as staircases. For vibration frequencies between 4 and 8 Hz, the recommended peak acceleration for human comfort for vibrations due to human activities is equivalent to 2.31% of *g*, for stairs with light use. In this guide, and based on the ISO 10137 standard (ISO 2007), the human footfall loading on stairs during ascending and descending is different in frequency and magnitude compared to that induced by walking on flat surfaces. The excitation forcing frequencies and the Fourier coefficients are given in Table 2.

Table 2. Forcing frequencies, f, and Fourier coefficients, α_i, for walking excitation on staircases (SCI 2007).

Harmonic, i	f (Hz)	α_i
1	1.2-4.5	1.1
2	2.4-9.0	0.22

Walking-Induced Lateral Loading

In addition to the vertical excitation, the lateral component of the human-induced walking loading may have a significant contribution but it is not specified in the above two design guides. Based on other resources (FIB 2005, Bachmann 1987, Bachmann and Ammann 1995), the frequency of the lateral loading is taken as half the walking frequency and the Fourier coefficients are $\alpha_1 = 0.1$, $\alpha_2 = 0.01$, and $\alpha_3 = 0.1$.

STAIRCASE MODELING

The four-story steel atrium staircase, shown in Figure 1, was modeled and analyzed using the commercially-available finite element (FE) program SAP2000 (CSI 2009). The staircase has a nine meter cantilever span, with stone finishes and composite steel construction landings (100 mm concrete placed on 8 mm steel plate). The balustrade is constructed using a 20 mm thick inner plate and an 8 mm thick outer steel plate. The stair stringers are HSS356x102x13 and HSS203x102x13, whereas the posts supporting the balustrade (located between the two plates) are HSS102x102x9.5 (Figure 2). The latter, together with the steel plates, effectively create a structural element which, jointly with the stringers and the rest of the structure, contributes to the overall stiffness against vibrations. The yield strength of all steel elements is $f_y = 345$ MPa. The main floors of the building consist of a 250 mm thick reinforced-concrete flat slab with 500 mm drop panels at the columns and at the edge, where the stair is connected to the slab. The drop panels at the edge provide an element with increased stiffness for the support of the stair. The concrete strength is typically $f_c' = 30$ MPa; however, at the connection between the stair and the slab a 60 MPa strong concrete is utilized. The dynamic modulus of elasticity for

concrete was taken as 35,000 MPa and 41,200 MPa, corresponding to the 30 MPa and 60 MPa concrete strengths, respectively.

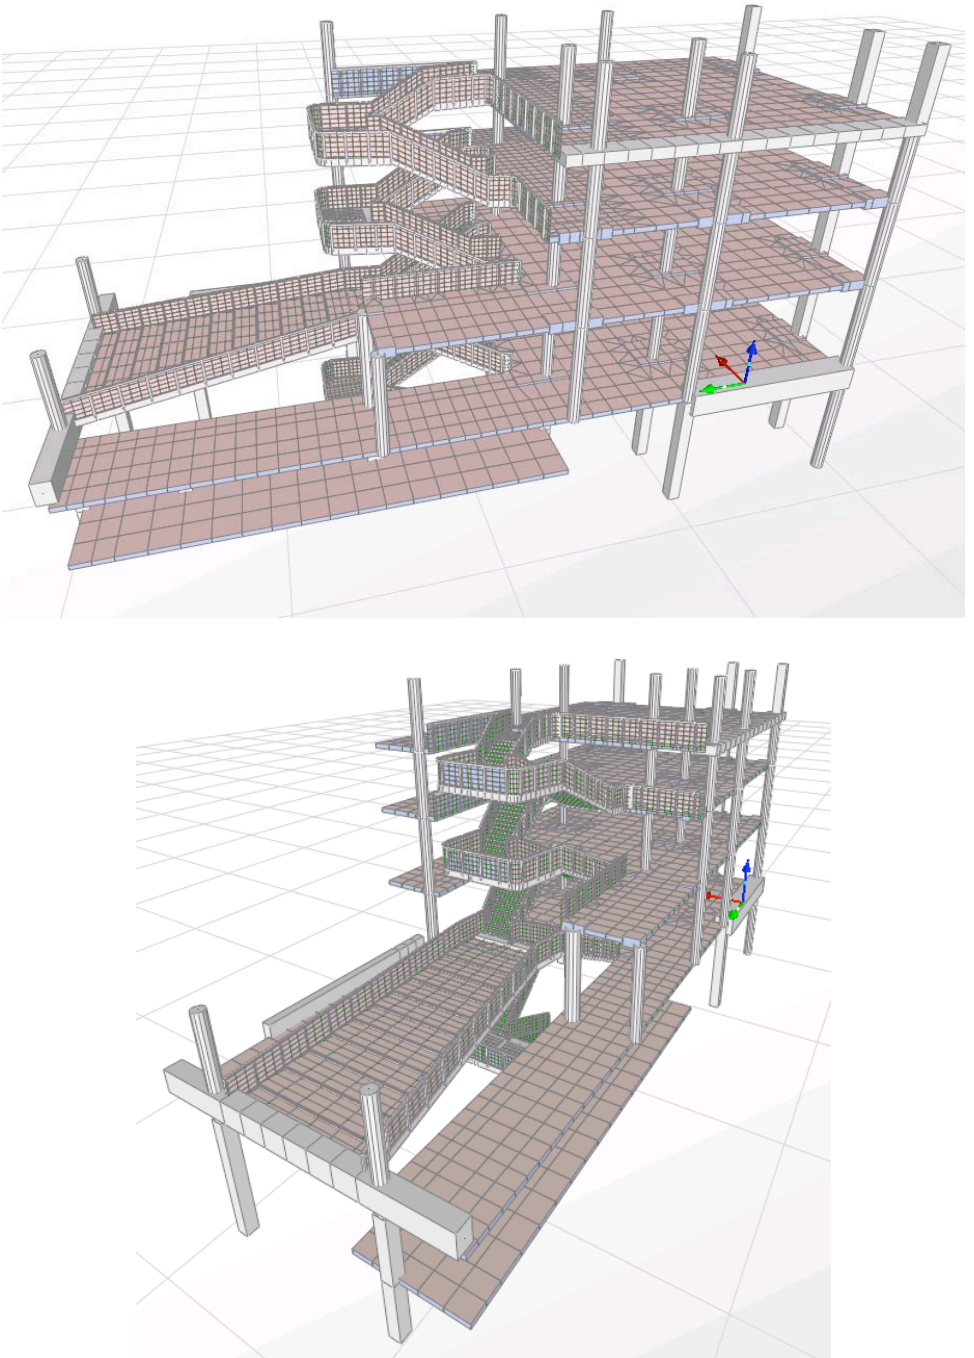

Figure 1. Feature staircase at a prominent academic institution in Toronto, Ontario, Canada.

