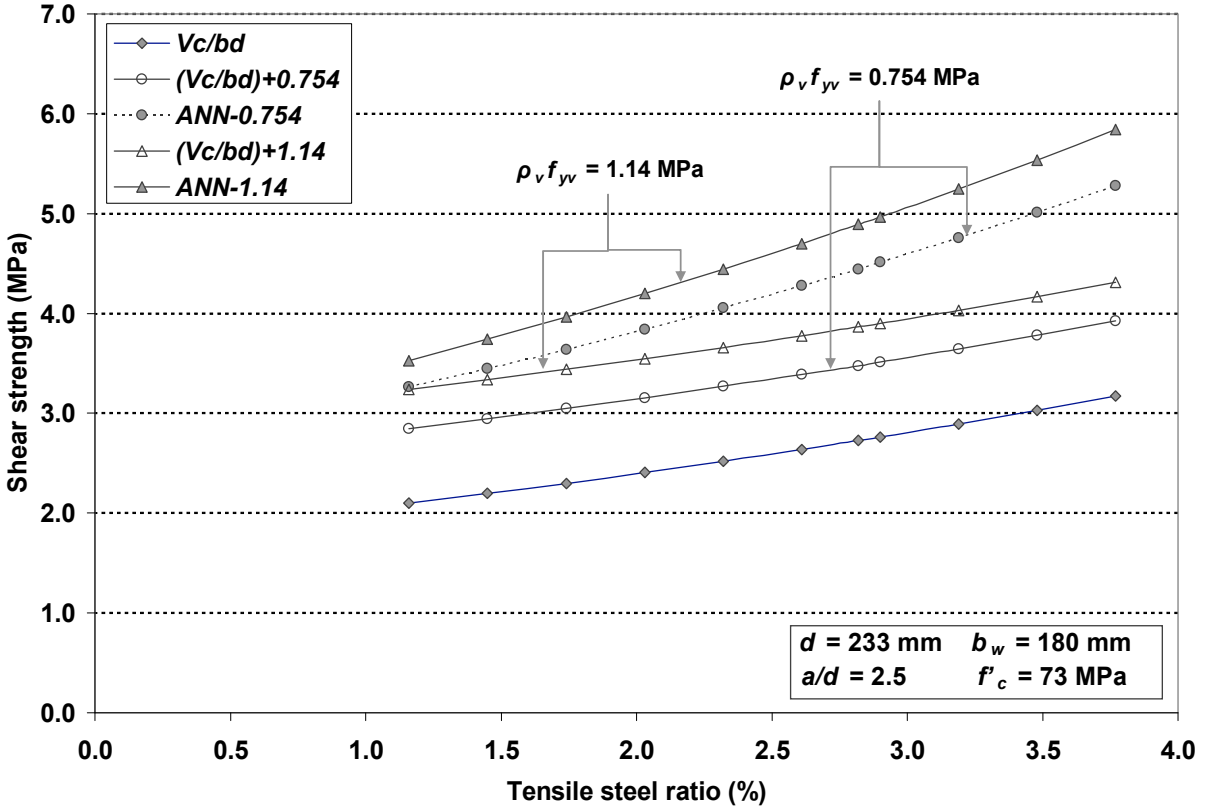

Fig. 4- Effect of stirrups on the contribution of ρ_l to the shear strength of RC slender beams

CONCLUSIONS

Results in this study obtained using the ANN model showed that the shear strength of RC slender beams with shear reinforcement depends on the amount of stirrups and it is up to 50% higher than values calculated using ACI 11-5 and the CSA simplified method. It was shown that calculating the shear strength of RC beams containing shear reinforcement by simply superimposing the capacity of stirrups to the shear capacity of a similar beam without shear reinforcement is not accurate and leads to unnecessarily conservative results.

Abstract

For many years, the design of reinforced concrete structures in the U.S. has been dominated by the use of steel reinforcement with a specified yield strength, f_y, of 60 ksi. Using steel reinforcement with a higher yield strength would introduce several benefits to the architectural, engineering, and construction industry. Not only would it allow for members with reduced cross sectional area, saving on material, shipping, and placement costs, but it would also help to overcome steel congestion, and facilitate concrete placement. This would directly lead to a better quality of construction, improved durability, and shorter construction times. One of the primary obstacles to the use of concrete members reinforced with ultrahigh strength steel (f_y greater than 80 ksi) is the paucity of experimental data.

The applicability of using steel with f_y up to 120 ksi as primary reinforcement in concrete members is explored in this experimental study by subjecting beams and columns reinforced with ultrahigh strength steel to a cyclic loading protocol. The mechanical behavior of these members is compared to similar members reinforced with conventional steel. Test data from this study show that the use of ultrahigh strength steel is a viable option for earthquake-resistant construction.

Introduction

For many years the design of reinforced concrete structures in the U.S. has been dominated by the use of steel reinforcement with a specified yield strength, f_y, of 60 ksi. Although higher values of f_y are allowed, it has been limited to 80 ksi since 1971 (ACI 318-71). ACI 318-08 (2008) permits the use of reinforcement with f_y of 100 ksi, but only if it is used for confinement reinforcement.

Steel with yield strength in excess of 80 ksi is currently commercially available in the U.S. and is often referred to as Advanced High Strength Steel (AHSS) or Ultrahigh Strength Steel (UHSS) (ISSI, 2006; ASTM A1011, 2010). In this study, the term UHSS is used to designate steel bars having yield strength in excess of 80 ksi and a fracture elongation of 6% or more in 8 inches. Figure 1 shows representative stress-strain curves of both conventional (Grade 60) and UHSS steels. After the introduction of ASTM A1035 (2005), there has been growing interest in UHSS bars. However, there is paucity of test data describing the behavior of concrete members reinforced with UHSS bars as longitudinal reinforcement.

Research Significance

The use of UHSS as longitudinal reinforcement is explored in this study by subjecting beams and columns to cyclic load histories. Specimens reinforced with UHSS are compared to specimens reinforced with Grade 60 steel.

There is no evidence in the U.S. of structures built or rehabilitated using UHSS as primary longitudinal and transverse reinforcement and designed to take full advantage of yield strengths in excess of 80 ksi for compression and tension stresses. This under-utilization is predominantly due to the shortage of experimental data, the lack of design guides, and the lack of coverage in existing building codes. In addition, UHSS in the U.S. only recently entered mass production.

Limits on the specified yield strength of reinforcing bars in the ACI 318 Code were originated in the 1963 edition (ACI 318-63, 1963). Their introduction was primarily related to the prescribed limit on compressive strain of 0.003 for concrete and to control crack width at service load.

The ACI 318-63 Code introduced strength design provisions with restrictions on the yield strength of non-prestressing steel. In Section 1505, ACI 318-63 specified an upper limit of 75 ksi on the yield strength of reinforcement used in compression and 60 ksi for reinforcement used in tension (unless special tests satisfied crack control requirements, in which case 75 ksi was permitted).

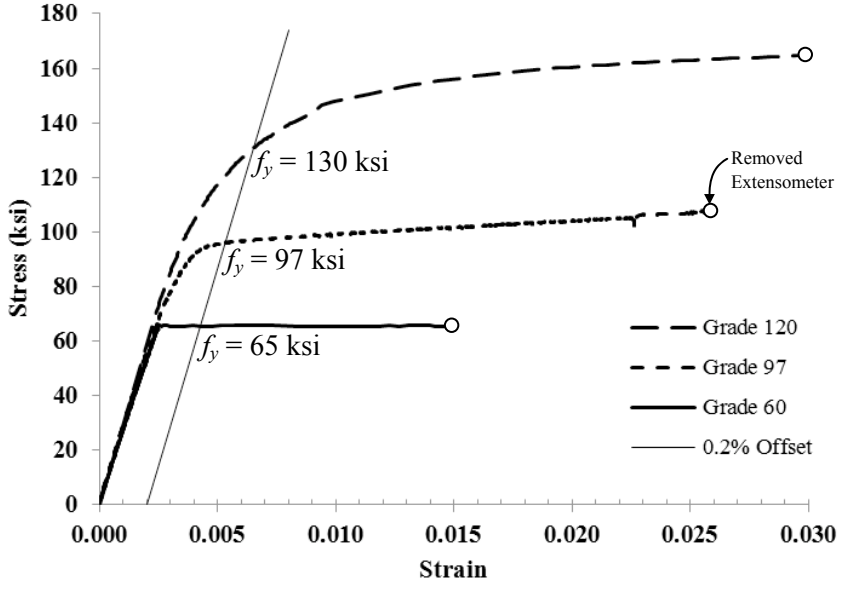

Figure 1. Measured Tensile Properties of Reinforcing Steel

In the 1971 edition of ACI 318 (1971), the limit on the specified yield strength of reinforcement (other than prestressing steel) was increased to 80 ksi for steel used in either tension or compression in order to continue accommodating the highest yield strengths covered by contemporary ASTM standards. The revised limits adopted by ACI 318-71 incorporated the findings from the extensive laboratory investigations reported in the 1960s by the eight-part report of the Portland Cement Association (Hognestad, 1961; Kaar, 1966) and by Todeschini et al. (1964). These studies were an

extension of the comprehensive column investigation initiated in 1929 by Richart and Brown (1934) under the direction of ACI Committee 105 on columns. These early efforts used longitudinal steel bars with an actual yield strength ranging from 55 ksi to 120 ksi where the fracture strain of steel typically exceeded 5%. Two conclusions about the findings of these reports are worth emphasizing: (1) in flexural members, "both maximum and average crack width are essentially proportional to reinforcing steel stress" (Kaar, 1966), and (2) "for steels with flat yield plateaus up to approximately 90,000 psi, the yield stress can be developed" in compression in tied columns (Todeschini et al., 1964).

A major effort in the 1980s and 1990s was led by Japanese researchers on the use of ductile reinforcing bars with nominal yield strengths in excess of 80 ksi for transverse and/or longitudinal reinforcement. A summary of 105 beam tests was presented by Otani, et al. (1996), who suggest that that the use of UHSS is commonplace in Japanese construction.

A design guide (ACI ITG-6R-10, 2010) recently published by the American Concrete Institute considers the use of UHSS steel conforming to ASTM A1035. However, the design stress is limited to 80 ksi for steel used in compression and to 100 ksi for steel used in tension.

Description of Experiments

To evaluate the mechanical behavior of concrete beams and columns reinforced with UHSS bars, a series of experiments was designed at Penn State University and Purdue University. The purpose of this series of tests was to evaluate the deformation capacity of such members when subjected to a cyclic loading protocol. Table 1 shows a summary of the specimens considered. The test variables include:

- Nominal yield strength of longitudinal reinforcement, (60, 97, and 120 ksi)
- Applied axial force (0 and 20% $f_c' A_g$, where f_c' is the concrete compressive strength, and A_g is the gross cross-sectional area of the specimen)

Table 1. Description of Test Specimens

Specimen		Axial Load	Longitudinal Reinforcement[a]			Transverse Reinforcement (2#3)	
		$A_g f'_c$ (%)	Top	Bottom	f_y, ksi	Spacing, in	f_y, ksi
Beams at Penn State (b=16", h=10", d=8")

#2	UC4-X	0	4#6	4#6	97	2	60
Columns at Purdue (b=9", h=12", d=10")							
#3	CC-3.3-20	20	3#7	3#7	60	2.5	60
#4	UC-1.6-20	20	2#6	2#6	120	2.5	60

[a] Reinforcement bars were provided by SAS Stressteel (f_y = 97 ksi) and by MMFX Technologies (f_y = 120 ksi)

The target concrete compressive strength was 6,000 psi. The geometry of typical beam and column specimens are shown in Figure 2. The specimens were loaded through the central stub so that they were in single-curvature bending. The shear span-to-effective depth ratio (a/d) for all specimens was approximately 3.

The amount of longitudinal reinforcement in each specimen was chosen so that the bending moment capacity of all specimens was approximately equal. So, for example, Specimen #3 (reinforced with 60-ksi steel) used approximately half the steel used in Specimen #4 (reinforced with 120-ksi steel). Transverse reinforcement was Grade 60 in all specimens and proportioned according to Chapter 21 of ACI 318-08.

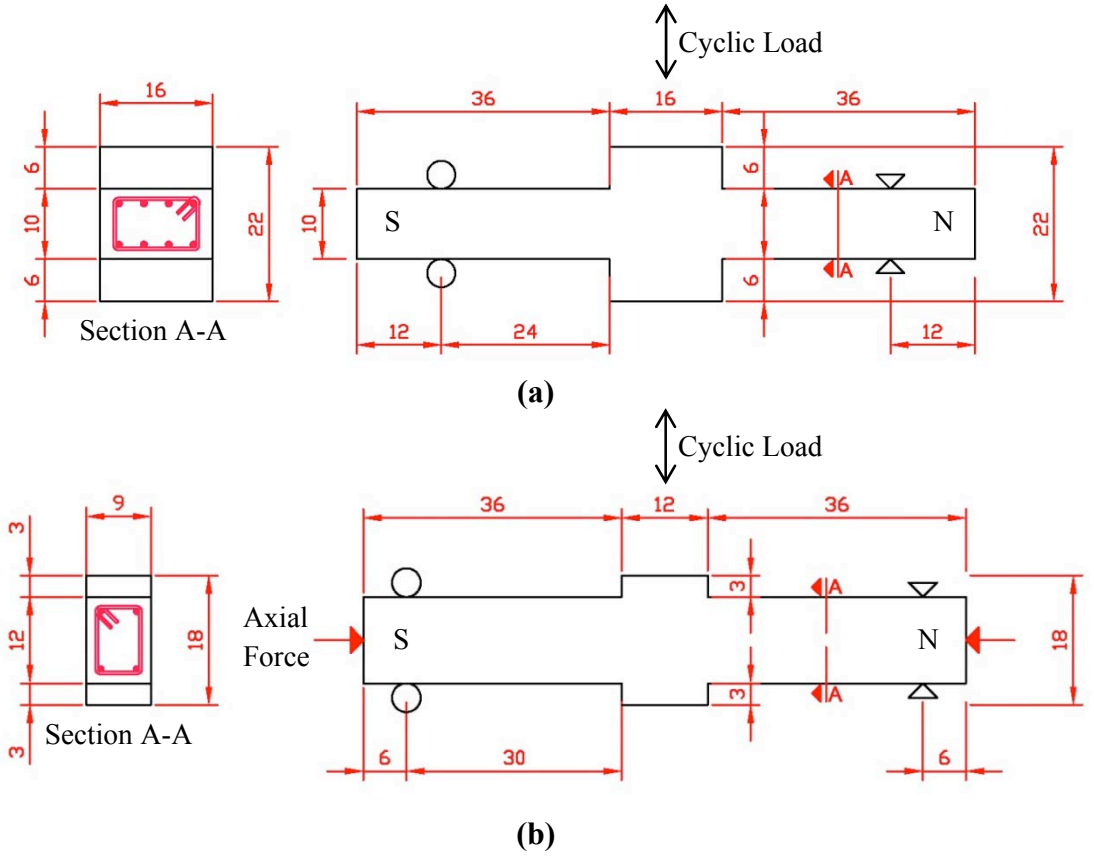

Figure 2. Geometry of Test Specimens, (a) Beams Tested at Penn State, (b) Columns Tested at Purdue (all dimensions in inches)

Loading Protocol

The drift ratio is defined here as the lateral displacement of the specimen divided by the shear span (corrected for the rotation of the central stub). The drift ratio history applied to each specimen, suggested by FEMA 461 (Applied Technology Council, 2007) is shown in Table 2 and is illustrated in Figure 3. Two cycles at each drift target are applied to the central stub at increasing amplitudes. After all cycles, the displacement is increased monotonically until failure (defined by a 20% drop in lateral-load carrying capacity from the peak value).

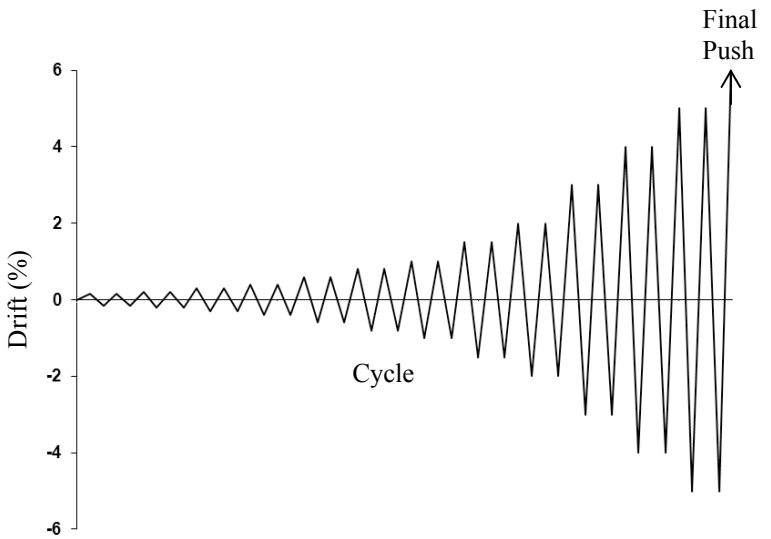

Figure 3. Loading Protocol

Experimental Results

Beams. Specimen #1, CC4-X, was designed according to ACI 318-08 requirements and built using 60-ksi steel as longitudinal reinforcement. Figure 4 shows the measured shear-drift response. The final push after all cycles from Figure 3 were completed is not shown. This specimen was capable of completing the predetermined cyclic loading protocol. At early stages of the test (up to 0.4% drift) only flexural cracks were observed. At the start of the first cycle to 0.4% drift, small inclined cracks were detected. The specimen completed cycles up to 1% without major damage. At this stage small signs of cover spalling could be observed. However the amount of spalling was small through 3% drift. In spite of wide flexural and shear cracks developing after 4% drift, the specimen completed the loading protocol without failure. In the final push, the north beam exceeded 10% drift. Figure 5 shows Specimen#1 at the end of the second cycle at 4% drift.

Specimen #2, UC4-X, had similar properties to Specimen #1 with the exception that it was reinforced longitudinally with UHSS. Figure 6 shows the measured shear-drift response without the final push. This specimen successfully completed the predetermined cyclic loading protocol. It was also capable of resisting the final push without failure up to a drift exceeding 10%. The specimen completed cycles up to 1% without major damage. The amount of spalling was small until 3% drift. In the first cycle of 3% drift, flexural cracks widened near the region of maximum bending moment. Inclined shear cracks started to grow at drifts greater than 1.5%. Large amount of concrete cover spalled off at 4% and 5% cycles. Figure 7 shows the specimen at the end of the second cycle at 4% drift.

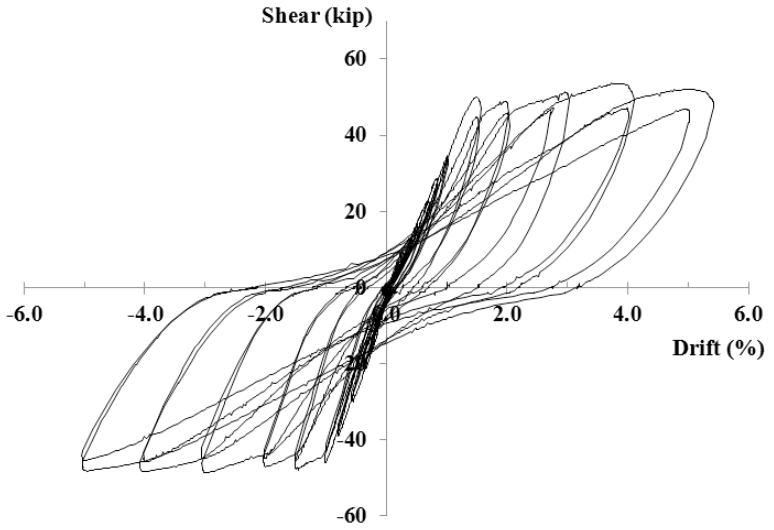

Figure 4. Shear Force vs. Drift Ratio, Specimen #1

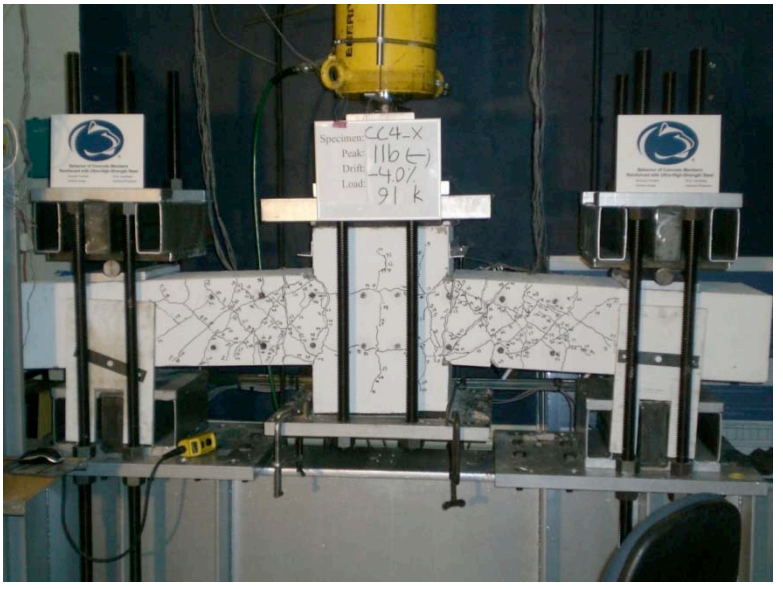

Figure 5. Specimen #1 at 4% Drift Ratio

In general both specimens had similar behavior. Specimen #1 (reinforced with Grade 60) showed a slight strength gain after yield while Specimen #2 (reinforced with UHSS Grade 97) had a nearly flat post-yield shear-drift envelope curve resembling the stress-strain curve of the steel. Both specimens completed all cycles in the loading protocol and reached drift ratios in excess of 10%. The hysteretic energy dissipated in Specimen #2 during a given post-yield hysteretic loop was smaller than the energy dissipated in the same loop for Specimen #1.

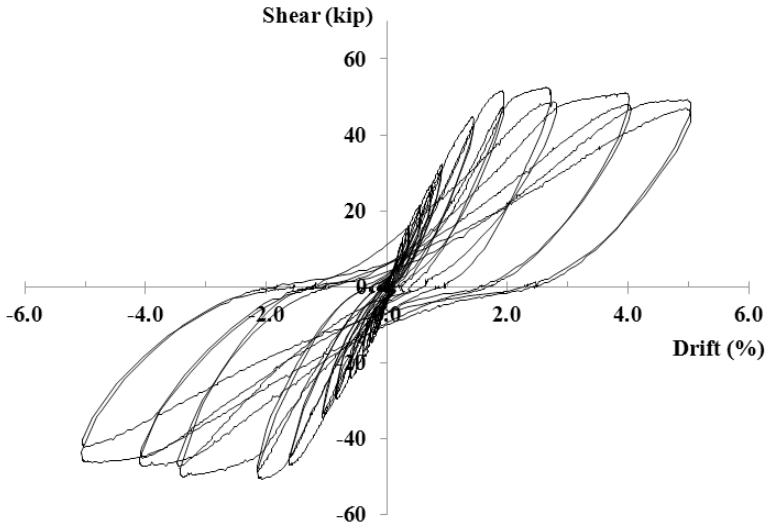

Figure 6. Shear Force vs. Drift Ratio, Specimen #2

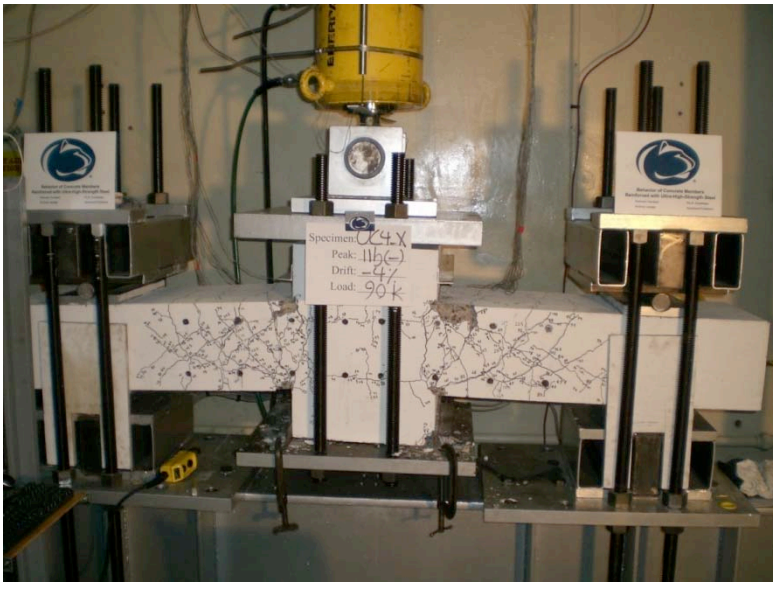

Figure 7. Specimen #2 at 4% Drift Ratio

Columns. Specimen #3, CC-3.3-20, was designed according to ACI 318 requirements. Figure 8 shows the measured shear-drift response of the specimen. It completed the first cycle at a drift ratio of 5%. At a drift ratio of approximately 1% during the second cycle to 5% drift, the longitudinal bars in compression buckled leading to a loss in lateral-load carrying capacity. A plausible explanation for the specimen failing at a drift ratio near zero is that the cracks on both sides of the specimen were open at that point. The axial load was carried predominantly by the longitudinal reinforcement, which led to buckling. Figure 9 shows the specimen at the end of the second cycle at 4% drift.

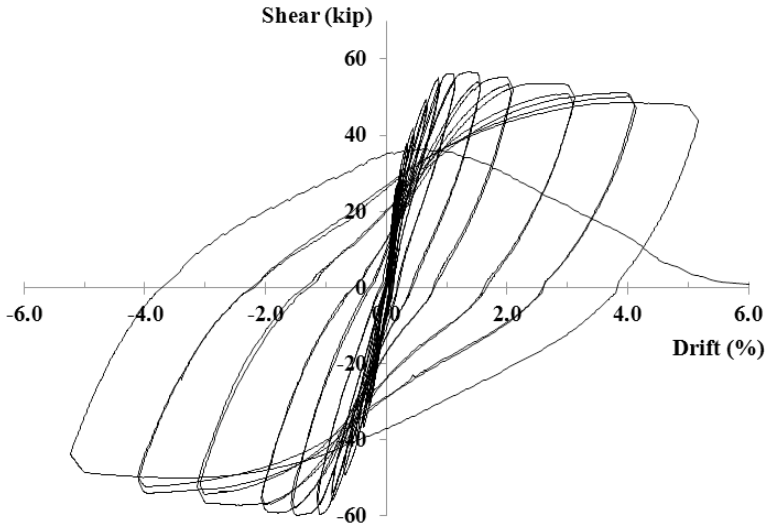

Figure 8. Shear Force vs. Drift Ratio, Specimen #3

Figure 9. Specimen #3 at 4% Drift Ratio

Specimen #4, UC-1.6-20, had properties that were similar to Specimen #3, with the exception that it was reinforced longitudinally with (approximately half as much) UHSS. Figure 10 shows the measured shear-drift response of the specimen. It completed the first half-cycle to a drift ratio of 5%, and the bars in compression buckled during the second half-cycle at that drift ratio. Testing was continued and the remaining longitudinal bars buckled at a small drift ratio (approximately 2%) during the second cycle at 5% drift ratio. Again, a plausible explanation is that the longitudinal bars need to carry a larger fraction of the axial load when the cracks in the concrete are open (typically at low drift ratios after having incurred large drift ratios). Figure 11 shows the specimen at the end of the second cycle at 4% drift.

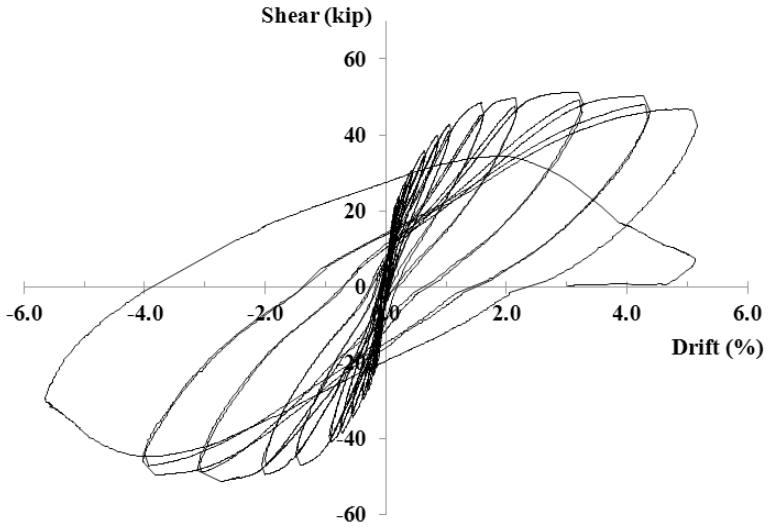

Figure 10. Shear Force vs. Drift Ratio, Specimen #4

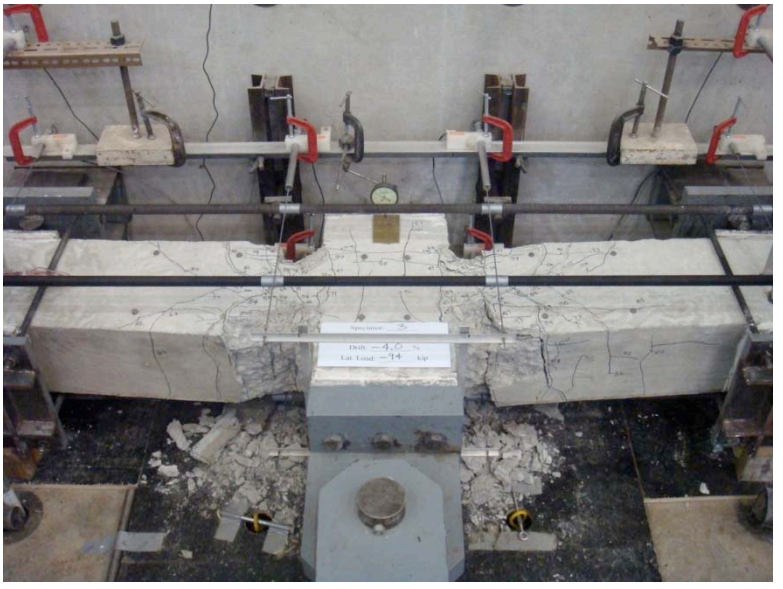

Figure 11. Specimen #4 at 4% Drift Ratio

Overall, the mechanical behavior of both columns was similar. The drift capacity of the column reinforced with Grade 60 steel and the column reinforced with UHSS Grade 120 were both 5%. However, there are at least two notable differences. The drift ratio at yield in Specimen #4 (UHSS steel) was approximately 50% higher than the drift ratio at yield in Specimen #3 (conventional steel). Also, the post-cracking stiffness of Specimen #4 is smaller than that of Specimen #3, which leads to less energy dissipation through hysteresis.

Conclusions

The test results presented here suggest that beams or columns with ultrahigh strength steel (UHSS) as longitudinal reinforcement have similar drift capacities to beams or columns reinforced with (approximately twice as much) conventional high strength steel. The tested beams tolerated drift ratios in excess of 10% without failure and the columns tested here tolerated ultimate drift ratios of 5%.

The specimens reinforced with UHSS required less steel than specimens reinforced with 60-ksi steel to reach the same moment capacity, resulting in less congestion. However, the reduction in steel caused a stiffness reduction upon unloading and reloading beyond cracking. The lower stiffness causes a reduction in energy dissipation as measured by the area of the hysteresis loops.

ABSTRACT

Sections 21.9.4.5 and 21.9.7.4 of ACI 318-08 limit the nominal shear strength, V_n of concrete coupling beams, including short beams with diagonal reinforcement, to $V_n \leq 0.83 A_{cw} \sqrt{f'_c}$ (with f'_c in MPa units, or $10 A_{cw} \sqrt{f'_c}$ with f'_c in psi units). Many experimental studies have been conducted on the design and detailing of diagonally-reinforced coupling beams for ductile behavior under seismic loading. The primary objective of the current ACI strength limit is to prevent the splitting and/or crushing of the diagonal strut in these beams. Through an analytical parametric investigation of isolated floor-level subassemblies, this paper shows that the boundary conditions utilized in the previous coupling beam experiments may not be adequate to investigate this important failure mode. The analytical model that forms the basis of the study uses a strut-and-tie representation of the forces developing inside a coupling beam under lateral loading. Multi-story coupled wall analyses are also conducted.

INTRODUCTION

Properly designed reinforced concrete (RC) coupled shear wall structures can provide large strength, stiffness, and energy dissipation under lateral loads; however, the design and construction of the coupling beams remain challenging due to the presence of large reversed-cyclic nonlinear rotation demands combined with large shear forces resulting in complex reinforcement details. For seismic conditions, Chapter 21 of ACI 318 (2008) prescribes extensive requirements for the design of coupling beams, especially for shorter beams where the nonlinear rotation and shear demands are more critical. The primary reinforcement in these beams consists of groups of diagonal bars that are confined by transverse reinforcement across the span of the beam and anchored into the walls. In addition, ACI 318 limits the nominal shear strength, V_n, of coupling beams to $V_n \leq 0.83 A_{cw} \sqrt{f'_c}$ (with f'_c in MPa units, or $10 A_{cw} \sqrt{f'_c}$ with f'_c in psi units). The commentary for this limit states: "Test results (Barney et al. 1980) demonstrate that beams reinforced as described in Section 21.9.7 have adequate ductility at shear forces exceeding $10 b_w d \sqrt{f'_c}$. Consequently, the use of a limit of $10 A_{cw} \sqrt{f'_c}$ provides an acceptable upper limit."

The main goal of the shear strength limit and transverse steel requirements in ACI 318 is to prevent the failure of the diagonal strut that develops inside a coupling

beam under lateral loading. Many experimental studies (e.g., Tassios et al. 1996; Galano and Vignoli 2000; Adebar et al. 2001; Kwan and Zhao 2002; Canbolat et al. 2005; Moretti and Tassios 2006; Wallace 2007; Fortney et al. 2008; Yun et al. 2008) have been conducted since the original study (i.e., Barney et al. 1980) that precipitated the current design and detailing requirements for diagonally-reinforced coupling beams. However, except for one beam in Adebar et al. (2001), all of the test specimens in these previous research programs were axially unrestrained. This boundary condition can provide an unconservative evaluation for the design of the beams, in particular with respect to the diagonal strut. This is because, as cracking occurs under lateral loading and the diagonal bars yield in tension, the centerline of the beam "elongates," which is resisted by the large in-plane stiffnesses of the shear walls, thus introducing compression forces into the beams. This effect is most prominent for deeper beams and especially near the base of the structure where the wall piers provide the largest restraint to the axial elongation of the beams. Furthermore, under reversed-cyclic loading into the nonlinear range, the in-plane stiffnesses of the wall piers vary by different amounts (due to differences in the wall axial forces), causing not only large compression forces, but also tension forces in the coupling beams.

Through an analytical parameter study, this paper evaluates the geometrical, reinforcement, and loading conditions that affect the behavior of diagonally-reinforced coupling beams under reversed-cyclic lateral loading. To isolate the primary load-resisting mechanisms of the structure, the analytical model uses a strut-and-tie representation based on Appendix A of ACI 318. Comparisons of the results with available test data show that, despite its simplicity, the strut-and-tie model is capable of adequately capturing the behavior of the beams. Using this model, the paper evaluates the effects of axial restraint and other parameters on the diagonal strut. Multi-story coupled wall analyses are also conducted to investigate the forces that develop in the beams.

The results from the study reveal that the reason crushing of the diagonal strut was observed in Barney et al. (1980), precipitating the current ACI 318 shear strength limit, is that these test beams had unequal areas of steel reinforcement in the two diagonals, which is not a realistic, practical detail. It is also found that the presence of a significant amount of fully-developed (i.e., achieving the yield strength of the steel) horizontal reinforcement crossing the beam-to-wall joints can induce earlier crushing of the concrete. The current ACI 318 recommendations for the horizontal reinforcement in diagonally-reinforced coupling beams are only in the ACI 318 commentary. The commentary figure (ACI 318 Fig. R21.9.7) notes partial requirements for the horizontal reinforcement as: "Horizontal beam reinforcement at wall does not develop f_y."; however, the commentary does not hold the same legal requirements as the main body of ACI 318. These recommendations could be more clearly stated to explicitly prevent the use of developed horizontal steel across the beam-to-wall joints in diagonally-reinforced coupling beams, since the tension forces in these bars could lead to increased compression stresses in the concrete.

ANALYTICAL MODELING AND VALIDATION

A nine-node two-dimensional strut-and-tie model consisting of concrete, RC, and steel members as shown in Fig. 1(a) forms the basis of the coupling beam

analyses in this paper. The steel members (solid lines) represent the primary reinforcement resisting both tension and compression forces during the cyclic loading of a beam, while the concrete members (dashed lines) are assumed to resist compression only (ignoring the tension strength of concrete). The RC members (double lines) have both steel and concrete elements. The goal is to develop a simple tool that can isolate the primary load-resisting components of a diagonally-reinforced beam; thus, allowing each component to be evaluated separately.

Nodes A, C, G, and I of the model are located where the centroids of the diagonal bar groups intersect with the top and bottom horizontal bar groups. These nodes are placed a small distance into the wall piers, providing a more realistic representation of the beam than simply placing the nodes at the beam ends. The other nodes are located equidistantly vertically and horizontally between the four corner nodes, with one node in the center so that a symmetric nine-node array is formed.

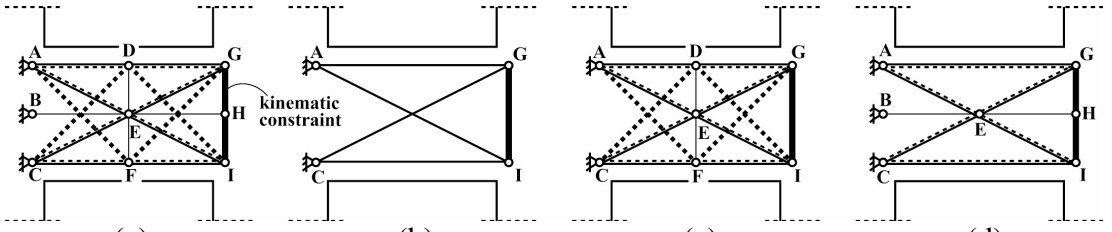

Figure 1. Strut-and-tie models: (a) nine-node model; (b) all-steel four-node model; (c) seven-node model; (d) model without concrete strut elements

RC Main Diagonal Elements. The main diagonal elements between Nodes A-E-I and C-E-G are RC elements. The steel area is equal to the total cross-sectional area, A_{sd} of the diagonal bar group. The concrete area, A_c is taken as the core area enclosed by the centerline of the ties around the diagonal reinforcement. A lower limit to A_c is set as $A_{c,min} = C_c / (0.85\beta_s f'_c)$. The calculation of $A_{c,min}$ is derived from a sectional equilibrium analysis of the beam. Assuming that all steel reinforcement is at yield and ignoring the strength of concrete in tension, the total compression stress resultant in the concrete, C_c can be found as $C_c = A_{sd} f_{yd} \cos(\alpha) + A_{sl} f_{yl} + A_{sm} f_{ym} - N_b - A_{sd}' f_{yd}' \cos(\alpha) - A_{sl}' f_{yl}'$, where, β_s=0.60 (assumed concrete strength reduction factor in accordance with Appendix A of ACI 318), A_{sd}, A_{sd}'=total areas of the tension and compression diagonal reinforcement, respectively (A_{sd}=A_{sd}' in most cases); A_{sl}, A_{sl}'=total areas of the developed tension and compression horizontal reinforcement (if present), respectively, at the top and bottom of the beam (A_{sl}=A_{sl}' in most cases); A_{sm}=total area of the developed horizontal reinforcement within the mid-depth of the beam (if present); f_{yd}, f_{yd}', f_{yl}, f_{yl}', f_{ym}=respective yield strengths for the reinforcement areas listed above; α=inclination of the diagonal bars with respect to the horizontal; and N_b=applied (external) axial force (compression negative) on the beam.

Note that C_c as described above is zero when all diagonal and horizontal reinforcement is symmetrical, no developed mid-depth horizontal bars are used (i.e., A_{sm}=0), and no external axial force is applied on the beam (i.e., N_b=0). This means that the internal resisting forces in the beam equilibrate through the reinforcing bars, with no significant compression forces in the concrete. Under this condition, a simpler "all-steel" strut-and-tie model with A_c=0 can be used, consisting of only the four corner nodes with the specified reinforcement as shown in Fig. 1(b).

RC Longitudinal Boundary Elements. The longitudinal boundary elements are RC elements between Nodes A-D-G and C-F-I. The steel area is equal to the total area of the developed horizontal bars at the top or bottom of the beam (i.e., A_{sl} or A_{sl}', which are taken as zero if the bars are not developed across the beam-to-wall joints). The concrete area is assumed to be the same as the area, A_c for the main diagonal elements (with no tension strength and an effective compression strength of $0.85\beta_s f'_c$).

Steel Longitudinal Mid-Depth Elements. The longitudinal mid-depth elements are steel elements between Nodes B-E-H with a total area of A_{sm} along the mid-depth of the beam (i.e., horizontal steel not included in A_{sl} and A_{sl}'). If the horizontal bars are not developed across the beam-to-wall joints, then, A_{sm}=0 and Nodes B and H can be removed from the model resulting in a seven-node truss as shown in Fig. 1(c).

Steel Transverse Elements. The transverse steel elements are located at the beam mid-span between Nodes D-E-F, with an assumed area equal to the total vertical leg area of the full-depth transverse reinforcement (e.g., hoops, stirrups) within one-quarter of the beam length on each side of the mid-span. This length is taken as the "tributary" length in determining the steel area lumped in the transverse elements.

Concrete Strut Elements. Four strut elements between Nodes A-F, C-D, G-F, and I-D model the concrete in compression in these regions. The concrete area in each element is taken the same as the area A_c for the main diagonals (with no tension strength and a compression strength of $0.85\beta_s f'_c$). For beams with very small length-to-depth aspect ratios, specifically $l_b/h_b<1.50$, the concrete strut elements are not used since most of the compression forces are carried through the main diagonal struts. Under this condition, the transverse elements become zero-force members, resulting in a model with just the main diagonal elements and longitudinal elements as shown in Fig. 1(d).

Assumed Loading and Boundary Conditions. The OpenSees software (Mazzoni et al. 2009) was used for the analysis of the strut-and-tie models above. The left end of the beam was fixed while the right end was free but not allowed to rotate (to result in symmetrical double curvature along the beam length). The modeling of axial restraint on the beam is described later. Gravity loads (e.g., beam self weight) were ignored and a transverse point load was applied at Node G to simulate the effects of lateral loading on the beam. The analyses were conducted in displacement control with Nodes G, H, and I (which were kinematically constrained) subjected to a prescribed reversed-cyclic transverse displacement history.

Material Idealizations. The zero-tensile-strength "Concrete01" material in OpenSees was used for all of the concrete elements. The compressive strength, set equal to $0.85\beta_s f'_c$, was assumed to be reached at a compressive strain of -0.002. Beyond this strain point, the compressive stress was assumed to remain constant to partially simulate the redistribution of the concrete stresses in an actual RC member. The "Reinforcing Steel" material, which allows for the modeling of strain hardening and Bauschinger effects, was used for the main diagonal bars. For the horizontal and transverse reinforcement, the simpler "Steel01" material was used. This material has an idealized bilinear stress-strain relationship. Two parallel Steel01 elements were

used for each longitudinal and transverse member to result in a trilinear stress-strain relationship capturing both the yield strength and the ultimate strength of the steel.

Model Validation. Comparisons between the measured and predicted lateral load versus displacement behaviors for six coupling beams tested in previous research are shown in Fig. 2. More information on the analytical model validation can be found in Barbachyn et al. (2011). In evaluating the model comparisons, it is re-emphasized that the main goal is to construct a simple tool that can isolate the most important load-resisting components of a diagonally-reinforced coupling beam, such that these components can be subsequently analyzed under different geometrical, reinforcement, and loading conditions. While it would be possible to develop more sophisticated models (e.g., using a finite element program), the strut-and-tie model remains the most effective tool for the investigation in this paper.

PARAMETRIC INVESTIGATION

For the purposes of this investigation, a prototype 14-story building structure with plan view in Fig. 3(a) was designed for a site in Los Angeles. The wall pier details at the base are shown in Fig. 3(b) and the coupling beam elevation is shown in Fig. 3(c). Steel with yield and ultimate strengths equal to 414 and 621 MPa (60 and 90 ksi), respectively, was assumed for all of the reinforcement. The compressive strength of the concrete was assumed as f'_c=41 MPa (6 ksi).

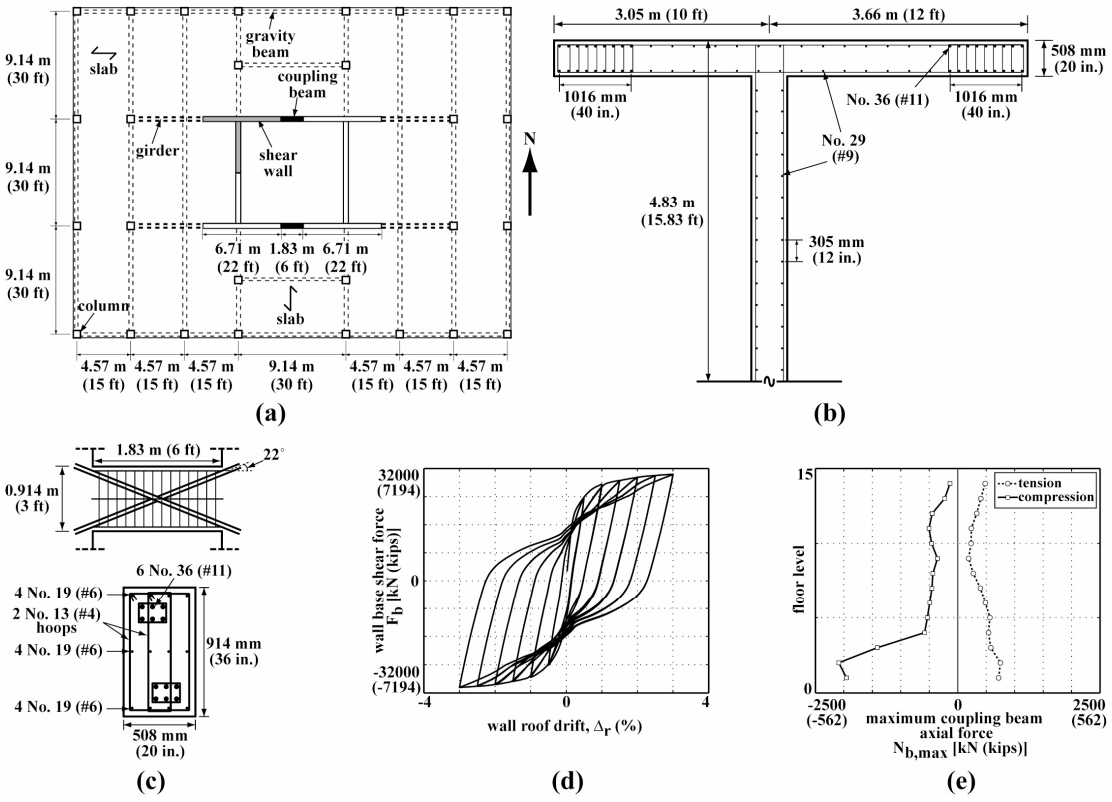

Figure 3. Prototype structure: (a) building plan; (b) wall base; (c) coupling beam (CB1); (d) base shear versus roof drift behavior; (e) maximum coupling beam axial forces

The coupling beams over the building height were assumed to be identical. This design (referred to as Beam CB1) with an aspect ratio, l_b/h_b=2.0 was used as the basis of the parametric investigation. The total area of each diagonal bar group is A_{sd}=6039 mm^2 (9.36 in^2) [6#36 (#11) bars] placed at an inclination angle of α=22°, resulting in a nominal shear strength of $V_n=2A_{sd}f_{yd}sin(\alpha)=0.62A_{cw}\sqrt{f'_c}$ (with f'_c in MPa units, or $7.5A_{cw}\sqrt{f'_c}$ with f'_c in psi units). The horizontal and transverse bars were selected according to the ACI 318 requirements. It was assumed that an adequate amount of transverse steel was placed around the diagonal bars to prevent buckling. The horizontal reinforcement [total of 12#19 (#6) bars] was not developed across the beam-to-wall joints (i.e., $A_{sm}=A_{sl}=A_{sl}'$=0 was assumed).

Two series of analyses were conducted based on Beam CB1. In the first series, the beam was assumed axially unrestrained (i.e., N_b=0) and was subjected to a series of reversed-cyclic displacements up to a maximum chord rotation of θ_b=9%. In the second series, external steel bars were modeled along the mid-depth of the beam (i.e., between Nodes B and H of the strut-and-tie model, with no connection to Node E) to simulate axial restraint conditions similar to the external bars used in the test specimen described in Adebar et al. (2001). The total area of the restraint bars was determined from a nonlinear reversed-cyclic lateral load analysis of the coupled wall structure in the E-W direction. For this multi-story wall analysis, the coupling beams were modeled using the strut-and-tie representation in Fig. 1(c) (since the horizontal bars were not developed into the walls) and the wall piers were modeled using fiber elements as described in Kurama and Shen (2008). Fig. 3(d) depicts the expected base

shear force versus roof drift angle behavior of the entire core wall structure and Fig. 3(e) shows the corresponding distribution of the maximum coupling beam axial forces over the wall height. A significant variation in the coupling beam axial forces can be seen over the height of the structure, with the largest compression forces developing near the base. Ultimately, the total area of the axial restraint bars in the coupling beam analyses was taken as A_{er}=2123 mm^2 (3.29 in^2), resulting in an axial restraint force of about -876 kN (-197 kips) at yield. This force is close to the average maximum compression force for the coupling beams over the height of the structure in Fig. 3(e). Variations in the restraint bar area were also investigated.

Note that in addition to compression, the coupling beam axial forces in Fig. 3(e) also show large tension effects. While these tension forces are not investigated further in this paper, it should be stated that they can cause more critical conditions than previously considered for the low-cycle fatigue fracture of the diagonal reinforcement.

Effect of Beam Depth. The variation of the beam depth, d_b, was simulated by changing the height of the strut-and-tie model to parametric depths equal to 0.5, 0.75, 1.25, and 1.5 times the original depth for Beam CB1, while all other properties of the beam stayed constant. The results from the investigation are shown in Figs. 4(a) through 4(f). The format of these figures is the same for all of the other parametric analysis results in this paper as follows: (a) shear force, V_b versus chord rotation, θ_b behavior for beams without axial restraint; (b) V_b versus θ_b behavior for beams with axial restraint; (c) normalized beam shear force at yield of diagonal steel, $V_{b,y}/(A_{cw}\sqrt{f'_c})$, where f'_c is in MPa units (psi units in parentheses); (d) maximum axial (i.e., horizontal) elongation of the beam, $\delta_{a,max}$ (i.e., horizontal displacement of the right end of the beam with respect to the left end); (e) maximum compression strains, $\varepsilon_{c,max}$ in the main diagonal and concrete strut elements; and (f) maximum tension strains, $\varepsilon_{t,max}$ in the main diagonal and steel transverse elements. The base case using Beam CB1 is depicted by the * markers whereas the □ markers show the parametric cases.

Looking at Fig. 4, an increase in the beam depth, d_b causes a small decrease in the normalized "yield" strength of the beam (i.e., strength at yield of diagonal reinforcement) since A_{cw} increases. As d_b is increased, the axial elongation, $\delta_{a,max}$ of the beam increases almost linearly, resulting in an increase in the tension strains, $\varepsilon_{t,max}$ of the diagonal reinforcement. The transverse steel strains remain very small throughout the parameter variation. An important observation is that for beams with axial restraint, the axial elongation and tension strains are smaller but there is a significant increase in the main diagonal and concrete strut compression strains, $\varepsilon_{c,max}$. As the depth is increased, the axially-restrained beams develop concrete strains at crushing level even though the ACI 318 nominal strength limit of $0.83A_{cw}\sqrt{f'_c}$ (with f'_c in MPa units) is not exceeded. It is concluded that the previous coupling beam experiments with no axial restraint may be unconservative for the crushing of concrete and buckling of reinforcement, especially for deeper beams.

Amount of Axial Restraint. Fig. 5 shows the analysis results where the total area, A_{er} of the axial restraint bars was varied. The variation in A_{er} was done proportionally with respect to the total area, A_{sd} of the diagonal reinforcement in the beam, ranging

from a ratio of 0 (i.e., no axial restraint) to 2.0. Note that the analysis cases presented in the other sections of the paper correspond to A_{er}/A_{sd} ratios of 0 and 0.35 (* markers in Fig. 5), and for the beam tested by Adebar et al. (2001), this ratio is equal to 1.44.

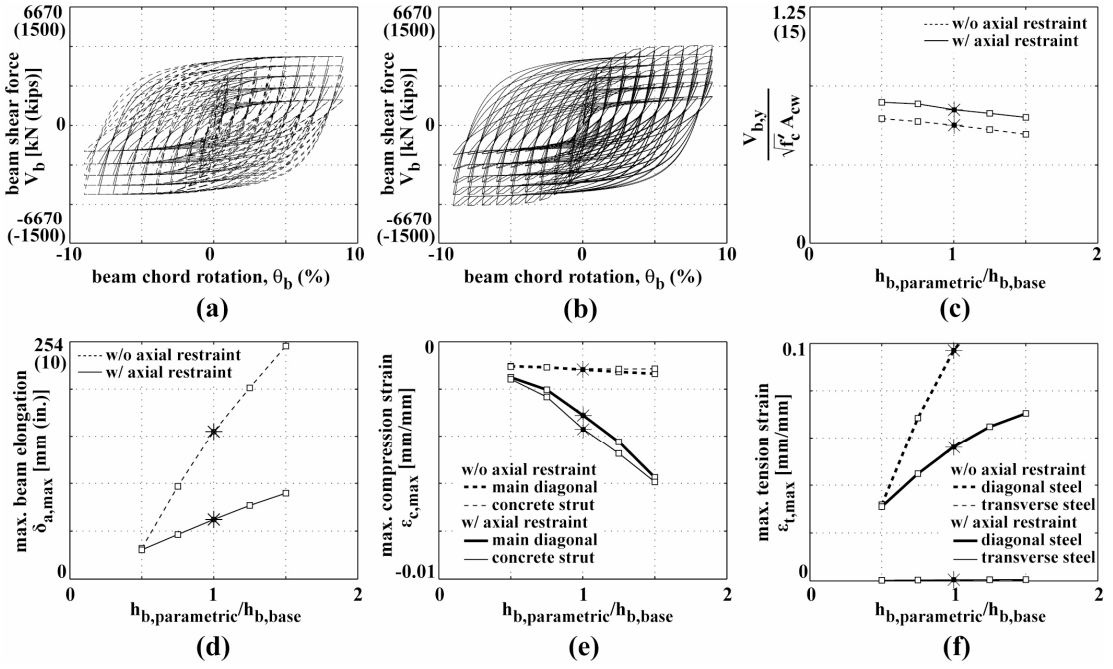

Figure 4. Beam depth, h_b: (a) without axial restraint; (b) with restraint; (c) normalized shear strength; (d) beam elongation; (e) compressive strains; (f) tensile strains

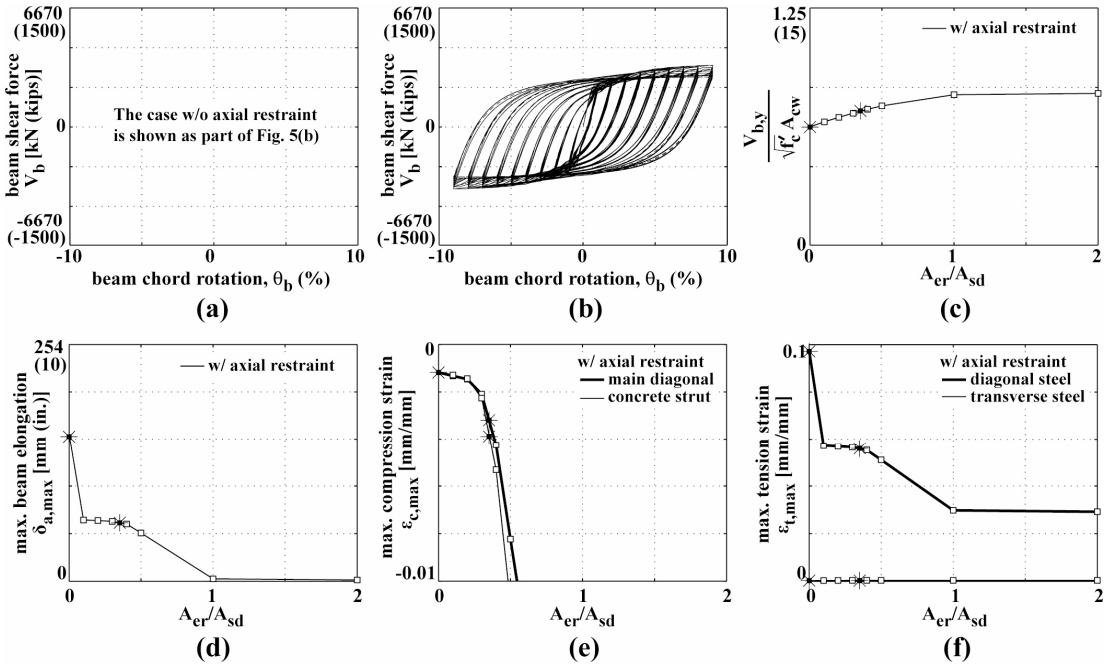

Figure 5. Amount of axial restraint: (a) no restraint; (b) with restraint; (c) normalized shear strength; (d) beam elongation; (e) compressive strains; (f) tensile strains

It can be seen from Fig. 5 that the effect of axial restraint on the lateral strength of the beam is relatively small but, as A_{er} is increased, there is a significant decrease in the axial elongations and tensile strains, and a significant increase in the compression strains. When A_{er} reaches about $1.0A_{sd}$, the axial elongation of the beam is restrained to zero and there is no additional change in the tensile or compressive strains as A_{er} is increased further. These findings confirm the need to include the restraining effect of the shear walls in the validation testing of RC coupling beams. Depending on the amount of axial restraint, beams that satisfy the ACI nominal shear strength limit can fail due to the failure of the diagonal strut.

Reinforcing Steel Areas. In this section, the reinforcing steel areas in the main diagonal and longitudinal boundary elements of Beam CB1 are varied. The concrete area A_c is kept constant in each case. As shown in Fig. 6, an increase in the main diagonal steel area, A_{sd} results in an almost proportional increase in the strength of the beam. The axial elongation of the beam is not significantly affected by this parameter; however, especially for axially-restrained beams, there is a considerable increase in the compression strains as the amount of diagonal steel is increased.

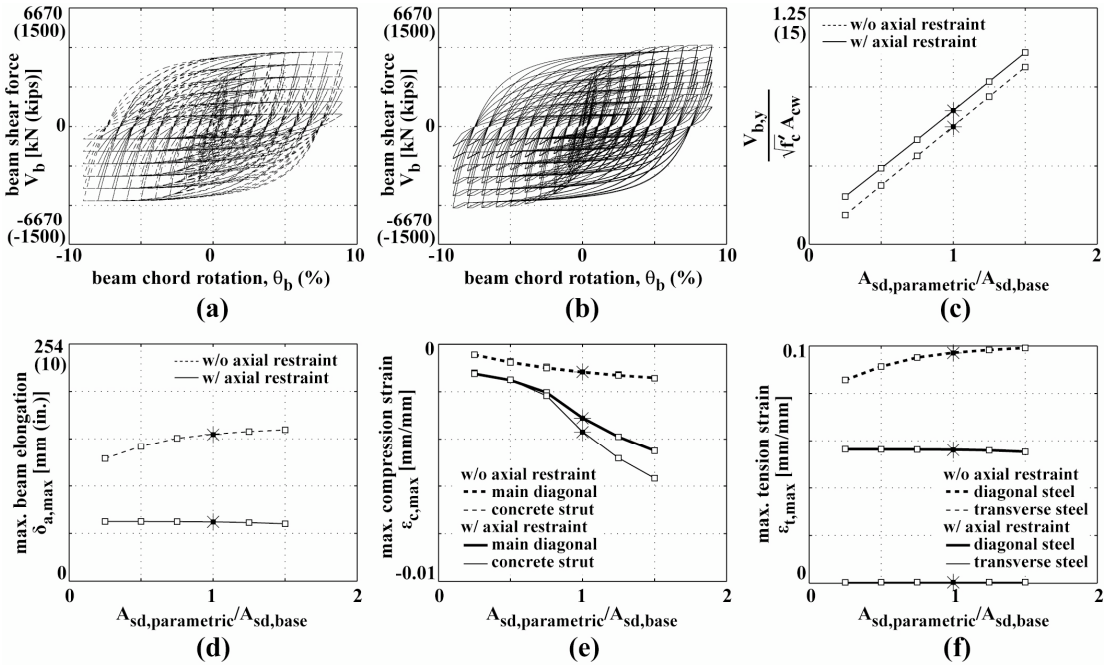

Figure 6. Main diagonal steel area, A_{sd} – symmetrical variation: (a) without axial restraint; (b) with axial restraint; (c) normalized shear strength; (d) beam elongation; (e) compressive strains; (f) tensile strains

The results in Fig. 6 correspond to cases where the reinforcement in the beam is varied symmetrically. In Fig. 7, another series of beams are analyzed where the total steel area of only one of the main diagonals is varied. While this is not a recommended design for practice, it is an important study since it shows the implications of the unsymmetrical reinforcement used in Barney et al. (1980), which had about 10% less steel in one diagonal than the other. It can be seen that as one

diagonal steel area is reduced by 10% and 20% with respect to the other diagonal, there is a significant increase in the maximum compression strains.

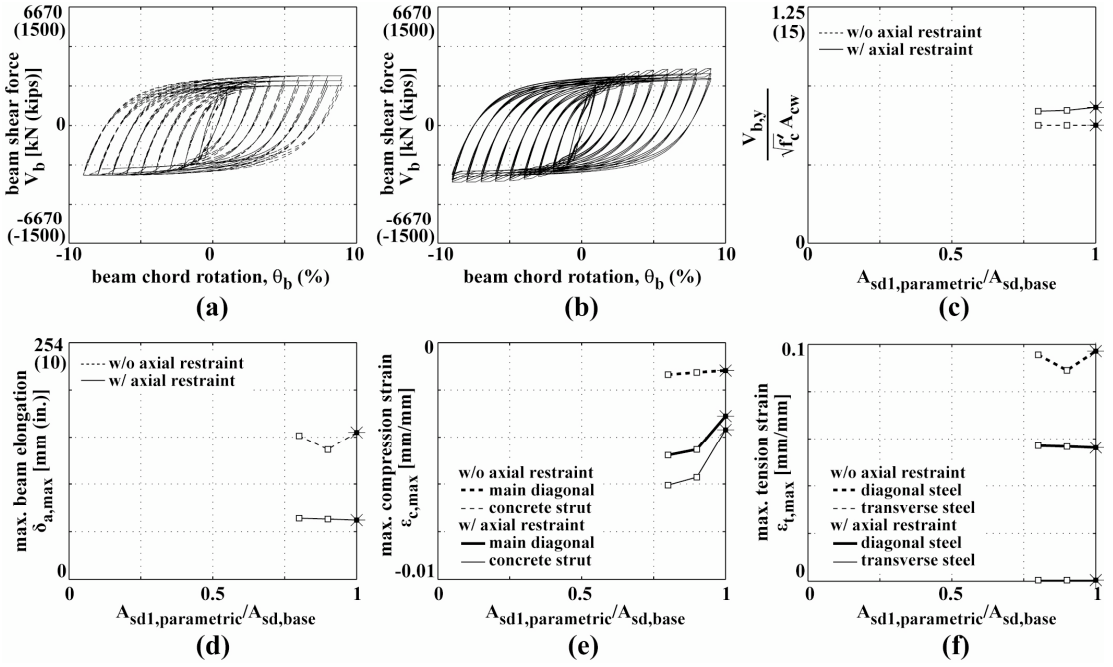

Figure 7. Main diagonal steel area, A_{sd} – unsymmetrical variation: (a) without axial restraint; (b) with axial restraint; (c) normalized shear strength; (d) beam elongation; (e) compressive strains; (f) tensile strains

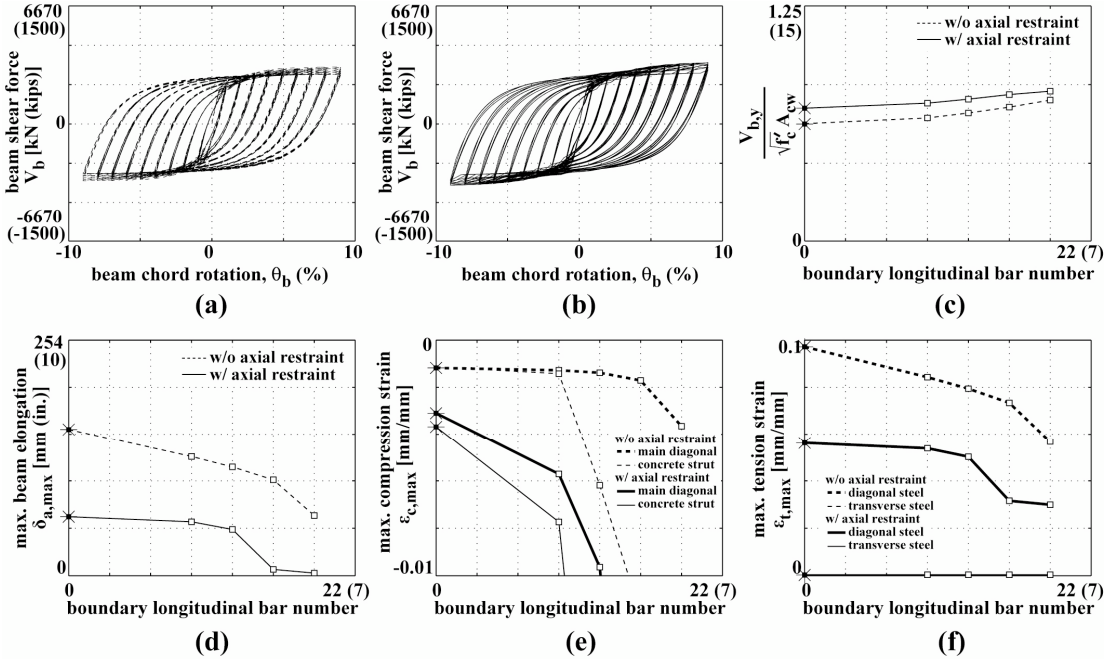

Figure 8. Boundary horizontal steel area, A_{sl}: (a) without axial restraint; (b) with axial restraint; (c) normalized shear strength; (d) beam elongation; (e) compressive strains; (f) tensile strains

Finally, the effects of the area, A_{sl} of the developed boundary horizontal reinforcement across the beam-to-wall joints are shown in Fig. 8. The analysis cases include the base case of no developed bars as well as 4 bars (top and bottom) of varying sizes [Nos. 10, 13, 16, and 19 (3, 4, 5, and 6)]. The mid-depth horizontal bar area, A_{sm} is held constant at zero. It can be seen that A_{sl} has little effect on the strength of the beam; however, as this reinforcement is increased, the compression strains in the beam also increase. If a significant amount of boundary reinforcement is developed, beams that satisfy the ACI nominal strength limit can fail due to the failure of the diagonal strut. Thus, it is not recommended to develop the horizontal bars through the beam-to-wall joints of a diagonally-reinforced coupling beam. As stated previously, this detailing requirement should be more clearly specified in ACI 318.

SUMMARY AND CONCLUSIONS

Through an analytical parameter study, this paper evaluates the geometrical, reinforcement, and loading conditions that affect the behavior of diagonally-reinforced coupling beams under reversed-cyclic lateral loading. The main findings and conclusions from the research, as limited to the variable ranges considered, are listed below.

(1) Despite its simplicity, the strut-and-tie model utilized in the paper provides a powerful tool to investigate the behavior of diagonally-reinforced coupling beams under lateral loads. For this investigation, the most significant advantage of this modeling technique is its ability to isolate the primary load-resisting components of a coupling beam.

(2) In a coupled wall structure under lateral loads, the large in-plane stiffnesses of the shear walls axially constrain the coupling beams, thus introducing significant axial forces into the beams. This effect is particularly large for the lower floor beams where compression failure of the diagonal struts can occur.

(3) Previous coupling beam experiments with no axial restraint can result in conditions that are unconservative for the crushing of the concrete and the buckling of the reinforcement. Thus, the results from these experiments cannot directly be used to validate the design and detailing of the compression diagonal.

(4) The use of unequal areas of reinforcement in the two diagonals most likely led to the failure of the compression diagonal in Barney et al. (1980), leading to the current nominal shear strength limit in ACI 318-08. Since an unsymmetrical reinforcement detail is typically unrealistic for practical applications, the ACI strength limit should be re-evaluated for coupling beams that are more representative of actual conditions.

(5) Depending on the amount of axial restraint, beams that satisfy the current nominal shear strength limit in ACI 318-08 can be unconservative due to the possibility of premature splitting and/or crushing of the diagonal strut. The axial restraint is more critical for beams with larger depth.

(6) Failure of the diagonal strut can also occur if a significant amount of horizontal steel reinforcement is developed across the beam-to-wall joints. The current ACI 318-08 commentary recommendations should be more clearly stated to

prevent the use of fully-developed horizontal steel across the beam-to-wall joints in diagonally-reinforced beams, with the possible relocation of the commentary recommendations to provisions in the main body of the ACI 318-08 document.

A Simple Method in the Preliminary Assessment of Historic Masonry Buildings

James S. Cohen, MASCE, PE[1]

[1]Associate Principal, Arup, 155 Avenue of the Americas, New York, NY 10013; PH (212) 229-2669; FAX (212) 229-1056; email: james.cohen@arup.com

As part of a large infrastructure project in New York City, many load bearing brick masonry structures are located adjacent to areas undergoing excavation, tunneling and blast. Due to the numerous structures involved, simplified methods to rapidly assess stability issues of the brick masonry load bearing walls and facades have been developed. Based upon these methods, repair techniques have also been developed and successfully implemented. The methods of analysis and sample results are presented with recommended areas of improvement. The relative sensitivities of the various parameters and assumptions required are also presented.

INTRODUCTION

As part of an on-going project, it has been necessary to development a means to rapidly assess numerous historic load bearing masonry buildings, constructed during the period circa 1850 - 1910. These structures have many construction features in common despite the age range but all predating modern design code. These include: non-supporting front and rear unreinforced multi-wythe facades, unreinforced multi-wythe load bearing side walls, suspended timber frame floors, and, shallow rubble wall foundations.

Most, but not all, buildings contain commercial space at ground floor level, often framed by cast iron columns. Masonry is typically supported on the cast iron columns via masonry arches, themselves resting on cast iron plates. Public records for these buildings providing floor plans and other information are often available showing these similarities.

Other features often present in the condition of these buildings, to varying degrees, include:

- Separation of bearing walls leading to reduced bearing of the timber framing
- Deteriorated mortar in the rubble walls
- Deteriorated mortar in the brick facade
- Deteriorated mortar in the bearing walls
- Uneven settlement
- Separation of the façade to the bearing walls along vertical edges
- Cast iron tie-backs intended to tie the facades back to the interior framing and/or bearing walls, often in a corroded condition
- Lack of plumb of the overall building

Clearly, this list represents a deterioration of the building over time, detracting from the strength or stability of the building and represents a change in condition from original.

Assuming that some deterioration may be acceptable, representing a reduction in the presumed factor of safety originally incorporated into the building design, additional deterioration may be unacceptable. Such additional deterioration may be imposed by adjacent construction, including excavation, tunneling and blasting.

Constant monitoring of these older structures becomes necessary to ensure that such factors of safety are not reduced below an acceptable level; i.e., that the buildings remain stable and functional. Of particular interest is the total lean of the buildings, whether parallel to the facades or to the bearing walls.

Brick masonry is inherently difficult to analyze as a model. Typically, for new construction, brick masonry is viewed as a uniform material with fixed properties. However, the material properties of the various materials, bond of mortar, the behavior of the brick/mortar assembly, the interaction between multiple withes of the assembly and the anisoptropic behavior of the materials all create difficulties for detailed analysis.

For older buildings, these difficulties are overshadowed by the unknown condition of the various mortar joints, likely hidden deterioration, historical use of differing bricks depending upon whether they were exterior or interior, visible or hidden, and other uncertainties. In many cases, adjacent contiguous buildings, which originally formed part of a continuous structural system of row buildings have been demolished, leaving former interior bearing walls exposed. It therefore becomes necessary to simplify the assessment of the stability of the buildings where conditions may be changing daily and multiple buildings, each unique in their own way, and time is not available for refining each model for a lengthy analysis.

What follows is a simplified approach to this problem which has been used with success in determining acceptable levels of stability for these buildings.

OBJECTIVES AND BENEFITS OF SPREADSHEET APPROACH

The basic objectives are:

- Provide guidelines for allowable tilt and lean of exterior unreinforced load bearing masonry walls due to effects of adjacent construction. Outward tilt and lean only are of interest, as inward tile is resisted by the floor system, stairway core and opposing wall.
- Provide rapid feedback to changing conditions regarding building exterior wall stability
- Assess sensitivity of results to various assumptions
- Provide means for mitigating potential instability

Current methods of rapid assessment are typically based on empirical rules, such as the "middle-third" rule, whereby there is no net tension on the extreme fibers of the wall assembly. Secondary effects which may contribute to the building stability are often ignored, such as castellation of the wall, internal dead loads which may provide a counterbalancing moment and friction. Typically these methods could be time consuming as each condition would need to be separately analyzed.

The spreadsheet assessment which has been developed by its nature allows for quick reappraisal. The spreadsheet also allows for quick assessment of sensitivity of results to varying assumptions. As the analysis is rapid, it can assume short-term conditions and, finally, there is an allowance in the standardized input for altered conditions on a building-by-building basis.

BASIC ASSUMPTIONS

Basic calculation assumptions are as follows:

- Wall acts as 3-sided plate fixed along three edges.
    - With regard to vertical edges, these must be fixed as the corner masonry is typically laid in alternating fashion. To be pinned would mean failure of the corner. The base condition is assumed fixed as the full moment is assumed to be resisted through eccentric loading of the base.
- Wall material properties are constant.
- Wall thickness is constant over the height of the building (exception: bearing walls, see below).
    - Weighted averages are incorporated for the effects of window openings and varying thicknesses from pier to infill brick to allow for the averaging effect on bearing area, bending and deflection.
- Window openings are ignored.
    - For flat plate deflection (assumed, see below) the critical location for the walls will be at the base of the walls.
- Vertical deflection is not accounted for in calculations.
- Initial deflection is linearly additive to wind induced deflections.
- Initial deflection is linear; i.e., the "flat plate" remains flat.
    - Initial calculations were based upon both circular arc and parabolic shape assumptions; however, the extreme sensitivity of the results to the specific shape of the curves, which were themselves assumptions, rendered them unusable.
    - Surface profiles taken of buildings have confirmed that flat plate assumptions are reasonable.
- P-delta effect is included on initial deflection but ignored on secondary deflection.
    - The mode of failure is assumed to be either crushing or overturning, not buckling.
- Wind pressure is constant over the façade.

    - This can be adjusted but was found to not have a significant effect on results.
- There is no tensile capacity in the masonry.
    - This assumption is based upon the observed deterioration of mortar joints. Inner wythes were typically fully deteriorated, the mortar only serving to transfer compressive forces. During probes the exterior brick units of the multi-wythe walls were found to have negligible bond in most instances.
- No allowance is made for the presence of tie-rods or masonry anchors.
    - These were observed to be present; however, their effectiveness could not be determined. Prior work had indicated that these could be fully deteriorated or that their connections may be ineffective. Their presence was therefore ignored for initial assessments.
- Deflection due to wind load adds to eccentricity of dead load.
- Edge loads are resisted by shear in interlocking brick at the façade vertical corners.
- The effects of masonry cracking on the wall response are ignored.
- The stabilizing effects of any stairway are ignored.
    - Where elevators are present, these will not be part of the original structure, suggesting substantial modification has been made to the building. These calculations would therefore not be applicable.

These assumptions are used for both façades and bearing walls. Additional calculation assumptions were found to be needed for bearing walls:

- Floor and roof dead and live loads are typically supported by the bearing walls via floor joists. The joists are typically supported by pockets formed in the multi-wythe walls. These bearing loads are eccentric to the wall in a direction which is beneficial in resisting outward tilting. The center of this bearing load is assumed to be ½ bearing length; hence, for a 4-inch bearing, the dead load will be centered 2-inches from the inside face of the bearing wall. This can be adjusted.
    - This was found to be a conservative assumption. As joists deflect the center of bearing will move towards the inner face. For joists supported by ledger beams, this assumption may be overly conservative.
- Friction between the joists and masonry contributes to stability (optional).
    - It is self-evident that wood beams/joists bearing on brick will resist sliding through friction. What is unknown is the coefficient of friction to be used.
- Snow is ignored, as it is a temporary and beneficial effect.
- Live load is ignored, as it is of unknown magnitude and is beneficial.
- Bearing walls act as beams supported between floors in resisting wind load.
    - This is a necessary assumption. For a typical 5-story building, three to four wythe bearing wall is typically 60 to 75 feet deep. Only nominal wind is required to destabilize the wall if it is assumed to be supported

along the front and rear edges only. As many of these structures have been in place for over 100 years, there must be other stabilizing effects. The coefficient of friction needed to enable this behavior is found to be reasonable to minimal in value.

- The deflection from beam-action from the previous assumption is negligible.

Further calculation assumptions are made where the thickness of bearing walls reduces above the first floor:

- Wall thickness reduces from the exterior.
- Presence of piers is ignored.
- Change in mass is reflected in both dead load compressive stress and negative moment induced by the eccentricity of the missing mass.

FAILURE CRITERIA

The issue of what constitutes acceptable levels of safety needs to be addressed. The author is not aware of this issue in any current building codes due to the historical nature of the buildings.

The prime focus of the calculations is overall stability of the exterior walls. Two modes of failure were therefore considered:

1. Material failure (crushing)
2. Overall stability

With regard to material failure, choice of material properties is clearly required. Use of allowable stresses, whether from current or previous codes, was adopted.

With regard to overall stability, there is no “allowable” stability or tilt of which the author is aware.

As the wall tilts, the center of force moves from the center of the wall thickness towards the outer fibers. Assuming that no tension can exist in the brick assembly (see earlier discussion), and assuming that the stress-strain curve is linear below allowable stress levels, then the form of the stress block resulting from combined vertical and outward loading will be triangular. As the outward load increases (whether due to wind or tilt), the maximum stress in the triangular block at the outer surface will increase while the width of the stress block will decrease. It was felt that limiting the size of the stress block to cover at least one brick would therefore constitute another “failure” criteria. Therefore, as the minimum wall thickness were typically 12 inches; i.e., 3 wythe, the limiting criteria would be that the stress block would be at least 1/3 wall thickness.

It is interesting to note that, in all cases, the controlling failure criteria was this “1/3 rule”. In no instance was vertical load ever sufficient to result in allowable stresses to be reached prior to the size of the stress block reducing below acceptable levels.

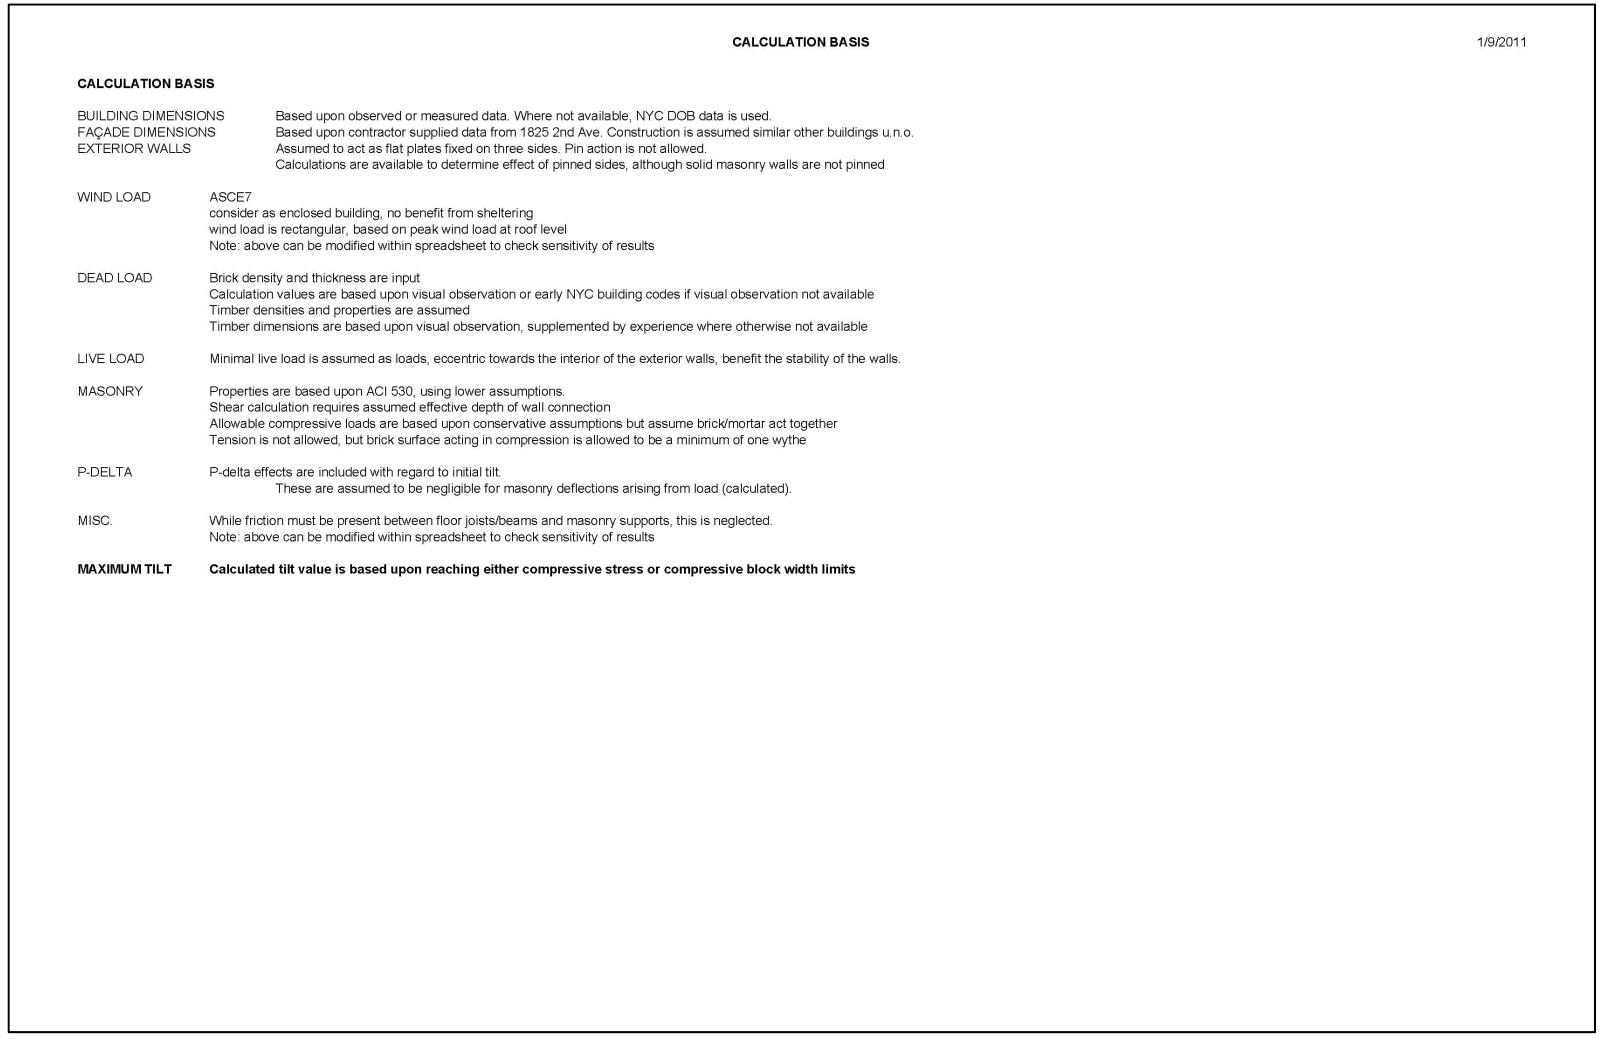
Clearly, there are other limiting criteria such as joist bearing failure. Such a failure could result not by an increase in load but through a reduction in bearing length which could arise from outward movement of the wall. This and other possible failure modes, were not included in the calculations. With specific reference to joist bearing failure, this was covered through direct observation of building movement combined with internal probes to determine existing conditions prior to any potential movement.

Once the failure criteria were established, an additional factor of safety was applied. This factor of safety is applied to the results of the overall calculations; i.e., tilt, and is additional to the inherent factors of safety in allowable compressive and shear stresses.

During calculations on the specific building, basic conservative assumptions are made regarding building height, width, wall thickness, material properties and floor construction. Where measured data is known, calculations will be more precise.

Figures 1 through 5 are extracted results of sample calculations following the above assumptions. Note the available flexibility in input and results. Additionally, while fixed edges are assumed for the flat plate calculation, comparative calculations are also made for the simply supported condition.

It is found that results are very sensitive to the wind pressure loading. This is not surprising, given the height and type of construction. With regard to bearing walls, the use of friction is required to show stability. This is also not surprising, as the effects of the floors framing into the bearing walls has a stabilizing influence on the building not unlike modern floor frame to multi-story columns. What is particularly interesting is both the low value of friction needed to obtain stability and the sensitivity of the results to the value of friction coefficient chosen.



A view of the results in Figure 2 will also show that, even when only the outer wythe of the bearing wall is mobilized, in this case, less than the 1/3 of the overall thickness, the compressive stress, with all dead load included, is still below allowable values.

CONCLUSIONS

A rapid method to assess historical masonry buildings has been developed. The tool is still under development, being refined with regard to variations in building configurations, load conditions and other details. Notwithstanding, it has provided a means to quickly identify buildings requiring possible mitigation. Additional tools have been developed with regard to mitigation strategies for securing the facades against further deterioration.

CALCULATION BASIS 1/9/2011

CALCULATION BASIS

BUILDING DIMENSIONS	Based upon observed or measured data. Where not available, NYC DOB data is used.
FAÇADE DIMENSIONS	Based upon contractor supplied data from 1825 2nd Ave. Construction is assumed similar other buildings u.n.o.
EXTERIOR WALLS	Assumed to act as flat plates fixed on three sides. Pin action is not allowed. Calculations are available to determine effect of pinned sides, although solid masonry walls are not pinned
WIND LOAD	ASCE7 consider as enclosed building, no benefit from sheltering wind load is rectangular, based on peak wind load at roof level Note: above can be modified within spreadsheet to check sensitivity of results
DEAD LOAD	Brick density and thickness are input Calculation values are based upon visual observation or early NYC building codes if visual observation not available Timber densities and properties are assumed Timber dimensions are based upon visual observation, supplemented by experience where otherwise not available
LIVE LOAD	Minimal live load is assumed as loads, eccentric towards the interior of the exterior walls, benefit the stability of the walls.
MASONRY	Properties are based upon ACI 530, using lower assumptions. Shear calculation requires assumed effective depth of wall connection Allowable compressive loads are based upon conservative assumptions but assume brick/mortar act together Tension is not allowed, but brick surface acting in compression is allowed to be a minimum of one wythe
P-DELTA	P-delta effects are included with regard to initial tilt. These are assumed to be negligible for masonry deflections arising from load (calculated).
MISC.	While friction must be present between floor joists/beams and masonry supports, this is neglected. Note: above can be modified within spreadsheet to check sensitivity of results
MAXIMUM TILT	**Calculated tilt value is based upon reaching either compressive stress or compressive block width limits**

Figure 1 - Example spreadsheet. Calculation basis.

Problems in the Repair of Historic Brick Masonry Buildings

James S. Cohen, MASCE, PE[1]

[1]Associate Principal, Arup, 155 Avenue of the Americas, New York, NY 10013; PH (212) 229-2669; FAX (212) 229-1056; email: james.cohen@arup.com

Older load bearing brick masonry structures are often in a condition of advanced deterioration and may be leaning, bowing, cracking or suffering some other form of deterioration. Problems may arise from nearby demolition, excavation or just a general lack of maintenance. Many of these may be in danger of imminent collapse. The problem of detecting problems, effecting repairs and stabilizing these buildings is presented. Case studies showing examples of these problems and possible solutions are presented.

INTRODUCTION

The aging building inventory and desire to renovate or adapt the existing building stock has led to the need to engage in the evaluation and repair of these ever-aging and deteriorating buildings. In almost all cases repairs are possible, but often the cost associated with these repairs is difficult to justify. Such difficulties may exist when repair involves partial reconstruction of the building or supporting foundations or installation of supplementary structural systems.

The following are examples of some of the issues which may be encountered during evaluation and repair.

HIDDEN DAMAGE

The original building, a masonry warehouse and manufacturing facility constructed circa 1862, consisted of four structures were at some time in their history connected and extended. At the time the author became aware of these structures a nearly total collapse of one and partial collapse of another had occurred. The collapses occurred simultaneously during an attempted renovation. A view of these buildings is given in Figure 1.

The collapse allowed a rare observation of the method of connecting the three wythes of the brick masonry wall. This can be seen in Figure 2. Although there are bonding courses, no mortar could be discerned connecting the individual wythes together.

In the rear significant vegetative growth against the buildings could easily be observed, as shown in Figure 3. Of greater significance was the growth between the wythes of the brick walls resulting in complete separation of the wythes and almost total loss of structural integrity. Figure 4 shows plant growth coming out from between the wythes at a joint in one of the walls. The growth has resulted in movement of the wall and separation of the brick.

Figure 1 - View of building frontage. Two facades are collapsed, the remaining two adjacent buildings remain intact.

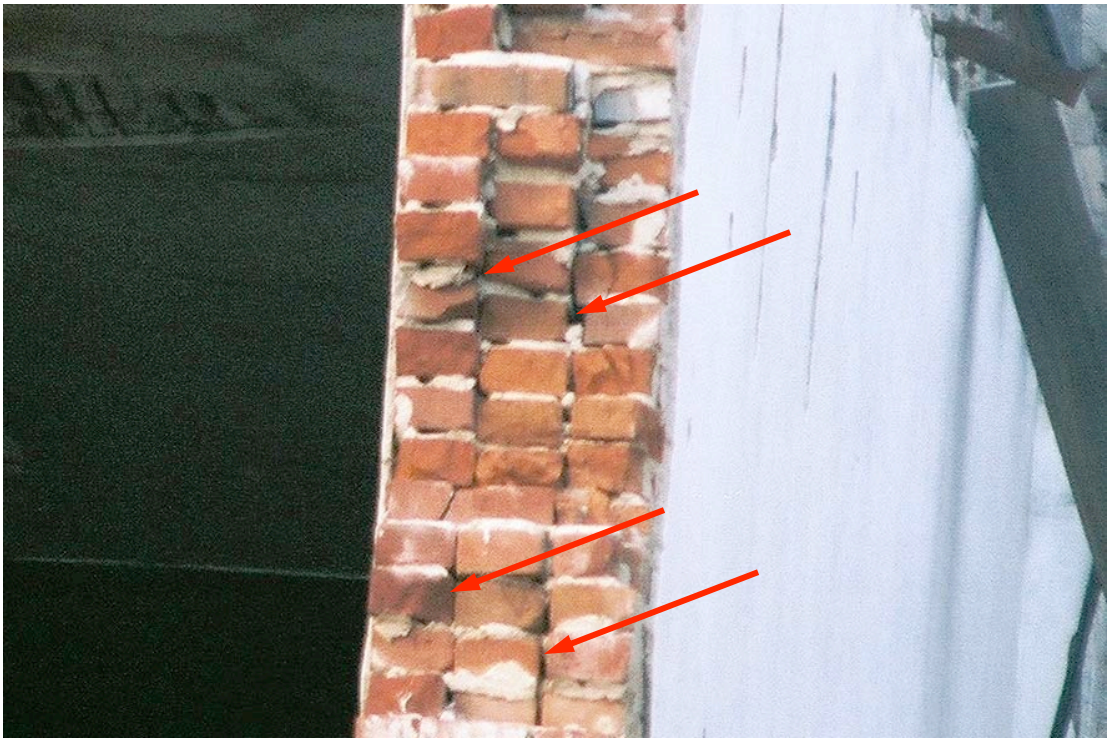

Figure 2 - Lack of mortar and separation of wythes would have been hidden.