The gravity loads applied to the staircase consist of the self weight of the structure, superimposed dead load of 1.9 kPa, and live load of 4.8 kPa. The gravity loads applied to each floor of the building consist of the concrete self weight, superimposed dead load of 1.5 kPa (at the floors above the ground) or 4.8 kPa (at ground floor), and live load of 4.8 kPa. For the dynamic analysis, the mass of the structure is based on the entire self weight and superimposed dead load, and 10 % of the live load. Four-noded shell elements were used for the modeling of area elements (floors, landings, stair treads, balustrade, etc.) and the consistent meshing was done manually to ensure proper connectivity between the nodes of the elements.

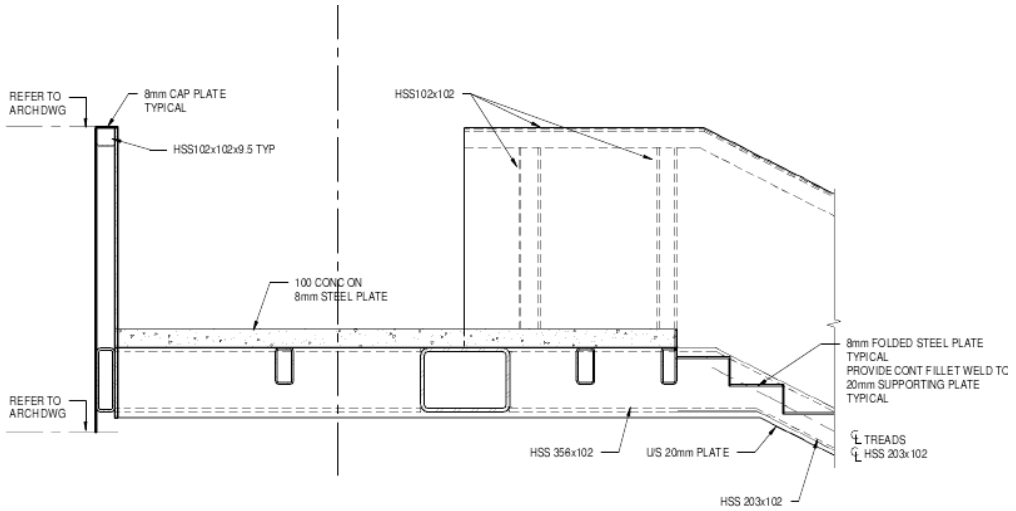

Figure 2. Detail of the staircase indicating steel sections used.

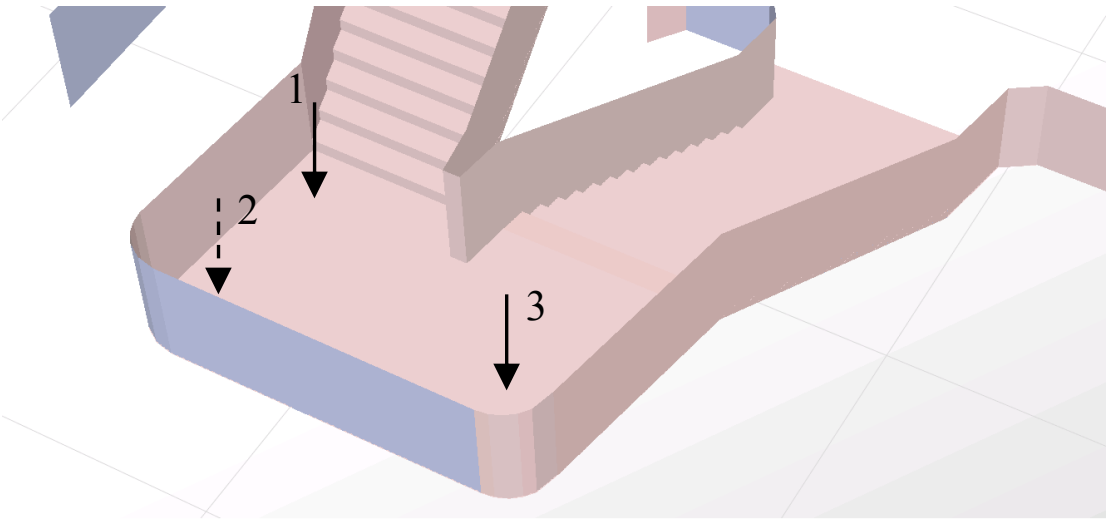
WALKING EXCITATION – LOAD CASES

Walking up and down the stair introduces an additional dynamic effect to the magnitude of excitation force imparted to the stair structure due to the body lifting or dropping onto the next tread. Hence, in applying the pace frequencies and the dynamic coefficients a differentiation was made between walking up and down the stair and walking on the landings. For the former case, the SCI (2007) parameters were incorporated in load case 1, where the loading function was applied at a small distance from the last tread (refer to load 1 in Figure 3). In load case 2 the SCI (2007) loading function was applied at the same location as for case 1; however, the measurement of the acceleration was made at a distance equal to one quarter of the mid-landing width, measured from the staircase edge (refer to loads 2 and 3 in Figure 3). Finally, in load case 3, the AISC (1997) loading function was applied at a distance equal to one quarter of the mid-landing width, measured from the edge of the staircase (refer to load 3 in Figure 3). This point is close to the maximum modal displacement for the first and second vertical vibration mode shapes.

The AISC vibration guidelines also specify a reduction factor, *R*, that accounts for the fact that full steady-state resonant motion is unlikely to be achieved for walking and that the person walking and the person feeling the resulting acceleration are not simultaneously at the location of maximum modal displacement (AISC 1997). The reduction factor should be taken as 0.5 for floors and 0.7 for pedestrian bridges (stairs qualify as indoor footbridges). For consistency, this factor was used also for the SCI loading function. However, it is to be noted that, for load case 2, the reduction factor *R* was taken as 1.0 (and not 0.7 as for the other load cases) because the measurement was not taken at the same point as that of the load application.