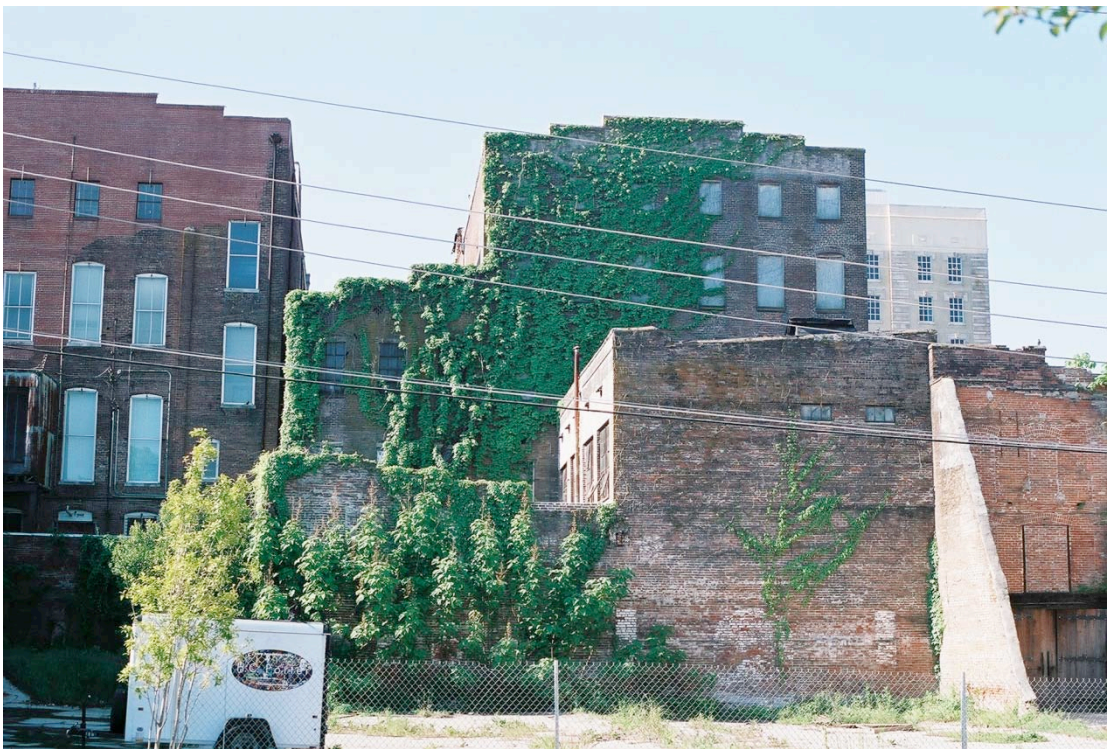

Figure 3 - Significant vegetation against the buildings. The rear of all four structures can be observed. The tree-like plant to the right has roots which commence within the brick wall and cannot be seen from the exterior.

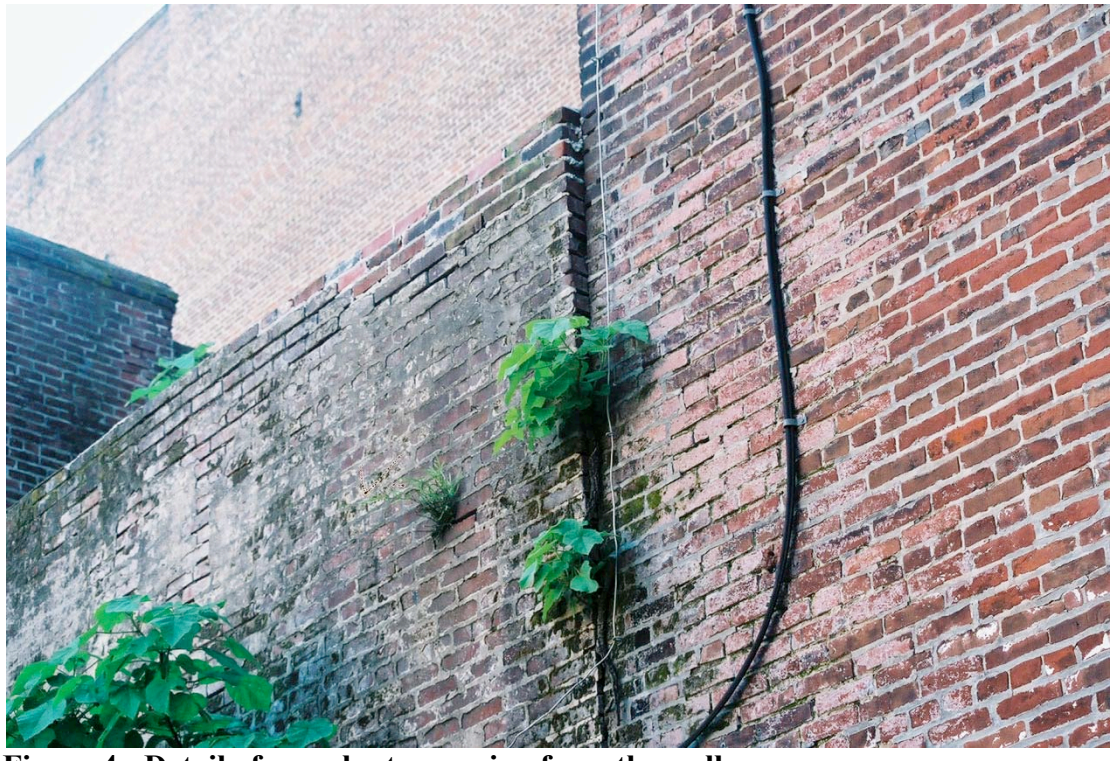

Figure 4 - Detail of one plant emerging from the wall.

In addition to these issues was significant evidence of powder post beetle attack to interior timber joists. Additionally, there was evidence of many prior collapses with missing floors and walls towards the rear of the building.

At the time of the collapse attempts were being made to repoint the masonry, but this was a surface treatment, as knowledge of the internal damage was unknown. Notwithstanding, the precipitating cause of the collapse was overloading of the roof due to ponding water, likely exacerbated by rotted joists, which were also visible at the upper levels, particularly in the vicinity of the collapse.

It is unlikely that the condition of the building at the time of collapse would have allowed for significant reclamation of the structure with the exception of the street facing Civil War era facades.

BUILDING MOVEMENT

Older buildings were generally built upon shallow foundations. Basements were generally located at foundation level. Where these are not located on firm ground, settlement over the years will occur. This is often aggravated by adjacent construction, disturbing the ground, particularly when excavation goes below the existing building's foundation line.

Buildings thus affected may lean, or tilt, typically in the direction of the adjacent construction.

Figure 5 shows underpinning which was undertaken to a building after damage had already occurred. Excavation below the level of the existing had taken place and soil had sloughed out from beneath the building. The building consequently cracked across its width and tilted towards the excavation. Underpinning was then installed to prevent further damage. In the figure the building is visible at the top, the original foundation in the center and the new underpinning beneath.

Careful observation will also show a shrinkage crack developing between the new underpinning and the original foundation wall. While drypack was applied, this was done after only a short period of time had elapsed from pouring the underpinning. Adjacent panels had already been placed and hardened. As a result, the more recent panel shrinks differentially from those adjacent. Depending upon the pattern of pours and ages of the various panels, damage to the original building will continue to occur.

Lean, or tilt, of the overall structure may occur without any evidence of adjacent excavation. Figure 7 is an illustration of extreme tilt of a building with no evident cause, other than age. The presence of the newer building provides a reference to the extent of movement experienced by the older building after completion of the new structure. This older building did, in fact, suffer a partial collapse shortly after this photograph was taken.

Figure 5 - New underpinning beneath original foundation of a building damaged by the adjacent construction. Shrinkage of the underpinning is likely to result in continued damage.

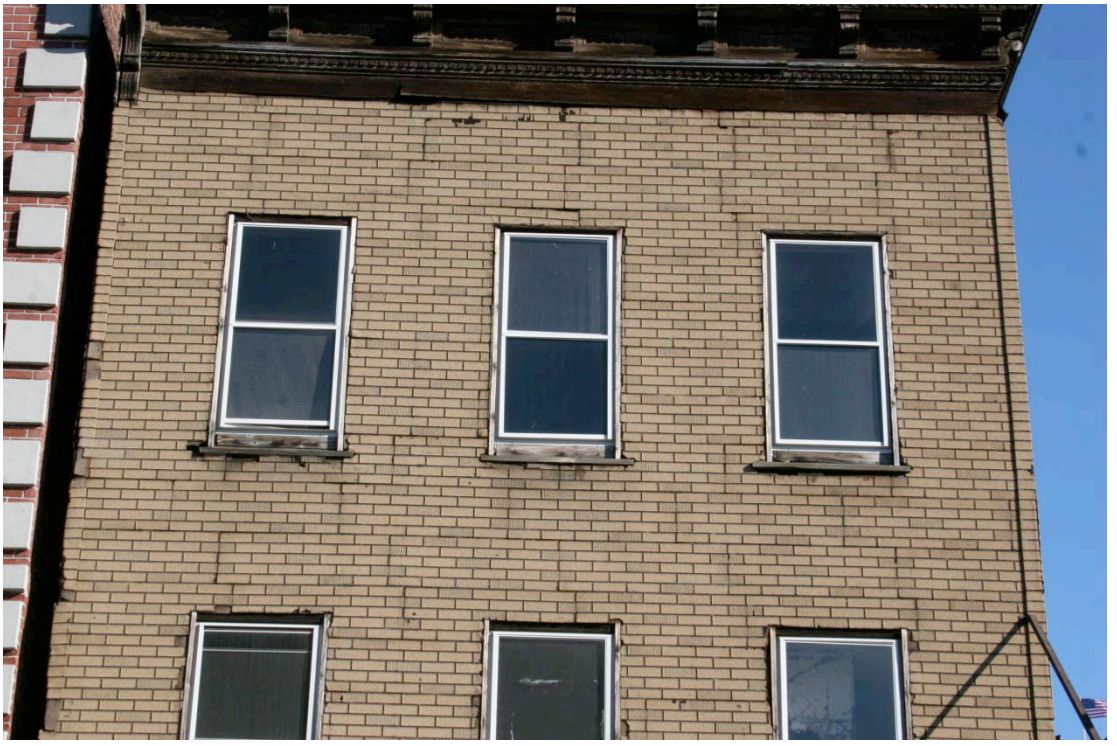

Figure 6 - Approximately 8 inches of tilt away from the newer building. The structure is also racking. A partial collapse of the side wall occurred shortly after this photograph was taken.

Frequently at issue in the repair of such structures is the desire to preserve the building for its historical value. This may hamper stabilization resulting in collapse as with the first example.

The potential for tilting is often dealt with by installing tie plates to the exterior of the building and connecting within. The intent is to tie the two outer walls together, or otherwise anchor one exterior point to an immovable point within the interior, such as a foundation or cross-wall.

Methods may involve simple plates on the exterior of a building at regular intervals, typically at floor levels. These can be unsightly and detract from the building. Sometimes decorative elements are substituted as a means to provide an aesthetically pleasing solution to the problem of attaching an external structural element to an older structure. Cast iron stars have sometimes been used for this purpose, as have other shapes.

The first problem encountered with regard to installation of tie plates is determining to what building component it is to be anchored. In addition to forces generated by any tilt, wind and other lateral loads may need to be transferred. Often this is the opposing wall, particularly for the narrower older buildings. Unfortunately, these opposing walls may not be accessible from the exterior, or the attachment may encroach on the adjacent property. Attempting to fix the tie-rod or cable to a blind side through anchors or other devices should first involve load tests to demonstrate the ability of the connection, and connecting part, to support the requisite loads.

Another issue is the pre-tension that needs to be present in the tie-rod. If cable is used, any slack present needs to be removed, as the ability of a cable to stretch may be beyond the ability of the supported wall to move without distress. This will also require regular inspection and retightening as the cable will stretch over time.

Rods need to be made snug; however, “snug” is a loose term that will require definition. The ability of the masonry to support the pretension in the rod needs to be determined. The sensitivity of the pre-tension to seemingly minor rotation of connecting threaded parts also needs determination. It is a simple matter to determine how much rotation of a nut will result in increased tension of a rod, but that is after all is first made “snug” and slack is removed.

With regard to substituting stars or other seemingly structural adornment as the anchor piece for a simple plate is also “proving” the ability of the anchor to be able to support the load. The masonry surface is unlikely to be flat and the anchor may similarly not be flat. A problem with these alternatives was recently demonstrated by a contractor’s proposal to use cast iron stars as anchors on a series of listed buildings. The loads involved were relatively low, particularly as the masonry was assumed to have only minor shear strength with which to resist the anchor load exerted by the plate on the face of the building. Notwithstanding, the decision was made to test a random sample of the stars to determine the likely breaking strength and hence factor

of safety in the completed installation. The test setup is shown in Figure 7. As the stars were uneven across their back, bearing, face, the test was arranged to see what load in bending the star arms might be able to resist.

The stars broke at widely varying loads, some as low as a few hundred pounds. Macroscopic examination of the fracture surface of these low breaks showed numerous inclusions and voids within the casting. Figure 8 shows one star following fracture. Most fractures had an evident initiation point for the failure. Maximum loads could be correlated to the size and location of these internal defects. In one instance the defect consisted of two pre-existing cracks, as was evident by the discoloration of these areas.

OCCUPANCY

It often happens that buildings may be occupied when repairs, strengthening or other mitigation strategy is being planned. This results in a desire to minimize the effects of the work and evaluation on the residents. Where the optimal solution may be to install ties across the building, the disruption to internal finishes and the need to temporarily relocate the occupants may be prohibitive.

Figure 7 - Test arrangement for cast iron star anchor

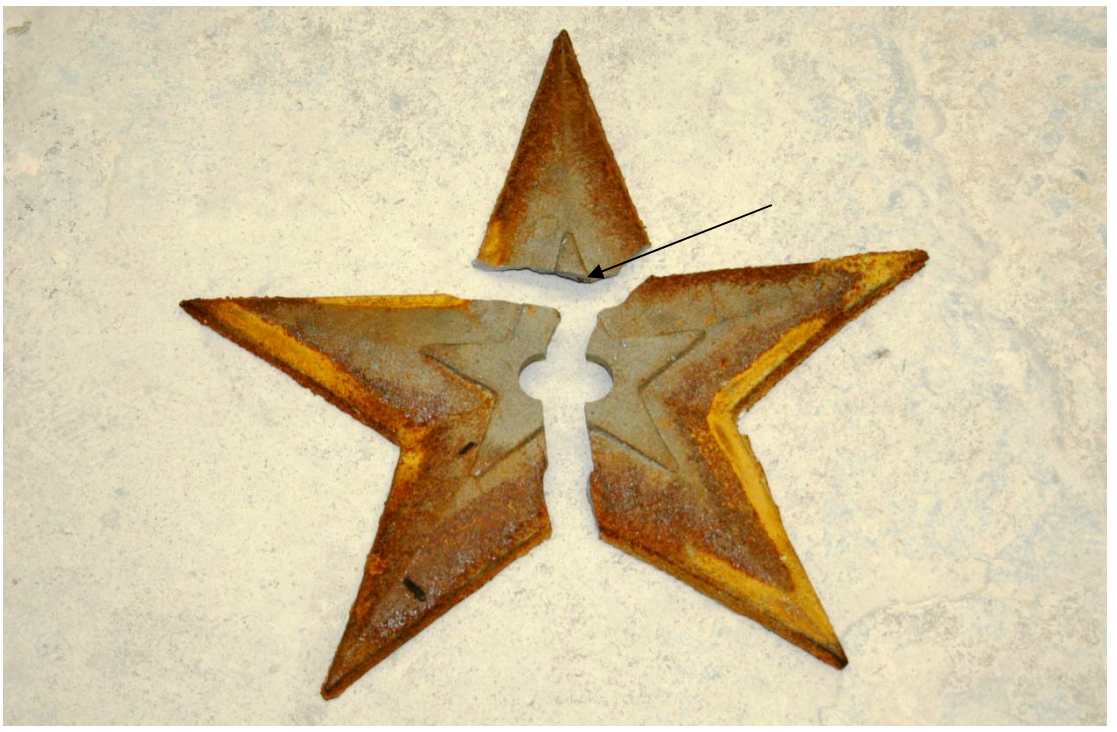

Figure 8 - Breakage of an anchor. Arrow points to defect in the casting.

While it is difficult to replace invasive inspection techniques to determine the condition of a structure, sampling methods and careful selection of probe locations may provide sufficient confidence in the results of the evaluation. Exterior observations can often lead to a more judicious selection of probe locations by identifying those areas or zones which have had seen prior repairs or alterations, or, alternatively, show the greatest tendency to water penetration or other deterioration.

Innovative solutions may be required to install the ties. As previously indicated, tie-rods or cables are often employed as a means of connecting opposing walls. These have the advantage of being located within a ceiling plenum or other hidden unused space. However, they often also typically require access to the ceiling space for installation. Alternative methods of tie the walls together may involve using the existing building elements as tie-rods. Typically floor joists are utilized for the purpose. Invasive procedures may then be limited to relatively small ceiling openings sufficient to effect a bolted connection from the externally applied tie-plate to the timber floor joist.

This latter solution can be used where the floor joist is continuous between opposing walls or are adequately tied together at interior walls to enable the forces to be transferred. Consequently, this approach is only possible for bearing walls, which also tend to have a closer spacing than the façades which run parallel to the floor joists.

Connecting to the floor joists from a façade is unlikely to have any true stabilizing effect on the façade as the bending stiffness of a floor joist in its weak is likely to be significantly lower than the stiffness of the masonry façade and the deflection available to the joist without distress will be much smaller than that available to the façade. Hence, to use the floor joists as a means of stabilizing the façade it becomes necessary to either mobilize the floor system as a diaphragm, create a strong, stiff element from the joists.

The former solution, while possible, assumes that the floor system, consisting of the sub-floor and any overlay, is sufficiently fixed to the floor joists to achieve a sufficient diaphragm for distribution of the façade tie-back loads. As the tie-rod load will necessarily be applied to the joists some vertical distance away from the sub-floor connection, it then also becomes necessary to connect the tie-rods to sufficient parallel joists in succession to avoid the possibility of rotating the joists and breaking their connection to the flooring. This may involve significant disruption to the existing ceiling finishes and, consequently, the residents.

An alternative approach is to create a truss from the parallel joists, thus converting their action from weak bending to purely tensile or compressive loads parallel to the grain of the timber. This will involve the addition of truss diagonals within the ceiling which, while disruptive, may only require removal of sufficient ceiling finishes to expose two or three joists.

An additional recent possibility for mobilizing multiple floor joists, using the floor system as a diaphragm, is the Cintec anchor. An anchor, surrounded by a fabric sock, is installed through pre-drilled oversized holes. Cementitious or other grout is injected through the middle of the anchor under low pressure. It passes through a series of grout flood holes into the fabric sock, inflating the entire assembly like a balloon. The advantage is the ability to install the anchoring system without removal of the ceiling finishes, thereby minimizing impact to the residents.

DEFINING THE STRUCTURAL SYSTEM

Older masonry buildings tended to be built to a prescriptive code, if any, such as the 1901 Building Code of the City of New York, an extract of which is presented in Figure 9.

These prescriptive codes provide a good deal of information on the potential construction of the existing building but may not be accurate on any specific structure. Alterations, repairs and strengthening strategies must be designed specific to the structure. Location of piers, details of cast iron assemblages and condition of materials can all vary.

Figure 10 below shows the results of a probe through a storefront. While it was known that there was a horizontal cast iron piece spanning between cast iron columns, it was not known that this consisted of discontinuous plates over which masonry arches were effectively spanning between columns. The system, which

appears to have been intended to use the cast iron in tension and the brick in compression, presumably also relied upon the bond between the infill masonry and the cast iron to complete the structural system.

Figure 9 - Exposed masonry arch over cast iron plate spanning between cast iron columns.

In general, sources of information contemporary to the historic building can assist in determining what structural system was envisaged by the designer or builder even if, in today's environment, such a system would not normally be implemented. These contemporaneous references can also provide information regarding construction methods, allowable loads, stresses and other physical properties of the materials in use at that time. This information is invaluable to assessing and repairing the older building.

CONCLUSIONS

Older load bearing brick masonry structures are often in a condition of advanced deterioration. Problems can arise from nearby demolition, excavation or just a general lack of maintenance. Many of these may be in danger of imminent collapse. While such structures may often be difficult to justify repairing, sufficient planning and investigation and awareness of the limitations being imposed on any investigation or repair may still lead to a successful outcome.

This paper can only present a small sample of the many issues facing repair and restoration of older buildings. It is hoped that the information and examples presented will help to inspire others.

Sec. 40.—*Walls of Unfinished Buildings.* Any building, the erection of which was commenced in accordance with specifications and plans submitted to and approved by the Department of Buildings prior to the passage of this Code, if properly constructed, and in safe condition, may be completed, or built upon in accordance with the requirements of law, as to thickness of walls, in force at the time when such specification and plans were approved.

Sec. 41.—*Walls Tied, Anchored and Braced.* In no case shall any wall or walls of any building be carried up more than two stories in advance of any other wall, except by permission of the Commissioner of Buildings having jurisdiction, but this prohibition shall not include the inclosure walls for skeleton buildings. The front, rear, side and party walls shall be properly bonded together, or anchored to each other every six feet in their height by wrought-iron tie anchors, not less than one and a half inches by three-eighths of an inch in size, and not less than twenty-four inches in length. The side anchors shall be built into the side or party walls not less than sixteen inches, and into the front and rear walls, so as to secure the front and rear walls to the side, or party walls, when not built and bonded together. All exterior piers shall be anchored to the beams or girders on the level of each tier. The walls and beams of every building, during the erection or alteration thereof, shall be strongly braced from the beams of each story, and when required, shall also be braced from the outside, until the building is inclosed. The roof tier of wood beams shall be safely anchored, with plank or joist, to the beams of the story below until the building is inclosed.

ABSTRACT

A structural reliability analysis was performed on concrete masonry under concentric axial compression to examine the reliability levels for masonry buildings designed to the current Canadian masonry standard CSA S304.1-04 (2004). The first order second moment method was used to carry out the analysis. Prism compressive strength for hollow and grouted concrete masonry was used as the model. Over 300 specified masonry compressive strength values were computed using test results available from North American investigations, mostly Canadian. The material and geometry statistical data needed were obtained from several Canadian concrete masonry producers. Based on the findings of this investigation, it is recommended that unreinforced masonry be assigned a material resistance factor (ϕ_m) different from reinforced masonry. For masonry members under compression, it is proposed that the current ϕ_m be increased from 0.6 to 0.65 for reinforced masonry and decreased from 0.6 to 0.5 for unreinforced masonry. The proposed factors correspond to reliability indices of 3.5 and 3.8 for reinforced and unreinforced masonry, respectively.

INTRODUCTION

The reliability of a structure is defined as the probability that it will not fail during a specified period of time under a given state of loading. The primary purpose of structural reliability is to control and manage the risk of failure to acceptable levels. In the late 1970's and early 1980's in Canada, Turkstra et al. (Turkstra and Daly 1978; Turkstra and Ojinaga 1980; and Turkstra et al. 1982) performed a series of reliability based analyses on structural masonry intended to help change the Canadian masonry design standard from the working stress method (the design approach of the time) to the limit states design approach. Test data for brick masonry walls under axial compression and out-of-plane bending were used. Turkstra proposed a value of 0.4 for the masonry material resistance factor (ϕ_m) in the early drafts of the 1994 Canadian masonry design standard (CSA S304.1-94). However, the proposed value was not adopted.

In the 1992 Drysdale's calculation published recently as an appendix to Laird et al. (2005), masonry prism strength was used as the model for a reliability analysis of masonry under compression. Compressive strength test data for two-unit high prisms were used. Recognizing that strength measured from testing two-unit high prisms is usually higher than the wall/true strength, a member variable was introduced to the reliability expression. The member variable and its coefficient of variation were judged to be 0.85 and 0.05; respectively. A masonry material resistance factor of 0.55 was proposed and adopted in the earlier edition of the Canadian masonry design standard (CSA S304.1-94). The resistance factor was later increased from 0.55 to 0.60 in the current Canadian masonry design standard (CSA S304.1-04) based on the same analysis.

The effect of workmanship on the reliability analysis of structural masonry is well recognized (Turkstra and Ojinaga, 1980; Turkstra et al., 1982; Drake et al., 2004 and Drysdale, 1992 in appendix to Laird et al., 2005). Some of the main sources of workmanship uncertainty are the thickness and filling of the mortar joints, wall plumpness, and compliance of geometry with design requirements, grouting procedures, and the level of quality control during construction. Turkstra et al. (1982) reported that the workmanship factor ranged from 1.0 for inspected masonry construction to 0.7 for uninspected masonry with coefficients of variation of 0.1 and 0.2; respectively. Turkstra and Ojinaga (1980) suggested an average workmanship factor of 0.8 with 0.15 coefficient of variation. Drysdale (1992, appendix to Laird et al., 2005) used a workmanship factor of 0.8 with a coefficient of variation of 0.2.

This paper reports on a structural reliability analysis that was performed on concrete masonry under concentric axial compression. The objective was to examine the reliability levels in the current Canadian masonry design standard (CSA S304.1-04). In this analysis, prism compressive strength for hollow and grouted concrete masonry was used as the model. Test data for the compressive strength of masonry prisms were gathered from available North American literature, mostly Canadian investigations. The material and geometrical statistical data needed for the reliability analysis were obtained from several Canadian concrete masonry producers.

TARGET RELIABILITY

The reliability of a structure is defined as the probability that it will not fail during a specified period of time for a given limit state. Structural reliability analysis is based on defining a level of safety or a reliability index β as shown in Figure 1. If the safety margin Y is the difference between the resistance R and the demand/load U, then β can be expressed in terms of the number of standard deviations, σ_Y, between $\bar{Y}$, the mean value of Y, and $Y = 0$.

$$\beta = \frac{\overline{Y}}{\sigma_Y} \qquad \text{Eq.1}$$

Structural reliability is sensitive to the value of the reliability index which is a function of a range of factors including the type of failure, estimated cost of failure

and existing levels of safety (Lawrence and Stewart, 2009). The target reliability index has to strike a balance between minimizing the probability of failure and construction cost. Higher reliability indices result in lower material resistance factors and hence higher construction cost.

A target reliability index for limit states design may be based on calibration to previous design codes, comparison to other structural materials, or acceptable risk compared to other human activities. MacGregor (1976) compared the risk of death for different activities to the risk of failure of structures. It was concluded that the probability of failure of a building should not be less than 10^{-5} per year. This corresponds to a probability of failure of 3×10^{-4} and $\beta = 3.45$ during the 30 year life of a typical building in Canada. Table A5 in the Canadian CSA S408 (1981−R2006) suggests that a value of $\beta = 4.0$ should be used for a normal importance building with a brittle type of failure. Consequently, a value of $\beta = 3.5$ is used for ductile structures with normal consequences of failure and a value of $\beta = 4.0$ is used for brittle structures with severe consequences of failure. Stewart and Lawrence (2006) proposed a reliability index value of 3.8 for structural unreinforced masonry in accordance with the Australian Standard AS 5104 (2005).

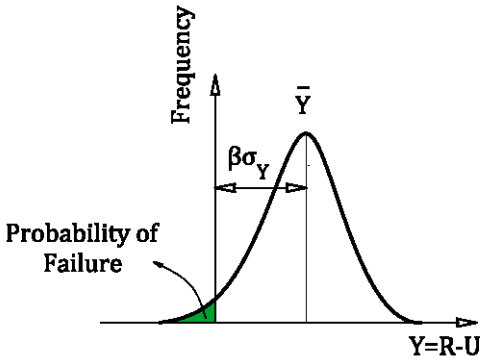

Figure. 1 Frequency distribution of the safety margin.

STRUCTURAL RELIABILITY METHODOLOGY

The first order second moment (FOSM) method has been used in structural reliability analysis since the 1970's. It is called first order in the sense that a linear function for the safety margin is used ($Y = R - U$) and second moment because it considers a special case of reliability estimation in which each variable is represented only by its mean, $\bar{Y}$, and standard deviation, σ_Y, (Melchers, 1999). Based on the FOSM method, two main approaches could be used to perform a structural reliability analysis: the separation function approach and the limit state function approach. The former was used in the current analysis.

In the separation function approach, a reasonable probability of failure is selected compared to an acceptable level of risk in other human activities. Having selected β and found the mean and coefficient of variation for resistance and load, a proper combination of the material resistance factor (ϕ) and load factor (λ) is determined.

The probability of failure, P_f, is expressed as:

$$P_f = P[\ln\left(\frac{R}{U}\right) < 0] \quad \text{Eq.2}$$

From the definition of β (Eq.1), one can write:

$$\overline{\ln(R/U)} \geq \beta\sqrt{\sigma^2_{\ln(R)} + \sigma^2_{\ln(U)}} \quad \text{Eq.3}$$

For a log-normal distribution, the coefficient of variation can be expressed as:

$$V_x^2 \cong \sigma^2_{\ln(x)} \quad \text{Eq.4}$$

Substituting in Eq.3, one can write:

$$\overline{\ln(R/U)} \geq \beta\sqrt{V_R^2 + V_U^2} \quad \text{Eq.5}$$

Where, V_R and V_U are the coefficients of variation for resistance and load, respectively.

$$\sqrt{A^2 + B^2} \cong \alpha A + \alpha B \quad \text{Eq.6}$$

Equation 6 was proposed (Lind, 1971) to linearize the right hand side of Eq.5 using a separation function α that enables treating resistance separate from load. The value of α ranges from 0.707 to 1.0 and depends mainly on the level of the reliability index and the live-to-dead load ratio. A slight change in the separation factor ($\alpha = 0.75 \pm 0.06$) was noted for a wide range of A/B ratios. A separation factor of 0.75 was used in the 1992 calculation by Drysdale (appendix to Laird et al., 2005) which is the basis for the masonry material resistance factor in both the 1994 and 2004 editions of the Canadian masonry standard (CSA S304.1-04). A value of 0.75 for the separation factor was used in the current study.

Using the separation function introduced in Eq.6, the reliability expresion (Eq.5) can be simplified as follows:

$$\bar{R}e^{-\beta\alpha V_R} \geq \bar{U}e^{\alpha\beta V_U} \quad \text{Eq.7}$$

The reliability expression in a resistance factor (ϕ) and load factor (λ) format is:

$$\phi R_n \geq \lambda U \quad \text{Eq.8}$$

Comparing Eqs. 7 and 8, ϕ can be expresed as:

$$\phi = \frac{\bar{R}}{R_n}e^{-\beta\alpha V_R} \quad \text{Eq.9}$$

Where, $\bar{R}$ and R_n are the average and nominal member strength, respectively.

Because of the interdependence of the resistance and the load factors, a correction factor less than 1.0 is applied when the target β is greater than 3.0 and greater than 1.0 when the target β is less than 3.0. Since the target β for structural masonry ranges from 3.5 to 4.0, Eq.9 is adjusted as follows:

$$\phi = C\frac{\bar{R}}{R_n}e^{-\beta\alpha V_R} \quad \text{Eq.10}$$

Where, C is a correction factor that can be derived using the procedure described by Fisher et al. (1978).

$$\mathrm{C} = \frac{1.086(1.0933 + 1.3936\ \mathrm{L/D})}{\mathrm{e}^{0.0275\,\beta}[1 + 0.03111\,\beta + (1 + 0.1313\,\beta)\mathrm{L/D}]} \quad \text{Eq.11}$$

Where, L/D is the live-to-dead load ratio.

STRUCTURAL RELIABILITY ANALYSIS

In this study, Eq.10 was used to examine the reliability levels for reinforced and unreinforced masonry designed according to the Canadian masonry standard CSA S304.1-04 under concentric axial compression. Hollow and fully grouted masonry prisms were used to represent unreinforced and reinforced masonry, respectively. Two statistical parameters need to be defined foe Eq.10, that is the mean and coefficient of variation of the resistance ratio ($\bar{R}/R_n$). These parameters were derived using a modified version of Eq.12 which was proposed by Galambos and Ravindra (1977):

$$\frac{\bar{R}}{R_n} = \frac{\bar{G}}{G_n} \times \frac{\bar{M}}{M_n} \times P \quad \text{Eq.12}$$

Where, $\bar{G}$, G_n, $\bar{M}$, M_n and P are the average geometrical property, nominal geometrical property, average material strength, nominal material strength, and professional ratio; respectively.

The compressive strength of a prism is not linearly related to the compressive strength of the unit. The British masonry code (BS 5628, 2005) and the Australian masonry standard (AS 3700, 2001) offer a relationship in which the characteristic masonry compressive strength is related to the square root of the unit strength. This implies that the square root of $\bar{M}/M_n$ should be used for computing the material statistical properties.

The effect of workmanship on the reliability of masonry structures is directly related to construction quality control. The British masonry code (BS 5628, 2005) recognizes two categories of quality control for unreinforced masonry: normal and special. Masonry partial safety factors ($\gamma_m = 1/\phi_m$) for normal inspection are higher than for special construction inspection. The effect of workmanship is more pronounced in unreinforced masonry than in reinforced masonry construction. Even with special inspection, the British code assigns lower partial safety factors for reinforced masonry

than for inspected unreinforced masonry. Based on the work by Turkstra et al. (1982), the workmanship factor *K* was taken in this analysis as 0.8 for unreinforced masonry and 0.9 for reinforced masonry with a coefficient of variation of 0.15 for both.

Considering the effect of workmanship and that prism strength is related to the square root of the unit strength, the statistical parameters for masonry resistance under compression are expressed as:

$$\frac{\bar{R}}{R_n} = \frac{\bar{G}}{G_n} \times \sqrt{\frac{\bar{M}}{M_n}} \times P \times K \qquad \text{Eq.13}$$

$$V_R = \sqrt{{V_G}^2 + \frac{1}{4}{V_M}^2 + {V_P}^2 + {V_K}^2} \qquad \text{Eq.14}$$

Where, V_G, V_M, V_P, and V_K are the coefficients of variation for geometry, material, professional, and workmanship factors; respectively. In Eq.14, the coefficient of variation of the material factor is multiplied by ¼ to account for the square root influence of the factor.

Hollow and grouted masonry prisms were used to represent masonry members under concentric axial compression. Instead of introducing a member variable based solely on judgement, prism compressive strength data were adjusted for the height-to-thickness ratio according to Table D1 of Annex D in the Canadian masonry design standard CSA S304.1-04. The adjusted values are believed to be representative of the compressive strength of masonry members.

Over 300 specified masonry compressive strength values were computed using test results for hollow and grouted concrete prisms from 31 journal articles, theses, and dissertations reporting research that has been carried out in North America, mostly in Canada. Table 4 of CSA S304.1-04 provides compressive strength values for 10-40 MPa concrete block units. A minimum grout compressive strength of 10 MPa is required for grouted masonry as per CSA A179 (2004). Experimental data points for masonry units having compressive strength lower than 10 MPa or higher than 40 MPa and for grout having compressive strength lower than 10 MPa were excluded.

The professional factor was determined by comparing the specified masonry compressive strength, computed from test data according to Annex C of CSA S304.1-04, to the nominal strength based on unit strength and mortar type as per Table 4 of CSA S304.1-04. It is well established that the professional factor computed from test results include variations of the test procedures and specimen variability in addition to the model inaccuracy (Stewart and Lawrence, 2006 and Ellingwood , 1981). Therefore, the variability in the professional factor could be expressed as:

$$V_P = \sqrt{{V_{model}}^2 - {V_{test}}^2 - {V_{spec}}^2} \qquad \text{Eq.15}$$

Where, V_P is the coefficient of variation (COV) of the professional factor, V_{model} is the COV of the model obtained from the ratio of measured to predicted strength, V_{test} represents the variation in the measured loads due to inaccuracies in the test measurements and/or the definitions of failure, and V_{spec} represents several uncertainties regarding the differences between the measured and actual parameters of the test specimens. Ellingwood (1981) suggested a value of $V_{test} = 0.02$ and $V_{spec} = 0.04$. These values are used in this study to compute the COV for the professional factor. The statistical parameters for the professional factor are summarized in Table 1.

Table 1. Statistical parameters for the professional factor.

Masonry Construction	Mean	V_{model}	V_P
Hollow	1.24	0.22	0.215
Grouted	1.34	0.22	0.215

To determine the material and geometry factors, 500 data points were collocated from five Canadian concrete block producers. The compressive strength of the blocks varied from 13 MPa to 34 MPa. The concrete block units were 390 mm in length and 190 mm in height. The block width varied from 90 mm to 240 mm in 50 mm intervals. The material ratio was obtained as the ratio of the measured compressive strength of the concrete block to its nominal compressive strength. Mortar was not considered in the analysis as part of the material ratio. To obtain the geometry ratio, the ratio between the actual and nominal cross-sectional areas was calculated. The statistical parameters for the material and geometry factors are given in Table 2.

Table 2. Statistical parameters for the material and geometry factors.

Property	Mean	Coefficient of Variation
Material (Unit Compressive Strength)	1.41	0.170
Geometry (Unit Cross-sectional Area)	1.00	0.002

Using the parameters of Tables 1 and 2, the mean and coefficient of variation for the resistance ratio ($\bar{R}/R_n$) were computed from Equations 13 and 14 for hollow and grouted masonry construction. The values are listed in Table 3.

Table 3. Statistical parameters for the resistance ratio ($\bar{R}/R_n$).

Masonry Construction	Mean	Coefficient of Variation
Hollow	1.178	0.276
Grouted	1.432	0.276

RESULTS AND DISCUSSION

Using Eq.10 and the statistical parameters in Table 3, relationships between masonry material resistance factor (ϕ_m) and the reliability index (β) were constructed and are plotted in Figure 2 for live-to-dead load ratios from 0.5 to 3.0. As can be seen from Figure 2, the relationship between ϕ_m and β is not sensitive to the live-to-dead load ratio (very close lines forming a bundle). This is consistent with the findings of other researchers (e.g. Bartlett, 2007 and Allen, 1975). The lowest values for the resistance factors occurred at a live-to-dead load ratio of three. As expected, the resistance factor decreased with increasing the reliability index. Increasing β from 3.5 to 4.0 resulted in a decrease in ϕ_m from 0.54 to 0.46 for hollow masonry and from 0.66 to 0.56 for grouted masonry. The higher ϕ_m values for grouted masonry compared to hollow masonry are attributed to the higher resistance ratio.

The target reliability index for masonry structures in the current Canadian masonry design standard CSA S304.1-04 is 3.5. While a reliability index value of 3.5 can be justified for reinforced masonry that exhibits ductile response, it is certainly not suitable for unreinforced masonry which is brittle is nature. A target reliability index of 3.8 is more appropriate for unreinforced masonry and is in conformance with the guidelines of the Canadian standard CSA S408 (1981–R2006). In Figure 2, if hollow masonry is considered representative of typical unreinforced masonry construction, the proposed reliability index of 3.8 corresponds to a resistance factor of 0.5. Considering grouted masonry to be representative of reinforced masonry construction and using a target reliability index of 3.5, the corresponding resistance factor for reinforced masonry is 0.66. Using different material resistance factors for unreinforced and reinforced masonry is not unusual and is adopted by many masonry design codes and standards (e.g. BS 5628, 2005). The Australian masonry design standard AS 3700 (2001) assigns material resistance factors of 0.45 and 0.75 for unreinforced and reinforced masonry, respectively.

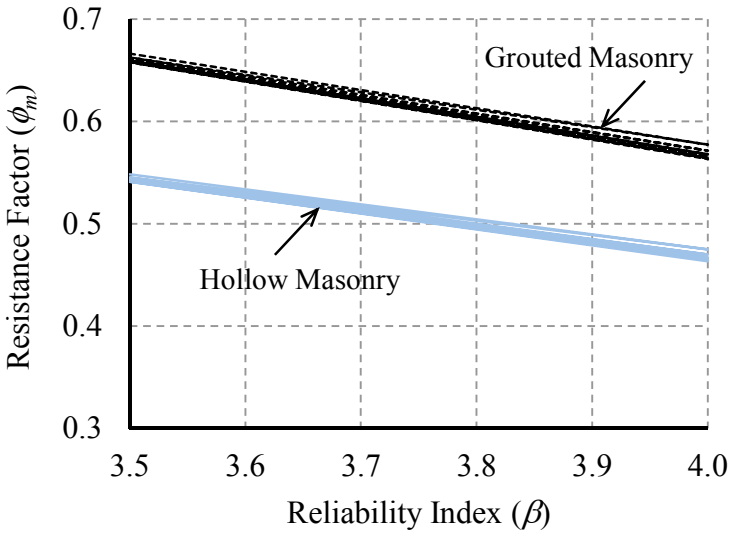

Figure 2. Relationship between the resistance factor and reliability index.

SUMMARY AND CONCLUSION

The scarcity of published research on the reliability of masonry structures in Canada suggests that the value of ϕ_m in the current and previous editions of the Canadian masonry design standard CSA S304.1 was not established on rigorous reliability analyses. It appears that calibration to the 1984 working stress design edition of the standard and engineering judgement played a greater role in selecting a value for ϕ_m.

The target reliability index of 3.5 used in the current Canadian masonry design standard is lower than the target reliability index for other comparable structural materials namely, concrete (Bartlett, 2007). While this value may be justified for reinforced masonry, it is not suitable for unreinforced masonry which lacks ductility. Following the recommendations of the Canadian standard CSA S408 (1981–R2006) and many international standards such as the Australian standard AS 5104 (2005) and considering the findings of recent research in the area of reliability of structural masonry (e.g. Lawrence and Stewart, 2009), a target reliability index of 3.8 is proposed for unreinforced masonry.

A structural reliability analysis was performed on concrete masonry under concentric axial compression to examine the reliability levels for masonry buildings designed to the current Canadian masonry standard (CSA S304.1-04). Based on the findings of this investigation, it is recommended that unreinforced masonry be assigned a material resistance factor different from reinforced masonry. For masonry members under compression, it is proposed that the current ϕ_m be increased from 0.6 to 0.65 for reinforced masonry and decreased from 0.6 to 0.5 for unreinforced masonry. This corresponds to a reliability index of 3.5 for reinforced masonry and 3.8 for unreinforced masonry. Under the current ϕ_m value of 0.6, the reliability index is 3.2 for unreinforced masonry and 3.8 for reinforced masonry.

Many researchers (e.g. Turkstra et al., 1982 and Bartlett, 2007) found that slenderness does not change the reliability index significantly. The current Canadian masonry standard addresses the slenderness effect separate from material resistance by using additional capacity reduction factors (ϕ_e and ϕ_{er}) of 0.65 and 0.75 for unreinforced and reinforced masonry construction. High eccentricity, however, is known to reduce the value of the reliability index particularly for unreinforced masonry construction (Turkstra and Ojinaga, 1980). The effect of eccentricity on the reliability level was not considered in this study and is a part of an ongoing extension to this investigation.

ACKNOWLEDGMENT

The authors wish to thank the Canadian Concrete Masonry Producers Association (CCMPA) and its member companies for providing third party test data for concrete block masonry units needed to carry out this analysis.

ABSTRACT

The use of wood blocking between wood rafters or trusses has been historically accepted by engineers as necessary to act as a wood roof diaphragm boundary edge member, to transfer chord forces to the chord and to transfer wind and seismic shear forces to the shear walls.

However, the use of eave blocking has been abandoned by many design engineers who argue it is not specifically code-required and that empirical testing has shown it is not needed. They argue that chord and shear forces can be resolved through the use of other framing members and metal connectors. However, engineering mechanics and metal connector manufacturers' limits dictate that eave blocking cannot be omitted.

In low load, low heel height cases, it could be argued that eave blocking may not be needed, but where roof diaphragms transfer wind and seismic forces, design engineers omitting eave blocking do so in denial of basic engineering principles.

INTRODUCTION

Blocking between wood rafters or trusses at roof eaves (commonly known as eave blocking) has historically been standard framing practice in wood construction, particularly at open eaves. Blocking typically consists of nominal two inch wide material, normally of a depth matching the height from the bottom of the roof sheathing to the top plate of the wall.

The installation of edge blocking serves several purposes. The blocking encloses the attic space, preventing birds and vermin from entering, and it is used as a means to assure accurate dimensional spacing between the rafters or roof trusses. It also provides a load path from the roof diaphragm to the exterior walls to transfer wind or seismic forces. However, as fire requirements and aesthetic considerations have resulted in the increased use of enclosed eaves, the installation of eave blocking has been abandoned by many design engineers.

The resultant construction cost savings in both material and labor has been justified by the argument that eave blocking is not specifically required by the code (Crandell, J., Rice, R., Foley, B, and Woeste, F., 2009). This argument has been shored by results from testing sponsored by the U.S. Department of Housing and Urban Development (HUD, 2002) that appears to show edge blocking may not be "empirically" needed (as opposed to required by engineering mechanics).

Whether or not the installation of eave blocking is actually required depends on a number of factors. These may be prescriptive, required by building code statute; or, when dependent on manufactured metal connectors to transfer shear and overturning forces, by limitations placed by the connector manufacturers' specifications; or finally, as an integral part of the lateral load-resisting system, as a means to maintain a complete load path from the roof diaphragm to the shear walls.

BUILDING CODE REQUIREMENTS

Lateral Support Against Rotation

One function of eave blocking is to prevent lateral rotation of the rafters/trusses at the wall supports. The International Residential Code (IRC) did not specifically require any eave blocking to prevent rotation of rafters/trusses under the 2006 edition. Some conditions are provided in the 2009 IRC under which eave blocking is required by Section R602.10.6.2 for lateral support against rotation, but only at sections above braced wall panels. Low wind/seismic regions require partial height (to allow attic venting per R806) eave blocking, but only at rafter/truss heel heights above 9.25 inches. High wind/seismic regions required eave blocking per Figures R602.10.6.2(1), R602.10.6.2(2) or R602.10.6.2(3) for all heel heights.

That the required blocking is only partial-height for attic ventilation seems unnecessary in that the blocking is only required over braced wall panels and not elsewhere along the wall line. IRC Figures R602.10.6.2(1), R602.10.6.2(2) and R602.10.6.2(3) do not provide a load path and serve solely to prevent rotation of the rafter/truss.

Similarly, the 2009 International Building Code (IBC) under *Conventional Light-Frame Construction* Section 2308.10.6 requires the use of blocking per Section 2308.8.5, which uses heel height limits to require lateral support against rotation of the roof framing. The heel depth-to-thickness ratio for roof framing is held to a maximum unblocked ratio of 5:1. This requirement exists only to resist rotation of the roof framing and does not address the transfer of wind or seismic forces.

In conclusion, the IRC does not at present prescriptively require eave blocking to resist rotation for rafters/trusses heel heights less than 9 1/4 inches, while the IBC does not prescriptively require eave blocking for heel heights less than 6 3/8 inches.

Load Transfer

The 2006 IBC's *General Design Requirements for Lateral Force Resisting Systems* section prescribed the use of "boundary members" to transmit tension and compression forces (Section 2305.1.2). This has been historically taken by engineers to indicate a requirement for eave blocking. Since wind/seismic chord forces are typically resisted by the wall top plates, an obvious load path would be developed from the roof diaphragm to the top plates through the eave blocking to the shear wall top plate. Load eccentricities from the roof diaphragm to the top plate in this arrangement are resolved through each block's individual end nailing. Under such a configuration eave blocking meets the IBC requirement for boundary members to transmit tension and compression forces.

However, the 2009 IBC deleted Section 2305.1.2 and under newly revised Section 2306.2.1 ("Wood structural panel diaphragms") defaults the design and construction of horizontal wood diaphragms to as in accordance with the American Forest & Paper Association's *Special Design Provisions for Wind and Seismic* (2005).

AF&PA's *Special Design Provisions for Wind and Seismic* Section 4.2.6 ("Construction Requirements") requires diaphragm "boundary elements" to transmit tension, compression and shear forces but does not specifically require those to be eave blocking. In arguing for the omission of eave blocking, it has been put forth that the roof diaphragm should instead be boundary-nailed to the fascia (the new "boundary element") in order to meet the code boundary nailing requirement.

Chord forces are then assumed to transfer from the roof diaphragm to the tops of the rafter/truss (the new "boundary elements"), through the rafter/truss, and through the metal connector holding the rafter/truss to the top plate, transferring the chord forces to the shear wall top plate. The assumption is typically made without the benefit of an engineering analysis, it happens "empirically".

Because the AF&PA does not specifically require for such a transfer to take place by using eave blocking, there is no prescriptive IBC code requirement to use eave blocking to transfer tension and compression forces. While such an arrangement may not be acceptable to engineers in that it places the rafter/truss in cross-grain bending, it has been argued that it technically meets code requirements for boundary elements to transmit tension, compression and shear forces.

The resultant load path would then be from the wood diaphragm to the roof rafter/truss, through the roof rafter/truss to the metal connector, and from the connector to the wall top plates. The resultant eccentricities of this load path are generally ignored by those proposing the deletion of eave blocking, who argue the metal connector can resist the overturning by transferring the force couple through the connector flanges nailed to the sides of the roof/rater truss. This will be further discussed in the following sections.

ANALYSIS REQUIREMENTS

Diaphragm

Figure 1a below shows a standard roof framing detail for a wood framed eave, with eave blocking. Figure 1b shows the same detail, without the eave blocking but substituting standard connection hardware.

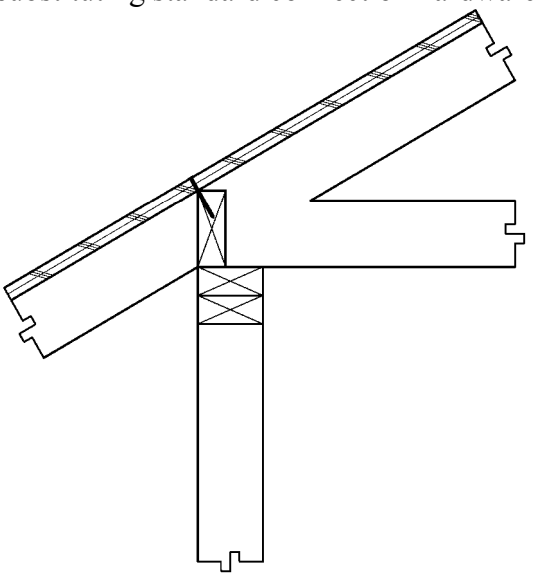

Fig. 1a – Wood Framed Eave With Eave Blocking.

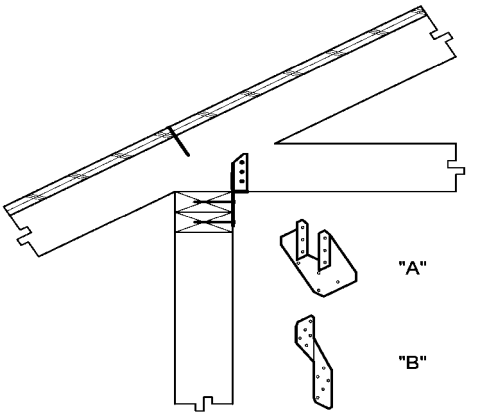

Fig 1b – Wood Framed Eave, No Eave Blocking.

Figure 1c shows again the same detail, without the eave blocking, at a masonry wall condition with standard connection hardware.

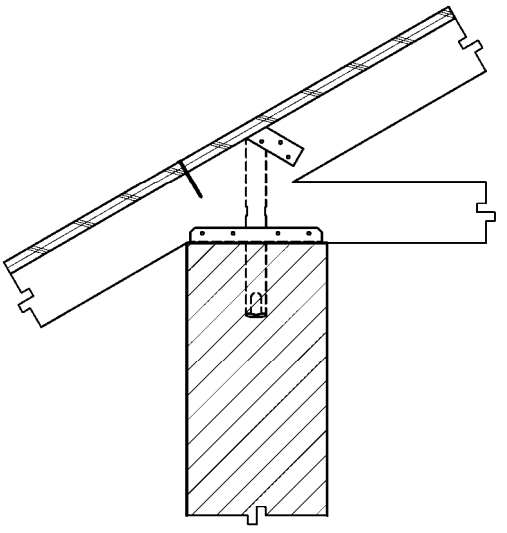

Fig. 1c – Masonry Wall Wood Framed Eave, No Eave Blocking.

In considering the need to transfer wind/seismic forces at roof eaves, two issues need to be addressed. First would be the resolution of resistant forces parallel to the direction of applied wind/seismic forces (the reaction shear forces). Second would be the resolution of resistant forces perpendicular to the direction of applied wind/seismic forces (the chord forces).

The reactive shear forces resisting wind/seismic forces for a flexible, unblocked diaphragm are typically determined from a tributary span length and a tributary wind/seismic load. Table I tabulates reactive shear values for different combinations of wind/seismic loadings (w) and different diaphragm length-to-depth ratios (L/d). Because we are only considering the analysis of eaves perpendicular to the roof framing and the roof trusses are assumed to span across the shorter dimension, the wind/seismic forces would act across the short direction of the diaphragm and we would only investigate the reactive shear forces from wind/seismic forces perpendicular to the roof framing (IBC Table 2306.3.1, Case 3 unblocked diaphragm).

Table I – Reactive Shear Forces.

Shear Flow (plf)					
L/d	0.25	0.33	0.50	0.67	1.00
w (plf)					
100	13	17	25	34	50
150	19	3	38	50	75
200	25	33	50	67	100
250	31	41	63	84	125
300	38	50	75	101	150

The results show the reactive shear forces fall within most popular sheathing thickness/nail size combinations for unblocked diaphragms. Diaphragm shear capacity would thus not seem to be a concern in eliminating eave blocking when considering reactive shear forces.

Chord forces for flexible, unblocked diaphragms are typically calculated as simple span moments between diaphragm supports, divided by the depth of the diaphragm. Table II tabulates chord forces for different combinations of wind/seismic loadings (w) and different diaphragm length-to-depth ratios (L/d), divided by the length of the diaphragm. Again considering chord forces perpendicular to framing but due this time to wind/seismic forces parallel to framing, we distributed the chord force into a "chord flow" acting along the diaphragm edge, namely, the chord force divided by the length of the diaphragm. We then compare these calculated chord flow forces along the diaphragm edge with the allowable diaphragm loading corresponding to an IBC Table 2306.3.1, Case 3 loading.

Table II – Chord Forces.

Chord Flow (plf)					
L/d	4.00	3.00	2.00	1.50	1.00
w (plf)					
100	50	38	25	19	13
150	75	56	38	28	19
200	100	75	50	38	25
250	125	94	63	47	31
300	150	113	75	56	38
350	175	131	88	66	44

The tabulated results show that the chord flow shear forces fall within most popular sheathing thickness/nailing combinations for unblocked diaphragms. In considering chord forces at diaphragms without eave blocking, diaphragm shear capacity does not appear to be a concern.

Mechanical Connectors

Typical roof wood rafter/truss to wood wall construction uses metal connectors such as those shown in Figure 1b, while typical roof wood rafter/truss to masonry wall construction uses connectors such as the one shown in Figure 1c. Available from a number of manufacturers, these connectors have load capacities (depending on the model used) of up to several hundred pounds per connector (Simpson Strong-Tie Company, 2009-2010).

The values tabulated in either Table I or Table II compare well with the allowable shear loads for these metal connectors. Provided the proper connector is selected and standard spacings are used, shear force demands from the diaphragm to the exterior walls can be met. These connectors would thus appear to meet the IBC Section 2305.1.2 requirement for the use of "boundary members" to transmit tension and compression forces.

However, where eave blocking is not used, the rafter/truss would receive the wind/seismic load from the diaphragm at the top of the rafter/truss and transfer it to the wall top plates at the base of the rafter/truss. This creates a rotational moment across the rafter/truss. Disregarding for the moment that this rotational moment induces undesirable cross-grain bending on the rafter/truss, in order for the wind/seismic load to successfully transfer into the top plates there would still need to be a free-body resolution of the rotational moment at the base of the roof rafter/truss.

The moment may be resisted by the metal connectors tying the rafter/truss to the top plates. In the case of a connector "A" as shown in Figure 1b, nailed flanges on either side of the rafter/truss could develop a resistive couple. Similarly, a connector "B" as shown in the same figure could be installed each side of the rafter/truss to resist the rotational couple. However, the rated load values for these connectors were

developed through testing that restrained the wood members from rotation. The rated load values represent capacities for straight shear transfer and do not assume a combination of shear and rotational loads. As such, the metal connectors are not approved by the manufacturer to resist rotational couples. Manufacturers specifically include catalogue warnings that the connectors are not intended to prevent cross grain bending (Simpson Strong-Tie Company, 2009-2010).

Engineers have the option to bypass the manufacturer's warnings and choose to apply engineering design concepts to analyze the connector. Such a study would have to include a complete free-body analysis and a unity equation check. Consideration would have to be given to the fact that the nails transferring the rotational couple forces would be in cross-grain shear. In addition, those intending to use "B" connectors should also consider the manufacturers' recommendation to use a minimum 2½ inch thick rafter/truss when installing the connectors opposite each other (Simpson Strong-Tie Company, 2009-2010).

Perhaps more importantly, the use of mechanical connectors such as "A" and "B" to transfer both shear and rotational forces requires a complete disregard for cross-grain bending across the rafter/truss. This condition is ignored by no-blocking proponents (Yaxley, Wilbur T., 2004) who will argue empirically for the rotational resistance provided by the fascia board, even though it is end nailed to the rafter/truss and numerically unable to provide the necessary resisting force couple. Similarly disregarded is that shear transfer may happen but only at the expense of rotational failure. A failed connection is still a failed connection.

Test results show that failure modes for anything but low-load/low-heel height conditions are generally not caused by shear failure but by some form of rotational failure (U.S. Department of Housing and Urban Development, 2004). On roof rafters this typically occurs as a cross-grain failure, an undesirable condition due to its sudden and inelastic failure mode. In roof trusses the failure is typically across the connector plates. In addition, there are no code-published allowable stress values for wood in cross-grain bending. Even if some existed, the need for an engineering analysis including a unity equation check for shear and cross-grain bending cannot be ignored.

EMPIRICAL TEST DATA

The U.S. Department of Housing and Urban Development (HUD) sponsored tests on roof truss to wall connections and reported the results in 2004. The tests involved four different attachment configurations, none using eave blocking. Two of the configurations used toe nails as the sole means of attachment. The third configuration used a combination of twenty-two toe nails and nine metal connectors. The fourth configuration used only four toe nails and nine metal connectors. The metal connectors were installed on only one side of the truss. All trusses used two-by-four inch members, so that heel heights and the resultant overturning forces were relatively small.

Test results showed a noticeable difference between toe-nail failure and metal connector failure modes. Toe-nail connection failure was defined by lower load capacities, splitting of the wood and lateral sliding of the truss along the top plate, with little out-of-plane truss rotation. Toe-nailed connections had such low capacities that out-of-plane rotations never really had the opportunity to develop to the point of failure. In essence, the toe-nailed connection failed in shear long before allowing the connection to fail in out-of-plane rotations.

Metal connector failures occurred at higher load capacities. In some cases the truss rotated out-of-plane, resulting in truss plate separations. In others, the metal connectors failed, either by failing in tension due to the overturning out-of-plane force couple, or by excessive deformation from localized buckling of the connector.

Metal connectors are load-rated by their manufacturer based on joint slip limits, rather than on failure load capacity. The HUD tests were based on failure load capacity and as such, the results report excessively high failure loads relative to manufacturer rated loads. This leads to excessively positive results that would seem to indicate the metal connectors are much more capable of resisting loads than they have been rated by their manufacturers. These findings have lead to euphoric misplaced calls for the abandonment of metal connectors allowable loads based on joint slip limits rather than by failure load analysis. In the HUD configurations tested, load failure occurred at deformations of over an inch, excessive by any measure and surely a condition that would benefit from the installation of eave blocking.

CONCLUSIONS

Roof eave blocking is not prescriptively required by either the IRC or the IBC to transfer wind/seismic forces. Eave blocking is only code-required to resist lateral rotation of the rafter/truss assemblies when prescribed height-to-width heel ratios are exceeded.

Strictly in terms of shear transfer, wood roof diaphragms in standard configurations do not appear able to develop large enough shear or chord forces to require the installation of eave blocking for additional diaphragm shear nailing. Similarly, metal truss connector shear load capacities appear sufficient to resist standard configuration shear or chord forces.

However, the use of only truss connectors in lieu of eave blocking requires a disregard of rotational bending across the rafter/truss assembly and its resultant cross-grain bending on the roof rafter/truss as well as its resultant force couple on the metal connector. A complete free-body analysis and unity equation check on both the roof rafter/truss for cross-grain bending and on the metal connector seem out of reach due to a lack of allowable wood cross-bending stress values and the fact that metal

connectors are prohibited by the manufacturer to resist cross-grain bending and that allowable shear values are based on joint slip limits.

The omission of eave blocking may be possible in some low-load, low heel-height conditions, when toe nails are used. Toe nail shear capacities are so low, cross-grain bending in low-heel conditions does not have the opportunity to develop as a concern. In other words, for low heel-height, light load cases requiring only toe-nailing at the roof rafter/truss connection to the top plate for shear transfer, cross-bending concerns could possibly be disregarded. The system would have to be designed to guarantee shear failure of the toe nailing before reaching a cross-bending failure. With some limits, low-load conditions might be possible without eave blocking.

However, once the decision to use metal connectors is made, the use of connector hardware greatly increases the shear load capacity over that of just toe-nailed assemblies. This increased shear load capacity brings about a rise in the potential for cross-grain rotational failure, either in the roof rafter or in the roof truss assembly. Any system that would use metal connectors between the roof rafter/truss and the wall top plate will require the use of eave blocking in order to avoid rotation as the failure mode.

At higher loads and particularly as the heel height increases, rotational forces and cross-grain bending cannot be ignored. In the absence of eave blocking, cross-grain rotation becomes a primary failure mechanism. Higher loads and higher heel heights also result in assembly deformations too excessive to be acceptable and well beyond the joint slip limits of the metal hardware. In designing higher-load assemblies (such as those in high wind and earthquake zones) the omission of eave blocking is not an acceptable engineering choice.

Truss Plates for Use as Wood-Concrete Composite Shear Connectors

Peggi L. Clouston, Associate Member ASCE[1] and Alexander C. Schreyer[2]

ABSTRACT

Wood-concrete composite systems are well established, structurally efficient building systems for both new construction and rehabilitation of old timber structures. Composite action is achieved through a mechanical device to integrally connect in shear the two material components, wood and concrete. Depending on the device, different levels of composite action and thus efficiency are achieved.

The purpose of this study was to investigate the structural feasibility and effectiveness of using truss plates, typically used in the making of metal-plate-connected wood trusses, as shear connectors for laminated veneer lumber (LVL)-concrete composite systems. The experimental program consisted of two studies. The first study established slip-modulus and ultimate shear capacity of the truss plates when used in an LVL-concrete push out assembly. The second study evaluated overall composite bending stiffness and strength in two full size T-beams when subjected to four-point bending. One beam employed two continuous rows of truss plates and the other employed one row.

It was found that the initial stiffness of both T-beams was similar for one and two rows of truss plates but that the ultimate capacity was approximately 20% less with the use of only one row.

INTRODUCTION

The concept of connecting a wood beam to a concrete slab to achieve composite action was first implemented in the early 1930's in U.S. timber bridge construction (Doehrer and Rautenstrauch 2006). The method of interlocking the two materials was rudimentary, relying on concrete shear keys formed through slots in the wood. Although not commonly seen in the U.S. today, this construction practice is becoming popular in Europe, particularly for rehabilitation and preservation of old timber structures. A variety of connectors have been used – such as nails, screws or spikes with and without concrete shear keys – each with varying degrees of structural efficiency as well as level of ease and cost of installation (Ahmadi and Saka 1993; Ceccotti A. 1995; Blaß and Schlager 1996; Gutkowski et. al. 2008). New proprietary mechanical connectors are also being developed - such as expanded steel mesh, modified screws and sophisticated steel hardware - and are commercially sold for residential, commercial and industrial applications (Bathon and Graf 2000; Clouston et al. 2004; Clouston and Schreyer 2008).

The advantages of using Wood-concrete composites are many. Composite action between the two materials results in stronger and stiffer floors than if the two materials are unconnected, as is commonly done in light-frame construction. The use of concrete with wood also enhances sound attenuation and vibration dampening, reduces fire risks, provides a more rigid floor diaphragm, and improves floor smoothness and durability. In addition, there are benefits to the environment from encouraging the use of more timber. Wood is the only renewable building material; it requires less energy and creates less pollution in manufacturing than alternative building materials, and it stores carbon absorbed from the air. The presence of concrete in the system would add thermal mass to absorb, store, and later release heat in a building to save on operating energy.

Despite the advantages of building with this technique, little research has been directed at adapting the concept to traditional North American light-frame construction. This construction approach is typified by the prevalence of small wood framing members with a 38mm thickness (also known as 2 inch nominal lumber). The shear connectors in existence generally require thicker wood cross sections than this so as to not remove or impact too much of the wood's capacity.

To this end, the objective of this study is to investigate the structural feasibility and effectiveness of using steel truss plates - used in the making of metal-plate-connected wood trusses - as shear connectors for wood-concrete composite systems. These ready-made connectors are intended for use with 38mm framing lumber and have teeth that puncture the wood to a depth of only 9.5 mm to make the mechanical connection.

EXPERIMENTAL PROGRAM

The experimental program consists of two sequential series of tests. The first series is a standard test configuration to determine slip modulus and connector shear strength, referred to as the push-out test. The second test is a full-scale four point bending test to compare the effect on structural performance of using one row of connectors versus two rows of connectors.

Materials

The wood used for both series of tests (push-out and bending) was 44mm thick x 133mm deep 2600Fb-1.9E Eastern Species Laminated Veneer Lumber (LVL) beams manufactured by iLevel by Weyerhaeuser. The metal plate connectors were pre-manufactured, 152mm wide x 304mm long, 20 gauge, MT20 steel truss plates by MiTek. The teeth of these plates are punched in pairs and formed at right angles to the face of plate. The concrete was high strength ready-mix by Sakrete with a minimum compression capacity of 27 MPa.

The specimens were fabricated into hybrid composites as shown in Figure 1. One half of the 152mm width of the truss plates was pressed into each of the two LVL boards so that half of the connector was embedded into the lumber leaving the other half to embed into the poured concrete. Plywood was glued to the top edge of the LVL to create a 19mm space between the LVL and the concrete to mimic permanent formwork on a jobsite. Two 12mm diameter washers were placed in-between the two LVL beams which were then fastened together using 64mm decking screws. The exposed truss plates were

hand-bent to a 45 degree angle. 150mm x 150mm wire mesh was placed on top of the bent connectors to prohibit concrete shrinkage. The concrete was then cast in place and let to cure for a minimum of 28 days. Specimens were tested under ambient laboratory conditions (approximately 16°C, 40% relative humidity).

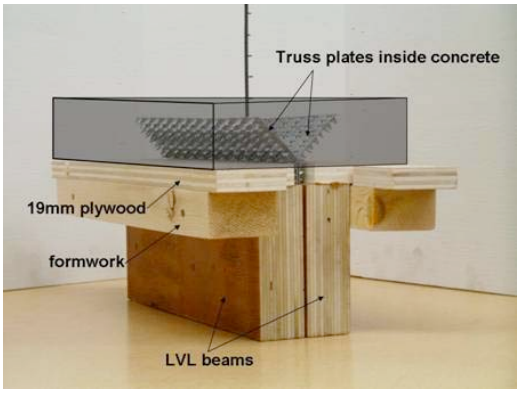

Figure 1 - LVL-concrete composite specimen

Method: Push-out tests

Five specimens were subjected to one-sided push-out tests. A schematic of the test set-up is illustrated in Figure 2. As no standard currently exists for wood-concrete composite shear tests, general guidelines of American Society for Testing and Materials standard, ASTM D 5652 were followed. The test assembly was similar to that used in previous studies (Clouston et. al. 2004 and 2005). A Linear Variable Displacement Transducer (LVDT) was placed at mid-height to measure slip displacement. Load was applied at a constant rate of 0.8 mm/min by a 133 kN capacity universal test machine under deflection control with real time data acquisition. The load was cycled first up to 20kN, then back to 8 kN and then to failure with the intent to remove slack in the specimen for accurate slip modulus measurement (similar to the ISO 6891 / DIN EN 26891 method).

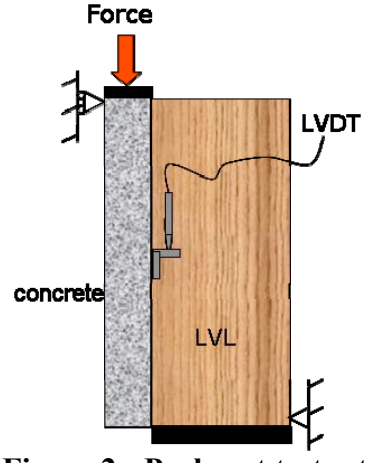

Figure 2 - Push-out test set-up

Method: Bending tests

Two T-beams were fabricated and tested in bending to investigate overall composite bending stiffness and strength. These beams used two 2743 mm long 44 mm x 133 mm LVLs as stringers. On top of these was a 19 mm plywood sheet (as permanent formwork), a 0.08 mm polyethylene (PE) sheet as moisture barrier during construction and an 89 mm thick concrete slab. Overall T-beam width was 436 mm (see Figure 3 for details).

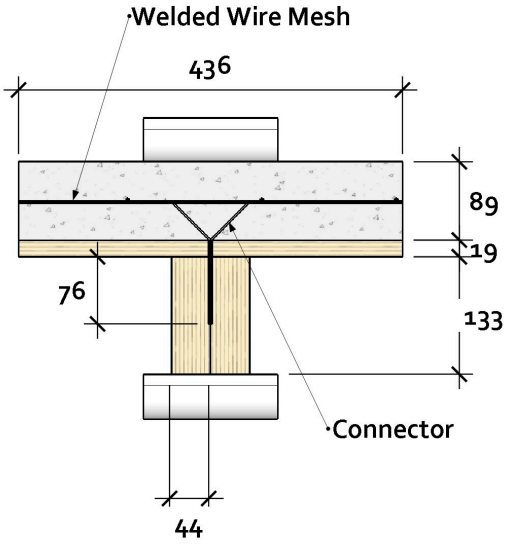

Figure 3 - Bending setup cross-section

Nailplate fasteners were pressed into the side of the LVL stringers into routed depressions, which had been recessed to a depth equal to the steel thickness. This was done so that the nailplates would sit flush with the surface of the LVL's side, therefore removing the need for spacers between both LVLs. The top portion of the nailplates that projected beyond the plywood was again bent at a 45 degree angle as illustrated in Figure 4. One of the beams featured two rows of connectors (one on each LVL) whereas the other only had one row (using staggered fasteners between the two LVLs). The top of the nailplates then served as support for a welded-wire mesh (152 mm square wire spacing), which was located approximately at ½ of the thickness of the concrete slab and tied to the nailplate fasteners. This wire mesh served solely as minimal reinforcement for crack reduction and was not intended to contribute to the composite connection.

Before adding concrete, screws were driven from below the plywood sheet to act as nonstructural connectors to hold the plywood in place. Overall, the plywood layer was not fastened to either the LVLs or the concrete in any way that would provide load transfer since it was only designed as non-structural formwork. As a final step, all seams were caulked with an elastomeric sealant so that no cement slurry could escape from the concrete mix.

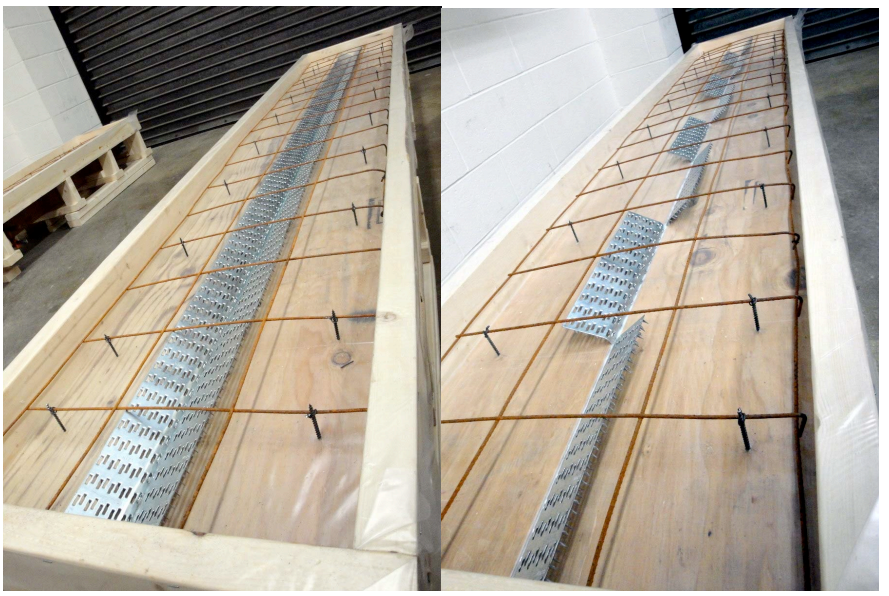

Figure 4 - Double-plated LVL beam with formwork
(left: two rows of fasteners, right: single-row with alternating fasteners)

After curing for 28 days, side formwork was removed and the beams were arranged in the 133 kN MTS testing frame using the four-point test setup illustrated in Figure 5 (see Figure 6 for a photograph). Load was applied through controlled crosshead displacement at a rate of 2.5 mm / min. Midspan displacement was recorded using an LVDT at the center of the span (on top of the concrete). All data were recorded in real-time using MTS software.

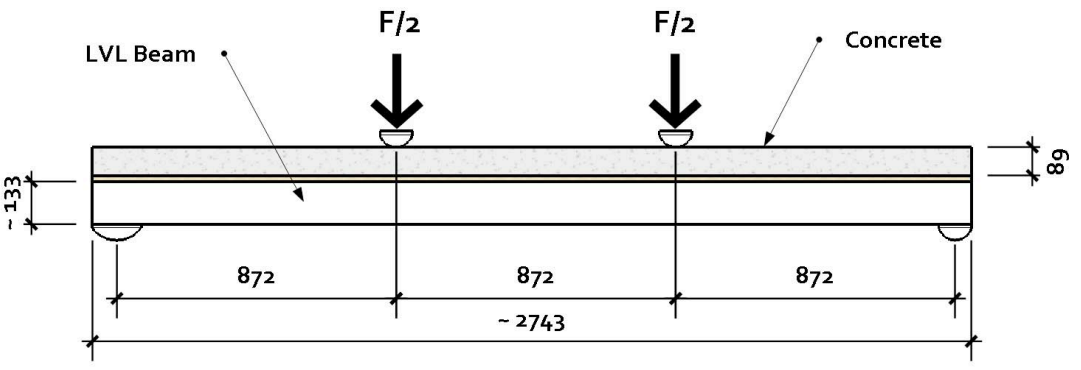

Figure 5 - T-beam bending test setup

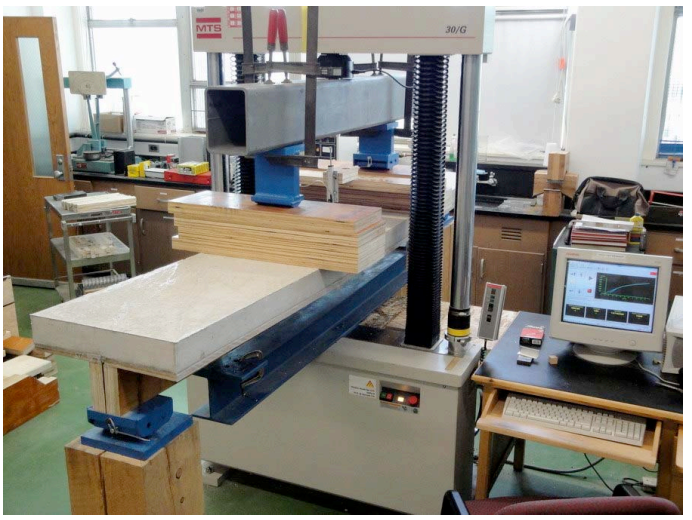

Figure 6 - T-beam in MTS test machine

RESULTS AND DISCUSSION

Push-out tests

A photograph of the failed specimen in the test fixture is provided in Figure 7. Some minor spalling of the concrete was observed but upon close inspection of the specimens (by removing the concrete and separating the LVL beams, as seen in Figure 8), it was apparent that all five specimens had failed by distortion and yielding of the truss plate at the shear interface between the plywood and the concrete. There was no obvious splitting of the wood at the location of the truss plate teeth.

Figure 7 - Shear failure of push-out specimen

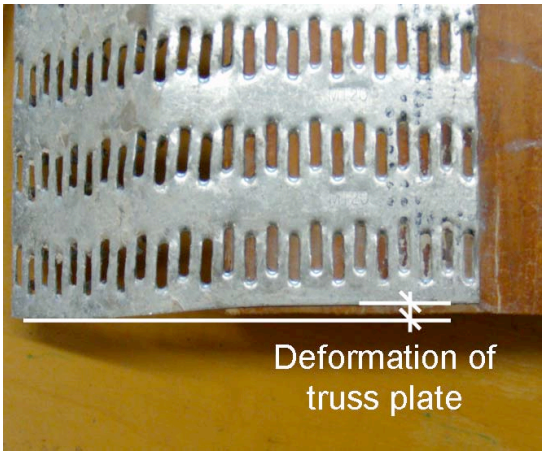

Figure 8 - Yielding of truss plate

The corresponding load / displacement curves of all five push-out specimens (reference Figure 9) indicate the ductile mechanical behavior of a steel failure mechanism (as opposed to the brittle nature of wood or concrete). Ductility was consistent for all specimens. The peak load varied moderately with a Coefficient of Variation (COV) of a 11.1%, again indicative of a reliable steel failure.

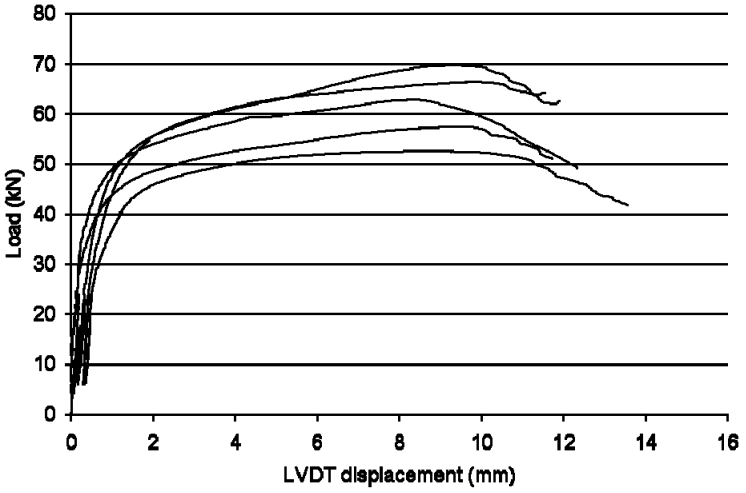

Figure 9 - Push-out tests: Load vs. LVDT displacement curves

Table 1 summarizes and quantifies the key findings of the push-out tests. The Slip Modulus, K, was determined by the slope of the linear portion of the load / displacement curve. The mean value of 128.1 kN/mm is within an expected range when compared with values previously published in the scientific literature: K=38.3 kN/mm for a notched shear key/anchor connector in 4x4 lumber (Gutkowski et. al. 2004) and K=415 kN/mm for an expanded steel mesh connector in Glulam (Clouston et. al. 2005).

Table 1 - Push-out test results

Specimen	Slip Modulus,K (kN/mm)	Peak Load (kN)
1	134.6	66.5
2	157.1	62.9
3	104.7	52.6
4	105.7	69.8
5	138.4	57.4
Mean	128.1	61.8
St. Dev.	22.6	6.9
COV	17.6%	11.1%

Bending tests

Both bending tests showed a similar failure behaviour as the push-out tests. Once all removable concrete had been broken away from the tested beams and the LVLs had been separated, it was visible (see Figure 10) that all deformation had occurred in the steel fastener in the area between the LVL beam and the concrete (i.e. the 19 mm gap created by the plywood layer). At the ends of the beam, concrete spalling and shear deformation at the LVL interface were both minimal (see Figure 11). Failure occurred mainly as shearing of the perforated steel and - at the ends of the beam - as partial tearing of the steel plate.

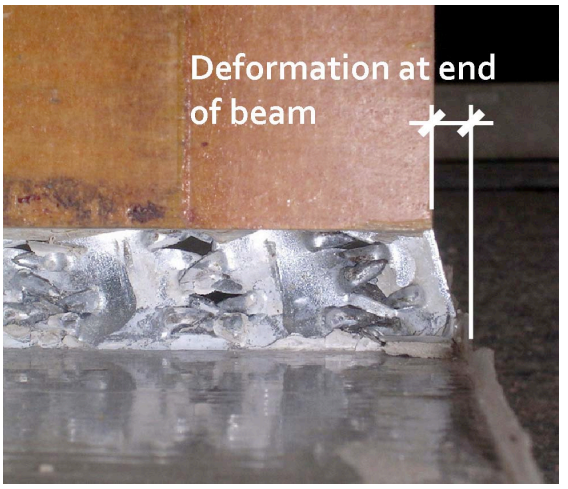

Figure 10 - Shear deformation in truss plate

Figure 11 - Tested specimens, broken apart for inspection

Load-displacement graphs for both tests (shown in Figure 12) revealed a relatively ductile failure behaviour with center-span displacements at break ranging between 40 mm and 55 mm. Ultimate failure was progressive tension failure in the LVL beam accompanied by minor crack development in the concrete. Peak load for the two specimens was 95.4 kN for the specimen with two fastener rows and 77.9 kN for the specimen with a single, alternating fastener row (i.e. 18.3 % less than the former).

It was interesting to discover that despite the drop in ultimate strength, initial beam stiffness (EI) was similar in both tests (1.88×10^9 kN·mm^2 and 1.70×10^9 kN·mm^2, respectively). This would suggest that for in-service design, the number of fasteners is not as critical as having a continuous connection. This, however, requires further tests for verification.

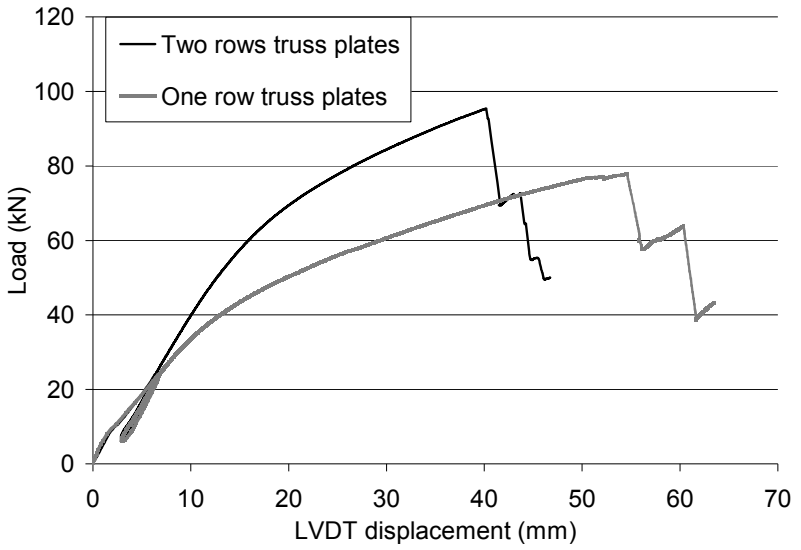

Figure 12 - Beam test graphs

CONCLUSION

An investigated was conducted into the viability of using ready-made MT20 truss plates as wood-concrete shear connectors. Two experimental test configurations were considered: push-out tests and 4-point bending tests with one row of connectors vs two rows of connectors. The push out tests indicate that the slip modulus achieved by using truss plates could be viable and within the same range of other commercially used shear connectors. It was also found that the initial beam stiffness (EI) of both T-beams with one and two rows of connectors was similar but that the ultimate capacity was approximately 20% less with the use of only one row.

ABSTRACT

A common model of light gauge, metal joist hanger is tested on a wood-to-wood connection for two conditions. One condition follows the commonly used test standard for joist hangers, which allows the support beam to be restrained from horizontal and rotational movement. The second condition (unrestrained) allows the support beam to freely move horizontally and in rotation. The results show that the unrestrained case is much weaker than the standard restrained case. For the model of hanger tested, the average ultimate load for the unrestrained case was 28% of the standard restrained case. The mode of failure for the unrestrained case is different than that for the restrained case. This documents the importance of providing means of restraining the supporting beam by methods other than the connection via the joist hanger. The ASTM testing method for joist hangers may need to be adjusted to account for this possible mode of failure.

INTRODUCTION

Light gauge, metal joist hangers are widely used in wood frame construction in North America and in many areas of the world that use light wood frame construction. Most modern homes, apartments, and light commercial buildings that use light wood frame construction will also use joist hangers to connect framing members to supporting beams. A joist hanger is commonly used to connect a floor joist to a wood beam. Another common use is to connect a wood truss to a heavier “girder” truss. Although they are commonly called joist hangers, it is likely that nearly half of the usage is in roof framing, which are most commonly wood roof trusses. One of the main benefits of the joist hanger connection is that it connects to the side of the supporting beam or girder truss. This allows the supported framing member to be at the same elevation as the supporting beam or girder truss.

The use of joist hangers allows the supporting beams to be flush with the supported framing. This allows for ceilings to be free of beams placed below the ceiling level. In many cases, the architectural advantage of using joist hangers justifies the small added cost. There are also architectural trends that encourage more complex framing and more open spaces. These trends require more support beams, trusses, and engineered lumber products, all of which require greater usage of joist hangers.

The trend to more complex designs and larger open spaces increases the occurrences of joist hangers that need to carry larger loads. The manufacturers of joist hangers have developed extensive arrays of joist hanger models for various geometric conditions and load capacities. A catalog from a major hanger supplier has over 70 pages devoted to joist hangers. Some of the joist hangers can be called beam hangers or girder hangers due to the large size and load capacity.

The author has been involved in the design of wood framing for many buildings that use very complex framing to achieve the architectural requirements. The most complex cases often involve roof framing with various hips, valleys, and roof openings. These requirements often cause framing from common trusses to be supported by a girder truss. In complex cases, one end of the girder truss is then supported by another girder truss, which is then supported by a third girder truss. See Figure 1.

Figure 1. Complex (4th order) roof framing: wood trusses connected by hangers

In each case joist hangers are used to transfer the increasing loads from truss to truss. This "fourth order" framing is unusual, but becoming more common. Third order framing is not difficult to find. Second order framing occurs on most wood frame

buildings that are larger than a simple box ranch home. All of this results in increased usage of joist hangers in more heavily loaded and more critical connections.

MOVEMENT AND RESTRAINT ON SUPPORTING MEMBERS

The purpose of this research is to test the effect of support restraints on the capacity of a joist hanger connection. In actual applications the supporting member of a joist hanger is commonly a wood beam or the bottom chord of a girder truss. The supporting member is always restrained from movement to some degree. The supporting member is always restrained from moving downward by the stiffness of the beam or girder truss and the supports for the beam or girder truss. This vertical restraint is the primary restraint in the direction of load.

Secondarily, the beam or girder truss has some restraint from lateral movement (perpendicular to the beam; in the longitudinal direction of the joist). Thirdly, the beam or girder has some restrain against rotation in the plane of the joist. Movement of the supporting beam in other directions is not usually considered to be related to the downward movement from gravity loads on a joist hanger connection and is not considered in this research.

One of the primary means of providing the secondary lateral restraint and the third rotational constraint is by the connection of the supporting member to the supported joist. The supported joist or truss is usually very stiff in the longitudinal direction of the joist and quite stiff in rotation in the plane of the joist. Other building elements that are connected to the beam or girder may also provide some lateral and rotational constraints.

In actual construction, the degree of restraint provided by these other building elements has great variability. The case of a roof truss supported by a girder truss at a location away from the supports of the girder truss may have very little lateral and rotational restraint. In some cases the main restraint is provided by an attached gypsum board ceiling. In other cases the ceiling is suspended, and the truss bracing is the main constraint.

One common condition is when floor decking is directly attached to the beam or girder. The floor decking may provide substantial lateral restraint and some rotational restraint when combined with other building elements. The connections of the beam or girder at the supports in combination with the lateral stiffness and torsional stiffness of the beam or girder also provide some restraint.

This research compares two cases. In one case the supporting beam of a joist hanger connection is restrained from lateral and rotational movement by blocking and metal rods. In another case the only restraint on the supporting beam is from the joist and

the joist hanger connection. The hypothesis is that the downward load capacity of the joist hanger will be significantly less when no additional restraints are provided to the connection.

REVIEW OF TESTING STANDARDS AND CODE APPROVALS

The current standard for testing joist hangers in North America is ASTM D 7147-05. This standard also provides a method of assigning the allowable loads for joist hangers.

The standard test method loads a joist that is connected to beams (or headers) at each end. Blocking and tensile reinforcement against the blocking is used to restrain the beams from lateral and rotational movement. A 3.18 mm (1/8 inch) minimum gap is specified between the joist and the beam before loading. See Figure 2.

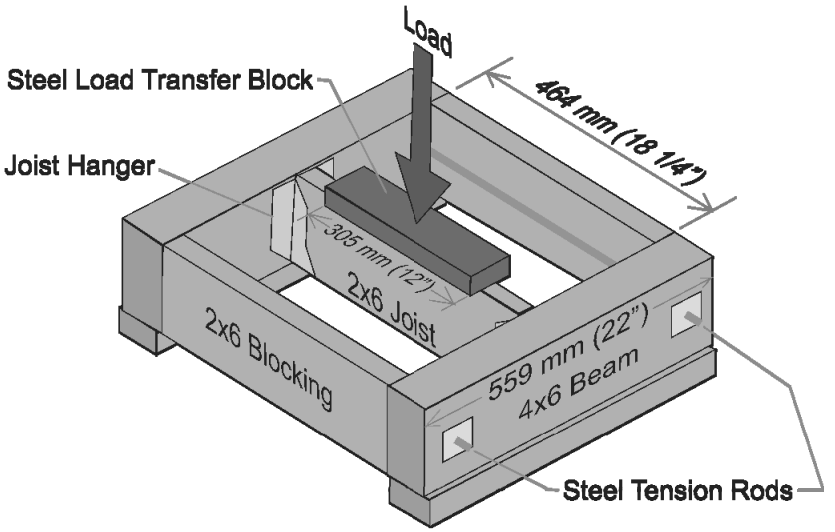

Figure 2. Standard test set-up with the actual dimensions used (restrained)

The allowable joist hanger load (for normal load duration) is specified as the lesser of the following:

The average ultimate load per joist hanger divided by 3.0, when six or more tests are performed.

The lowest ultimate load per joist hanger divided by 3.0, when less than six (but at least three) tests are performed.

The average load per joist hanger at which the measured vertical deflection is at 3.18 mm (0.125 inches).

The test method is based on a short term test. The test method specifies the rate of movement of the test machine crosshead of between 0.8 to 5.1 mm (0.03 and 0.20 in.)

per minute. The ultimate load shall not be reached in less than 5 minutes. Although the test standard uses an ultimate design value divided by 3.0, the actual safety factor is much less than 3.0, after adjusting the short term test results to a normal (ten year) duration of load.

The allowable joist hanger load is also not allowed to exceed a calculated load based on the allowable values of the steel in the joist hanger and the allowable values for the fasteners used in the connection. An addition limitation is based on the calculation of wood bearing and fasteners of the joist bearing on the seat of the hanger.

Design values for joist hangers are not listed in the *2009 International Building Code* (IBC). The use of joist hangers in the United States is usually based on the acceptance by the Building Official of an evaluation report. Evaluation reports are commonly produced by the ICC Evaluation Service, Inc. (ICC-ES) or other recognized agencies that perform technical evaluations of building products. In almost all cases, the test report for a joist hanger is produced and owned by the manufacturer of the joist hanger. The actual test reports are considered to be confidential and are not published. The test reports and other materials are submitted to the evaluation agency as justification of the design values listed in the published evaluation report. Although much testing is performed on joist hangers, very little information is published on the subject of testing joist hangers.

MATERIALS USED

The lumber, joist hangers, and nails used were purchased at retail building supply outlets. Both the lumber and the joist hangers were purchased at two different companies. The quality of both lumber and joist hangers appeared similar at both sources.

A commonly used hanger model was chosen for testing to represent the “middle of the field”. Size and load capacity was also selected to fit the available testing equipment. A “face mount” hanger was selected. A face mount hanger has no top flange, so all load must be transferred to the supporting beam by the fasteners.

The joist hanger selected was a Model HUS26 manufactured by one of the major suppliers in the United States. This hanger model is widely used and readily available in the United States. At least two manufacturers use this same model number for a joist hanger with a similar (but not identical) design and allowable capacity. The hanger model is considered to be heavier and more expensive than the lightest hangers that are commonly used. This hanger would normally be selected for a heavier required capacity, but it is not the heaviest used in this size category.

The joist hanger is made from 16 gauge galvanized steel. The measured steel thickness was 1.40mm (0.055 in.). The hanger is designed to fit a 2x6 joist but can also be used for a larger joist. This hanger is also commonly used to connect a roof truss to a girder truss. Since the bottom chord of many common trusses are 2x4 and the bottom chord of most girder trusses are 2x6 or 2x8, this size fits well with many roof trusses.

For the maximum capacity, this joist hanger model uses fourteen 89x4.12 mm (3.5x 0.162 in.) 16d common nails connecting directly from the hanger into the supporting beam. An additional six 16d common slant nails are installed into the joist at or near a 45 degree angle. These slant nails are in double shear. They penetrate the end of the joist and into the header at the slant angle.

The nails used were sold and labeled as 16d common nails and appeared to be typical of framing nails. They were measured at 89 mm (3.5 in.) long (from bottom of head to tip). The measured diameters varied from 4.01 to 4.17 mm (0.158 to 0.164 in.). The nail surface was smooth and bright. The nail shafts had eight slight, transverse indentations on each side in an area from 5 to 15 mm (0.2 to 0.6 in.) from the nail head. The head diameters were 9.1mm (0.36 in.) and the head thickness was 1.6 mm (0.062 in.).

The lumber was similar to, but somewhat more consistent than, lumber that is often used in actual construction. The lumber was purchased as #2 and better Douglas Fir. The beam (or header) members were 4x6 and the joist member were 2x6. The pieces were selected to avoid major lumber characteristics in the hanger area that may weaken the connection. Some more common characteristics such as small knots, small drying checks, and minor slope of grain were present. The lumber was graded as surface green, and all lumber was air-dried at room temperature, until the measured moisture content was between 11 and 15%. Care was taken to avoid drying below 11%.

All materials were accurately cut. All nails were driven by hand using a 0.57 kg (20 ounce) hammer. To provide consistent nailing, a pilot hole was drilled for all nails. The depth of the pilot hole was near one-third the nail length. The pilot holes were drilled with a 2.38 mm (3/32 in.) inch bit, which is 59% of the nail diameter. The *2005 National Design Specification for Wood Construction* (2005 NDS) allows pilot holes up to 75% of nail diameter without capacity reduction.

TESTING METHODS

Except as noted herein all procedures specified in ASTM D 7147-05 were followed. A 305 mm (12 in.) long steel load transfer block was used to distribute load along the top of the joist and avoid excess crushing. All assemblies were preloaded to 4.45 kN

(1000 lbf) before testing. The movement rate of the crossheads was from 3.8 to 5.1 mm (0.15 to 0.20 in.) per minute.

Six assemblies were made using the ASTM D 7147-05 arrangement (Figure 3) with blocking used to restrain the supporting 4x6 beam (or header) members from lateral or rotational movement. 9.5 mm (3/8 in.) metal rods were used as tension reinforcement just inside the blocking. This kept the 4x6 beams tight against the blocks. These assemblies are referred to as the "restrained" assemblies. The blocks were cut 6 mm (0.25 in.) longer than the 2x6 joist, so that a 3 mm (1/8 in.) gap between the joist and the beam at the joist hanger could be maintained. Polyethylene tape was applied to the each end of the joist to minimize load transfer due to friction at the end of the joist. Digital indicators were located at each joist end to measure vertical displacement of the joist with respect to the supporting beam. The measurement was taken from the mid-height of the joist to a point ¼ the beam height from the bottom of the beam.

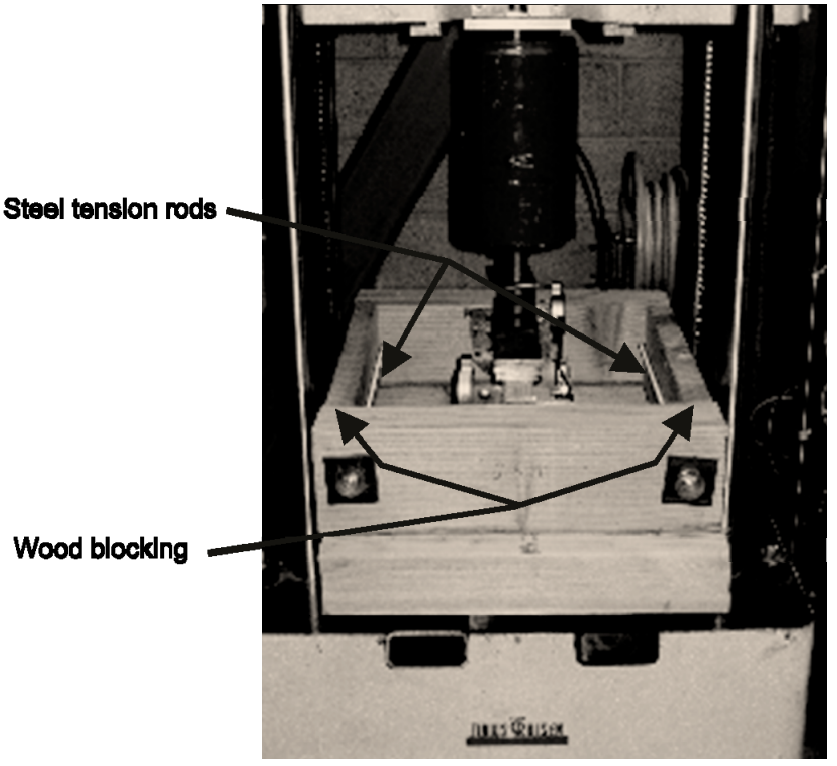

Figure 3. Restrained test configuration

Six other assemblies were made to allow unrestrained lateral movement and rotation of the supporting beam. These assemblies are referred to as "unrestrained". The only restraint against lateral movement and rotation is that provided by the joist and joist hanger connection of the joist to the beams. A heavy steel wheel was mounted to each end of the beams. The wheel is mounted to a welded steel bracket to support the 4x6 beam. The axle of each wheel is located at the centroid of the cross-section of

the 4x6 beam. This arraignment allows free rotation about the centroid and lateral movement. The steel wheel had tapered roller bearings to allow low friction and heavy loads. The steel wheels roll on smooth steel box sections that rested on the bed of the testing machine. The length of the beam was shortened to 267 mm (10.5 in.) to fit the wheels, steel brackets, and steel box sections into the testing machine. This short beam length also avoids significant bending of the beam. See Figure 4. All other aspects including the gaps and polyethylene tape are the same for both types of assemblies.

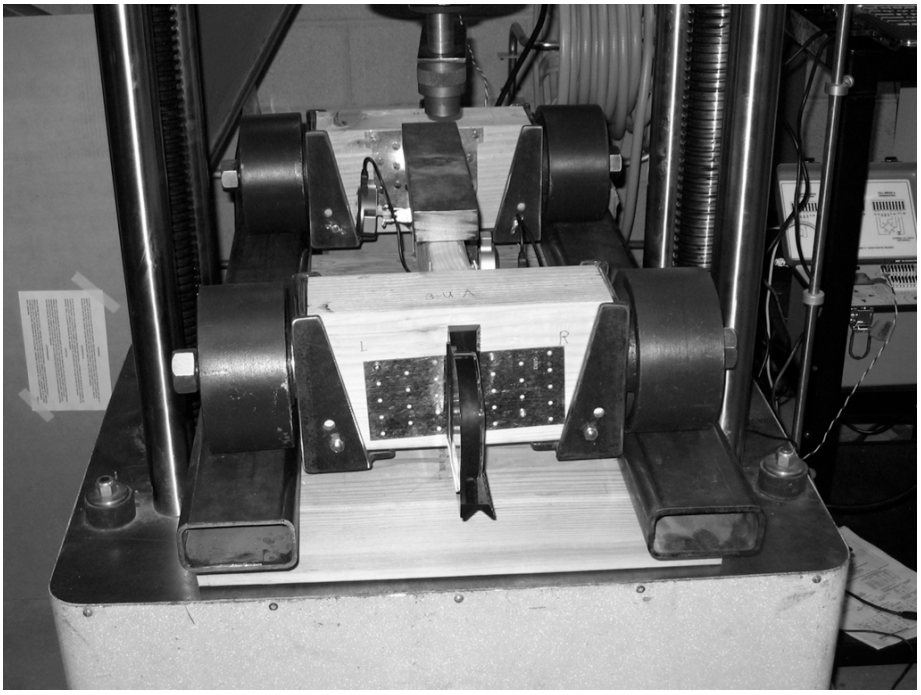

Figure 4. Unrestrained test set-up

In addition to the measurement of the vertical joist deflection, the unrestrained assemblies had digital indicators to measure the horizontal movement of the beam from the joist at each joist end. The horizontal measurement was taken against the mid height of the beams. A balance protractor was also placed on each beam to take visual measurements (within one degree) of the rotation of the beams.

RESULTS FOR RESTRAINED ASSEMBLIES

The average ultimate load per hanger was 28.7 kN (6449 lbf) for the restrained assemblies as shown in Table 1. The mode of failure for all tested restrained assemblies was wood failure (horizontal shear, splitting and bending) of the joist member that was supported by the hanger. See Figure 5. After the much shear splitting of the joist, the joist ultimately failed in tension stress due to the increase in tensile-bending stress resulting from the lack of full composite action within the joist.

Due to the wood failure (i.e. horizontal shear), the full capacity of the hanger connection was not achieved.

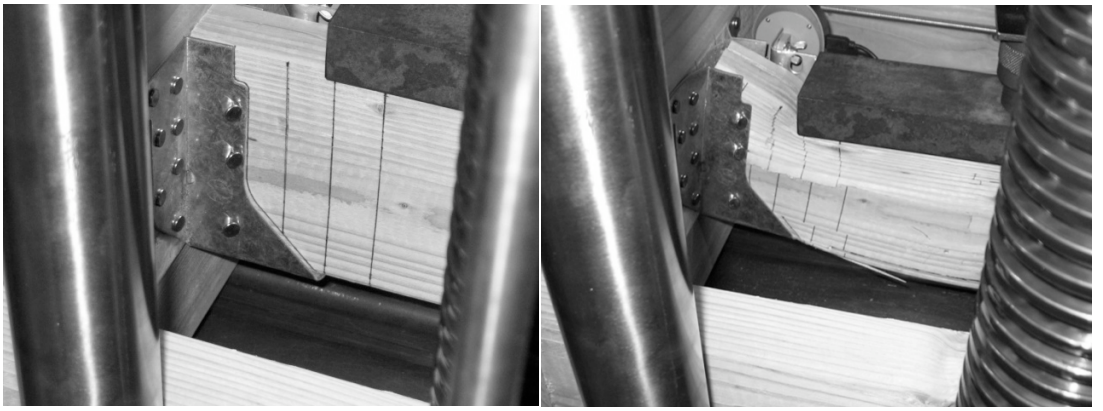

Figure 5. Before and after horizontal shear failure in joist

In test 4-R an attempt to reinforce the joist within the limits allowed by ASTM D 7147-05 was tried. It was hoped that the reinforcement might prevent the shear failure of the joist. A piece of laminated veneer lumber (LVL) was glued onto each face of the center portion of the joist. See Figure 6. The reinforcement extended to a distance up to 51mm (2 in.) from the end of each hanger, which is the maximum reinforcement allowed by ASTM D 7147-05. The result was still a shear failure in the unreinforced area without a large increase in capacity.

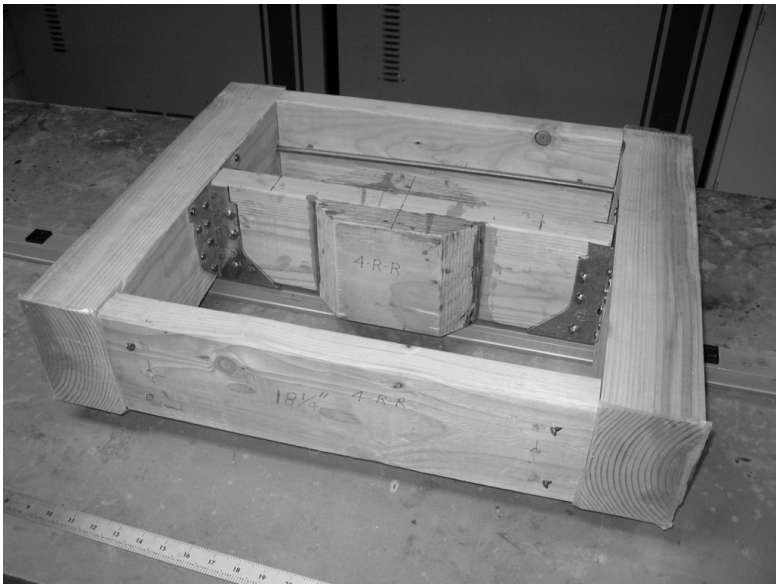

Figure 6. Assembly 4-R with reinforced joist

The average shear stress in the joist at ultimate load for the restrained assemblies can be calculated by beam theory as 8.081 MPa (1172 psi). This compares to an allowable shear stress for Douglas Fir-Larch of 1.24 MPa (180 psi), based on normal duration of load per the 2005 NDS. Based on this comparison it is not surprising that

the shear stress of the joist limited the ultimate load for the restrained assemblies. A higher ultimate load for the restrained assemblies could be expected, if a larger joist is used and/or a joist material with higher shear capacity is used, such as some engineered lumber products. This may explain why the results of these tests (average 28.7 kN or 6449 lbs) are much lower than the average ultimate value of 44.5 kN (10,000 lbs) reported in the hanger manufacturer's catalog of 2005.

RESULTS FOR UNRESTRAINED ASSEMBLIES

The average ultimate load per hanger was 8.08 kN (1817 lbf) for the un-restrained assemblies as shown in Table 1. The mode of failure for all tested un-restrained assemblies was due to movement of the hanger and the attached beam away from the end of the joist. This movement was both horizontal and rotational. This movement caused the hanger seat to rotate allowing the joist to slide down the seat and away from the beam.

Table 1. Average ultimate load for unrestrained cases is 28% of restrained cases

	Restrained Cases	
	Max. Load per Hanger	
Test	lbf	kN
1-R	6053	26.9
2-R	5658	25.2
3-R	7236	32.2
4-R	6981	31.1
5-R	6389	28.4
6-R	6377	28.8
Average	6449	28.7
COV	531	2.4

	Un-restrained Cases	
	Max. Load per Hanger	
Test	lbf	kN
1-U	1520	6.76
2-U	2274	10.12
3-U	2148	9.55
4-U	1353	6.02
5-U	2058	9.15
6-U	1548	6.89
Average	1817	8.08
COV	354	1.58

The hanger connection has some moment due to the offset of the seat of the hanger from the center of the supporting beam. When the beam is unrestrained, the only mechanism to resist this moment and prevent rotation is the connection of the beam to the hanger and to the joist. The joist cannot rotate within the plane of the joist, since it is supported at two locations. This moment is resisted by a force couple within the connection. See Figure 7.

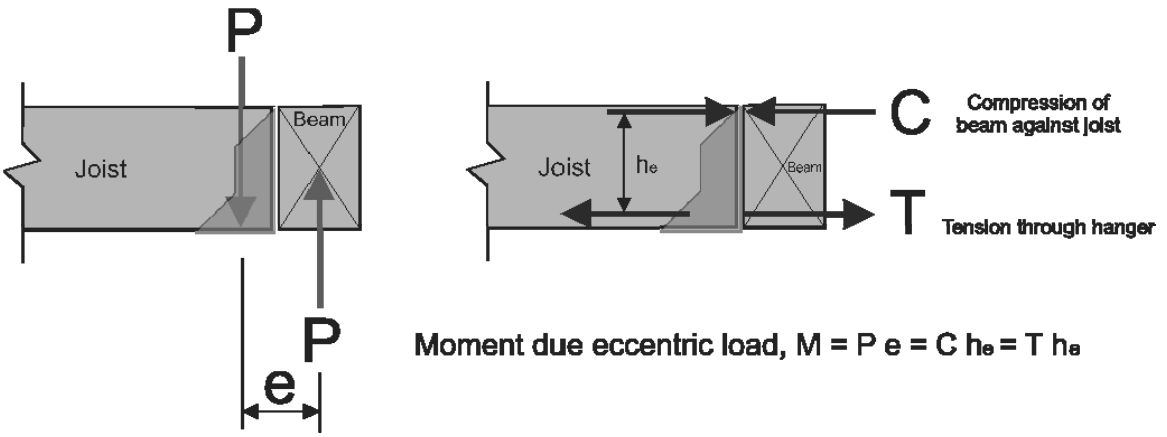

Figure 7. Forces and moment caused by the eccentric load on the hanger

During loading, the top of the beam rotates towards the joist until the small gap between by the beam and the joist closes. After the gap is closed, the upper portion of the beam bears against the joist in compression. The bottom of the beam rotates away from the bottom of the joist, but is restrained by the connection of the beam to the joist hanger and the joist hanger to the joist. This restraint results in a horizontal tension force through the joist hanger connector. See Figure 8.

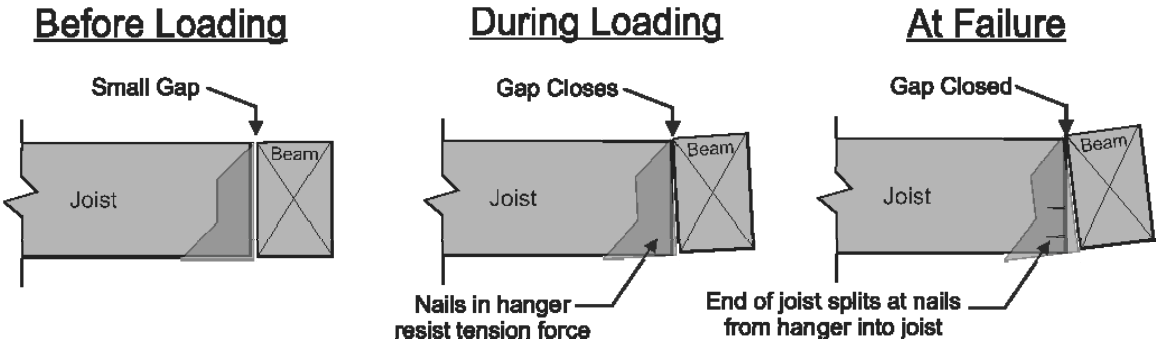

Figure 8. Mode of failure for the unrestrained case

The ultimate mode of failure is due to the nails from the joist hanger into the joist shearing through wood near the end of the joist. This shearing is parallel to the grain of the joist and very close to the joist end. See Figure 9. It is well known that nail connection into wood are weak in this mode of failure. Wood fasteners require reasonable end distances for this type of loading to achieve the design value of the fasteners.

Figure 9. Failure of unrestrained case by nails splitting out of the end of the joist

COMPARE RESULTS: RESTRAINED AND UNRESTRAINED ASSEMBLES

The average ultimate load per hanger was 28.7 kN (6449 lbf) for the restrained assemblies and 8.08 kN (1817 lbf) for the unrestrained assemblies. This difference is clearly statistically significant. This confirms the hypothesis that the downward load capacity of the joist hanger is significantly less when no additional restraints are provided to the connection. The average ultimate load for the unrestrained assemblies was 28 percent of the average ultimate load for the restrained assemblies.

The average ultimate load per hanger for the unrestrained assemblies (8.08 kN or 1817 lbf) was less than the design value for the hanger of 11.4 kN (2565 lbf), based on normal duration of load. Since the test is a short term load the difference is larger, if we compare it to a design value of 14.8 kN (3335 lbs) for a short term loading such as wind.

DISCUSSION

A scaled comparison of the testing results to the design values and the manufacturer stated average ultimate load is shown graphically in Figure 10. These results are

concerning because they shows that the ultimate strength for the unrestrained case is lower than the design values that are commonly used.

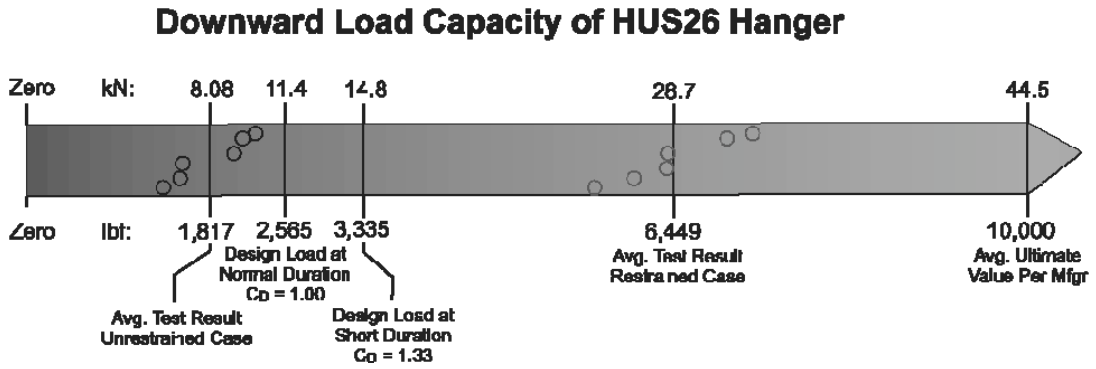

Figure 10. Scaled comparison of load values for hanger connection

It is not clear, as discussed earlier, how much lateral and rotation restraint is provided by actual construction. It is likely that the degree of constraint varies widely based on the type of connection, the related framing, and finish materials in the vicinity of the connection. Wood-to-wood connections within roof truss systems may often have less restraint than connections in floor systems.

It is likely that almost all common construction provides some level of support constraint. The unrestrained case tested is an extreme case with no support constraint. This should be considered as an extreme lower limit of what is possible.

Due to the wide variety of models of hangers it would be a mistake to assume that all hanger models will have such a large reduction in capacity without support restraints. The identified mode of failure should be very different with face-mount hangers. Hanger size may be a factor, since the length of the moment arm in the unrestrained mode of failure decreases with shorter hangers. The use of slant nailing in the connection from the hanger to the joist may weaken the connection in the unrestrained mode of failure.

The testing uncovered a mode of failure that can occur in real construction but cannot occur in the ASTM D 7147-05 testing standard. This may indicate that some changes are needed in the testing standard. Possibly an unrestrained test could be incorporated with a lower safety factor to prevent this mode of failure.

CONCLUSION

The capacity of a wood-to-wood joist hanger connection is greatly reduced if there is no lateral and rotational constraint on the supporting beam, for the model of joist hanger tested. If the supporting beam is not restrained, the mode of failure is different than what occurs by the standard testing method of ASTM D 7147-05.

The ASTM D 7147-05 testing standard allows the usage of constraints on the supporting beam. If the supporting beam is not constrained by other building elements, this may result in an over estimation of the capacity of some connections. Building designers should be aware of this so that the supporting beam is braced to provide the needed lateral and rotational resistance. Further research is needed to determine methods to provide this lateral and rotational resistance.

ABSTRACT

Strength is defined as the capacity of a material or element to resist load and can be graphically portrayed on a load-displacement curve by the point at which the maximum load is sustained, regardless of the displacement at which it occurs. It has long been recognized that the strengths of structural materials typically exhibit some sensitivity to load duration. Most strength of materials textbooks, for example, touch on the subject of strength versus load duration and indicate that structural materials subjected to very short term loading exhibit strengths that are enhanced relative to slower loading regimens. Less well-recognized is the fact that the strengths of some structural materials under very long duration loading are substantially reduced relative to what are typically taken to be their ultimate capacities, although for years, the wood engineering community has incorporated a factor into the codes that explicitly acknowledges wood's reduced capacity under long duration loads. This paper addresses the often misunderstood phenomenon of load duration effects in wood members.

INTRODUCTION

While the building code now reflects the effects of long-duration loading for design of wood, there exists relatively little technical discussion in the literature of the general subject of the behavior of wood subjected to long-duration stresses, other than requiring that wood intended to resist long-duration stress be designed to lower stress levels than wood designed to resist only short duration loads. As a result, the engineering community-at-large does not appear to be well-versed in the actual mechanics that justify the design capacity reduction when long-term loads are to be considered. The reduction in capacity under long-term loading ought not be construed as a "loss-of-capacity", which term suggests that some increment of strength is absent when it ought to have been present, nor does it result from "decay", which suggests similarity to decay damage from biological attack. Both these terms, as well as a long list of others, wrongly suggest the existence of damage that requires repair. To the contrary, the reduced long-term capacity of wood relative to its enhanced capacity under impact and to its capacity under short duration loading is not damage, but is simply the normal and predictable effect of long-term loading.

LOAD DURATION-DEPENDENT CHARACTERISTICS OF WOOD

For more than six decades, the engineering community has incorporated a factor into building codes and standards that explicitly acknowledges wood's reduced capacity under long duration loads. While the building code provisions for design of wood reflect the effects of long duration loading -- by requiring that wood intended to resist long duration stress be designed to lower stress levels than wood designed to resist only short duration loads -- this reduction factor is one of a continuum of factors used to adjust the load-duration dependency of wood as a function of duration. As wood's capacity is deemed to be relatively lower under the influence of long duration -- essentially permanent -- loads, the load duration factors that have been established for permanent loads are less than 1.0. Similarly, in recognition of wood's enhanced capacity under short duration loads, the established load duration factors are greater than 1.0. Simply, wood (like a number of other structural materials) exhibits different strengths under different load duration regimes.

Load Duration Factors in Design

In allowable stress design, allowable stresses must be multiplied by the load duration factor (C_D) that matches the shortest duration load in each load combination. Typical load duration factors (AF&PA, 2005) are provided in Table 1 below.

Table 1. Load Duration Factors for Wood.

Load Duration	C_D	Typical Design Loads
Permanent	0.9	Dead Load
Ten years	1.0	Occupancy Live Load
Two months	1.15	Snow Load
Seven days	1.25	Construction Load
Ten minutes	1.6	Wind/Earthquake Load
Impact	2.0	Impact Load

These load duration factors are based on the *Madison Curve* (Figure 1), which was developed by the Forest Products Laboratory in Madison, Wisconsin, and have been used in design practice since the 1940s (Breyer *et al*., 2007). A similar factor, the time effect factor (λ), is used for load resistance factor design.

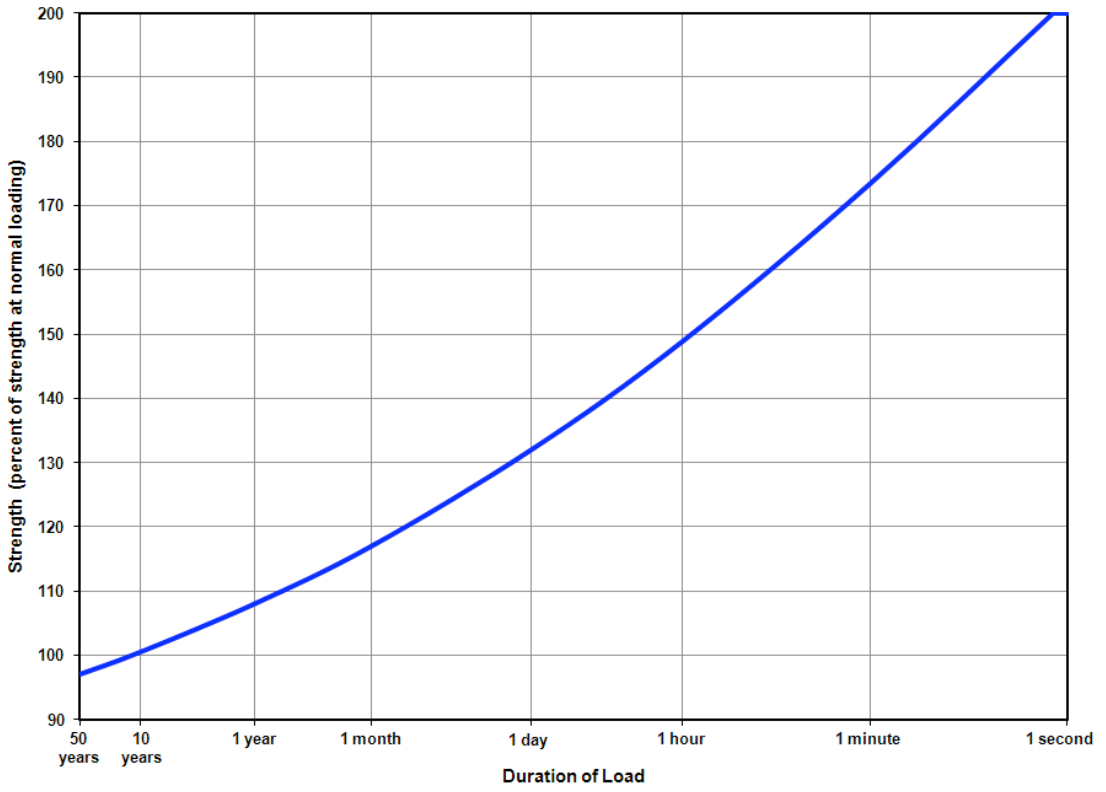

Figure 1: The *Madison Curve* -- variation of wood strength with duration of load, based on data from the Forest Products Laboratory (2010).

For most wood-framed structures, the load duration factor for permanent dead load typically does not govern the design, since design live loads in wood-supported structures tend to be as large as or larger than the design dead load. Adjustments to wood design values are linked to the cumulative time that such loads are applied; when combined with the exponential relationship between strength and load duration, AF&PA (2001) concludes, "the accumulated effects of loadings less than the maximum load the member is designed for are considered negligible and noncritical." Over the years, a number of terms have been used to describe the relationship between load duration and strength in wood, including creep rupture (Corotis and Sheehan, 1986) and damage accumulation (Murphy *et al*., 1987 and AF&PA, 2001). We note that the AF&PA no longer uses the term "damage accumulation" in their most recent commentary (2006). The discontinued use of this term appears consistent with the goal of helping to eliminate confusion regarding this phenomenon.

Failure

At the point where the demand exceeds the capacity of a wood member, regardless of whether it is long-duration demand that exceeds long-term capacity or short-duration demand that exceeds short-term capacity, the wood member will break. Figures 2 and 3 depict failures of wood members and/or structures that failed spontaneously after supporting relatively constant levels of load for many years. None of these failed structures was known to have experienced substantial changes to the loads they

supported for long periods of time prior to the occurrence of failure. Moreover, none of these members or structures exhibited decay or deterioration in the failed regions, or experienced sudden changes in moisture content, or anything else to which their spontaneous failure could be directly attributed.

Figure 2: View of a 4x16 roof purlin that failed under long-term dead load.

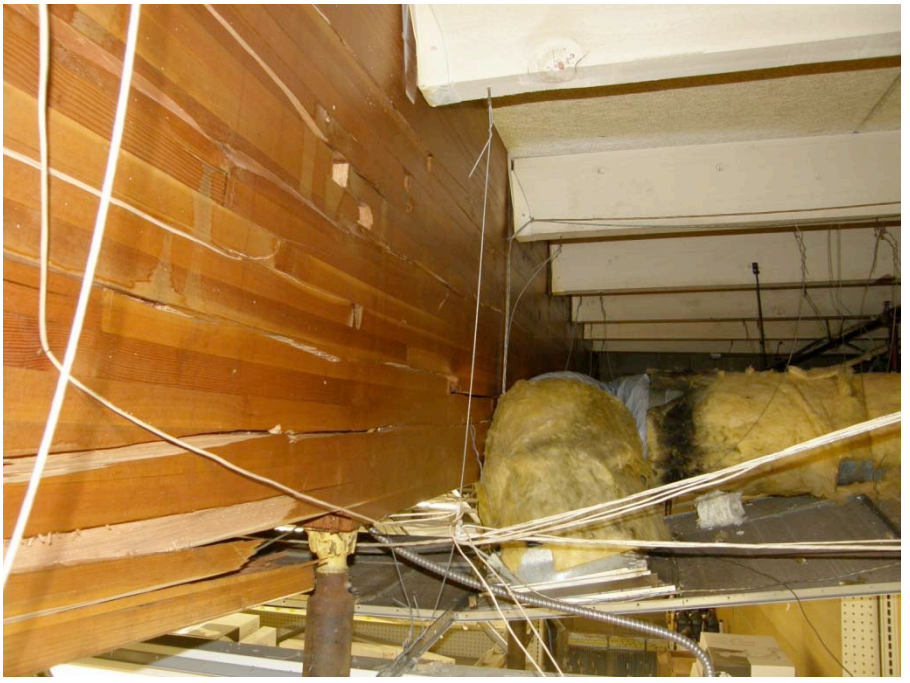

Figure 3: View of a large glu-lam beam that failed under long-term dead load.

The failure of these members is attributable to the simple fact that when load in a wood member is sustained for long periods of time, at some point the induced stresses may exceed the member's long-term capacity. Figure 4 graphically depicts an idealization of this occurrence. In the figure, the horizontal axis tracks the passage of time, the right-side vertical axis tracks the intensity of the sustained load and the left-side vertical axis tracks the member demand-to-capacity ratio (D/C). As the plot depicts, over time, the member D/C approaches and eventually reaches 1.0, even as the sustained load remains constant. At the instant of time when the member D/C rises above 1.0, the member will theoretically fail -- no decay, no sudden change in load, no external influence needed. The failure is simply a result of the time (duration) that the load has been supported by the wood member; as stated above, this time-dependent characteristic has been recognized in design practice since the 1940s. It is important to note, however, that wood itself exhibits significant variation in its mechanical properties, as discussed in greater detail in Paret *et al*. (2011), and that these variations often play a significant role in the failure of wood members.

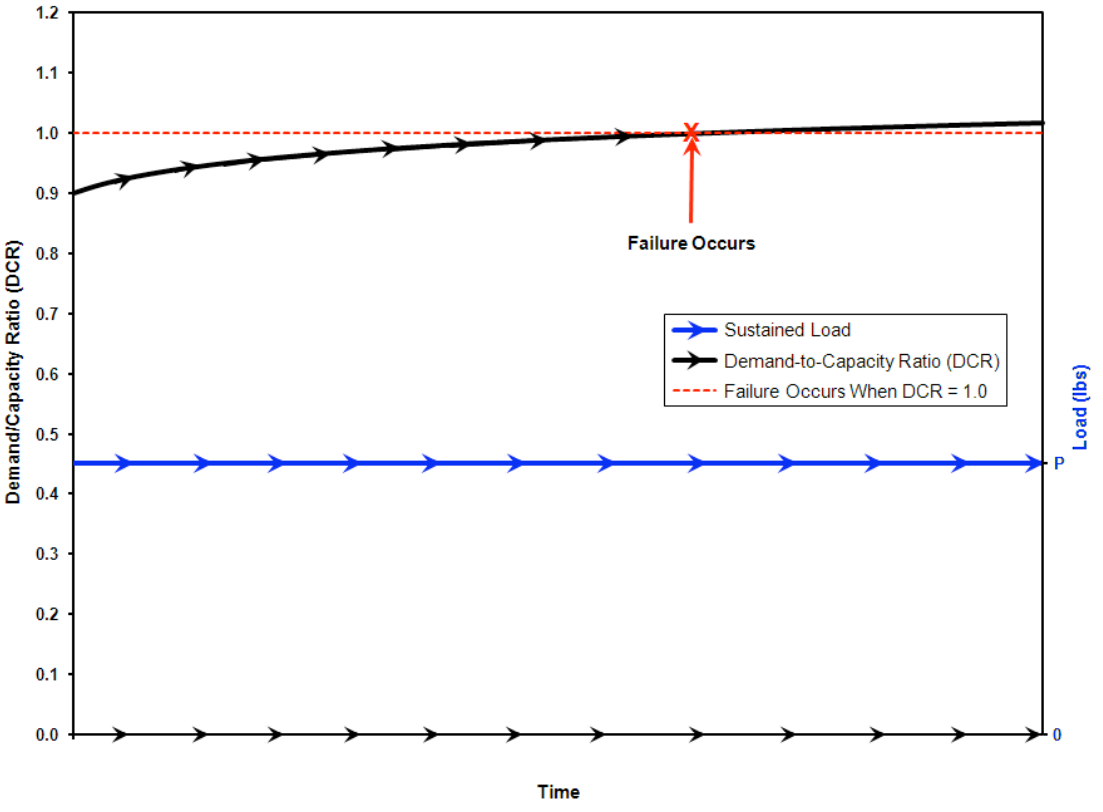

Figure 4: Although the demand remains the same, the natural time-dependent properties of wood can eventually result in failure.

OTHER STRUCTURAL MATERIALS EXHIBIT SIMILAR BEHAVIOR

A highly relevant, but similarly under-appreciated, analogy to the behavior of wood under the influence of long-duration loading can be found in concrete. Engineers almost universally understand that concrete gets stronger with time as cement hydration continues (Figure 5). Just as the 28-day compressive strength of concrete is

usually far greater than its seven-day strength, the compressive strength of concrete that is one year old is usually significantly greater than 28-day old concrete, and so on and so forth as can be seen in the figure. Regardless, a cylinder of older concrete can be made to "appear" weaker than younger concrete of the same mix design -- simply by prolonging the loading rate of the test used to determine strength of the older concrete -- because the compressive strength of concrete is sensitive to loading rate / load duration much like wood. In fact, a cylinder of concrete loaded to a fraction of its short term compressive strength will fail if the load is ramped up slowly enough or applied long enough.

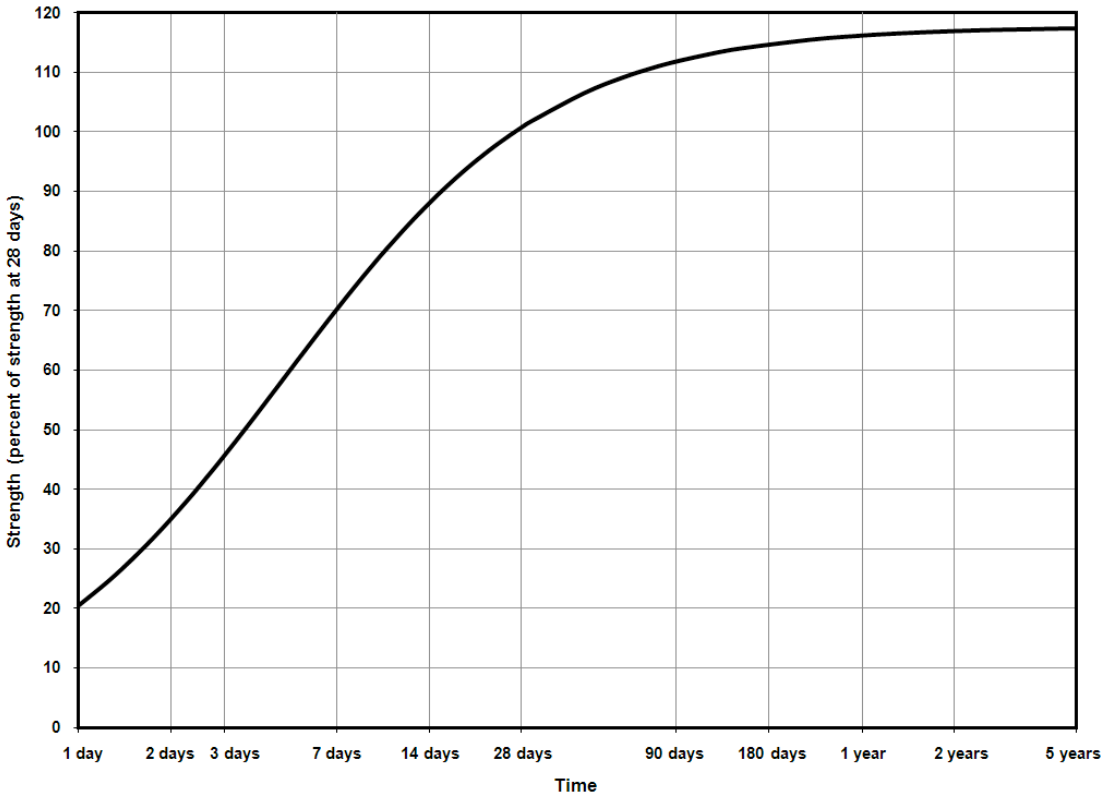

Figure 5: Increase of concrete strength with age (from Nilson, 1987).

Figure 6 shows the relationship between the compressive strength of concrete and rate of load application (from McHenry and Shideler, 1956). Like wood, concrete exhibits greater capacity under short duration loads than it does under longer duration loads, despite the acknowledged fact that the concrete exhibiting lower capacity is actually stronger (because it is older) than the concrete exhibiting greater capacity. As is the case for wood, this relationship is fundamentally a demand-side phenomenon that results from the differences in the way that the material responds to short duration and long duration loading. Concrete does get stronger over time, but it has lower strength under the influence of long duration loads than it does under short duration loads, and thus may "appear" to be weaker if the loading time is prolonged. Since concrete experiences strength gain over time, it would clearly be incorrect to characterize the lower strength that concrete exhibits under the influence of long-duration loading as a "loss-of-capacity". The same holds true for wood.

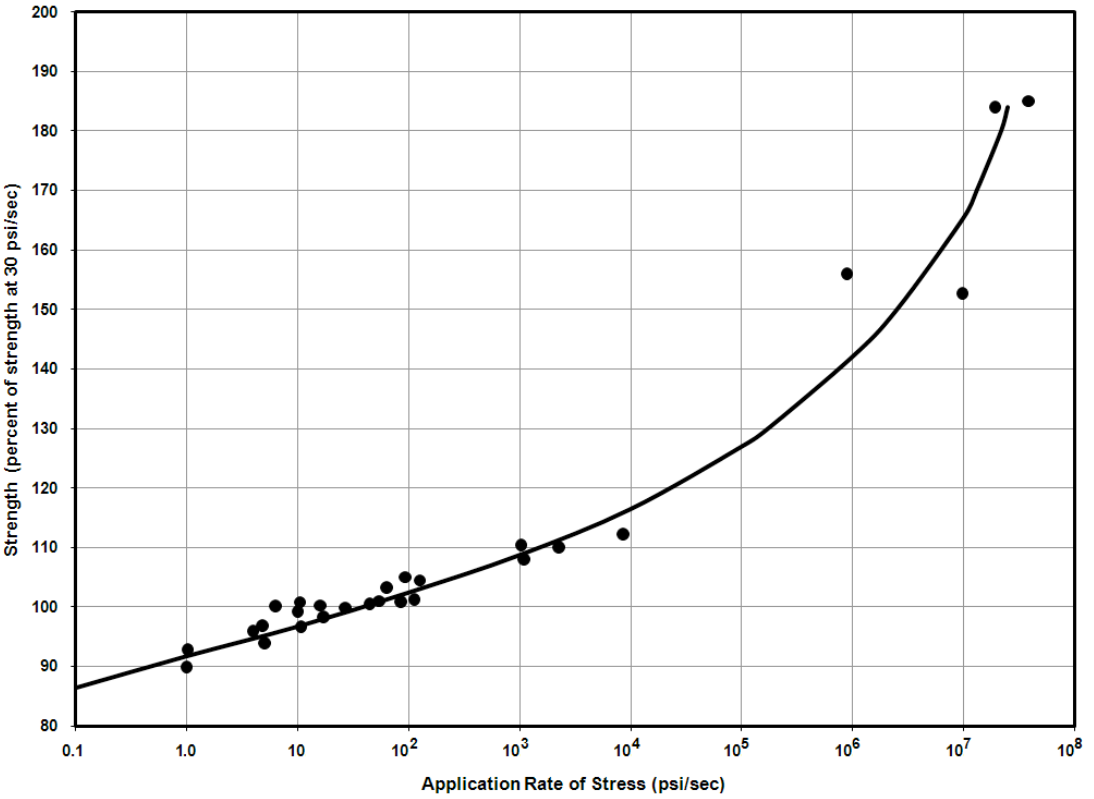

Figure 6: Variation of concrete compressive strength with application rate of load (data from McHenry and Shideler, 1956).

Steel also exhibits a similar variation of strength with loading rates, as noted in numerous studies, including Fisher and Iwankiw (2002), and as shown in Figures 7 and 8 (from Tanaka *et al*.). Like wood and like concrete, steel exhibits higher strengths under short duration loads than it does under long duration loads, but does so even more dramatically than both of the other two materials. Again, the lower strengths exhibited by steel under long duration loads are not indicative of a "loss-of-capacity", but reflect instead the sensitivity of steel to loading rate. Note that typical design procedures for routine steel structures do not consider these effects.

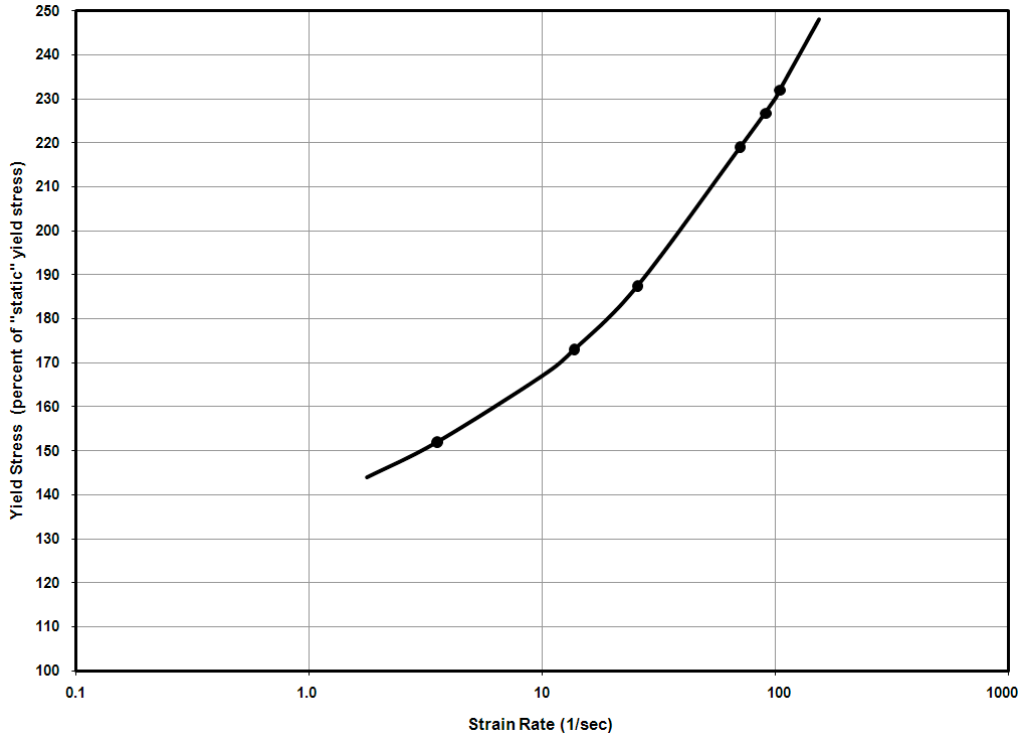

Figure 7: Variation of steel stress with strain rate: yield point data, from Tanaka *et al*., 1966.

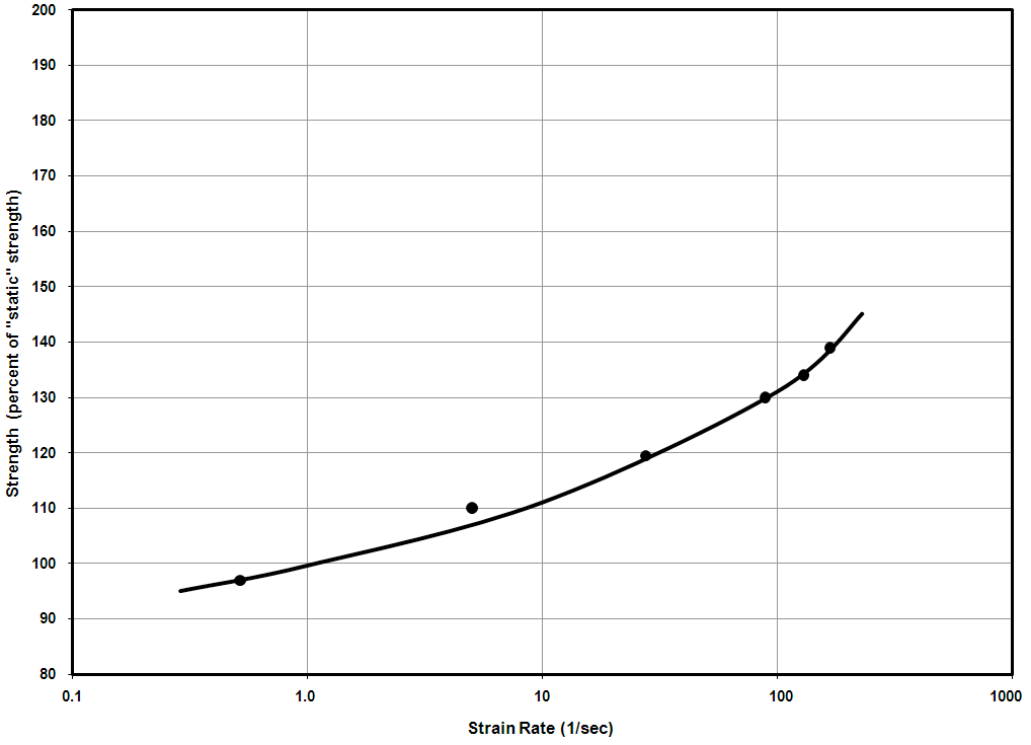

Figure 8: Variation of steel stress with strain rate: 4 percent strain data, from Tanaka *et al*., 1966.

STRUCTURAL CONTEXT IN WHICH TO VIEW THE LOAD-DURATION DEPENDENT BEHAVIOR OF STRUCTURAL MATERIALS

As presented above, commonly used structural materials exhibit similar loading rate/load-duration dependent properties despite having inherently different properties in multiple other respects. Despite these differences, however, these materials do, perhaps surprisingly, share this fundamental load duration dependency, though the different materials express this dependency somewhat differently. While a discussion of the mechanics of this dependency is beyond the scope of this paper, it remains worthwhile to contextualize the significance of this dependency to facilitate communication about what it really means when structural elements "fail" in the absence of obvious external influences. In our view, the context in which occurrences such as these should be viewed is as follows:

1. The strength of the material is a function of the length of time loads are applied.
2. Wood members (and elements of other materials with similar relationships between load-duration and strength) naturally have lower strengths for longer-term loads and higher strengths for shorter-term loads.
3. This natural response is predictable and is taken into account during design and analysis conducted in accordance with current codes. It would likely not have been appropriately considered during design prior to the 1940s.
4. Wood members (and elements of other materials with similar relationships between load-duration and strength) do not *become* stronger when they are loaded with a short-duration load; they merely *are* stronger as a result of the loading regime. Similarly, wood members (and elements of other materials with similar load-duration strength relationships) do not become weaker under long-duration loads; they merely have a lower strength associated with long-duration loads.
5. The lower strength associated with longer duration loads is neither the result of an "event" nor the consequence of "wearing out", "decay", or "deterioration", and is not something that requires repair. Note that the potential need or desire to strengthen a wood member to safely support extant sustained loads over a longer term is an issue separate and apart from "repair".

FINAL THOUGHTS

In the case of wood, the perceived lack of clarity about the net effect of long-term duration loads could potentially be eliminated simply by normalizing the load duration factors and the allowable stresses for wood so that the tabulated unmodified allowable stresses are matched with the longest duration design loads (i.e., dead load only, over the design life of the structure -- say 50 or 100 years), resulting in a 10 percent reduction in tabulated allowable stresses. For long-term loads greater than 10 years, the load duration factor would then equal 1.0, and for all loads and load combination of shorter duration, the load duration factor would be equal to the current load duration factor divided by 0.9, as shown in Table 2.

Table 2. Proposed* Load Duration Factors for Wood

Load Duration	C_D*	Typical Design Loads
Permanent	1.0	Dead Load
Ten years	1.11	Occupancy Live Load
Two months	1.28	Snow Load
Seven days	1.39	Construction Load
Ten minutes	1.78	Wind/Earthquake Load
Impact	2.22	Impact Load

* Assumes tabulated unmodified allowable stresses have been reduced by 10 percent.

As with most code provisions, providing the lowest allowable stress or lowest strength as the default would help eliminate the chance that an inexperienced engineer might forget to apply the factor, resulting in a potentially (slightly) unconservative design. Of course, given that load cases where dead loads only govern are fairly rare, and given the fairly small reduction in allowable capacity, this proposed change may not be worthwhile, but it would clarify that all wood members are not experiencing decay or deterioration simply as a result of long-term loads; merely adjusting the allowable load tables and the load duration factors by an equal but opposite factor (0.9) would eliminate any potential inference that such decay or deterioration is occurring.

CONCLUSIONS

For many structural materials, including wood, strength is dependent on the duration of loads that are applied to the material. In the case of wood, this phenomenon has been misunderstood or misrepresented on occasion as decay or deterioration, but, in reality, is not related to and should not be conflated with decay or damage from external phenomenon. Instead, the relationship between capacity and load duration is both natural and expected in wood, and the lower strength of wood under long-duration loads is not decay or deterioration any more than higher strength under shorter-duration loads is “anti-decay” or “reverse-deterioration”.

ABSTRACT

The 14th Edition of AISC's *Steel Construction Manual* will be available in the summer of 2011. The new manual includes and is based on the 2010 AISC *Specification for Structural Steel Buildings*. Because of the new specification, as well as some other modifications to the connection design procedures, the 14th Ed. Manual will include revisions to some of the existing 13th Ed. tables.

Many of the changes in the 2010 Specification are clarifications and minor adjustments, along with some important substantive changes in Chapter I, composite design, and a new Chapter N on quality control and quality assurance. Some of the other notable revisions include:

- Revised scope statement related to seismic design (Chapter A)
- Structural integrity is addressed (Chapter B)
- Stability design procedures are reorganized (Chapter C, Appendices 7 and 8)
- Revised the available shear strength values for bolts (Chapter J)
- Revised the slip-critical strength limit state for bolts (Chapter J)
- Tabulated the HSS connection design equations (Chapter K)
- New Appendix on Inelastic Analysis and Design (Appendix 1)

In addition to the changes to the Specification, several changes and improvements related to connection design were also made to the Manual. These include:

- Revised bolt value tables for both bearing and slip-critical connections (Part 7).
- Revisions and additions to the eccentrically loaded weld group tables (Part 8).
- Clarifications to the discussion of connecting elements subject to flexure (Part 9).
- Revisions to the design procedure for conventional single-plate shear connections (Part 10).
- A revised discussion on the design of flexible moment connections (Part 11).

INTRODUCTION

The AISC *Specification for Structural Steel Buildings* (AISC, 2010a) is the standard for the design, fabrication and erection of steel buildings in the U.S. and the basis of the AISC *Steel Construction Manual* (AISC, 2011). The new *Specification* is dated June 22, 2010, based on the ANSI accreditation date and the next AISC *Manual* will be the 14th

Edition of that publication and will be available in the summer of 2011. Reminiscent of the 6th Edition, the cover will be burgundy in color, and will contain some important updates. The 14th Edition continues to address both the allowable stress design (ASD) and load and resistance factor design (LRFD) methods similar to the 13th Edition. Although a concerted effort was made to minimize the number of changes in the 2010 *Specification*, ongoing research and innovation and industry practice have led to revisions and new provisions for member and connection design in the new *Specification* that are reflected in the *Manual.* The AISC *Specification* is located in Part 16 of the *Manual*, and continues to serve as the basis for the *Manual*—there would be no *Manual* without a *Specification.* New revisions to look for in the *Specification* are found in the scope statement (Chapter A), referenced material standards (Chapter A), structural integrity (Chapter B), composite design (Chapter I), quality control and quality assurance (new Chapter N), and inelastic analysis. Connection-related changes in the *Specification* occur in both weld and bolt design (Chapter J). The *Manual* covers some connection design topics not addressed specifically in the *Specification* and some of these topics have been updated, such as coped beam design, prying action, bracket plates, and single plate connections.

SCOPE

The scope statement in Chapter A of the 2010 AISC *Specification* clarifies the role of ASCE/SEI 7, *Minimum Design Loads for Buildings and Other Structures* (ASCE, 2010), by saying, "Wherever this Specification refers to the applicable building code and there is none, the loads, load combinations, system limitations, and general design requirements shall be those in ASCE/SEI 7." Further, the scope statement is now more generalized and revised to defer to the applicable building code. Previously, the scope indicated that building designs requiring an R factor of 3 or less were only required to satisfy the AISC *Specification*, and application of the AISC *Seismic Provisions for Structural Steel Buildings* (AISC, 2010b) was not required in that case. In some special cases, seismic detailing according to the AISC *Seismic Provisions* is required even when the R factor is less than 3. These cases are discussed in a new "Scope" statement appearing at the front of the 14th Edition *Steel Construction Manual*, as well as in a user note in the *Specification* Section A1.1.

NEW MATERIAL SPECIFICATIONS

Specification Section A2, Referenced Specifications, Codes and Standards, lists all of the publications and their titles that are referenced in the *Specification* or are acceptable for use with *Specification*. In addition to updating existing standards, such as AWS D1.1/D1.1M (AWS, 2008), RCSC *Specification for Structural Joints Using High Strength Bolts* (RCSC, 2009), and the AISC *Code of Standard Practice for Steel Buildings and Bridges* (AISC, 2010c), one new ASTM material standard included is ASTM A1043/A1043M (ASTM, 2005). This ASTM specification limits the yield to tensile strength (F_y/F_u) ratio to 0.8 and the Charpy V-notch toughness is 40 ft-lb @ 70 °F with CVN testing completed in accordance with ASTM A673/A673M, frequency H

(ASTM, 2004). These specifications make this an ideal material to use in seismic applications as the requirements exceed those required by the AISC *Seismic Provisions*.

Part 1 of the AISC *Manual* references this new material as well as providing dimensions and properties for new shapes that are available from suppliers. As in the past, the Dimension and Properties tables list shape designations consistent with ASTM A6 (ASTM, 2009). In the 14th Edition *Manual*, four new HP18 shapes, six new HP16 shapes, and one new MC shape (MC12×14.3) are listed.

STRUCTURAL INTEGRITY

AISC added new language to Section B3.2 of the *Specification* and in Part 2 of the *Manual* to clarify the application of the requirements given in the International Building Code. In response to the World Trade Center tragedy in 2001, the goal of the requirements is to provide some minimum robustness in the connection. The first related requirements appeared in the 2008 New York City Building Code, followed by the 2009 International Building Code. The integrity provisions given in the IBC apply to high-rise buildings assigned to Occupancy Categories III or IV. High-rise buildings are defined as those "having an occupied floor greater than 75 ft above fire department vehicle access" (AISC, 2011). The provisions also state that column splices must resist a minimum tension force and beam end connections a minimum axial tension force on the beam. Geschwindner and Gustafson (2010) examine these structural integrity requirements for single plate connections and make a comparison between the IBC and NYC methods. The AISC *Specification* states that "design for structural integrity requirements shall be based on nominal strength rather than design strength (LRFD) or allowable strength (ASD), unless specifically stated otherwise in the applicable building code." The IBC stipulates that the nominal axial tension strength of the beam end connection equal or exceed either the required vertical shear strength for ASD or 2/3 the required vertical shear strength for LRFD, but not less than 10 kips. Additionally, the *Specification* notes that limit states based on limiting deformations or yielding can be ignored when making the structural integrity check as the intent is to preclude brittle rupture failures. Bearing bolts in short slots parallel to the direction of the tension load are acceptable with the bolt assumed to be at the end of the slot.

MEMBER DESIGN

The revisions in the 2010 *Specification* are minimal related to members subject to compression, flexure, combined compression and flexure, and shear. In both Chapters E (Design of Members for Compression) and F (Design of Members for Flexure), a user note roadmap has been added at the beginning of the chapter to direct the user to the appropriate limit states for the various cross sections. For compression member design, there are two noticeable revisions. In Section E3, Flexural Members Without Slender Elements, the limit between elastic and inelastic buckling has been reformatted in terms of the elastic buckling stress, F_e, to remove a discontinuity that occurred in 2005. In Section E6, Built-Up Members, the equations to determine how many bolted or welded

connectors are required in built-up members have been revised. The formulation is based on more recent research and evaluation of all existing test data (Sato and Uang, 2007).

In Chapter F, there are slight modifications to the equations for the bending coefficient, C_b, and the limiting laterally unbraced length for inelastic buckling, L_r, as well as a new section providing an explicit local buckling check of tee stems. The equation for C_b has been modified as follows:

$$\text{2010:} \quad C_b = \frac{12.5M_{max}}{2.5M_{max} + 3M_A + 4M_B + 3M_C} \qquad \text{(F1-1)}$$

$$\text{2005:} \quad C_b = \frac{12.5M_{max}}{2.5M_{max} + 3M_A + 4M_B + 3M_C} R_m \leq 3.0 \qquad \text{(F1-1)}$$

The modifier, R_m, and the limit of 3.0 have been removed in the 2010 *Specification* equation, however, the 2005 version is still available int the commentary. The 2010 equation is only applicable to singly symmetric members in single curvature and doubly symmetric shapes. For other situations, see the 2010 *Specification* Commentary.

The equation for L_r was algebraically manipulated to remove the torsional constant, J, from the denominator of the term under the radical so there was a solution if $J = 0$. The equation for L_r has been modified as follows, with both equations giving identical results:

$$\text{2010:} \quad L_r = 1.95 r_{ts} \frac{E}{0.7F_y} \sqrt{\frac{Jc}{S_x h_o} + \sqrt{\left(\frac{Jc}{S_x h_o}\right)^2 + 6.76\left(\frac{0.7F_y}{E}\right)^2}} \qquad \text{(F2-6)}$$

$$\text{2005:} \quad L_r = 1.95 r_{ts} \frac{E}{0.7F_y} \sqrt{\frac{Jc}{S_x h_o}} \sqrt{1 + \sqrt{1 + 6.76\left(\frac{0.7F_y}{E}\frac{S_x h_o}{Jc}\right)^2}} \qquad \text{(F2-6)}$$

Section F9.4 provides a new local buckling check for tees stems in flexural compression based on the *Guide to Stability Design Criteria* (Ziemian, 2010). The 2005 *Specification* did not have provisions for the local buckling strength of stems of tee sections under a flexural compressive stress gradient. The commentary explained that the local buckling strength was accounted for in the equation for the lateral-torsional buckling limit state when the unbraced length approached zero, but this led to confusion.

The most notable revision to Chapter H (Design of Members for Combined Forces and Torsion) is a new optional solution for doubly symmetric rolled compact members subject to single axis flexure and compression. Section H1.3 provides a procedure to replace the interaction equations in Section H1.1, which can be overly conservative where the axial limit state is out-of-plane buckling and the flexural limit state is lateral-torsional buckling (Ziemian, 2010). The optional solution is permissible when the

moments are primarily about the major axis, the ratio of required flexural strength about the minor axis to the available flexural strength about the minor axis is less than 0.5, and the torsional effective length does not exceed the minor axis effective length. Using this option, the limit state of in-plane stability is checked using the usual interaction equations of Section H1.1. Additionally, the limit states of out-of-plane buckling and lateral-torsional buckling are checked using the following equation:

$$\frac{P_r}{P_{cy}}\left(1.5-0.5\frac{P_r}{P_{cy}}\right)+\left(\frac{M_{rx}}{C_b M_{cx}}\right)^2 \le 1.0 \qquad (H1-2)$$

COMPOSITE DESIGN

Chapter I, Design of Composite Members, includes some new and expanded provisions and underwent a major reorganization for the 2010 AISC *Specification*. Some of the changes include new provisions for the following topics: local buckling of filled members, compressive axial force, load transfer, diaphragms and collectors, composite beam-columns, and steel anchors. The chapter was reorganized as follows:

2005	2010
I1. General Provisions	I1. General Provisions
I2. Axial Members	I2. Axial Force
I3. Flexural Members	I3. Flexure
	I4. Shear
I4. Combined Axial Force and Flexure	I5. Combined Axial Force and Flexure
	I6. Load Transfer
	I7. Composite Diaphragms and Collector Beams
	I8. Steel Anchors
I5. Special Cases	I9. Special Cases

Section I1 includes tables providing limiting width-to-thickness ratios for compression steel elements subject to axial compression and subject to flexure in filled composite sections. These new slenderness provisions allow noncompact and slender sections in filled members, while previously they were only allowed if tested and analyzed. For axial compression, the compact/noncompact limit, λ_p, is the same as that in the 2005

AISC *Specification*. The other limits are based on an evaluation of past and more recent research (Varma and Zhang, 2009).

One important new criterion applies to both encased and filled composite columns: The available compressive strength need not be less than that specified for the bare steel member as required by Chapter E (Design of Compression Members). This revision resulted when it was discovered that occasionally the calculated available strength of a composite member could result in a lower value that the bare steel member, which is not a logical conclusion.

Section I7 provides performance language addressing the design and detailing of composite diaphragms and collector beams. Supplemental information is provided in the commentary as guidance to designers.

An additional revision that appears throughout the *Specification* is that the term steel anchor has replaced the term shear connector. Specifically, the 2010 *Specification* addresses steel headed stud anchors and channel anchors. The change in terminology in Section I8, Steel Anchors, is to be consistent with the more general provisions on anchorage in ACI 318 Appendix D. Provisions are added for edge distances of steel anchors along the axis of a composite beam for normal and lightweight concrete. New steel anchor provisions for shear, tension, and the interaction of shear and tension are also provided for other forms of composite construction, referred to as composite components.

In Section I8.2, the strength of a steel headed stud anchor is defined for a composite flexural member where steel anchors are embedded in a solid concrete slab or in a composite slab with decking. The equation is identical to the 2005 *Specification* version:

$$Q_n = 0.5 A_{sa} \sqrt{f'_c E_c} \le R_g R_p A_{sa} F_u \qquad \text{(I8-1)}$$

The revision here is in the R_p factor which has been reduced to 0.75 for the solid slab case after evaluation of existing and recent research (Pallares and Hajjar, 2010).

QUALITY CONTROL AND QUALITY ASSURANCE

The AISC *Specification* has historically addressed quality control minimally and more recent versions included provisions in Chapter M—referring to the RCSC *Specification* and AWS D1.1 for inspection guidelines. In a response to requests from the Building Seismic Safety Council, NCSEA and others, the 2010 AISC *Specification* includes a new Chapter N on Quality Control and Quality Assurance. The chapter is consistent with IBC Chapter 17, the RCSC *Specification*, and AWS D1.1, and as stated in Section N1, Chapter N "provides a plan of requirements for the minimum observation and inspection tasks deemed necessary to ensure quality in structural steel construction". The AISC *Seismic Provisions* stipulates additional quality criteria for high-seismic design. The goal of the new chapter is to provide a uniform plan with a relatively high level of assurance,

and effective consistent requirements. Chapter N also stipulates nondestructive testing requirements in Section N4, which are not available in other standards.

Quality control is implemented by the fabricator and quality assurance is provided by a third party when required by the authority having jurisdiction, applicable building code, purchaser, owner, or engineer of record. Sections N5 and N6 provide a detailed list of the tasks required to put together a quality control or quality assurance plan for structural steel buildings and composite construction, respectively. Each task is identified as a task to perform (P) or a task to observe (O). Perform means that the task must be performed for each joint or member and observe means that the task is to be observed on a random basis. Tasks assigned to be performed generally cannot be properly treated using random sampling techniques. These terms differ from common building code terminology, which assigns tasks to be observed continuously and periodically.

The chapter concludes with Section N7, Approved Fabricators and Erectors, and Section N8, Nonconforming Materials and Workmanship. Section N7 says that when a fabricator or erector participates in an approval process acceptable to the authority having jurisdiction, such as the AISC Quality Certification program, quality assurance inspections may be waived. Section N8 explains how nonconforming materials and workmanship are to be handled.

INELASTIC ANALYSIS

Appendix 1 of the 2010 AISC *Specification* is, perhaps, the first significant step towards an AISC performance based design specification. By moving some provisions to other more appropriate places in the *Specification*, Appendix 1 now addresses only inelastic analysis. In all cases, the strength limit states defined in Chapters D, E, F, G, H, I, J and K must be considered, but if they are detected by an inelastic analysis, they are not subject to the applicable provisions in the *Specification*. If a nonlinear analysis is performed, the interaction equation of Chapter N need not be checked. This chapter allows the designer to use a more sophisticated analysis.

ORGANIZATIONAL REVISIONS

Some sections of the 2010 AISC *Specification* were reorganized for ease of use and clarification with little or no modification, such as Table B4.1, Chapter C and Chapter K. Table B4.1 that provides limiting width-thickness ratios for compression elements is now split into two tables in order to clarify the different terminology that should be used for compression elements in members subject to axial compression (Table B4.1a) and in members subject to flexure (Table B4.1b). Table B4.1a refers to nonslender and slender elements while Table B4.1b refers to compact, noncompact and slender elements.

The direct analysis method that was located in Appendix 7 in the 2005 *Specification* has been moved up into Chapter C, as the method of choice for stability design. The other two methods, effective length and first-order analysis have been relegated to Appendix 7. AISC committee members suggested this reorganization because the direct analysis

method is thought to allow a more accurate determination of the load effects in the structure through the inclusion of the effects of geometric imperfections and stiffness reductions directly within the structural analysis. The method also allows use of $K = 1.0$ in calculating the in-plane column strength within the beam-column interaction equations of Chapter H. Additionally, the 2010 *Specification* includes provisions for neglecting P-δ when using the direct analysis method. It is acceptable to neglect P-δ when (1) gravity loads are supported by vertical columns, walls and frames, (2) $\delta_{max}/\Delta_{max} \leq 1.7$, and (3) one-third or less of the total gravity load on the structure is supported by columns that are part of the moment-resisting frames in the direction of translation. In no case can this apply if members are subject to compression and flexure. As in 2005, Chapter C provides a complete list of stability requirements that the stability design must account for. In 2010, one additional requirement must be considered: the uncertainty in stiffness and strength.

The provisions of Chapter K for HSS connection design have been organized into tables for plate-to-round HSS connections, plate-to-rectangular HSS connections, round HSS-to-HSS truss connections, rectangular HSS-to-HSS truss connections, round HSS-to-HSS moment connections, rectangular HSS-to-HSS moment connections, and effective weld properties for connections to rectangular HSS. Each connection type includes a figure to exemplify the variables used and the configuration. It is hoped this new arrangement will simplify HSS connection design. Section K4 includes the weld design rules for T-, Y- and cross-connections which are expanded to include moments, as well as axial loads. "Fit for purpose" design rules for overlapped connections have been incorporated where the welds may be designed to resist branch forces in HSS truss-type connections by using the effective length concept. Many HSS truss web members are subjected to low axial loads and, in such situations, this weld design philosophy works well.

CHANGES AFFECTING CONNECTION DESIGN

Though AISC strove in the cycle between 2005 and 2010 to minimize changes to the *Specification* and the *Manual*, some changes that affect connection design were made because they were felt necessary to maintain safety, improve economy, or add clarity for the user. In some instances a change in one document precipitated changes in the other.

This portion of the paper is intended to highlight some of the more significant changes that affect connection design. It is not meant to be comprehensive listing of all the changes.

CHANGES IN THE 2010 SPECIFICATION AFFECTING CONNECTION DESIGN

There are number of significant changes, which affect connections designed using the 2010 *Specification*. These changes affect the design of bolts, welds and connecting elements.

Changes to the Design of Welds

Base Metal Check for Partial-Joint-Penetration Welds

In Table J2.5, which provides the base and weld metal strengths for welded joints, the base metal strength for partial-joint-penetration welds in tension was changed to be based on the rupture strength rather than the yield strength. This change was made because the welds are sized using the rupture limit state. Limiting the base metal at the fusion line between the base metal and the weld metal to the yield strength was therefore inconsistent and unnecessarily restrictive.

Out-of-Plane Loading of Fillet Welds

The 2010 *Specification* removes the limitation that fillet welds must be loaded in-plane in order to use the directional strength increase provided by Equations J2-5 or J2-9b. Research by Gilbert Grondin of the University of Alberta and Amit Kanvinde of the University of California–Davis (Kanvinde, 2009) indicated this limitation is unnecessary. It is interesting to note that the Eccentrically Loaded Weld Group tables in Part 8 of the *Manual* have incorporated the strength increase for out-of-plane loading for quite some time.

Fillet Weld Groups of Non-Uniform Size

The design of fillet weld groups using Sections J2.4(a) and J2.4(c) has been clarified to indicate that these provisions can only be applied to uniformly sized fillet weld groups. This is important change since the load-deformation behavior is affected by variations in size as well as loading angle (Muir, 2008). Fillet weld groups composed of variously sized weld elements can be designed using Section J2.4(b), which appropriately accounts for size variations.

Changes to the Design of Bolts

Nomenclature

The most immediately obvious change to Section J3, which provides requirements for bolted connections, is one of nomenclature. To improve convenience and readability of the *Specification*, which essentially treats conventional and TC bolts as interchangeable, various bolts with common strength levels have been grouped. ASTM A325, F1852 (TC bolts), A354 Grade BC, and A449 bolts have been grouped together and referred to as Group A bolts. Similarly, ASTM A490, F2280 (TC bolts), and A354 Grade BD bolts have been grouped together and referred to as Group B bolts. These new designations should not to be confused with the existing faying surface preparation designations also referred to as Class A and Class B.

Nominal Shear Strength

A more significant change, in terms of design, is an increase in the shear strength of bolts. Historically, the shear strengths of fasteners and threaded parts provided in Table J3.2 have included a length reduction factor of 0.80. This reduction factor accounted for uneven force distributions among the bolts in end-loaded connections caused by deformation of the connection material. While this variation in load occurs only in end-loaded connections, the reduction factor is applied to all connections for simplicity. Tide (2010) reviewed available test data on which the 0.80 length reduction factor was based. Using reliability-based procedures, it was determined that if the connection length were limited to 38 in., a length reduction factor of 0.90 could accommodate the effects of differential strain. Again for simplicity the reduction is applied to both end-loaded connections up to 38 in. in length and all direct loaded connections.

Similar to provisions in previous specifications, the 2010 *Specification* includes a further reduction for longer connections. An additional length reduction factor of 0.75 is applied to connections longer than 38 in.

Since the majority of bolted connections are neither end-loaded nor greater than 38 in. long, the committee felt the economy provided by this change justified the work required to accommodate the change by the engineering profession and construction industry.

Slip Resistance

Due to new data and some uncertainty about statements made in the literature, the 2005 *Specification* contained a two tier approach to the design of slip-critical connections, which could be designed assuming slip was either a serviceability limit state or a strength limit state. This was a significant change from previous editions of the AISC *Specification* and the RCSC *Specification*, and was not viewed favorably by the committee, engineers, or the industry. Therefore, significant effort was dedicated to finding a better solution.

Several research programs were aimed at bettering the knowledge of these connections.

Gilbert Grondin of the University of Alberta conducted a survey of available data to determine appropriate resistance factors and slip coefficients. Based on this study the value of the slip coefficient, μ, for Class A faying surfaces was changed from 0.35 to 0.30 primarily to better reflect the observed behavior of connections with clean mill scale and roughened galvanized surfaces. The slip coefficient for Class B surfaces was found to be slightly conservative but the Committee decided to leave $\mu = 0.50$ for blast cleaned surfaces and blast cleaned surfaces with Class B coatings. Grondin also looks at the consequences of slip, specifically by modeling the behavior of a long-span truss utilizing oversize holes in all plies of the bolted connections. This work in conjunction with the analysis of the data, helped to lead to the resistance factors contained in the 2010 *Specification*.

Peter Dusicka of Portland State University studied the effect of multiple fills on the slip resistance. This work, which was still in process as the new specification was being

finalized, indicated the number of fillers in a joint could reduce the slip strength and lead to the inclusion of a fill factors, h_f.

Jerome Hajjar of the University of Illinois (Borello, 2009) tested a series of slip-critical bolted splice connections configured to emulate those found in long-span trusses. The nominal strength of the tested connections approached the 3-million pound capacity of the testing equipment, more accurately mirroring joints currently used in steel construction. The results confirmed that the presence of oversize holes did not cause a reduction in slip strength, a fact that was not clearly established in the literature. The tests also supported Dusicka's conclusion that multiple fillers tended to reduce the slip resistance, though with an important exception when additional bolts were added to develop the fillers.

The Hajjar tests were also configured to establish the shear strength of bolts in oversize holes with and without thick fillers, as previous tests had only included fillers up to 3/4 in. The results showed that bolts in oversize holes could develop their full design shear strength with a maximum reduction of 15% regardless of filler thickness. These tests indicated that the slip into bearing was accompanied by a significant increase in strength beyond that predicted by the slip strength, a strength beyond that extrapolated from previous tests on joints with fillers. Based on these tests, Section J5, has been modified so that the reduction factor, $[1 - 0.4(t - 0.25)]$, used to account for the presence of fills need not be less than 0.85 regardless of the thickness of the filler.

Default to Snug Tight Condition

Finally, there is an additional simple—but important—change in Section J3.1 that permits bolts to be installed to the snug tight condition when used in bearing type connections except where noted elsewhere in the *Specification*. All bolts required to be tightened to a condition other than snug-tight are required to be clearly identified on the contract documents. Note that this is not intended to preclude use of ASTM F1852 or F2280 (TC) bolts in these joints, as these are acceptable for use with the snug-tight designation, even when installed such that the spline is ruptured.

Changes Affecting Connecting Elements

The 2005 *Specification* addressed the strength of elements subjected to tension, shear, block shear and compression but did not address flexure. It was never the intention of the Committee to imply that connecting elements need not to be checked for flexure, but rather to allow these checks to be addressed when appropriate in the *Manual*, similar to other connection design limits. Though the 2010 *Specification* does explicitly address the strength of elements in flexure, the discussion is brief and merely references the *Manual* and other sources. This recognizes that flexure as we normally envision it often cannot develop in short connection elements, and consideration of flexure is a matter of engineering judgment.

CHANGES IN THE 14TH EDITION MANUAL AFFECTING CONNECTION DESIGN

There are number of significant changes, which affect connections designed using the 14th Edition of the Manual. These changes include changes due to the increased *Specification* bolt shear strengths, improvements made to the discussion on the design of coped beams, and clarifications to the prying action checks.

Specification Increase in Bolt Strengths

The increase in bolt shear strengths in the *Specification* led to widespread changes to the *Manual*. Obviously the tables providing bolt strengths in Chapter 7 had to be revised to reflect the change in the *Specification*, as did tables providing connection strengths in Chapter 10. Design Examples, available on-line, also had to be revised to remain consistent with the *Specification*. In most instances, however, the underlying design procedures used in connection design were not affected, with one notable exception— the conventional configuration of the single plate shear connection, referred to here as the conventional shear tab. While design procedures for most connections discussed in the *Manual* are based on rational models, often confirmed through testing, the design procedure for the conventional shear tab has from the start been highly empirical.

Though the effect of the increased bolt strengths was considered for a broad range of connection types, changes were only required to the procedure used for the conventional shear tab due to its inherent empiricism. The design eccentricities contained in the 13th Edition of the *Manual* were derived by dividing the observed connection strength, when governed by the bolts, by the nominal bolt strength given in by the *Specification* to determine an effective number of bolts. This effective number of bolts divided by the total number of bolts in the group is essentially the C-value provided in the Eccentrically Loaded Bolt Group tables in Part 7 of the *Manual* and can be used to determine an effective eccentricity. Since the design eccentricity was derived based on the nominal shear strength of the bolt, an increase in this value in the *Specification* reasonably precipitated an increase in the design eccentricities presented in the *Manual*. Where eccentricities were assumed to be zero in the 13th Edition, they are now assumed to be equal to half the distance separating the weld group from the bolt group, referred to as "a" in the *Manual*. In the process of reexamining the data, some changes to the prescribed ratio between the bolt diameter and the plate thickness were also made, removing the limitation altogether for shallow connections utilizing short slots and making the limit more restrictive for deeper connections utilizing standard holes.

Design of Coped Beams

The discussion in the 13th Edition of the Manual on the design of coped beams was found to be unclear and incomplete. In some instances it was not clear which limit states were likely to govern and some geometries the designer would be left without a recommendation as to the proper design procedure. The Specification Committee's Task Committee 6 worked with the Manual Committee to resolve these issues for the 14th

Edition of the Manual. The current text is more clearly written and provides a conservative catchall design procedure for conditions not meeting the geometrical constraints required of the provisions based on Yura's work. It also addresses conditions where the tension flange cope is longer than the compression flange cope.

Prying Action

Several seemingly minor, but important revisions were made to the prying action procedure in the *Manual*. The discussion of prying action in the *Manual* can be interpreted as providing essentially three different paths to determine the adequacy of a connection relative to prying action. The first assumes that the fitting geometry has not been established, the second calculates the prying force, which could then theoretically be used to check the adequacy of the connection (though this path is not fully described), and the third checks the adequacy of a connection based on a known fitting geometry. Though a thorough knowledge of the principles underlying the checks would reveal that the variable α could not exceed 1.0, this was not clearly spelled out in previous editions of the *Manual* and so was clarified in the 14th Edition. An informal survey of practicing engineers also revealed that the methods used to determine the effective connection length, p, relative to each bolt was not clearly understood nor was the upper limit that should be placed on this value. Clearer language and sketches were introduced to overcome this deficiency.

Bracket Plates

Bracket plate buckling, as described in Part 15 of the 13th Edition of the Manual, was based on a model developed by Salmon and Johnson (1996). However, the assumptions implicit in this model were not felt to accurately reflect common practice. For example the top, horizontal plate must be firmly attached to the support to satisfy the Salmon and Johnson model. However, this is not always the possible. As a result the buckling check was revised to the more general and conservative approach used in checking double copes and single plate shear connections.

CONCLUSION

As discussed here, the 2010 AISC *Specification for Structural Steel Buildings* and the 14th Edition *Steel Construction Manual* include a limited number of important updates and new topics. The AISC *Manual*, with the AISC *Specification* as its basis, continues to be the resource for steel design, fabrication and erection.

ABSTRACT

Seismic design provisions for use with steel sheathed cold-formed steel framed shear walls have been proposed for inclusion in the National Building Code of Canada with the associated detailing and design procedures found in the AISI S213 North American Lateral Design Standard for cold-formed steel structures. The design procedure, including recommended seismic force modification factors (R-values), was based on the results of an extensive series of monotonic, reversed cyclic and dynamic tests, as well as non-linear time history dynamic analyses of representative building structures. An approach adopted from the FEMA P695 incremental dynamic analysis procedure is being used to evaluate and improve the seismic design procedure. An overview of the process followed in the conception of the seismic design provisions is provided in this paper.

INTRODUCTION

A research project was initiated at McGill University in 2008 with the objective of developing a design method for cold-formed steel (CFS) shear walls sheathed with steel panels that could be used in conjunction with the National Building Code of Canada (NBCC) *(2005)*. The intent is for this method to be included in the Canadian section of the North American standard for cold-formed steel framing – lateral design (AISI S213) *(2007)*. An extensive program of single-storey shear wall displacement based tests was first carried out to establish a database of information. This information was then supplemented with dynamic shake table tests of single and double-storey shear wall specimens.

The equivalent energy elastic-plastic (EEEP) analysis approach was chosen to derive key design parameters for the shear walls including; nominal shear strength, resistance factor, elastic stiffness, overstrength, drift limit, ductility and test-based seismic force modification factors. This data evaluation procedure is consistent with that used to establish the Canadian wood sheathed / CFS framed shear wall design provisions in AISI S213. Single-storey shear walls of various configurations were tested under monotonic and CUREE reversed cyclic displacement based loading protocols; a selection of these walls was subjected to combined gravity and lateral loading. The walls varied in terms of framing and sheathing thickness, detailing and

aspect ratio. The shape, thickness and grade of the steel-frame members are common to the CFS industry; furthermore, these steel members are typically used for applications in which load bearing is involved. Additional test data from Serrette *et al. (1996)*, Serrette *(1997, 2002)*, Ellis *(2007)*, Yu *et al. (2007)* and Yu & Chen *(2009)* were also relied on in the development of the design method.

Using the design approach established through evaluation of the displacement based test data single and double-storey shear wall specimens were configured to be tested dynamically. These tests were the first of their kind to be carried out on steel sheathed / CFS framed shear walls. The intent was to use the results of the dynamic tests to validate and improve the accuracy of the response provided by dynamic software such as OpenSees *(McKenna et al. 2006)*, and to observe the behaviour of the double-storey specimens in order to identify whether the assumptions made in modeling, such as perimeter element design, are appropriate. The scope of the dynamic testing included five single-storey and five double-storey shear walls constructed of a typical CFS frame sheathed with 0.46 mm or 0.76 mm steel sheathing. The walls were designed as per the Canadian provisions proposed for inclusion in AISI S213. Each wall was subjected to a suite of dynamic tests ranging from impact tests to measure damping, forced vibration tests to obtain the natural period of vibration as well as ground motions representative of the seismic hazard in Canada. Dynamic models based on the results of the displacement based test walls were initially used to predict the inelastic behaviour of the walls prior to testing on the shake table such that the loading protocols could be established.

All of the test data was used in the development of non-linear time history dynamic building models that will be relied on to investigate the seismic performance of structures having a lateral system constructed with steel sheathed CFS shear walls. As a final, and still ongoing, phase to the research project non-linear time history dynamic analyses of multi-storey CFS framed structures is being carried out following an approach adopted from FEMA P695 *(2009)* on the quantification of building seismic performance factors. Input earthquake records are to be scaled to the site specific uniform hazard spectra for various cities across the county. The calculated inelastic storey drifts and the failure probabilities from the FEMA P695 incremental dynamic analysis procedure will then be utilized to evaluate and improve the seismic design procedure for steel sheathed CFS framed shear walls.

DISPLACEMENT BASED TESTING

As part of the research program 54 steel sheathed single-storey shear wall tests (18 configurations) were carried out at McGill University in 2008 *(Balh et al., 2010; Balh & Rogers 2010; Ong-Tone & Rogers 2009)*. The walls, which consisted of framing elements and a steel sheathing panel on one side measured 610 x 2440 mm, 1220 x 2440 mm, 1630 x 2440 mm and 2440 x 2440 mm in size. The frame was constructed using tracks (92.1 mm web, 38.1 mm flange) and studs (92.1 mm web, 41.3 mm flange and 12.7 mm lip) connected together with No. 8 x 12.7 mm wafer head self-drilling / self tapping screws. Simpson Strong-Tie S/HD10S hold-down devices were placed at the bottom of each chord stud to anchor the shear wall to the test frame. The shear walls varied in framing thickness (0.84 mm or 1.09 mm), sheathing thickness (0.46 mm or 0.76 mm) and detailing of the fasteners. Each panel

was attached to the frame with No. 8 x 19 mm self drilling / self tapping pan head screws spaced at 50 mm, 100 mm or 150 mm over the perimeter and at 300 mm along the field stud(s). The 1830 mm and 2440 mm long walls required the use of two sheathing panels butted together at a single internal stud. The shear walls were tested using two displacement based loading protocols; monotonic and CUREE reversed-cyclic protocol *(Krawinkler et al., 2000).* A specially constructed reaction frame, with a 250 kN capacity dynamic actuator having a displacement range of ± 125 mm, was used to test each shear wall under stroke control while measuring the resistance and relevant deformations. Detailed information on the test program can be found in the reports by Balh & Rogers *(2010)* and Ong-Tone & Rogers *(2009)*.

An additional series of 14 walls reinforced with quarter point blocking between studs and thicker chord studs was tested under a combined gravity (constant 12.5 kN / 1.22 m long wall) and lateral monotonic or reversed cyclic protocol in 2010 (Figure 1). The intent was to improve the detailing and design of the chord stud elements such that the inelastic behaviour would, for the most part, be restricted to the sheathing and its connections.

Figure 1 : Displacement based single-storey shear wall test setup

The monotonic and reversed cyclic test specimens exhibited elastic shear buckling of the sheathing panels at relatively low lateral loads followed by the development of a tension field (Figure 1). At ultimate load the failure of each test wall could often be attributed to the sheathing-to-frame connections where steel bearing, fastener pull-out, fastener pull-through and tear-out were observed (Figure 2). Unzipping of the fasteners along the perimeter of the shear wall was also common. In some cases deformations were observed in the framing elements, especially when the thicker sheathing was combined with a screw spacing of 50 mm. Twisting of the

chord studs occurred due to the horizontal component of the tension field that developed in the sheathing *(Balh & Rogers 2010; Ong-Tone & Rogers 2009)*. In addition, uplift of the track elements took place due to the vertical component of the tension field (Figure 2).

Figure 2 : Shear wall test specimens showing bearing damage at screw connections, as well as chord stud twisting and track uplift caused by tension field forces *(Balh et al. 2010)*

DYNAMIC SHAKE TABLE TESTING

To justify the proposed seismic design approach derived from these displacement based tests it was necessary to investigate the performance of representative shear walls by means of dynamic shake table tests. The scope of testing included; single-storey and double-storey walls, which were constructed of a typical screw connected CFS frame sheathed with steel sheet panels. The intent was to use the results of the dynamic tests to monitor the behaviour of the walls, to identify whether the performance is consistent with the displacement based tests, to obtain measures of damping and natural period of vibration and to validate and improve the accuracy of the force-deformation response provided by dynamic models. A 12.5 kN gravity load was first applied on the test wall once it had been constructed and assembled on the shake table. Each wall was then subjected to a suite of excitations; impact test to measure the linear-viscous damping ratio, harmonic excitation to estimate the natural period of vibration, and ground motions representative of the seismic hazard in Quebec and Vancouver Canada. Five single storey (1.22 x 2.44 m) and five double-storey (1.22 m x 5.18 m) walls were included in the scope of testing. The double-storey walls consisted of a 2.44 m high first storey wall, on top of which a 0.3 m deep CFS framed floor structure was attached followed by another 2.44 high second storey wall. The test wall was then connected to a pin supported mass structure located on the laboratory strong floor adjacent to the shake table (Figure 3). This mass structure represented the seismic mass tributary to the wall being tested. The base of the structure was also connected to the shake table such that the mass structure experienced the same dynamic excitation as the test wall.