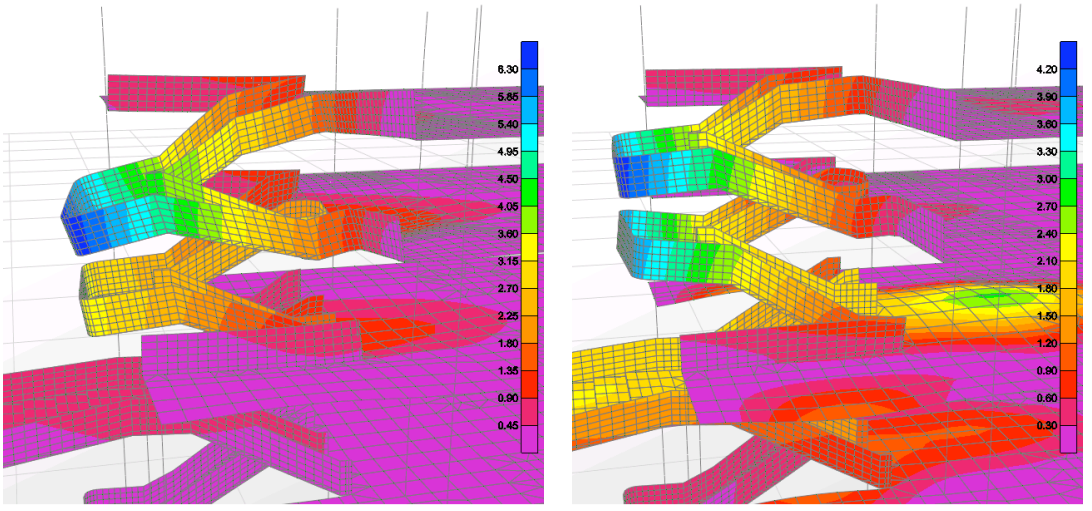


Figure 3. Walking excitation load cases for the staircase.

ANALYSIS RESULTS

The linear time-history dynamic analysis was performed using the FE program SAP2000 (CSI 2009). The first and second modes of the stair are shown in Figure 4 and their periods are 0.202 and 0.157 seconds, respectively. Figure 5 shows the acceleration as a function of time for the three load cases mentioned previously.

Damping has a significant effect on accelerations. It is well known that there is a linear relationship between the two parameters such that increasing the damping ratio by a certain percentage results in a decrease of the acceleration by a similar percentage. For example, accelerations are expected to double by using a damping ratio of 0.5% of critical (as per the SCI P354 guidelines) instead of 1.0% (as per the AISC guide 11). To determine the best estimate for the actual damping ratio to be used in the numerical analysis, dynamic measurements were conducted on a relatively similar existing atrium stair. The data was collected through acceleration measurements using a heel drop technique on the stair ramps and two landings. As a result, the percentage of critical damping thus obtained was consistent for both the lower and upper landings at slightly over 4%.

(a) (b)

Figure 4. Mode shapes of the staircase
(a) First mode (T=0.202 s) and (b) Second mode (T=0.157 s).

The modal damping ratios at the lower and higher frequencies of the stair vibration spectrum were similar and in the range of 4 to 5% of critical damping. However, it is to be noted that the heel drop measurement technique tends to overestimate the damping because it measures not only the energy dissipation but also the transmission of vibrational energy to other structural components, the latter being known as geometric dispersion (AISC 1997). For typical office buildings this technique gives 190 % higher values than the method based on the Fourier spectrum of the response to impact (AISC 1997). Therefore, from the performed measurements on the existing staircase it was concluded that a damping ratio around 1.0 % would be an appropriate estimation for such type of steel structure.

Figure 5 shows that the peak acceleration values obtained for load cases 1, 2 and 3 are 1.65, 3.21 and 1.98% of *g*, respectively, when a damping ratio of 0.5% of critical is considered. For a damping ratio of 1.0% of critical, the maximum acceleration values obtained for load cases 1, 2 and 3 are 0.84, 1.64 and 1.05% of *g*, respectively. These values were compared to vibration design criteria given in the SCI (2007) and AISC (1997) guidelines and the stair satisfied the criteria for a damping ratio of 1% of critical. The former guidelines indicate an RMS acceleration limit of 2.31% of *g*, and this corresponds to load cases 1 and 2, whereas the latter recommend a peak acceleration limit of 1.5% of *g*, which is applicable to load case 3. It is interesting to also note that, for a load case that is similar to load case 3 but in which the forcing frequencies and Fourier coefficients prescribed by the SCI guidelines were used, the resulting peak acceleration amplitudes were 4.59 and 2.34% of *g*, for damping ratios of 0.5 and 1.0% of critical, respectively. This is represented by load case 3-SCI-P354 illustrated in Figure 5(d). The latter values are more than double the values obtained from load case 3, which is based on AISC 11 design guide.