Design of the dynamic wall specimens was initially carried out following the resistance values obtained from the displacement controlled tests with assumptions regarding the selection of the boundary elements that followed the current AISI S213

provisions for wood sheathed walls. Blocking between studs was added to the walls to limit the extent of chord stud twisting.

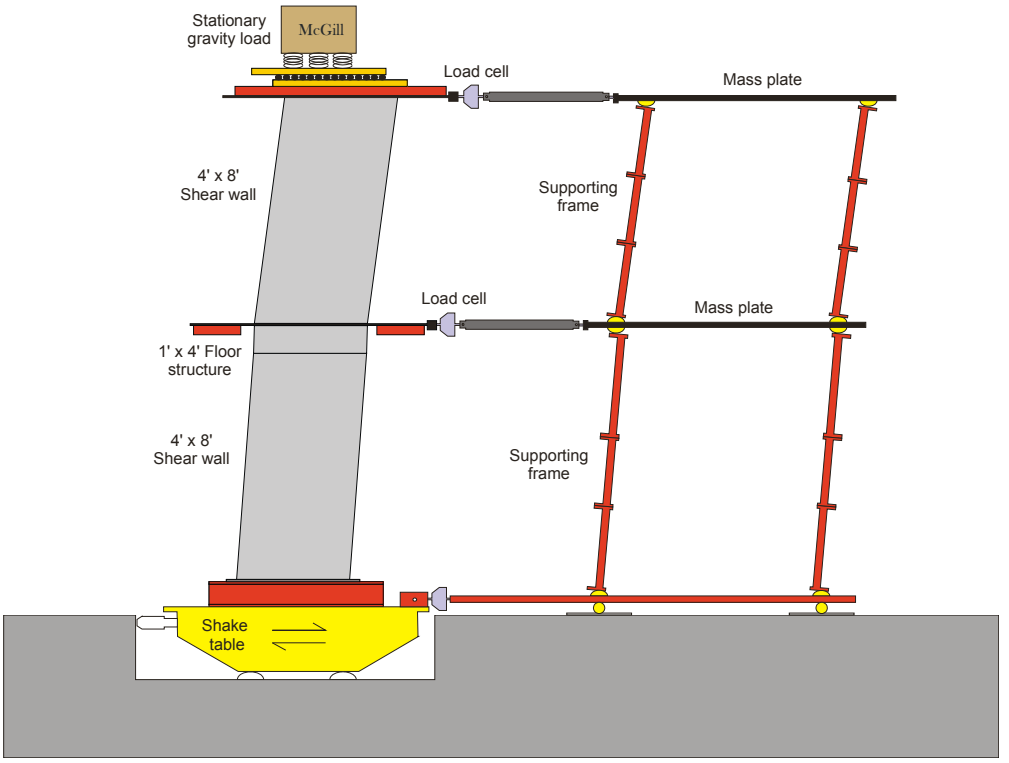

Figure 3 : Schematic of two-storey shear wall shake table dynamic test setup

Figure 4 : Dynamic double-storey shear wall test setup & failed wall specimen

The single-storey dynamic wall tests resulted in a measured performance that was similar to that obtained for the displacement based reversed cyclic tests, although the initial stiffness was somewhat smaller. However, the double-storey walls revealed a weakness in the procedure to select the chord stud members. An unexpected out-of-plane bending failure of the chord stud under compression took place due to the eccentric application of the axial force on this element. The design of subsequent double-storey walls was modified such that the axial force on the chord was considered to be applied eccentric to the centroid of the section and for the ground storey also accounted for the axial force originating in the upper storey. The eccentricity due to the location of the sheathing at the outer edge of the studs, as well as the accidental eccentricity from the gravity and seismic forces in the upper wall segment were accounted for in the design. In this fashion a beam-column design approach was taken that incorporated weak and strong axes moments as well as an axial compression force. The double-storey test wall that failed due to chord stud bending was then rebuilt and retested using the same dynamic protocol. Chord stud failure was avoided in this follow-up test; the wall exhibited the shear buckling and sheathing connection failure modes as anticipated. This shows the need for a more rigorous treatment of the chord stud design for these shear walls than what is currently found in AISI S213.

The results of the single and double-storey dynamic tests were then used to calibrate hysteretic models for use in building analyses. Some modifications were made to the initial models that were used to predict the behaviour of the dynamic shear walls prior to testing. For example, measured damping values between 5 % and 7 % of critical damping were used to aid in the selection of elastic and hysteretic damping in the model.

CURRENT DESIGN RECOMMENDATIONS

Similar to wood sheathed CFS shear walls *(Branston et al. 2006)*, the shear resistance versus deformation behaviour of steel sheathed shear walls under lateral loading is highly nonlinear. The Equivalent Energy Elastic Plastic (EEEP) method *(Park 1989; Foliente 1996)* was relied on to provide a bilinear elastic-plastic curve, which was then used to evaluate the performance of each shear wall. This approach is consistent with that used by Branston *et al. (2006)* in the development of Canadian shear wall resistance values and other related design values for the wood sheathed shear walls that are listed in the AISI S213 Standard. The EEEP method is valid for the analysis of results of both monotonic and reversed-cyclic tests. A backbone curve is constructed for the positive and negative displacement ranges of the resistance versus deflection hysteresis of each reversed cyclic test. The typical nonlinear force versus displacement response of a CFS framed shear wall is simplified for design by means of a bi-linear curve for which the plateau portion is set as the nominal shear resistance, S_y. This plateau section is established by equating the energy dissipated in testing (area under the backbone or monotonic curve) with the area under the bilinear curve, or as shown in Figure 5 by setting A1 = A2. The bilinear curve is limited by the ultimate failure displacement, assumed to occur at the 0.8 post-peak resistance, and the initial slope which is defined using the secant stiffness positioned through the

position defined by 40% of the ultimate load. El-Saloussy & Rogers *(2010)* also used the EEEP method to analyze the results from steel sheathed shear wall tests run by Yu *et al. (2007)* and Yu & Chen *(2009)*.

The EEEP analyses provided for a tabulated list of nominal shear resistance values, S_y, for CFS framed / steel sheathed shear walls. Table 1 provides these shear resistance values along with the corresponding wall configuration. Additional information on the derivation of this design information can be found in the report by Balh & Rogers *(2010)*.

Table 1. Proposed nominal shear resistance, S_y, for CFS frame / steel sheathed shear walls[1,2,8]

Assembly Description	Max. Aspect Ratio (h/w)[3]	Fastener Spacing[4] at Panel Edges (mm(in))				Designation Thickness[5,6] of Stud, Track, and Blocking (mm) (mils)	Required Sheathing Screw Size[7]
		150(6)	100(4)	75(3)	50(2)		
0.46 mm (0.018") steel sheet, one	2:1	4.13	-	-	-	0.84 (33)	8

[1] Nominal resistance (kN/m) is to be multiplied by the resistance factor, ϕ=0.7, to obtain the factored shear resistance

[2] Sheathing is to be connected vertically to the steel frame

[3] Nominal resistances are to be multiplied by 2w/h for aspect ratios greater than 2:1 but no greater than 4:1

[4] Field screws to be spaced at 300 mm on centre

[5] Wall stud and track shall be of ASTM A653 grade 230 MPa with a minimum uncoated base thickness of 0.84 mm (0.033") for members with a designation thickness of 33 mils, and ASTM A653 grade 230 MPA with a minimum uncoated base thickness of 1.09 mm (0.043") for members with a designation thickness of 43 mils

[6] Substitution of wall stud or track is not permitted

[7] Minimum No. 8x12.7mm (1/2") self drilling / self tapping screws shall be used

[8] Tabulated nominal resistances are applicable for lateral loading only

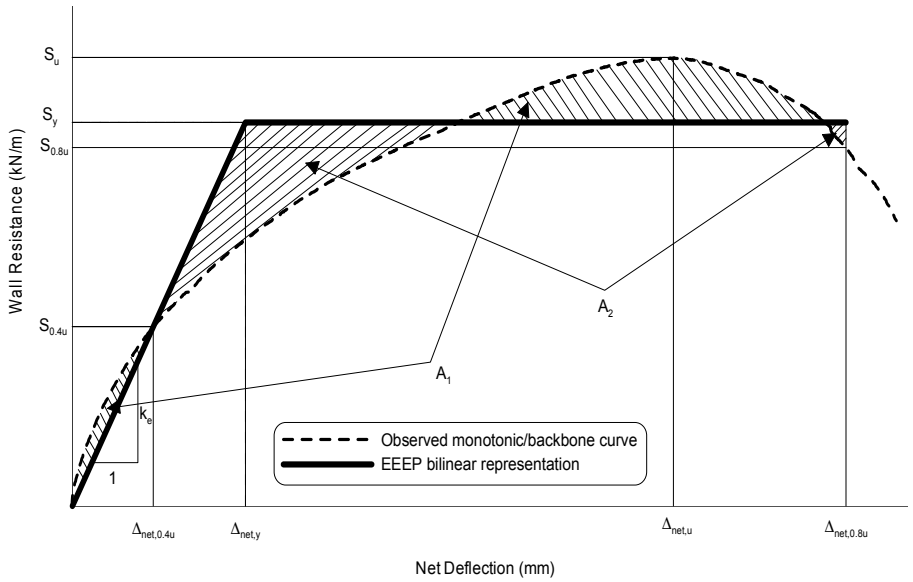

Figure 5 : Equivalent Energy Elastic-Plastic (EEEP) model *(Branston et al. 2006)*

In addition to the lateral resistance of the CFS framed shear walls two force modification factors are required for seismic design according to the NBCC. The ductility-related force modification factor, R_d, is a measure of the fuse element's ability to dissipate energy through inelastic deformation. The average value for R_d from displacement based test results was 2.87 *(Balh & Rogers 2010)*. At this time it is suggested that a value of 2.5 be considered to be consistent with the R_d value currently specified in AISI S213 for wood sheathed shear walls. A second force modification factor, R_o, represents the reserve of strength within the structure. Its calculation was based on the procedure recommended by Mitchell *et al. (2003)*. The average R_o value taken from the displacement based test results is 2.1; a value of 1.7 is suggested, again because of the R_o value for wood sheathed shear walls in AISI S213. These 'test-based' R-values require further verification by means of non-linear time history dynamic analyses of multi-storey CFS framed structures following an approach adopted from FEMA P695 *(2009)* on the quantification of building seismic performance factors.

DYNAMIC ANALYSES

The purpose of the non-linear time history dynamic analyses phase of the research is to evaluate the proposed seismic design method by predicting the performance of representative buildings during an earthquake. An approach adopted from FEMA P695 *(2009)* on the quantification of building seismic performance factors is currently being utilized to identify the probability of failure of these CFS framed structures. Input earthquake records (both synthetic and recorded) were scaled to the site specific uniform hazard spectra for various cities across the county. The OpenSees software with nonlinear dynamic analysis ability is being utilized for the purpose of modeling the tested walls and ultimately the representative building

structures. The calculated inelastic storey drifts and the failure probabilities from the FEMA P695 incremental dynamic analysis procedure will then been utilized to evaluate and improve the seismic design procedure.

Beam-column elements were used to model CFS frame components (Figure 6): elements with linear behaviour represent the chord-studs and rigid elements represent the tracks. Since tracks were attached to the relatively rigid frame during testing, and would also be attached to the foundation or floor structure in a building, using rigid elements was deemed to be realistic for their modeling. Also, track to chord stud hinge-moment connections were modeled with rotational springs. Total lateral displacement of walls was separated into two components: shear displacement representing the sheathed CFS frame displacement due to the shear force and uplift displacement representing the wall's rigid rotation because of anchor rod elongation. Zero length Springs with linear behaviour were placed at bottom of the walls to capture uplift displacement. The floor flexibility also was considered by using two linear diagonal trusses with the stiffness found from the test data.

A fictitious frame consisting of a beam-column element with "co-rotational coordinate transformation" capability and a connecting truss element was made with the gravity weight and mass load exerted at floor levels to account for the P-Δ effect of the vertical loads. The mass sourced from the mass plate and a part of the steel frame contributing to the seismic mass was lumped at top of each floor. This mass was 33.38 kN for the single-storey walls and 35.64 kN and 33.20 kN in first and second floor for double-storey walls, respectively. Rayleigh damping with 2% damping ratio was considered in the nonlinear analysis although the test-measured damping ratio in the linear domain was almost 7%.

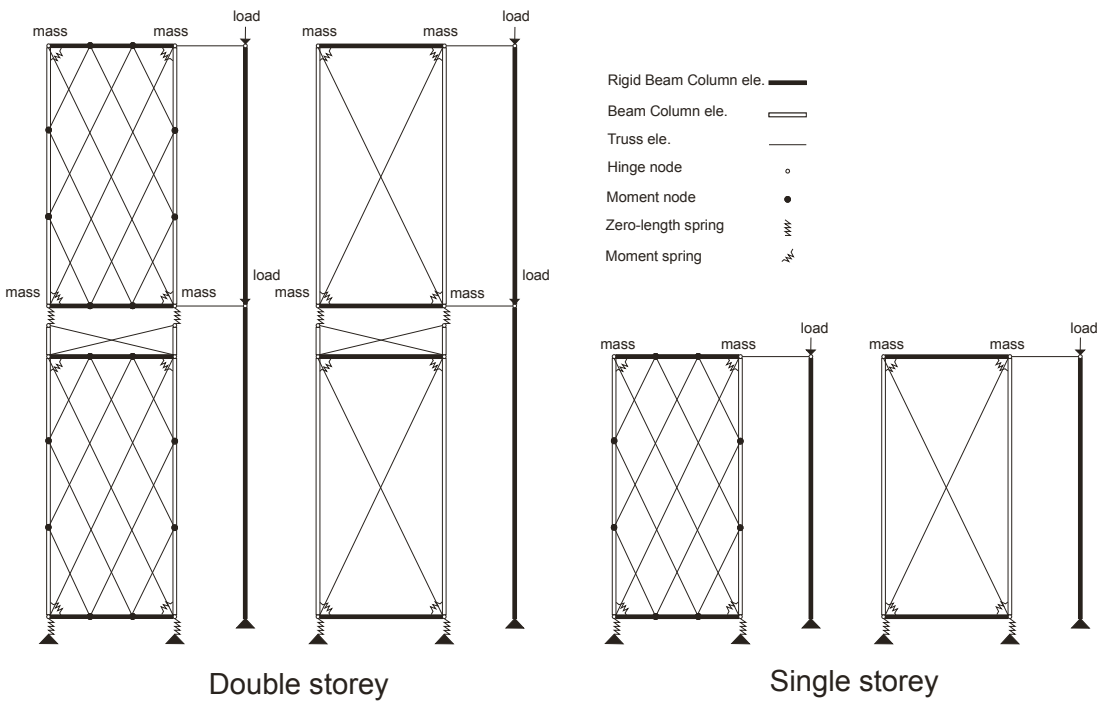

Figure 6 : Schematic of dynamic models

In order to capture the non-linear inelastic shear displacement behaviour of the walls diagonal truss elements with Pinching04 material were included in the model and calibrated to represent the characteristics of the steel sheathing and its connecting screws. Various diagonal truss element patterns are being evaluated, hence the two different schemes illustrated in Figure 6. Pinching04 material parameter values were initially extracted from the strength-displacement hystereses of the displacement based tested walls; these parameters were later modified using the dynamic test wall data such that the model and dynamic test strength and total displacement time histories matched adequately (Figure 7). Once calibration of the models with the dynamic shake table test results has been achieved models of representative building structures will be developed and used in an evaluation of the proposed design method using an approach adapted from the FEMA P695 methodology.

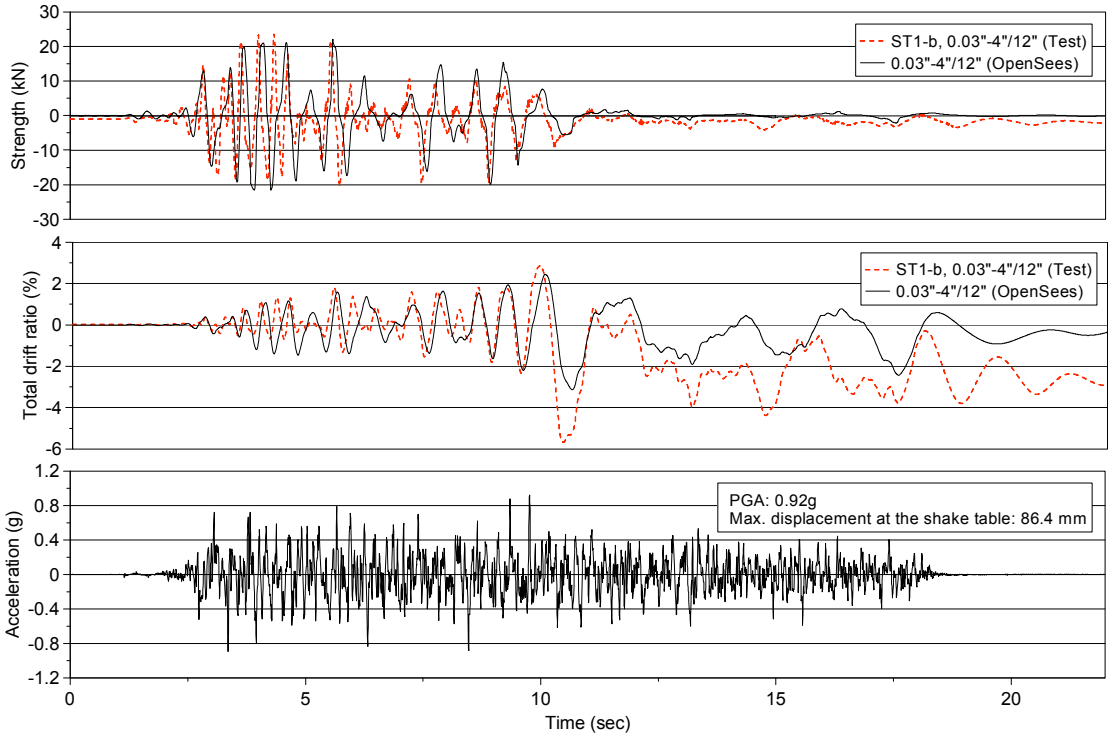

Figure 7 : Example time history of single storey dynamic shear wall test (ST1-b) and model prediction

CONCLUSIONS

To address the lack of Canadian design provisions for steel sheathed / cold-formed steel framed shear walls a test program was carried out comprising 68 single-storey steel sheathed shear walls. Two displacement based loading protocols; monotonic and CUREE reversed-cyclic were implemented for these tests. Shear wall tests completed by Yu *et al*., Yu & Chen and Ellis were incorporated with the McGill University shear wall tests to widen the database from which design values were

derived. The tests were analyzed using the EEEP method which provided a bilinear elastic-plastic curve that can be considered equivalent to the nonlinear behaviour exhibited by the shear walls. Based on the test results a resistance factor, ϕ, of 0.7 is recommended and nominal resistance values, S_y, are proposed. These nominal resistance values are only applicable for lateral loading and do not take into account the effects of gravity loads. 'Test-based' seismic force modification factors R_d and R_o of 2.5 and 1.7, respectively, are suggested for the interim design of steel sheathed shear walls. Based on the information obtained from these displacement based tests a suite of ten dynamic shake table tests was run on single and double-storey shear walls. The shake table tests have provided additional force versus deformation hysteretic data as well as time history data, damping information, and period of vibration estimates to facilitate the development of non-linear time history dynamic models that can accurately reproduce a shear wall's behaviour. These models have been calibrated with the dynamic shear wall test data and are currently being used to develop models of representative buildings that will be designed using the proposed seismic design resistances and R-values described herein. These models will be subjected to ground motion records and the results of the analyses will then be evaluated in terms of the probability of collapse as per the FEMA P695 methodology. Given the ongoing nature of this research the 'test-based' design procedure which has been proposed may be modified dependent on the findings of the final dynamic analysis phase of the study.

Seismic Design of Diagonal Strap Bracing Using AISI S213

Greg Greenlee, P.E.[1]

[1] Engineering Partners International LLC, 9001 East Bloomington Freeway, Suite 123, Bloomington, MN; PH 952-884-0481; FAX 952-884-0491; email: ggreenlee@engineeringpartners.net

ABSTRACT

Diagonal strap bracing is a common means of providing lateral stability for a low rise commercial or residential structure in cold formed steel framing and can be used in wind and seismic design. When designing this type of force resisting system there are a number of design and serviceability considerations that should be investigated. These include loads, strap size, fastener quantity, connection detailing, and construction practices. In seismic applications it is particularly important to understand the behavior of diagonal strap bracing. Accordingly predicting the ductility of the system is critical. This presentation will discuss seismic design of diagonal strap bracing in using the provisions of AISI S213-07, the *North American Standard for Cold-Formed Steel Framing - Lateral Design*.

INTRODUCTION

Structures require a resisting system to transfer lateral loads imposed on them. Typically these loads are from wind or seismic forces. A commonly used type of lateral force resisting system in residential and low rise commercial cold-formed steel applications is diagonal flat strap bracing. When designing this type of force resisting system there are a number of design and serviceability considerations that should be investigated. These include loads, strap size, fastener quantity, connection detailing, and construction practices.

Previously the Cold-Formed Steel Engineers Institute (CFSEI) published a technical note titled *Design of Diagonal Strap Bracing Lateral Force Resisting Systems for the 2006 IBC*. The current edition of the *North American Standard for Cold-Formed Steel Framing - Lateral Design* has added guidance for the design of flat strap bracing, particularly in seismic regions. This paper re-presents some of the information from the CFSEI technical note and incorporates the new seismic provisions contained in AISI S213-07.

TYPES OF DIAGONAL STRAP BRACING

Diagonal strap bracing can be detailed in a variety of different styles. Commonly diagonal strap bracing is used on the outside flange of perimeter load bearing studs (Figure 1). Another option is to use double sided diagonal strap bracing where there

are straps on both the inside and outside flange of the studs. With either of these styles the strap may either be a wide strap connecting directly to the stud and track (Figure 2), or a narrower strap where a gusset plate is used to make the connection between the strap and the stud and track (Figure 3).

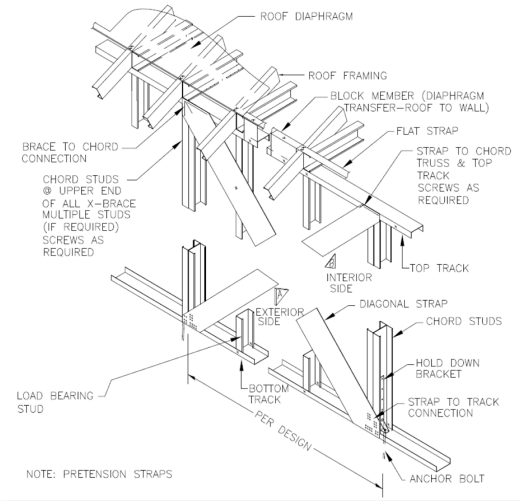

Figure used with permission of the Steel Framing Alliance

Figure 1

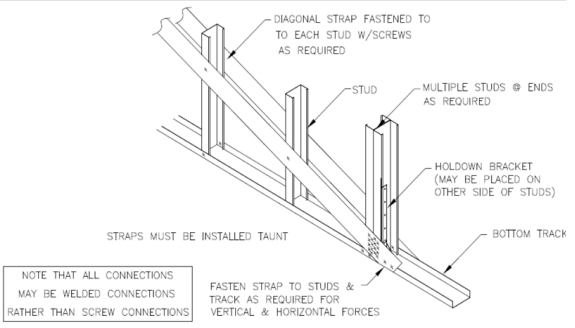

Figure used with permission of the Steel Framing Alliance

Figure 2

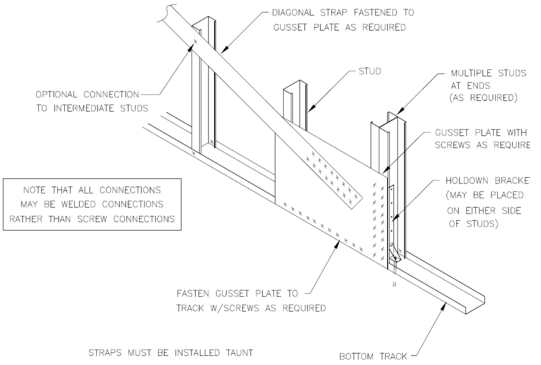

Figure used with permission of the Steel Framing Alliance

Figure 3

Wide straps that connect directly to the stud and track may be preferred over straps with gusset plates for a couple of reasons. First the gusset plates and associated fasteners add thickness to the wall which may be difficult to conceal with siding or exterior finish. Second, wider straps connecting directly to the stud and track will ultimately require fewer fasteners which will reduce installation time.

GENERAL DESIGN CONSIDERATIONS

When designing diagonal strap bracing there are a number of items to be investigated which are influenced by the type and geometry of the diagonal strap bracing. The provisions of the AISI Standard *North American Specification for the Design of Cold-Formed Steel Structural Members* (AISI S100-07) can be used to design these elements.

The width of the brace will be primarily dependent on two things. First, it must be properly sized to resist the design tensile forces in the member. Second, if it is not desirable to use a gusset plate at each end of the strap a wider strap may be required to allow the strap to connect to both the stud and track.

Connections and members must also be adequately sized to transfer loads. Where the studs are load bearing the effects of gravity loads in resisting and adding to overturning loads must be considered. Other potential design checks include induced eccentricity in the wall from a single sided strap, material over strength, and axial capacity of the chord studs. Finally, it will be necessary to properly design overturning restraints (holdowns), collectors and boundary elements.

It should be noted that because diagonal strap braces are tension only members the bottom track may be in compression between the diagonal strap and in tension outside of the brace. Often an anchor bolt is used to transfer shear loads from the bottom track to the foundation. If anchor bolts are in a compression area of the track, compressive axial capacity should be investigated. To resolve this anchor bolts may be placed in a tension area of the bottom track, or outside of the brace. Naturally this becomes an issue if the brace is located at a corner or end of a wall segment. Regardless of the anchor bolt location, bolt bearing on the web of the track and shear transfer shall be checked.

SPECIAL SEISMIC REQUIREMENTS

Special seismic requirements for diagonal strap bracing are included in Section C5.2 of AISI S213-07. These special seismic requirements are included to ensure predictability and properly controlled ductility in the system. Specifically, it gives additional requirements for material properties, connections, chord studs, anchorage and straps.

Material Properties. Industry studies have shown the yield and tensile strength of steel is generally higher than the specified minimum. This over-strength can result in performance inconsistent with the expectation of the building code. To address this

tensile and yield strength factors (R_y and R_t) have been introduced. These shall be used in the absence of verified physical properties.

Connections. As discussed above strap members are often constructed with material having a yield strength greater than specified. The design of the connections should account for this potential strap over-strength to ensure a predictable, ductile failure mode.

The available strength of connections is required to exceed the expected yield strength of the strap bracing member; but need not exceed the amplified seismic load. The expected yield strength of the strap member is equal to $A_g R_y F_y$ (applying the yield strength factor described).

Welded connections are required to be used unless:

1. An alternate connection permits gross cross section yielding of the strap member under cyclic loading per ASTM E2126
2. Calculations demonstrate gross cross section failure will occur prior to net section fracture and $R_t F_u / R_y F_y > 1.2$

These requirements apply to connections for strap members, boundary members and collectors.

Chord Studs. Similar to the requirements for connections, the available strength of the chord studs is required to exceed the expected yield strength of the strap bracing member; but need not exceed the amplified seismic load.

Anchorage. Uplift forces in the vertical boundary members shall be resisted by anchoring directly to the foundation. The track member shall not be used to resist these forces in bending.

ADDITIONAL REQUIREMENTS

The eccentricity resulting from single sided strap members shall be considered in the design. The standard defines eccentricity as half of the stud depth.

During construction it is important that the strap is installed taut. This is contained in section C5.2.4 of S213. A taut strap will ensure that the strapping immediately engages when a lateral load is applied. Pre-tensioning is a potential means to guard against loose straps. It is important, however, to ensure the strap is not overly pre-tensioned. Doing so may reduce the load carrying capacity of the strap.

RESEARCH

There have been a number of recent research programs investigating the performance of strap braced walls. The results of some of these programs have been used to develop the special seismic requirements added to AISI S213. Other programs are still ongoing, but provide important design and detailing information. The

commentary of AISI S213 provides additional insightful background information resulting from some of the more recent research programs.

ABSTRACT

Metal Building Systems (MBS) make up a substantial portion of non-residential, low-rise construction in the U.S. Given their wide spread use, it is desirable to understand their performance during a seismic event. Previous pseudo-static, cyclic testing indicates an absence of ductility in these systems. This lack of ductility arises from the inherent design concepts behind using web-tapered frames with no flange or web compactness limits, causing buckling limit states to govern the strength of the frames. In light of the lack of ductility, it is obvious that the current practice of designing MBS moment frames as Ordinary Moment Frame (OMF) systems, with R=3.5, is inappropriate. Also, simple analytical studies suggest that MBS supporting large masses, such as concrete or masonry exterior cladding or interior mezzanines, may be particularly vulnerable to the lack of ductility. For these reasons, it is desirable to develop a safe, economic, and reliable design procedure for MBS. Earthquake simulation testing of MBS has been performed to provide test data to start this development.

Three full-scale MBS specimens have been tested on the NEES/UCSD Large High Performance Outdoor Shake Table. Specimen 1 consisted of a single story MBS frame with metal side wall panels to represent the majority of MBS buildings. Specimen 2 was similar to the first, except with heavy concrete sidewall panels. Specimen 3 consisted of a MBS frame built with compact flanges, a mezzanine attached to one sidewall, and a concrete wall attached to the other. Results from each battery of tests will be presented in this paper.

INTRODUCTION

A very common form of construction in low-rise, non-residential structures is the metal building system (MBS). MBS are typically built from steel moment frames in their transverse direction and braced frames or shear walls in their longitudinal direction. The transverse frames are usually made with built-up I-sections, many times with tapered webs, which have been optimized to minimize material weight. These built-up sections are usually made without consideration of slenderness limits and frequently have slender or noncompact webs and flanges. These plates often

cause the governing limit state of the frames to be some type of buckling, a non-ductile behavior. These frames can be clad with an assortment of materials ranging from steel decking to concrete tilt-up panels.

MBS are built in a variety of locations, including high seismic zones. Currently, the building codes treat these frames as any other structural steel moment resisting system. MBS frames are usually designed as ordinary moment frames (OMF) or intermediate moment frames (IMF) as defined in ASCE/SEI 7 (ASCE, 2005) and AISC 341 (AISC, 2005b), effectively assuming an ability of the system to dissipate energy through some ductile, inelastic behavior.

While, historically, MBS perform well in large seismic events, previous pseudo-static cyclic testing at UCSD, has revealed a concerning lack of ductility in the cyclic behavior of the transverse frames used in these systems (Hong and Uang, 2006). This suggests that the assumptions made by the current building codes concerning the ductility of these systems are incorrect and the design provisions used for more traditional steel systems with rolled shapes are likely inapplicable to MBS. The research also suggested that the good past performance of these systems is due to a high level of system overstrength. Since MBS are typically very light structures, the transverse frames are usually controlled by non-seismic load combinations. This is the source of the overstrength. Thus, there is a potential lack of safety in systems with large masses, such as MBS with hard wall attachments or mezzanines, when designed according to the current code provisions (Hong and Uang, 2007). It is clear that additional seismic testing was needed to develop applicable, economic, and safe design provisions for MBS frames.

OBJECTIVE AND SCOPE

Three full-scale MBS building specimens were tested at the NEES/UCSD Large High Performance Outdoor Shake Table (LHPOST). The objective of these experiments was to test MBS frames to investigate their performance when subjected to high level seismic motions. It was desired to determine if MBS frames with heavy wall attachments or mezzanines exhibited different margins of safety against collapse than typical MBS with metal sidewalls only. Finally, the data gathered from the tests will be used to calibrate analytical models for use with a FEMA P695 (ATC, 2009) study for new design provisions.

TEST PROGRAM

NEES Shake Table

Test specimens were constructed and tested on the LHPOST. The shake table has a surface area of 7.6 m x 12.2 m and has a maximum payload of 20 MN. It is capable of motions with accelerations of up to 4 g, velocities of up to 1.8 m/s, and has a stroke of ±0.75 m.

Test Buildings

Each test specimen was to represent two interior bays of a MBS building. The specimens consisted of two 18.29 m clear span MBS frames with 6.10 m eave height and spaced at 5.49 m. Since the size of the specimens exceeded the dimensions of the table, a frame was built using W36x302 cantilevered beams and mounted to the table with adequately prestressed threaded anchoring rods. The test setup is shown in Figure 1. The frames were composed of web-tapered, built-up sections using steel plates with nominal yield stress of 379 MPa. All connections within the frames were of the bolted end-plate type. Where steel decking was used as cladding, light gauge metal girts or purlins were incorporated to mount the decking onto the frames. Each specimen had diagonal bracing in each sidewall as well as in the plane of the roof. Each frame was bolted to the testing apparatus at the column base plates. Additional mass, in the form of three 25.4 mm x 203 mm x 9.14 m steel plates, was added at the roof level to represent the remainder of the tributary mass of two full interior bays. These masses were located directly above and along each frame, above the roof decking, and were bolted to pieces connecting them to the frame rafters. The rafter flanges were laterally braced with purlins and flange braces.

Specimen 1 had only steel deck cladding at the side walls. The column flanges were laterally braced with girts and flange braces along their height. Specimen 2 had two 254 mm x 3.05 m x 6.71 m precast concrete panels at each side wall. These concrete panels represented a hard wall cladding of approximately 2.873 kN/m^2 spread over two interior bays. The walls were connected to the frame using spandrel beams bolted at the panel zones. These connections, as well as the connections of the wall base to the test apparatus, were designed to be of pin type. The column flanges were unbraced for their full height. Specimen 3 had one sidewall which resembled Specimen 2, using the same concrete panels and unbraced column flanges. The other side wall was clad with metal decking similar to Specimen 1. This sidewall also had a mezzanine attachment. The mezzanine was composed of built-up, I-beam sections with bolted connections designed as pin type. The floor mass of the mezzanine was represented with one of the 3.05 m x 6.71 m concrete

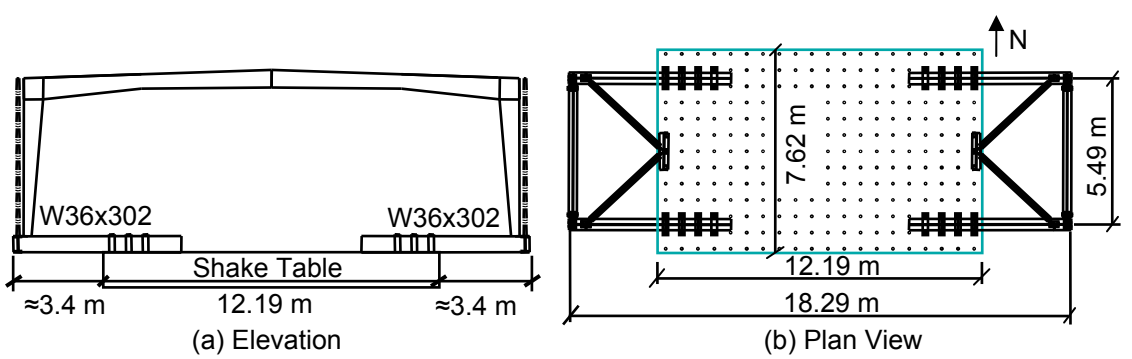

Figure 1. Test Setup

panels. Diagonal bracing was used to brace the mezzanine in the out-of-plane direction.

Each specimen was designed according to the International Building Code 2006 (ICC, 2006). Gravity loads consisted of self weight, 144 N/m^2 collateral load, 958 N/m^2 reducible roof live load, and flat roof snow load of 1,005 N/m^2. Wind loads were calculated using a wind speed of 38 m/s. The seismic load resisting system was designed and detailed as OMF with one exception. The third specimen used seismically compact flanges (AISC, 2005b) in the columns and in the rafters near the knee joint in addition to other OMF requirements. The first two specimens were designed using S_{DS} of 1.031 and S_{D1} of 0.592, while the third specimen used S_{DS} of 1.000 and S_{D1} of 0.400. Gravity load combinations controlled the rafter sizes for the first and second specimens. While wind load combinations controlled the column sizes for Specimen 1, seismic drift limitations per ASCE/SEI 7 (ASCE, 2005) controlled the column sizes for Specimen 2. Both rafters and columns for Specimen 3 were primarily sized to meet the compactness criteria set forth by the designer.

Instrumentation

Each test building was thoroughly instrumented. Strain gauges and rosettes were located at several sections along each column and rafter. Displacement transducers were used to measure slip, rotation, and uplift of the column bases and slip of the mounting frame. String potentiometers were used to measure the displacement of each frame at the roof and base as well as the mezzanine of the third specimen. Accelerometers were located at several sections along each rafter, on the mounting frame, on the roof mass plates, and in the panel zones to measure accelerations in three perpendicular directions. Over 300 separate data channels were used on each specimen.

Test Sequence

Each specimen was subjected to a variety of ground motions with the shake table. Five ground motion records were chosen from motions used in FEMA P695 (ATC, 2009). These ground motions were from 1979 Imperial Valley (H-DLT 352), 1989 Loma Prieta (CAP 000), 1992 Landers (YER 270), 1994 Northridge (LOS 000), and 1999 Chi-Chi (TCU084_001). A white noise motion and a short duration impulse type motion were used to assess the dynamic characteristics (natural periods and equivalent viscous damping) of each specimen at various times in the test sequence, intermittently between seismic record tests to detect and track accumulating damage. Prior to testing, preliminary finite element models were used to estimate the fundamental periods of each specimen. Each ground motion record was scaled such that its 5% damped pseudo-acceleration response spectrum value, at the estimated fundamental period, was some percentage of the value of the Design Basis Earthquake (DBE) response spectrum defined in ASCE/SEI 7 (ASCE, 2005), using R=1, at that same period. An example of this scaling is shown for the Imperial Valley (IV) motion in Figure 2. Tests were named using initials based on the particular ground motion record and a number representing the percentage of DBE to

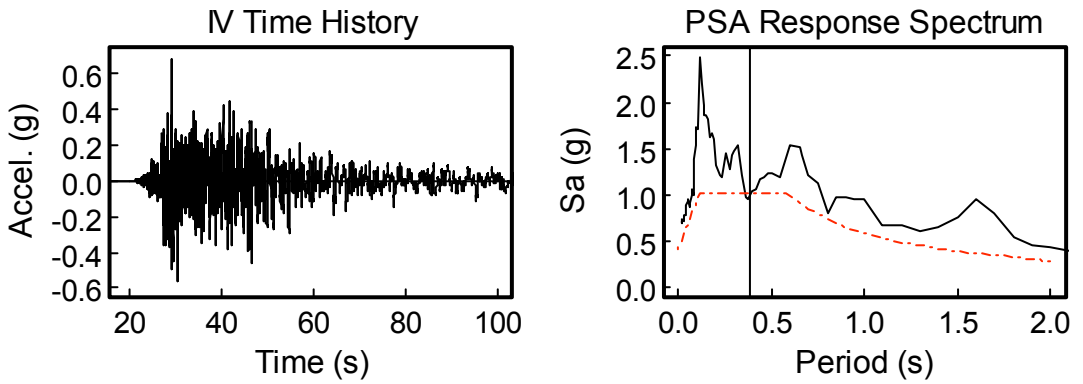

Figure 2. Imperial Valley ground motion scaled to match 100% DBE at estimated period of Specimen 1

which it was scaled, such as IV150 for the IV motion scaled to 150% DBE. Since the periods at which the records were scaled were only estimates, the actual percentage of DBE acceleration exciting the specimens varied from the number in the test name. The general test sequence for each specimen started with white noise and impulse motions, followed by each ground motion record scaled to a low percentage of DBE. For all specimens, the IV motion was used for high level tests for consistency and ease of result comparison. After the low level tests, IV tests were performed at increasing scale factors until limiting circumstances prevented further testing.

TEST RESULTS

Specimen 1

After the initial white noise and impulse tests, the fundamental period was determined to be 0.39 s. This differed from the value of 0.52 s determined from the initial analytical model. The damping ratio was determined to be about 1.5%. This measured fundamental period was used to set the scale factors for the remaining tests. After some low level ground motion records, the Imperial Valley motion was scaled up progressively to investigate the capacity of the structure. Hysteretic behavior can be seen in Figure 3 for IV100 through IV300. Testing went without problems until the IV150 test.

During the IV150 test, the anchor rods at the southeast columns sheared off. Because of this failure, the remaining three columns had to transfer the seismic loads. Despite the changed structure, no limit states were reached anywhere in the frame. After this test, a fix was made at all four column base plates using welds. These welds were placed such that minimal stiffening of the base plate connection would occur.

After the repair, testing continued with the IV200 and IV250 tests. The response of the structure until the IV250 test was essentially elastic with no limit states reached and no significant energy dissipation. During the IV250 test, the north rafter experienced a lateral-torsional buckle (LTB) at the east pinch point. This was

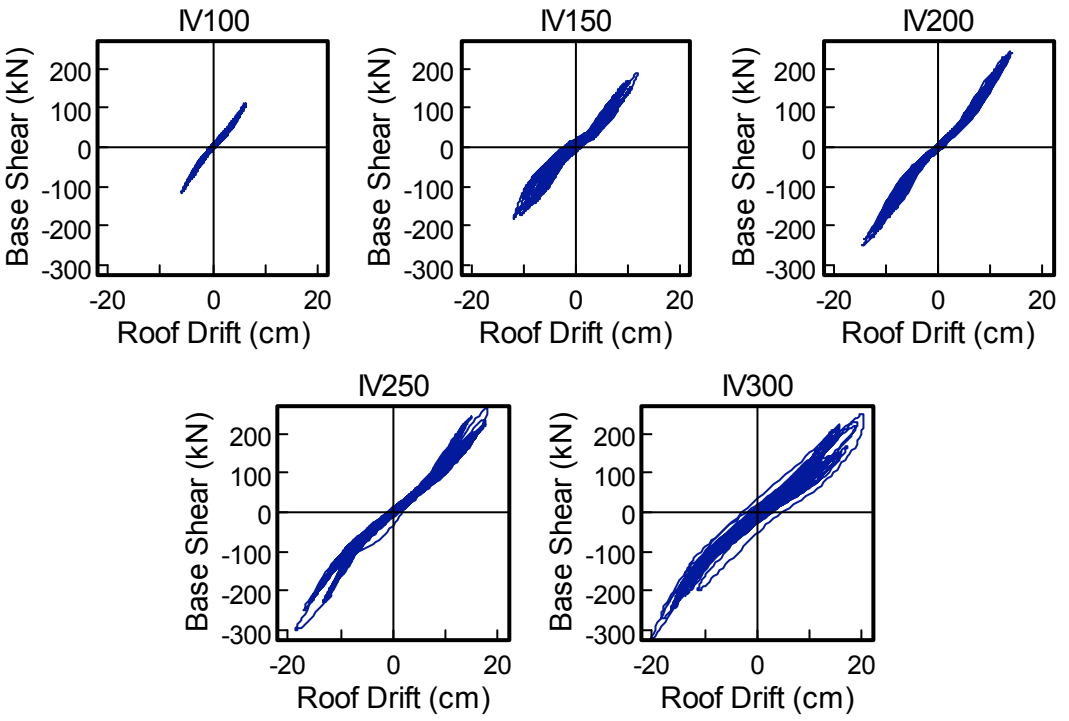

Figure 3. Specimen 1 hysteretic responses

consistent with the predicted failure mode and location. Strain gauge data from a time just prior to buckling implies a moment diagram which should cause LTB according to member strength predicted by AISC 360 (AISC, 2005a). The buckling caused large forces in the flange braces on either side of the affected unbraced length. The forces were large enough to damage the purlin at the other end of the flange brace (See Figure 4). The buckle in the rafter can be seen in Figure 4. The load-displacement curve showed a sharp drop in strength at the point of buckling, as expected. This sharp drop agrees with the nonductile behavior observed in the previous cyclic testing (Hong and Uang, 2006). After the buckle, the stiffness had degraded but the structure continued to behave elastically with a lower lateral stiffness.

Even though the structure reached a limit state, the structure was still standing and safely stable. Some weld cracking occurred at the column base fixes made previously. These welds were repaired and an additional IV300 test was performed. During this test, LTB occurred at two additional pinch point locations in the rafters. These buckles were associated with more sharp drops in strength and further degraded stiffness. In addition to the new LTBs, the initial LTB location experienced a rupture at the bottom flange (See Figure 4). This was due to low-cycle fatigue and the large lateral displacements at the LTB location. Since the structure was ruptured, it was deemed unsafe to continue testing.

During the testing this structure experienced a base shear of 224 kN when the first LTB limit state was reached. A maximum base shear of 325 kN was observed. When compared to the design base shear of 22.2 kN, a very significant amount of system overstrength is apparent. A maximum drift of 3.6% was reached during the final test.

(c) Flange Rupture

Figure 4. Observed damage during shake table testing of Specimen 1

Specimen 2

The fundamental period for Specimen 2 was determined to be 0.48 s. The damping ratio was determined to be between 1% and 2%. After determining the proper scaling factors for the ground motions from the fundamental period, low level testing was performed. The analytical model suggested a failure at a much lower level of base shear compared with the first specimen, so low level testing was performed at the 10% DBE level instead of 25%. Higher level testing was then performed with the Imperial Valley motion. Hysteretic behavior is shown in Figure 5. Behavior was essentially elastic until the IV100 test.

During the IV100 test, the north rafter experienced LTB at the east pinch point, the same limit state reached as the first specimen. Once again, the strength dropped sharply at the point of buckling and the structure experienced a degradation of stiffness. The LTB at the pinch point was the predicted failure mode and location.

The IV150 test caused LTB at all three remaining pinch point locations in the rafters. The LTBs all caused stiffness degradations and sharp decreases in strength. The initial LTB experienced a flange rupture in the same manor as the first specimen. Also, the large forces in the flange braces caused damage to the connections at the purlin. Photos of the flange brace damage, LTB, and flange rupture can be seen in Figure 7.

When the first limit state was reached, the base shear was 348 kN and a maximum base shear was observed at 427 kN. Compared with a design base shear of 100 kN, the system overstrength was far less in this specimen than in the first. This specimen exhibited no ductile behavior and had no significant energy dissipation. A maximum drift of 3.6% was reached during the IV150 test.

After removing the wall attachments and roof decking, this specimen was subjected to a pseudo-static pull-over test. The top of each frame was attached to a stationary point with a cable and the table was used to pull the base away from the support. This test provided a pull-over curve for the damaged structure. The measured response is shown in Figure 6, corrected for second-order effects which would have existed prior to removal of the large masses. A maximum base shear of 166 kN was observed, showing a greatly reduced strength capacity of the buckled structure. However, this post-buckling strength continued through to a very large displacement of 47 cm (7.8% drift). The extreme displacements further distorted the LTBs in the east rafter pinch points, while new top flange local buckles occurred in the western portions of the rafters. Extreme nonlinearities, eventually causing rupture, were seen in the base plates during the pull-over test. This suggests that column bases may be a source of some energy dissipation. Figure 8 - Figure 9 shows the displaced shape and various damages observed during the pull-over test.

Figure 9. Specimen 2 base plate deformation after pull-over test

Specimen 3

The third specimen had a fundamental period of approximately 0.45 s and a damping ratio of 1% - 2%. Low-level motions up to IV50 showed no inelastic behavior. Hysteretic behavior can be seen in Figure 10. During the IV100 test, elastic shear buckling occurred in the south east panel zone. Comparing moment and axial force demands calculated from the strain gauges to the panel zone strength defined by AISC equations (AISC, 2005a), this buckling was easily predicted.

After the IV100 test, additional tests were run through IV250. During these tests, all four panel zones experienced elastic shear buckling and low-cycle fatigue, eventually causing large ruptures in each web. Interestingly, during the test which caused rupture, IV200, and subsequently, the specimen exhibited significant energy dissipation as evidenced in the larger hysteretic loops seen in IV200 and IV250. Another important observation was that the structure remained elastic and undamaged outside of the panel zone areas. Panel zone damage can be seen in Figure 11.

This specimen reached its first panel zone buckling limit state at a base shear of 262 kN. Comparing this with a design base shear of 87.4 kN, it is seen that this specimen had much lower system overstrength than the first specimen. The maximum base shear reached was 405 kN and the maximum drift was 5.3%. This is the only specimen that exhibited any significant energy dissipation.

IMPLICATIONS

The results of these experiments have a few significant implications. Firstly, a low level of structural damping was observed. It would be prudent for designers of MBS to account for the structures having 1% - 2% damping, rather than the 5% assumed by the codes, when determining seismic force demands. Secondly, the differing levels of system overstrength verify that MBS with large masses have a propensity to be less reliable compared with light MBS. All three structures were designed with R=3.5. This assumes that if the structure were to remain elastic during a DBE level earthquake, the elastic demand would be about 3.5 times its design base shear. The specimens behaved primarily elastically up to this demand level. Since, for the most part, the test buildings did not exhibit ductile post-buckling behavior, it is reasonable, in design, to call the load causing the first limit state to be reached the capacity. A safety factor can be easily calculated for each specimen by dividing the

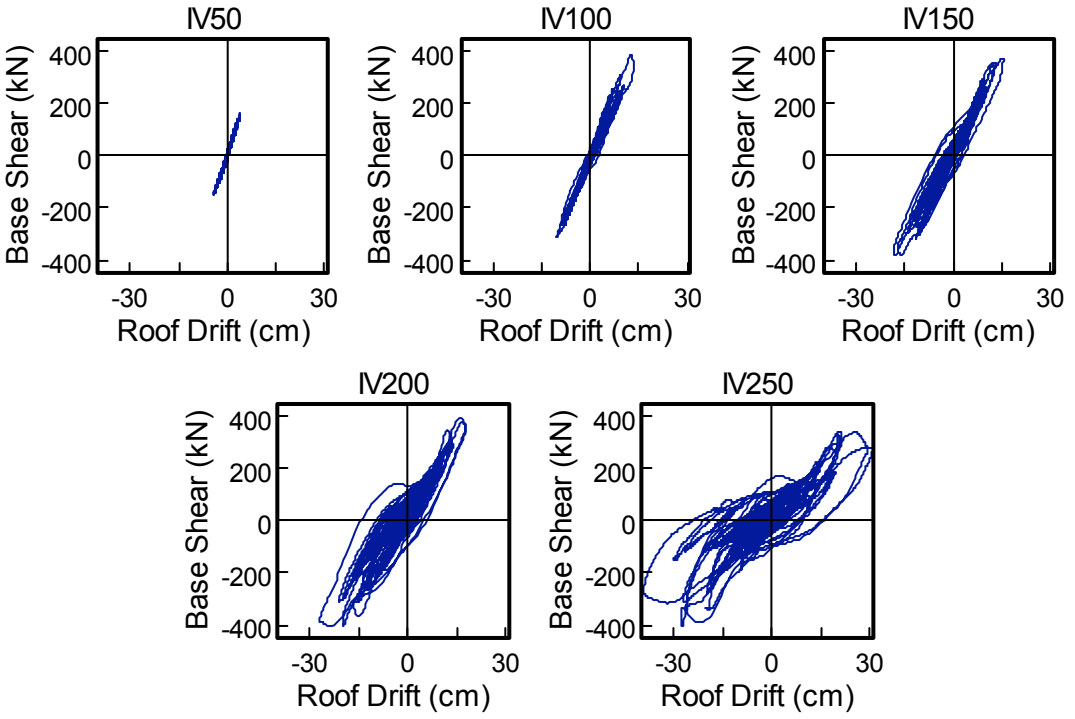

Figure 10. Specimen 3 hysteretic responses

Figure 11. Specimen 3 panel zone damage after completion of testing

observed capacity by the elastic design base shear. Safety factors for each specimen, in order, were 2.88, 0.99, and 0.86. This clearly shows that the two specimens with heavier masses were insufficient to resist DBE level earthquakes without reaching their reliable capacity. It is easily seen that the original assumption of R=3.5 is incorrect and an R=1 is likely more applicable. Use of this R value would have ensured that the structures were designed to resist the elastic DBE level forces which were demanded. However, since neither of the two specimens collapsed, perhaps a rethinking of the overall concepts of the seismic design should be considered for these elastic systems.

CONCLUSIONS

Overall, the MBS specimens were surprisingly robust. The first specimen, despite lacking ductility, showed very large system overstrength and was able to withstand a base shear approximately 290% of the DBE level without damage. Even though the second and third specimens were damaged at or below the DBE level, they remained standing and did not collapse. These results verify that the safety margin against collapse of MBS with larger masses is much lower than a typical, light MBS. They also show a significant lack of ductility in the buckling limit states. Finally, the panel zone limit states in the third specimen suggest a possible energy dissipation mechanism using shear buckling.

Currently, this research is continuing by the development of numerical models calibrated to the test data gained by these experiments. These numerical models will be used in a FEMA P695 (ATC, 2009) study. This study will test newly developed design criteria, which take into account the unique characteristics of these systems and provide an economic and safe solution for seismic design of MBS.

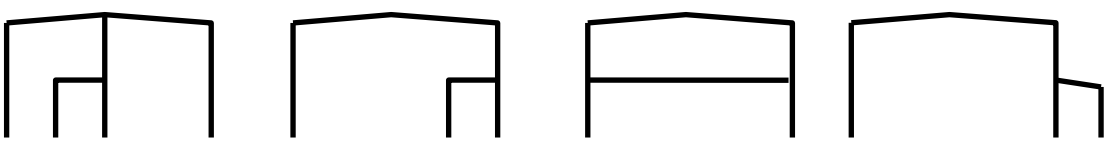
ABSTRACT

Metal Building Systems (MBS) are frequently constructed with mezzanines contained in their floor plans. These mezzanines can be heavy and have a significant impact on the seismic design and performance of the MBS. When a mezzanine is attached to the MBS, it is not clear to the designer whether it should be treated as a one- or two-story building. It is also not clear how the seismic forces should be distributed vertically. Validity of common assumptions about mode shapes and the first-mode dominating system response was investigated. A codified design procedure was compared with a simpler procedure commonly used by MBS designers. A parametric study suggests that the current building code procedure for vertical distribution of seismic forces may be inapplicable to the design of MBS moment frames because it does not properly address the unique dynamic characteristics of the system. The parametric study and a recommendation for a design procedure are presented in this paper.

INTRODUCTION

It is not uncommon that Metal Building Systems (MBS) are designed with partial floor mezzanines attached (See Figure 1). These mezzanines can range in size from a small fraction to almost the entire building area. In addition to a large variation in size, they can carry very light to very heavy gravity loads compared to the weight of the remainder of the structure. This variability leads to uncertainty

Figure 1. MBS with mezzanine attachment



about how to treat the mezzanines when calculating seismic force demand on the MBS moment frames. The codes are not clear when to treat a mezzanine as a separate floor or as an attached mass (Bachman, et. al., 2008). If the designer treats the mezzanine as a floor, ASCE/SEI 7 (ASCE, 2005) provides a method of distributing seismic base shear to each story in the building. This method is based on some assumptions that may not apply to the whole range of mezzanine configurations found in MBS. It is desired to investigate the code method for distributing seismic loads, as well another common design method, to determine their applicability to MBS frames with mezzanines.

BACKGROUND AND THEORY

In a MBS, a partial floor mezzanine may be located in a corner, along a side or end wall, or even central to the floor area and not attached to a wall (See Figure 2). Regardless of location and orientation, one may think of a MBS with a mezzanine as a two degree-of-freedom (2-DOF) dynamic system. There are two natural modes of vibration in a 2-DOF system. The elastic response of a 2-DOF system, to a ground motion, is determined by the individual responses of each mode. Discussion will be limited to elastic response only since the current practice is to determine seismic load distribution based on elastic properties. Each mode in a classically damped building is defined by a natural period and an equivalent viscous damping ratio. These modes each vibrate the structure in a constant displaced shape with only the amplitude of the shape varying (i.e., mode shape). Each mode is treated as a single degree-of-freedom (SDOF) system subjected to the ground motion, and using superposition, the sum of their responses defines the total 2-DOF response. To perform this modal analysis, the designer must be able to determine the two periods and mode shapes.

The damping ratios, ζ_n, are usually a product of engineering judgment. ASCE/SEI 7 (ASCE, 2005) assumes 5% damping for all structures. However, recent shake table testing of three full-scale MBS, at UCSD, has revealed a damping ratio of 1% - 2% for these systems (Uang, et. al., 2011).

Determination of the natural periods and mode shapes is straightforward from dynamics. The periods and mode shapes are functions of the mass and stiffness matrices. These matrices may be derived using either flexibility or stiffness methods. The flexibility method may lend itself well to current MBS design software. Alternatively, a variation of the stiffness method, which may be appealing to MBS designers, is presented here. In developing this method, a MBS moment frame with a mezzanine attachment to one column will be used. However, this same method can be used for a frame with any mezzanine configuration or lean-to structure.

(a) Central **(b) Side** **(c) Full** **(d) Lean-to**

Figure 2. MBS mezzanine configurations

MBS designers are familiar with determining the lateral stiffness of the moment frame, k_f. Some design software automatically reports this parameter. If not readily available from design reports, it is easily obtained by applying a half-unit lateral load at each eave location, similar to the common practice used when applying seismic equivalent lateral forces. The average eave displacement corresponding to this load case is inverted to give the frame stiffness. A less available parameter is the mezzanine stiffness, k_m. This parameter can be found by restricting lateral displacement at the eaves, by placing single direction supports (rotation and vertical movement is allowed), and applying a unit lateral load at the mezzanine. The corresponding displacement of the mezzanine is inverted to give k_m. An additional parameter that will be used is α. Parameter α is the fraction of the mezzanine load that is transferred up to the remaining frame. It is obtained by the sum of reactions at the eaves, due to the mezzanine-unit load case mentioned above. It is a measurement of how much stiffer the remaining frame is compared with the column section below the mezzanine. These parameters define the 2-DOF stiffness matrix:

$$\mathbf{k} = \begin{bmatrix} k_{11} & k_{12} \\ k_{21} & k_{22} \end{bmatrix} = \begin{bmatrix} k_m & -\alpha k_m \\ -\alpha k_m & k_f - \alpha^2 k_m \end{bmatrix}$$

The 2-DOF mass matrix is much simpler to obtain:

$$\mathbf{m} = \begin{bmatrix} m_{11} & 0 \\ 0 & m_{22} \end{bmatrix} = \frac{1}{g} \begin{bmatrix} W_{mezz} & 0 \\ 0 & W_{roof} \end{bmatrix}$$

where W_{mezz} and W_{roof} are the tributary weights of the mezzanine and roof stories, respectively, and g is the acceleration of gravity.

Natural periods (T_n) and mode shapes (ϕ_n) may be determined from **k** and **m** directly through an eigenvalue analysis. Because there are only 2 modes, it is easy to obtain closed-form solutions. To aid in later investigations, two additional variables will be defined and used in the closed-form equations. The first, K_r, is the ratio of k_z to k_f. The second, M_r, is the ratio of W_{mezz} to W_{roof}. Using these parameters, the following closed-form equations for T_1, T_2, ϕ_1, ϕ_2 are provided below:

$$T_1 = 2\pi \sqrt{\frac{1}{2}\left[\frac{k_m}{m_{11}} + \frac{k_f}{m_{22}} + \frac{k_m \alpha^2}{m_{22}} - \sqrt{\frac{k_m^{\,2}}{m_{11}^2} - \frac{2k_m k_f}{m_{11} m_{22}} + \frac{2k_m^{\,2}\alpha^2}{m_{11} m_{22}} + \frac{k_f^{\,2}}{m_{22}^2} + \frac{2k_f k_m \alpha^2}{m_{22}^2} + \frac{k_m^{\,2}\alpha^4}{m_{22}^2}} \right]}$$

$$T_2 = 2\pi \sqrt{\frac{1}{2}\left[\frac{k_m}{m_{11}} + \frac{k_f}{m_{22}} + \frac{k_m \alpha^2}{m_{22}} + \sqrt{\frac{k_m^{\,2}}{m_{11}^2} - \frac{2k_m k_f}{m_{11} m_{22}} + \frac{2k_m^{\,2}\alpha^2}{m_{11} m_{22}} + \frac{k_f^{\,2}}{m_{22}^2} + \frac{2k_f k_m \alpha^2}{m_{22}^2} + \frac{k_m^{\,2}\alpha^4}{m_{22}^2}} \right]}$$

$$\phi_1 = \begin{bmatrix} 2\left(\frac{1}{\alpha} - \frac{M_r}{K_r\alpha} - M_r\alpha + \sqrt{\frac{1}{\alpha^2} - \frac{2M_r}{K_r\alpha^2} + 2M_r + \frac{M_r^2}{K_r^2\alpha^2} + \frac{2M_r^2}{K_r} + \alpha^2 M_r^2}\right)^{-1} \\ 1 \end{bmatrix}$$

$$\phi_2 = \begin{bmatrix} 2\left(\frac{1}{\alpha} - \frac{M_r}{K_r\alpha} - M_r\alpha - \sqrt{\frac{1}{\alpha^2} - \frac{2M_r}{K_r\alpha^2} + 2M_r + \frac{M_r^2}{K_r^2\alpha^2} + \frac{2M_r^2}{K_r} + \alpha^2 M_r^2}\right)^{-1} \\ 1 \end{bmatrix}$$

The Equivalent Lateral Force (ELF) method of determining seismic force demand in a structure is commonly used in MBS design. As defined in ASCE/SEI 7 (ASCE 2005), this method computes the design seismic base shear, V_b, as a function of a design response spectrum, and the fundamental natural period of the structure. The design response spectrum depends on ground motion parameters, S_{DS} and S_{D1}, which vary over the U.S. After V_b is found, a portion of this force must be distributed to each story level. The method used to distribute force relies on two assumptions. First, all of the mass is assumed to vibrate in the first mode. Second, the first mode shape is assumed. These assumptions are made because the actual force distribution depends on the stiffness of the structure, which is not known before a design is available. Both of these assumptions will be investigated to determine their validity for MBS frames with mezzanines.

Before the investigations can begin, the exact solution must be obtained. As previously mentioned, the response of an elastic structure to a ground motion is the summation of each modal response. The base shear at any time, t, for a 2-DOF system can be defined as:

$$V_b(t) = M_1^* A_1(t) + M_2^* A_2(t)$$

$$M_n^* = \frac{\left(\phi_n^T \mathbf{m}\begin{bmatrix}1 & 1\end{bmatrix}^T\right)^2}{\phi_n^T \mathbf{m} \phi_n}$$

where $A_n(t)$ is the pseudo-acceleration response of a SDOF with T_n and ζ_n (Chopra, 2007). M_n^* is the effective modal mass, or the amount of mass vibrating in the nth mode. A modal mass participation factor, M_{pn}, can be found for each mode by dividing the effective modal mass by the total mass of the system, M_{tot}. The equation for V_b may be rewritten:

$$V_b(t) = \left(M_{p1} A_1(t) + M_{p2} A_2(t)\right) M_{tot}$$

Therefore, the base shear response depends on both the modal mass participation factors and the ground motion.

The story forces **F** can also be determined from modal superposition:

$$\mathbf{F}(t) = \left(M_{p1} A_1(t) \frac{\mathbf{m}\phi_1}{\sum_{j=1}^{2} m_j \phi_{j1}} + M_{p2} A_2(t) \frac{\mathbf{m}\phi_2}{\sum_{j=1}^{2} m_j \phi_{j2}} \right) M_{tot}$$

Therefore, the story forces depend on the modal mass participations factors, the ground motion, and the mode shapes.

By assuming the first mode dominates all responses, the modal mass participation factors are set to 1 and 0 for the first and second mode, respectively. The analysis can be further simplified since the peak value of A_1, s_a, determines the demand on the structure. This peak value is found from the design response spectrum in ASCE/SEI 7 (ASCE, 2005). This simplification of **F** results in the following equation:

$$\mathbf{F}_{\max} \approx M_{tot} s_a g \frac{\mathbf{m}\phi_1}{\sum_{j=1}^{2} m_j \phi_{j1}} = V_b \frac{\mathbf{m}\phi_1}{\sum_{j=1}^{2} m_j \phi_{j1}}$$

ASCE/SEI 7 uses a method of calculating these story forces, which assumes the shape of the first mode. It is assumed to be a function of the height of each story and a parameter k, which depends on the first natural period. This assumed shape takes a linear or parabolic form depending on k, resulting in the following equation for the ELF at story i, which will be referred to as the ASCE 7 method.

$$F_i = V_b \frac{W_i h_i^k}{\sum_{i=1}^{2} W_i h_i^k}$$

where Wi is the tributary weight at story i.

Another common practice in the MBS design industry is to assume the first mode shape is equal to unity at each level, resulting in an equation for story forces that depends only on the distribution of weight, which will be referred to as the Weight method:

$$F_i = V_b \frac{W_i}{\sum_{i=1}^{2} W_i}$$

PARAMETRIC STUDY

To determine the validity of the two assumed mode shapes and the assumption that the first mode dominates response, a parametric study was performed. The parameters varied were α, K_r, and M_r. These three parameters completely determine the mode shapes and the modal mass participation factors.

Realistic bounds on these parameters were needed. When one considers a mezzanine as simply a mass attached at mid-height of a MBS frame, it is apparent that lean-to structures might also be treated this way (See Figure 1). Since lean-to structures are very light, compared to the remainder of the MBS, values of M_r approaching 0 are possible. If one considers a mezzanine which spans the full length of the frame, and attached at both end columns, values as high as 20 are reasonable. These two values set the bounds for M_r. A reasonable lower limit for K_r is likely between 1 and 2. This limit may be exceeded in some cases with centrally located mezzanines, so values approaching 0 were also considered, though most likely not common. A realistic upper bound on K_r was not able to be determined, so 50 was chosen initially. Finally, α must necessarily be bounded by 0 and 1; however some reasonable assumptions lead to tighter bounds for this study.

Firstly, this study assumes that the majority of MBS frames are designed with pinned bases. Secondly, the height of the mezzanine was assumed to be at or near 50% of the eave height. With these two assumptions, a lower bound may be set by considering a pin-pin, prismatic, column supporting the mezzanine at mid-height. This setup would result in an α of 0.5. Many times, the upper end of the column will not be pinned, and the column will be tapered, resulting in higher values of α. An actual tapered MBS frame column was modeled with a fixed upper support, resulting in an α of 0.8. Since no frame column is perfectly fixed at its upper end, this was deemed a reasonable upper bound. A value of $\alpha = 0.6$ is a good preliminary guess when calculating the above stiffness matrix. With reasonable bounds determined, both mode shapes were calculated at increments of each parameter. Modal mass participation factors were also calculated for each increment of parameter.

First-Mode-Only Assumption

It was first desired to determine if the first mode truly dominated structural response for these systems. To do so, the modal acceleration responses for each mode, as well as the modal mass participation factors were needed. The case which would have the most likely possibility of violating this assumption would be when the spectral acceleration of the first mode was as small as possible compared with that of the second mode. It was found that a reasonable upper limit on MBS frame periods is 1 s, making the scenario easy to compose. Using spectral acceleration maps from ASCE/SEI 7, a random sample of S_{DS} and S_{D1} values were computed in high seismic regions. It was found that 0.4 was a reasonable lower bound ratio of S_{D1}/ S_{DS}. Since an upper bound on the period of MBS was 1 s, S_{D1}=0.4 was taken as the spectral acceleration of the first mode and S_{DS} =1 was taken for the second mode.

Since the modal mass participation factor was calculated at each value of the three parameters, there was a very large sample of M_{p1} available to determine a reasonable value to use for investigation. The mean and standard deviation of M_{p1} were found to be 0.984, and 0.019, respectively. Since these values are based on a uniform likelihood of each parameter, these values are incorrect. However, further investigation suggests they are still reasonable values. To allow plotting, one of the three parameters needed to be removed from consideration. To do this, the mass participation factor was averaged over all α values for each value of K_r and M_r.

Figure 3 shows the range of M_{p1} values as a function of K_r. It can be seen that when $K_r > 2$, M_{p1} can vary between 95% and 100%. Therefore, it was determined that the previous values were reasonable, and a $M_{p1} = 0.984 - 0.019 = 0.965$ was assumed

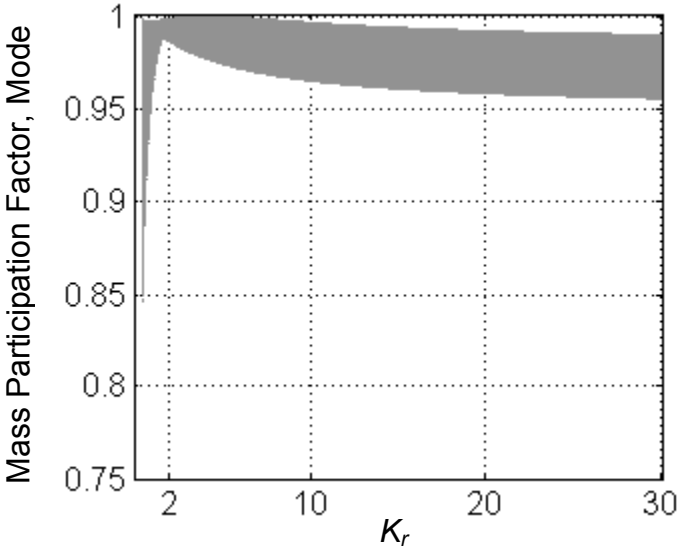


Figure 3. Range of mode 1 mass participation factor vs. K_r

with $M_{p2} = 0.035$. Using the 2-mode equation shown above for base shear, the following maximum modal base shears are found:

$$V_{b1,\max} = (0.4)(0.965)M_{tot} = 0.386M_{tot}$$
$$V_{b2,\max} = (1.0)(0.035)M_{tot} = 0.035M_{tot}$$

revealing that the second mode has a maximum contribution to total base shear of only 9.1% of the maximum contribution from the first mode. Thus, it seems reasonable to assume that the first mode dominates the response of these systems. However, the peaks of the modal responses do not always occur simultaneously so at some time, t, the response may be completely determined by the second mode. This may lead to the invalidity of this assumption when considering internal forces such as column shear or moment around the mezzanine attachment. Also, for systems with $K_r < 2$, M_{p1} becomes very small and these results are likely invalid. For the remainder of this investigation, the base shear results will be deemed sufficient to hold the first-mode-only assumption valid.

Force Distribution Methods

Next, it was desired to investigate the methods used to vertically distribute ELFs. From the parametric study and simplifying assumptions mentioned above, it was straightforward to compute the percentage of base shear assigned to each story using the exact first mode equation, the ASCE 7 method, and the Weight method. When using the ASCE 7 method, a $k = 1$ was assumed for simplification. If $k > 1$, the

error of the ASCE 7 method should be expected to increase. The error was measured by the difference between a given method and the exact equation for each parameter value. This error is the percentage of the base shear that is incorrectly assigned to a story. Again, to allow plotting, one of the three parameters needed to be removed. For each value of M_r, and K_r, the maximum error for any value of α was taken. This allowed an upper bound error envelope to be plotted for any value of M_r and K_r.

Plotting revealed that the behavior at $K_r > 30$ was approximately constant with respect to K_r. Three-dimensional plots for the error over the parameter space are shown in Figure 4 and Figure 5 for the ASCE 7 method and the Weight method, respectively. These figures show a region of high error at low values of K_r. A maximum error envelope, over all values of M_r, is shown in Figure 6. It can be seen that as K_r becomes small, the potential errors of both methods increase sharply. The change in error tapers off around $K_r = 3$. This is consistent with the region in which the first modal mass participation factor becomes significantly reduced, which may make the first mode only assumption invalid, also invalidating either method for distributing story forces. It can also be seen that when $K_r > 3$, the errors tend to depend primarily on M_r. Figure 7 shows a maximum error envelope as a function of M_r. This envelope assumes $K_r > 3$. This plot suggests that the simple Weight method for story force distribution is generally more accurate than the ASCE 7 method. As M_r approaches zero, the errors also approach zero. This is expected since $M_r = 0$ corresponds to a system with no mezzanine. Both methods exactly calculate a SDOF system. The Weight method is more accurate because its assumed mode shape more closely matches the actual mode shape.

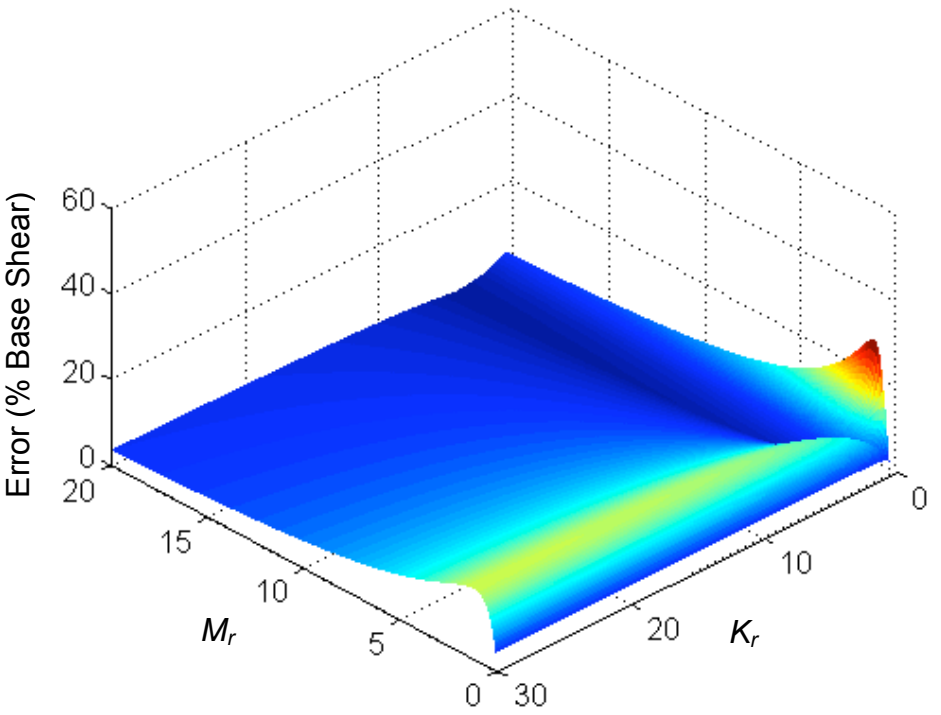

Figure 5. Error of Weight method for distribution of seismic story forces

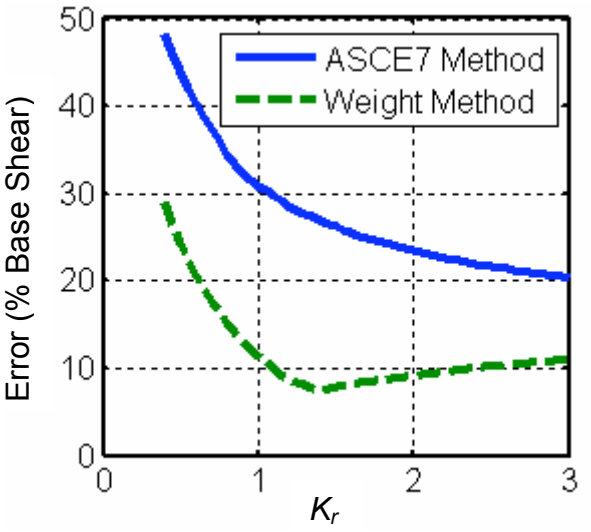

Figure 6. Error envelopes at low K_r values

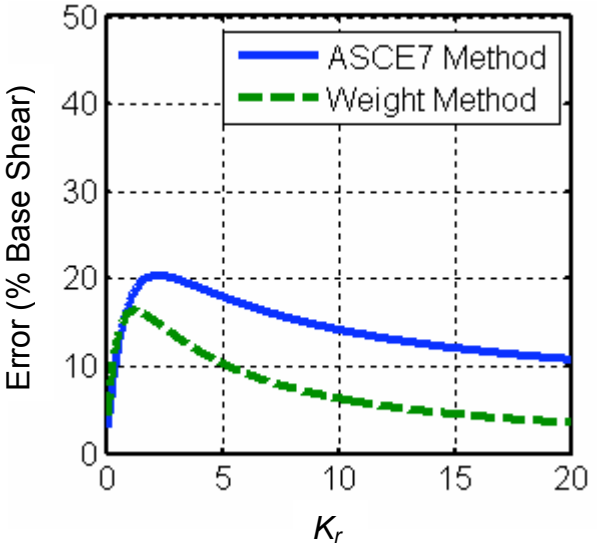

Figure 7. Error envelopes when $K_r > 3$

IMPLICATIONS

In light of the evidence found in these investigations, the Weight method is recommended for use in seismic design of MBS with mezzanines or lean-to attachments when $K_r > 2$, which should be most cases. It is possible that the ASCE 7 method may be improved by including an estimated α in the equation. Future research will investigate this possibility. Both methods give errors of about 20% or less and may be acceptable. If increased accuracy is desired, the Weight method can be used to determine forces for a preliminary design. After a design is in place, the closed-form solutions presented earlier
can be used to determine the first mode shape. This accurate mode shape will determine a better estimate of the story forces, and this process can be repeated until the designer reaches the desired accuracy. It is unlikely, given the general uncertainty level in seismic force determination, that accuracy of this level is necessary, and the Weight method will be sufficient to distribute story forces for design.

It is likely, especially for structures with mezzanines attached to a frame
column, that the second mode could have a significant effect on the internal forces for which the structure must be designed. A simple method to determine if this is the case and then account for it is not readily available; however, a more complicated method of modal response spectrum analysis may be performed. Modal response spectrum analysis may be necessary when $K_r < 2$ as well. Modal response spectrum analysis requires further assumptions about how modes interact, some of which will likely have economic impact on the design of MBS. As an example, when using the square-root-of-sum-of-squares (SRSS) method to combine modal responses, a given response quantity loses its sign (Chopra, 2007). If the response were an internal bending moment, this would render use of the moment gradient, to increase capacity, impossible. This would likely result in increased frame member sizes and a reduced

overall economy. A direct summation of modal responses has the potential to be a better solution for MBS designers. This will be investigated further in future research.

CONCLUSIONS

Common assumptions about seismic forces were investigated. It was shown that in a reasonable worst-case, the second mode could contribute to the base shear response, at a maximum, less than 10% of that which the first mode was capable of contributing. It seems valid that only the first mode's contribution be included when calculating seismic force demands. Since the first mode shape cannot be known until a preliminary structure is designed, two common story force distribution methods were compared with the actual first mode force distribution. Because both methods made assumptions about the mode shape, both produced low errors. The Weight method was found to be generally more accurate throughout a reasonable range of structural parameters and is recommended for use in design. There is room for improvement on the ASCE 7 method which may help make it more accurate. This research will continue with an effort to develop a method to dismiss or account for contribution of the second mode when designing for internal forces. Regardless of whether a mezzanine is considered a floor or not, the results found in this paper are valid as long as the structure can be idealized as a 2-DOF system.

ABSTRACT

Research was conducted to investigate the seismic behavior of steel plate shear walls with in-span plastic hinges. Results show that the development of in-span plastic hinges has detrimental impacts on the behavior of the structure through inducing: (1) significant vertical and residual deformations on the HBEs (i.e. shakedown phenomenon); (2) only partial yielding of the infill plates; (3) lower global plastic strength compared to the values predicted by code equations; and (4) total HBE rotations greater than 0.03 radians after the structure was pushed cyclically up to a maximum lateral drift of 3%. Nonlinear time history analyses also demonstrated that the severity of the ground excitations accentuated the shakedown phenomenon.

INTRODUCTION

There have been numerous experimental and analytical studies investigating the behavior of unstiffened Steel Plate Shear Walls (SPSW) in the past thirty years. An extensive summary of that research has been presented in Sabelli and Bruneau (2007). Much of that research has focused on designing and modeling of the SPSW web plates, analysis methods, and validation of satisfactory cyclic inelastic and seismic performance. Few have focused on alternative ways to analyze and design SPSW horizontal and vertical boundary elements (HBEs and VBEs). Xue and Lu (1994) suggested means to reduce demand on VBEs, including connecting the infill panel to only the HBEs. Berman and Bruneau (2008) developed an analytical procedure to obtain correct forces in the VBEs. Lopez-Garcia and Bruneau (2006) and Qu *et al.* (2008) investigated possible inadequate performance of HBEs, building on the work of Vian and Bruneau (2005).

This paper presents the results of an analytical investigation on the seismic behavior of steel plate shear walls having HBEs designed to have different plastic collapse mechanisms. In the first SPSW, formation of in-span plastic hinges on HBEs is possible, whereas in the second SPSW, plastic hinges can only occur at the ends of HBEs. Results and observations from pushover analyses and time-history analyses are used to assess the relative performance of the two SPSWs.

STRUCTURE DESCRIPTION & ANALYTICAL MODEL DEVELOPMENT

As a case study to investigate the possible significance of in-span HBE plastic hinges, a three-story single-bay SPSW was selected. Bay width and typical story height were arbitrarily chosen equal to 20 and 10 ft, respectively, resulting in an infill plate aspect ratio of 2.0. It was also assumed that the structure is located on Class D soil in downtown San Francisco, California and designed for an office building. Total weight of the structure W_t is 1085 kips, distributed as 352 kips on the first two stories and 381 kips on the roof. The total base shear V resisted by the structure was 176 kips, distributed as lateral loads along the height of the building of 92 kips, 56 kips, and 28 kips from the third to the first floor. Two design procedures were applied to design the boundary elements: (1) the Indirect Capacity Design approach (AISC 2010) and (2) the capacity design approach which combines the procedure proposed by Vian and Bruneau (2005) for HBEs and that proposed by Berman and Bruneau (2008) for VBEs. The resulting sizes of VBEs and HBEs obtained by the two different design procedures are compared in Figure 1. For SPSW designed by the capacity approach (SPSW-CD), all the HBE demand-capacity ratios exceed 0.98, except one at 0.95. For SPSW designed by the indirect capacity approach (SPSW-ID), the HBE ratios varied from 0.88 to 0.99; but this slight difference from the second SPSW case will not violate the conclusions reached by this study as will be shown later.

To investigate the behavior of both SPSW-ID and SPSW-CD, two analytical models were developed in SAP2000 program: (1) a strip model for monotonic pushover analysis and (2) a dual strip model for cyclic pushover analysis and time history analyses. In this study, twelve strips were provided at every floor to model the infill plates of the two 3-story SPSWs. The *Axial-P Hinge* (set to exhibit correct hysteretic tension-only behavior, per Purba and Bruneau 2010) was chosen to define the inelastic behavior of the strips. The *Fiber P-M2-M3 Hinge* was chosen to define plastic hinges in the VBEs and HBEs, which automatically accounts for the interaction between the axial loads and moments that can occur in the HBEs and VBEs.

NONLINEAR STATIC ANALYSIS (PUSHOVER ANALYSIS)

A monotonic pushover analysis was conducted for both SPSW-ID and SPSW-CD until each structure reached a 4% lateral drift. At 4% drift, the base shears are 311 and 477 kips for the respective structures; for comparison, their respective theoretical

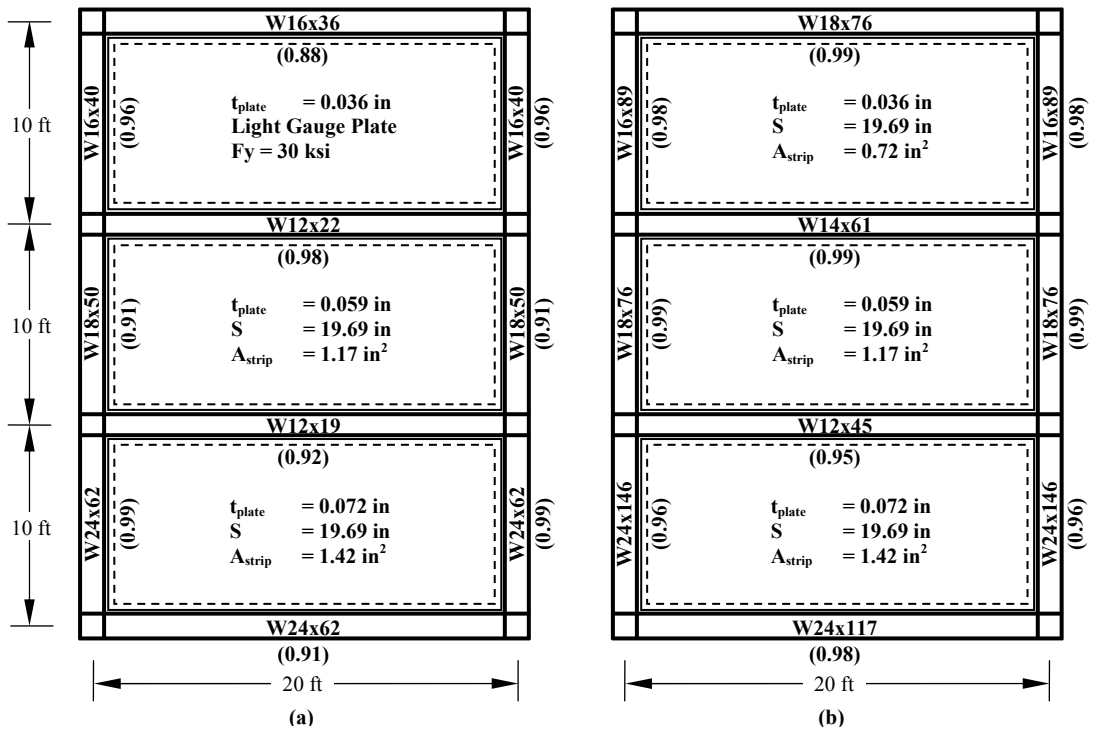

Figure 1. VBE and HBE Sizes (a) SPSW-ID; (b) SPSW-CD

values are 351 and 488 kips, obtained using the plastic analysis equations for uniform plastic collapse mechanism (Berman and Bruneau 2003). For SPSW-CD, the two values are in a good agreement with only a 2.3% difference. However for SPSW-ID, the theoretical base shear is 13% more than obtained from the monotonic pushover analysis. This because SPSW-ID did not follow the uniform plastic collapse sway-mechanism but rather consists of a 'sway' and 'beam' combined mechanism. Four in-span plastic hinges have developed on the HBEs of SPSW-ID and significant vertical deformations were observed along the HBEs spans of SPSW-ID.

In a seismic excitation environment, when a structure experiences cyclic loading, plastic hinging along an HBE span could lead to an unbounded progressively increasing deformation. This detrimental impact on a structure is called a "shakedown phenomenon". To investigate whether this phenomenon develops in the HBEs of SPSW-ID and SPSW-CD, and whether it may detrimentally affect structural performance, cyclic pushover analysis was conducted. A progressively increasing cyclic displacement history of up to 3% drift (in increment of 0.5%) was applied to the top floor of the structure for this purpose.

Figure 2(a) shows the plastic hinge and strip yielding distributions on SPSW-ID. When the structure experienced +1% lateral drift, a total of four plastic hinges (1 partial plastification and 3 fully plastic) occurred at the HBE ends; and somewhat the same distributions occurred at the reversed excursion of −1% lateral drift. In addition, three strips (the right-leaning or left-leaning strips for the positive or negative direction, respectively) on the second and the third floor remained elastic and only two strips on the first floor had yielded. Though more strips yielded as the

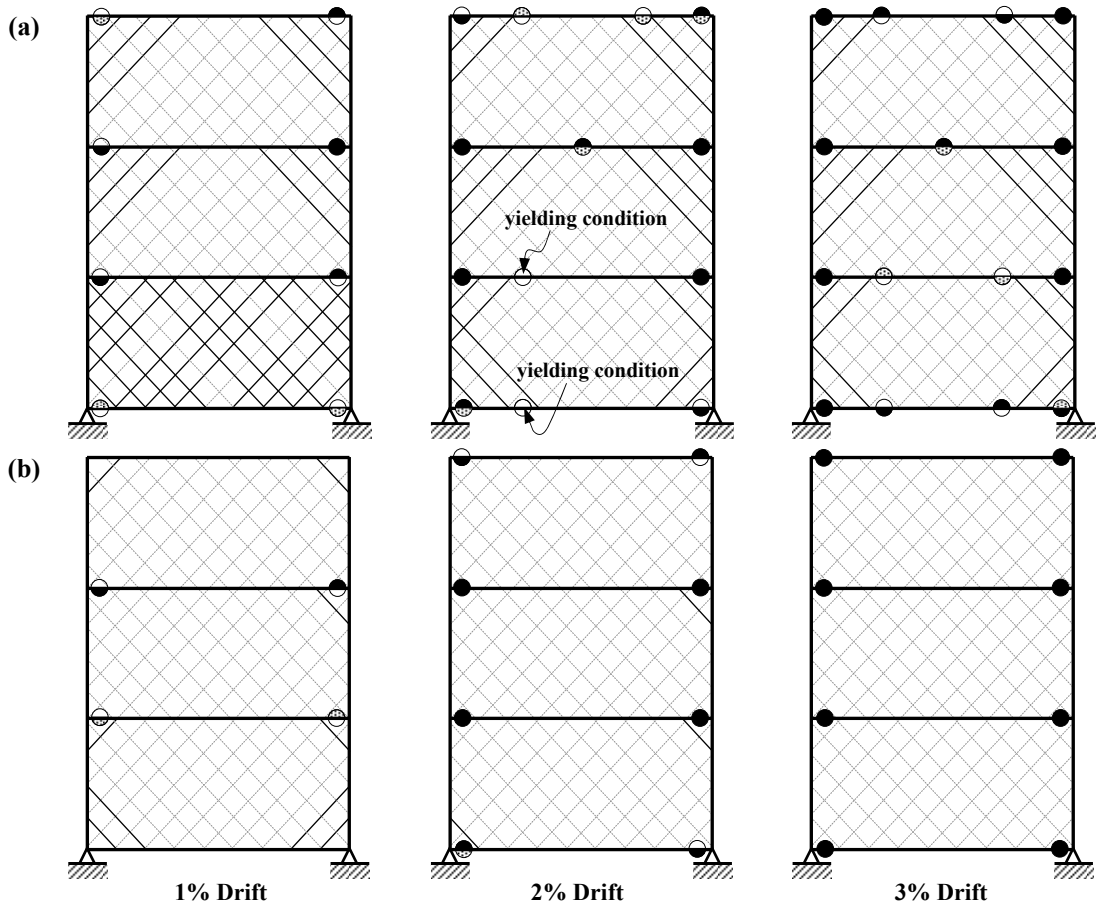

Figure 2. Plastic Hinge and Strip Yielding Distributions on (a) SPSW-ID; (b) SPSW-CD

pushover displacement increased, some strips remained elastic. Moreover for the plastic hinge distribution, beyond the plastic hinges that occurred at the HBE ends, three locations of in-span plastic hinges were also observed on HBE2 and HBE3 at the end of 2% drift cycle; and the yielding condition occurred along the span of HBE0 and HBE1. At the end of the 3% drift cyclic, in-span plastic hinges on the HBEs occurred at 4 locations for both positive and negative drift excursions. In contrast with SPSW-CD [presented in Figure 2(b)], most of the strips had yielded at the end of the 1% drift cycle and only four right-leaning strips and five left-leaning

strips in total had remained elastic. All strips have completely yielded at the end of the 3% drift cycle. In addition, all plastic hinges have developed at the HBE ends of SPSW-CD and no in-span plastic hinge developed.

A most significant phenomenon observed is the HBE vertical downward deformation of SPSW-ID, progressively increasing and of significant magnitude as the lateral drift increased, as one example is shown in Figure 3. This figure compares vertical displacement history at the mid-span of the top HBE for both SPSWs. The backbone-displacement slope (i.e., displacement at maximum drift) of SPSW-ID is stiffer than that of SPSW-CD. This implies that the HBE vertical downward displacement for SPSW-ID increases faster than that for SPSW-CD. In other words, the shakedown phenomenon due to cyclic pushover displacement detrimentally affects the structural performance of SPSW-ID. The same trend was also exhibited with the residual displacements (i.e., displacement when the structure returns to its original position at 0% drift). Moreover, note that the shakedown phenomenon on SPSW-ID would be even worse if a smaller W-section had been used for the top HBE such that its demand-to-capacity ratio was closer to 1.0; recall that a value of 0.88 (as shown in Figure 1) was obtained for that top HBE in the SPSW-ID case, compared to the corresponding 0.99 value at the top HBE of SPSW-CD. If anything, this discrepancy reinforces the conclusions reached by this case study.

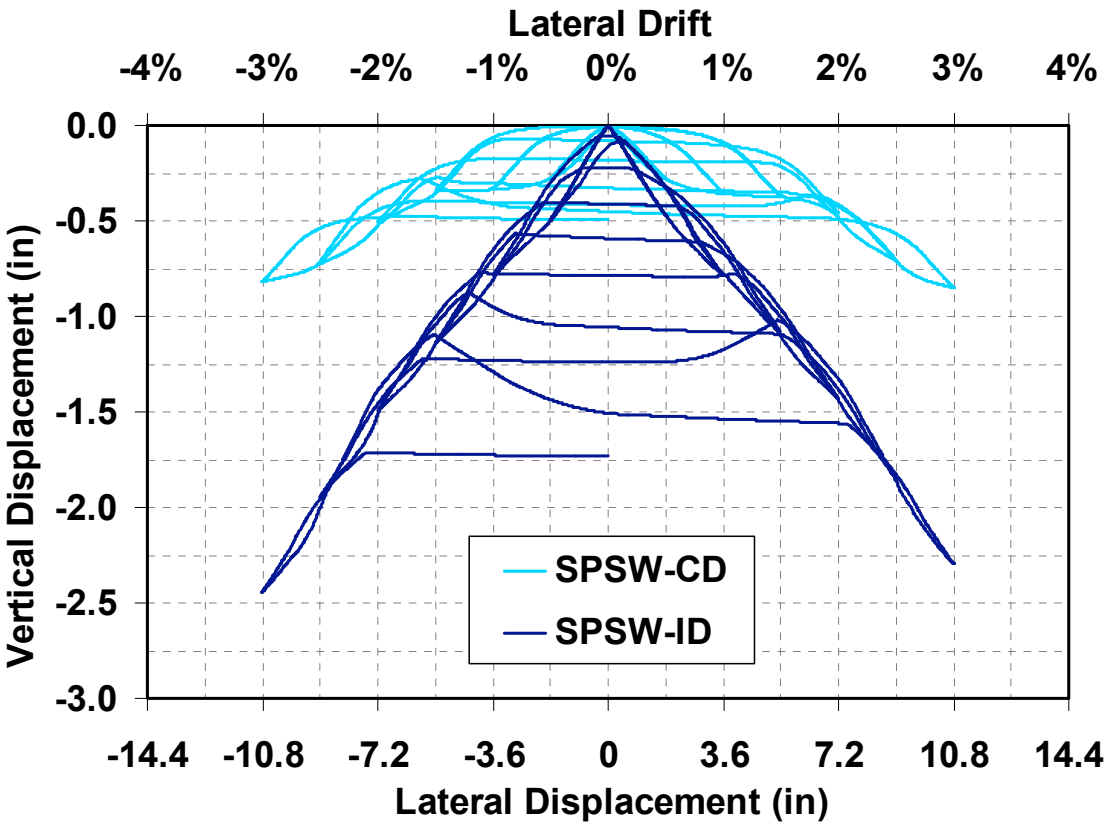

Figure 3. History of HBE3 Vertical Displacement (Cyclic Pushover)

Another approach that can be used to examine the behavior of the two SPSWs is by comparing the moment-rotation hysteresis of their HBEs, as done in Figure 4, which plots the normalized moment-rotation hysteresis of HBE2 (as an example) obtained during the cyclic pushover displacements. Interestingly, the moment-resisting ends of the HBEs of SPSW-ID developed a cross-section rotation greater than 0.03 radians after the structure was pushed cyclically up to a maximum lateral drift of 3%. Such a significantly high cyclic rotation demand would be difficult to achieve using the type of moment resisting connections used in SPSW (the AISC 2010 Seismic Specifications only require that Ordinary-type connections be used in SPSW). In fact, it might also be difficult to achieve with special moment resisting frame (SMRF) beam-to-column connections approved by AISC 2010, which are experimentally verified to perform well up to +/–0.04 radians total rotations, or +/–0.03 radians plastic rotations. By comparison for SPSW-CD, all HBE total rotations obtained were less than or equal to 0.03 radians under the same cyclic pushover displacements up to 3% drift.

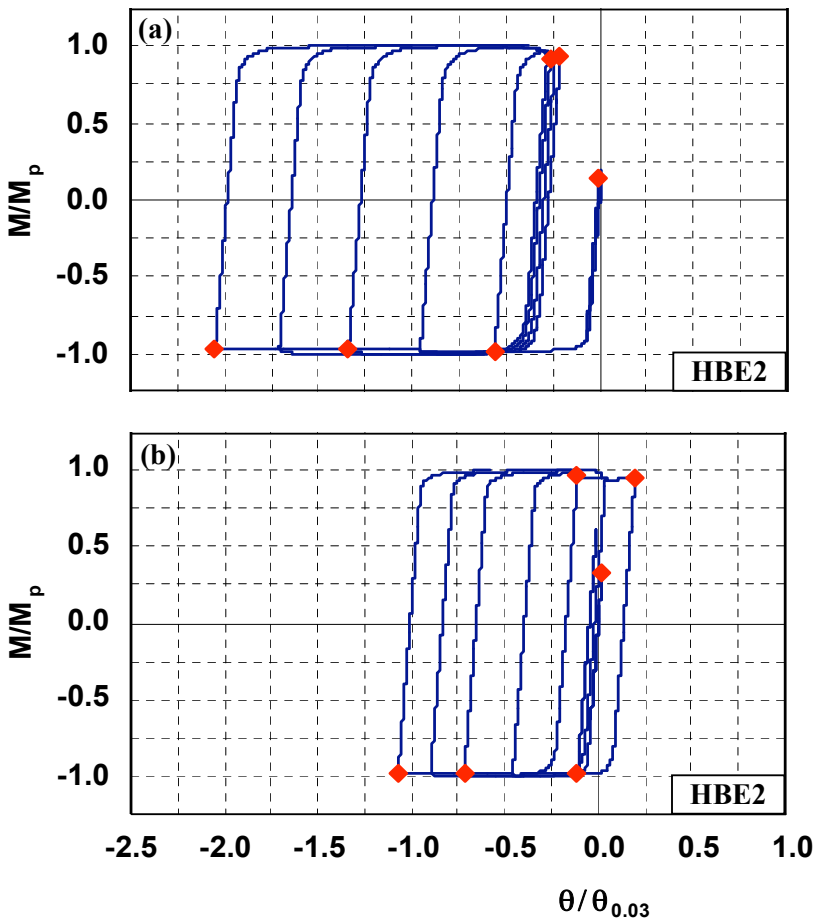

Figure 4. Normalized Moment Rotation Hysteresis at HBE Left End for (a) SPSW-ID; (b) SPSW-CD

NONLINEAR TIME HISTORY ANALYSIS

While several key seismic behaviors of steel plate shear walls having HBEs designed to have different plastic collapse mechanisms have been discovered through the incrementally cyclic pushover analysis, conducting nonlinear time history analysis remains necessary to investigate whether those previous results would be replicated during earthquakes excitations and whether additional seismic behaviors for the aforementioned SPSW systems would emerge as a consequence of the random nature of earthquake records. Three synthetic time histories of ground acceleration were generated for this purpose

The nonlinear time history results show that the shakedown phenomenon is still observed, with maximum and residual vertical deformations more apparent on SPSW-ID than on SPSW-CD. HBE3 vertical downward displacement for SPSW-ID increased faster than that for SPSW-CD as the lateral drift increased. For example, when SPSW-CD reached a lateral drift of 1% for the first time, the largest HBE3 vertical displacement at the same drift for SPSW-ID was 2.25 larger; and became 4 times larger as the ground excitation increased and caused a 2% lateral drift on both structures.

The nonlinear time history analyses were then extended to investigate the performance of both SPSWs under the more severe Maximum Considered Earthquake (MCE). It was observed that as the severity of the synthetic ground motions increased (consequently generating higher lateral drifts on both SPSWs), HBE vertical deformations of SPSW-ID especially at the top two floors significantly increased compared to the corresponding magnitudes in the DBE case. By comparison for SPSW-CD, only minor changes of HBE vertical deformations occurred. Hence, when formation of in-span plastic hinges on HBEs is possible, such as in the case of SPSW-ID, the more severe the ground excitations, the worse the shakedown phenomenon.

CONCLUSIONS

An analytical investigation on the seismic behavior of steel plate shear walls having boundary elements designed by two different philosophies was conducted. It was demonstrated that plastification along HBE spans (i.e., in SPSW-ID) has detrimental impacts on the behavior of the structure. Nonlinear time history analysis also demonstrated that the severity of the ground excitations accentuated the shakedown phenomenon on SPSW-ID, while this was not the case for SPSW-CD. These conclusions on the behavior of the SPSW-ID are equally applicable to SPSWs designed by any method for which in-span hinges is not explicitly prevented.

ABSTRACT

This paper describes the recent experimental researches on the steel plate shear wall (SPSW) at National Center for Research on Earthquake Engineering (NCREE). In addition, the design implications learned from the test results are presented. In 2007, the cyclic tests of four full-scale two-story narrow SPSWs confirm that the yielding of the first story column can be confined in the bottom of the column when the proposed capacity design principle is followed. Test results also suggest that, when the column hinging is allowed at a location slightly above the column base, the column size can be cost-effectively reduced without comprising the seismic performance of the SPSW. In 2009, the cyclic test of a reduced scaled coupled SPSW (C-SPSW) substructure was conducted at NCREE. The specimen was the 2/5-scaled substructure of the lowest two-and-half-story of a 6-story C-SPSW prototype building. The C-SPSW specimen consisted of two SPSWs connected together by the coupling beams. In addition to a constant vertical force representing the gravity load effects, cyclic increasing displacements and the associated overturning moments were applied at the boundary of the specimen using the Multi-Axial Testing System (MATS) in NCREE. Test results suggest that the proposed design method, which aims to limit the hinging of the bottom column within the bottom quarter column height, could be a choice of design in the practice. The test results confirm that the effect of the coupling beams in reducing the axial forces in the inner boundary columns. The relationship between the coupling beam rotation and the story drift is explored based on the test data. Test results suggest that the cyclic responses of the C-SPSW specimen can be satisfactorily predicted using the general purposes frame response software incorporating the strip model.

INTRODUCTION

Steel plate shear wall (SPSW) has seen increased usage in North America and Asia in recent years. An SPSW is composed of a structural frame and infill steel plates. The beams and columns surrounding the infill plates are named boundary beams and boundary columns, respectively. SPSW can effectively resist horizontal earthquake forces by allowing the development of diagonal tension field action after the infill plates buckle in shear. The input energy is then dissipated through the cyclic yielding of the infill plates in tension. The boundary elements in an SPSW must to be designed to anchor the plastic tension field action of the infill plates. Recently, many researches (Vian and Bruneau, 2005; Berman and Bruneau, 2008; Qu and Bruneau, 2010) focused on the capacity designs for the boundary elements. In 2007, the objective of the cyclic tests of four 2-story narrow SPSWs at National Center for Research on Earthquake Engineering (NCREE) was to verify the capacity design method for the boundary column proposed by Tsai *et al*. (2010). The test results confirm the effectiveness of Tsai *et al.*'s method in limiting the plastic hinge formation on the boundary column at the column base.

The infilling the steel plate into the structural frame would conflict with the architectural demand for the doorways. In a tall and slender SPSW, the significant overturning moments will result in high axial forces in the boundary columns. Moreover, the tall SPSWs likely behave in the flexure-dominated deformation mode under the lateral forces. It would cause the steel plates in the top stories of the wall to fail in developing the plastic tension field action. The coupled steel plate shear wall (C-SPSW) is considered as a solution to the application of SPSW in the high-rise buildings. In order to investigate the seismic behavior and design of C-SPSW, cyclic test of a recued-scaled C-SPSW substructure was conducted at NCREE in 2009 using the brand-new Multi-Axial Testing System (MATS) facility. In addition, a new design philosophy of boundary column was examined based on the test results of the C-SPSW.

CYCLIC TESTS OF FOUR TWO-STORY NARROW SPSWS

Column capacity design philosophy. The main objective of this experiment is to verify the effectiveness of the column capacity design proposed by Tsai *et al*. (2010). The objective of the design method was to limit the hinging of the column to the column base. Figure 1 illustrates the philosophy of the proposed method. The action on the boundary elements of an SPSW subjected to lateral forces can be considered as the superposition of two parts. One part is only due to frame sway (see Figure 1a-left) while the other is due to panel forces (see Figure 1a-middle). For properly portioned SPSWs, the infill plates would develop the plastic tension field prior to the yielding of the columns. The yield panel forces acting on the boundary elements can be considered as distributed loads with a tension field angle α (AISC, 2005a) from the vertical. The horizontal yield panel force acting on the 1st story columns is denoted as ω_{ch1}.

The top and bottom halves of Figure 1a demonstrate two types of the bending moment distribution patterns on the compressed column. The bending moment from

the frame sway action can be assumed as linearly distributed (Figure 1a-left). The quadratic- distributed moment (Figure 1a-middle) can be estimated by assuming that the column has fixed ends and the column is subjected to a distributed load ω_{ch1}. If the column strength is sufficient to resist enough swaying moment, as shown in the right top of Figure 1a, the maximum superposed moment will locate at the bottom end, which implies that the plastic hinge will form at the bottom end (Figure 1b-top). Tsai *et al.* (2010) derived the equation for the column moment demand based on this kind of moment distribution (right top of Figure 1a). If the column is smaller, as shown in the bottom half of Figure 1, the plastic hinge would form above the bottom end.

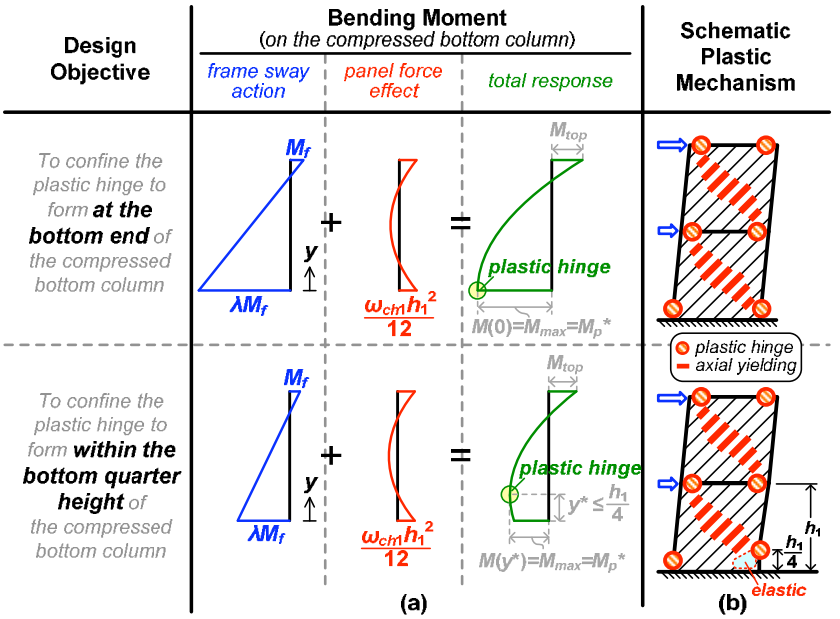

Figure 1. Philosophies of the design methods for the bottom column of SPSW.

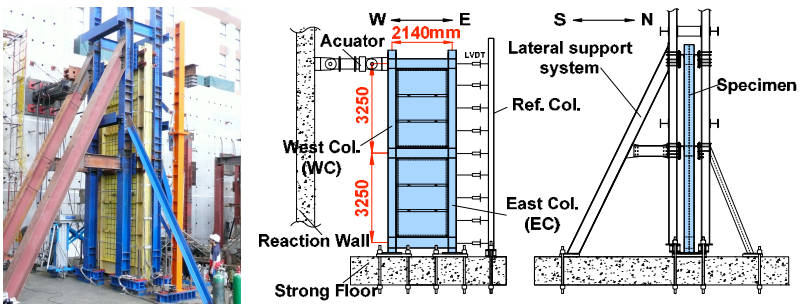

Figure 2. Test setup of cyclic tests of four 2-story narrow SPSWs.

Experimental program. Four 2-story 2.14-meter wide by 6.5-meter tall narrow SPSWs were cyclically tested to a 5% rad. roof drift at NCREE. All four specimens had the same center-to-center line dimensions. All the infill steel plates were 2.6 mm thick low yield strength (LYS) steel with a measured yield stress, f_{yp} = 195MPa. All boundary elements were made of A572GR50 steel. The key differences in the

specimens were the size of the boundary elements and the use of restrainers. The aspect ratio of the infill plates ranged from 0.62 to 0.64, which was less than the lower limit (0.8) specified by 2005 AISC seismic provisions (AISC 2005a). Figure 2 shows the test setup. Increasing cyclic horizontal displacements were applied on the top level of the specimens through two actuators.

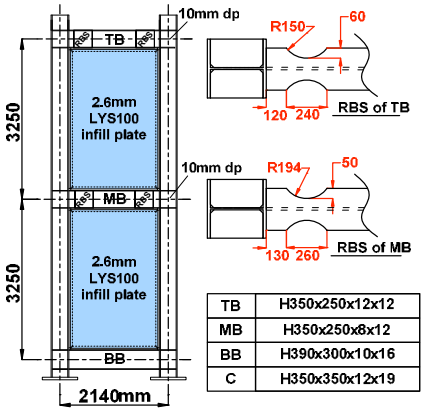

Figure 3. Details of Specimen N.

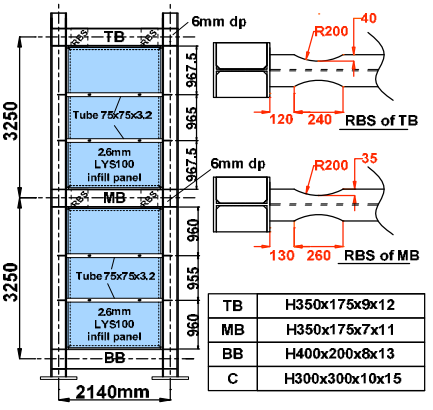

Figure 4. Details of Specimen RS.

This paper focuses on the cyclic performances of three of the four specimens. The details of the specimens and the sizes of the boundary elements are provided in Figures 3 and 4. Specimens N and S are typical unstiffened SPSWs; Specimen RS is a restrained SPSW (R-SPSW) (Tsai *et al*., 2010). The boundary elements are classified into four categories and abbreviated as: the top beam (TB), the middle beam (MB), the bottom beam (BB) and the column (C). All beam-to-column connections are welded moment connections. Specimen N was normal, named from the fact that the column complied with the proposed capacity design method (Tsai *et al*., 2010). The boundary elements in Specimen S were smaller than those in Specimen N. The column in Specimen S did not satisfy the proposed capacity design method. Specimen RS was identical to Specimen S except it adopted two pairs of restrainers for each story. As the restrainers can reduce the horizontal panel force effect on the boundary column, the boundary columns in Specimen RS conformed to the proposed capacity design method (Tsai *et al*., 2010). Figure 5 shows the predicted plastic mechanism of the three specimens based on the proposed capacity design method. As the boundary column strength in Specimen S was insufficient, it was expected that a plastic hinge would form within the column height.

Experimental results and learned implications. Figure 6 shows the lateral force versus story drift relationships of Specimens N, RS and S. In general, all specimens remained elastic before a drift of 0.3%. The boundary elements slightly yielded at this stage. Plastic hinges on the boundary elements were observed at the boundary element ends at a roof drift level of about 1.0% radian. As the roof drifts exceeded 2.5% radians, flange or web local buckling occurred gradually at the plastic hinge zones. Nevertheless, the load-carrying capacity did not decrease significantly.

Figure 7 shows the overall views of the specimens after the tests. Based on the flaking of the whitewashes, the locations of the plastic hinges agree with the

predictions shown in Figure 5. As shown in Figure 8, the plastic hinges developed at the first story column bottom ends can be recognized from the flaking of the whitewashes. Two types of plastic hinges can be observed in the columns. One is the plastic hinge developed when the column is compressed. This kind of plastic hinge can be observed on the column web shown in the photo (Figure 8c) as a ring shape. This is due to the occurrence of web local buckling at the center of the ring. The other type of plastic zone develops when the column is tensioned. In this case, uniform web yielding would be evident as shown in the photo (Figure 8c) at the column bottom end. As there is no plastic hinge zone forming within the column height for Specimens N and RS, these two types of plastic zones overlapped at the column bottom ends (Figures 8a and 8b). On the other hand, in Specimen S, the ring-shape zone was evidently above the column bottom end where uniform yielding zone developed (Figure 8c). The distance from the bottom end to the ring center is about two times the column depth. It clearly indicated that, in Specimen S, the plastic hinges formed away from the bottom ends when the columns were compressed.

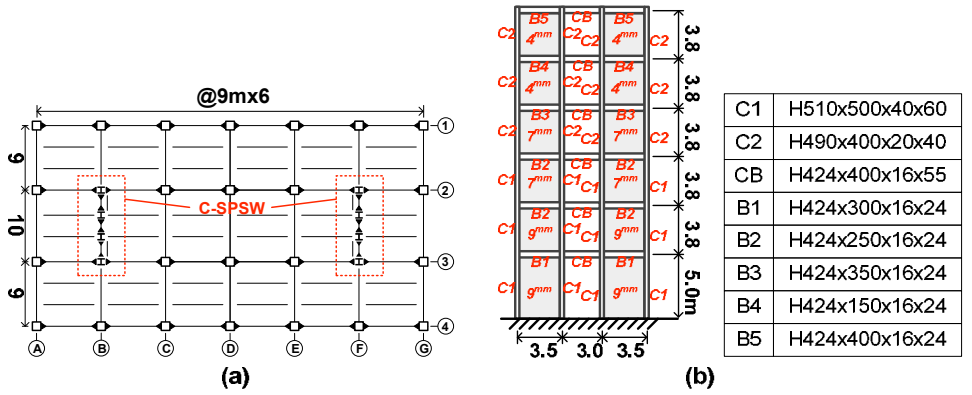
(a) Specimen N (b) Specimen RS (c) Specimen S

Figure 7. Specimens after tests.



(a) Specimen N (b) Specimen RS (c) Specimen S

Figure 8. Plastic zones on the columns.

Test results confirm that the proposed capacity design is effective in limiting the plastic hinge formation to the column base. However, the cyclic responses shown in Figure 5 indicate that Specimen S possessed satisfactory ductility and load carrying capacity. This suggests that the cyclic performance of an SPSW might not be significantly deteriorated when it has plastic hinges slightly above the column bases. To achieve a more economical SPSW, a slight under-design for the column as illustrated in the case of Specimen S should be acceptable.

CYCLIC TEST OF A REDUCED-SCALE C-SPSW SUBSTRUCTURE

Specimen design. A prototype 6-story coupled steel plate shear wall (C-SPSW) building (see Figure 9) was designed based on the model U.S. standards (AISC, 2005a and 2005b). The site is located at the east zone of the Chiayi City in Taiwan. A 2-D strip model (Thorburn *et al*., 1983) for the C-SPSW was developed using the structural analysis program SAP2000 to check that the infill plates and the other frame elements remain elastic under the code prescribed LRFD load combinations (AISC 2005b). The seismic load was calculated according to Taiwan seismic building code (ABRI, 2002).

Figure 9 (a) Floor plan and (b) elevation of the prototype C-SPSW building.

The bottom boundary column of the prototype 6-story C-SPSW was selected based on a new column capacity design philosophy (Chang, 2009): the plastic hinge on the bottom column is allowed to form above the bottom end but shall be limited within the bottom quarter column height as shown in the bottom half of Figure 1. This design philosophy would result in a more economical design results than the previously proposed design method (Tsai *et al.*, 2010), which limits the plastic hinge formation at the column base. The coupling beams of the 6-story C-SPSW prototype were designed as shear links. By extending the current provisions (AISC 2005a) for the link beam of the eccentrically braced frame (EBF) to the design of the coupling beams, the coupling beam section was selected in accordance with the relationship $e < 1.6M_p / V_p$, where M_p and V_p are the plastic flexural and shear strength of the coupling beam, respectively.

Using the 6-story C-SPSW prototype as a basis, a 40% scale specimen was constructed as the bottom 10.5-m high substructure of the original C-SPSW. The region of the substructure contains the lowest two and half stories of the original structure (shown in Figure 10-left). The infill plates were 3.5-mm thick low yield strength (LYS) steel with a measured yield stress f_{yp} = 220MPa. All the boundary elements and coupling beams were made of A572GR50 steel. The design results of the test specimen are shown in Figure 11. The Reduced Beam Section (RBS) was employed at the ends of the boundary beams. The spacing of the stiffener plates in the coupling beam webs was determined based on the rotational demands of the coupling beams predicted from a finite element analysis. A shell model of the 2/5-scaled C-SPSW specimens was developed using the commercially available

software ABAQUS/Standard. A nonlinear pushover analysis up to a 5% rad. roof drift was conducted to obtain the rotational demands of the coupling wall.

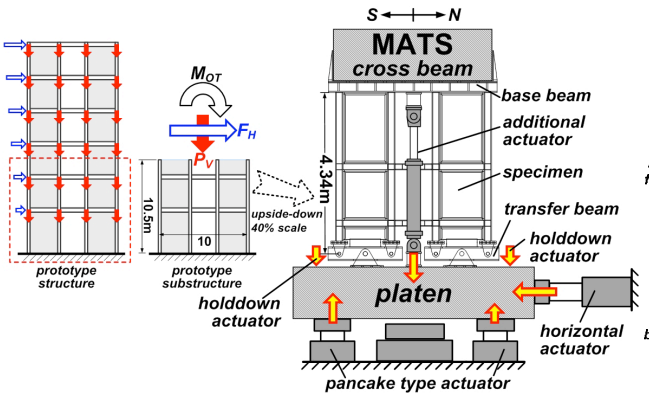

Figure 10: Test setup of cyclic test of reduced-scaled C-SPSW substructure

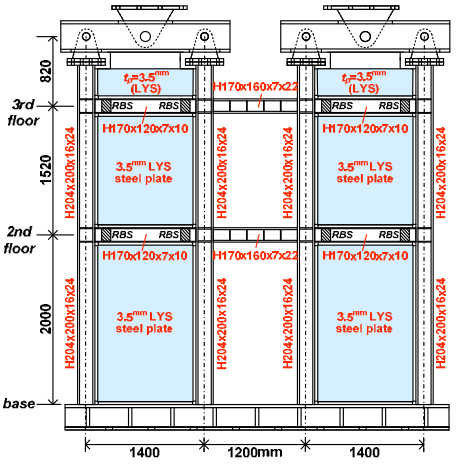

Figure 11: Schematic of the C-SPSW substructure specimen

Experimental Program. The specimen was tested using the Multi-Axial Testing System (MATS) at the NCREE. In order to simulate the effects of the upper substructure acting on the bottom two-and-half story substructure, as illustrated in Figure 10, the specimen was subjected to the cyclic lateral forces, F_H, the cyclic overturning moments, M_{OT}, and a constant 1400 kN vertical force, P_V, which represents the gravity load. The specimen was set upside down in the MATS. The base beam of the specimen was mounted on the cross beam of MATS. The top boundary of each SPSW was connected with a transfer beam. The column top ends were pin-connected with the transfer beam ends; and the top steel plate was welded to the transfer beam using the fishplate connection. The mid-span of the transfer beam was pin-supported on the platen. A lateral support system was constructed on the platen and the reaction frame (A-frame) of MATS.

The actuator system applied forces on the platen. Two horizontal actuators were employed to apply the lateral displacement on the specimen through the platen. Two cycles of 0.1%, 0.2%, 0.3%, 0.5%, 0.75%, 1.0%, 1.5%, 2.0%, 3.0%, 4.0% and 5.0% rad. roof drifts were imposed sequentially on the specimen. The vertical actuators can be classified into 3 categories: (1) two rows of vertical pancake type actuators pushing the bottom of the platen. The difference in the applied forces between the two rows of actuators induced the overturning moment effects on the platen; (2) two built-in hold down actuators which were mounted on the A-frame and pushing the top face of the platen; and (3) two additional actuators which were anchored between the platen and the cross beam. The two additional actuators provided a constant 1960 kN vertical compressive force on the platen. It should be noticed that the pancake type actuators must be always in contact with the platen in compression. The hold down actuators and additional actuators provided vertical compressive forces on the platen to insure the six pancake type actuators were always in compression.

The resultant forces of these vertical actuators applied a constant vertical force (P_V = 1400 kN). The relationship between the resultant moment M_{OT} of these vertical actuators and the lateral force F_H applied by horizontal actuators is: M_{OT} = F_H × (2.51 m). The relationship is calculated based on the inverted triangle vertical distribution of the lateral forces, which was determined from the current Taiwan's seismic code (ABRI, 2002).

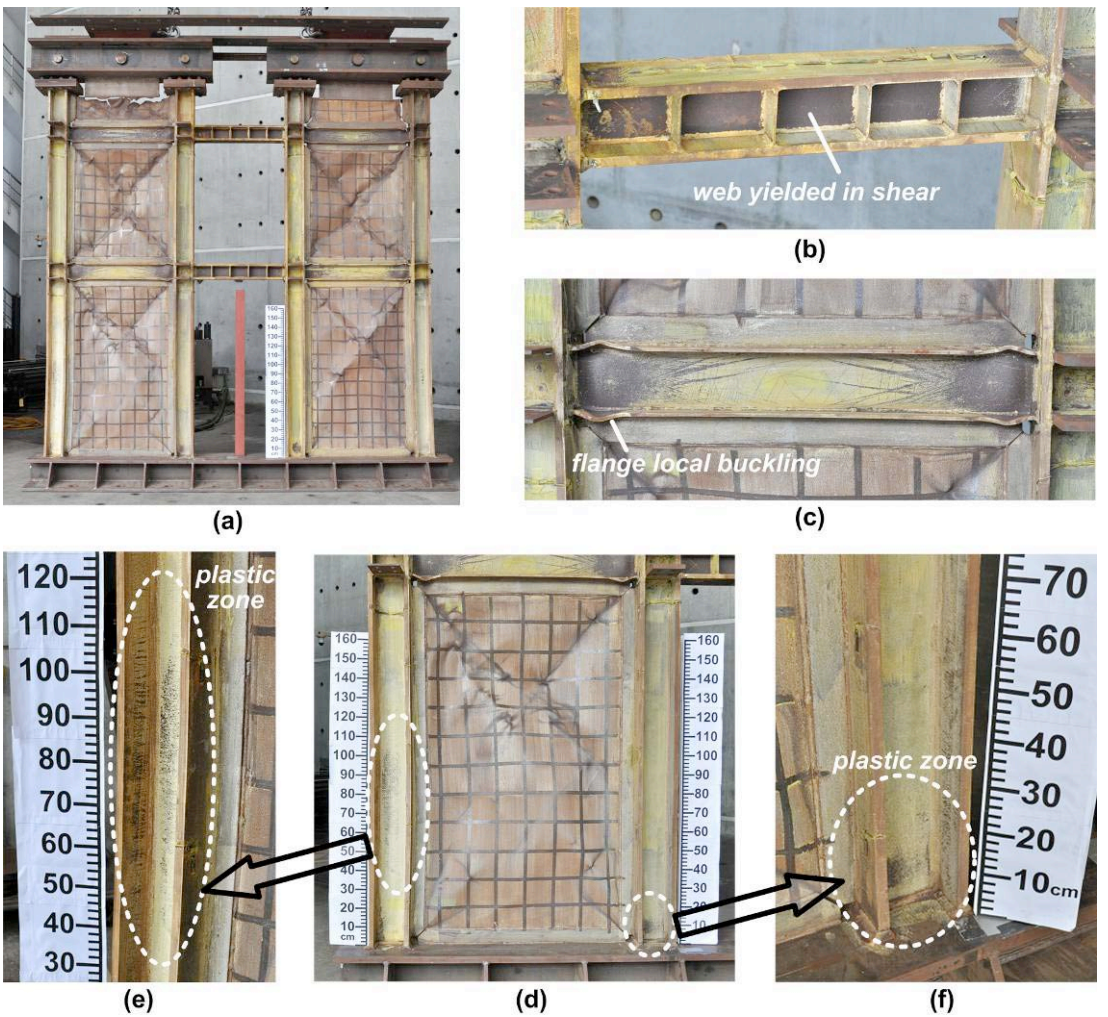

Figure 13: Deformed shapes of the specimen after test: (a) overall; (b) the 3rd floor coupling beam; (c) the 2nd floor boundary beam; (d) the 1st story of the southern SPSW; the plastic zones on the (e) outer and (f) inner bottom columns.

Test results and design implications. Figure 12 illustrates the force versus displacement relationship of the specimen. The C-SPSW specimen exhibited an excellently ductile behavior and dissipated significant amount of hysteresis energy during the cyclic loading test. The lateral and vertical load-carrying capacities did not notably deteriorate when the overall drift of the specimen reached 5% rad. An unanticipated fracture occurred at the early stage of the test. The weld between the fishplate and the transfer beam at the 3rd story of the southern SPSW were totally torn off at 1% rad. roof drift. However, that fracture did not significantly deteriorate the load-carrying capacity of the specimen. Thus, the test went on until the two cycles of 5% rad. roof drift had been completed.

After the test, as shown in Figure 13a, the flaking of the whitewashes on the specimen showed that the specimen had developed the plastic mechanism. The coupling beams developed shear plastic hinges (Figure 13b). The flexural plastic hinges formed at the ends of the boundary beams (Figure 13c) and near the column bases (Figures 13d, 13e and 13f).

Figure 13d shows the flaking of the whitewashes on the bottom (first story) columns of the northern SPSW after the test. As shown in Figure 13e, the plastic zone on the outer bottom column spread over a range from 40 to 100mm measured from the column base. On the other hand, the plastic zone on the inner bottom column concentrated at the column base (Figure 13f). The plastic zone on the outer column was wider than that on the inner column. In addition, the plastic zone on the outer column was located at a higher position than that on the inner column. The difference in the distribution of the plastic zone between the outer and inner columns could be attributed to that the axial force in the inner column was smaller than that in the outer column because of the coupling beam effect illustrated in Figure 14. Hence, the reduced flexural strength of the outer column was smaller than that of the inner column.

Figure 15 shows the relative deflections of the first story columns in northern SPSW when the lateral forces approached zero during the first cycle of the various drift levels. As shown in the top right of Figure 15, the relative deflection is defined as the difference between the absolute deflection and the reference line, which is the straight line from the top end to the bottom end of the column. The relative deflection can be utilized to estimate the inward flexural deformation of the column induced by the horizontal tension field forces of the infill plate. The column deflections measured when the lateral forces approaches zero in the various drift levels could represent the residual deflection after the specimen has experienced such level of drift. As shown in Figure 15, it can be found that residual "pull-in" deformations on the outer column were much larger than those on the inner column. This should be attributed to that the axial forces in the outer column were much higher, thus, the flexural strength of the outer column is smaller due to the axial-flexural interaction effect. However, form the Figure 15, it can be found that the maximum residual deflection of the outer column was about 10 mm (= $h_1/200$) after the specimen had suffered a 2.1% rad. first story drift. The 1/200 of the story height could serve as the deflection index limiting the development of large secondary forces in the columns (Ellingwood, 2003). Moreover, the past test (Tsai *et al.*, 2006) has shown that peak story drift of a well-designed SPSW specimen during

the collapse prevention level (2/50 hazard level) earthquake was about 2.0 to 2.5% rad. The test results suggest that, even if the plastic zones on the bottom columns had spread over the bottom half of the column height, the residual "pull-in" column deflection would not cause a significant secondary effect.

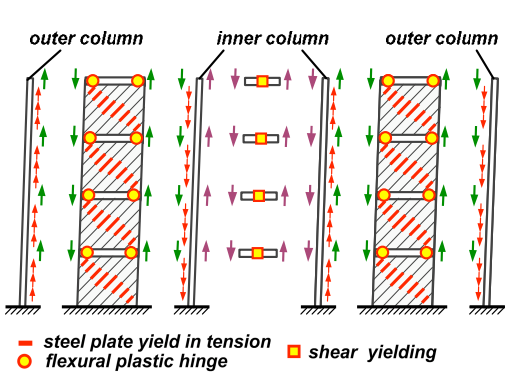

Figure 14: Effects of the coupling beam on reducing the axial forces in the inner boundary columns.

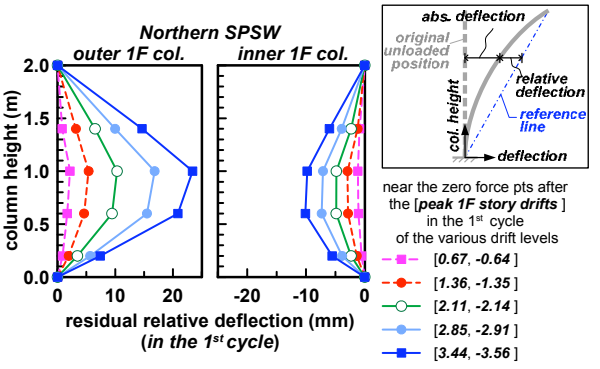

Figure 15: Residual relative deflections of the bottom columns in the northern SPSW in the various drift levels.

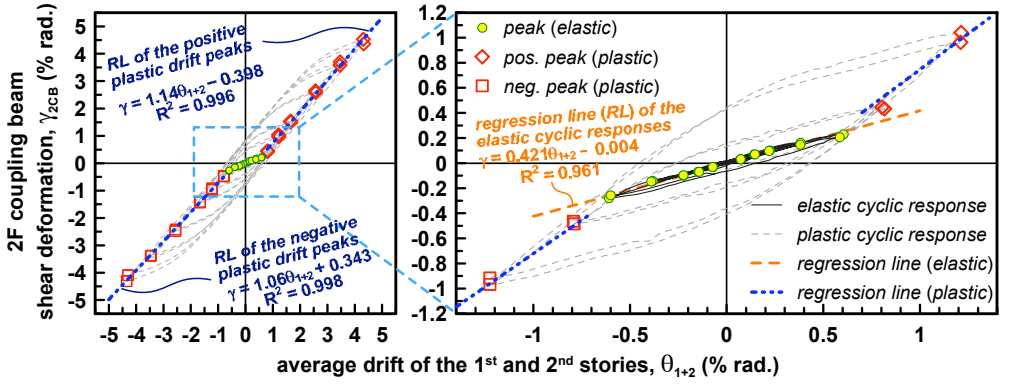

Figure 16: 2F coupling beam shear deformation (γ_{2CB}) versus the average drift (θ_{1+2}) of the 1st and 2nd story relationship.

Figure 16 shows the shear deformation of the second floor (2F) coupling beam, γ_{2CB}, versus the average drift, θ_{1+2}, of the 1st and 2nd story relationship. The slope of the line composed of the data at the various level peak drifts had a sudden change as the story drift reached about 0.75% rad. It indicates that the plastic shear hinge developed at this drift level. From the data at the peak drifts after the shear yielding, it can be found that the plastic shear deformation of coupling beam is close to the inelastic story drift. It suggests that, for seismic design purpose, the plastic rotational demand of the coupling beam at the bottom of a C-SPSW can be estimated as the design story drift. The design of the stiffeners in the coupling beam could be based on the estimated rotational demand.

Simulation. In this research, as shown in figure 17, a strip model (Shishkin *et al.*, 2010) for the C-SPSW specimen was constructed using the nonlinear frame analysis

program PISA3D (Lin *et al.* 2008). The tension field actions of the infill plates at the 1st, 2nd and 3rd story were represented by twelve, eleven and eight truss elements, respectively. The orientation of the tensile strips was determined from the tension field angle prescribed by the modern U.S. building codes (AISC, 2005a). In addition, a diagonal compression strut (Shishkin *et al.*, 2010) was employed to represent the compressive stiffness and strength of each infill plate. The columns were modeled using the PISA3D Fiber Beam-Column element. The boundary beams, coupling beams and the transfer beams were represented by using the PISA3D Beam-Column element. The reduced beam section (RBS) regions were simplified using a prismatic beam segment with the same cross sectional properties as those of the most reduced section. All beam-to-column joints were modeled using rigid end offsets with a rotational spring to representing the flexibility of the panel zone. Special constraints were set to represent the pin-connections between the transfer beams and the boundary columns. The platen in the MATS was modeled by a rigid frame consisting of a rigid beam and two rigid columns representing the half height of the platen. Except the rigid frame presenting the platen was modeled using elastic material, the material properties of the elements representing the infill plates, beams and columns were bilinear, fitting the coupon test results.

Nonlinear pushover analysis up to 5% rad. roof drift was carried out on the strip model. The constant 1400 kN vertical force P_V, the lateral displacement control with a load pattern composing of a horizontal force F_H and a overturning moment, M_{OT}, were applied on the node at the mid-span of the rigid beam representing the platen. Figure 12 shows that the analytical pushover results agree well with the experimental hysteresis loop. Figure 18 shows that the analytical relationship between the shear deformation of the 2F coupling beam and the average story drift of the 1st and 2nd stories quite match the test results.

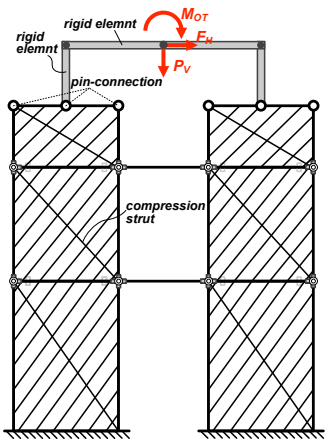

Figure 17: Strip model for the C-SPSW specimen.

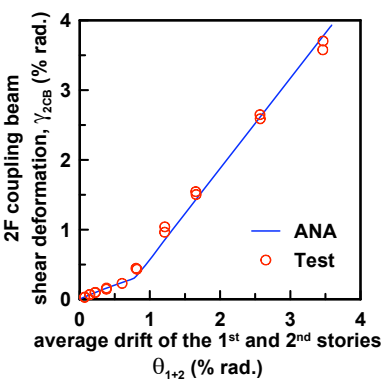

Figure 18: Comparison of experimental and analytical γ_{2CB}-θ_{1+2} relationships.

CONCLUSIONS

The test results of the Specimen S in 2007 and the reduced-scaled C-SPSW specimen in 2009 showed that the plastic hinge formation slightly above the column

base would not result in significant deterioration of strength and ductility. This suggests that the proposed column capacity design, which aims at limiting the plastic hinge on the bottom column within bottom quarter column height, could be a choice of design in the practice. The test results suggest that the rotational demand of the coupling beam at the lowest level of a C-SPSW can be estimated as the design story drift. The strip model can predict the overall and local responses of the C-SPSW specimen very well. Further studies on the seismic design and behaviours of the C-SPSW can be conducted using strip models.

ABSTRACT

The coupled steel plate shear wall (C-SPSW) system is emerging as a promising configuration for resisting lateral loads in high seismic regions. A C-SPSW is composed of two wall piers, which are special steel plate shear walls (SPSW), joined at the floor levels by coupling beams. The C-SPSW configuration is expected to retain the benefits of the conventional SPSW configuration and provide additional structural efficiency while introducing greater flexibility related to building services and function. However, current provisions do not address analysis and design of C-SPSWs and further research is needed to develop these guidelines. As part of a multi-institution NEESR project on steel plate shear walls, this research explores design procedures for C-SPSW, which build on current provisions for conventional SPSWs. These design procedures are evaluated in the context of a six-story prototype structure. The response of the prototype structure under static loading is studied using numerical models to investigate behavior and performance and to evaluate design procedures. To further study C-SPSW behavior and to validate the design procedures, a large-scale subassembly is being developed for laboratory testing. The preliminary experimental setup and specimen design are described here.

INTRODUCTION

Steel plate shear walls (SPW) are a robust and economical lateral force resisting system in seismic regions. A SPW is comprised of a steel frame (with either flexible or rigid beam-to-column connections) with steel infill web plates as shown in Figure 1a. The frame columns and beams are known as vertical boundary elements (VBE) and horizontal boundary elements (HBE) respectively. Commonly the steel web plate is slender and unstiffened, providing negligible compressive resistance (Sabelli and Bruneau 2006). Lateral force is resisted by developing diagonal tension in the web plate post-buckling. The boundary elements anchor the diagonal tension field,

enabling the web plate to yield. The web plate yielding mechanisms dissipates a significant amount of energy and provides excellent ductility.

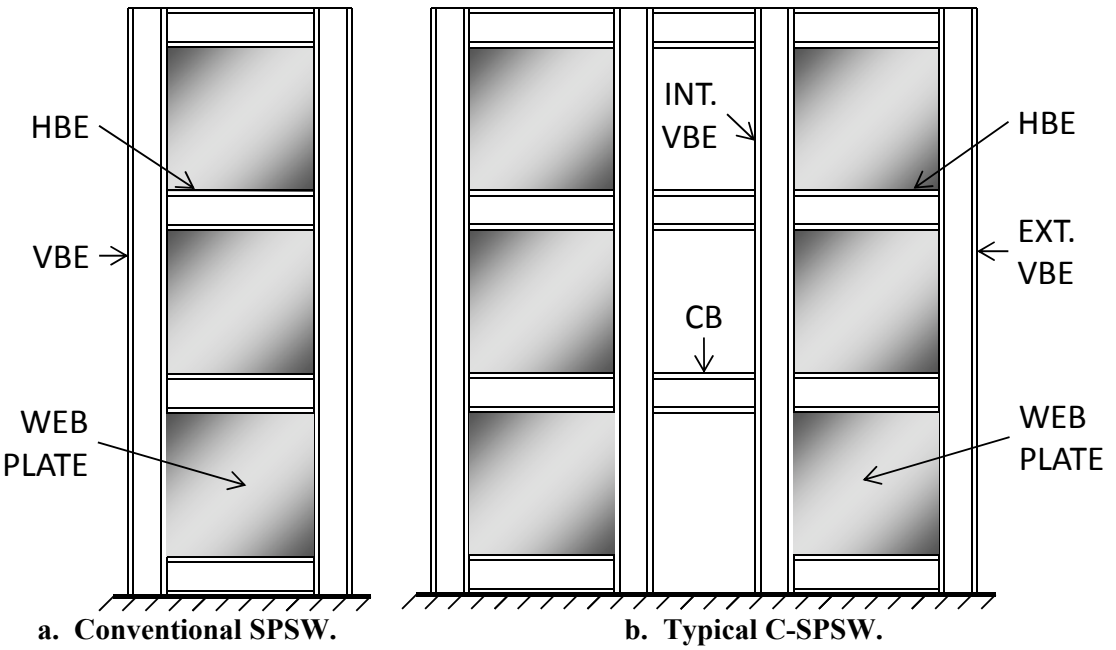

Figure 1. Steel plate shear walls.

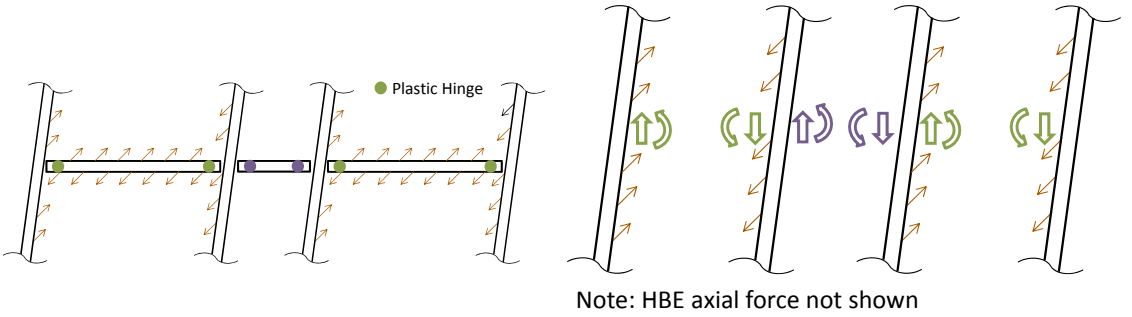
The 2005 AISC *Seismic Provisions for Structural Steel Buildings* (AISC 2005) and the 2005 ASCE 7-05 *Minimum Design Loads for Buildings and Other Structures* (ASCE 2005) introduced provisions for Special Steel Plate Shear Walls (SPSW). In a SPSW the boundary elements are connected by moment connections and the web plate is unstiffened and slender. The boundary elements are sized based on a capacity design methodology to remain elastic under full yielding of the web plates. The resultant of the web plate tension on the boundary elements is assumed to act at an angle α, derived based on elastic strain energy (Thorburn et al. 1983).

In a typical building layout, it is not uncommon for the bay width of the gravity columns to be over 10 m and the story height to be as small as 4 m. However, the *Seismic Provisions* limit a SPSW panel length-to-height ratio to a maximum of 2.5 (AISC 2005). Therefore the designer may choose to place two SPSWs within a single bay. The present research explores the behavior of Coupled Special Steel Plate Shear Walls (C-SPSW). A C-SPSW system is comprised of two SPSWs linked by coupling beams (CB) at the floor level as shown in Figure 1b. The C-SPSW system is expected to maintain many of the benefits of the conventional SPSW system while providing additional efficiency, energy dissipation and architectural flexibility.

Limited research has been conducted on the design, behavior and analysis of C-SPSW systems. As part of a multi-institution NEESR project on steel plate shear

walls, C-SPSW behavior is explored. A preliminary design methodology is introduced which is consistent with the existing SPSW provisions. Several six-story prototype buildings are designed to validate the methodology. The prototype buildings are analyzed under static push-over loading conditions. In order to further explore the behavior of C-SPSWs, two large-scale specimens will be tested in the NEES MUST-SIM facility at the University of Illinois at Urbana-Champaign. These specimens will consist of the lower three stories of a six-story prototype building. The loading and boundary conditions applied to the lower three-story subassembly will be based on the analysis of the six-story prototypes.



PRELIMINARY DESIGN METHODOLOGY

A preliminary design methodology was developed for C-SPSW systems based on the existing SPSW provisions, which proportion the SPSW at the plastic strength level, assuming that the web plates have completely yielded in tension. The boundary elements are then designed based on the capacity of the web plates. This capacity design of the boundary elements can lead to a surrounding moment frame with significant lateral resistance. Therefore an elastic analysis is performed to determine the proportion of the story shear that is resisted by the moment frame (Sabelli and Bruneau 2006). The web plates are then sized to resist the remaining portion of the story shear. In a C-SPSW system, a larger portion of the lateral load is resisted by frame action due to the coupling beams. Therefore, compared to conventional SPSWs, a smaller portion of the story shear is resisted by the web plates, reducing their required thickness.

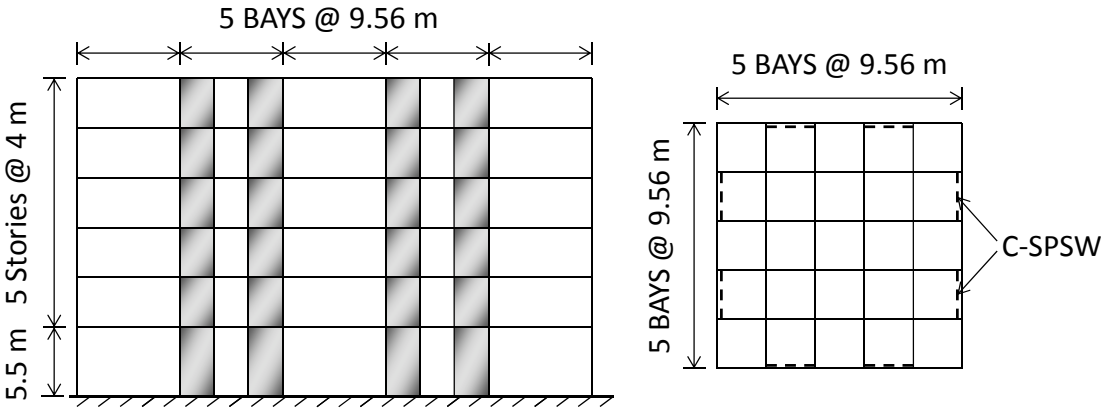
The HBEs in a SPSW are permitted to develop hinges at their ends; however they are to remain elastic within the span in order to anchor the web plates. At the design strength level, the HBEs are subjected to the imbalance caused by the tension in the web plates above and below. Since the web plates are thinner in the C-SPSW system than the conventional SPSW system, the capacity design requirements are reduced, allowing lighter HBEs to be selected.

In a SPSW, the vertical boundary elements are sized to resist the yielding of the web plates as well as hinging of the HBE ends as shown in Figure 2a. Since a conventional SPSW is symmetrical, both VBEs are identical. However, in a C-SPSW, the four VBEs can be grouped into two categories; internal and external VBEs (indicated on Figure 1b). In both VBEs of a conventional SPSW and the external VBEs of a C-SPSW, the axial demand consists of the vertical component of the web plate tension and the reactions from the HBEs, assuming plastic hinges have developed at their ends. However, for the internal VBEs in a C-SPSW, the shears developed in the CBs partially negate this axial force, as shown in Figure 2b (HBE

axial force not shown). For consistency with the capacity design and ultimate strength methodology employed for the conventional SPSW system, the CBs in the C-SPSW system are assumed to also develop plastic hinges at their ends.

a. Plastic loads. **b. Free-body diagram of VBEs.**

Figure 2. Plastic strength mechanism.



The shears and moments in the VBEs can be estimated by considering each story individually. The web plate tension component in the horizontal direction provides a distributed load between the ends of each segment. Where an HBE connects to a VBE, moment demands on the VBE above and below the connection are assumed to be equal to half of the plastic flexural strength of the HBE. For the internal VBEs of the C-SPSW system, moment from the CBs can be applied in a similar manner (Figure 2b). The moments from the coupling beams are additive to the HBE moments, increasing the shear and moment demands on the VBEs. However, the axial load reduction in the VBEs that occurs due to the CBs has a more significant effect and often internal VBEs are lighter weight than the external VBEs.

For preliminary purposes, the coupling beams were sized based on the size of the HBEs. Since the design procedure is based on plastic strength calculations, the CBs were selected based on their plastic moment strength compared to the HBEs. Further research is warranted to develop CB design procedures to achieve the desired performance.

PROTOTYPE DESIGNS

To validate the preliminary design methodology, three prototype six-story buildings were designed. The geometry of the prototype building was based on the nine-story SAC prototype buildings presented in FEMA-355C (FEMA 2000). Due to force limitations for future experimental testing, the top three stories of the nine-story SAC building were truncated. The basement was replaced with a fixed base at the ground level. The bay width was slightly increased from 9.15 m to 9.56 m to match discrete laboratory pier spacing. The elevation and floor plan of the prototype building are

shown in Figure 3. The gravity loads and story masses from the original prototype buildings were used unmodified ($1.0x10^6$ kg for the first story and $9.9x10^5$ kg for the remaining stories).

a. Elevation **b. Plan**

Figure 3. Prototype building layout.

The prototype structures were configured with four sets of C-SPSWs (8 walls total) along the perimeter in each direction (Figure 3). The shape of the design response spectrum provided in ASCE 7 was used to determine the design loads (ASCE 2005). However, since the SAC ground motions (Somerville et al. 1997) will be used for future nonlinear analysis, the spectral ordinates from FEMA-355C (FEMA 2000) were used. According to ASCE 7, the prototype building's approximate fundamental period is 0.55 sec. The design response spectrum is shown in Figure 4. The design loads were determined using the ASCE 7 Equivalent Lateral Force Procedure. The roughly inverted triangular load profile is shown in Figure 5.

The prototype buildings were designed with three different coupling beam sizes. The coupling beams were selected to have 100%, 200% and 400% of the plastic capacity (i.e., plastic section modulus) of the HBEs at each story (denoted CB/HBE). The VBEs were selected from the W24 family (610 mm nominal depth); the HBEs were selected from the W18 family (460 mm nominal depth). For the two lower CB/HBE ratios the CBs were selected from the W18 family; for the remaining design they were selected from the W24 family. With the selected geometry, the first story of the building violates the panel aspect ratio limit (AISC 2005); therefore a rectangular HSS restrainer was added (Tsai et al. 2010). The prototype with 200% HBE/CB ratio is summarized in Table 1. Column splices occur at mid-height of the story.

Table 1. Prototype Design based on 200% CB/HBE.

Story/Level	Height	t_w	VBE_{EXT}	VBE_{INT}	HBE	CB
	m	*mm*				
7	25.3				W18X40	W18X86
6	21.3	1.59	W24X94	W24X131	W18X40	W18X86
5	17.4	1.59	W24X94	W24X131	W18X40	W18X86
4	13.4	1.59	W24X162	W24X146	W18X50	W18X97
3	9.4	2.66	W24X162	W24X146	W18X50	W18X97
2	5.5	3.18	W24X370	W24X229	W18X50	W18X97
1	0.0	3.18	W24X370	W24X229	W18X211	

During design, a strip model (Berman and Bruneau 2003) of the system was constructed in SAP2000 (*SAP2000* 2009) to determine the proportion of the story shear resisted by the web plates and to calculate deflections based on the ASCE 7 approximate amplified elastic deflection method (ASCE 2005). The strength-based designs satisfied the deflection check.

NONLINEAR ANALYSIS

To validate design performance, the prototype buildings were modeled using OpenSees (*OpenSees* 2010). Strip models were used for the walls, with the web plates represented by 15 elastic-perfectly plastic truss elements oriented at an angle α, which is based on the tension field behavior. The boundary elements were nonlinear beam-column elements with fiber sections based on the OpenSees Steel02 constitutive model. The member depths were represented by rigid offsets. The coupling beam constitutive models were calibrated based on link tests at Portland State University (Dusicka and Lewis 2010). The lateral load was evenly distributed between the four beam-column joints on each floor. The gravity load was initially

applied followed by incrementally increasing lateral load. A leaning column that carried the tributary gravity load of the C-SPSW was also included to appropriately capture the destabilizing effects of gravity-only columns. A corotational coordinate transformation was used to capture geometric nonlinearities.

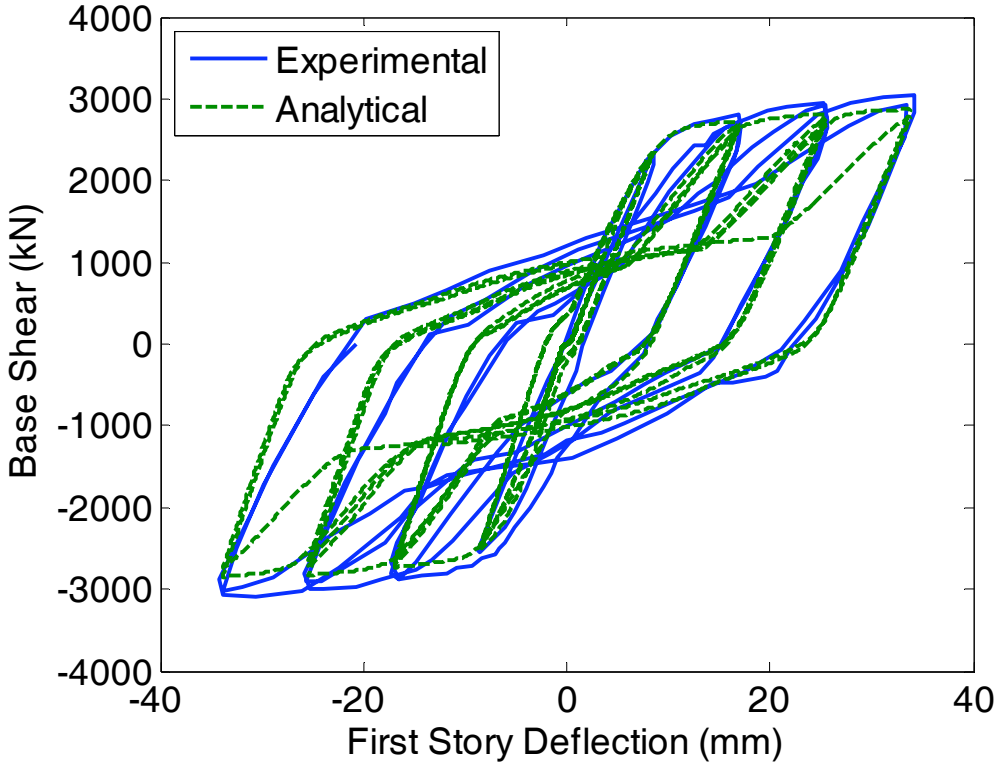

Figure 6. Comparison of Driver (1997) experimental and analytical simulations.

The SPSW test that was conducted at the University of Alberta (Driver et al. 1997) was used to validate the modeling assumptions. Base shear versus first story deflection for the experimental and analytical simulations is shown in Figure 6. The strip model closely traces the experimental response. Therefore the strip model was deemed sufficiently accurate for evaluating global system response.

The prototype buildings were subjected to pushover analyses based on the Equivalent Lateral Force load distribution (Figure 5). The base shear normalized by the design load versus the roof drift is presented in Figure 7. The global response is characterized by an initial linear region followed by yielding and strain hardening. All three designs exhibit a similar stiffness; however the higher CB/HBE designs had higher yield strength. This indicates that some of the benefits of the coupling are not accounted for in the design process.

The story drift at 2% roof drift for the prototypes is shown in Figure 8. For the 100% CB/HBE design, the maximum story drift occurs at the fifth floor level. However, the 200% and 400% CB/HBE design achieves their maximum story drift at the fourth and third floor levels respectively. The response of the 400% CB/HBE design is the most uniform.

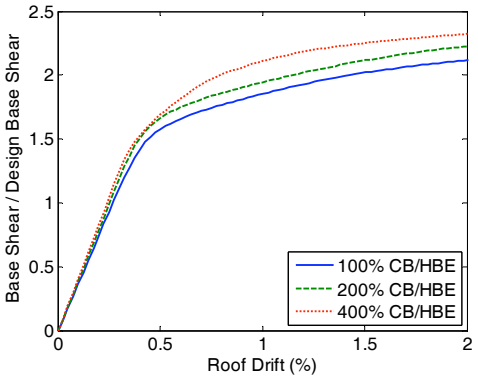

Figure 7. Bases shear versus roof drift of prototype designs.

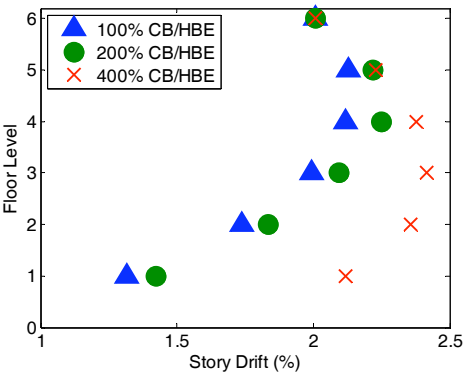

Figure 8. Story drift profiles.

To assess the level of coupled behavior, the degree of coupling (Canadian Standards Association 1994) was calculated as the ratio of the overturning moment resisted by the couple formed by the axial force in each wall pier to the total overturning moment (Figure 9),

$$DC = \frac{M_{OT}}{M_{TOTAL}} = \frac{M_{OT}}{M_{OT} + \Sigma M_{WALL}}.$$

The degree of coupling (DC) is shown in Figure 10 versus roof drift. The degree of coupling is initially constant since the system is initially elastic. In the 100% CB/HBE prototype the DC drops as the CBs begin to yield, increasing the relative stiffness of the individual wall piers to the coupling beams. However, as the CBs yield, the DC once again levels off. The other two prototypes experience an initial increase in the DC as the individual piers yield, lowering their relative stiffness. As the CBs then begin to yield, the DC once again becomes constant.

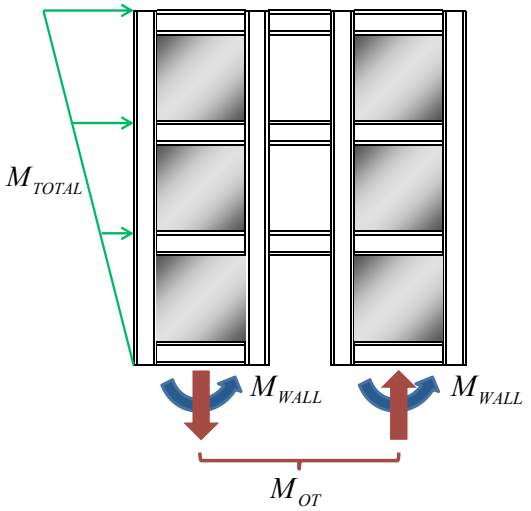

Figure 9. Illustration of Degree of Coupling

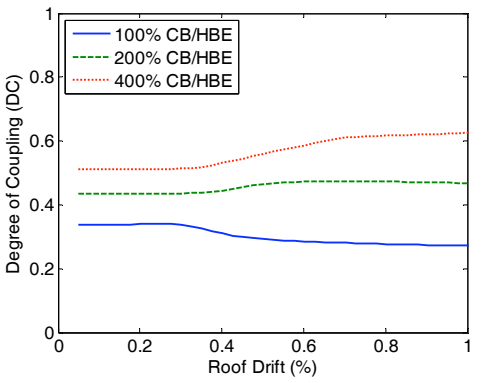

Figure 10. Degree of coupling versus roof drift of prototype designs.

EXPERIMENTAL SETUP AND TEST SPECIMENS

To further explore the behavior of C-SPSW system, two specimens will be tested in the NEES MUST-SIM facility at the University of Illinois at Urbana-Champaign. Each wall pier will be loaded by a Loading and Boundary Condition box (LBCB). Each LBCB is able to impose six degrees-of-freedom in load, displacement or mixed-mode control.

The maximum distance between the strong floor and the LBCB platen is approximately 6 m. Two LBCBs will be placed in the closest position; the distance between the centroids of the loading platens is approximately 2.7 m. The VBE base plates and bottom HBE will be bolted into a 50 mm thick plate that will be pretensioned to the strong floor. A similar connection at the top of the specimen will be used with an adapter plate between the specimen and the LBCB platen.

Each test specimen will be a three-story subassembly of a six-story prototype frame described above. Based on geometric constraints, the specimens will be constructed at approximately half-scale (0.43 scale). Since the two LBCBs may artificially constrain the top coupling beam, it will be excluded. The geometry of the test setup is shown in Figure 11.

The VBEs of the prototype are assumed to be braced at each story (provided by the lateral force resisting system in the perpendicular direction). The specimen will be tied back to the strong wall at each VBE-to-HBE connection to replicate this design assumption and to prevent global out-of-plane instability.

The control algorithms will be developed based on the behavior of the analytical strip model described above. The displacements and loads at the top of the third story (i.e., at the top of the subassembly) for each wall pier under a pushover loading protocol will be condensed down to six degrees-of-freedom. The relationship between these demands will be analyzed and simplified mathematical expressions developed to establish a control algorithm. These simplified controls will then be expanded to allow for an arbitrary loading plan. The control algorithms will be validated on an analytical model of the three story subassembly. The global and local behavior of the bottom three stories of the six-story model will be compared to the response of the subassembly model under the proposed control algorithms. The control algorithms will be further vetted in the MUST-SIM small-scale laboratory using rubber specimens.

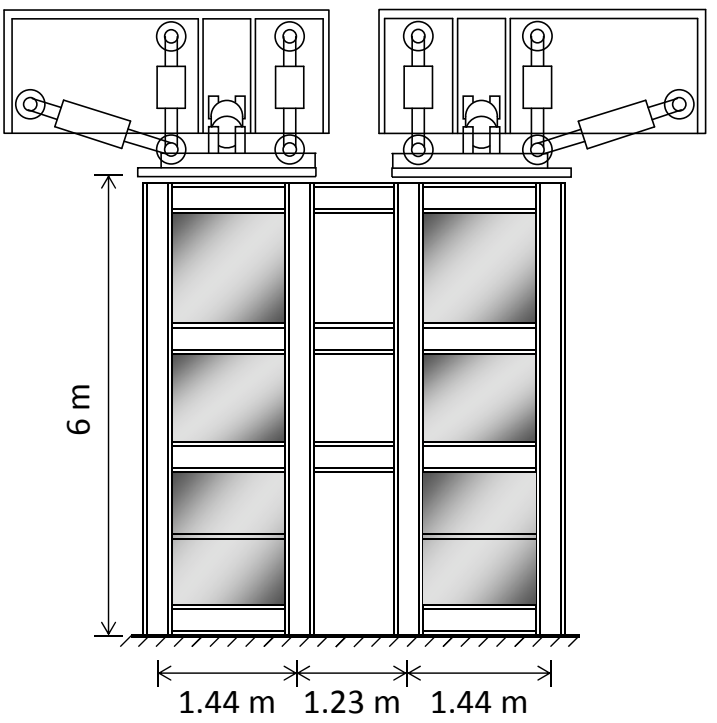

Figure 11. Elevation of experimental configuration.

The specimens will be instrumented with strain gages to capture boundary element and web plate local behavior. Linear displacement transducers will be used to record global displacements and to provide control feedback. To capture more localized response of the specimen, with focus on the infill plates, a Nikon Digital Motion Measurement (DMM) system, which uses light emitting diode targets on the

specimen, will be used. Additionally, a Nikon handheld laser scanner will be used to capture high resolution deformed geometry of the specimens at intervals throughout testing. In particular, this will allow accurate determination of the buckled shape of the web plates.

CONCLUSIONS

Coupling of special steel plate shear walls (SPSWs) is a logical choice in many configurations. The literature does not adequately explore the design and behavior of a coupled special steel plate shear wall system (C-SPSW). A preliminary design methodology was presented which remains consistent with the current design methodology for SPSWs. The design methodology is validated by designing three six-story prototype structures. These structures are studied analytically under push-over loading conditions. The three structures demonstrated similar initial stiffness with a slight correlation between degree of coupling and yield strength (i.e., strength increases as degree of coupling increases). Increasing the degree of coupling shifted the floor with the highest story drift downward.

To further study the behavior of the C-SPSW system, three-story experimental specimens will be used. These specimens represent the lower three stories of the six-story prototype buildings at approximately half-scale. Control algorithms will be developed to replicate the response of the lower three stories of a six-story building. The layout of the experimental tests and instrumentation are presented.

Analyzing the C-SPSW system with time-history analysis will provide additional understanding to the underlying mechanisms. These results will be used to confirm that the design assumptions are valid. Completion of the experimental testing will be used to validate the modeling assumptions and provide confidence in the analytical results. Ultimately, the analytical and experimental results will lead to design recommendations and allow for widespread application of the C-SPSW system.

Seismic Design and Analysis of Self-Centering Steel Plate Shear Walls

By Patricia M. Clayton[1], Daniel M. Dowden[2], Ronny Purba[3], Jeffrey W. Berman[4], Laura N. Lowes[5], Michel Bruneau[6]

ABSTRACT:

An innovative Self-Centering Steel Plate Shear Wall (SC-SPSW) system is proposed. It relies on post-tensioned (PT) beam-to-column connections that allow beams to rock about their flanges and provide system re-centering capabilities. A design procedure for the SC-SPSW system, developed based on a performance based design (PBD) approach, is presented, followed by analytical results for a prototype SC-SPSW building designed using this PBD approach, and subjected to a suite of ground motions simulating three different seismic hazard levels. The results of the nonlinear response history analyses show the proposed SC-SPSW design procedure to adequately achieve the desired enhanced performance objectives. Concepts of capacity design principle are integrated in the above approach, to prevent in-span plastic hinges of the beam considering reduced moment capacity due to the presence of axial and shear forces and to ensure that PT reinforcement remain elastic, among other things. To facilitate understanding of the behavior and design of an SC-SPSW system, the moment, shear and axial force distribution along the length of a boundary beam are established based on first principles. Closed form formulations describing the moment, shear and axial force beam diagrams are developed based on component capacity design approach and are used in the performance-based system design approach.

INTRODUCTION

Steel plate shear wall (SPSW) systems are frames having steel plates (a.k.a. webs) connected between their beams and columns (Sabelli and Bruneau, 2007). During severe earthquakes, the unstiffened plates of ductile SPSWs buckle in shear and yield by developing a diagonal tension field, together with plastic hinging of the beams at their ends. While SPSW systems are desirable for their significant stiffness, strength, and energy dissipation, strategies to eliminate residual drifts and to localize structural damage only in easily replaceable structural elements are desirable in SPSWs (as in other systems). In moment resisting frames, use of post-tension (PT) rocking moment connections was analytically and experimentally investigated to provide frame self-centering capability and to limit hysteretic damage to replaceable energy dissipating elements during earthquakes (e.g., Ricles *et al.* 2001, Christopoulos *et al.* 2002; Garlock *et al.* 2005; Rojas *et al.* 2005; to name a few). Building on this idea, this paper investigates the potential of achieving Self-Centering Steel Plate Shear Walls (SC-SPSW) by using similar post-tensioned rocking beam connections. In this proposed system, the SC-SPSW web plate is the replaceable energy dissipation element, and beam-plastic hinging is eliminated. The system combines the advantages of high lateral stiffness, a substantial energy dissipation capacity, and self-centering capability, at the expense of additional challenges to understanding the flow of forces within the structure compared to conventional SPSW (themselves, more complex than moment frames).

The objective of this paper is to provide insights on SC-SPSW's beam and system fundamental behavior, through free-body-diagrams of individual beams and non-linear response history dynamic analyses of multistory frames. This is done by developing equations for the moment, shear and axial force diagrams along the HBE from a capacity design approach based on yielding of the SPSW web plate, showing the respective contribution of each factor to the total demand. These closed-form solutions are then integrated into a design procedure proposed to aid in the selection of PT reinforcement area and HBE sizing to prevent in-span plastic hinging of the beam, to keep PT reinforcement elastic at a specified target drift, and to select an adequate initial PT force. Lastly, a performance-based design procedure for the SC-SPSW system is proposed that incorporates this fundamental behavior knowledge and component capacity design method with response-based performance objectives. The seismic response of a prototype SC-SPSW designed using the proposed design procedure was evaluated using non-linear response history dynamic analyses.

BASIC PRINCIPLES OF SELF-CENTERING SPSW SYSTEMS

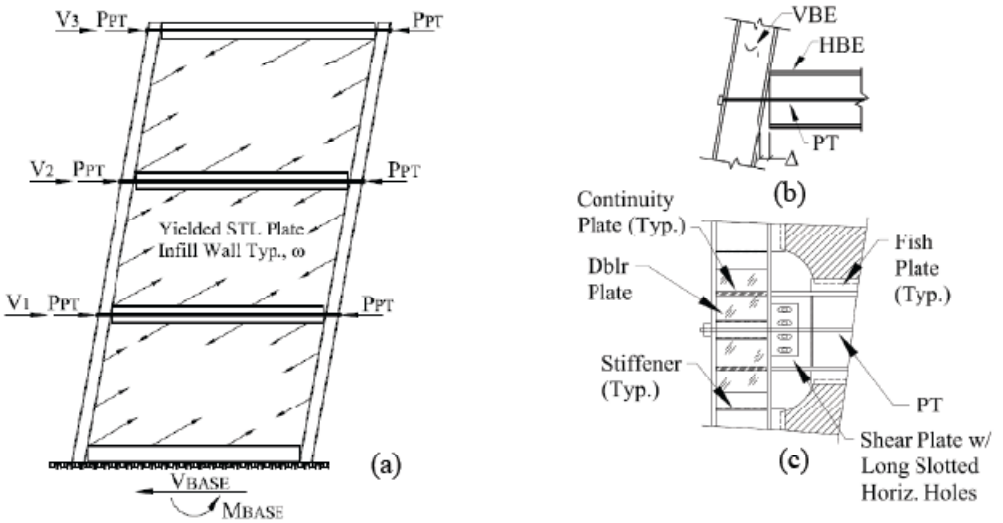

Fig. 1. SC-SPSW: (a) Yield Mechanism; (b) rocking joint; (c) rocking detail

Fig. 1a shows the free-body-diagram (FBD) of a SC-SPSW frame, where HBE is the horizontal boundary element, VBE is the vertical boundary element, P_{PT} is the post-tension (PT) axial compression force applied to the HBE, V_i is the externally applied lateral forces at story i due to applied seismic forces, and ω is the diagonal tension yield force per unit length developed by the steel web plates (Sabelli and Bruneau 2007, Berman and Bruneau 2008).

A SC-SPSW differs from a conventional SPSW in that HBE-to-VBE rigid moment connections in a conventional SPSW are replaced by PT rocking moment connections. This allows a joint gap opening to form between the VBE and HBE interface about a rocking point (i.e. connection decompression), leading to a PT elongation, this being the self-centering mechanism (shown schematically in Fig. 1b). One possible rocking detail configuration is shown in Fig. 1c. The PT boundary frame is designed to essentially remain elastic and hysteretic energy dissipation is intended to be provided by the web plate only. The total hysteretic response of a SC-SPSW is provided by the combined elastic response of the PT boundary frame and the inelastic energy dissipation of the web plate.

FREE-BODY-FORCE DIAGARAM

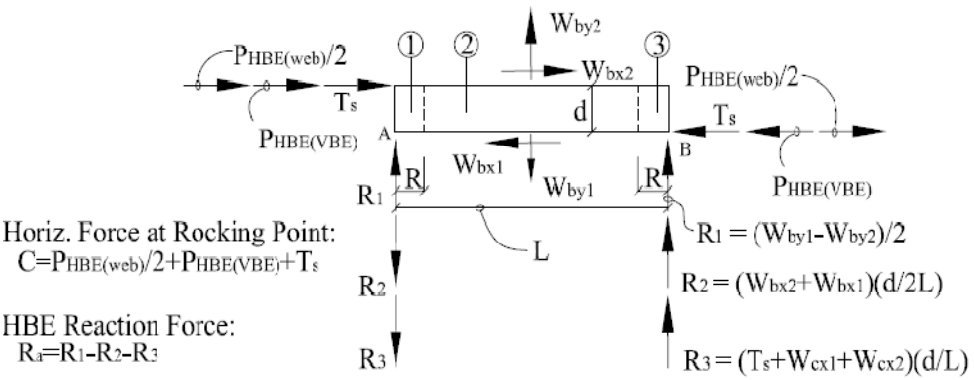

Fig. 2. Force Resultant FBD of HBE

Fig. 2 shows the FBD of an HBE and VBE element located at an intermediate floor level of a SC-SPSW frame once the web plate has fully yielded and the connection has decompressed for a rightward drift, where W_{bx1}, W_{bx2} and W_{by1}, W_{by2} are respectively the horizontal and vertical force resultants along the length of the HBE, W_{cx1},W_{cx2} and W_{cy1}, W_{cy2} are respectively the horizontal and vertical force resultants along the height of the VBE, subscripts *1* and *2* respectively denote the level below and above the HBE, L is the HBE span length, d is the HBE depth and R is the length of the web plate corner cut-out at each end of the HBE provided to accommodate the HBE-to-VBE joint rocking connection detailing and to reduce the potential for corner tear out of the web plate due to high localized web plate strain effects during opening of the rocking joint connection.

The horizontal forces at the rocking point $P_{HBE(web)}$, $P_{HBE(VBE)}$ and T_s shown on Fig. 2 are the reactions due to the story shear contribution due to the web plate, horizontal component of web plate yield forces acting along the VBE and PT tension force calculated as follows:

$$P_{HBE(web)} = W_{bx1} - W_{bx2} = \frac{1}{2}(t_1 - t_2)F_{yp}(L - 2R)\sin(2\alpha) \tag{1}$$

$$P_{HBE(VBE)} = W_{cx1} + W_{cx2} = (\omega_{cx1} + \omega_{cx2})\left(\frac{h}{2} - \frac{d}{2} - R\right) \tag{2}$$

$$T_s = T_o + \frac{A_{PT}E_{PT}}{L_{PT}}\left(\Delta_{drift} - \Delta_{loss}\right) \tag{3}$$

where t_1 and t_2 are the web plate thicknesses below and above the HBE respectively, α is the angle of inclination of the diagonal tension field from the vertical axis, F_{yp} is the web plate yield stress, h is the story height, T_o is the initial PT force applied at the time of construction of the SPSW system, A_{PT}, E_{PT} and L_{PT} are the sectional area, modulus of elasticity and length of PT provided. Additionally, Δ_{drift} is the total drift induced elongation of the PT when the SC-SPSW joint connections open due to rocking action at the HBE-to-VBE joints during building drift and Δ_{loss} is the PT relaxation due to HBE axial shortening calculated as:

$$\Delta_{drift} = 2\left(\phi_{drift}\frac{d}{2}\right) = \phi_{drift}d \tag{4}$$

$$\Delta_{loss} = \frac{P_{HBE(VBE)}}{k_b + k_{PT}} + \left(\frac{k_{PT}}{k_b + k_{PT}}\right)\Delta_{drift} \tag{5}$$

where ϕ_{drift} is the relative joint rotation, k_b and k_{PT} are the axial stiffness (i.e. AE/L) of the HBE and PT elements respectively. Note that for use with multistory frames, the additional lateral story shear force at each HBE level due to multi-story PT frame stiffness (i.e. VBE's fighting beam growth) would have to be considered for preciseness in calculating the HBE demands (Kim and Christopoulos 2009).

Development of HBE Moments

The moment distribution to be used in the design of an HBE of a SC-SPSW can be determined from the FBD of Fig. 2 by taking moment equilibrium at three locations identified where x is any distance from point A leading to:

$$M_1 = \frac{Cd}{2} + R_a x \tag{6}$$

$$M_2 = R_a x + C\frac{d}{2} + \left(W_{by2} - W_{by1}\right)\left(\frac{x-R}{2}\right) + \left(W_{bx2} + W_{bx2}\right)\frac{d}{2} \tag{7}$$

$$M_3 = R_a x + C\frac{d}{2} + \left(W_{by2} - W_{by1}\right)\left(x - \frac{L}{2}\right) + \left(W_{bx2} + W_{bx1}\right)\frac{d}{2} \tag{8}$$

It is instructive to plot the moment distribution along the length of an HBE for a SC-SPSW frame. For illustrative purposes only, to avoid abstract complexities in keeping the problem parametric, all results here are presented in terms of an example. This example considers a W18x HBE with a clear span of 5.74 m (226 inches) and a story height of 3.89 m (153 inches) of a single bay frame. The SPSW web plates consists of 14 Gauge (1.83 mm) and 18 Gauge (1.77 mm) thicknesses below and above the HBE respectively with a corner cut-out radius of 254 mm (10 inches). Area of PT steel was arbitrarily chosen to produce a maximum moment of 60% of the full HBE plastic moment capacity at the end span of the HBE for an arbitrary 2% lateral drift, with a T_o of 30% of the assumed yield strength of the PT. A yield stress of 207 MPa (30 ksi) was assumed for the web plates, an ultimate yield stress of 1034 MPa (150 ksi) was assumed for the PT reinforcement and ASTM A572 (F_y = 345 MPa) steel was used for the boundary frame. After providing substitution of all applicable defined parameters into Eqns. (6) to (8), the resulting moment equations will each yield five distinct components which are separated and plotted on Fig. 3a with the composite moment diagram plotted in Fig. 3b.

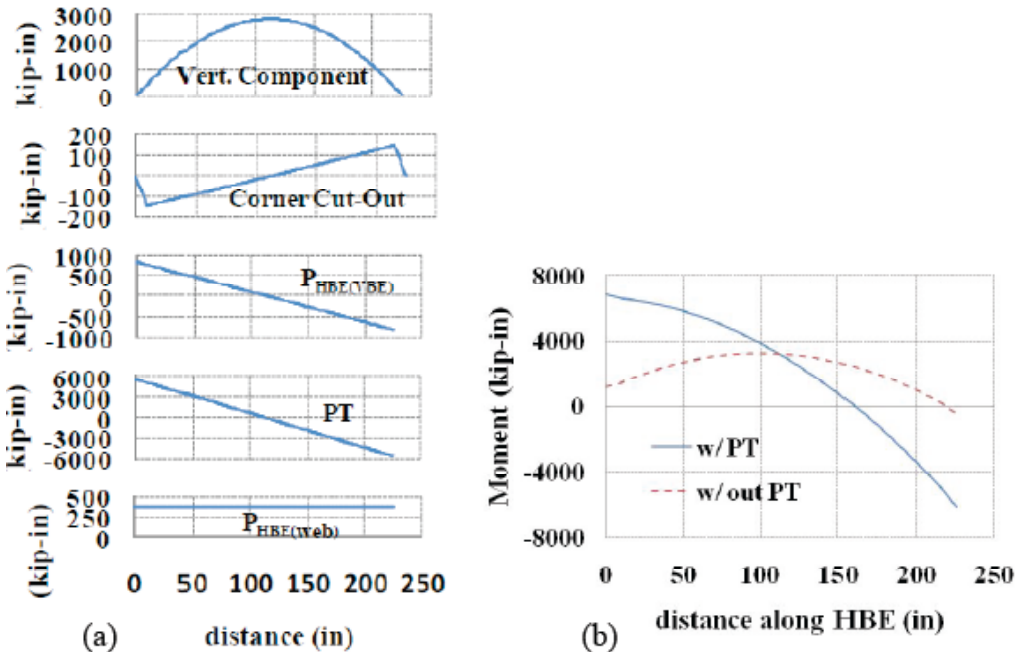

Fig. 3. (a) HBE Moment Components (b) Composite Moment Diagram

It is observed from the moment diagrams that the horizontal reactions at the rocking point will always generate double curvature moments at the ends of the HBE. Additionally, the moment diagrams are of identical shape, only the moment magnitudes are different. The contribution to the HBE moment from the VBE horizontal reaction at the rocking point, will always be additive to the HBE moment produced by the PT component. Without the PT, it can be seen that the maximum moment occurs close to the HBE mid-span, which is not desirable for reasons described later. Therefore, in addition to acting as a self-centering mechanism, the PT forces can be designed to shift the point of maximum moment towards the ends of the HBE (although at the cost of increased HBE moment demand).

Development of HBE Shears and Axial Forces

The shear distribution to be used in the design of an HBE incorporating self-centering components can be determined using the same free-body-diagrams developed earlier for the HBE moments. As a result, for the same 3 zones defined previously in terms of ω defined earlier follows:

$$V_1 = R_a = \frac{(\omega_{by1} - \omega_{by2})(L-2R)}{2} - \frac{(\omega_{bx2} + \omega_{bx1})(L-2R)}{2L}d - (\omega_{cx1} + \omega_{cx2})\left(\frac{h}{2} + \frac{d}{2} - R\right)\left(\frac{d}{L}\right) - T_s\left(\frac{d}{L}\right) \quad (9)$$

$$V_2 = R_a - (\omega_{by1} - \omega_{by2})(x-R) \quad (10)$$

$$V_3 = R_a - (\omega_{by1} - \omega_{by2})(L-2R) \quad (11)$$

Similarly, for axial forces over each of the three zones:

$$P_1 = C = \frac{(\omega_{bx1} - \omega_{bx2})(L-2R)}{2} + (\omega_{cx1} + \omega_{cx1})\left(\frac{h}{2} - \frac{d}{2} - R\right) + T_s \quad (12)$$

$$P_2 = C - (\omega_{bx1} - \omega_{bx2})(x-R) \quad (13)$$

$$P_3 = C - (\omega_{bx1} - \omega_{bx2})(L-2R) \quad (14)$$

DESIGN CONSIDERATION OF SELF-CENTERING CONNECTION

The above understanding of behavior and closed-form solutions also serve to aid in the selection of PT reinforcement area and HBE sizing to force the maximum HBE moment to be at its ends, to prevent in-span plastic hinging and account for moment-axial-shear interaction in the HBE, to keep PT reinforcement elastic, to select an adequate initial PT force, and to account for PT losses due to HBE axial shortening.

Knowing that PT force influences HBE moment distribution (Fig. 3), it is proposed here to design for the smallest PT force needed to shift the point of maximum moment to occur at the HBE ends. One should recognize that the moment distribution including a PT force contribution will vary depending on the magnitude of drift. For SC-SPSW systems to have a comparable performance with conventional SPSWs (e.g.,Park *et al.* 2007; Qu and Bruneau, 2009), it is proposed here that the PT reinforcement be designed to remain elastic at least up to 4% drift to maintain its self-centering capability. In addition to the above requirement, it is proposed that SC-SPSW be designed such that the total PT force that shifts the point of maximum moment to the HBE ends is reached at the target drift. This is proposed to avoid the formation of plastic hinges along the HBE span which can detrimentally impact the behavior of SPSW (Purba and Bruneau 2010).

Building on the system behavior and performance objectives presented above, the following design procedure for SC-SPSW HBE-to-VBE connection is proposed.

1. Select initial boundary elements sizes and web plate thickness (of many possible approaches, this could be done by designing a conventional SPSW, although other approaches are acceptable too).
2. Design the self-centering connection with the least PT forces that would result in the maximum moment occurring at the HBE ends at the target drift.
3. Select post-tension to ensure that the PT reinforcement remain elastic at least up to 4% drift.
4. Select the initial PT force applied to the self-centering connection.
5. Select the least cross sectional areas of PT reinforcement that satisfy the previous conditions.
6. Consider the effect of PT on reducing the HBE plastic moment as well as the effect of PT losses due to axial shortening to assess the adequacy of the HBE.
7. Iterate as needed to reduce the HBE size, ensuring that the HBE moment capacity reduced due to axial and shear forces remains adequate.

PERFORMANCE-BASED DESIGN OF SYSTEM

The fundamental system behavior and HBE-to-VBE design procedure previously described can be incorporated into a design procedure for the overall SC-SPSW system. For design of the system, a performance-based design approach has been developed to achieve the following structural performance objectives:

1. *No connection decompression under wind or gravity loading.* The decompression moment, M_d, of the PT connection ($M_d=T_o\ d/2$, where d and T_o were defined previously) should be designed to be greater than the HBE end-moments induced under wind or gravity loading.
2. *System recenters and no repair required under frequent earthquake demands* (i.e. the demand representing the 50% probability of exceedence in 50 year earthquake [50/50]). Recentering is assessed using a residual drift limit of 0.2%, corresponding to out-of-plumb limits in construction. The no repair limit state is assessed using a peak story drift limit of 0.5%, the median drift at which web plate repair is required in conventional SPSW experimental studies (Baldvins et al. 2010).