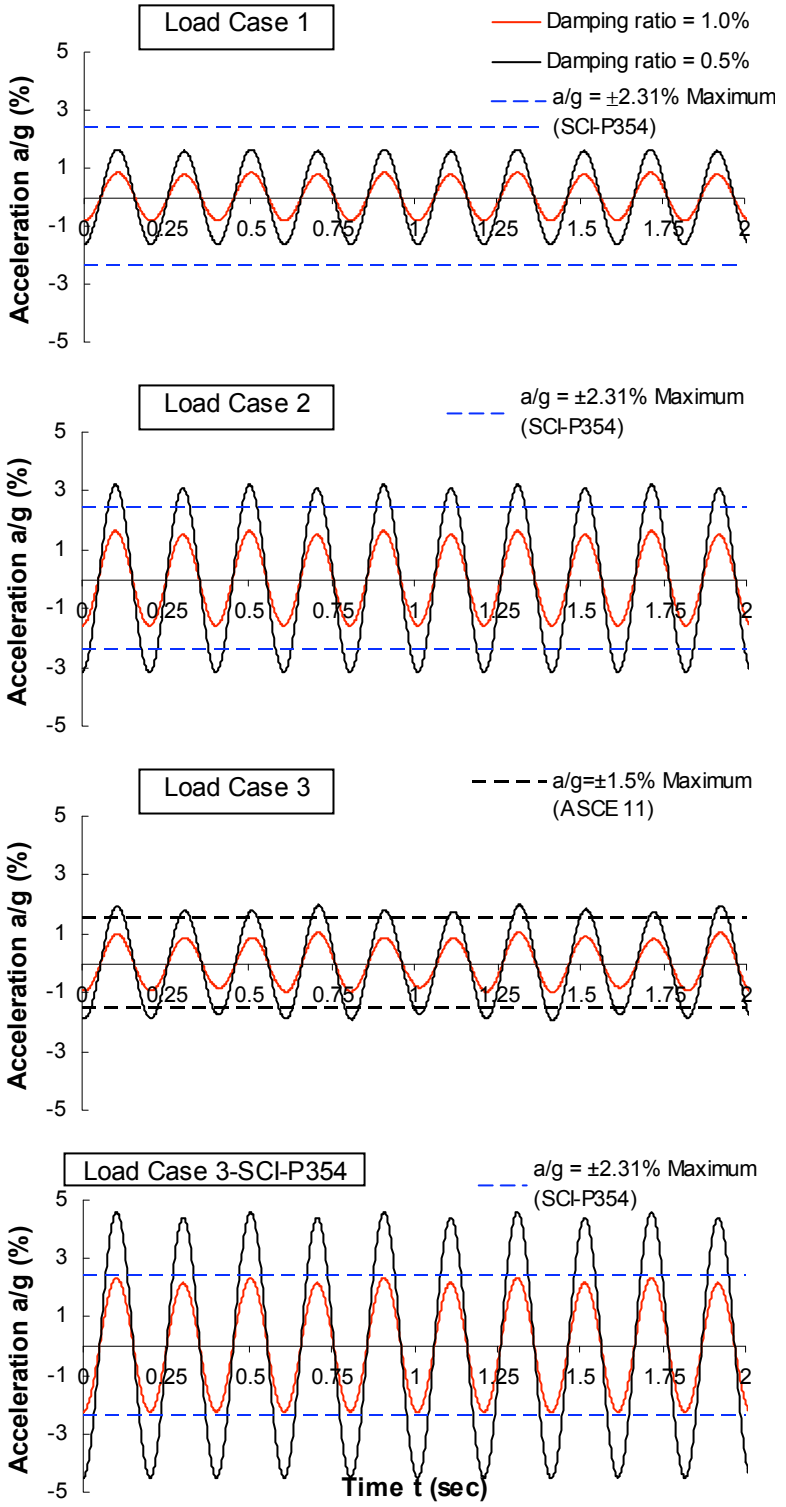

Figure 5. Acceleration-time curves for the four load cases with damping ratios of 0.5 and 1.0% of critical.

CONCLUSION

Designing a staircase to be insensitive to vibrations due to human activity is often challenging. The long spans, low mass, in conjunction with a low damping ratio, can result in a low-frequency system that responds with high human-induced accelerations. The damping ratio and the pace frequency have a significant influence on the vibration behavior of the structure. The AISC 11 design guide, which is the document used in North America predominantly for vibration design, contains no specific requirements for staircases. The UK SCI-P354 design guide, however, provides some specific information pertaining to the design of staircases. The study demonstrates that a large and inconsistent scatter of accelerations is obtained from the FE analysis by using the approaches specified in different guidelines. It also emphasizes that the damping ratios recommended in the guidelines may not be indicative of the actual values and should be used with caution when designing staircases for vibrations. It is recommended that more research should be performed to reach a consensus in order to provide better estimates of the damping ratio and forcing functions for vibration-sensitive structures. Based on the presented study, a damping ratio of 1% of critical is recommended for welded steel staircases with stone finishes and composite landings, or similar construction. In addition, pace frequencies of 1.6-2.2 Hz using the Fourier coefficients indicated in the AISC 11 guide should be used at the landings, whereas pace frequencies of 1.2-4.5 Hz and Fourier coefficients specified in the SCI P354 guide are recommended along the stair treads.

ABSTRACT

This paper presents a case study of a 39-foot long, curved, conventionally framed monumental stair. The stair experienced considerable vibration issues under normal loading. A retrofit solution was designed and implemented to mitigate the vibrations. Before and after vibration results are included, as well as the design calculations for determining the repair.

The paper includes an additional case study of a concrete slab on steel beam framed office building that started to experience vibration problems when the Owner removed steel and glass partitions during a remodel. The design solution, equations, and before and after results are presented.

CASE STUDY 1: 39-FOOT CURVING MONUMENTAL STAIR

The monumental stair in the main lobby of Sherman Hospital in Elgin, Illinois (Figure 1) was envisioned to take pedestrians up and around the massive, four-story Tree of Life centerpiece sculpture without calling attention to the stair itself. To this end, the stair was designed with transparent glass guard panels and with a structural spine only 12 inches deep. To complete the visual effect, the stair was designed such that no supports were needed at the mid-span landing. The structure of the stair comprises three 2x12-inch sloping, curved plate stringers with a 1/2 inch thick, folded steel tread plate. Stair treads are topped with 1-1/2 inch thick terrazzo tile. The 12-ton stair was manufactured in three sections in the shop of Chicago's David Architectural Metals, Inc., and was then transported and assembled at the job site. During final assembly, deflection at the mid-span landing was measured to be in excess of the expected 0.9 inch (refer to Table 2). The additional deflection was traced to movement of the end attachment points, which were subsequently reinforced.