3. *System recenters and only web plate repair required under design earthquake demands* (i.e. approximated here as the demand representing the 10% probability of exceedence in 50 year earthquake [10/50]). The web plate may have significant yielding; however, the boundary frame and PT elements should remain elastic and the system should recenter. The damaged web plate can be replaced relatively quickly and simply, resulting in a more rapid return to occupancy following an earthquake (Qu et al. 2008). The story drift at this hazard level should be less than the 2% code-based drift limit for design level earthquakes.
4. *Collapse prevention for the maximum credible earthquake* (i.e. the demand representing the 2% probability of exceedence in 50 year earthquake [2/50]). Residual drifts and minor frame yielding may occur; however, soft story mechanisms and significant PT and frame yielding should be avoided. A target drift limit of this performance objective was assumed to be 4%, based on engineering judgment and the drift at which significant strength loss was observed in conventional SPSW experimental studies (Baldvins et al. 2010).

The following performance-based design procedure, as shown in Fig**.** 4, was developed to meet the previously described performance objectives.

1. Make initial assumptions about SC-SPSW geometry and number of walls in the building.
2. Determine the seismic loads and lateral load distribution. Here a modified load distribution as developed by Chao et al. (2007) was used to account for higher-mode effects, as SC-SPSWs and other self-centering PT systems (Garlock 2003) designed using typical code-based load distributions have exhibited larger drift demands and damage in the upper stories due to these higher-mode effects.
3. Design the web plates to remain elastic under 50% in 50 year loads.
4. Design the PT connection to have sufficient stiffness to ensure recentering under the influence of P-Delta effects.
5. Capacity design the PT and HBE to remain elastic and prevent in-span hinging at 4% drift according to the procedure previously described.
6. Capacity design the VBE to remain elastic up to 5% drift (Berman and Bruneau 2008).
7. Check that design meets code-based drift limits and that the required amount of PT can fit reasonably within the depth of the HBE.
8. Iterate as needed until a final design is converged upon.

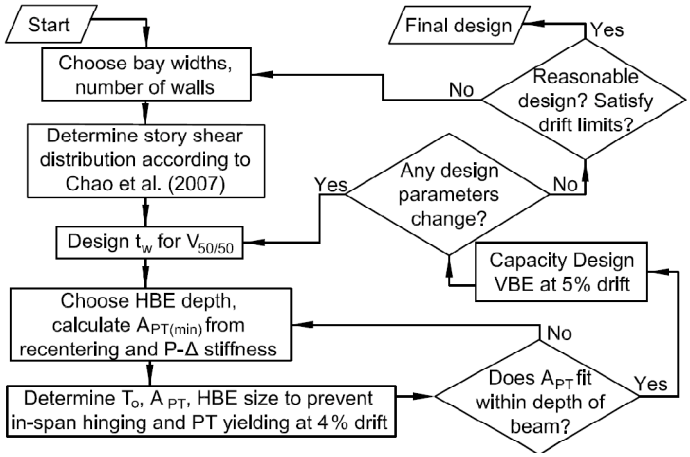

Fig. 4: SC-SPSW performance-based design procedure

A prototype 3-story SC-SPSW was designed according the proposed system design procedure. The 3-story building has story heights of 3.96m (13ft) with plan dimensions, loading, and seismic masses equivalent to those of the 3-story SAC building. The building was assumed to be on soil of Site Class D with spectral response parameters compatible with the ground motions developed for the Los Angeles, California location in the SAC project (Gupta and Krawinkler 1999). The prototype building was designed to have six 4.57m (15ft) wide bays of SC-SPSW in each direction of the building. The web plates were designed using available thicknesses of ASTM A36 steel, and the PT was designed using ½" diameter, Grade 270, seven-wire strand with a cross sectional area of 98.7mm^2 (0.153in^2) and a yield stress of 1689MPa (245ksi). Table 1shows the resulting prototype SC-SPSW design.

Table 1: 3-story prototype SC-SPSW design parameters

Story	Web Plate Thickness (mm)	HBE size	VBE size	# of PT strands	Initial PT force, T_o (kN)
1	7.94	W24x229	W14x605	16	231
2	6.35	W30x211	W14x605	12	503
3	4.18	W14x302	W14x605	32	467

NONLINEAR RESPONSE HISTORY ANALYSES

To assess the adequacy of the proposed performance-based design procedure, a numerical model of the prototype SC-SPSW was subjected to a suite of ground motions representing the seismic hazard levels considered in the design, and the response of the structure was evaluated. The numerical model was developed in OpenSees (Mazzoni et al. 2006). The steel web plates were modeled using the tension strip method consisting of a series of tension-only truss elements oriented in the direction of the diagonal tension-field. The plate material had a yield stress of R_yF_y, where F_y was 248MPa (36ksi) and R_y was 1.3 to account for the ratio of expected to nominal yield strength of A36 plate steel (AISC 2005a).

A PT connection model was developed to allow the HBE to rock about its flanges and cause PT elongation and to allow for shear load transfer without inhibiting the rocking action. The PT connection model (Berman et al. 2010) consisted of (1) stiff horizontal compression-only springs located at the HBE flanges to allow for decompression of the flanges at gap opening, (2) compression-only diagonal springs to transfer shear forces while allowing for gap opening and rotation, and (3) rigid link elements connecting the end of the HBE to the connection springs to ensure that the end of the HBE in contact with the VBE remains planar and is orthogonal to the HBE's longitudinal axis at that point. The tension only truss elements used for the PT elements were connected to the VBEs and were placed within the depth of the HBE.

The boundary frame elements were modeled using nonlinear beam-column elements with fiber cross-sections. The fibers were modeled using the Giuffre-Menegotto-Pinto material model, with an effective yield stress of 345MPa (50ksi), a rounded yield surface to help with numerical convergence, and 2% strain hardening. P-Delta columns were placed symmetrically on each side of the wall to simulate the gravity loads that would contribute to P-Delta effects on the wall. Seismic masses were lumped at the HBE-to-VBE connections, and damping was modeled using Rayleigh damping of 2% in the first and third modes. The earthquake ground motion records used in the nonlinear dynamic analyses were those developed for the SAC project for the Los Angeles site, with 20 ground motions for each seismic hazard level considered in the design procedure (50/50, 10/50, and 2/50).

The response parameters that were evaluated during the dynamic analyses were the peak story drift, $\theta_{s,max}$; the peak residual story drift, $\theta_{resid,max}$; and the HBE and VBE damage value, D_{HBE} and D_{VBE}, respectively, as evaluated by the interaction equation per Eqn. H1-1 (AISC 2005b), where a damage value of one indicates combined axial-flexural hinging. The median and 84th percentile responses for these parameters are shown for each seismic hazard level in **Table** 2.

Table 2: Response parameter values for prototype SC-SPSW

Response Parameter	50% in 50 yr		10% in 50 yr		2% in 50 yr	
	Median	84th percentile	Median	84th percentile	Median	84th percentile
$\theta_{s,max}$(%)	0.40	0.61	0.54	0.84	1.16	1.86
$\theta_{resid,max}$(%)	0.002	0.002	0.002	0.002	0.002	0.002
D_{HBE}	0.52	0.63	0.59	0.71	0.74	0.84
D_{VBE}	0.37	0.53	0.43	0.56	0.66	0.74

The results in **Table** 2 show that the SC-SPSW was able to recenter ($\theta_{resid,max} < 0.02\%$) at the 50% and 10% in 50 year hazard levels (Performance Obj. 2 and 3), and had no frame yielding (D_{HBE} and $D_{VBE} < 1.0$) at the 2% in 50 year hazard level (Performance Obj. 4). The prototype SC-SPSW had peak story drifts less than the 2% code-based drift limits at the 10% in 50 year hazard level (Performance Obj. 3), and the model had story drifts less than the 0.5% no web plate repair drift limit under the 50% in 50 year earthquake at the median level (Performance Obj. 2). Also, as the peak story drifts are well below the 4% target drift assumed in the PT design at the 2% in 50 year hazard level, there were no instances of PT yielding in any of the models at this hazard level (Performance Obj. 4). From all of these results, it is shown that the proposed performance-based system design procedure is capable of producing SC-SPSWs that can meet the intended performance objectives.

CONCLUSIONS

Fundamental behavior of a SC-SPSW was presented, in terms of closed form equations for moment, shear, and axial forces along the HBE. These formulations and development of the free-body-diagrams presented, not only provide insight on the behavior of a SC-SPSW system, but also provide a means to inform design. On the basis of that knowledge, a proposed HBE and PT connection design procedure based on a capacity design approach was formulated. Additionally, a SC-SPSW system design procedure was presented based on proposed structural performance targets and capacity design of the HBE and PT connection components using the previously described methods. The results of a series of nonlinear response history analyses on a prototype SC-SPSW designed according to the proposed performance-based method indicate that the system is capable of achieving the proposed performance objectives at three different seismic hazard levels. The findings presented indicate that SC-SPSW systems could be a viable alternative to traditional lateral force resisting systems. Future research is needed to further validate this system, including experimental work to investigate its behavior and self-centering characteristics.

Abstract

Steel plate shear walls are generally considered to be economical only in high seismic regions, primarily because the high levels of ductility and resilience under cyclic loading have been demonstrated almost exclusively by tests on walls that contain expensive detailing at the beam-to-column connections. However, the lower demands on seismic load resisting systems in low and moderate seismic regions may permit the use of far more economical fabrication options. The use of modular construction methods is one option for reducing the costs associated with fabrication and erection. Modular components with repetitive fabrication processes can be produced in the shop and assembled in the field by bolts, eliminating the need for field welding entirely. This paper describes several potential modular options and discusses their advantages and disadvantages in terms of economics and constructability. The performance of one of these concepts (with different means of meeting capacity design requirements) is evaluated using detailed finite element models.

Introduction

Although steel plate shear walls (SPSW) are gradually gaining prominence within the structural engineering community as a viable seismic load resisting system for buildings, they are generally considered to be economical only in high seismic regions. This is primarily because the high levels of ductility and resilience under cyclic loading that make them so desirable in these regions have been demonstrated almost exclusively by tests on walls that contain expensive detailing at the beam-to-column connections. However, the lower demands on seismic load resisting systems in low and moderate seismic regions may permit the use of more economical fabrication options that have yet to be validated in terms of reliability and performance.

One option for reducing costs in the fabrication and erection of steel plate shear walls is the use of modular construction. As buildings normally have a constant story height and bay width over their height, modular components with repetitive fabrication processes can be produced in the shop and assembled in the field economically. When the field erection is carried out 100% by bolting the component modules together, cost-effective and very rapid assembly is possible.

However, the resulting assembled modular shear wall has several distinct differences from most of the walls that have been tested in the laboratory, and the performance of these walls requires verification. As such, a research investigation has been initiated at the University of Alberta to assess the potential of modular steel plate shear walls for general use in low and moderate seismic regions. This paper describes several potential modular options and discusses their advantages and disadvantages. Some results of detailed finite element analyses of these walls are presented that indicate that good performance can be expected in low and moderate seismic regions, despite significantly reduced fabrication and erection costs. A laboratory test to confirm the performance will be carried out in the next phase of the research.

Modular construction of SPSWs

Most steel plate shear wall research has been conducted with the primary aim of maximizing ductility and robustness under severe cyclic loading, without any explicit consideration of fabrication and erection costs. This has resulted in onerous capacity design rules in current codes and standards, such as CSA Standard S16-09 (CSA 2009) and AISC 341-05 (AISC 2005), for achieving a ductility-related force modification factor, $R_d = 5.0$ (Type D Plate Wall in S16) and $R = 8$ (Special Plate Shear Wall in AISC 341). The current provisions in S16-09 for achieving $R_d = 2.0$ (Type LD Plate Wall) state that the requirements for $R_d = 5.0$ must be met, with certain relaxations. These provisions were not developed independently for the $R_d = 2.0$ case. It is anticipated that simple and relatively inexpensive detailing can be used in steel plate shear walls and still achieve $R_d = 2.0$ due to the nature of the system itself.

In this paper, three concepts for steel plate shear walls are considered that are designed specifically to minimize in-place cost. The main characteristics that distinguish these concepts from conventional steel plate shear walls are that the beam-to-column connections are simple shear connections and that they constitute modular systems that require no field welding. Double web angle beam-to-column connections are assumed, although other types of simple and semi-rigid connections, including Tee connections, end-plate/header-plate connections, seated beam connections, etc., constitute reasonable alternatives that could be selected based on fabricator preference and cost.

All concepts considered allow construction of shear walls with relatively wide bays without the need for unconventional shipping arrangements. The infill plates in all concepts are spliced with single-sided lap plates. The arrangement of the infill plate splices can be changed based on ease of erection. All bolts are intended to be pre-tensioned to avoid slip at design loads.

Concept 1

Figure 1 shows modular steel plate shear wall Concept 1. This concept is intended to minimize the piece sizes that need to be handled in the field and may have applications in small projects or rehabilitation work. It is repetitive in nature and attempts to maximize the number of similar pieces. The figure shows double web angle connections for which the angles are connected to the columns in the shop (by bolting or welding), and then in the field the beams are connected to the angles by bolts. The fish plates are welded to the column and beam centerlines in the shop, and

then after assembling the frame in the field, the infill plates are bolted to the fish plates. Although the infill plates are connected to the surrounding frame via fish plates, in order to reduce the number of bolts other means of connection could be acceptable.

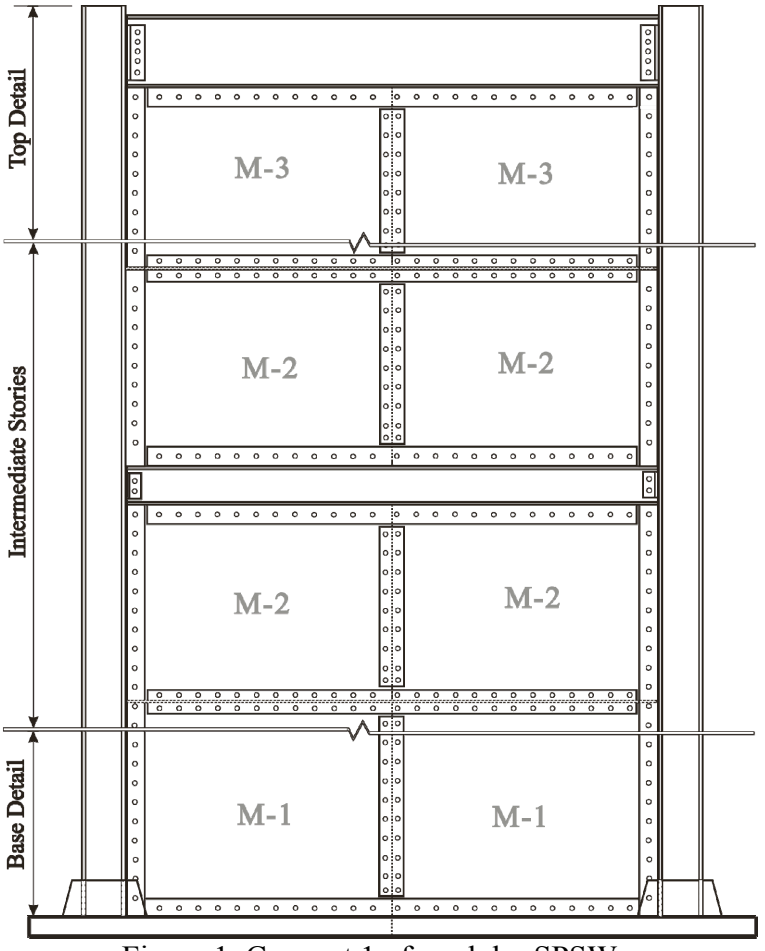

Figure 1. Concept 1 of modular SPSWs.

This concept consists of modular infill plates with only three module types: base module (modules M-1), top module (modules M-3), and intermediate story modules (modules M-2). As long as the heights of the intermediate stories and the associated beam depths are consistent, all modules M-2 will be identical. The field assembly and erection of numerous infill plate pieces may increase construction time in comparison with other concepts.

Since plastic hinges occur at the column bases, stiffener plates at both sides of the columns are provided to increase the ductility of this region. However, to keep the shear at the hinge location as low as possible, the height of the plates should be limited.

If the gravity-load induced axial compression in the infill is significant, it could be alleviated by a planned construction sequence. For instance, delay in the installation of some infill plate splices allows the columns of the system to shorten due to gravity loads prior to fixing of the splice plates (Seilie and Hooper 2005).

Concept 2

While Concept 1 is intended to minimize the piece sizes that need to be handled in the field, Concept 2 is intended to minimize the number of pieces by maximizing shop assembly. Figure 2(a) shows an elevation view of this system and the locations of each module have been demarcated by dashed lines. Figure 2(b) shows a detail of two complete modules after assembly. Again, this concept is repetitive in nature and attempts to maximize the number of similar pieces. In this concept, the larger modules, as compared to Concept 1, necessitate shear connections of the beams to the columns in the shop, and it has been assumed that fish plates are unnecessary under shop conditions. Due to the nature of this concept, moment resisting beam-to-column connections can be exercised as well.

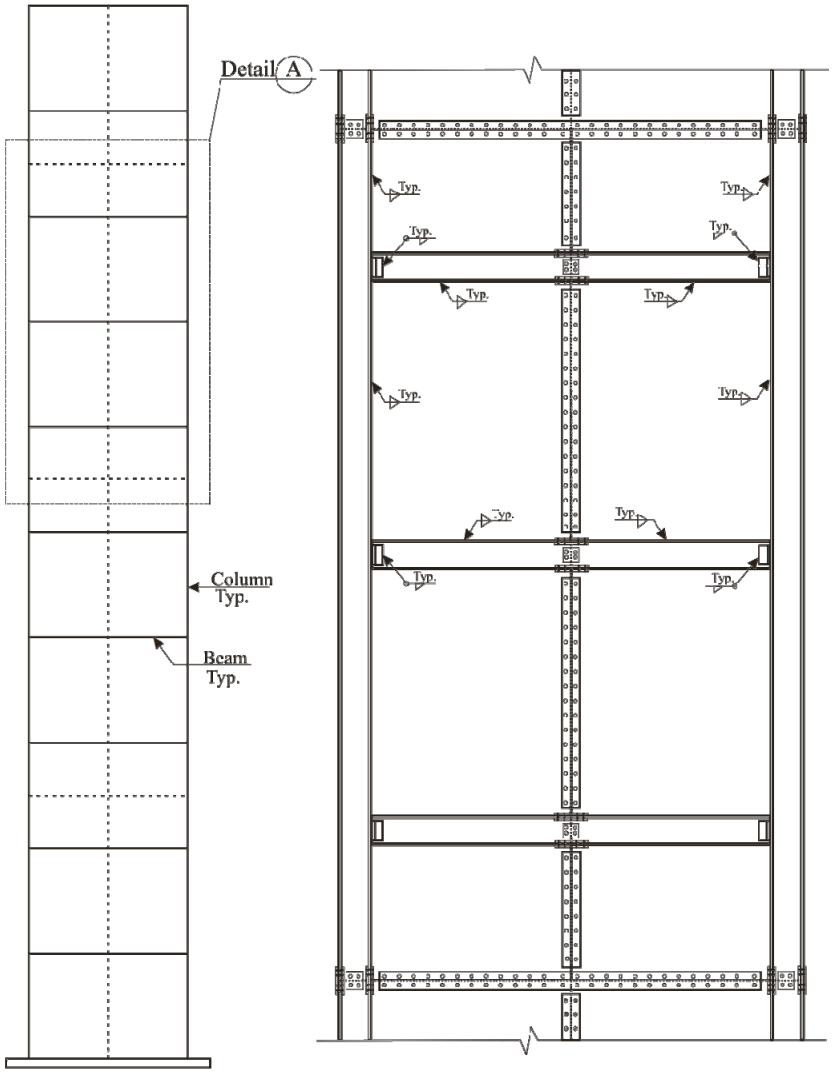

Figure 2. Concept 2 of modular SPSWs:
(a) Overview of SPSW concept; (b) Assembled modules of the system.

The modules of Concept 2 are shown in Figure 2 as being three stories in height (assumed to be the maximum practical size for shipping and lifting) and one-half bay wide, permitting this concept to be used for bays up to twice the maximum shipping load width. Usually there is no specific limitation on the shipping length. Shipping widths within 3.5 m are acceptable in most cases, while widths over 3.7 m require special permits and/or escorts in most jurisdictions, even if the site access permits oversize loads (Wong 2010).

One of the advantages of this system is its speed of construction. Each module has sufficient out-of-plane stiffness during construction and consists of a three-story tier. A potential disadvantage is that the vertical splice may create significant erection and plumbing challenges. Some measures may need to be exercised to alleviate the gravity-load induced axial compression in the infill plates, which can delay the development of tension-field action in the system.

Concept 3

Concept 3, depicted in Figure 3, consists of three module types: base module (module M-1), top module (module M-3), and intermediate story modules (modules M-2). The objective is to provide modules of a single story in height (mid-story to mid-story), with effectively no limit to the bay width imposed by shipping concerns. As long as the heights of the intermediate stories and the associated beam depths are consistent, all modules M-2 will be identical. In modules M-1 and M-3, the infill plate is welded to the base plate and the top beam, respectively, in the shop. In module M-2, the infill plate on both side of the intermediate beam is welded to the beam's flanges in the shop, which eliminates the need for horizontal fish plates.

Fish plates are welded to the column flanges in the shop and shear wall modules are connected to these fish plates on site by bolts. Lap splices are used to connect the modules to each other. Column splices are provided at every third story (aligned with the adjacent module boundary).

Two potential beam-to-column connection details have been shown in Figure 3 (Concepts 3a and 3b). In Concept 3a, a continuous fish plate is used, and at each connection, both beam flanges on one side of the web are coped and a single angle connection is added to the other side of the beam's web, as shown in Figure 4(a). In Concept 3b, the fish plate is terminated at the intersection with each beam and a conventional simple or semi-rigid beam-to-column connection, such as a double angle connection, is used (Figure 4(b)).

If the gravity-load induced axial compression in the infill is significant, it could be treated as explained for Concept 1.

A disadvantage of this system is the lack of out-of-plane stiffness of the modules during handling. These modules consist of large infill plates, with free edges equal to a half-story height, which needs some consideration regarding design and/or erection of the system. One option is to provide temporary perimeter stiffening to the infill plates to facilitate handling until final installation of the panel is completed. Each panel should be planned and detailed to mitigate this construction issue.

Numerical studies

The numerical studies presented in this section represent part of the planning process for a laboratory test of a two-story modular steel plate shear wall that will provide evidence of the performance that can be expected from such a system. As such, the dimensions used are

approximately representative of a half-size wall. Due to the nature of numerical analysis, however, this is not expected to impact conclusions arising from these studies about expected overall shear wall performance. Discussions with steel industry personnel have led to the conclusion that Concept 3 is the most promising in terms of practicality and economics and it forms the basis of the numerical investigation.

Based on previous large scale tests (Dastfan and Driver 2010), it has been found that lap-spliced infill plates in combination with high-strength pretensioned bolts (the bolts are designed for bearing and pretensioned to meet the requirement (e.g., CSA 2009) that all bolts resisting cyclic loading should be pretensioned high-strength bolts) provide lateral performance similar to a continuous infill plate. As a result, the performances of the three concepts discussed in the previous section are expected to be similar to each other, as well as similar to a SPSW with shear beam-to-column connections and continuous infill plates (i.e., no splices). In this study, the base model shown in Figure 5 has been selected to obtain the expected performance of a shear wall without splices. The columns are W250×115 sections, the intermediate beam is a W250×58 section, and the top beam is a W460×67 section. Infill plates have 4.8 mm thickness. All the material properties for the columns, beams, and infill plates are selected from the test by Driver et al. (1997). Both infill plates have a yield stress of 340 MPa.

The commercial general-purpose finite element code ABAQUS is selected to model the wall. All components of the wall are modelled using four-node shell elements with reduced integration (S4R element). Material and geometric nonlinearities are both considered. The von Mises yield criterion, along with the kinematic hardening rule is used. The numerical model has been verified by Moghimi and Driver (2010).

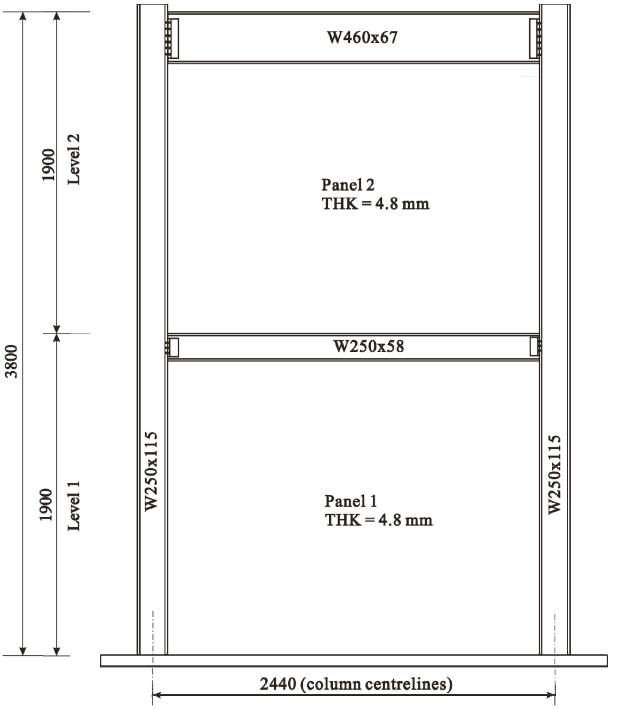

Figure 5. Elevation of base model for numerical studies.

The numerical model of Concept 3 is the same as Figure 5, but with a 2 mm horizontal slit at the mid-height of the first story (the critical story) and with a single-sided lap splice plate connecting the adjacent parts of the infill plate, as depicted in Figure 3. Each side of the splice plate is connected to the adjacent infill plate by bolts (the holes are not modeled and the bolts are modeled with connector constraint at the center of each bolt).

In order to deal with the problem in capacity design related to using infill plates that are thicker than theoretically needed for strength, resulting in large demands on the boundary members, two methods of "weakening" the plate are investigated. In the first, shown conceptually in Figure 6, an intermittent connection is provided at the horizontal infill plate splice to focus the tension field into "bands" that accelerate yielding of the infill plate and therefore reduce the demand on the boundary members (particularly the columns). The total length of the three splices in the model is about half of the width of the infill plate. The second method uses a continuous splice and circular holes are cut into the infill plate in a regular diagonal pattern, as described by Purba and Bruneau (2009). In the model, 14 holes of 200 mm diameter and 17 holes of the same diameter are used in the first and second story infill plates, respectively.

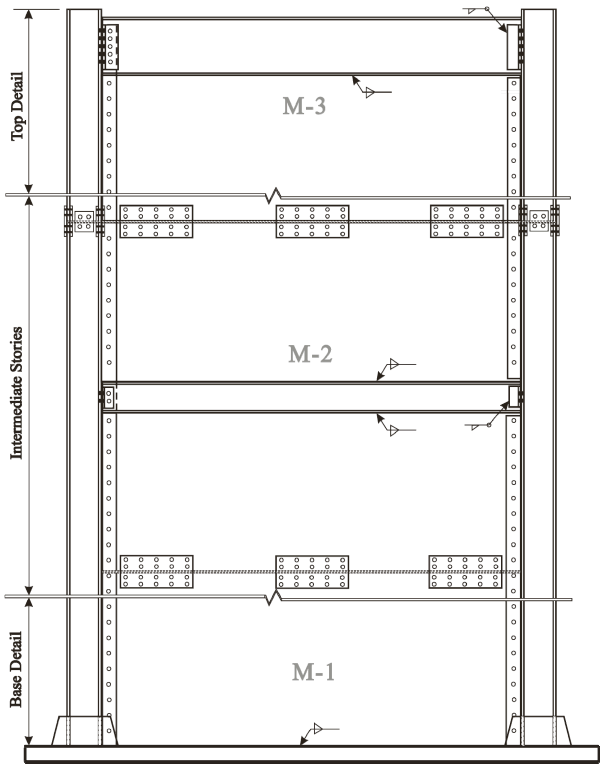

Figure 6. Concept 3 SPSW with intermittent splices.

Each wall is loaded under a monotonically increasing lateral force at each of the two stories. Figure 7 shows the story shear versus story deflection pushover curve for the first panel of each wall. There is little difference between the curves for the base model and the continuous splice.

Figures 8(a), (b), (c), and (d) show the effective plastic strain distributions in the four walls at a lateral deformation of 70 mm for the intermediate beam. Although modular SPSWs are not

intended for high-ductile applications, this lateral deformation is well beyond the target displacement for $R_d = 5.0$. (The target displacement evaluation methods based on design codes and standards represent a mean target displacement value for the design earthquake, and there is considerable scatter about the mean. Thus, ASCE 41-06 (2007) requires that the system be evaluated for a control-node displacement range of zero to 150 % of the target displacement.)

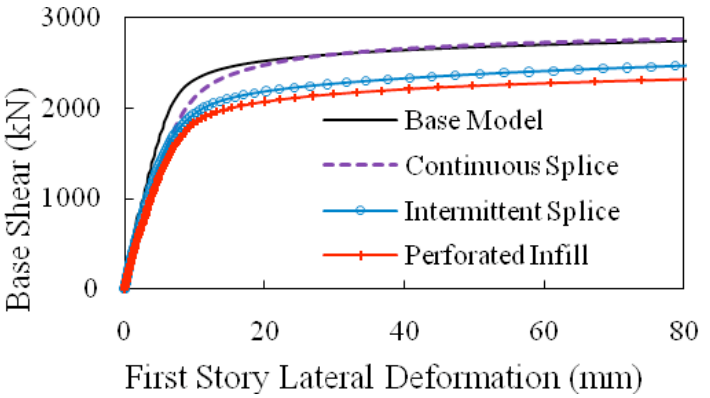

Figure 7. Story shear vs. story deflection of Panel 1.

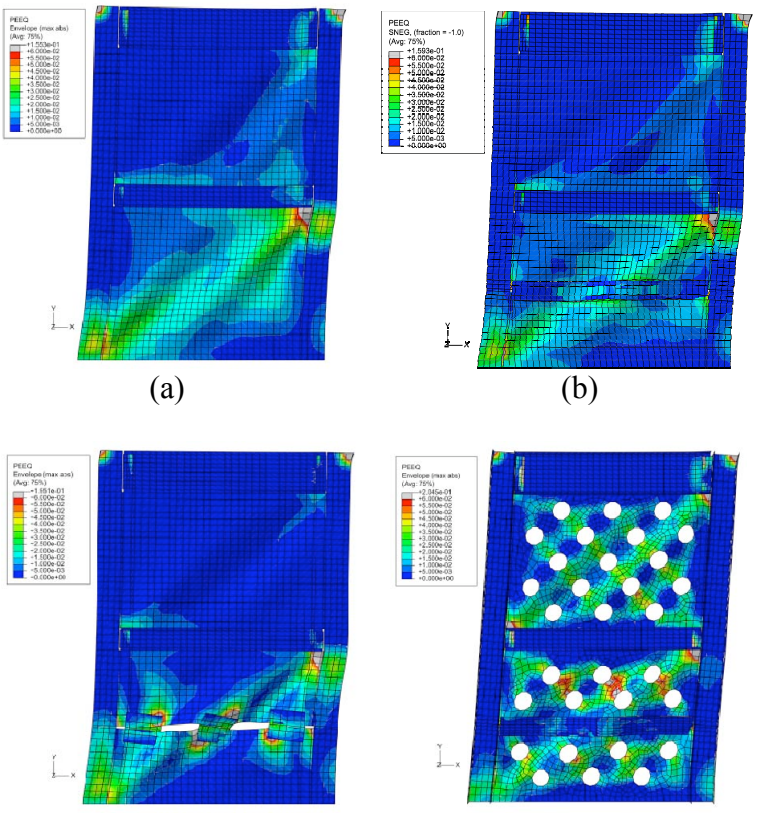

Figure 8. Effective plastic strain distribution: (a) Base model; (b) Continuous splice; (c) Intermittent splice; (d) Perforated infill.

From Figure 8 it can be seen that at a deformation of about 150 % of the target displacement for $R_d = 5.0$, there is a high strain concentration for the Intermittent Splice case (at the splice locations) and the Perforated Infill case (between the holes), while both the Base Model and the Continuous Splice case appear to provide reliable performance even at a very high level of lateral deformation. It can also be seen that the Perforated Infill case imposes a high demand on the first story shear connections, which is the result of the increased effect of frame action in this system, as explained later.

Previous research has shown that most SPSW systems have a high shear resistance, which in many cases leads to thinner infill plates than the minimum practical thickness for handling and welding. Using plates thicker than required for strength imposes increased force demands on the columns. Thus, an important issue for any new SPSW system is the amount of force demand (axial load, shear, and moment) on the columns. Figure 9(a) shows the horizontal component of the total force applied by the infill plate to the first story of the right column versus the first-story lateral deformation, and Figure 9(b) shows the associated vertical component of the force applied to the column by the infill plate. The figures show that the perforated infill plate is most effective in reducing the forces applied to the columns by the infill plate, but these forces do not represent the total demand on the columns.

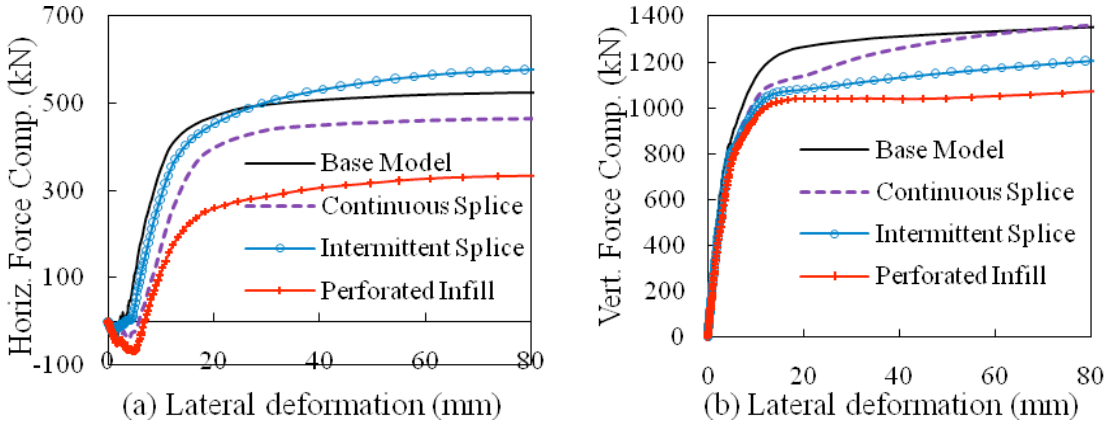

Figure 9. Force demands on the first story of the right column from the infill plate: (a) Horizontal force component; (b) Vertical force component.

Figures 10(a) and (b) show the total internal shear and axial compression demands, respectively, on the right column bases. These figures depict the actual demands on the columns from both the infill plate and frame action, and the columns are designed for these internal forces. Although Figure 9(a) shows that the force demand on the right column from the infill plate is smaller for the Perforated Infill case than for the other walls, Figure 10(a) indicates that the total shear demand on the column base (and also the moment demand) is actually higher at lateral deformations greater than about 35 mm. The reason for this apparent paradox is attributed to the augmented effect of frame action in the Perforated Infill case, which prevents a reduction in the total demand on the columns despite the fact that the perforated infill plate itself imposes a smaller demand. Further investigation is required to characterize this phenomenon.

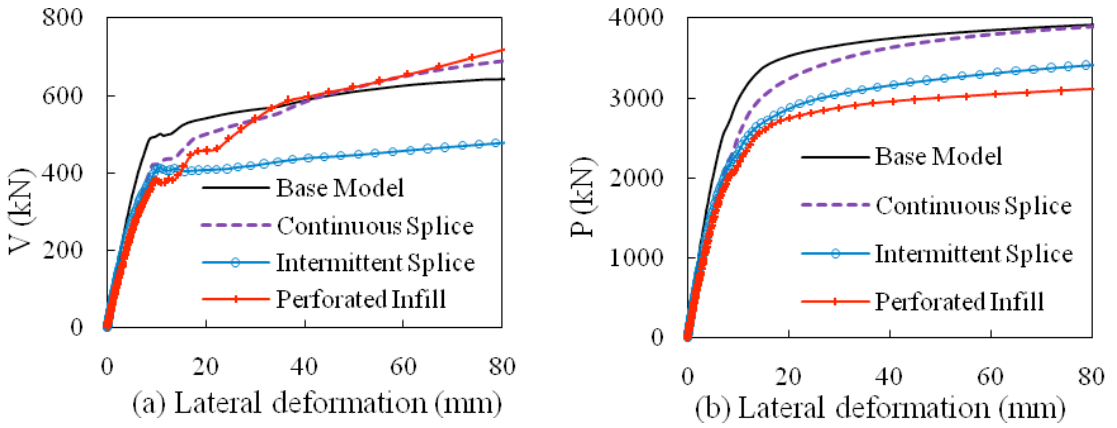

Figure 10. Total force demands on the right column base: (a) Shear force; (b) Axial compression.

Of the three modular cases evaluated in the numerical investigation, the one with the continuous splice showed the best overall pushover performance in terms of lateral shear strength, more uniform stress and plastic strain distributions, and possibly a lower P-delta effect. Also, it has been found that simple shear beam-to-column connections do not eliminate the frame action of the SPSW system, although they reduce its effect in comparison with rigid beam-to-column connections.

Conclusion

This paper provides some ideas related to the potential use of modular construction for SPSW systems in low and moderate seismic regions. The pros and cons of each system are discussed in terms of constructability and explicit consideration of fabrication and erection costs. Also, the inelastic pushover performance has been evaluated for the most promising modular concept. Concept 3, with a continuous infill plate splice, shows reliable performance but with higher forces applied by the infill plate to the columns in comparison with using intermittent infill plate splices or perforated infill plates. Meanwhile, both the Intermittent Splice case and the Perforated Infill case show some signs of infill plate tearing at large deformations. Although the simple beam-to-column connections reduce the frame action, they provide more rotational freedom in the connections and prevent the formation of plastic hinges in the columns near these joints at the design loads.

Nonlinear Dynamic Analysis of Structures Using Modal Superposition

K. K. F. Wong[1]

[1]Engineering Laboratory, National Institute of Standards and Technology, MS 7302, 100 Bureau Dr., Bldg. 226, Room B-264, Gaithersburg, MD 20899-7302, USA; PH (301) 975-6361; FAX (301) 975-4032; email: kfwong@nist.gov

ABSTRACT

A fast nonlinear dynamic analysis algorithm is proposed based on modal superposition of structural response incorporating both material and geometric nonlinearities. Because linear modal superposition has found great acceptance in performance-based seismic engineering, it is here extended to the nonlinear domain by using the force analogy method to address material nonlinearity, where the stiffness force is computed by a change in displacement instead of using the traditional way of changing stiffness. Geometric nonlinearity is incorporated into the analysis using stability functions. State space method is used to explicitly calculate the dynamic responses of each modal single-degree-of-freedom system. Through the combination of force analogy method, stability functions, state space method, and modal superposition, numerical simulations are performed and results are demonstrated to be both accurate and efficient.

INTRODUCTION

Buildings constructed in seismic regions are subjected to earthquake activity and are required to be designed such that their seismic capacity must exceed the corresponding seismic demand with sufficient ductility. While design codes and standards have been developed to establish the seismic capacity in design, estimating the seismic demand in nonlinear structures has always been a challenging task mainly because of the lack of accurate scientific computing tools. Since the time when Newmark (1959) began studying the linear response history analysis for studying seismic effects on civil engineering structures, the development of current seismic design procedures relying on this type of linear analysis technique has advanced significantly because of its fundamental simplicity in the calculation procedure. However, while linear dynamic analysis is so popular, it has a shortcoming because all structures are designed with the anticipation that they will behave nonlinearly when a major earthquake occurs.

Significant research works have been attempted to extend the linear dynamic analysis to the nonlinear domain (e.g., Liu 2003 and 2005, Au and Yan 2008), but presently nonlinear dynamic analysis techniques are employed in seismic design only in some special occasions, mainly because the analysis itself is a time-consuming process. Current nonlinear dynamic numerical algorithms require significant computation time to update the stiffness matrix to accommodate for nonlinearity in structures. In addition, many simulations need to be considered due to the uncertainties in earthquake ground motions. Even though nonlinear response history analysis is

believed to be the most accurate method of computing the seismic demand, it requires a huge computational effort, making the analysis impractical in the design process. Therefore, a fast analysis method with high accuracy in predicting the maximum seismic demand is needed, yet the development of such a nonlinear dynamic analysis algorithm remains a challenge without deeper understanding of the theory of nonlinear structural analysis and dynamics.

In this research, linear dynamic analysis based on modal superposition is extended to analyze structural responses in the nonlinear domain – known here as the Nonlinear Modal Analysis (NMA). While the force analogy method is a simple nonlinear analysis tool based on initial stiffness that treats material nonlinearity as an equivalent force, the state space method is a dynamic algorithm that can perform time-stepping calculations explicitly to progress the effects of the equivalent force on structural responses to the next time step. Although some results through the combination of these methods have been published (Yang et al. 2004, Zhao and Wong 2006, Zhang et al. 2007, Chao and Loh 2007), none of these works studied the nonlinear structural responses in the modal coordinate system. In addition, it is the intent of this research to develop a rigorous approach for treating geometric nonlinearity in dynamic analysis through the use of stability functions as the closed-form solution. Accuracy and efficiency are demonstrated through applying the algorithm on an example 10-story frame by comparing output results with existing commercial software packages including Perform-3D and SAP2000.

FORCE ANALOGY METHOD

The detailed derivation of the force analogy method has been presented in Wong and Yang (1999). Consider a moment-resisting frame with n degrees of freedom (DOFs) and m plastic hinge locations (PHLs), let the total displacement $\mathbf{x}(t)$ at each DOF be represented as the summation of the elastic displacement $\mathbf{x}'(t)$ and the inelastic displacement $\mathbf{x}''(t)$:

$$\mathbf{x}(t) = \mathbf{x}'(t) + \mathbf{x}''(t) \tag{1}$$

Similarly, let the total moment $\mathbf{m}(t)$ at the PHLs of a moment-resisting frame be separated into elastic moment $\mathbf{m}'(t)$ and inelastic moment $\mathbf{m}''(t)$:

$$\mathbf{m}(t) = \mathbf{m}'(t) + \mathbf{m}''(t) \tag{2}$$

The displacements in Eq. (1) and the moments in Eq. (2) are related by the equations:

$$\mathbf{m}'(t) = \mathbf{K}'(t)^T \mathbf{x}'(t) \quad , \qquad \mathbf{m}''(t) = -\left[\mathbf{K}''(t) - \mathbf{K}'(t)^T \mathbf{K}(t)^{-1} \mathbf{K}'(t)\right] \boldsymbol{\Theta}''(t) \tag{3}$$

where $\boldsymbol{\Theta}''(t)$ is the plastic rotation at the PHLs, $\mathbf{K}(t)$ is the $n \times n$ global stiffness matrix, $\mathbf{K}'(t)$ is the $n \times m$ stiffness matrix that relates the plastic rotations at the PHLs and the forces at the DOFs, and $\mathbf{K}''(t)$ is the $m \times m$ stiffness matrix that relates the plastic rotations with the corresponding moments at the PHLs. These stiffness matrices are functions of time when geometric nonlinearity with varying axial load is incorporated in the dynamic analysis, and they can be formed by assembling the individual element stiffness matrices in the appropriate DOFs and PHLs. For the ith

column member of the structure with plastic hinges at both ends, the axially-loaded element stiffness matrices related to shear and bending can be written as:

$$\mathbf{K}_i(t) = \left[\begin{array}{cc:cc} s'EI/L^3 & \bar{s}EI/L^2 & -s'EI/L^3 & \bar{s}EI/L^2 \\ \bar{s}EI/L^2 & sEI/L & -\bar{s}EI/L^2 & scEI/L \\ \hdashline -s'EI/L^3 & -\bar{s}EI/L^2 & s'EI/L^3 & -\bar{s}EI/L^2 \\ \bar{s}EI/L^2 & scEI/L & -\bar{s}EI/L^2 & sEI/L \end{array}\right]$$

$$\mathbf{K}_i'(t)^T = \left[\begin{array}{cc:cc} \bar{s}EI/L^2 & sEI/L & -\bar{s}EI/L^2 & scEI/L \\ \bar{s}EI/L^2 & scEI/L & -\bar{s}EI/L^2 & sEI/L \end{array}\right] \qquad \mathbf{K}_i''(t) = \left[\begin{array}{cc} sEI/L & scEI/L \\ scEI/L & sEI/L \end{array}\right]$$

where

$$s = \frac{\lambda(\sin\lambda - \lambda\cos\lambda)}{2 - 2\cos\lambda - \lambda\sin\lambda} \qquad c = \frac{\lambda - \sin\lambda}{\sin\lambda - \lambda\cos\lambda}$$

$$\bar{s} = s + sc = s(1+c) = \frac{\lambda^2(1-\cos\lambda)}{2 - 2\cos\lambda - \lambda\sin\lambda} \qquad s' = 2\bar{s} - \lambda^2 = \frac{\lambda^3\sin\lambda}{2 - 2\cos\lambda - \lambda\sin\lambda}$$

$\lambda = (P(t)/EI)^{0.5} \times L$, $P(t)$ is the time-varying axial compressive force in the column which causes the stiffness matrices to be also time-varying, and E, I, and L are the elastic modulus, moment of inertia, and length of the column member, respectively. The relationship between plastic rotation $\mathbf{\Theta}''(t)$ and inelastic displacement $\mathbf{x}''(t)$ is:

$$\mathbf{x}''(t) = \mathbf{K}(t)^{-1}\mathbf{K}'(t)\mathbf{\Theta}''(t) \tag{4}$$

Substituting Eq. (3) into Eq. (2) and making use of Eqs. (1) and (4), then rearranging the terms gives the governing equation of the force analogy method:

$$\mathbf{m}(t) + \mathbf{K}''(t)\mathbf{\Theta}''(t) = \mathbf{K}'(t)^T\mathbf{x}(t) \tag{5}$$

NONLINEAR MODAL ANALYSIS

When the force analogy method is used, the stiffness force is calculated by multiplying the global stiffness matrix $\mathbf{K}(t)$ with the elastic displacement $\mathbf{x}'(t)$. For an n-DOF system with plastic hinges at both ends of each member subjected to earthquake ground motion, the equation of motion can therefore be written as

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}(t)\mathbf{x}'(t) = -\mathbf{M}\ddot{\mathbf{g}}(t) + \mathbf{F}_h(t) \tag{6}$$

where $\mathbf{M}$ is the $n \times n$ mass matrix, $\mathbf{C}$ is the $n \times n$ damping matrix, $\dot{\mathbf{x}}(t)$ is the $n \times 1$ velocity vector at each DOF, $\ddot{\mathbf{x}}(t)$ is the $n \times 1$ acceleration vector at each DOF, $\ddot{\mathbf{g}}(t)$ is the $n \times 1$ ground acceleration vector corresponding to each DOF, and $\mathbf{F}_h(t)$ is an $n \times 1$ force vector that takes into consideration the geometric nonlinearity of the entire structure (i.e., the P-Δ effect), such as the force imposed on the structure using a P-Δ column. In two-dimensional modeling, this force is related to the displacement of the structure, and it can be computed by the formula $\mathbf{F}_h(t) = \mathbf{K}_h\mathbf{x}(t)$, where $\mathbf{K}_h$ is the $n \times n$ stiffness matrix computed using the column heights and axial gravity forces of the

P-Δ column members. Note that the *P*-δ effect has been included in $\mathbf{K}(t)$.

Let $\mathbf{K}(t) = \mathbf{K}_o - \mathbf{K}_G(t)$, where $\mathbf{K}_o$ represents the initial stiffness due to gravity load only, and $\mathbf{K}_G(t)$ represents the change in stiffness due to the variation of axial forces while subjected to the earthquake ground motion. Now replacing the elastic displacement $\mathbf{x}'(t)$ in Eq. (6) by the difference of total displacement $\mathbf{x}(t)$ and inelastic displacement $\mathbf{x}''(t)$ that is rewritten using Eq. (1), it follows that

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}_o\mathbf{x}(t) = -\mathbf{M}\ddot{\mathbf{g}}(t) + \mathbf{K}_h\mathbf{x}(t) - \mathbf{K}_G(t)\mathbf{x}(t) + \mathbf{K}(t)\mathbf{x}''(t) \tag{7}$$

Following a similar procedure for the treatment of *P*-Δ effects discussed in Wilson (2002), define $\mathbf{K}_e = \mathbf{K}_o - \mathbf{K}_h$, where $\mathbf{K}_e$ represents the elastic stiffness of the structure. Now substituting Eq. (4) into Eq. (7) gives

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}_e\mathbf{x}(t) = -\mathbf{M}\ddot{\mathbf{g}}(t) - \mathbf{K}_G(t)\mathbf{x}(t) + \mathbf{K}'(t)\mathbf{\Theta}''(t) \tag{8}$$

Let the modal displacement response $\vec{\mathbf{q}}(t)$ be the $r \times 1$ vector of the form

$$\mathbf{x}(t) = \mathbf{\Phi}\vec{\mathbf{q}}(t) = \begin{bmatrix}\boldsymbol{\varphi}_1 & \boldsymbol{\varphi}_2 & \cdots & \boldsymbol{\varphi}_r\end{bmatrix}\begin{bmatrix}\vec{q}_1(t) & \vec{q}_2(t) & \cdots & \vec{q}_r(t)\end{bmatrix}^T \tag{9}$$

where $\mathbf{\Phi}$ is the $n \times r$ modal matrix – a collection of the first *r* mode shapes $\boldsymbol{\varphi}_i$ in column form, and *r* is the number of modes to be considered in the analysis, where $r \le n$. Differentiating the modal displacement $\vec{\mathbf{q}}(t)$ with respect to time gives the modal velocity $\dot{\vec{\mathbf{q}}}(t)$, and differentiating it once again with respect to time gives the modal acceleration $\ddot{\vec{\mathbf{q}}}(t)$. Now substituting Eq. (9) into Eq. (8):

$$\mathbf{M}\mathbf{\Phi}\ddot{\vec{\mathbf{q}}}(t) + \mathbf{C}\mathbf{\Phi}\dot{\vec{\mathbf{q}}}(t) + \mathbf{K}_e\mathbf{\Phi}\vec{\mathbf{q}}(t) = -\mathbf{M}\ddot{\mathbf{g}}(t) - \mathbf{K}_G(t)\mathbf{x}(t) + \mathbf{K}'(t)\mathbf{\Theta}''(t) \tag{10}$$

Pre-multiplying Eq. (10) by $\mathbf{\Phi}^T$, it follows that

$$\begin{aligned}\mathbf{\Phi}^T\mathbf{M}\mathbf{\Phi}\ddot{\vec{\mathbf{q}}}(t) + \mathbf{\Phi}^T\mathbf{C}\mathbf{\Phi}\dot{\vec{\mathbf{q}}}(t) + \mathbf{\Phi}^T\mathbf{K}_e\mathbf{\Phi}\vec{\mathbf{q}}(t) \\ = -\mathbf{\Phi}^T\mathbf{M}\ddot{\mathbf{g}}(t) - \mathbf{\Phi}^T\mathbf{K}_G(t)\mathbf{x}(t) + \mathbf{\Phi}^T\mathbf{K}'(t)\mathbf{\Theta}''(t)\end{aligned} \tag{11}$$

While assuming that the damping matrix $\mathbf{C}$ exhibits proportional damping property, let $\vec{\mathbf{M}} = \mathbf{\Phi}^T\mathbf{M}\mathbf{\Phi}$, $\vec{\mathbf{C}} = \mathbf{\Phi}^T\mathbf{C}\mathbf{\Phi}$, and $\vec{\mathbf{K}} = \mathbf{\Phi}^T\mathbf{K}\mathbf{\Phi}$ be the diagonal modal mass, modal damping, and modal stiffness matrices, respectively. This gives *r* modal equations:

$$\vec{m}_i\ddot{\vec{q}}_i(t) + \vec{c}_i\dot{\vec{q}}_i(t) + \vec{k}_i\vec{q}_i(t) = -\boldsymbol{\varphi}_i^T\mathbf{M}\ddot{\mathbf{g}}(t) - \boldsymbol{\varphi}_i^T\mathbf{K}_G(t)\mathbf{x}(t) + \boldsymbol{\varphi}_i^T\mathbf{K}'(t)\mathbf{\Theta}''(t) \quad i = 1,...,r \tag{12}$$

where $\vec{m}_i$, $\vec{c}_i$, and $\vec{k}_i$ are the *i*th modal mass, damping, and stiffness, respectively.

STATE SPACE METHOD

For all *r* modes given in Eq. (12), let the three terms on the right hand side of the equation be treated as the equivalent modal forces:

$$\vec{m}_i\vec{a}_i(t) = \boldsymbol{\varphi}_i^T\mathbf{M}\ddot{\mathbf{g}}(t) \quad i = 1,...,r \tag{13}$$

$$\vec{f}_{mi}(t) = \boldsymbol{\varphi}_i^T\mathbf{K}'(t)\mathbf{\Theta}''(t) \quad i = 1,...,r \tag{14}$$

$$\vec{f}_{Gi}(t) = \boldsymbol{\varphi}_i^T\mathbf{K}_G(t)\mathbf{x}(t) \quad i = 1,...,r \tag{15}$$

where $\vec{a}_i(t)$ is the modal ground acceleration, $\vec{f}_{mi}(t)$ is the equivalent modal force due to material nonlinearity, and $\vec{f}_{Gi}(t)$ is the equivalent modal force due to geometric nonlinearity. Representing each modal equation in Eq. (12) in the state space form:

$$\dot{\vec{\mathbf{z}}}_i(t) = \mathbf{A}_i\vec{\mathbf{z}}_i(t) + \mathbf{G}_i\vec{f}_{mi}(t) - \mathbf{G}_i\vec{f}_{Gi}(t) + \mathbf{H}_i\vec{a}_i(t) \quad i = 1,...,r \tag{16}$$

where

$$\vec{\mathbf{z}}_i(t) = \begin{Bmatrix} \vec{q}_i(t) \\ \dot{\vec{q}}_i(t) \end{Bmatrix}, \quad \mathbf{A}_i = \begin{bmatrix} 0 & 1 \\ -\omega_i^2 & -2\zeta_i\omega_i \end{bmatrix}, \quad \mathbf{G}_i = \begin{bmatrix} 0 \\ 1/\vec{m}_i \end{bmatrix}, \quad \mathbf{H}_i = \begin{bmatrix} 0 \\ -1 \end{bmatrix}$$

and ω_i and ζ_i are the natural frequency and damping ratio of the *i*th mode, respectively.

The solution to the first order linear differential equation given in Eq. (16) is

$$\vec{\mathbf{z}}_i(t) = \mathbf{e}^{\mathbf{A}_i(t-t_0)}\vec{\mathbf{z}}_i(t_0) + \mathbf{e}^{\mathbf{A}_i t}\int_{t_0}^{t}\mathbf{e}^{-\mathbf{A}_i s}\left[\mathbf{G}_i\vec{f}_{mi}(s) - \mathbf{G}_i\vec{f}_{Gi}(s) + \mathbf{H}_i\vec{a}_i(s)\right]ds \quad i = 1,...,r \tag{17}$$

where t_0 is the initial time of integration. The state transition matrix $\mathbf{e}^{\mathbf{A}_i t}$ of a SDOF system is

$$\mathbf{e}^{\mathbf{A}_i t} = e^{-\zeta_i\omega_i t}\begin{bmatrix} \cos\omega_{di}t + \dfrac{\zeta_i}{\sqrt{1-\zeta_i^2}}\sin\omega_{di}t & \dfrac{1}{\omega_i\sqrt{1-\zeta_i^2}}\sin\omega_{di}t \\ -\dfrac{\omega_i}{\sqrt{1-\zeta_i^2}}\sin\omega_{di}t & \cos\omega_{di}t - \dfrac{\zeta_i}{\sqrt{1-\zeta_i^2}}\sin\omega_{di}t \end{bmatrix}$$

and ω_{di} is the damped natural frequency of the *i*th mode computed by the formula $\omega_{di} = \omega_i(1-\zeta_i^2)^{0.5}$. Define $t_{k+1} = t$, $t_k = t_0$, and $\Delta t = t - t_0$, it follows that Eq. (17) can be discretized and integrated as

$$\vec{\mathbf{z}}_{k+1}^{(i)} = \mathbf{F}_d^{(i)}\vec{\mathbf{z}}_k^{(i)} + \mathbf{G}_d^{(i)}\vec{f}_{mk}^{(i)} - \mathbf{G}_d^{(i)}\vec{f}_{Gk}^{(i)} + \mathbf{H}_d^{(i)}\vec{a}_k^{(i)} \quad i = 1,...,r \tag{18}$$

where

$$\mathbf{F}_d^{(i)} = \mathbf{e}^{\mathbf{A}_i\Delta t} \quad , \quad \mathbf{G}_d^{(i)} = \mathbf{e}^{\mathbf{A}_i\Delta t}\mathbf{G}_i\Delta t \quad , \quad \mathbf{H}_d^{(i)} = \mathbf{e}^{\mathbf{A}_i\Delta t}\mathbf{H}_i\Delta t$$

$\vec{\mathbf{z}}_k^{(i)}$, $\vec{f}_{mk}^{(i)}$, $\vec{f}_{Gk}^{(i)}$, and $\vec{a}_k^{(i)}$ are the discretized forms of $\vec{\mathbf{z}}_i(t)$, $\vec{f}_{mi}(t)$, $\vec{f}_{Gi}(t)$, and $\vec{a}_i(t)$, respectively, and the superscript *i* in parenthesis denotes the calculation is based on the *i*th mode. Once the modal displacement and velocity responses embedded in $\vec{\mathbf{z}}_k^{(i)}$ are obtained, the modal relative acceleration response can be calculated using Eq. (12):

$$\ddot{\vec{q}}_k^{(i)} = \vec{f}_{mk}^{(i)}/\vec{m}_i - \vec{f}_{Gk}^{(i)}/\vec{m}_i - \vec{a}_k^{(i)} - \vec{c}_i\dot{\vec{q}}_k^{(i)}/\vec{m}_i - \vec{k}_i\vec{q}_k^{(i)}/\vec{m}_i \quad i = 1,...,r \tag{19}$$

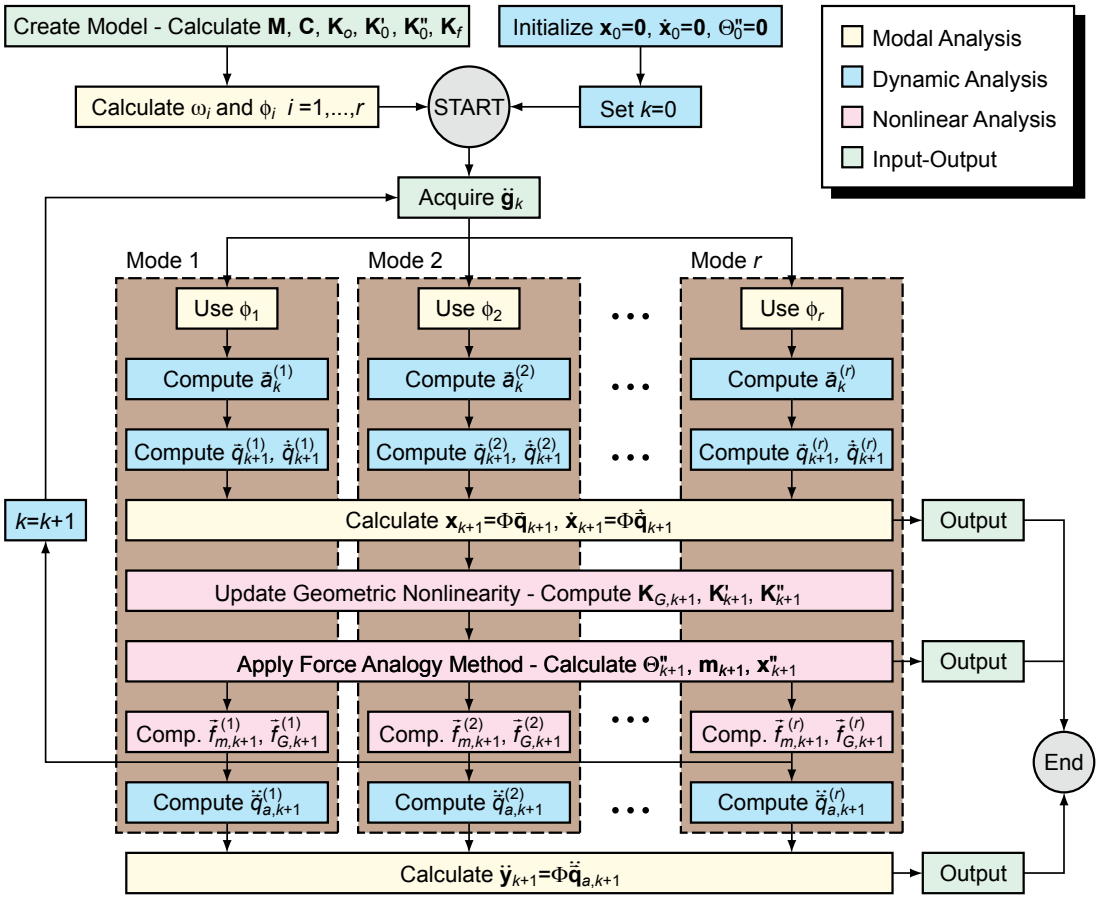
The absolute acceleration of the *i*th mode, $\ddot{\vec{q}}_{a,k}^{(i)}$, can be calculated by summing the relative acceleration in Eq. (19) with the modal ground acceleration defined in Eq. (13):

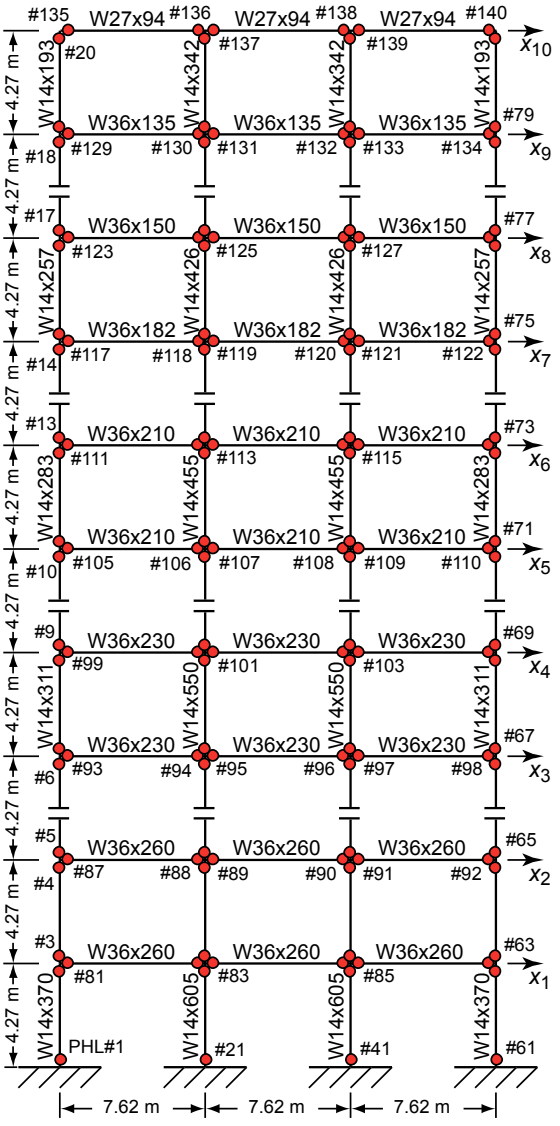
$$\ddot{\vec{q}}_{a,k}^{(i)} = \ddot{\vec{q}}_k^{(i)} + \vec{a}_k^{(i)} \quad i = 1,...,r \tag{20}$$

Finally, the absolute acceleration of the structure $\ddot{\mathbf{y}}(t)$, or $\ddot{\mathbf{y}}_k$ in discretized form, is computed as:

$$\ddot{\mathbf{y}}_k = \ddot{\mathbf{x}}_k + \ddot{\mathbf{g}}_k = \mathbf{\Phi}\ddot{\mathbf{q}}_k + \mathbf{\Phi}\vec{\mathbf{a}}_k = \mathbf{\Phi}\ddot{\mathbf{q}}_{a,k} = \mathbf{\Phi}\left[\ddot{q}_{a,k}^{(1)} \quad \ddot{q}_{a,k}^{(2)} \quad \cdots \quad \ddot{q}_{a,k}^{(r)}\right]^T \tag{21}$$

Figure 1 shows the flowchart of the proposed calculation procedure for performing the nonlinear response history analysis. Note that nonlinearity causes coupling between modes, as shown in Figure 1. Therefore, all r modes are required to be run simultaneously in order to perform modal combination at each time step.





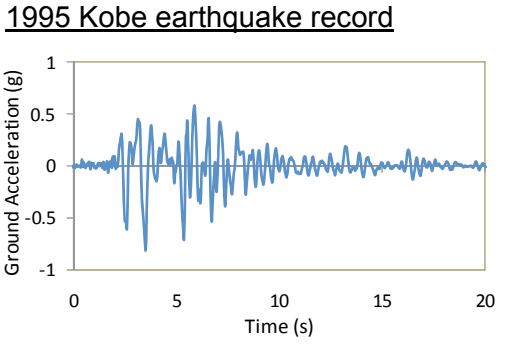


Figure 1. Flowchart for deriving the fully nonlinear response history analysis.

NUMERICAL SIMULATION

Consider a 10-story moment-resisting steel frame as shown in Figure 2. Let the mass be 218.9 Mg on each floor. This gives 10 elastic periods of vibration based on $\mathbf{K}_e$ as summarized in the figure. The damping is assumed to be 3% in all modes for the purpose of this study, even though larger damping ratio may be used in the higher modes which can be easily adjusted in any modal analysis that uses modal coordinates as the mathematical representation. A total of 140 PHLs as shown in Figure 2 are used in the analysis, all of which are assumed to exhibit elastic-plastic behavior with

moment capacity $m_c = \sigma_Y Z$, where $\sigma_Y = 248.2$ MPa is the yield stress of steel, and Z is the plastic section modulus of the member. All beams are subjected to a 21.89 kN/m uniform gravity load, while interaction between axial force and moment capacity is ignored in the columns. Gravity loads of 5,978 kN are applied on each floor of the *P*-Δ column to simulate the geometric nonlinearity of the global structure.

Mass: 218.9 Mg per floor

Dead Load: 21.89 kN/m per beam

P-Δ Column: 5,978 kN per floor

Mode	Period (s)	Damping
1	1.546	3%
2	0.559	3%
3	0.339	3%
4	0.237	3%
5	0.181	3%
6	0.148	3%
7	0.123	3%
8	0.105	3%
9	0.094	3%
10	0.082	3%

Figure 2. Ten-story moment-resisting steel frame model with earthquake record.

To demonstrate the accuracy and efficiency of the current NMA algorithm, the NMA structural responses using all 10 modes subjected to the 1995 Kobe earthquake ground motion as shown in Figure 2 are compared to those obtained using Perform-3D (P3D) and SAP2000 (SAP). Since no interaction between axial force and moment capacity is assumed in this study, only moment hinges are used to model all the PHLs for both beams and columns in P3D. Nonlinear link elements are used to model the plastic hinges in SAP, since the computation will be very time-consuming if the plastic hinges in the beam element are explicitly modeled in the

program. The global displacement, velocity, and absolute acceleration responses at the selected floors between various analysis methods are compared in Figures 3, 4, and 5, respectively. The local plastic rotations at selected beam and column PHLs using both NMA and P3D are also compared in Figure 6. Table 1 summarizes the computation time of each analysis method.

Table 1. Computing time of various programs of fully nonlinear dynamic analysis.

	NMA	P3D	SAP-DI	NMA(v)
Computing Time* (1.0 × Kobe)	107 s	78 s	940 s	19 s
Computing Time* (1.3 × Kobe)	109 s	85 s	1,146 s	22 s

* Based on 32-bit desktop computer with 2.4 GHz Intel processor and 3 GB RAM.

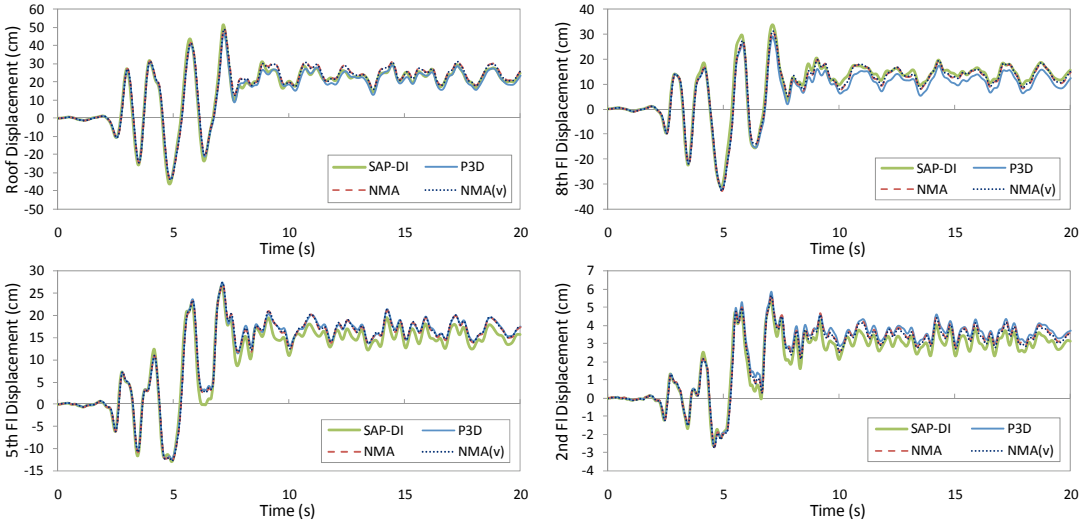

Figure 3. Comparison of displacement responses at selected floors due to 1.0 × Kobe.

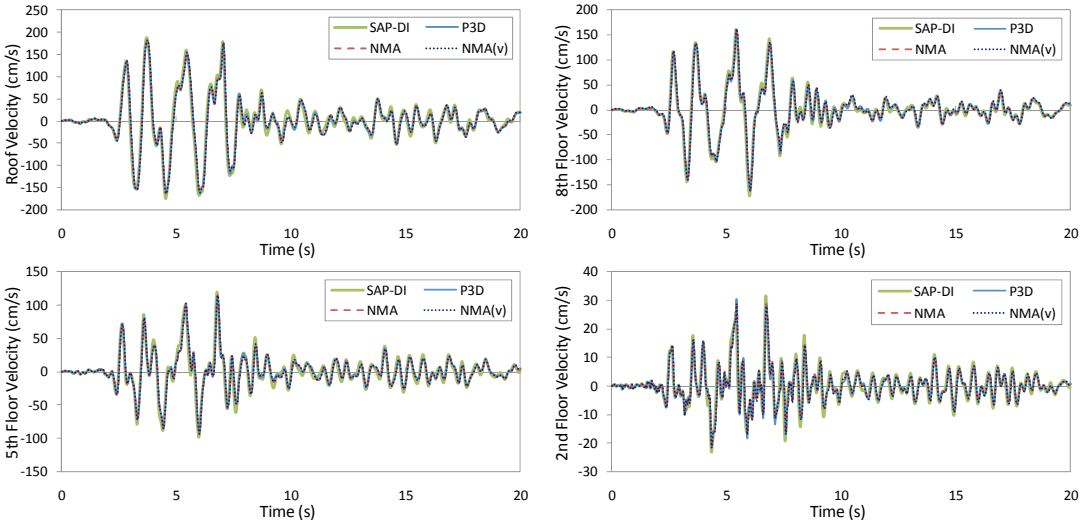

Figure 4. Comparison of velocity responses at selected floors due to 1.0 × Kobe.

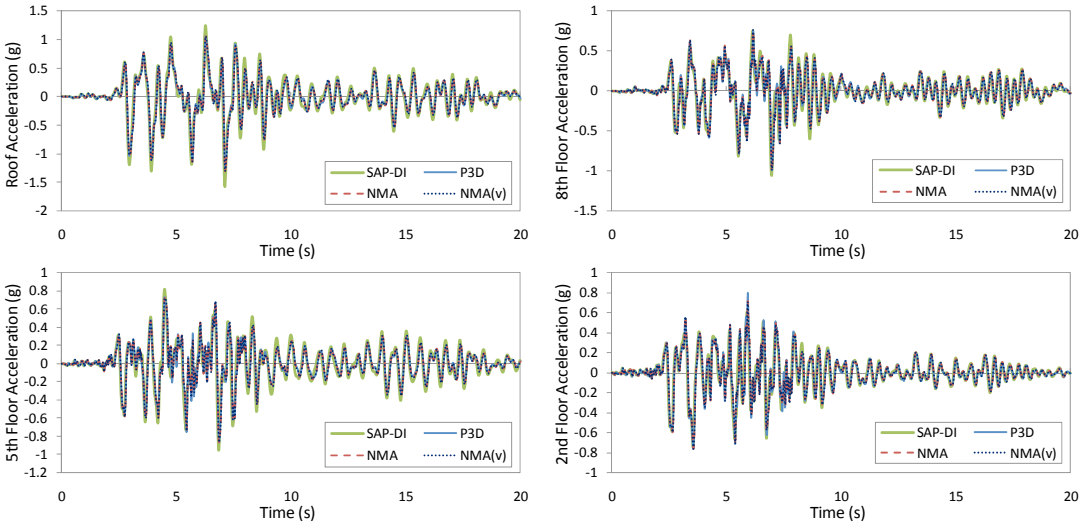

Figure 5. Comparison of acceleration responses at selected floors due to 1.0 × Kobe.

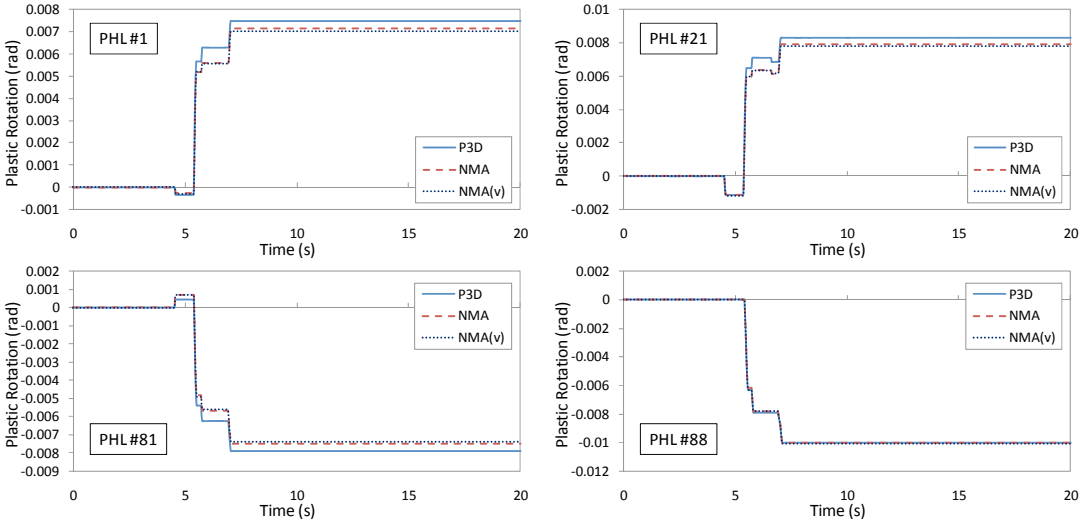

Figure 6. Comparison of plastic rotation at selected PHLs due to 1.0 × Kobe.

Comparison of Table 1 suggests that the computation using the NMA algorithm is quite time-consuming when the change in stiffness for $\mathbf{K}_G(t)$ matrix is updated at every time step. Since the elastic stiffness matrix $\mathbf{K}_e$ has already taken into consideration the local *P*-δ effects due to gravity loads and also the global *P*-Δ effects due to both gravity and earthquake loads in the proposed algorithm, it is sensible to consider another case of NMA where no update is performed (i.e., set $\mathbf{K}_G(t) = \mathbf{0}$), denoted here as NMA(ν). This gives $\vec{f}_{Gi}(t) = 0$ for all modes according to Eq. (15), which eliminates the need to update the local *P*-δ effects due to earthquake loads. Results using NMA(ν) are also shown in Figures 3 to 6 and Table 1 for comparisons.

Figures 3 to 6 show that results from both NMA (i.e., full update) and NMA(ν) (i.e., no update) compare well with other methods of analysis, demonstrating the accuracy and efficiency of the proposed NMA algorithms. It is therefore quite motivating to study the structural responses with greater nonlinear effects, such as at a

limit state of near collapse, by magnifying the ground motion. At this collapse prevention limit state, significant geometric nonlinearity comes into play, which may cause greater differences in the results between NMA and NMA(ν). Similarly, greater material nonlinearity is expected for larger earthquake while causing soft stories in the structure to become more apparent, which can give an indication as to whether the structure is properly designed according to the modern building code.

By subjecting the 10-story frame to the 1995 Kobe earthquake ground motion (all shown in Figure 2) with an amplification factor of 1.3, the global displacement, velocity, and absolute acceleration responses between various analysis methods are compared in Figures 7, 8, and 9, respectively. The local plastic rotations at selected beam and column PHLs using both NMA and P3D are compared and shown in Figure 10. In addition, the computation time of each analysis method due to the Kobe earthquake record with an amplification factor of 1.3 has been summarized in Table 1.

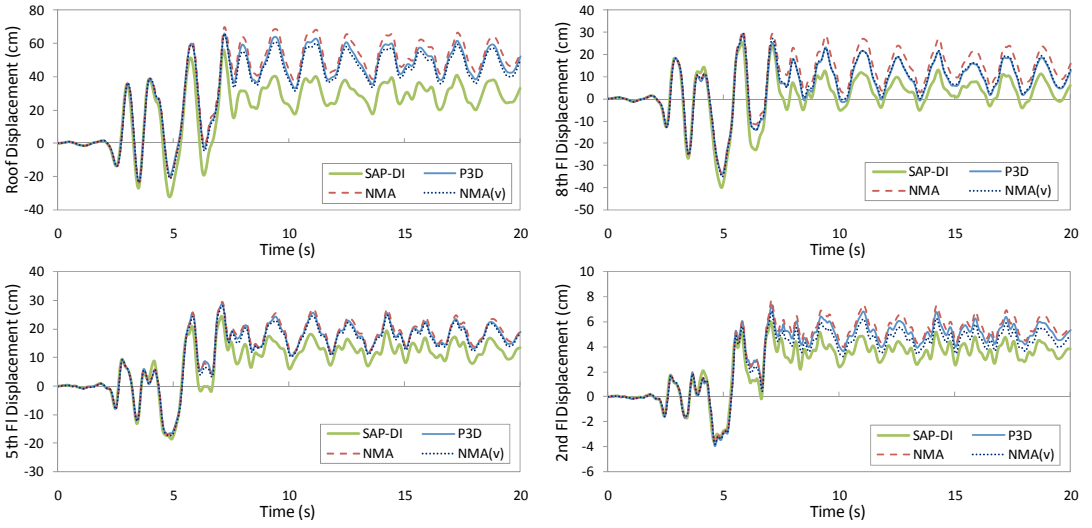

Figure 7. Comparison of displacement responses at selected floors due to 1.3 × Kobe.

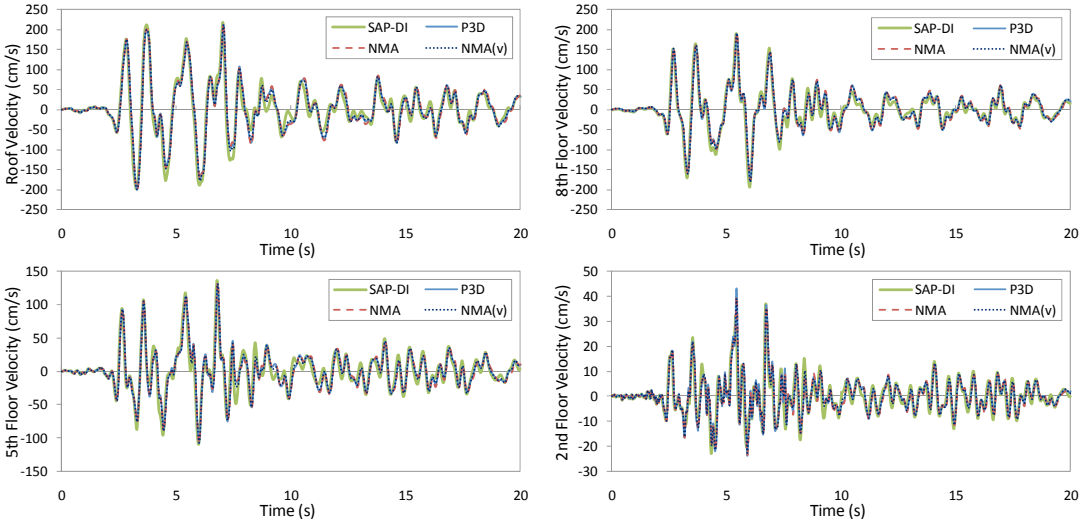

Figure 8. Comparison of velocity responses at selected floors due to 1.3 × Kobe.

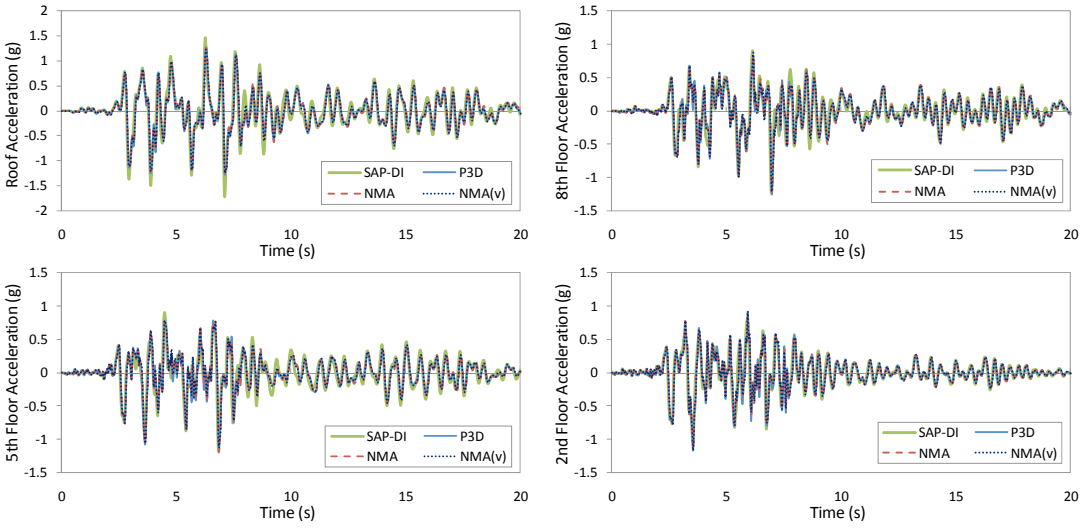

Figure 9. Comparison of acceleration responses at selected floors due to 1.3 × Kobe.

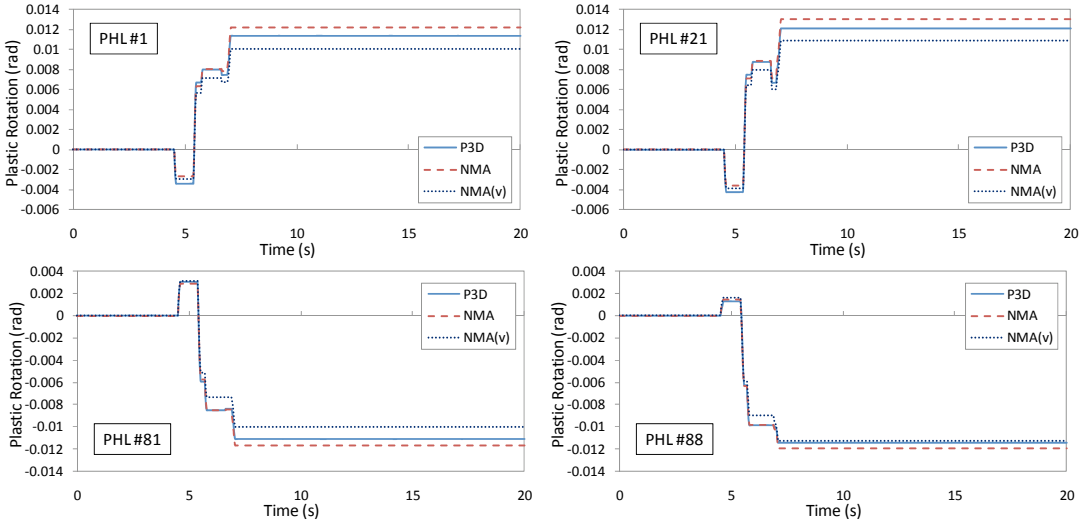

Figure 10. Comparison of plastic rotation at selected PHLs due to 1.3 × Kobe.

Comparison of results in Figures 7 to 10 again demonstrates the accuracy and efficiency of the proposed NMA algorithms. In particular, NMA(v) results seem to be very close to the NMA results and those from Perform-3D, indicating that updating the time-varying nonlinear stiffness matrices due to geometric nonlinearity may not be an important concern in performing nonlinear response history analysis. However, further study, particularly using taller structural models loaded up to near collapse, is necessary to prove this point.

CONCLUSIONS

A nonlinear dynamic analysis algorithm for computing the dynamic response of structures subjected to earthquake excitation based on modal superposition was presented. This algorithm combined the force analogy method, state space method, and

stability functions while transforming the analysis into the modal coordinates. Although modal coupling occurs because of the material and geometric nonlinearities in the analysis, this coupling is decomposed back into each mode using equivalent modal forces. By using the proposed algorithm, numerically simulated results were compared with those obtained from Perform-3D and SAP2000, and excellent agreement was obtained. These results demonstrate that the proposed algorithm has the potential of becoming a useful scientific computing tool that contains high accuracy and efficiency. More importantly, it has the potential of expanding the scope of nonlinear response spectra analysis that may have a greater impact on seismic design.

DISCLAIMER

Certain commercial software may be identified in this paper in order to specify the analytical procedure adequately. Such identification is not intended to imply recommendation or endorsement by the National Institute of Standards and Technology (NIST), nor is it intended to imply that the software identified are necessarily the best available for the purpose.

Use of Nonlinear Analysis in the Context of the ASCE 7 Seismic Load Provisions

Finley A. Charney[1]

[1]Virginia Tech, Department of Civil and Environmental Engineering, 200 Patton Hall, Blacksburg, Virginia, 24061; PH (540) 231-1444; email: fcharney@vt.edu

ABSTRACT

This paper describes the use of nonlinear analysis within the context of the ASCE 7 seismic load provisions. The methods of analysis that are discussed include P-Delta analysis, nonlinear static analysis, and nonlinear dynamic analysis. All methods of analysis are discussed at the systems (entire structure) level. The use of nonlinear static analysis to perform sub-system evaluation is also described. Also provided in the paper is an assessment of the adequacy of the current analysis techniques in the context of advances that have been made in computational power and analysis capabilities over the last 40 years. Recommendations for improvements in the ASCE 7 analysis procedures are provided at the end of the paper.

INTRODUCTION

The use of nonlinear analysis is becoming more common in structural earthquake engineering, even though ASCE 7 (ASCE, 2010) does not require any form of nonlinear analysis for "traditional" buildings that do not incorporate seismic isolation or passive energy systems. Nonlinear dynamic response history analysis is permitted for traditional systems, and requirements for performing such analysis are provided in Chapter 16 of the ASCE 7. When used, nonlinear dynamic analysis is performed on the system level, meaning that the entire structure is analyzed, and the analysis forms the basis for deciding if the design is acceptable. Currently, the main use of nonlinear dynamic analysis is to assess the performance of buildings that do not satisfy height limits, or for which values of R, C_d, and Ω_o are not provided.

ASCE 7 does not list nonlinear static pushover analysis as permitted method, and for that reason, it does not provide any requirements for performing such analysis. ASCE 41 (ASCE, 2007) allows pushover analysis under certain circumstances, and provides requirements for performing such analysis. Presumably, these procedures, where applicable, could be used in association with ASCE 7 if approved by the local building official, and if independently reviewed by a panel of experts.

While ASCE 7 does not permit nonlinear static analysis as the basis of system design and evaluation, there are cases where limited forms of such analysis would be useful. Examples of such analysis include assessment of weak story irregularities, computing story β factors in P-Delta analysis, and computation of story strength after removal of components as required for redundancy factor (ρ) evaluation. These uses for nonlinear static analysis are described later in this paper.

It is essential that P-Delta effects (a nonlinear effect in itself) be included in all seismic analysis. Currently, ASCE 7 is set up such that linear analysis should not directly include P-Delta effects. Instead, such effects are evaluated through the use of displacement and force magnifiers that are computed on the basis of the results of first order static analysis. This method is seriously flawed because it does not capture the effects of residual inelastic deformations, and it is these deformations that lead to dynamic instability and collapse of some structures.

In the remainder of this paper the above issues are addressed in some detail, starting with P-Delta analysis, moving next to nonlinear static analysis, and finally, nonlinear dynamic analysis.

P-DELTA ANALYSIS

Section 12.7.3 of ASCE 7 requires that P-Delta effects be included in structural modeling, but this is inconsistent with Eqn. 12.8-16 because the stability ratio, θ, determined from this equation should be based on displacements that do not include P-Delta effects. Eqn. 12.8-16 is as follows:

$$\theta = \frac{P_x \Delta I_e}{V_x h_{sx} C_d}$$

It is important to recognize that the stability ratio θ is simply the ratio of the "Geometric Stiffness" of the story (P_x/h_{sx}) to the "Elastic Stiffness" of the story ($V_x C_d / \Delta I_e$), and that when properly computed, θ is independent of the value of C_d and I_e.

If P-Delta effects are included in the analysis, it is permitted to divide the value of θ determined from equation 12.8-16 by the quantity (1- θ). This avoids the potential problem of including P-Delta effects twice in the same analysis. A more rational approach would be to run the analysis twice, once without P-Delta effects and once with P-Delta, and compute the stability ratio for each story as follows:

$$\theta = 1 - \frac{\Delta_o}{\Delta_f}$$

where Δ_o is the story drift computed without P-Delta, and Δ_f is the drift from the analysis which includes P-Delta effects. Where P-Delta effects are included in the analysis, member forces and displacements need not be multiplied by the quantity 1/(1- θ) because this effect is already included.

The stability ratio θ is not permitted to exceed $0.5/\beta C_d$, where β is "the ratio of shear demand to the shear capacity" of the story under consideration. Thus, β is the inverse of the over-strength of the story. Taking β as 1.0 is usually conservative,

but doing so may lead to situations where the limit on θ is exceeded. Unfortunately, the determination of β is not straightforward, even for simple systems such as moment resisting frames.

Consider, for example, the frame shown in Figure 1. If the columns are stronger than the girders, the story mechanism and the computed story strength shown in Part (a) of the figure may be used. For weak column - strong beam systems, the mechanism and computed strength indicated in part (b) of the figure is applicable. Both of the equations shown in Figure 1 come from the commentary of the AISC Seismic Provisions (AISC, 2005). Mechanism (a) is reasonable for special moment frames, but may not be applicable to ordinary or intermediate moment frames where the columns might be weaker than the beams. Some might argue that mechanism (a) is not viable because it cannot occur unless hinges form at mid-height of the columns above and below the level where the girder hinges form. This hinge formation is not possible for strong column systems. The use of nonlinear static analysis to determine story strength and the story β factor is discussed later in this paper.