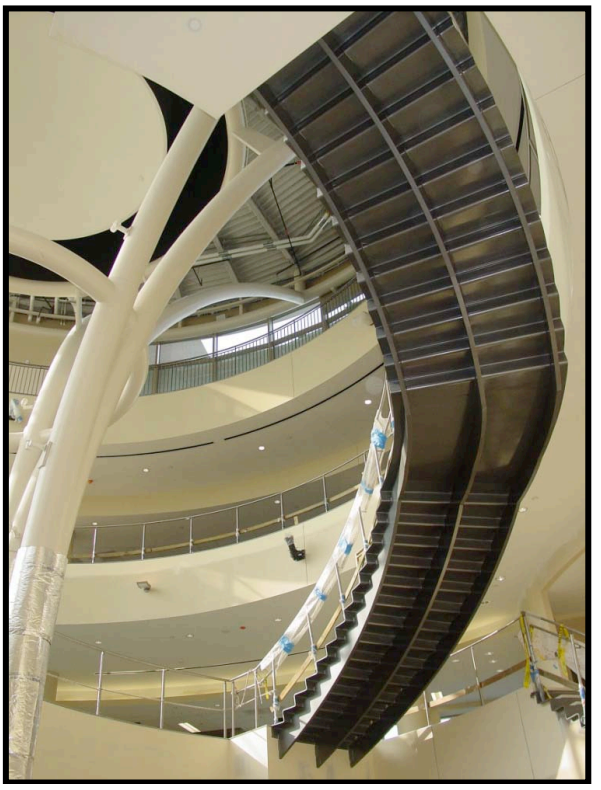

Figure 1. Bottom view of 39-foot curving monumental stair

Five months before the scheduled opening, the Owner started to complain of excessive vibration of the stair. Several options to remediate the vibration were discussed, including tensioning the stair with cables, adding a mid-span support, adding flanges to the bottoms of the stringers, and adding a tuned mass damper. The Construction Manager, Owner and Engineer decided the tuned mass damper offered the most cost-effective, aesthetically pleasing solution. Costs would be half, and the fabrication and installation labor would only be a fifth, of that needed for the other options. Before making a final decision to design a tuned mass damper solution, KJWW tested the stair to determine the nature of its vibration response.

Vibration testing was performed using Gulf Coast Data Concepts Model X6-2 USB accelerometer (Figure 2). This is an inexpensive, self-contained, three-axis recording accelerometer with a USB interface for setup and data download to a computer. At the time of the pre-installation test, the X6-2 software gave it a resolution of 0.001 G and a frequency limit of 160 Hz.

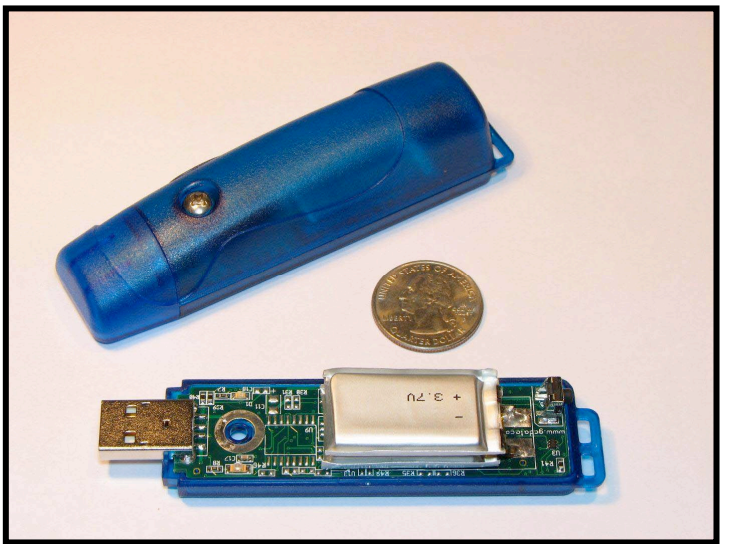

Figure 2. Gold Coast Data Concepts Model X6-2 Accelerometer

Pre-installation testing consisted of one or two people walking up or down the stair, with one or no people standing on the mid-span landing. The accelerometer was placed near the outer edge of the mid-span landing. No effort was made to normalize the test to match the test loading, frequency, position, and duration to those assumed for the Design Guide 11 criterion (Murray, Allen & Ungar, 1997). Table 1 lists the results. Figures 3 and 4 show the acceleration time trace and velocity spectra for Test #4. Note the spectra displays 1/3 Hz increments and, therefore, the response levels indicated in Figure 4 are somewhat less than the true 1 Hz spectrum levels of the stair. From the results, KJWW concluded: 1) the stair has a fundamental frequency of 4.23 to 4.56 Hz, 2) the vibration movement at the mid-span landing is 21.04 to 21.39 degrees from vertical, and 3) the vibration response of the stair to typical loading conditions is within the Reiher-Meister "strong" range.

Table 1—Results of Pre-Remediation Stair Vibration Testing

Test #	# people on landing	# people walking	Up or down	Frequency (Hz)	Vz (in/sec)	Vx (in/sec)	Angle (deg)	Peak G
1	0	1	Up	4.56				
3	0	1	Down	4.23	0.104	0.040	21.04	0.008
4	1	1	Up	4.23	0.263	0.103	21.39	0.019
5	1	1	Down	4.56				
6	0	2	Down	4.23	0.139	0.054	21.23	0.010