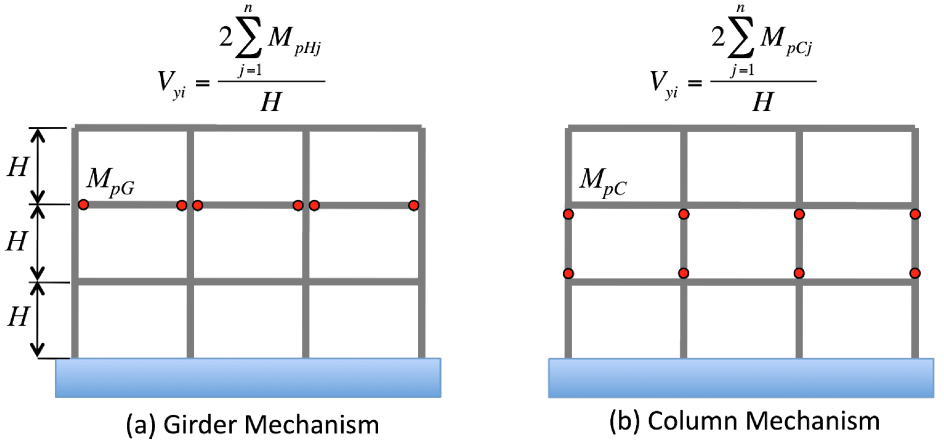

Figure 1. Computing Story Capacity for P-Delta Effects

The stability ratio computed by Eqn. 12.8-16 is a reasonable measure of the sensitivity of elastic structures to P-Delta effects. However, modification of member forces and displacements by the quantity 1/(1- θ) is not reasonable, particularly when θ exceeds 0.1. This is because inelastic dynamic response of systems with larger values of θ tend to have large residual deformations, and these deformations, which are not included in linear analysis, may eventually result in dynamic instability and collapse.

This problem is well known (e.g Gupta and Krawinkler, 2000), and several attempts have been made to modify ASCE 7 to provide more rational methods to assess the significance of P-Delta effects. One approach which was not approved for ASCE 7-10 is described in Part 1 of the *2009 NEHRP Recommended Seismic Provisions* (FEMA, 2010). This procedure establishes the upper limit on θ as 0.1, unless a nonlinear pushover analysis indicates that the post-yield slope of the

pushover curve is continuously positive up to the Target Displacement as defined by ASCE 41 (ASCE, 2007). The pushover analysis should include P-Delta effects, and must include degradation of strength. Alternatively, values of θ in excess of 0.1 may be allowed if it is demonstrated that the system complies with the requirements of nonlinear dynamic analysis as stipulated in Chapter 16 of ASCE 7. Peer review is required for either method of analysis.

NONLINEAR STATIC ANALYSIS

Nonlinear static analysis is not a "permitted" method of analysis in Table 12.6-1 of ASCE 7, and therefore cannot be used as the basis for designing the entire structural system. However, there are cases where nonlinear static analysis would be useful within the context of an ASCE 7 analysis and design:

1. *Determination of the presence of Lateral Strength-Weak Story or Lateral Strength– Extreme Weak Story irregularities*. Such irregularities are evaluated on the basis of the ratio of the lateral strength of two adjacent stories. If the strength of the lower story is less than 80 percent of the strength of the upper story the Weak Story irregularity exists, and if the strength of the lower story is less than 65% of the strength of the upper story, an Extreme Weak Story irregularity exists.

2. *Determination of the redundancy factor, ρ.* For certain situations this factor is evaluated by determining if the story strength is reduced by more than 33% when a key component of that story (e.g. a brace) is removed from the system. This approach is demonstrated in a redundancy factor example prepared by Charney (2010).

3. *Computation of the factor β which is used to determine the upper limit on the computed story stability ratios, θ associated with P-Delta analysis.* The β factor is the ratio of the factored seismic demand to the story capacity.

4. *Determination of the horizontal seismic load effect with overstrength, E_{mh}.* Generally, this factor is taken as $\Omega_o Q_e$, but an exception states that E_{mh} need not be taken as greater than the maximum force that can develop in the element as determined from a rational plastic mechanism analysis or nonlinear analysis utilizing realistic expected values of material strengths.

For items 1 and 3 above, analysis could be as simple as that shown in Figure 2, where a limited pushover analysis is used to determine the strength of a story of a moment frame. For item 2 a full three dimensional nonlinear static analysis analysis would be required. It might be possible to establish substructure models for item 4, but the larger models developed for items 1 through 3 could be utilized. Relatively simple force-deformation relationships (not including strength degradation) could be used for each of the situations because all that is required from the analysis is the computation of story strength.

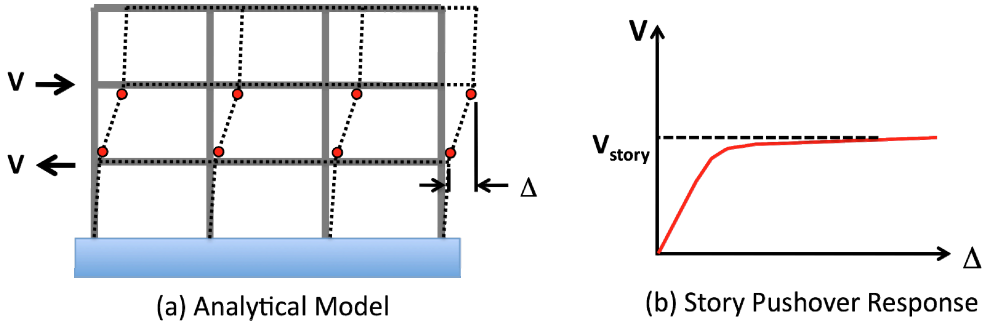

Figure 2. Using Pushover Analysis to Determine Story Strength

While not a required part of an ASCE 7 evaluation, several other aspects of the system performance could be developed using nonlinear static analysis. These include the following:

1. More realistic assessment of the potential for dynamic instability by using a nonlinear static pushover analysis to determine if the post-yield slope of the pushover curve is positive up to the target displacement.

2. Assessing the system compliance with strong column – weak beam requirements of ACI 318 and ANSI/AISC 341.

3. Visualization of the sequence of yielding, assessment of system over strength, and assessment of overall system ductility.

The above three points would require a more detailed model than required for the code compliance assessments listed earlier.

NONLINEAR DYNAMIC RESPONSE HISTORY ANALYSIS

Nonlinear Response History Analysis is generally used when the structure being designed does not adhere to the system limitation requirements of Table 12.2-1 of ASCE 7, or when the system is not listed in the table. The authority to circumvent Table 12.2-1 is provided in Section 12.2.1. The most common use of NHRA is in association with the design of tall buildings, wherein the structural system exceeds the height limitations of Table 12.2-1, or where a hybrid system, such as an outriggered core-wall is used. The Chapter 16 guidelines for performing the analysis define the basic requirements in terms of selecting and scaling of ground motions, modeling criteria, determination of design values for member forces and deformations, and acceptance criteria. However, these requirements are lacking in detail, and should be supplemented with a variety of guidelines that have been published, including those produced by the Structural Engineers Association of Northern California (SEAONC, 2007), the Los Angeles Tall Buildings Council (LATBC, 2008), the Council for Tall Buildings and Urban Habitat (CTUBH, 2008),

FEMA (2009), the Pacific Earthquake Engineering Research Center (PEER, 2010), and the National Institute for Standards and Technology (NIST, 2010).

While nonlinear dynamic analysis is generally regarded as the best method of analysis available, there are a number of barriers to a broad acceptance in the design community. These barriers include the lack of a comprehensive design basis that makes direct use of the analysis, concerns (real or perceived) about the complexity of the analysis, a general lack of training in dynamic response history analysis and in nonlinear analysis, and the necessity to select and scale aground motions for the analysis.

The placement of the linear and nonlinear dynamic analysis procedures in a separate chapter (Chapter 16) is also a barrier to acceptance. In the author's opinion the ground motion selection and scaling aspects of Chapter 16 should be moved into Chapter 11, and the analysis procedures should be moved into Chapter 12. This would generate the impression that linear dynamic and nonlinear dynamic analyses are simply two tiers of a hierarchy of increasingly sophisticated (and presumably increasingly accurate) methods of analysis.

While it would be effective, the above recommendation retains the rest of Chapter 12, which is seriously outdated. A better approach would be to completely rewrite Chapter 12 in terms of a comprehensive approach that utilizes both linear and nonlinear analysis in rational ways. The next section of this paper provides an outline for such an approach.

NONLINEAR ANALYSIS IN FUTURE EDITIONS OF ASCE 7

The current edition of ASCE 7 [ASCE 7-10] has evolved primarily from the ATC 3-06 *Tentative Provisions for the Development of Seismic Regulations for Buildings* (ATC, 1976). This document was published in 1978, before personal computers were generally available, and before nonlinear static or dynamic analysis was practical outside of a research environment. With the exception of the nonlinear dynamic analysis procedures that are provided in Chapter 16 of ASCE 7-10, code provisions for performing analysis for new buildings have remained relatively stagnant since 1978. Given that ASCE 7 will not be updated until 2016 and adopted until 2018, forty years could pass without any significant changes to the required analysis procedures in ASCE 7.

In the same 40 years, very significant advances will have been made in computer capacity and availability, and nonlinear static and nonlinear dynamic response history analysis will be available through number of commercially available programs. While not entirely automatic, the programs simplify some of the more tedious tasks associated with nonlinear modeling, even going so far as to provide "standard" force-deformations relationships that comply with ASCE 41. As mentioned earlier, there are several detailed sets of recommendations for performing nonlinear dynamic analysis, including those provided by Chapter 16 of ASCE 7-10.

Given all the advances over the past 40 years, one can wonder why the seismic provisions have not caught up. In the Author's opinion, part of the problem is that advanced analysis procedures are basically incompatible with the current analysis philosophy, which is based on two-dimensional linear procedures and a variety of ad-hoc corrections to account inelastic behavior, three-dimensional behavior, and dynamic response. Thus, the only way to remedy the situation is to start with a clean slate, and develop an analysis procedure that is consistent with modern technology, and with the principles of performance based design. The basic tenants of the new analysis method should be as follows:

1. The Equivalent Lateral Force method would be used only for preliminary analysis.

2. All analysis should be performed in three dimensions.

3. Diaphragms should be modeled as semi rigid.

4. All final analysis should directly incorporate P-Delta effects, and the sensitivity to such effects should be based on a comparison of results with and without P-Delta effects included.

5. The analytical model should be developed such that, at the minimum, a nonlinear static pushover analysis can be performed. The pushover model would be used to evaluate weak story irregularities, determine system redundancy factors, establish system and component overstrength requirements, assess the compliance with strong column - weak beam requirements, assess the likelihood of dynamic instability associated with P-Delta effects, and determine (in association with other factors) the required final level of analysis.

6. Based on the results of (5) above, the final analysis should be either a linear or nonlinear dynamic response history analysis. Analysis would be based on standardized suites of ground motions, scaled appropriately.

7. Accidental torsion should be included by adjustment of the center of mass of the floor diaphragms.

8. All analysis should include simultaneous application of the ground motions in two orthogonal directions.

9. Acceptance criteria for deformation should be based on shear-strain based damage measures, wherein such strains are monitored at the corners of the building. Acceptance would be based on mean response for both linear and non linear analysis, but nonlinear analysis results would be studied in sufficient detail to determine if outliers pose a significant risk.

A key aspect of the requirements would come in point (5) above where the decision is made whether or not to perform a nonlinear dynamic analysis. This decision could be based on a number of factors, including occupancy category, sensitivity to P-Delta effects, sensitivity to torsional response, type of hysteretic behavior, and use of seismic isolation or passive energy systems. Linear dynamic analysis would most likely be used for the majority of structures. Tola (2010) has shown that linear response history analysis is a very effective replacement for the equivalent lateral force method and the modal response spectrum methods of analysis.

There are numerous advantages to the above approach, and among the most significant is that inelastic behavior is explicitly investigated for all structures. The use of linear response history analysis as the "basic" method would be beneficial because analysts would use such procedures to develop expertise in performing response history analysis, and this would be very useful preparation for those circumstances where nonlinear dynamic analysis would be required. The required inelastic modeling of all structures would also provide useful experience in those cases that nonlinear dynamic analysis is ultimately required. An additional benefit of the above approach would be the direct incorporation of performance based design principles, and unification with the methods of analysis that are used to assess the performance of existing buildings.

ABSTRACT

The need to perform cost-effective seismic rehabilitation of essential facilities has made the use of nonlinear analysis techniques an attractive option. The estimation of seismic demands on structures requires explicit consideration of the structural inelastic behavior. Therefore, nonlinear procedures such as pushover analyses are inevitably going to be more widely used.

This paper presents a case study of a 10-story Pre-Northridge steel moment frame hospital building in California that was analyzed using nonlinear pushover analysis approach. Nonlinear force-deformation relationships and acceptance criteria of primary structural components were modeled in accordance to ASCE 41-06 and supplemented by experimental component testing results. Given the nature of steel moment frame buildings constructed during this era, existing connections are highly susceptible to damages during a major earthquake which could lead to an unfavorable failure mechanism. Based on nonlinear pushover analysis results, potential structural deficiencies will be identified and different rehabilitation methods will be presented. Besides, the comparisons of retrofit scopes between conventional and nonlinear methods will be highlighted.

Finally and most importantly, this paper also addresses some challenges found by the authors in the implementation of nonlinear pushover analysis in seismic retrofit application, as well as recommendations from practitioner perspectives.

INTRODUCTION AND BACKGROUND

This paper covers the process followed to improve the seismic performance of an existing non conforming hospital building in Southern California, so that it meets the requirements of current California seismic regulations. Back in 1994 Senate Bill 1953 (SB 1953) was passed as an amendment to the Alfred E. Alquist Hospital Seismic Safety Act of 1983 (Alquist Act), which was enacted to emphasize that essential facilities such as hospitals should remain operational after an earthquake.

The provisions of SB 1953 were developed to regulate the seismic performance of numerous existing, mostly pre-1973 buildings, which were not addressed by the original Alquist Act. SB 1953 established that hospital owners must conduct seismic evaluations on all pre-1973 hospital buildings providing critical care services, and implement seismic rehabilitations if needed.

The purpose of the paper is to examine the effectiveness and benefits of a nonlinear static procedure for the seismic analysis and retrofit design of an existing steel moment frame building. This subject building is on one of the mid-rise hospital buildings located in San Diego, California. The building was constructed in the early 70's using a steel moment frame as lateral system, with Pre-Northridge moment connections, and it is a non-compliant building per 2007 CBC (ICC 2007).

In order to meet the code requirements, the building was analyzed and will be retrofitted based on the results from nonlinear pushover analysis. By implementing this advanced analysis approach, the building's seismic performance was better understood and led to a more efficiently use of retrofit methods. The basis of the seismic analysis and design process is Chapter 34A of 2007 California Building Code (CBC), which in turn, references ASCE 41-06 *Seismic Rehabilitation of Existing Buildings* (ASCE 2007) with some modifications.

BUILDING DESCRIPTIONS

The subject building, a hospital building in San Diego, California, was constructed in 1973 and is a non-conforming building as defined in SB 1953. The building has eight stories above grade, with a roof-top mechanical penthouse. The building has a rectangular shape, measuring approximately 110 feet by 100 feet. The construction consists of light-weight and normal-weight concrete filled metal deck over wide flange steel girder system. The foundation system consists of isolated spread footing below all columns. The lateral force resisting system consists of steel moment frames. Figure 1 shows a three-dimensional view of the building and Figure 2 shows a typical East-West elevation of the building.

This building has two unique structural characteristics. Firstly, this building has a total of 10 moment frame columns and all of them would be subjected to bi-axial bending actions under seismic forces. Secondly, weld filler materials used at the moment connections were low-notch tough type, i.e., E70-T4 electrodes, which is non-compliance to the current code.

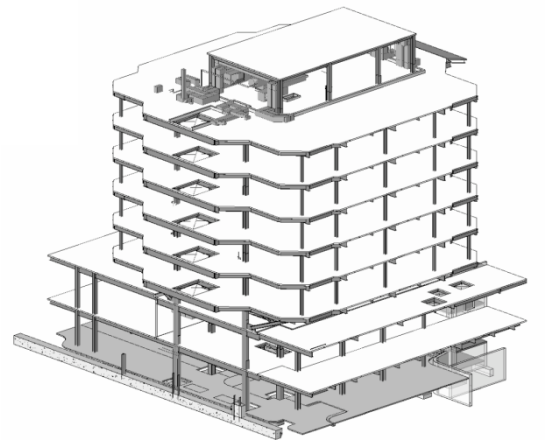

Figure 1. Three-dimensional view of the building

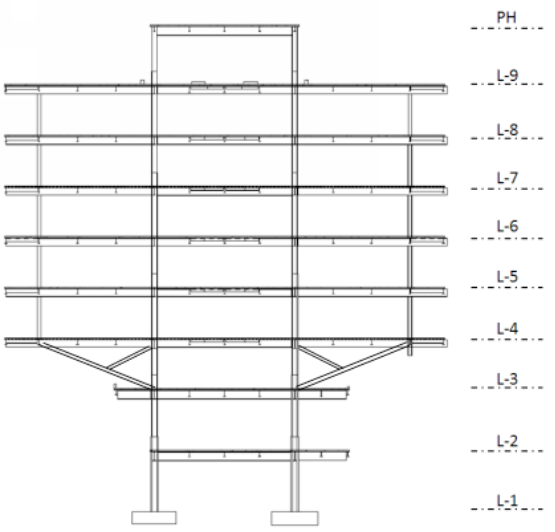

Figure 2. Typical East-West elevation of the building

ANALYTICAL MODELS

Geometrical Modeling

In the analytical model, only the primary lateral force resisting system (LFRS) of this building, steel moment frames, were modeled using Perform-3D (CSI 2006). Beams and columns were modeled using frame elements. Diaphragms were explicitly modeled using four-noded quadrilateral elements. Seismic masses were proportionally distributed on the diaphragm as nodal masses. The supports below each column were modeled as fixed base which mimics the condition of the proposed retrofitted foundation. Figure 3 shows a three-dimensional analytical model created in Perform-3D.

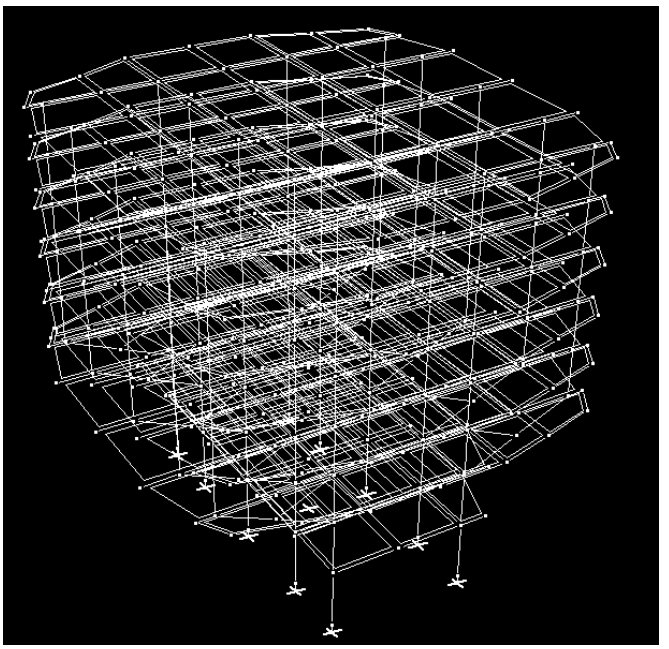

Figure 3. PERFORM-3D nonlinear model

Material Modeling

Material properties, based on a material testing program conducted for this project, were used to derive the non-linear backbone curves for plastic hinge behavior of steel beams and columns. In this project, the non-linear backbone curves given in ASCE 41-06 were implemented in the analysis for existing and retrofitted (i.e., welded top and bottom haunches) conditions. With the presence of the low-notch tough welds in the existing moment connection, cyclic test results are required by 2007 CBC to statistically substantiate the non-linear backbone curves used in the analysis. Experimental testing will be described later in this paper.

Diaphragms were modeled elastically as they were expected to remain elastic. During the course of analysis, if the diaphragm demands exceed the diaphragm capacity, inelastic materials would be used to capture the actual diaphragm behavior and force distributions.

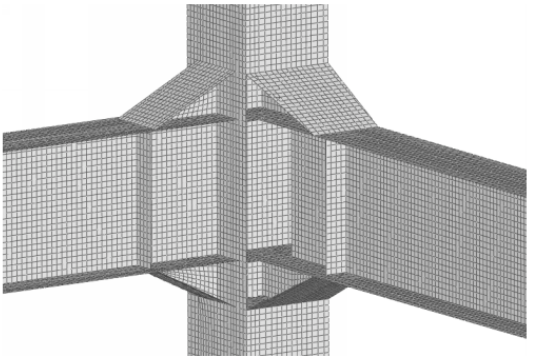
In order to achieve the performance-based design objectives, inelastic behavior of each component had to be limited to the target building performance level which translated to the so-called acceptance criteria. "Life Safety" is the target building performance level of the retrofitted building and the associated acceptance criteria of each structural component are recommended by ASCE 41-06.

Column Bi-axial Bending Effects

As previously mentioned, the lateral-force resisting system of this building is provided by spatial steel moment frames with moment connected beam framing into both the strong- and weak-axes of the wide-flange columns. The purpose of this supplemental study is to show that the presence of a statically loaded transverse beam

in a bi-axial moment connection has a small effect on the cyclic behavior of a strong-axis and weak-axis moment connection.

The detailed analyses were performed by Professor Chia-Ming Uang his student at University of California, San Diego, using the general purpose finite element analysis software ABAQUS. The model simulate the moment connection with W24 beams in both directions, with the proposed retrofitted scopes, i.e., welded top and bottom haunches (FEMA 2000) and welded cover plate to strengthen the column weak-axis. Figure 4 shows the ABAQUS model of the retrofitted bi-axial moment connection.



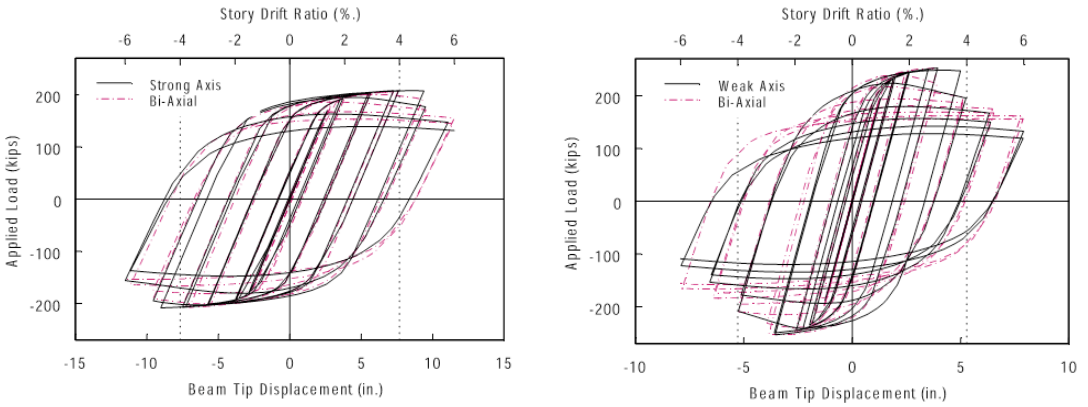


Figure 4. ABAQUS model of bi-axial moment connection

The cyclic loading protocol per AISC Seismic Provisions (AISC 2005) was imposed to the investigated beam end to simulate the story drift while the transverse beam was loaded statically to its expected plastic moment capacity. Figure 5a concludes that the global response of uni-axial bending and bi-axial bending is very similar when beam was cyclically loaded about the column strong-axis. Similar conclusion can be drawn for the beam cyclically loaded about the column weak-axis as shown in Figure 5b.

From this study, the bi-axial bending effect was not considered in the derivation of non-linear backbone relationship in the beam plastic hinges.

(a) Strong-axis bending **(b) Weak-axis bending**

Figure 5. Comparisons of hysteresis curves

Gravity and Lateral Load Modeling

Gravity loads and vertical component of seismic forces were applied as nodal and element loads on the primary lateral force resisting system. Self-weight of walls, beams and columns were included as part of gravity loads.

A fundamental mode lateral load pattern was used as recommended in ASCE 41-06. Fundamental mode load pattern is a vertical distribution proportional to the shape of the fundamental mode in the direction under consideration.

EXPERIMENTAL COMPONENT TESTING

The component testing is intended to serve two purposes in this project. Firstly, to validate the performance of moment connection with the presence of low-notch tough welds in the existing conditions. Secondly, to substantiate the non-linear modeling parameters and acceptance criteria of the retrofitted moment connections, as indicated in ASCE 41-06 that the non-linear modeling parameters and acceptance criteria can be derived using the experimentally obtained cyclic response characteristic of the subassembly.

The test specimens would closely represent the typical beam-to-connection connections in strong- and weak-axis of the building given that: (1) beam depth to column depth ratios will be essentially the same as those in the actual building, and (2) materials used for construction of the specimens will be representative of those used in the actual building.

A total of six specimens will be tested at the University of California at San Diego. All specimens represent the retrofitted condition using welded top and bottom haunches. Four specimens represent the beam bending about the column strong-axis and two specimens represent the beam bending about the column weak-axis.

The test set up shown in Figure 6 shows the vertical displacement δ_{act}, which is the control variable. The applied load will be monitored using a load cell, attached to the actuator. Each test specimen would be instrumented to measure the response quantities necessary to develop the non-linear backbone curves and acceptance criteria. The test specimens would be subjected to fully, reversed cyclic loading at increasing displacement levels in accordance with the loading protocol specified in the AISC Seismic Provisions (AISC 2005). Results for the specimens will be normalized to nominal strength and average backbone curves will be calculated. Design parameters and acceptance criteria will be developed based on the procedures outlined in Section 2.8.3 of ASCE 41-06 Supplement No.1.

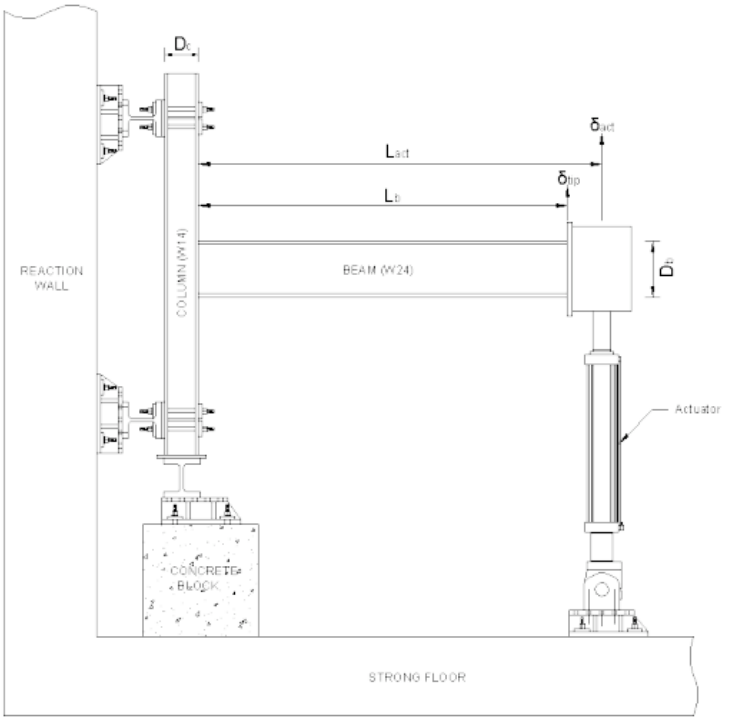

Figure 6. Experimental test set up at UCSD

RESULTS AND DISCUSSIONS

Overall Structural Performance and Mechanisms

Non-linear response of the building before and after retrofit can be illustrated in Figure 7 that compares the pushover curves of existing and retrofitted buildings in East/West and North/South directions. The solid lines represent the retrofitted condition while the dash lines represent the existing condition. It is clear that the overall structural responses are greatly improved after the building has been retrofitted both in strength and ductility.

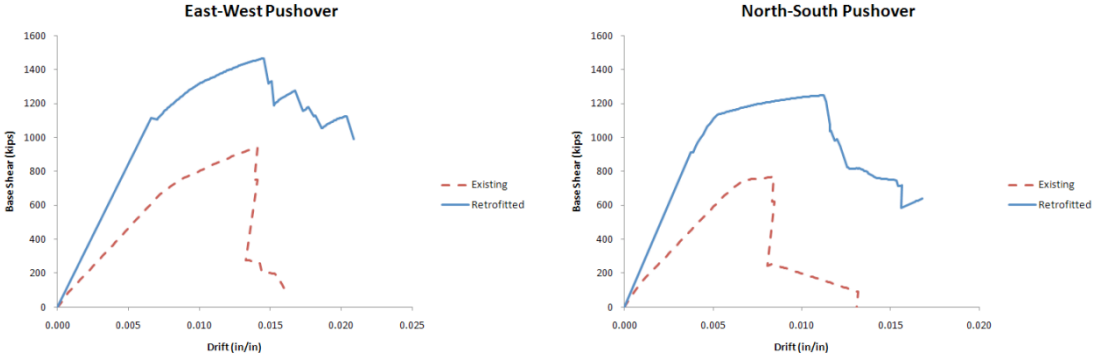

Figure 7. Pushover curves for existing and retrofitted structure

There are two main structural deficiencies of the existing building. Those are a soft-story and excessive inter-story drifts in the lower floors.

For soft-story mechanism, plastic hinges were formed in the columns between the 1st and 3rd floors. Figures 8a and 9a illustrate the soft-story mechanism of the existing building in the East/West and North/South direction, respectively. The red dots indicate the locations of potential plastic hinges. Soft-story mechanism is undesirable because of limited ductility which could lead to a potential loss of vertical load carrying ability. This explains an abrupt drop in the pushover curve of the existing building in Figure 7. As soon as the soft-story mechanism was developed, the structure loses the vertical load carrying capacity which will eventually lead to a structural collapse.

At the same time, excessive inter-story drifts at the lower floors, as shown in Figures 8a and 8b, would adversely increase P-Delta effects on the columns and eventually exacerbate the soft-story mechanism to develop much earlier.

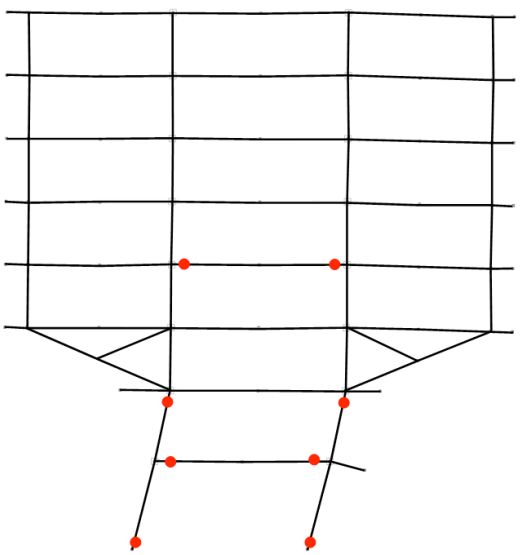

Figure 8a. Existing Structure (E/W)

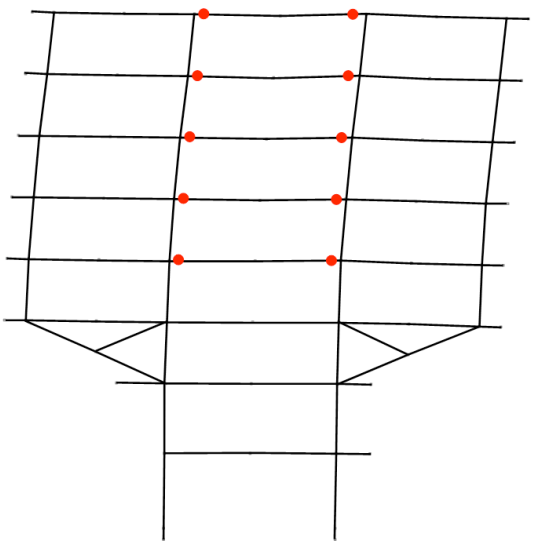

Figure 8b. Retrofitted Structure (E/W)

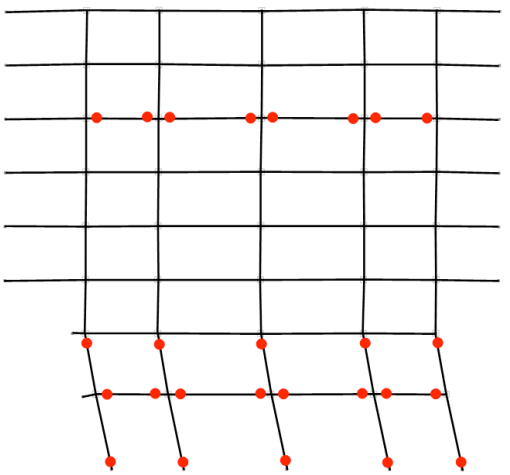

Figure 9a. Existing Structure (N/S)

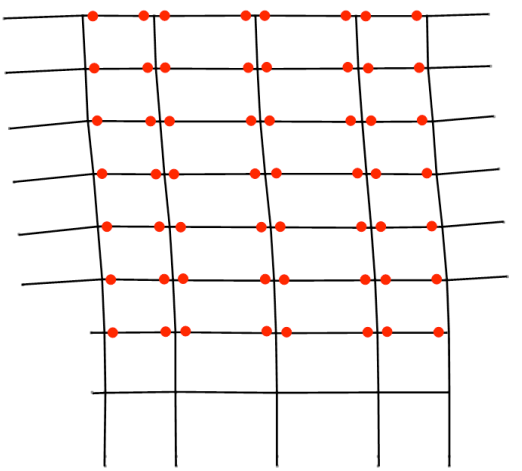

Figure 9b. Retrofitted Structure (N/S)

However, the building exhibits totally different building mechanism after retrofit work has been implemented. As indicated in Figures 8b and9b, strong column-weak beam mechanism would be achieved using the retrofit methods described later in this paper. Plastic hinges form in the beams which is desirable and in turn yields the greater system ductility.

Seismic Retrofit Methods

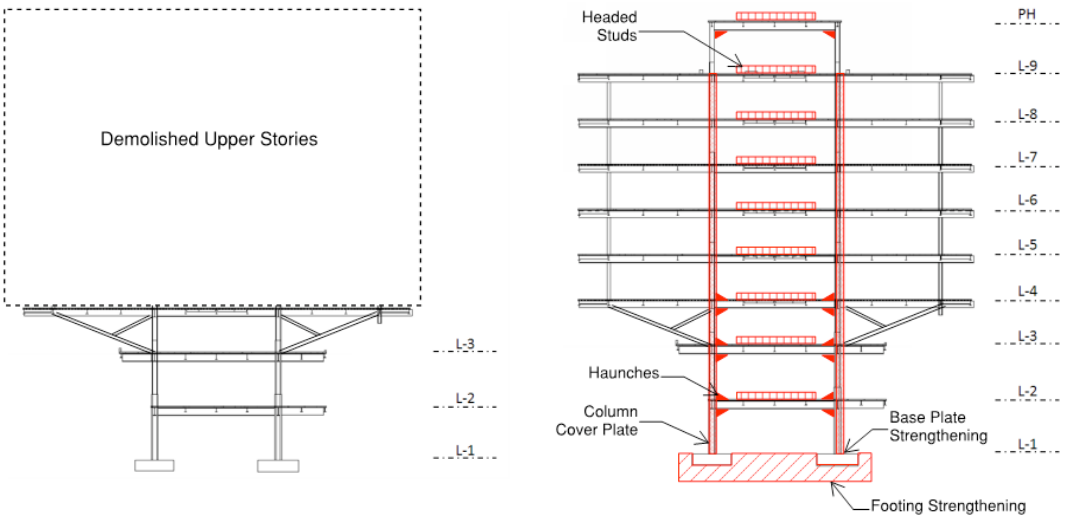
Based on nonlinear analysis results, several retrofit methods were investigated to achieve the target structural performance level and the preferred building mechanism, more importantly, with minimal disruptions to the functionality of the building. Figures 10b and 11b graphically illustrate the retrofit scopes of this building.

For the mitigation of soft-story mechanisms, all ten columns that are part of lateral-force resisting system were strengthening using welded cover plates. These additional plates were to increase strength and stiffness. Added strength would prolong the formation of column plastic hinges and subsequently force a beam hinging mechanism. Additional stiffness is intended to reduce inter-story drifts, hence minimize the demands induced by P-Delta effects.

To accommodate the expected inelastic drift, the plastic hinges in the beams (with Pre-Northridge moment connections) must be developed within the beam span, remote from the face of the column. This behavior could be obtained by locally stiffening and strengthening type fully restrained moment connections. In this project, welded top and bottom haunches will be implemented at several locations throughout the building. With this type of connection, the inelastic action (plastic hinges) will be forced to take place away from the column face, where its performance is less dependent on the material and workmanship of the welded joint. In the case where only bottom haunch can be installed, the replacement of the existing welds with the conforming welds will be part of the retrofit scopes.

Another mean to minimize inter-story drifts is to impose a fixed condition at the base of building. The capacity of existing spread footings was neglected and new mat foundation was proposed to provide fixity at the base of columns. Column base plate strengthening was proposed accordingly.

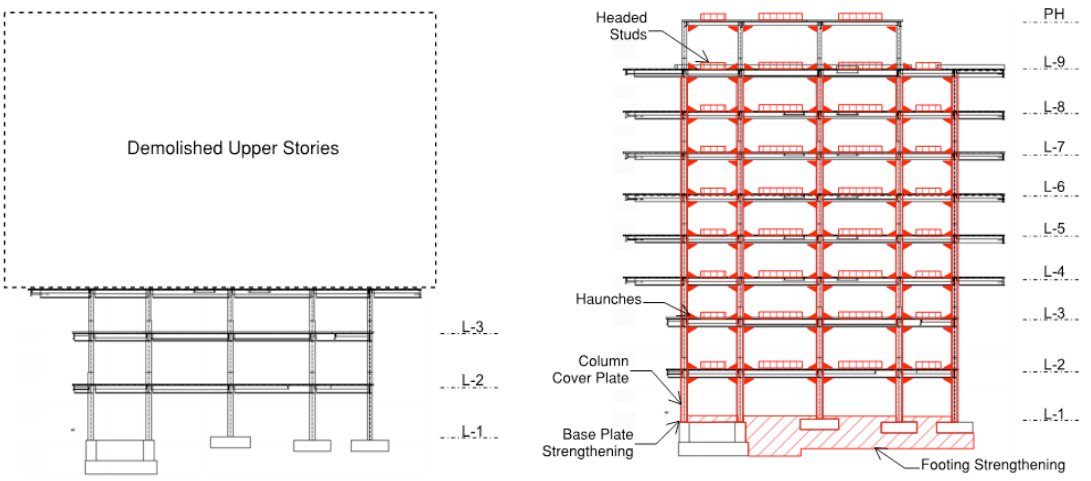
Although this building has concrete filled metal deck over wide flange steel girder system, they are lack of headed studs. Therefore, new welded head studs will be installed along the moment frame beams at every floor as part of the retrofit scopes. They were designed to have adequate shear capacity to transfer inertia forces from the diaphragm to the lateral-force resisting system.



Benefits of Nonlinear-based versus Conventional-based Retrofit Scopes

One of the major benefits for using nonlinear pushover analysis in seismic retrofit projects is an understanding of the possible building mechanisms and strategically modification of the structure to clearly achieve a favorable mechanism. Consequently, retrofit of unnecessary areas and missing retrofit of critical areas can be avoided. Scopes of retrofit based on conventional approach or Linear Dynamic

Procedure (LDP) can be drastically reduced when Nonlinear Static Procedure (NSP) is implemented.



Figures 10 and 11 show the comparison between the retrofit scopes based on conventional versus non-linear approach for East/West and North/South moment frame, respectively. Based on the conventional approach, the demolition of the upper stories (4th to Penthouse) was previously proposed. Based on the non-linear approach, the building owner can save the upper floors with some localized retrofit works.

As the scope of retrofit reduced, overall construction cost also significantly decreased. In addition, construction process can be incrementally performed in phases. Consequently, the disruption of hospital operations can be greatly minimized during the construction.

Figure 10. Nonlinear versus conventional E/W frame retrofit

(a) Conventional Approach (b) Nonlinear Approach

Figure 11. Nonlinear versus conventional N/S frame retrofit

SOME RETROFIT DESIGN CHALLENGES

As mentioned previously, a major goal of the proposed retrofit is to implement it with minimal disruptions to the operations and functionality of the building. This constrain was the condition that led to the major project design challenges, which are described below.

- The required strengthening of the foundation created the two most challenging aspects of the project. First, the new mat foundation will have to be built below six existing spread footings using underpinning method and tied back to the two existing wall footings. Second, all foundation work will have to be performed below the slab-on-grade using tunneling and mining approaches. This solution had been driven by the amount of disruptions in the first floor lobby area above and the infection control aspects of the operating hospital if the foundation work ought to be done from above the slab-on-grade.
- The presence of major electrical and mechanical equipment on the 4th floor and penthouse, forced the development of alternate retrofit details for those regions, although, not in all cases it was possible to develop such alternate details, creating coordination challenges for the other disciplines involved in the project. These challenges, therefore, had to be resolved by the entire design team.

CONCLUSIONS

This paper presents a seismic retrofit case study of a hospital building in Southern California. The structure was analyzed and the seismic retrofit designed using both non-linear and conventional approaches. In addition, experimental component testing was included as part of the process such that the designer can abandon excessively conservatisms embedded in the design standard/code. The final

retrofit strategies were proposed based on the non-linear pushover analysis results and the retrofit methods were discussed in details.

Having a better understanding of the structural performance and failure mechanism, thanks to the nonlinear based analysis, helped to better address the key structural deficiencies of the building. As a result, less invasive and more effective retrofit strategy can be implemented. Most importantly, cost saving can be maximized while the disruption of hospital operations can be significantly minimized during the construction.

The graphical comparisons of the retrofit scopes attests how much saving may be put on the owners by implementing nonlinear analysis over the conventional analysis method.

Finally, this paper presents some design challenges that the authors faced during the design development phase and some viable workaround solutions.

ACKNOWLEDGEMENT

The authors would like to thank Professor Chia-Ming Uang and Mr. Dong-Won Kim for assisting on the column bi-axial effect study and for conducting an upcoming component testing at University of California, San Diego.

Seismic Vulnerability Assessments of Marine Structures Using Non-Linear Static Analysis Procedures

Edward. H. Stehmeyer III, P.E., M. A.S.C.E.[1]

[1]Collins Engineers, Inc., 1180 Sam Rittenberg Boulevard, Suite 105, Charleston, SC 29407; PH (843)763-1576; email: estehmeyer@collinsengr.com.

ABSTRACT

As part of maintenance and future planning for marine structures, a condition assessment and load rating are traditionally performed every 2 to 5 years, depending on the use and importance of the structure. Traditionally, the load rating of these structures only considers the "day-to-day" vertical service loading. As a greater understanding of the inherent, seismic hazards present in areas of the United States with marine infrastructure including those on the east and west coasts, vulnerability studies of existing structures are becoming more common. These studies estimate the expected behavior of the structure under a variety of loading conditions. This assessment helps determine if the facility needs to be repaired, given its current condition, or upgraded for changes in operational loading or use. This paper will demonstrate the implementation of non-linear static analysis techniques for assessing the vulnerability of existing marine infrastructure. In particular, the effects of concrete pile deterioration and concrete pile-to-pile cap connectivity on the service and lateral/seismic resistance of a typical pile supported marine structure is presented. The impact of considering the current condition state of the structure throughout the analysis will be emphasized.

INTRODUCTION

The importance of marine infrastructure is often overlooked by the public; however, its usefulness following a natural disaster, such as an earthquake can be immeasurable. The recent damage at the Port of Port-au-Prince, Haiti following a 7.0 magnitude earthquake demonstrated the potential for serious damage to a vital rescue and aid transportation point. As a result, owners of marine infrastructure have begun to seriously consider incorporating seismic vulnerability studies into their routine structural condition inspection and assessments. This paper will highlight the seismic assessment process for a marine structure as it progresses from preliminary drawing review to performing a comprehensive condition survey, followed by a service and seismic lateral loading analysis to determine the displacement capacity. The importance of considering the current structural condition of the substructure elements and the proper modeling of their connection to the superstructure are emphasized as they relate to the service and seismic resistance of the facility.

SEISMIC VULNERABILITY ASSESSMENT PROCESS

The seismic vulnerability assessment of any type of structure involves several common phases. In general, it includes (1) a Preliminary Drawing Review, (2) a Structural Condition Investigation, (3) a Service Load Assessment, and (4) a Seismic Load Assessment. The goal of these studies is to develop a comprehensive condition assessment of the structure that identifies deficiencies that affect the service loading capabilities of the structure as well as identify the vulnerability of the structure to seismic loading. The unique portion of the assessment phase for marine infrastructure is the above water and underwater structural condition assessment that have to be performed as part of phase 2. The following serves to briefly describe the key elements in each phase.

PRELIMINARY DRAWING REVIEW

Conducting a preliminary drawing review is the best preparation for conducting an efficient field investigation. The focus of this review should not only be on the general layout of the structure, but also on the critical structural details that support service and seismic loading. This will establish a checklist of items that need to be verified in the field to determine the as-built construction of the structure.

STRUCTURAL CONDITION INVESTIGATION

For many marine structures, the condition investigation will involve above-water and below-water investigations to document the structure's existing condition. Often the normal deterioration of a structure in a marine environment can limit the structure's capacity for both service and seismic loading. Deterioration in the form of concrete cracks and spalls or corroded steel elements could potentially cause weak links in the structural system. The product of the condition investigation is a report detailing the extent of deterioration throughout the facility and the potential impacts of these defects on the overall performance of the structure.

SERVICE LOAD ASSESSMENT

The service load assessment is typically performed only when significant deterioration is noted or when the intended use of the facility changes. This assessment will provide the owner with a service load capacity for the structure based on its existing condition. In addition, recommended repairs as necessary to meet or exceed the current service loading demands will be included. Often, these deficiency repairs should be made even if a seismic assessment is not being performed.

SEISMIC LOAD ASSESSMENT

The seismic load assessment of a marine structure traditionally considers either the existing condition or the repaired condition of the structure based on the findings of the Service Load Assessment. The appropriate regional seismic hazard is

applied to the structural model and the displacement capacity of the elements is compared to the displacement demand of the seismic hazard. This is referred to as performance based design and assessment which has been adopted for the design of new bridges (Caltrans 2010, SCDOT 2008) and for pier and wharf structures (MOTEMS 2010).

EXAMPLE MARINE STRUCTURE

A typical concrete wharf structure that was constructed in 1974 was chosen to demonstrate the service load and lateral/seismic assessment process of a marine structure. The structure consists of a grid of prestressed concrete piles supporting reinforced concrete pile caps that run in the transverse direction and a reinforced concrete deck structure that spans between caps in the longitudinal direction. The wharf measures 677 feet long by approximately 64 feet wide. The structure is also surrounded by adjacent structures on all sides. A typical section of the demonstration structure is shown in Figure 1. The wharf has a mixed operational use including storage and berthing for vessels. The distance from the deck to the channel bottom varies from 14 feet on the inboard side to 56 feet on the outboard side at mean-low water.

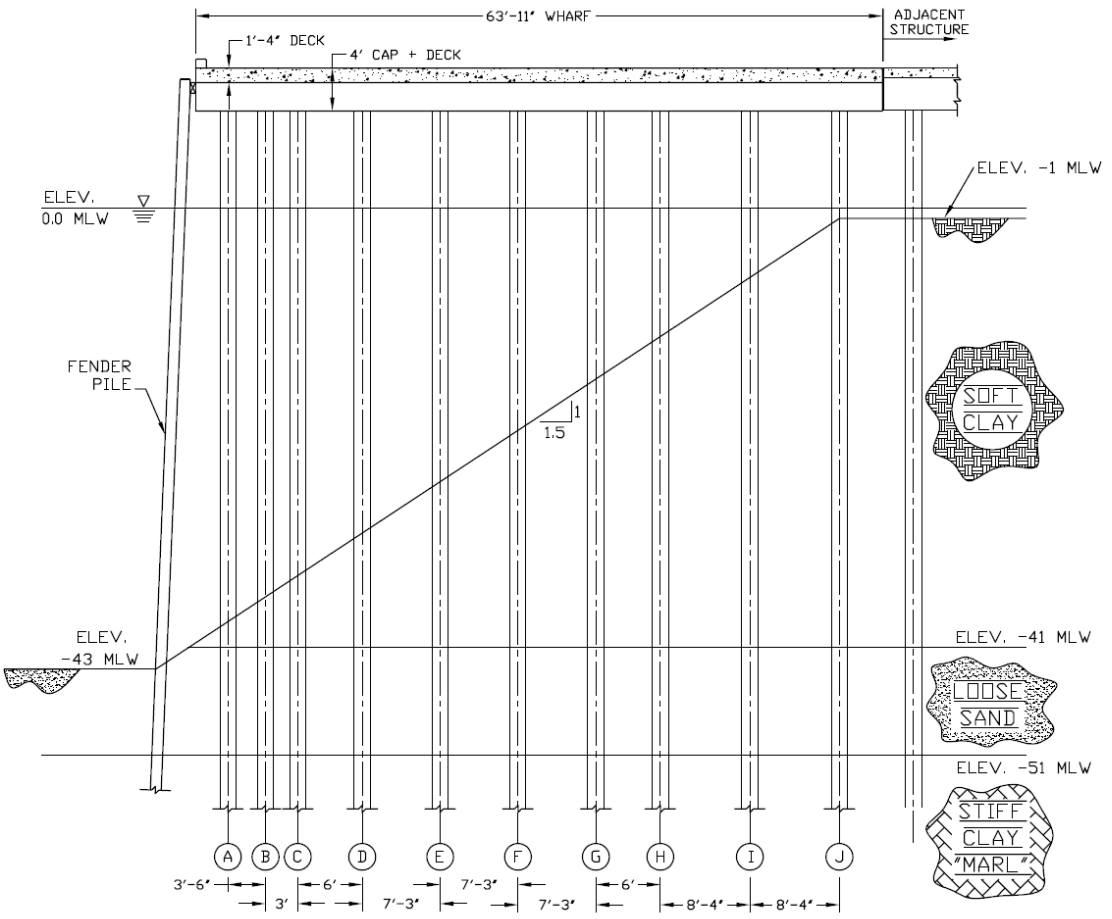

Figure 1: Example Wharf Structure Typical Section

The existing plumb piles in this structure measure 18 in. square and are 83 feet long based on an existing design drawing review. The longitudinal reinforcing consists of 16 - 7/16 in. 250 ksi prestressing strands in a square pattern. Shear reinforcement and confinement are provided from 40 ksi number 5 gage steel wire, spaced at 3 in. over the first and last 4 feet of the pile, and 6 in. spaces through the remaining pile length. The compressive strength of the concrete was f'_c = 5,000 psi, as was common based on the time period when the facility was constructed (MOTEMS 2010). The effective prestress force in the strands was set equal to $P_s = 0.7 \times f_{pu} \times A_{ps}$. This calculation results in an effective prestressing force of 18.9 kips per strand, including losses. The original design plans show that the top of the piles were connected to the pile cap using 4 in. of embeddedment into the pile cap and 4 – number 8 rebar dowels with 18 inches of embedment into the cap. The original pile cross section is shown in Figure 2.

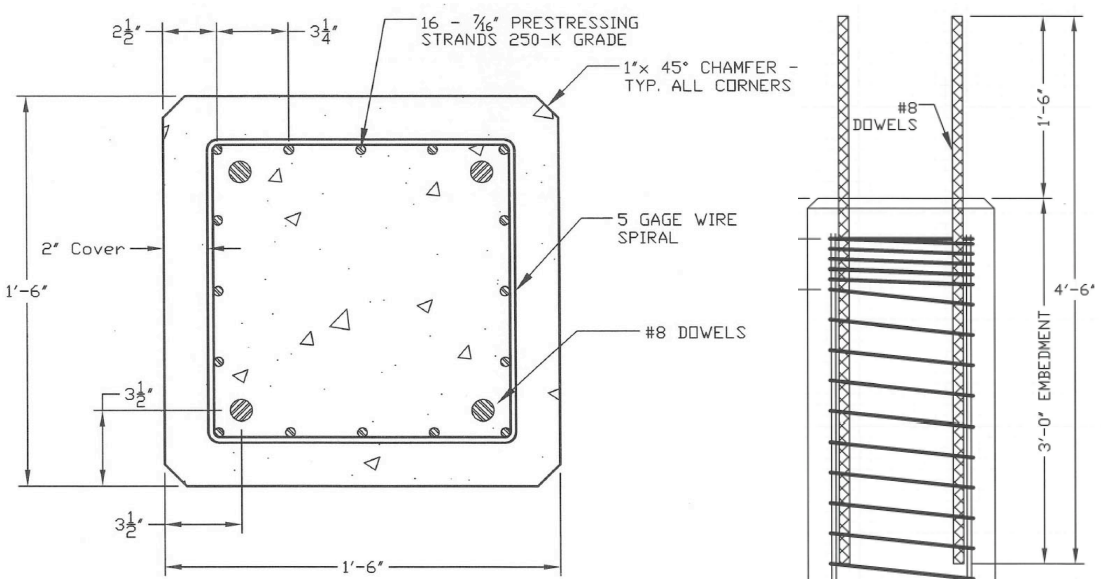

Figure 2: Original Prestressed Concrete Pile Section & Top Connection

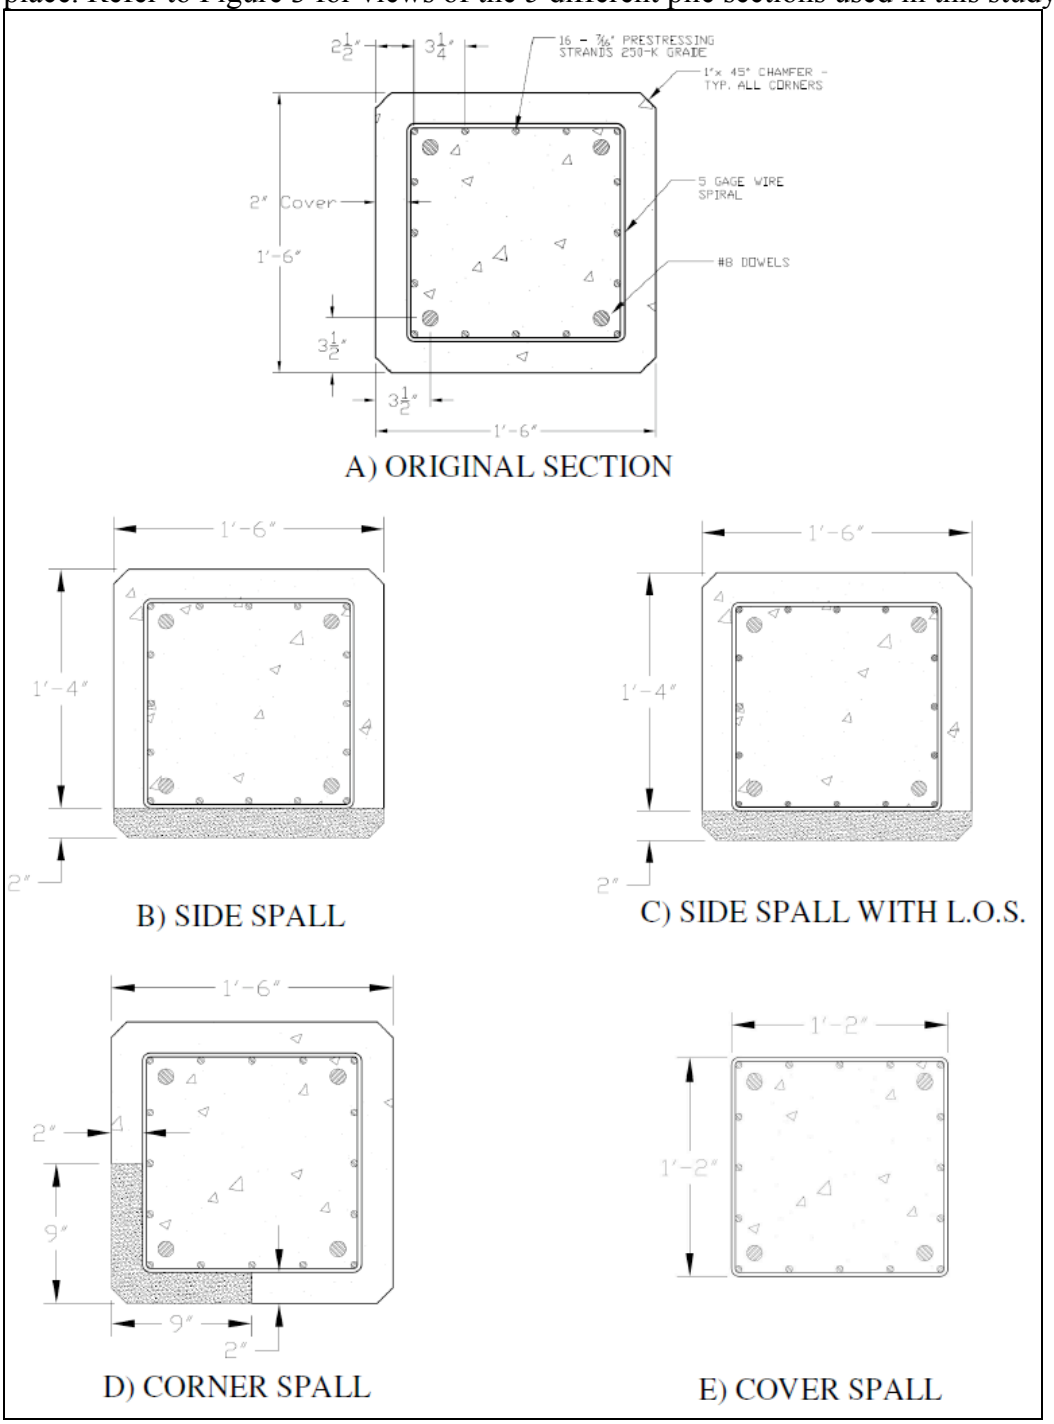
EFFECT OF PILE CONDITION ON SERVICE AND SEISMIC CAPACITY

In order to demonstrate the importance of considering the structure's existing condition state in service load and seismic assessments, a moment-curvature analysis is performed. The structural capacity of a single prestressed concrete pile supporting the example marine structure is analyzed in 5 different condition states. Namely, the "original section" model considers the section with no defects, while the remaining models consider typical defects observed in marine structures. In particular, the "side spall" model considers the loss of the cover concrete on one side of the section, and the "side spall with LOS" model considers a single sided cover spall and loss of section (LOS) of the exposed prestressing strands. It should be noted that since the area of 5 prestressing strands are reduced, the effective prestress in each of the strands in the section were increased or decreased based on a proportional stiffness

approach. The "corner spall" model considers a corner spall defect in the pile section and the "cover spall" model considers complete loss of the cover concrete in the section analysis. This cover spall can be thought of as either an extensive impending spall where the concrete is not bonded well to the core, or as the condition of a severely damaged pile where significant deformation of the element has already taken place. Refer to Figure 3 for views of the 5 different pile sections used in this study.



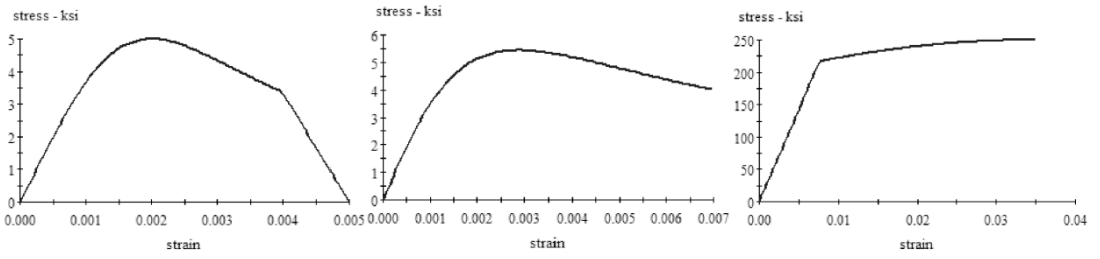


Figure 3: Various PS Concrete Pile Sections Used in the Cross Section Analysis

MOMENT-CURVATURE ANALYSIS

For each cross section case, the moment curvature and axial-moment interaction curves are developed using the software XTRACT (Imbsen 2005). This analysis includes non-linear material models and widely recognized properties and limits for concrete and prestressing (Caltrans 2010, SCDOT 2008, MOTEMS 2010).

A Mander unconfined concrete model was implemented for the concrete outside of the core of the pile while a confined concrete model was used for the inner core (Mander and Priestly 1988). Since the shear reinforcing is modeled through confinement in the pile core, the only other material needed for the model is the prestressing steel. The prestressing strands were modeled using a prestressed steel material model with properties consistent with 250 ksi strand material (Caltrans 2010, SCDOT 2008, MOTEMS 2010). The effective prestress identified previously was also included in the cross sectional analysis. The stress strain curves for the material models are depicted in Figure 4.

A) Unconfined Concrete B) Confined Concrete C) Prestressing Strand

Figure 4: Non-Linear Material Models for the Prestressed Concrete Pile

The original section and cover spall sections were only run for a single direction of moment loading since the section is symmetrical. The defects used in the other cross sections cause an asymmetric condition about the primary x-x axis, therefore moment curvature analyses were performed for positive and negative bending about the x-x axis and the y-y axis.

The results of the cross section analysis revealed several interesting observations as shown in Figures 5 and 6. Since the deteriorated sections are not symmetric about the primary bending axes, different values of effective yield moment, effective yield curvature, and transformed moment of inertia are realized. The cover spall moment curvature behavior is similar to a normally reinforced concrete section since it does not have any unconfined concrete in compression that eventually spalls off. Similar performance of the side spall sections was observed when the moment caused compression on the side where the cover concrete had spalled off. As expected, when the moment was applied to the side opposite of the identified defects, the moment curvature behavior is close to that of the original section. In addition, bending about the minor axis typically exhibited closer behavior

to the original section since the compressive area in both positive and negative bending was only slightly reduced by the defect.

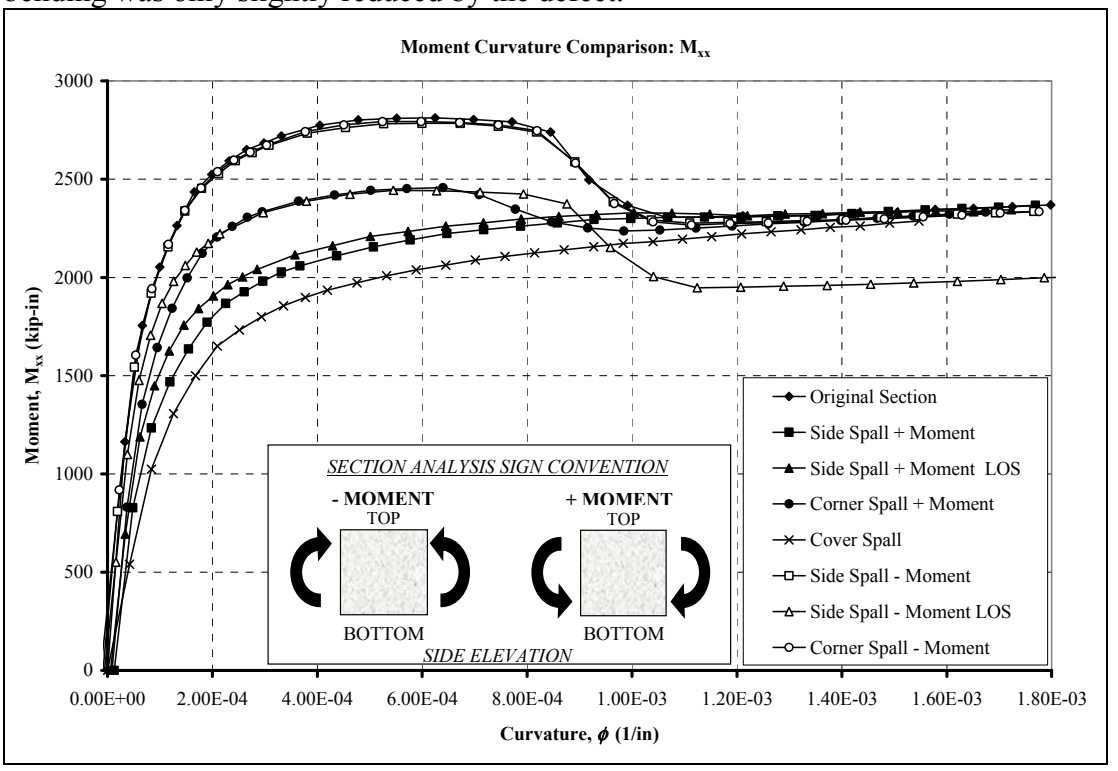

Figure 5: Moment - Curvature Comparison for Moment about the X-Axis

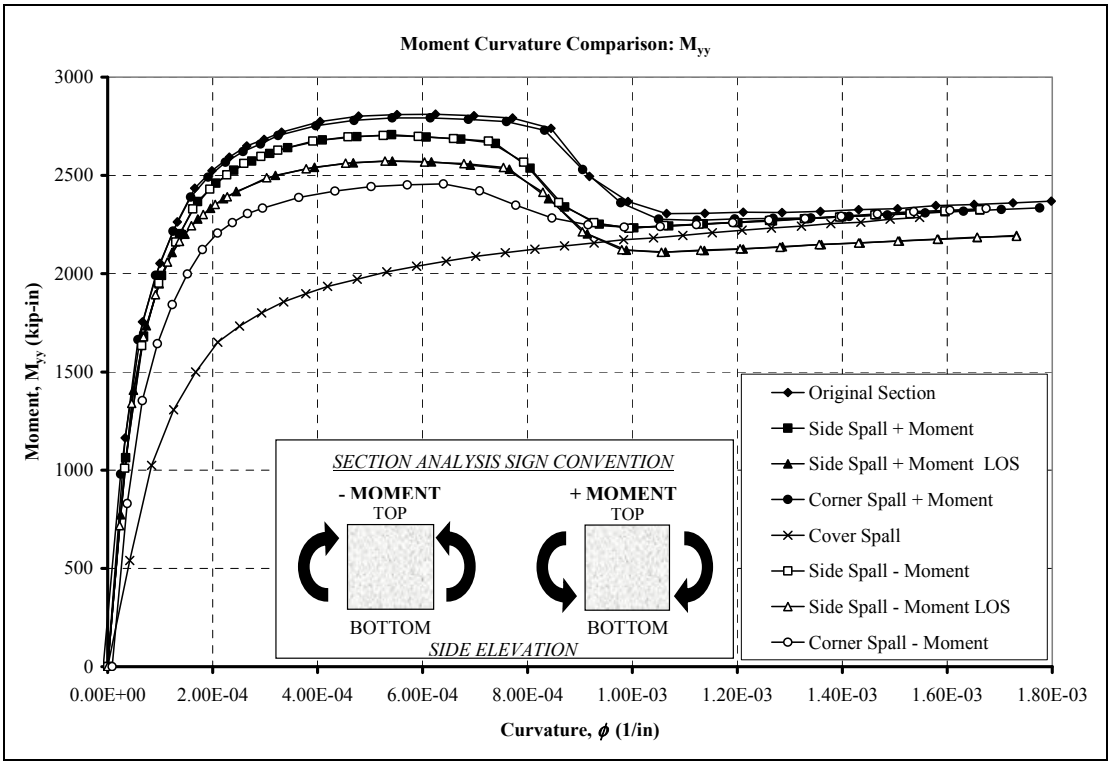

Figure 6: Moment - Curvature Comparison for Moment about the Y-Axis

The cross section "Side Spall with LOS" exhibits a similar shape to the original section; however, the overall performance was lower for a moment applied causing tension in the strands with a loss of section. The resulting effective cross section properties for each section are illustrated in Table 1.

Table 1: Effective Cross Section Properties

Cross Section	Area, A_g (in^2)	Total Area of Steel, A_{pst} (in^2)	Trans. Moment of Inertia, I_{tx} (in4)	Trans. Moment of Inertia, I_{ty} (in4)	Eff. Yield Moment, M_{ye} (kip-in)	Eff. Yield Curvature, f_{ye} (1/in)	Curvature Ductility
Original	324	1.728	9879	9879	2766	0.000188	9.55
Side Spall +M	288	1.728	7486	8917	2192	0.000227	7.812
Side Spall -M	288	1.728	7486	8917	2733	0.00018	9.81
Side Spall +M with LOS	288	1.593	7363	8833	2218	0.00018	9.572
Side Spall +M with LOS	288	1.593	7363	8833	2341	0.000134	13.92
Corner Spall +M	292	1.728	8502	8502	2365	0.000174	9.597
Corner Spall -M	292	1.728	8502	8502	2740	0.00018	9.88
Cover Spall	196	1.728	4347	4347	2003	0.000254	6.08

The axial-moment interaction of each section was also calculated considering code reductions for strength (ACI 2005). In each case, the overall capacity of the section was reduced by the identified deficiencies. The curve typically shifts inward on the side of the graph corresponding to moment causing compression on the side missing cover concrete. In addition, the largest difference in overall capacity was seen in the cover spall section with a 45% reduction in maximum moment capacity compared to an 18% to 22% reduction for the other sections. It is important to realize that these defects not only reduce the strength of the member, but they also reduce the stiffness and overall ductility of the member.

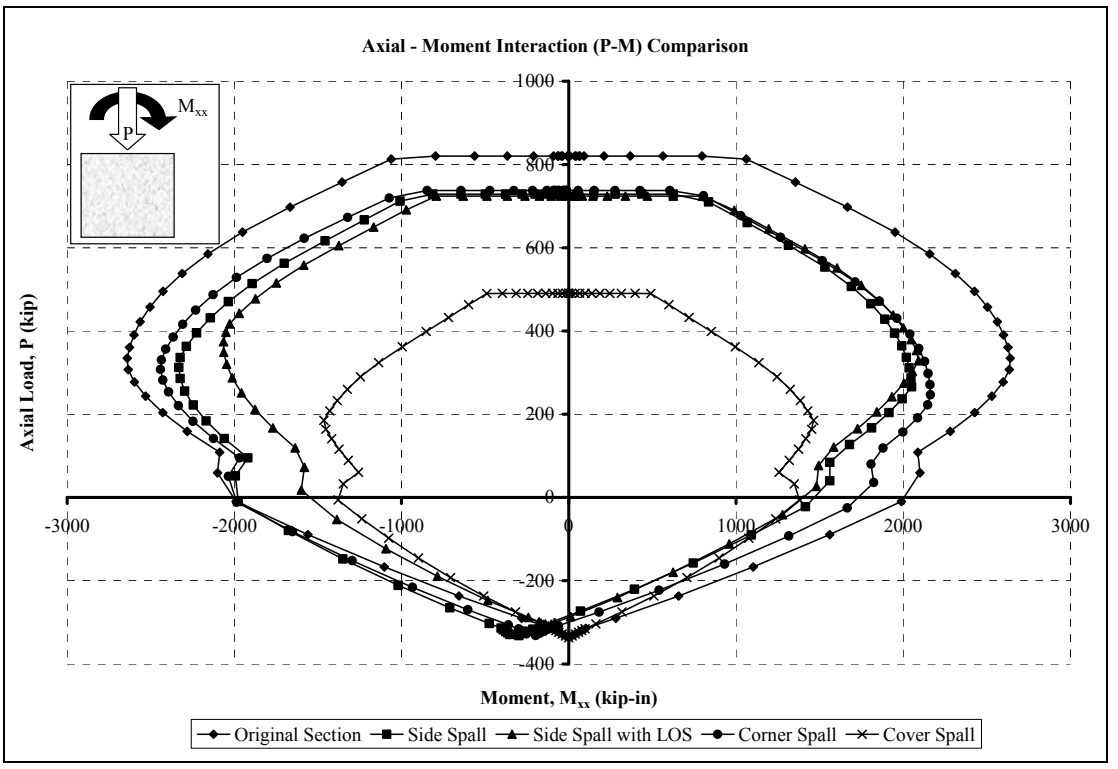

Figure 7: Axial - Moment Interaction Comparison for Moment about the X-Axis

EFFECT OF PILE-TO-PIILE CAP CONNECTION ON SEISMIC CAPACITY

The pile to pile cap connection plays an important role in the lateral and seismic resistance of a moment frame marine structure. These structures, while typically flexible, rely on frame action to resist seismic excitations. The frame action requires the piles to endure moment and shear loading along their length with various moment distributions based on the pile top to pile cap connection condition. As part of the seismic vulnerability assessment of the example structure, the effectiveness of the pile top connection is considered.

PILE-TO-PILE CAP CONNECTION MODEL

The dowels extending into the pile cap are #8 rebar which will not fully develop the original pile section moment capacity at the connection. In addition, this size of reinforcement would require an embedment length of 29 in. in the 4,000 psi compressive strength concrete cap (ACI 2005). Since only 18 in. of embedment is provided, a partial fixity condition exists and the reinforcement will only be able to develop 62% (18/29) of the rebar yield stress. The limiting moment capacity, M_{LIM} is calculated using the limiting steel stress. The pile-to-pile cap connection is modeled as an elasto-plastic Moment-Curvature hinge at the connection of the pile to the pile cap. The first leg of the curve represents the section stiffness up to the limiting moment. The cracked section moment of inertia is used to determine the limiting curvature value. The hinge is incorporated in a global finite element model of the wharf to determine the non-linear pushover capacity of the pile bent.

SUPPORTING SOIL MODEL

The soil chosen for this study is a typical soil profile found in the harbor region of Charleston, South Carolina. The upper 40 feet of the soil column consists of soft, organic clay. Below this clay layer, a 10 foot thick loose sand layer was identified. These upper layers are supported by stiff clay that is locally referred to as "marl". The soil profile was modeled in the software program L-Pile (Ensoft 2010) to obtain the non-linear "p-y" curves for the soil over the height of the soil column. It should be noted that as the channel bottom deepens along the bent, the soft clay layer springs are re-calculated at the appropriate depths. For the purposes of this study, the soil profile is assumed to be parallel along the width of the wharf and consistent along the length of the wharf. Table 2 illustrates the layer thickness, soil properties, and corresponding non-linear spring models used to represent the soil.

Table 2: Soil Properties and Corresponding p-y Models

Soil Type	Thick-ness (ft)	Eff. Unit Weight, γ' (pcf)	Cohe-sion, c (psf)	Friction Angle, ϕ (Deg.)	Lateral Subgrade Modulus, k (pci)	Strain Factor, ε_{50}	p-y Model
Soft Clay	40	46	250	0	30	0.02	Matlock (1970)
Loose Sand	10	56	N/A	30	20	N/A	API Sand (1987)
Stiff Clay	>85	56	2500	0	1000	0.005	Stiff Clay w/ F.W.

NON-LINEAR PUSHOVER ANALYSIS – PILE CAP FIXITY STUDY

In order to assess the impact of pile-to-pile cap fixity on the lateral performance of the wharf bent, a 2-D finite element structural model is developed using SAP2000 (CSI 2010) as shown in Figure 8. Four different models were developed for this study. They include variations of fixity between the pile and pile cap from fully fixed, to fully pinned at the top. The effects of partial fixity are also modeled by an elasto-plastic hinge for the doweled connection into the cap. Two models are developed using this technique with hinge properties consistent with the limited development length and one that considers the dowels to be fully developed for comparison purposes. The model also incorporates the non-linear moment curvature hinge behavior of the original pile section along its length using the SAP2000 section designer. A pushover analysis was performed by incrementally pushing the models to the left and right up to 48 in. of displacement. The models also had the tributary seismic weight applied during the analysis.

The results of the non-linear pushover analysis are presented in Figure 9. It can be seen that the pile-to-pile-cap connection model plays a significant role in the overall capacity of the bent. As expected the fixed and pinned top case bound the responses of the bent with the partial fixity lying between. It is interesting to note

that the limited, partial fixity case represents a decrease of 24% from the fully fixed case and a decrease of 6% from the fully developed rebar model. No significant differences were noted between pushing to the right versus the left for this structure.

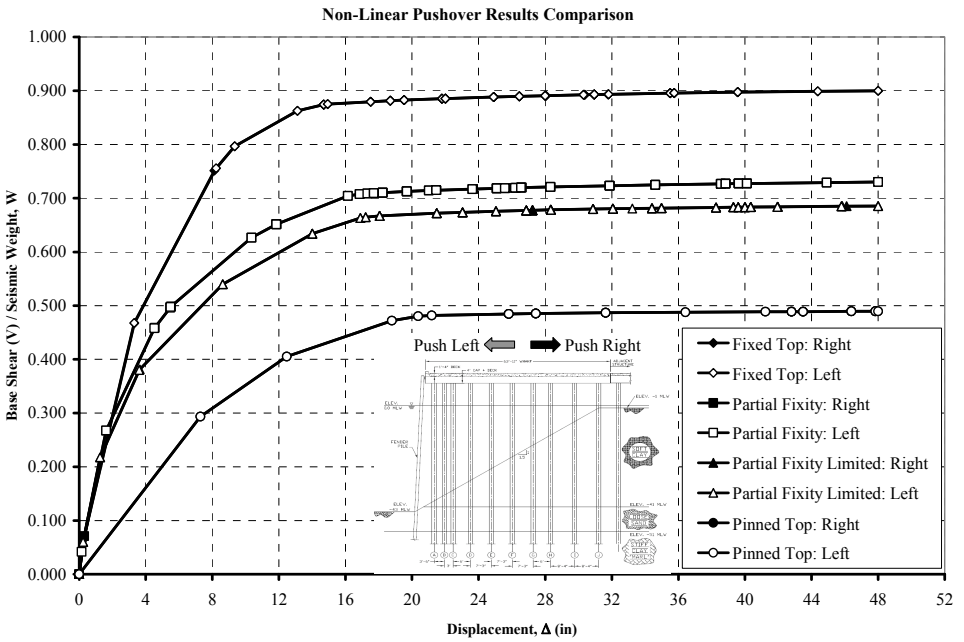

Figure 9: Non-Linear Pushover Comparison for Pile-to-Pile Cap Fixity Study

CONCLUSIONS

This paper briefly described the typical phases associated with a service and seismic condition assessment of marine structures. An example marine structure was then analyzed using non-linear procedures to emphasize the importance of evaluating the structure considering its existing condition including defects such as spalls and rebar or prestressing strand loss of section. The chosen defects vary in severity and were shown to decrease the maximum moment capacity of the selected pile by between 18% to 45%. The defects location also played a crucial role in the decrease in section capacity. In particular, if moment loading causes compression where a concrete spall defect is located, the decrease is larger than if the moment causes tension in the concrete spall area. The study also found that the proper modeling of the pile-to-pile cap fixity in the global structural model has a significant impact on the lateral / seismic capacity of the structure achieved through a non-linear pushover analysis. The use of fully fixed pile top to cap connection is not always applicable, and assuming a fully pinned connection, may be overly conservative. This study demonstrated a technique for incorporating partial fixity that more accurately represents the expected seismic capacity of the pile bent. Combining the results of a thorough structural condition investigation and the proper use of these non-linear analysis techniques, the expected seismic vulnerability of marine structures can be achieved and updated as the structure's intended use or condition changes.

ABSTRACT

In order to aid in post-earthquake response and recovery efforts, hospitals and other critical structures must remain operational after a design level seismic event. Protective systems (base-isolation and supplemental damping) provide a means to reliably and economically achieve improved structural and nonstructural performance. Viscous wall dampers (VWDs), originally developed in Japan, will be used in this first U.S. application to provide supplemental damping and enable a new 15 story hospital in San Francisco, California to achieve stringent performance goals. This paper introduces the innovative VWD devices, describes the results of full-scale prototype testing, summarizes VWD properties, and explains modeling techniques for implementation in nonlinear response history analysis. By using VWDs in this hospital application, the overall steel weight was reduced by an amount that more than offset the installed cost of the VWD devices and a unique lateral system was designed that will enable improved structural performance, when compared with traditional systems. Also, floor accelerations in the upper floors of the building were significantly decreased, thereby reducing the costs associated with nonstructural bracing, especially for the central utilities plant located on the top floor.

INTRODUCTION

Viscous Wall Dampers originated in Japan, where they have been used for more than 20 years and in over 100 projects. VWDs consist of a stiffened steel tank filled with viscous "fluid" and one or more steel vanes that extend into the tank of viscous fluid. The VWD tank connects to a girder within a steel moment resisting frame line at one level and the vane assembly connects to the girder at the level above (see

Figure 1). Interstory drift and interstory velocity result in in-plane movement of the vane within the tank. Viscous shearing of the fluid relative to the tank wall and vane provides damping and energy dissipation.

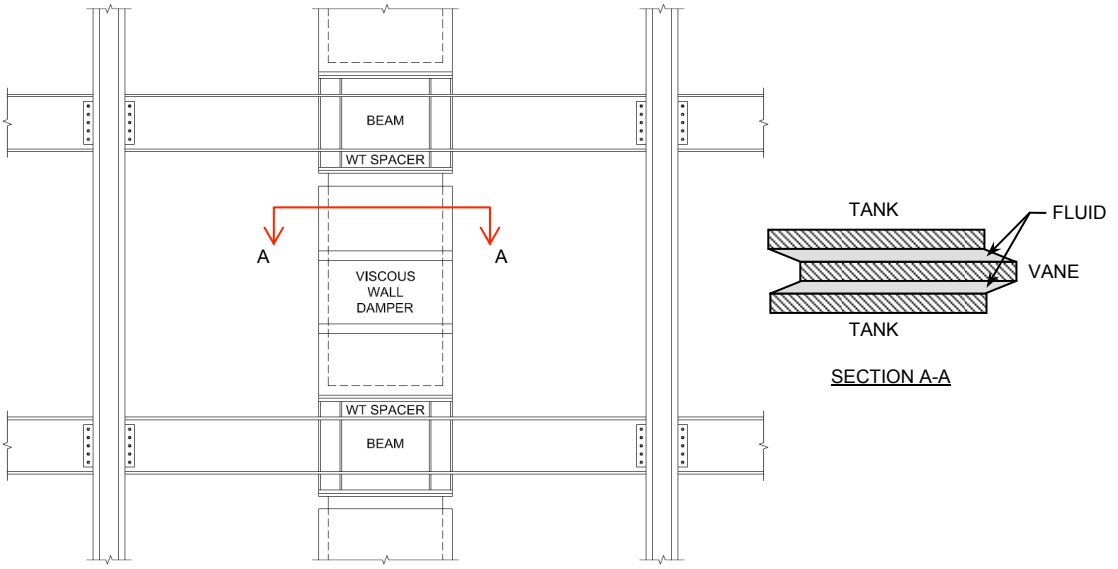

Figure 1. Typical VWD framing elevation.

Hospitals are critical to post-disaster response and recovery efforts. Lessons from past earthquakes have shown that while structural seismic performance has improved something as small as a sprinkler piping leak in an operating room can put a hospital out of commission until repairs are made. This damage to nonstructural components is typically sensitive to floor accelerations. One way to reduce the magnitude of floor accelerations, and reduce the corresponding damage, is with the use of protective systems (i.e. base isolation, or supplemental damping). The Structural Engineer, Architect, and Owner of a new hospital to be located in San Francisco, California, only 11 km from the San Andreas Fault, opted to use innovative viscous wall damper technology to help achieve stringent structural and nonstructural performance goals.

The new hospital (see Figure 2) is 15 stories above grade, with two below-grade levels for parking. Levels P3 through Level 4 occupy the entire site, which measures 385 ft by 275 ft. The building plan area reduces at Levels 5 and 6, and reduces again at Levels 7 through 14 to form the nursing tower. The building roof is up to approximately 250 ft above sloping grade. Level 15 includes an exterior roof with air handling units and in interior central utilities plant. Cooling towers, additional air handling units and emergency generators are located on the Level 16 roof. The lateral force resisting system above grade consists of steel moment resisting frames with 153 supplemental VWDs, provided by Dynamic Isolation Systems, Inc.

This project represents the first U.S. application of these devices, which were originally developed in Japan, and therefore project-specific prototype testing was

conducted in order to characterize VWD wind and seismic performance, determine appropriate device properties for use in nonlinear response history analysis (NRHA), and satisfy building code requirements.

Use of viscous wall dampers having displacement, velocity, cyclic-history and temperature dependent force-deformation properties necessitated the use of NRHA for design. A VWD modeling approach was developed to capture the displacement and velocity dependence, and cyclic-history and temperature dependent properties are considered using an upper and lower bound numerical damper properties analysis approach. The use of advanced analysis techniques allowed the design team to integrate this new VWD technology into this unique structure and ensure that the building seismic performance objectives will be achieved.

Figure 2. Architectural rendering of hospital building.

VISCOUS WALL DAMPER DEVICES

Each VWD consists of a narrow steel tank connected to the lower floor, an inner steel plate (vane) connected to the upper floor, and a viscous fluid in the small gap between the tank and vane plates. During seismic excitation, relative floor movement causes the vane to move through the viscous fluid. The damping force from the shearing action of the fluid is dependent on the displacement and velocity of this relative motion. Wall dampers are used as a passive energy dissipation system to

reduce seismic accelerations and interstory drifts, as well as reduce wind-induced vibration.

VWDs can also be constructed with two vanes. In the case of the double-vane damper there are three plates that form the tank. A double-vane VWD gives twice the damping force with only a small increase in plan size (i.e. thickness of the VWD).

The viscous fluid used for wall dampers is a non-toxic, odorless, transparent fluid with a viscosity of about 90,000 poise at 30°C (95°F). The device can be made to fit typical openings in a building. Dampers with widths of 6 ft to 20 ft and heights of 6 ft to 14 ft (with spacers) have been used in buildings. The force of the damper is approximately proportional to the effective area of the vane.

VWDs operate at atmospheric pressure and do not have seals that require maintenance throughout the service life of the device, unlike other types of viscous dampers. Other than periodic inspection and inspection after a seismic event, VWDs are a maintenance-free system.

When used in steel framed buildings, the VWD tank and vane are typically field bolted to T-stubs that have been welded to the damper bay beams in the shop. Large diameter high-strength bolts are used to transfer damper overturning forces to adjacent structural framing and a series of pretensioned high-strength bolts are used to prevent slip between the steel T-stub and VWD tank and vane components. T-stubs are used to account for variations in the clear distance between framing members, while maintaining a consistent VWD height to minimize device production costs. Other connection configurations are possible when needed to satisfy unique project requirements.

PROTOTYPE TESTING

As part of rigorous regulatory agency review for this first U.S. project utilizing VWDs, project-specific full-scale testing of the devices was required to establish expected wind and seismic performance and determine appropriate properties for modeling the devices in PERFORM-3D (CSI, 2006). Prototype tests on a series of dampers were performed at the University of California, San Diego's Caltrans Seismic Response Modification Device Test Facility. One 7 ft wide by 12 ft tall double vane prototype specimen ready for testing is shown in Figure 3. The dampers were tested to a variety of displacements and velocities (sinusoidal and earthquake motion) in single and bi-directional loading conditions.

Chapter 18 of ASCE 7-05 (ASCE, 2006) requires a series of sinusoidal cyclic prototype tests at the maximum earthquake device displacement to establish device performance. ASCE 7-05 also specifies a 15% tolerance limit on various damper properties, depending on whether the device is displacement- and/or velocity-dependent, compared with the average value from the code prescribed five fully

reversed cycles. VWDs are both displacement- and velocity-dependent and therefore must satisfy the cycle variation tolerance for force at zero displacement (F_0), force at maximum device displacement (F @ D_{max}), effective stiffness (K_{eff}), and area of hysteresis loop (E_{loop}). These parameters are illustrated for typical VWD load-deformation response in Figure 4.

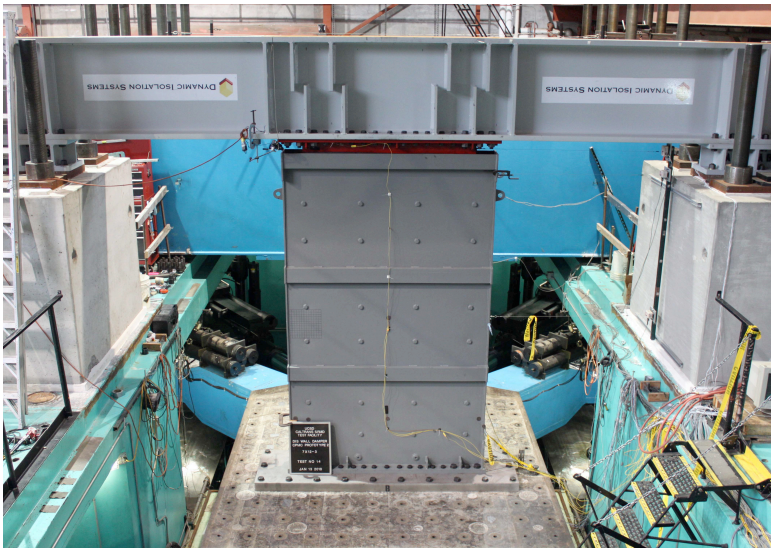

Figure 3. Prototype VWD 7 ft by 12 ft test specimen.

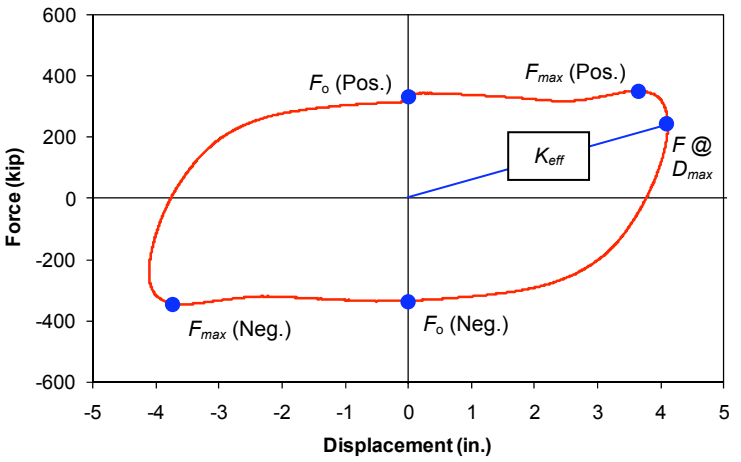

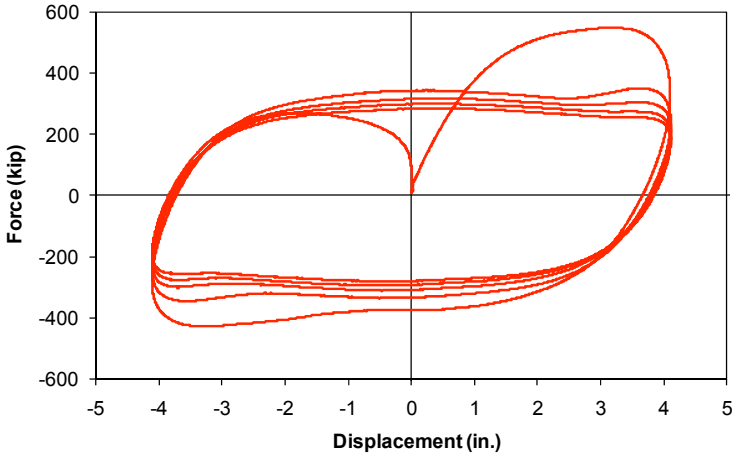

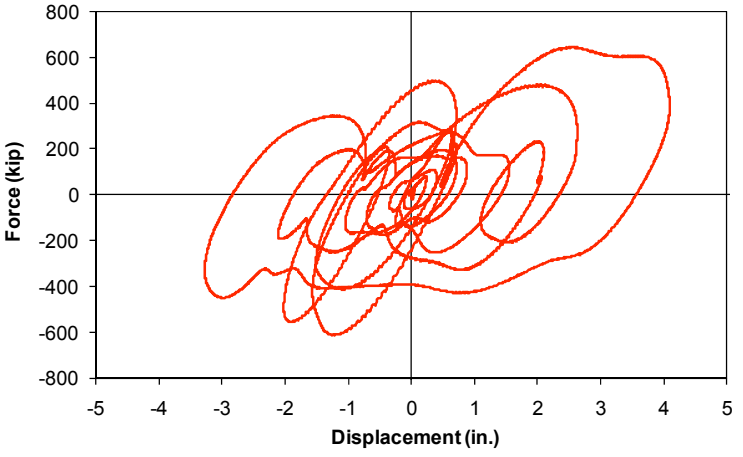

Figure 4. VWD property definitions.