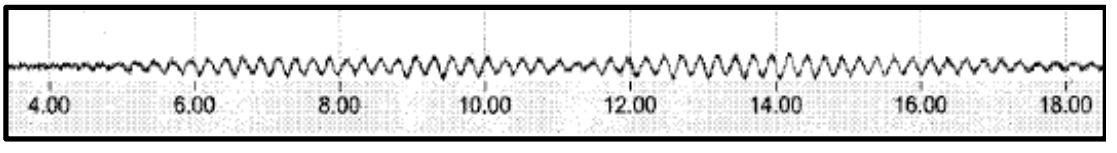

Figure 3. Pre-Installation Test #4 - Acceleration Time Trace

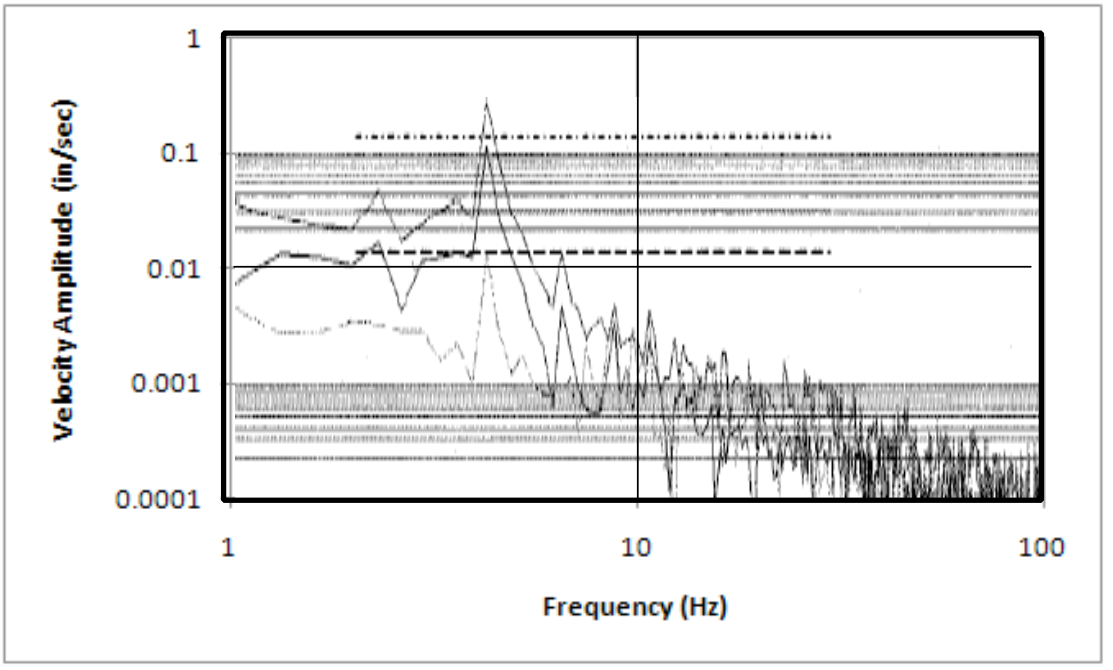

Figure 4. Pre-Installation Test #4 - Velocity Spectra of Acceleration Trace Shown in Figure 3

While testing proceeded, KJWW reviewed the design of the stair according to the recommendations of Steel Design Guide Series 11 "Floor Vibrations Due to Human Activity." (Murray, Allen & Ungar, 1997) Following the procedure outlined in Chapter 4 of Design Guide 11 for determining the acceptability of an indoor footbridge, the stair was evaluated using two different simplifying assumptions. The stair was viewed as: 1) a pinned-pinned beam loaded by a constant value running load and 2) a pinned-pinned curved beam loaded by a constant value running load. In both simplifications, mid-span deflections were calculated as if the stair were rotated to horizontal, however, neither simplification is fully accurate. Analyzing the stair as a beam neglects the torsional loading of the stair. Analyzing the stair as a curved beam neglects the helical shape of the stair. In addition, the effect of adding a 1/2-inch thick bottom plate to the entire length of stair was calculated using the curved beam assumption. Table 2 lists the results of each calculation step.

Table 2: Results of Design Guide #11 Calculation Steps

Calculation	Analyzed as beam	Analyzed as curved beam	Added bottom plate
Span (ft)	39.4	39.4	39.4
Running mass (lbm/ft)	590.7	590.7	704
Bending Moment of Inertia (in^4)	2181	2181	3913
Polar Moment of Inertia (in^4)	n/a	72679	74411
Radius of Curvature (ft)	n/a	23.4	23.4
Self weight deflection (in) **1**	0.51	0.95	0.64
Natural frequency (Hz) **2**	4.97	3.64	4.43
Weight (lbm):	23283	23283	27767
Peak acceleration (G) **3**	0.069	0.111	0.070
Maximum acceptable peak acceleration [150% DG#11] (G)	0.023	0.024	0.023

Note 1. Field testing measured an actual self weight deflection of 1.0 inch.
Note 2. Field testing measured a natural frequency of 4.23 to 4.56 Hz.
Note 3. Field testing measured a peak acceleration of 0.019 G.

Comparing the calculation results in Table 2 with the test results in Table 1, the measured natural frequency of the stair falls between the two calculated values. The maximum measured peak acceleration of 0.019 G was only 17% to 28% of the predicted values of 0.069 to 0.111 G. This difference is mainly due to the tests being conducted with a forcing frequency of approximately 3.9 Hz instead of the 4.23 Hz natural frequency of the stair. Figure 5 illustrates the theoretical response curve of a harmonically forced, single degree of freedom system having 1% to 10% damping. Since the tests were conducted at approximately 0.9 times natural frequency, and the stair damping is assumed to be 1%, Figure 5 shows that, all other variables being equal, the stair acceleration produced in the tests would have been expected to be only 9% of those predicted. The steepness of the response curve for forcing frequency ratios between 0.8 and 1.2, combined with the fact that it took 14 seconds to traverse the 27 steps, suggest that, had the walker's step been just 0.02 seconds quicker, the measured stair acceleration would have reached peak response levels. Also, it should be expected that the forcing function created by descending a stair has a higher amplitude than that created by walking a level footbridge due to the added vertical kinetic energy of the walker. These test results suggest that, for stairs, the value of the constant force used in Equation 2.3 of Design Guide 11 may be one to two times the weight of the person. This is analogous to increasing the value of dynamic coefficient in Equation 2.4 of the Design Guide when considering the response of floors to rhythmic activity.

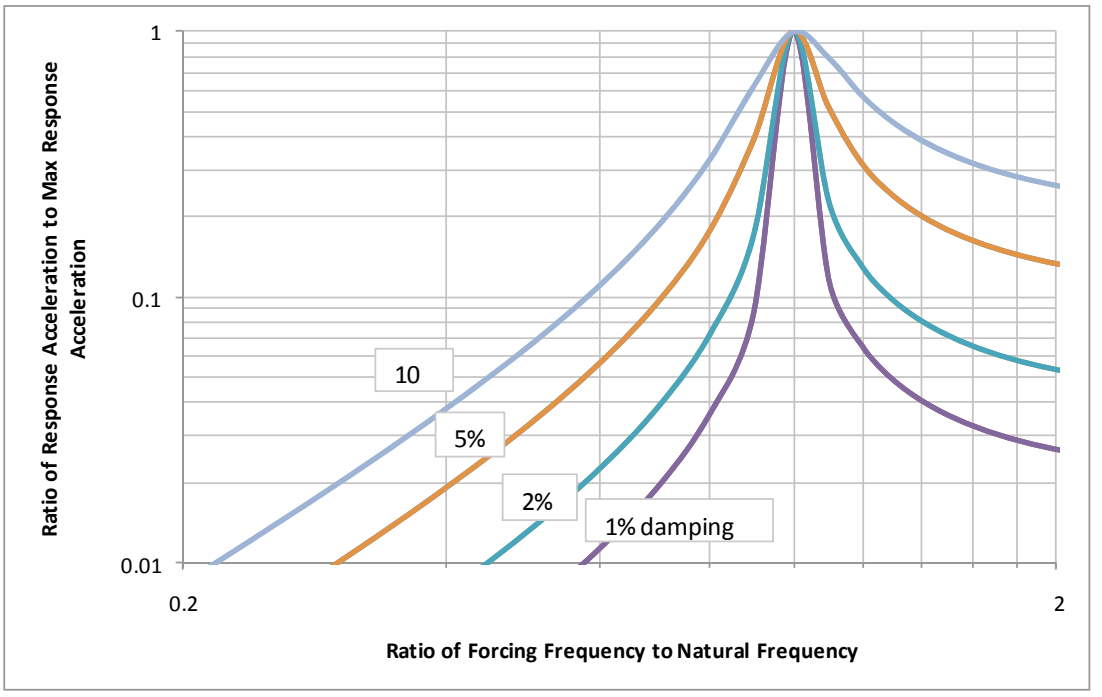

Figure 5. Theoretical response curve of a harmonically forced, single degree of freedom system having 1% to 10% damping

With test data and vibration calculations in general agreement, the option of adding a bottom plate was ruled out, and a tuned mass damper appeared to be the best choice for mitigating stair vibration while maintaining the intended look of the structure. The tuned mass damper would need to fit under the mid-span landing. Once installed, a thin sheet of metal would be welded across the bottoms of the stringers under the landing to hide the assembly from view. The allotted space limited the design. To avoid the complications of multiple dampers, it was decided to design one damper to fit between the middle and outer stringers. To minimize the magnitude of secondary rotational damper oscillations, the damper was limited to a footprint of 2x3 feet.

The tuned mass damper design started with estimates of its size and performance. With an available headroom under the mid-stair landing of only 12 inches, the damper mass was estimated as equivalent to four, 2x3 feet by 1/2-inch thick steel plates, with a total weight of 484 pounds. A 484-pound damper on a 23,283-pound stair should yield a damping ratio of approximately 0.07 and replace the 4.23 Hz natural frequency peak of the stair with two smaller peaks at 3.93 Hz and 4.55 Hz. Matching the measured 4.23 Hz frequency of the stair, the 484-pound tuned mass damper would require a total spring constant of 886 pounds per inch. To allow for tuning of the mass damper, an additional 143 pounds would be required to cover the 3.93 to 4.55 Hz damped frequency range. For the 92-pound step function called out in Design Guide 11, the expected damper spring deflection would be approximately 0.1 inch.

Using the above estimates as a guide, four off-the-shelf equipment mounting springs were selected for the design. The Mason SLFH-104 springs are rated for 200

pounds per inch and a 500-pound load, which gives the tuned mass damper an 800 pound per inch spring constant.

A complication in the design was the fact that the landing does not vibrate vertically, but rather 21° from vertical. To achieve a parallel motion in the tuned mass damper, the damper weights were designed to follow a 21° cam while the weights themselves remain horizontal throughout the cycle. To allow fine tuning, the weight assembly consists of three 101-pound plates, one 61-pound plate, two 30-pound plates, and ten 10-pound plates.

Before installation, the effectiveness of the tuned mass damper on the stair was determined by allowing it to operate on top of the landing. Table 3, and Figures 6 and 7 show results from a typical test in this series.

Table 3—Results of TMD Stair Vibration Testing

Test #	# people on landing	# people walking	Up or down	Frequency (Hz)	Frequency (Hz)	Vz (in/sec)	Vx (in/sec)	Angle (deg)	Peak G
1	1	1	Down	3.91	4.90	0.107	0.048	24.2	0.007