Additional cyclic and simulated earthquake testing was conducted to enable the design team to characterize expected device performance, provide data to establish device damping and stiffness properties, and for calibration of numerical models. A design level earthquake test was performed at the beginning and end of each day of testing and results from these tests were used to demonstrate that damper properties

did not degrade with repeated cycles, even after approximately 20 tests at design to maximum considered earthquake level displacement. Figure 5 shows typical load-deformation response for cyclic and simulated earthquake tests. The larger first-cycle force observed in Figure 5(a) will be discussed in the damper property modification factor section below.

(a) Cyclic test

(b) Earthquake test

Figure 5. Typical load vs. deformation response.

ASCE 7-05 damper prototype testing requirements also prescribe subjecting the device to a wind test of not less than 2000 continuous fully reversed cycles of wind loading at displacement amplitudes expected in the design wind storm. A wind engineering consultant was retained to help establish this expected wind displacement. Building wind displacements are made up of a static component, quasi-static component oscillating at approximately 10 times the building natural frequency, and a dynamic component oscillating at approximately the building natural frequency. The results of previous wind tunnel testing of a model of the building combined with the building dynamic properties were used to characterize the

building response during a 100-year wind event. This building response data was used to develop a realistic wind test loading sequence consisting of the following steps: 1) Apply static displacement offset, 2) Apply simultaneous combination of quasi-static and dynamic cycles in both the in-plane and out-of-plane directions (Figure 6 shows an example of one quasi-static displacement cycle with the superimposed dynamic cycles), and 3) Remove static displacement offset.

Figure 7 shows the load-deformation response for one typical quasi-static cycle of the wind testing sequence. Note that the static displacement offset has been removed from the plotted data. Five iterations of 1000 dynamic wind load cycles were conducted back-to-back with no significant drop in damper properties. Wind test results also confirmed a significant level of damping is provided by the VWDs, even for small amplitude wind-induced displacements.

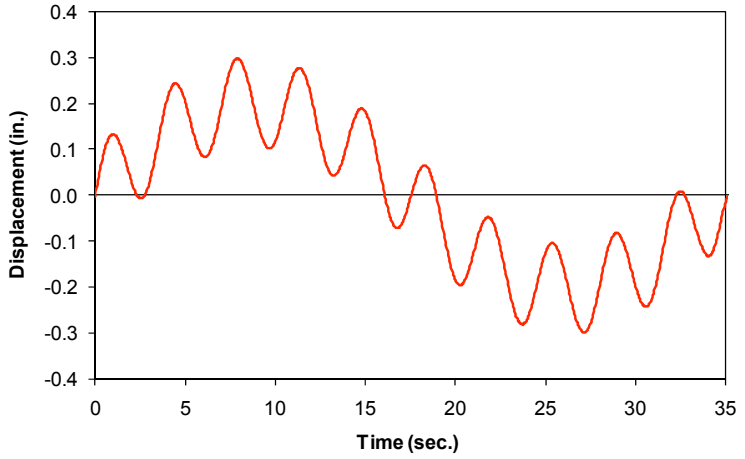

Figure 6. Typical cycle of wind test displacement protocol.

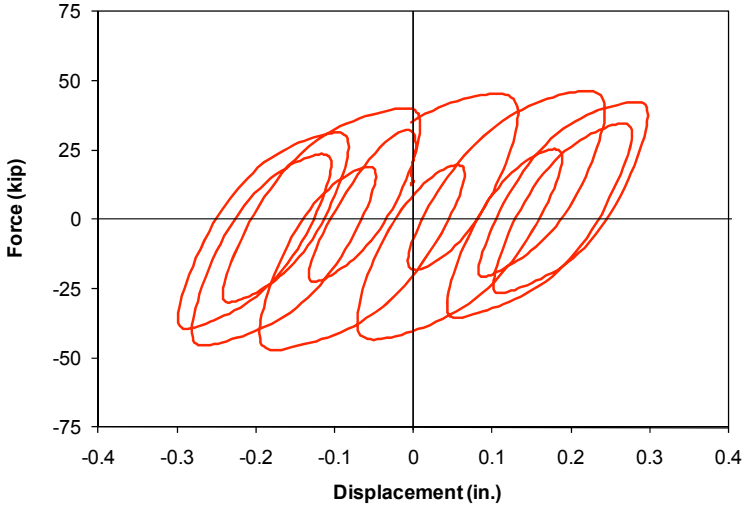

Figure 7. Typical wind test load vs. deformation response.

Damper production testing is also required by ASCE 7-05 Chapter 18 prior to installation of damping devices in a building. Production testing is intended to verify that the force-velocity-displacement characteristics of the actual devices fall within the allowable range assumed in design of the structure. Simulated production tests were conducted on prototype dampers to establish benchmark data for use in actual production testing.

DAMPER PROPERTIES AND MODELING

Based on the results of project specific testing and previous testing in Japan, VWD properties and a modeling scheme were developed for implementation in nonlinear response history analysis using the computer software package PERFORM-3D.

Damper Model

The damper model consists of a linear spring in series with a nonlinear damper (Maxwell Model). This damper model was implemented with the PERFORM-3D viscous bar element made up of a fluid damper and linear elastic bar component. The damper force versus velocity relationship was represented by Equation 1 and an additional force cap.

$$F = CV^{\alpha} \qquad \text{(Eq. 1)}$$

where: C = damping coefficient, F = damper force, V = damper velocity, α = damper velocity exponent. The damper velocity exponent ($\alpha = 0.7$) was selected based on empirical Japanese practice and fit of the damper model to prototype test data. PERFORM-3D implements a multi-linear discretization of the Equation 1 force versus velocity relationship. The additional force cap was based on observations from testing.

The compound viscous bar element (dashpot and linear elastic spring) was located at story mid-height and is connected to the beam above and below with rigid vane and tank elements. Interstory drift causes relative displacement between the two damper nodes and activates the viscous bar element. A portion of a typical frame with dampers is shown in Figure 8.

Stiffness of the VWD vane and tank components was included in the dashpot-spring damper model properties that were determined based on the results of prototype testing. Therefore, the component properties of the elastic vane and tank elements (Column, Steel Type, Nonstandard Section) in the PERFORM-3D model were considered to be essentially rigid.

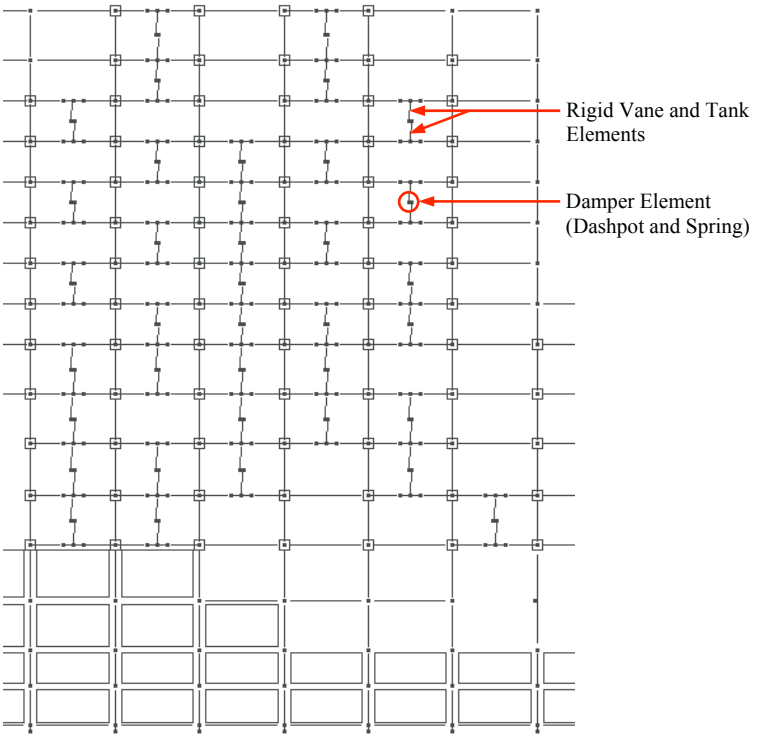

Figure 8. PERFORM-3D model typical damper bays.

Damper Properties

The load-deformation response of VWDs is temperature, displacement, velocity, and cyclic-history dependent. Temperature and cyclic-history dependence are accounted for by use of the property modification factors discussed in the next section. Figures 9 and 10 show the displacement and velocity dependence of the VWD load-deformation response for representative cyclic prototype tests. In general, VWD forces tend to increase for larger displacement amplitudes and larger velocities.

Fluid damper and linear elastic bar component properties, for use in PERFORM-3D, were determined with an iterative process based on prototype test results and a simple PERFORM-3D model of the prototype specimens. Results from PERFORM-3D simulation of a test was compared to prototype test results to determine damper properties that provided the best match over a range of different displacement amplitudes and velocities. This data was also examined to verify that damper properties used in the overall building model satisfied project-specific design criteria requirements for the match between prototype test and numerical simulation results.

Damper Property Modification Factors

In order to appropriately account for the expected range of building response due to variation in damper properties due to first-cycle effect, temperature variation, aging, and specification tolerance an upper and lower bound damper properties analysis scheme was adopted. The force-based nominal damper properties determined from prototype testing were modified by an upper bound or lower bound damper property

modification factor and two analysis cases were completed. Displacement based demands were typically controlled by analysis with lower bound damper properties and force based demands by upper bound damper property analysis.

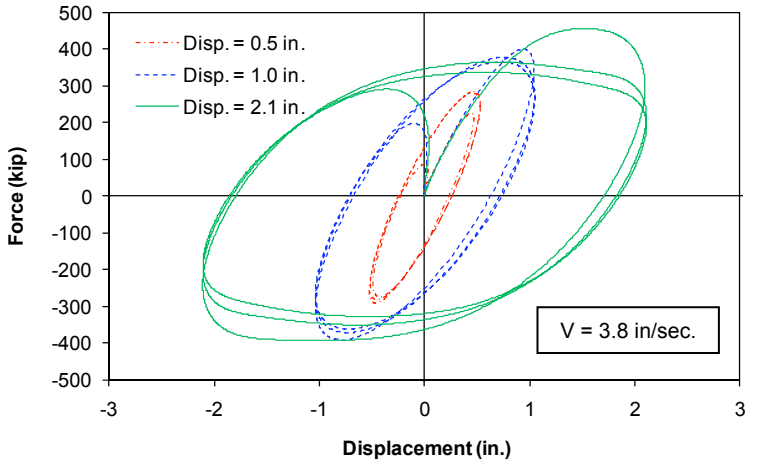

Figure 9. Typical displacement dependent cyclic load vs. deformation response.

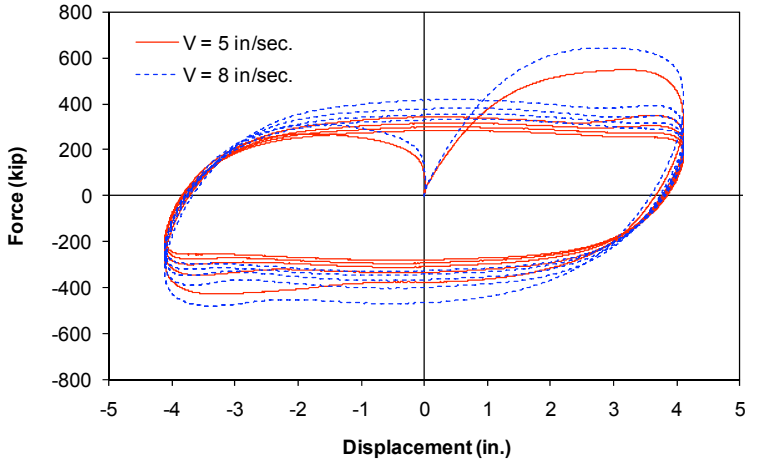

Figure 10. Typical velocity dependent cyclic load vs. deformation response.

As observed in Figures 5(a), 9, and 10, VWDs typically exhibit a higher force capacity on the first excursion to large displacements (cyclic-history dependence). This phenomenon is not captured by the damper model implemented in PERFORM-3D and is referred to as the first-cycle effect. A first-cycle effect upper bound damper property modification factor (>1.0) is used to ensure the structure is adequately designed for the increased force demand resulting from the first-cycle effect. To establish the appropriate values for first-cycle factors maximum positive and maximum negative force data from prototype testing was compared with maximum values from PERFORM-3D simulation of the tests. The maximum value

of the test force divided by PERFOM-3D simulation force was used to establish the first-cycle factor for a given damper size and earthquake demand level.

Table 1 provides a summary of upper and lower bound damper property modification factors. The first-cycle factor was established as described above and other factors were established based on Japanese experience with past projects, or in the case of the individual damper specification tolerance factor based on ASCE 7-05 requirements.

Table 1. Property modification factors.

System Modification Factors (λ)	Upper Bound Property Multiplier (λ_{max})	Lower Bound Property Multiplier (λ_{min})
First Cycle Effect, λ_{1st}	1.55 to 1.82	1.0
Temperature, λ_{temp}	1.05	0.87
Aging, λ_{aging}	1.05	0.95
Specification Tolerance, $\lambda_{spec,a}$ (average of all dampers)	1.1	0.9
Specification Tolerance, $\lambda_{spec,i}$ (individual dampers)	1.15	0.85

ADDITIONAL DESIGN CONSIDERATIONS

Damper bay beams are expected to form a plastic hinge near the column face, but should remain elastic at the damper face. Beams can be initially sized based on the expected moment demand from the VWDs considering upper bound damper properties.

The presence of VWDs in moment frame bays alters the typically assumed inflection point location at mid-span of the beam under lateral loading. The VWD applies a large moment at the center of the damper bay beam that is only partially out-of-phase with moment frame action. The decrease in assumed inflection point location due to VWDs may result in a clear span to depth ratio less than the prequalification limits for beam-to-column moment frame connections specified in AISC 358-05s1 (AISC, 2005) and project-specific moment frame connection testing may be required.

To limit column and foundation overturning forces, dampers are often offset in a checkerboard pattern instead of a single stack up the height of the building. While this is effective at reducing overturning forces, special consideration must be given to the drag members needed to transfer seismic forces between adjacent offset dampers. The ductility of beam sections that are efficient as flexural members is often significantly reduced for combined compressive and flexural loading (Newell, 2008). Stockier sections may provide improved ductility and increased axial load capacity.

In addition to improved structural performance, use of protective systems, such as VWDs, reduces seismically induced building floor accelerations when compared to more traditional seismic force resisting systems. This reduction in floor acceleration demands can result in better performance of nonstructural components (i.e. less damage) and reduced construction costs associated with nonstructural bracing. NRHA results can be used to determine floor acceleration values for use in calculation of nonstructural component horizontal seismic design forces, instead of using the default equation in ASCE 7. For this hospital, roof level nonstructural component seismic design forces were reduced by approximately 30%. This will result in a significant savings in the cost of nonstructural bracing, especially since the central utilities plant will be located near the hospital roof level.

SUMMARY

The first U.S. implementation of Viscous Wall Dampers has been designed for a hospital located in San Francisco, California. VWDs were selected for this project because they will provide a reliable, maintenance-free, cost-effective protective system to ensure stringent performance goals are achieved. The use of supplemental damping will reduce seismic induced floor acceleration demands, reduce nonstructural bracing costs, and reduce potential nonstructural damage after an earthquake.

Full-scale VWD prototype testing was conducted per the requirements of Chapter 18 of ASCE 7-05, to establish expected wind and seismic performance and determine appropriate properties for nonlinear response history analysis with PERFORM-3D. VWDs were modeled with a viscous bar element consisting of a fluid damper and linear elastic bar components. An analysis approach considering upper and lower bound damper properties was adopted to appropriately consider the expected range of building response resulting from potential variability in VWD properties.

ABSTRACT

This paper summarizes the seismic analysis and rehabilitation design of a fifteen story steel moment resisting frame building in Oakland, California, less than five miles from the Hayward Fault. The building was constructed with connection details that were found to be vulnerable to fracture in the 1994 Northridge earthquake.

Previous testing of the existing connections indicated that the welded connections were highly vulnerable to fracture, and consequently the building presented a risk to life safety in the event of a major earthquake. Seismic strengthening to meet the State of California Guidelines for the Seismic Retrofit of State Buildings Risk Level III resulted in a requirement to reduce the story drifts to 1.5% in a 475-year return period event.

After considering several retrofitting schemes including connection strengthening, BRBF's and seismic isolation, a scheme that included strengthening sixty percent of the existing pre-Northridge moment frame connections and adding viscous dampers was selected.

Since the existing moment connections had performed so poorly in previous testing, and because the size of the members in this building exceeded those that had been previously tested, a series of four full-scale tests were performed to confirm the validity of the connection upgrade design.

Two phases of advanced analysis techniques were performed in the rehabilitation design; a study phase with multi-mode two-dimensional nonlinear pushover analyses along with single-degree-of-freedom nonlinear dynamic time-history analyses; and a working drawings phase with nonlinear response history analyses of building frames to refine the scheme and perform member checks.

The extra steps taken beyond typical engineering practices were intended to provide better assurance that the project's performance goals would be met during the design basis seismic event.

INTRODUCTION

Building Description

The Caltrans District 4 Office Building, located in the downtown section of Oakland, California, is a 15-story steel moment frame structure designed to meet the 1988 Uniform Building Code and constructed in 1991. The building has one basement level, a first story lobby/public space level, four levels of above grade parking, and ten stories of office space. The building is rectangular in plan with a large atrium above the parking levels.

Moment Frame Vulnerability

Caltrans structural engineers were very aware of the damage caused to steel moment frames by the Northridge earthquake and so a brief study was commissioned that identified the building as Risk Level V, as defined in the Guidelines for the Seismic Retrofit of State Buildings (Guidelines, 1994, Rev. April, 2001). In accordance with the state guidelines, the building needed to be seismically upgraded to meet Risk Level III. The Guidelines include a table that attempts to categorize potential levels of building performance and associated risk. The description for levels III and V are presented below:

	Risk Level III	**Risk Level V**
Building:	Minor structural damage: repairable. Moderate non-structural damage: extensive repair.	Substantial structural damage: partial collapse likely: repair may not be cost-effective. Extensive non-structural
Risk to Life:	Minor	Substantial
Systems:	Disruption of systems for days to months	Total disruption of systems: repair may not be cost-effective
Occupancy:	Return within weeks, with minor disruptions	Totally vacated during repairs

The project design criteria were written to incorporate the recommendations of both FEMA 351 and 356 in order to meet the state guidelines. The state guidelines were interpreted to result in the following expected performance:

- A significant number of connection fractures may occur for DBE design earthquake; however, local collapse of framing is not expected.
- Repair of the lateral system (e.g. existing moment frame connections) may be required to restore the building to Risk Level III.
- After the DBE, a complete lateral system will still exist that should have sufficient capacity to permit occupancy of the building within weeks, while detailed inspection and any required repair of the lateral system is performed, or continues.
- FEMA 351 was used as the basis for design to establish Risk Level III drift limits. Structural life safety drift limits were established using 75% of the collapse prevention limits in FEMA 351. Appendix A was used to determine the expected variability of the drift response for the MCE and to calculate a project specific Demand Variability Factor.
- FEMA 356 life safety limits were used to establish column plastic hinge deformation limits.

SEISMIC GROUND MOTION DESIGN CRITERIA

Site-specific response spectra were developed for this site to represent the Design Base Earthquake (DBE, BSE-1) and the Maximum Considered Earthquake (MCE, BSE-2), in accordance with FEMA 356. These spectra were based upon deterministic considerations of both the San Andreas and Hayward faults and represent anticipated earthquakes of Richter magnitude 7.0 and 7.25. The site-specific response spectra are shown in Figure 1.

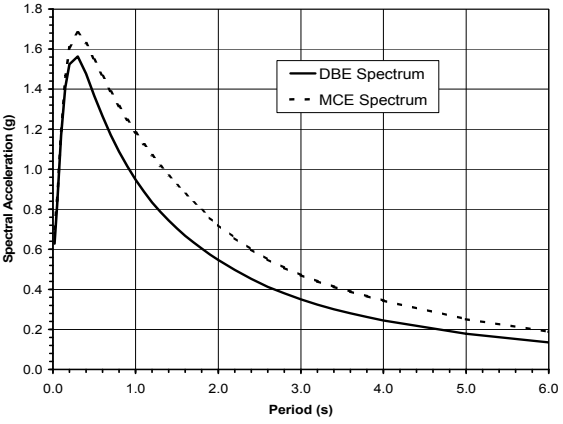

Figure 1. Project Design Response Spectra

Seven pairs of time-histories for use in the nonlinear response history analysis were also developed and scaled in accordance with FEMA 351 requirements. Directivity effects were not considered since the building is oriented approximately 45 degrees to the Hayward fault.

SELECTED RETROFIT SCHEME

The retrofit scheme was designed in two phases, a study phase and a working drawings phase. Four strengthening schemes were developed during the study phase of the project: an all-connection-strengthening scheme, a connection-strengthening-plus-dampers scheme, a buckling restrained brace scheme, and a base isolation scheme. Each scheme was designed to meet the design criteria and the schemes were compared on the basis of construction cost and associated "soft" costs such as construction phasing, long-term and short-term staff relocation and other facility down time. Items also considered long-term architectural impacts to the building as well as projected cost for repair after a significant seismic event.

DESCRIPTION OF SELECTED SCHEME

The retrofit scheme chosen by the owner was the connection-strengthening-plus-dampers scheme. The transverse frames are shown in Figure 2; the configuration is similar in the longitudinal direction.

The particulars of the scheme are as follows:

- Connection upgrades and dampers have been placed at the same locations to minimize number of work locations.
- Maximum practical damper sizes have been used to reduce number of work locations.
- The damper layout avoids interference with major points of entry and interior building flow.
- Of 1218 existing moment-resisting connections in building, 746 connections were strengthened (60% of connections).
- 228 dampers have been added at perimeter locations only, ranging from 225k to 670k dampers with $\alpha = 0.4$, and C ranging from 80 k $(\text{sec/in})^{0.4}$ to 240 k $(\text{sec/in})^{0.4}$.

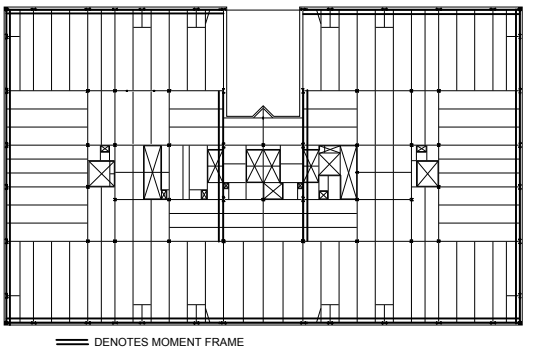

Figure 3. Typical Floor Plan.

CONNECTION TEST PROGRAM

FEMA 351 presented a series of pre-qualified data for existing beam to column configurations strengthened by various means. However, due to the large column sizes found within the existing building, none of the details could be specified and utilized within the building without supplemental testing. A series of alternative types of strengthening schemes were considered for upgrading the existing joints. These included the welded bottom haunch (WBH), the welded top and bottom haunch (WTBH) and the bolted bracket modification (BB).

The first test specimen was the welded bottom haunch and rib plates at the top. This detail with similar parameters had been tested previously under the SAC joint Venture and NIST/AISC testing programs. The SAC tested connections showed good response; however this specimen experienced an abrupt fracture through the column during the first negative excursion at approximately 2% drift. Subsequent finite element analysis (FEA) demonstrated the large strain demands that occur at the top flange weld, which led to the specimen fracture.

The second test specimen was the welded top and bottom haunch and is shown in Figure 4. Similar procedures were developed for the top and bottom haunch and used to size all members and connections. Pre-test FEA was also conducted for both specimens to better connection behavior. This specimen performed quite well, achieving 5% drift before a fracture occurred in the beam flange due to low cycle fatigue. Figure 5 shows the hysteretic loops for this specimen.

The third test specimen incorporated a series of four cast steel bolted brackets. This connection could have potentially eliminated field welding in the retrofit, leading to significant cost savings through avoiding the need for welding precautions in an occupied building. These brackets are a proprietary element that had been extensively tested on smaller sizes in previous research, and have been implemented on a number of projects for both post-earthquake repair and seismic retrofits. Note the member sizes in this building are substantially larger than what has been previously studied for this connection type. The specimen performed without incident through the 3% drift cycles. During the first half cycle to 4% drift, one of the column high strength bolts fractured in tension. Shortly the remaining column bolts and the existing beam to column flange weld all fractured suddenly. This fracture then propagated through the column web connection. No distress was noted in the bolted brackets.

The double welded haunch connection was chosen to retrofit the connections. A final test was conducted utilizing the double welded haunch on one side of the column and stiffened gusset plates on the other side. These gusset plates are being tested to simulate conditions where the dampers are connected to the existing moment frame. Finite element analyses on this connection have indicated that the most significant demands on this connection result from the member going through the building drifts (as opposed to the direct forces generated by the damper elements themselves).

ANALYSIS TECHNIQUES

Two types of analysis were used on the project. A simplified analysis was performed during the initial study phase of the project based on the Equivalent Linearization Procedure (FEMA 440, 2004), and nonlinear dynamic response-history analysis (NRHA) was performed during the working drawings phase. Separate analysis programs were used for each type of analysis, SAP 2000, and PERFORM-3D.

Study Phase Analysis

The simplified analysis performed during the study phase of the project utilized SAP 2000 models, and a mixture of nonlinear static pushover analysis, spreadsheets, and nonlinear dynamic response-history analysis (NRHA) of single-degree-of-freedom (SDOF) models.

A pushover was performed of the selected retrofit scheme for the first three modes in each horizontal direction. Initial estimates of the target displacement for each mode were established using the Equivalent Linearization Procedure described in FEMA 440 Chapter 6. The displacement reducing effect of the added dampers was estimated using an iterative spreadsheet based procedure. The added damping was calculated using the pushover load vector, the displaced shape of the building at the target displacement, the damper sizes and distribution, and the building effective period. The target displacement of each mode was then reduced by the corresponding displacement reduction factor ("B-factor"), adopted from FEMA 450.

Once the scheme was finalized an additional check was performed on the target displacement of the first mode, the primary contributor to drift in the building. The pushover curve from the first mode pushover was idealized to a SDOF model, with nonlinear spring and damper elements that represent the behavior of the both the new and existing building structural components. NRHA was performed to confirm the target displacement of that mode, which was approximately 10% less than that calculated using FEMA 440.

In the final step, the pushover analysis results for each mode are combined in a statistical manner (CQC) to determine the overall performance of the retrofitted building.

Working Drawings Phase Analysis

In the working drawings phase of the project two two-dimensional models were constructed in PERFORM-3D, one for each direction of moment frames. Gravity columns were included in both models for secondary effects. Rigid diaphragms were assumed.

The moment frames are built with compound elements comprised of elastic frame elements with discrete inelastic hinges.

Beam elements used an inelastic moment-rotation hinge for strengthened connections or an inelastic fiber section for the existing connections. A fiber section is comprised of axial-only fibers assigned locations along a vertical axis. Each fiber is then assigned a chosen inelastic material property. The cross section will act inelastically in tension, compression, and bending but is considered to remain elastic in shear. The existing connection fiber is comprised of three different types of fibers: one fiber representing the top flange, one fiber representing the bottom flange, and one fiber for each of the bolts in the shear tab – shown in Figure 6.

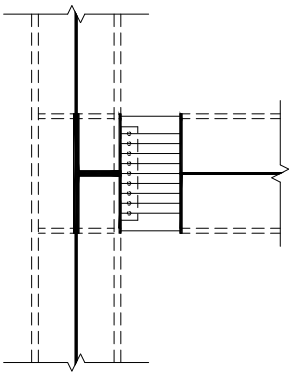

Figure 6. Graphical representation of beam connection fiber model.

Using the fiber elements allows the existing connection model to closely mimic tested behavior. The key aspects of using the fiber section to model the existing connection are that the fiber model captures:

- The top and bottom flanges fracturing at different moments, both which are significantly below the expected moment strength of the beam.
- The effect of the prying action that occurs on the bolts in the shear tab, and the individual fracture of each shear tab bolt at the expected bolt ultimate strength.

Other aspects of the mode include:

- Column elements utilize inelastic axial moment interaction (PMM) hinges.
- Column splices are included in the model as nodes.
- The basement walls remain elastic and are modeled as elastic shear wall elements.
- The base of the model consists of inelastic soil springs with properties developed from force-deflection curves provided by the geotechnical engineer.
- The dampers are modeled using an elastic bar and an inelastic damper element.
- Floor diaphragms were checked separately using inertia forces determined from the analyses.

Two-dimensional frame analyses were used for both phases of the analysis since the building has been found to be torsionally very regular. Torsion was accounted for in the design of the retrofit scheme by increasing drifts computed from the two-dimensional analyses by a factor determined from a linear response spectrum analysis of the full 3D SAP model including the dampers.

CONNECTION MODEL VALIDATION

To validate the existing fiber connection model, the existing connection test specimen was modeled and subjected to the same loading protocol as the original connection testing (Kim and Stojadinovic 2003). The correlation between the model and the test specimen is shown in Figure 7.

The slab was not included in the existing test specimen or in the fiber model. The potential contribution to the connection flexural strength is relatively small and the effect was not expected to substantially change the analysis results.

The fiber model revealed that a second type of slab interaction occurs with the steel frame. Post-fracture lengthening of the bay occurs due to the diagonal length between beam flanges in compression exceeding the original clear length of the bay during each drift excursion. This mechanism, which is shown in Figure 8, could result in overall frame lengthening of several inches over the dimension of the building. This behavior is not observed in subassemblage connection tests as the beam is unrestrained, and so no additional lateral resistance is generated. In the initial version PERFORM-3D model, very large axial loads were generated in the beam due to the slab, which was modeled as a rigid diaphragm. In the building, the axial loads would be limited by the slab strength, which is limited by tensile yielding of the reinforcement and bearing of the slab concrete against the column flanges, and by the capacity of the shear studs. Since there was no test data available to validate the strength and stiffness characteristics of this mechanism the effect was removed from the PERFORM-3D model by releasing the axial load in the beams. This slab-beam coupling mechanism would not have generated sufficient resistance to substantially alter the evaluation of the building or the scope of the subsequent strengthening scheme; however, it might improve the outcome in other more marginal cases. Further research is required to more clearly understand this behavior.

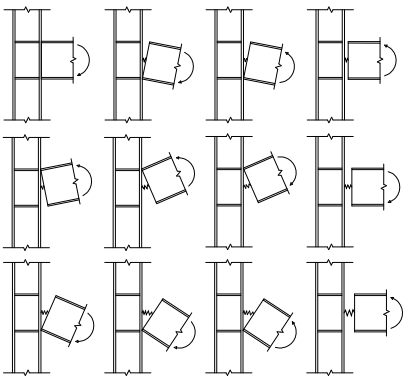

Figure 8. Ratcheting effect observed in connection test model

ANALYSIS RESULTS

Study Phase Analysis Results

The displacement and drift results from the study phase analysis are shown in Figure 9. The distribution of connection strengthening and dampers obtained using this analysis was relatively uniform throughout the height of the building – approximately 60% of connections at each floor with dampers distributed up the height of the building.

The pushover curves for the first three modes in the transverse direction are shown in Figure 10 together with the equivalent viscous damping computed for that mode. The higher modes were in general elastically performing, and were much more heavily damped than the first mode.

The pushover analyses performed in SAP2000 were not able to capture the fracture events due to the high degree of nonlinearity in the connection behavior and the large number of fracture events that occur near simultaneously. Consequently, the existing connections were modeled with only the residual post-fracture hysteretic characteristics of the connection. Although this was a conservative assumption, this resulted in a significant variation in the computed drift profile when the results were subsequently compared to those from NRHA in the working drawings phase of the project, see Figure 11.

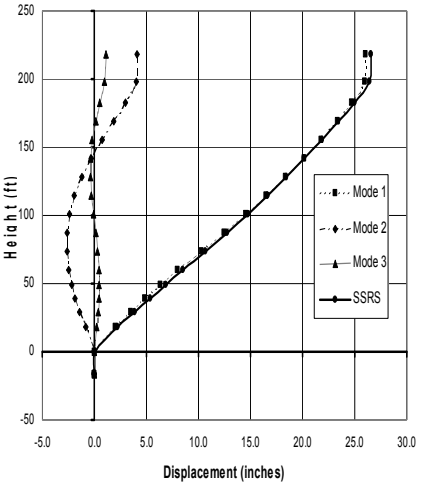

Figure 9. Study phase analysis displacement and drift results.

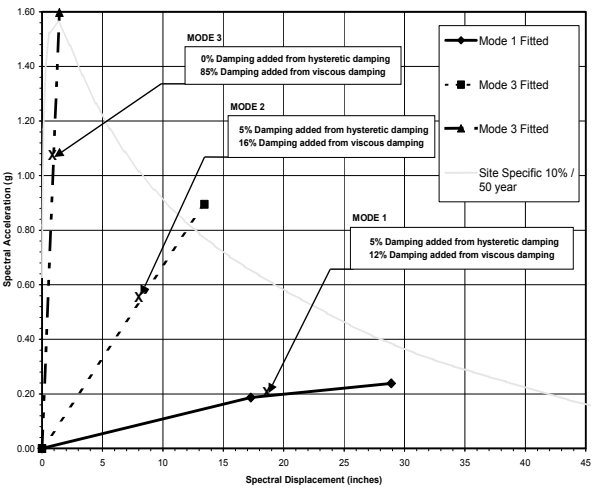

Figure 10. Capacity spectrum results for study phase analysis.

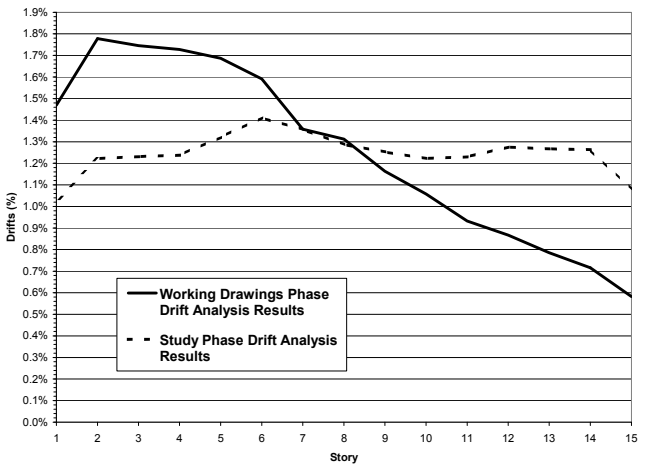

Figure 11. Study Phase and Working Phase Average Drift Comparison

Working Drawings Analysis Results

The drift performance of the building is shown in Figure 12. Results for three conditions are shown, (1) the existing structure with fracturing connections, (2) the structure with all connections fixed – representing either an all-connection strengthening scheme or the performance where fracture of the connections does not occur, and (3) the structure with the selected retrofit scheme consisting of dampers and 60% connection strengthening. The results shown are the average of the maximum drift response from each time-history analysis.

In the NRHA of the building in the existing condition, connection fractures were observed to propagate from the bottom of the building upward, resulting in high drift demands in the lower portion of the building compared to the upper portion (Figure 13). Beams with existing connections in the upper portion of the building retained a significant portion of their original stiffness by reverting to a "pin-fixed" condition following fracture of both bottom flanges within one beam span.

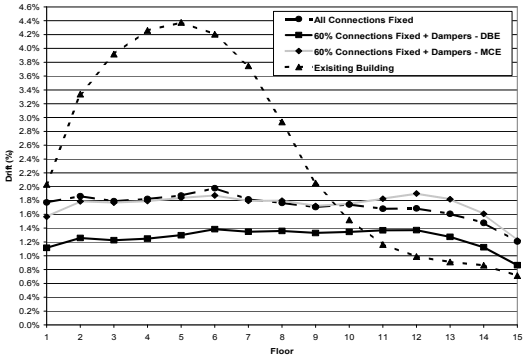

Figure 12. Average drift results for all existing connections, all connections fixed, and 60% connections fixed plus dampers (DBE/MCE).

CONCLUSIONS

The Caltrans District 4 Office Building is a steel moment resisting frame building with connections similar to those that fractured in the 1994 Northridge, California earthquake. After studying various schemes, a combination of moment connection retrofits and the addition of viscous dampers was chosen to meet the performance goals established by the State of California.

The type of rapid weld fracture observed in the existing connection test specimens (Kim and Stojadinovic 2003) has typically not been observed in other moment frame connection tests. The reasons for this behavior have not been fully understood but may be related to the deep column sections present in the test specimens. The drift performance of the Caltrans building with existing connections modeled clearly shows that this condition, if it exists for all connections in the building, presents a significant risk to life safety for the building occupants.

Deep columns were commonly used in high-rise steel frame construction prior to 1994 due to the stiffness advantage that they represent. If connections of this type perform in a similarly brittle fashion then buildings using this connection type may be less safe than would otherwise be assumed. Further research is needed to more completely understand this condition.

However, as shown through the project's testing program, the connections of deep column moment frames can be successfully retrofitted to prevent fracture of the connection and develop plastic hinges within the frame beams.

The simplified analysis used to estimate the performance of the proposed retrofit scheme was reasonably successful in estimating the overall extent of strengthening work required to achieve the desire performance. However, the simplified analysis substantially underestimated the drift in the lower stories and overestimated the drift in the upper stories. This resulted in a substantial revision to the damper and connection strengthening scheme configuration based on the initial response from the PERFORM-3D response history analysis.

Nonlinear response history analyses were successfully completed using PERFORM-3D to verify the performance of the existing and retrofitted structure. Highly nonlinear existing connection behavior was successfully captured using a fiber model. The computer model of the building produces a connection failure pattern observed in 1994 Northridge earthquake, with primarily bottom flange fractures observed at existing connections. The hysteresis of the existing connection closely matches the test data.

The extra steps taken beyond typical engineering practices were intended to provide better assurance that the project's performance goals would be met during the design basis seismic event.

ACKNOWLEDGEMENTS

Funding for this project was provided by the California Department of General Services.

ABSTRACT

The Bowls Project in San Francisco, California was synthesis of music, history, architecture, and engineering inspired by ancient Babylonian clay bowls. The structure is a base-isolated pair of intersecting masonry domes using the Mediterranean system of tile-vaulting.

Construction of the domes as an unreinforced masonry structure would not be permitted by the San Francisco Department of Building Inspection if not for an alternate means of compliance through a base-isolated design. The typical ASCE 7-05 approval process for base-isolated structures is expensive and time-consuming – the review cost alone would have exceeded the entire budget for this small project.

The Department of Building Inspections recognized the seismic protection that base-isolation would provide to the domes and agreed to permit the design using full scale testing of the completed structure to validate design properties of the isolation system. This not only made the project feasible, it allowed the schedule to move from conception to completion in only 2 months.

The isolators use a Ball-N-Cone design by Worksafe Technologies. Upon completion of the masonry dome construction on the isolated plinth, the structure was pulled to maximum displacement and released in a series of "snap back" tests in orthogonal directions. The plinth and the top of the dome were monitored with accelerometers to capture the acceleration time history in free vibration. The data was used to confirm the maximum acceleration of the plinth, the damping ratio, fundamental period, and hysteretic behavior of the isolation system.

This method to verify isolation system properties satisfies the intent of ASCE 7-05 by providing engineers with the design properties and surpasses the intent by providing these properties under actual load conditions. Future applications could provide artists, architects, and engineers the ability to build innovative, efficient structures in high seismic areas with the assurance that structure performs as intended.

INTRODUCTION

The Bowls Project is an interactive sound sculpture/immersive performance installation created by interdisciplinary artist Jewlia Eisenberg and architectural designer Michael Ramage. The Bowls Project takes place within a stunning masterwork of ancient-meets-modern design: two intersecting vaulted masonry domes. The Bowls Project is inspired by texts drawn from Babylonian demon bowls, women's amulets common from 300-700 CE in the area now known as Iraq. These demon bowls were inscribed with a householder's secrets and desires and then buried upside-down under the doorway to protect her home. Demon bowl inscriptions are about secrets of the home: love and sensuality; angels and demons; and the trials and joys of daily life. They explore domestic secrets in unexpected ways, suggesting a spirit-rich world that is strange and inspiring.

The form of The Bowls Project draws on the shape of the Babylonian ceramics, using two intersecting domes of different sizes to create a larger performance space and a smaller intimate contemplative space. The profile of the domes grows out of the static structural analysis, giving a compression-only form under dead load.

Creating the space using the materials and methods that Michael and Jewlia envisioned was not without its obstacles. The team had an ambitious, one-of-a-kind project to complete on a very aggressive schedule. The San Francisco Building Code does not allow the new construction of un-reinforced masonry structures. Degenkolb Engineers was added to the project team in order to engineer a system that would meet the intent of the building code, by providing a life-safe structural system. The City granted a construction permit to the project through an alternate means of compliance, which allowed for full scale testing of the completed building and base isolated system. The conventional process for approving base-isolated systems typically involves months of prototype testing and peer review. Full scale testing of base isolated structures is normally impossible, or extremely impractical due to the large forces required to displace a full scale building. The scale of The Bowls project provided a unique opportunity to apply an isolation system design usually reserved for sensitive equipment on a larger-than-normal scale without being too large to render full scale testing impractical. The successful completion of this project opens doors to full scale testing opportunities of similar sized projects, including single family residences, large equipment and other future art projects.

Figure 1. The Bowls Project.

THE BOWLS PROJECT

The tile-vaulted dome has roots in medieval Mediterranean cultures and was revisited by the 19th-century architect and engineer Raphael Guastavino, who brought the technique to the United States, eventually building over 1000 structures with this technique[12]. Tile vaulting relies on fast-setting gypsum mortar and thin tiles to build elegant structural spans with a minimum of formwork. The structures typically work in compression only, and are used with great architectural and structural expression in the works of Antoni Gaudi and others in the Barcelona region. Tile-vaulting can be applied and adapted for contemporary architecture, where there is a benefit to using ancient techniques with new materials. A number of buildings using tile vaulting have been recently completed where structural form, minimal material, and constructability were paramount concerns. These include The Pines Calyx and Crossway House in Kent, England, and the Mapungubwe Interpretive Centre in South Africa. Because the structures are designed for compressive loads, tile-vaulted structures are not typical in earthquake regions. The Bowls Project was the first application of a novel hybrid tile-vault, using geotextile for reinforcing between the layers of masonry.

Tile-vaults are built in multiple layers of thin tiles with a thick (~1/2") mortar bed between the layers. Usually the vaults are in layers of three or more tiles to give enough thickness to withstand asymmetric loads. The Bowls Project domes are constructed from autoclaved aerated concrete (AAC) tiles reinforced with geotextile

for earthquake safety. AAC is lightweight foamed concrete that is easy to cut, has minimal environmental impact, and works well with the tile vaulting technique due to its surface roughness. The minimum compressive strength of AAC is low (580 psi), but the stresses in the domes, due to their large contact area, are an order of magnitude lower, with a maximum of 23 psi. The dome construction incorporates a geogrid (Tensar TriAx 160) embedded in the mortar layers. The geogrid, typically used for reinforcing road-beds, adds a level of omni-directional tensile properties to the composite through a mechanical bond between the mortar and masonry. Ongoing research at Cambridge University is quantifying the improvements possible so that tile-vaulted structures can be safely built in areas with moderate earthquake risk. Because the geogrid is only effective for moderate earthquakes, and is currently experimental, the additional base isolated plinth was required in San Francisco.

Understanding and quantifying the forces in the masonry domes relies on thrust-line analysis[3] and applying an equivalent static loading for dynamic earthquake analysis[4]. By tilting the interactive thrust-line model (Figure 2), the amount by which the thrustline escapes the geometry can be calculated. The distance of the thrust line from the geometry, the thrust value and lune element size are used to calculate the additional performance envelope given by the geotextile. The graphic analysis is conservative -- it assumes that the thrust line returns to the centerline of the masonry at the supports, which with reinforcing isn't necessary. Just as the thrust line can (and does) exit the masonry geometry throughout the span, it can do so at the base. Choosing a thrust line that is shifted to the left in the counter-clockwise rotated EQ model would result in drastically lower tensile forces where the thrust line exits the masonry.

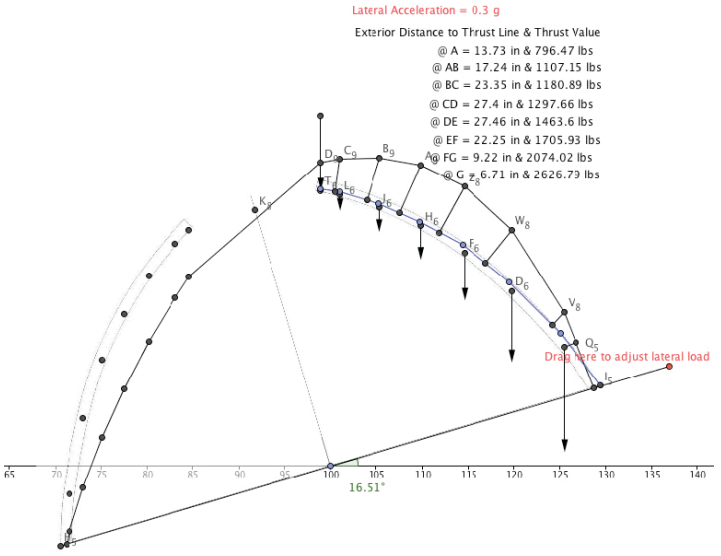

Figure 2. Example Output of Thrust Line Analysis for Seismic Loading

The vaulted masonry domes were supported by a steel and wood plinth connected to the supporting structure by 30 Ball-N-Cone seismic isolators. The weight of the

domes was supported by 1-1/8" plywood spanning to 2x8 joists at 16" o.c.. Additional blocking was provided around the perimeter of the domes. The joists were hung from wood nailers on top of W6 steel beams. The W6 steel beams were centered at 6'-6" in each direction forming a four bay by five bay platform measuring 26' x 32'-6" to the outer framing. The lateral inertial force of the masonry (and the static thrust from the vault) was transferred to the plywood diaphragm through plywood rings cut to fit the inner and outer diameters of the walls. The diaphragm was screwed to the 2x nailers and the nailers were bolted to the top flange of the W6 beams.

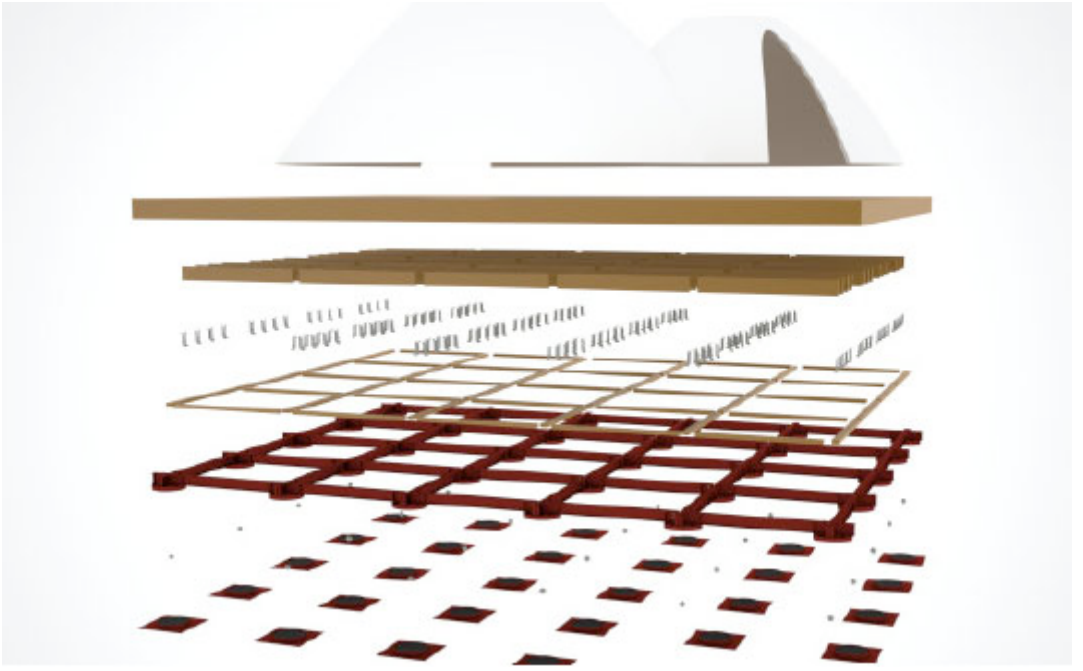

Figure 3. 3-D Rendering of Plinth Construction.

An isolator was located at each beam intersection. The isolator surface was formed from 5/8" steel plate, which was pressed into the specified shape required by design. Perimeter rings provided stability to the curved plates as well as a lip to limit displacement of the ball bearing. The top plates were welded directly to the beam intersections. The bottom plates were welded to ¼" steel plates and arranged and leveled on site. Since The Bowls Project was constructed as a temporary installation, ease of construction, demolition, and reuse were primary design considerations of the plinth. The steel elements were designed as bolted modules to be assembled in the field. P-Δ loading at the maximum isolator displacement was considered in the design of the framing and connections.

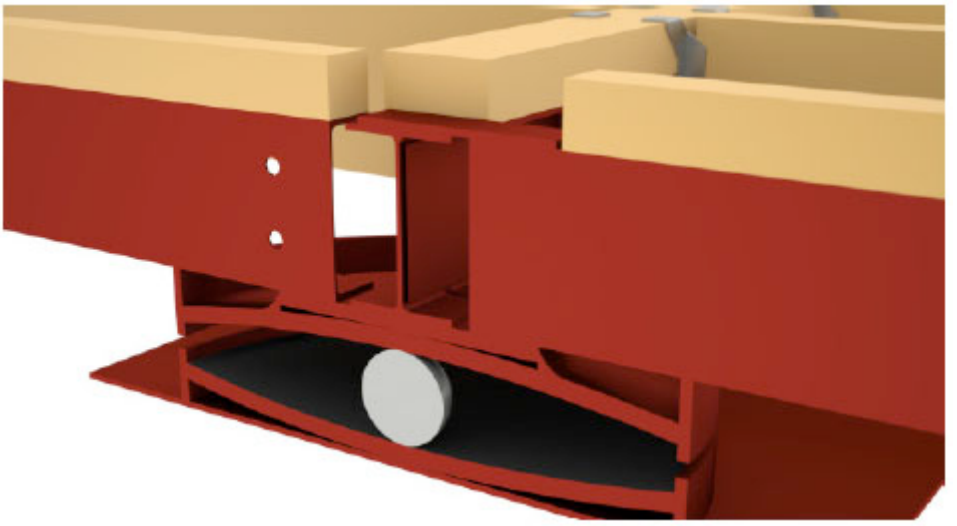

Figure 4. 3-D Section through Isolator.

The seismic isolators use a design derived from the Ball-N-Cone isolator by WorkSafe Technologies. A 3-1/2" diameter steel ball bearing is located between two concave plates. In a seismic event, the top plate displaces relative to the bottom plate, causing the ball to roll along both surfaces. The initial stiffness is a function of the weight divided by the effective pendulum length, *l*, which is equal to two times the difference in the radius of the concave plate and the ball diameter. Near the perimeter of the plate, a constant restoring force is provided by a constant slope which meets the curved surface at a tangent. A steel ring around the edge of each plate provides a lip to limit displacement; however the isolators were designed to meet the displacement demand of the MCE earthquake in San Francisco. The interface of the steel ball bearing to the steel plate provides very little rolling friction resistance and subsequently very little damping. Neoprene liners were applied to the surface of each plate to increase the rolling friction resulting in greater damping.

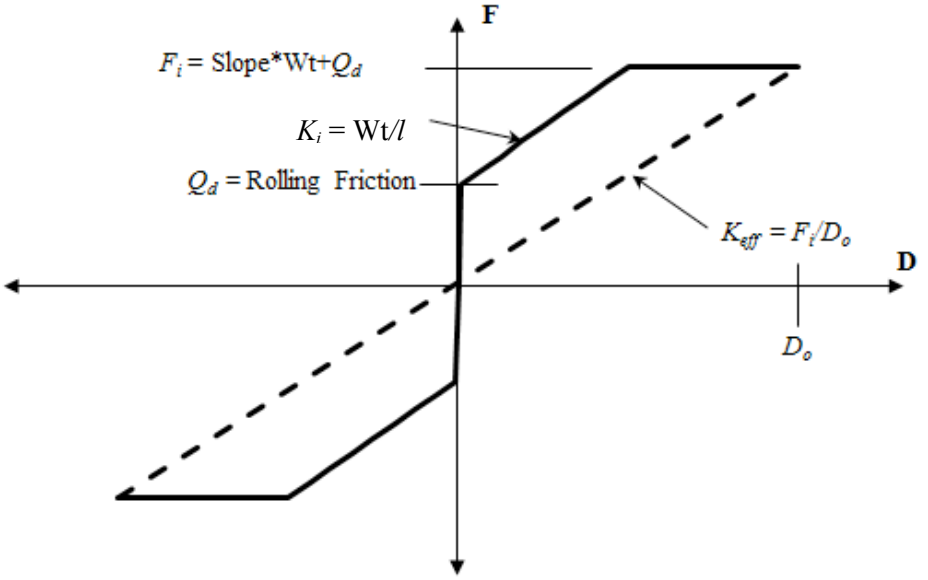

Figure 5. Theoretical force-deformation behavior of Ball-N-Cone isolator.

The method of fabricating the isolators was unique to The Bowls Project. Flat 5/8" circular steel plates were pressed into the required shape, which proved to be much more cost effective than machining.

CODE BASED DESIGN AND APPROVAL PROCESS FOR BASE ISOLATED BUILDINGS

ASCE 7-05 permits isolated structures to be designed using the Equivalent Lateral Force, Response Spectrum, or Response History Procedure. Most designs in the United States use the Response History Procedure based on a suite of ground motion pairs and a nonlinear analytical model to capture the dynamic response of the isolation system.

The Equivalent Lateral Force Procedure is limited to regularly-configured low-rise structures with low seismicity, and firm soil. In addition, the isolation system must have an effective period less than 3 seconds, adequate period separation from superstructure, adequate restoring force and be capable of accommodate the displacement demands from the maximum capable earthquake (Reference ASCE 7-05, Section 17.4.1 for limitations of Equivalent Lateral Force Procedure)

The Equivalent Lateral Procedure is an iterative process based on equivalent linear isolator properties, effective (or secant) stiffness damping. The 1-second spectral acceleration is a known quantity from the site. Isolator Displacement (D_D or D_M) is a function of effective stiffness and damping, which are functions of an initially assumed displacement. The process confirms isolator displacement and yields the Isolated Base Shear, V_b (which is used in one of the minimum base shear requirements for dynamic procedures). The Equivalent Lateral Procedure was used to determine the maximum displacement and isolated base shear for The Bowls project. These quantities were confirmed through full scale testing.

ASCE 7-05 enforces the Design Review and Testing requirements of 17.7 and 17.8 regardless of analysis procedure selection. An argument could be made to waive the Design Review requirements for simple projects that are designed using the Equivalent Lateral Procedure.

The ASCE 7-05 process for Design Review of isolated structures begins with the selection of an independent peer review team. This team is tasked with

a. Review of site specific seismic criteria, including the development of site specific-spectra and ground motion histories,
b. Review of preliminary design, including determination of total design displacement, total maximum displacement, and lateral force level,
c. Overview of prototype testing,
d. Review of the final design of the entire structural system, and all supporting analyses,
e. Review of the isolation system quality control testing program.

The intent of the code-based Design Review and Testing program is to prove the effectiveness of the seismic isolation system and the superstructure design under the dynamic loads that could result in the event of a major earthquake. The design team for the Bowls Project did not have the time or financial resources to engage a peer review team and complete testing prior to construction.

The San Francisco Department of Building Inspections saw the value provided by full scale testing as an alternate means to meet the intent of the code. The design team provided criteria for a series of "Snap-Back" tests in which the plinth was pulled sideways, away from its stable resting position, and then released. The test results were compared against the theoretical results in order to validate isolation system properties and the acceptability of the masonry superstructure to resist the seismic forces transferred through the system. These forces were calculated (and proved) to be on the order of 1/6 the force that would be seen in an equivalent fixed base structure.

In addition to testing all of the components of the isolation system the full scale testing also generates lateral loads within the supported dome superstructure. This was particularly important in this case because the dome construction was not an approved structural system. The testing therefore validated the structural integrity of the dome at the same time as the performance of the isolation system. This approach is not possible in a fixed base design because it would be necessary to confirm that the dome can accommodate the required ductility demands in addition to resisting the required lateral forces.

The lateral forces generated in the dome superstructure were approximately 0.1g. While this was slightly less than the computed design earthquake acceleration of 0.13g the results were judged to be acceptable based on the absence of any observable damage following several tests.

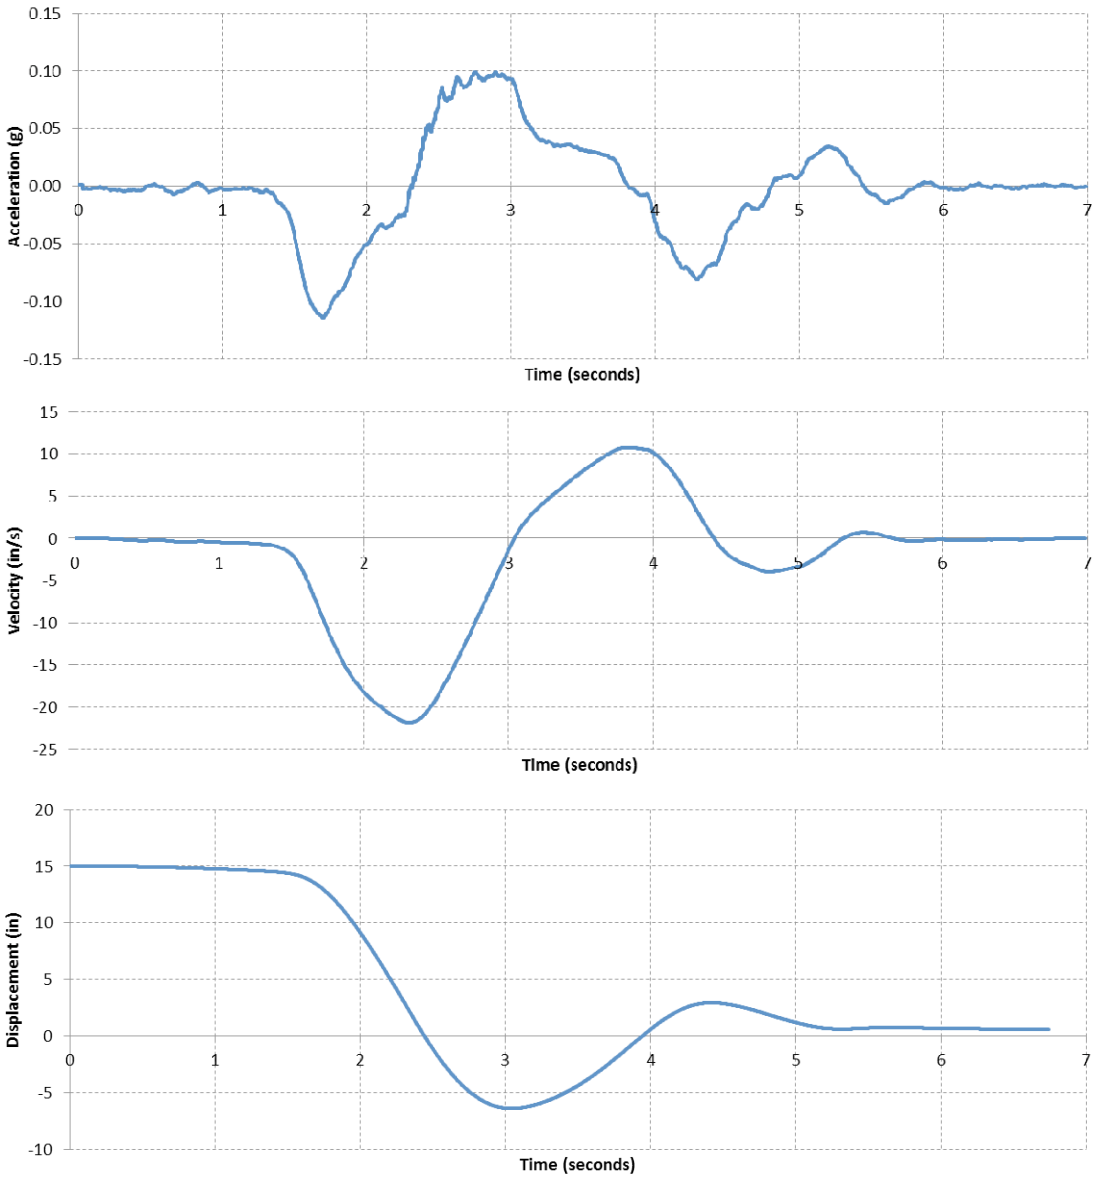

Figure 6. Snap-Back Test Results

The rubber liner in the isolators provided a significant amount of damping, which limited the number of cycles in a snap-back test. The isolation system damping values were estimated using the logarithmic decay of the recorded displacement trace. Because the damping value is relatively high, the trace decays quickly. Using 15" initial displacement, the first half cycle measured 6.4", and the first full cycle measured 2.9" on the return. These values result in about 25% effective damping.

The hysteresis loop computed using the target isolation properties is shown overlaid on the test hysteresis loop in the following figure. The results are very close to the originally assumed effective stiffness.

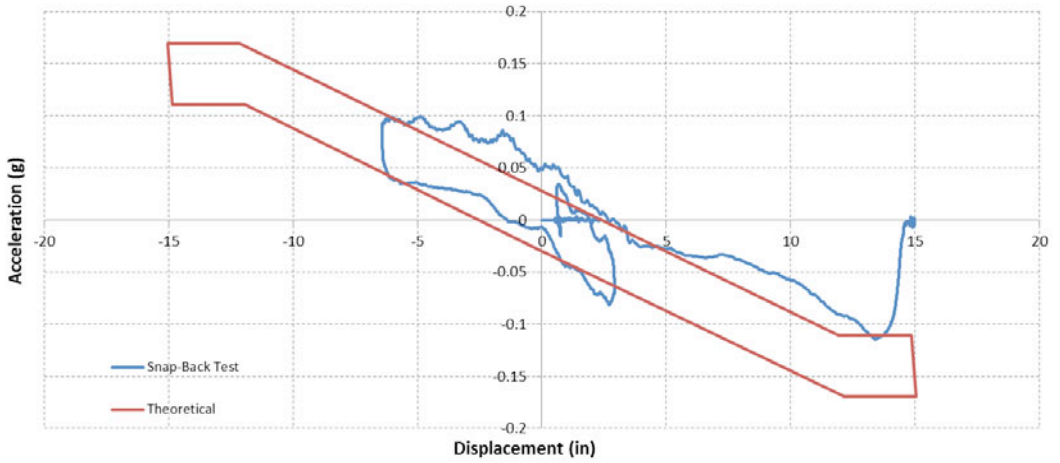

Figure 7. Snap-Back Hysteresis

In order to justify the cyclic performance of the isolators, dynamic test results were achieved by repeated cycling of a segment of the plinth back and forth under human power. The forced cyclic response maintained about 15" maximum displacement per cycle. The uncertainty of the input force (in opposite directions from either side of the plinth) distorts the fullness of the acceleration-displacement loops, consequently making the damping ratio difficult to quantify, The average theoretical result, with no initial acceleration, has been plotted for reference. The average of the dynamic loops closely traces the average theoretical properties although the individual loops may be distorted from the input force. Despite the nuances from the low-tech test method, the results indicate that the isolators would perform acceptably under dynamic earthquake loading.

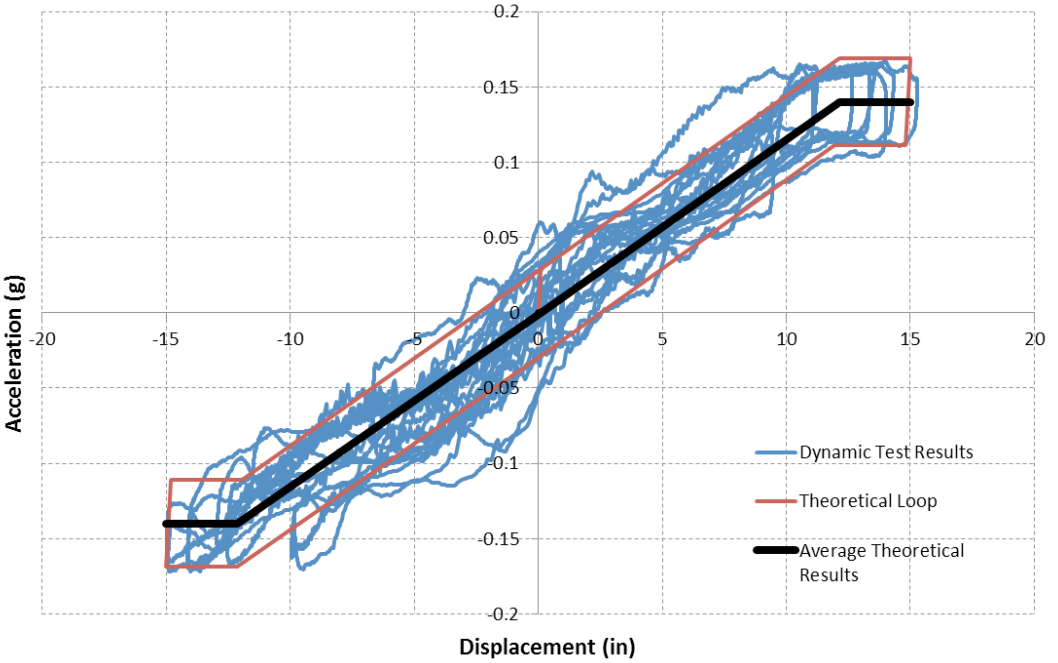

Figure 8. Isolation System Hysteresis under Dynamic Loading

FULL SCALE TESTING ALTERNATIVE

The Full Scale Testing Alternative must meet the intent of ASCE 7-05 in order to demonstrate effective functioning of the seismic isolation system and stability of the superstructure and supporting platform under the dynamic loads that could result in the event of a major earthquake. ASCE 7-05 requires testing as a means to establish and validate the deformation characteristics and damping values of the isolated system. The full scale testing alternative focuses on the validation of the design using knowledge of base-isolation principles and consistency in fabrication to establish isolator properties.

The limits defined by the Equivalent Lateral Procedure establish expected upper bound force and displacement under lateral loads. Regardless of design procedure, in the current practice of design in the United States, engineers forgo the "prototype" tests and jump straight to system design with the confidence that isolators can be fabricated to meet design parameters. Prototype testing in the laboratory is used as a means to confirm the adequacy of a design.

The proposed Full Scale Testing Alternative pushes the validation of design properties to the final stage of construction. In addition to the code acceptance criteria, care should be taken to include project specific performance criteria for the superstructure. Project size, required testing loads, and ability to provide safety to all persons involved in the test are pertinent considerations for the use of Full Scale Testing.

ASCE 7-05 establishes acceptability criteria in section 17.8.4. Using this section, the following conditions must be satisfied:

1. The force-deflection plots for all tests specified in Section 17.8.2 have a positive incremental force-resisting capacity
2. For each increment of test displacement specified in Section 17.8.2.2, and for each vertical load case specified in Section 17.8.2.2,
    a. For each test specimen, the difference between the effective stiffness at each of the three cycles of test and the average value of effective stiffness is no greater than 15 percent.
    b. For each cycle of test, the difference between effective stiffness of the two test specimens of a common type and size of the isolator unit and average effective stiffness is no greater than 15 percent.
3. For each specimen, there is no greater than a 20 percent change in the initial effective stiffness over the cycles specified in item 4 of Section 17.8.2.2.
4. For each specimen, there is no greater than a 20 percent decrease in the initial effective damping over the cycles specified in item 4 of Section 17.8.2.2.
5. All specimens of vertical-load-carrying elements of the isolation system remain stable where tested in accordance with Section 17.8.2.5.

For the Bowls Project, the test procedure required two "snap-back" tests in each principle direction at full displacement. Since the system was tested as a whole, comparative tests between individual specimens were not required. The acceptance criteria for the isolation system were modified from ASCE 7-05 as follows:

1. Loop has positive incremental stiffness in each direction. *[Similar to Item 1 above]*
2. For the tests in each direction, K_{eff} at each displacement cycle above 3" shall be within 15% of the average value for the two tests. *[Similar to Item 2a above]*
3. The value of K_{eff} at the cycles closest to D_d and D_m during the 4th test shall be within 15% of the value in the first test.
4. The effective damping, beta, at the cycles closest to D_d and D_m during the 4th test shall be within 15% of the value in the first test.
5. All isolators shall be stable during each test, no delamination of liners observed, or jamming or deformation of the ball bearings.

In addition to the isolation system acceptance criteria, project specific acceptance criteria for The Bowls Project were the following:

1. No collapse of masonry, global or local.
2. No cracks greater than 1/8" following the test.
3. Hairlines cracks shall be repaired following completion of the test sequence.
4. From the recorded test hysteresis loop demonstrate that the isolator stiffness and damping characteristics match the values used in the calculations, specifically:

K_d	>=0.63 k/in	for test displacement closest to D_d=7.7"
K_m	>=0.39 k/in	for test displacement closest to D_m =15.6"
β_d	>=23%	for test displacement closest to D_d =7.7"
β_m	>=19%	for test displacement closest to D_m =15.6"

   The acceptability values may be adjusted to match actual test displacements.
5. The plinth acceleration must exceed 0.13g, the code minimum base shear determined for the isolation system in these calculations for the design earthquake.

The isolation system proved to have a very high damping level, sufficient to prevent the snap-back tests from achieving the larger displacements listed above. However, the testing did confirm that the isolation system met the requirements for the design level earthquake displacements following adjustment of the target properties for the actual test displacement. The cyclic testing was used to validate the isolator properties for the maximum capable earthquake displacements.

CONCLUSIONS

The unconventional structural system of The Bowls Project necessitated use of base-isolation as a protective system, and the scale of the project allowed an unconventional testing method. A conventional structural system or a building more massive than The Bowls would have rendered base isolation unnecessary and/or full-scale in-place testing impractical. The combination of high seismicity, vaulted masonry construction, design team creativity and local jurisdiction cooperation provided a unique opportunity for innovation.

The application of full-scale testing as an alternative to testing individual (or pairs) or isolators allows smaller scale isolation projects to be viable. Time and budget constraints for conventional approval of an isolated system for The Bowls Project would have never allowed the project to get off the ground. The process in itself is similar to the current design-practice, where isolators are tested in order to verify assumed properties, instead of to establish design properties.

This approach appears to have great potential to improve the adoption rate for small isolated structures, particularly when alternate structural systems are used.

ABSTRACT

The WorkSafe ISO-Base planks, Isolated Raised Access Floor and Isolated Equipment Platform take a new approach to protection of building contents in seismic areas by implementing isolation technology. Seismic isolation has been in use since the 1970s to protect buildings and other large structures from earthquake shaking in seismically active areas around the world. Seismic isolation technology works by decoupling the isolated component from the ground, essentially allowing the ground to move underneath the component without transmitting the damaging accelerations above the plane of isolation. WorkSafe Technologies owns the patents on the Ball-N-Cone isolation technology, which uses a steel dish and ball bearing to provide seismic isolation and has developed systems for isolating individual cabinets as well as entire access floors. The technology has now been extended to include large isolated platforms, suitable for large heavy items such as equipment, art installations and potentially light framed residential construction. The patented Ball-N-Cone isolators are well suited to the lighter vertical loads associated with building contents compared to those present in larger building and bridge structures. The WorkSafe ISO-Base planks are unique in applying isolation technology to individual server cabinets, or rows of cabinets. The Isolated Raised Access Floor (IRAF) applies the same isolation technology, but to an entire access floor by moving the isolation plane to the base of the access floor pedestals. The benefits of using isolation as opposed to conventional bracing are two-fold – critical equipment is protected against damaging earthquake accelerations and facility managers do not have to deal with installing traditional bracing, with the associated concrete drilling and relatively heavy construction in the sensitive data center environment. The Isolated Equipment Platform extends the use of the Ball-N-Cone isolator to heavier components such as large pieces of equipment, art installations and potentially light framed construction. This paper presents several case studies on the applications of equipment isolation and the benefits it provides.

INTRODUCTION

Traditional fixed base building structures and their contents are prone to significant damage when subjected to the high horizontal accelerations from large earthquakes. The seismic performance of typical fixed based buildings designed in accordance with current building codes assumes nonlinear response of the building's lateral force resisting system as codified in the response modification coefficient (R).

Furthermore, floor accelerations of a fixed base structure can be significantly higher than the input earthquake horizontal ground acceleration. This amplification of the earthquake horizontal accelerations up the height of a building is included in building codes for the design of the structure as well as the anchorage of contents. Fragile contents such as computers, servers, data storage systems, networking equipment, pharmaceutical filling equipment, and museum contents are especially susceptible to damage when subjected to high lateral accelerations.

Damage to the building structure can be reduced or eliminated by designing the structure to remain nearly elastic when subjected to the design level earthquake ground shaking. However, this will generally increase the accelerations that the building contents will be subjected to. Other alternatives to reducing damage to the structure include energy dissipation systems or a capacity design approach. Both of these methods will still result in relatively high lateral accelerations on building contents. The only method to significantly reduce damage to the building structure and its contents is to base isolate the entire building.

Seismic isolation has been in use since the 1970s to protect buildings and other large structures from earthquake shaking in seismically active areas around the world. Base isolation decouples the building from the earthquake horizontal accelerations, significantly reducing lateral demands on the structure and contents. However, building a new base isolated facility is not always possible and retrofitting an existing structure with base isolation is prohibitively expensive, except for rare cases. With WorkSafe Technologies Ball-N-Cone isolation products there is now an alternative to isolating the entire structure.

WorkSafe ISO-Base planks, Isolated Raised Access Floor and Isolated Equipment Platform take a new approach to protection of building contents in seismic areas by implementing isolation technology.

WorkSafe Technologies owns the patents on the Ball-N-Cone isolation technology, which uses a steel dish and ball bearing to provide seismic isolation and has developed systems for isolating individual cabinets as well as entire access floors. The technology has now been extended to include large isolated platforms, suitable for large heavy items such as equipment, art installations and potentially light framed low-rise construction. The patented Ball-N-Cone isolators are well suited to the lighter vertical loads associated with building contents and lightweight structures compared to those present in larger building and bridge structures.

The WorkSafe ISO-Base platforms are unique in applying isolation technology to individual server cabinets, or rows of cabinets. The Isolated Raised Access Floor (IRAF) applies the same isolation technology, but to an entire access floor by moving the isolation plane to the base of the access floor pedestals. The benefits of using isolation as opposed to conventional bracing are two-fold – critical equipment is protected against damaging earthquake accelerations and facility managers do not have to deal with installing traditional bracing, with the associated concrete drilling

and relatively heavy construction in the sensitive data center environment. The Isolated Equipment Platform extends the use of the Ball-N-Cone isolator to heavier components such as large pieces of equipment, art installations and potentially light framed construction.

FUNDAMENTALS OF BASE ISOLATION

The concept of base isolation is to decouple the structure from the horizontal components of the earthquake ground motion by creating an isolation plane. The isolation plane is created by introducing a structural system that has a relatively low lateral stiffness between the structure to be isolated and the foundation or supporting elements. The low lateral stiffness of the isolation system gives the isolated structure a fundamental frequency that is lower than both the fixed base structure and the earthquake ground motion frequencies with the most damaging accelerations. The isolated structure responds primarily in the first mode, which consists of lateral displacement of the isolation system, and the structure above remains almost rigid. Figure 1 shows a comparison of the idealized response of an isolated and fixed base structure to earthquake ground shaking.

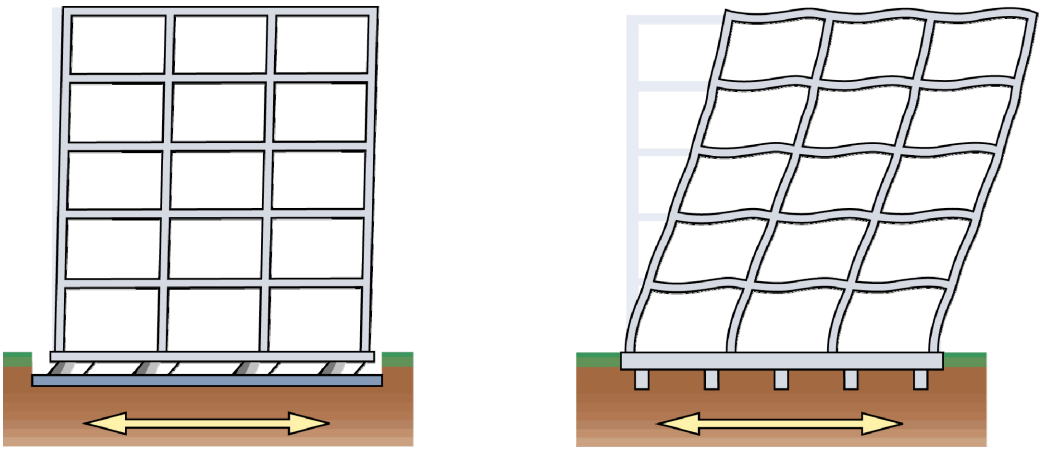

Figure 1. Comparison of Response Between Isolated and Fixed Base Structure

The benefit of base isolation is that the horizontal accelerations on the structure and components above the isolation plane are significantly reduced when compared with a fixed base structure, as much as 5 to 10 times, depending on the application. An additional benefit is that the elements above the isolation plane can be easily designed to remain elastic due to the significant reduction in horizontal accelerations, which greatly reduces or eliminates damage to the structure and contents.

BALL-N-CONE ISOLATOR

There are two basic types of isolation systems that are routinely used for the base isolation of buildings and bridges: elastomeric bearings and sliders. The Ball-N-Cone

isolator represents a third type of isolation system and uses a ball bearing sandwiched between two steel dishes. The typical Ball-N-Cone isolator used in the ISO-Base planks is shown in Figure 2.

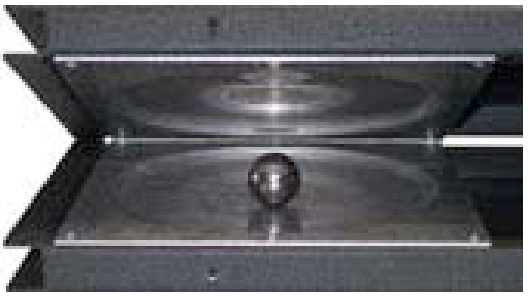

Figure 2. Ball-N-Cone Isolator (ISO-Base Plank)

The isolator consists of a 1.5-inch diameter hardened steel ball bearing and two 8-inch diameter steel dishes. Larger isolators have also been manufactured and tested. The isolator functions by the top and bottom dishes moving relative to each other by rolling of the steel ball bearing. The profile of the steel dish consists of mainly a cone with a slope of approximately 1:10 (rise to run) connected by a small radius transition at the center, as shown in Figure 3. The lateral displacement capacity of a Ball-N-Cone isolator is approximately two times the radius of a dish.

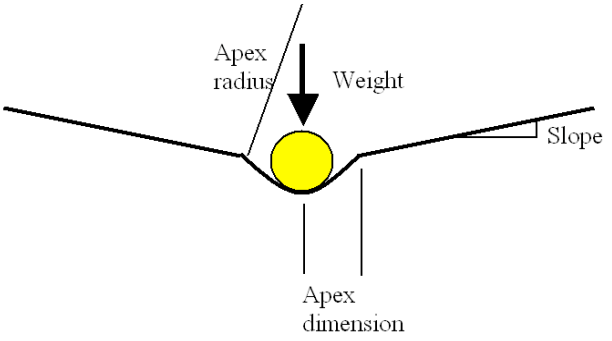

Figure 3. Idealized Profile of Ball-N-Cone Isolator

The vertical load carrying capacity of a Ball-N-Cone isolator is typically limited by the strength of the dish or its supporting elements. The ball bearings, which are typically hardened to Rockwell 59C, have a very high strength and are not the limiting factor. For a typical ISO-Base plank the maximum load is on the order of 1,000 pounds. If the dish is adequately supported an increase in the vertical load results in the ball bearing penetrating the surface of the dish, creating a small indentation. When the isolator displaces laterally the ball tracks through the dish, leaving an indication of its path.

The structural properties of a system using Ball-N-Cone isolators is a function of the apex radius (R), the slope of the dish (S) and the weight on the ball bearing (W). The initial stiffness is a function of the weight and radius, Ki = W/(2R). Once the ball moves out of the apex of the dish, which is relatively small, the system has a constant restoring force, which is a function of the slope of the dish and the weight on the ball bearing, Fr = SW. The low slope (0.1) of a typical Ball-N-Cone limits the lateral accelerations that can be transmitted above the isolation plane to approximately 10% of gravity, which is significantly lower than a typical fixed base system. Because the system has a nonlinear elastic force-deformation curve the period of the system depends only on the slope of the dish and the displacement demand. For a standard ISO-Base plank, which has a slope of approximately 0.1 and a diameter of 8-inches, the period at maximum displacement, calculated using the secant stiffness, is approximately 2.9 seconds.

Unlike sliding isolators or lead-rubber bearings the Ball-N-Cone isolator exhibits very low damping. System damping is primarily due to rolling friction between the ball bearing and the steel dishes. Because the vertical loads are typically limited to a low value, the resulting rolling friction is also low resulting in system damping on the order of 1-2%. For applications with vertical loads less than 500 pounds per isolator, a polymer liner can be bonded to the two dishes. The polymer liner increases rolling friction and as a result leads to an increase in system damping.

APPLICATIONS OF BALL-N-CONE ISOLATION

Ball-N-Cone isolators are best suited for applications with relatively low axial loads (less than 15,000 pounds) due to the practical limitations of component availability and system design. These applications include protection of data center components, such as computer racks, network storage racks and associated equipment, entire data centers (by isolating the floor) and large components such as pharmaceutical fill-finish equipment and art installations. Future applications include light framed construction, such as single family residential. The following sections describe the range of applications of Ball-N-Cone isolators.

ISO-Base Seismic Isolation Planks for Computer Racks

The first wide spread use of Ball-N-Cone isolators is in WorkSafe Technologies ISO-Base seismic isolation planks for computer racks typically found in data centers. The benefits of base isolating computer racks is three fold; first, the equipment is protected from the high lateral accelerations that a fixed base rack would be subjected to, second, the horizontal forces that the supporting structure (typically a raised access floor) are subjected to are reduced, and third, cumbersome mechanical anchors are eliminated, providing increased flexibility to data center managers.

A typical ISO-Base plank assembly used to isolate a single rack is shown in Figure 4. Each plank consists of two dishes interconnected be small steel tubes. Two create an isolation platform for one computer rack two planks are placed on the floor face up,

followed by four ball bearings with two additional planks on top facing down. The two adjacent top and bottom planks are interconnected with bolted steel tubes.

Figure 4. Typical Isolation Platform for Computer Rack using ISO-Base Planks

The modular nature of the system allows the isolated platform to grow, such that an entire row of racks can be isolated, as shown in Figure 5.

Figure 5. ISO-Base Planks Assembled into Rows

As discussed previously, the standard ISO-Base planks are fitted with 8-inch diameter dishes, which means that the lateral displacement capacity of the system is 8-inches. Eight inches of lateral displacement capacity for a system with low damping results in full protection for earthquakes with a one second spectral acceleration of 30% of gravity or less. To improve the seismic performance of the system, polymer liners can be bonded to the dishes. This enhancement provides full protection for earthquakes with a one second spectral acceleration of approximately 45% of gravity. This provides full protection for most locations except for areas in high seismic regions, such as coastal California. To best determine the performance of an ISO-Base installation a structural engineer should perform a site specific analysis taking in to consideration the following items: seismicity, including near-field effects, height of installation in a building, lateral system of the building, soil conditions at the site, rack weights and configuration.

Based on testing conducted at the University of British Columbia, should isolator lock-up occur, the performance of the rack is equivalent to a fixed based rack. The result is that the ISO-Base planks provide full protection for all but the rarest earthquakes. To address the potential life-safety hazard associated with toppling of the racks, several additional enhancements have been developed. These include ball bearing restraints, which prevent the balls from rolling out of the dishes and limit straps, which prevent the top and bottom planks from separating. These elements are shown in Figures 6 and 7.

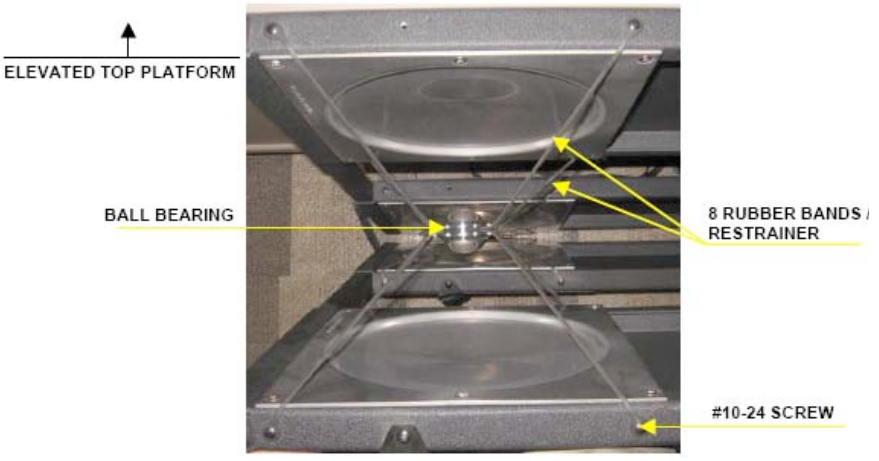

Figure 6. Ball Bearing Restraints

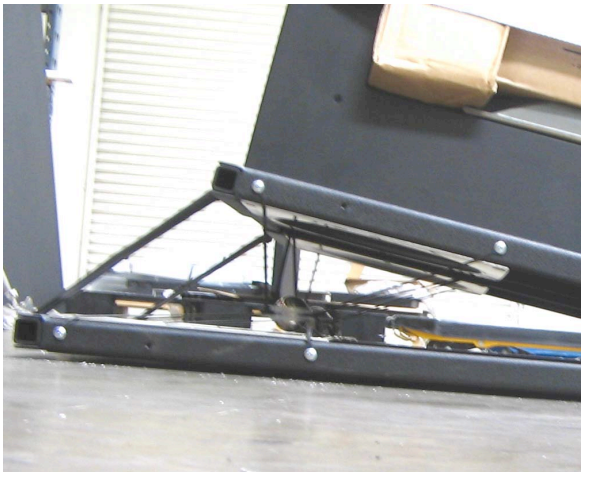

Figure 7. Limit Straps

Testing has shown that no mechanical connections are required between the bottom planks and supporting structure, even for the case of isolator lock-up. The computer racks are typically secured to the top plank with nylon straps, which have been shown through testing to be adequate to keep the racks in place on the top plank. The ease of installation is ideal for data center managers as it allows full protection of the racks without permanent anchoring typically associated with mechanical anchoring,

providing a flexible solution for seismic solution. To provide even more flexibility and earthquake protection an isolated raised access floor has been developed. The isolated access floor can be designed for any seismic hazard level and allows for complete flexibility in the arrangement of data center components.

Isolated Raised Access Floor

The Isolated Raised Access Floor has been developed to provide data center owners with maximum seismic protection and complete flexibility in data center configuration. By moving the isolation plane to the bottom of the raised floor pedestals, data center owners are free to configure their cabinets in any manner they desire. Furthermore, there is no need to move the racks on and off ISO-Base planks or deal with complicated fixed base anchorage. The Isolated Raised Access Floor is suitable for both new and existing construction; it can easily replace an existing raised access floor with a few simple modifications to allow for floor lateral displacement. The floor has been designed to use standard 24-inch square raised access floor tiles, allowing existing data center owners to reuse components from their current floor. Figure 8 shows an image of the structural system of the Isolated Raised Access Floor.

Figure 8. Isolated Raised Access Floor Structural System

The design features modular bolted construction allowing for ease of on-site installation. The Ball-N-Cone isolators are larger than those used in the ISO-Base planks, allowing for higher axial loads and larger lateral displacement capacity. The floor can be designed to have pedestal spacing of four to six feet, allowing the system to work within an existing facility. A typical cross section through the Isolated Raised Access Floor is shown in Figure 9.

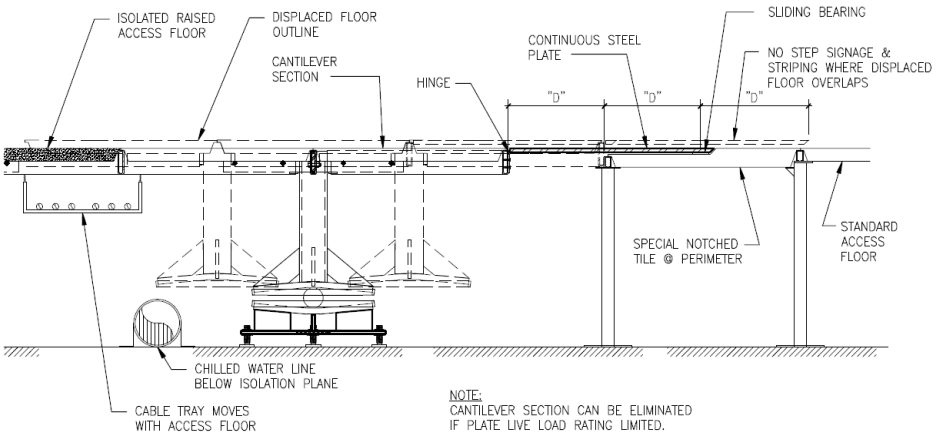

Figure 9. Typical Isolated Raised Access Floor Cross Section

As shown in the section, data and power cables can be suspended from the bottom of the access floor and large chilled water pipes can be located between the isolated pedestals. The Ball-N-Cone isolators sit on leveling feet allowing for leveling of the floor system.

The Isolated Raised Access Floor has been tested on the shake table at the University of British Columbia and its performance has been validated. Currently the floor can be designed to have a lateral displacement capacity of up to 18 inches. If the seismic demands exceed this displacement capacity, for example a data center located near the top of a flexible building in a high seismic area, the floor can be designed to include viscous dampers to reduce the displacement demands. The dampers can be installed around the perimeter of the floor below the space typically reserved for CRAC units.

Isolated Equipment Platforms

Isolated Equipment Platforms take the concept of the ISO-Base planks and Isolated Raised Access Floor and extend it to a more general case. Isolated Equipment Platforms can be used for the seismic protection of a wide range of components, from complex pharmaceutical fill-finish lines composed of multiple individual components to fragile art installations. Similar to the isolated floor, the equipment platforms can be designed with a displacement capacity of up to 18 inches. Vertical loads can be upwards of 15,000 pounds per isolator, which typically use a 3.5-inch diameter high strength ball bearing. The design of the isolated platforms is tailored to meet the specific needs of the application.