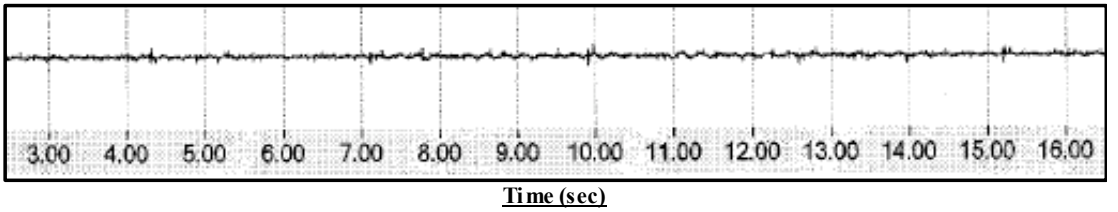

Figure 6. TMD Test #1 - Acceleration Time Trace

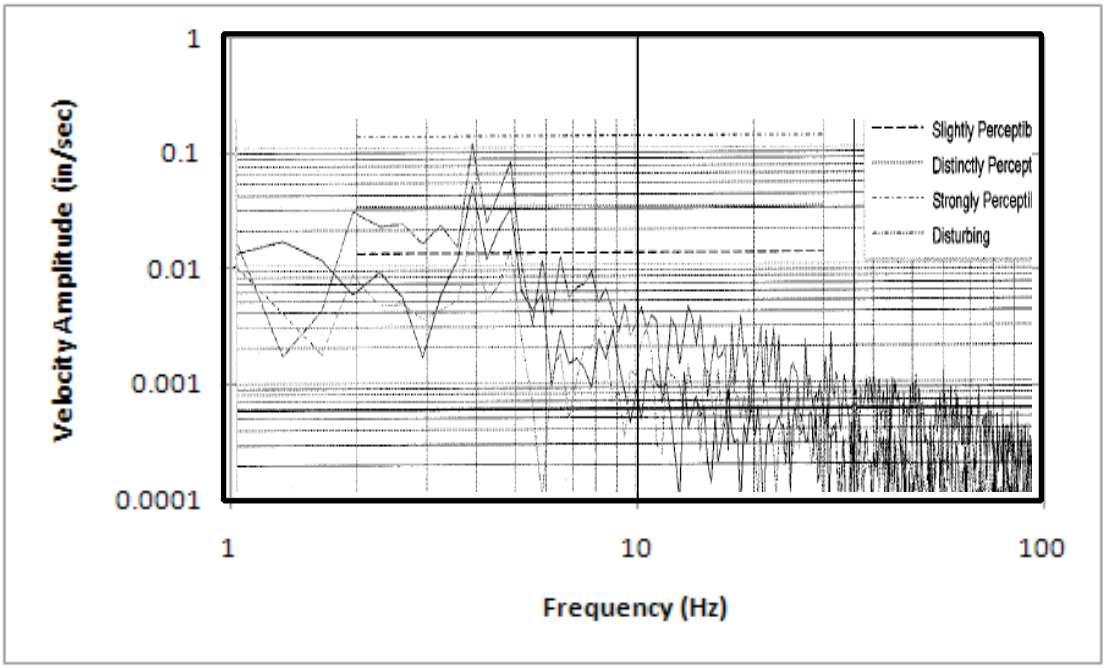

Figure 7. TMD Test #1 - Velocity Spectra of Acceleration Trace Shown in Figure 6

Figure 8 shows the tuned mass damper assembled for testing. Also visible in this figure is one of the two 21° cam followers. Figures 9a and 9b show two views of the installed damper.

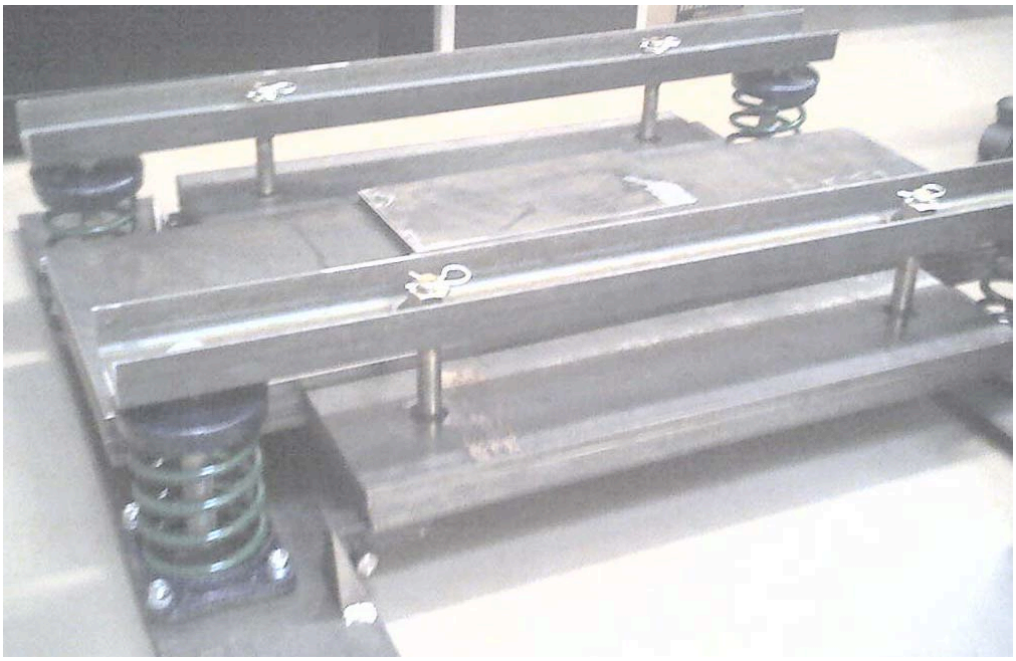

Figure 8. Tuned Mass Damper Assembled for Testing 21° Cam and Follower in Foreground

Figure 9a. Tuned Mass Damper Installed Under Mid-Span Landing

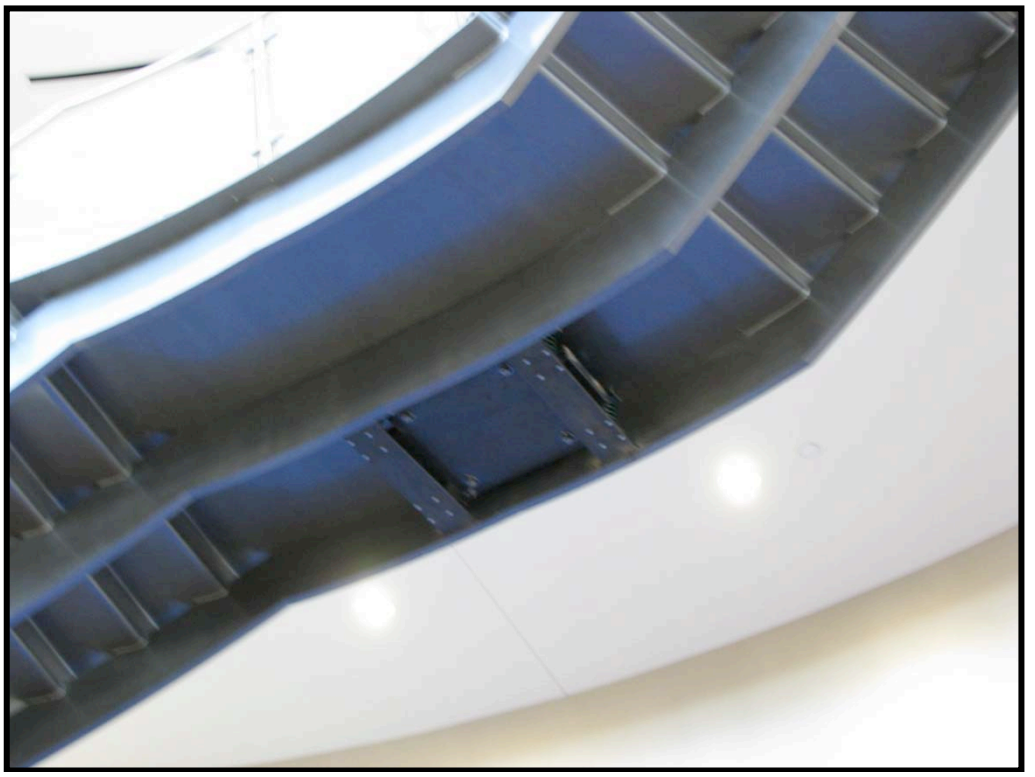

Figure 9b. Tuned Mass Damper Installed Under Mid-Span Landing

Comparing the pre- and post-damper measured responses, the stair vibration fell from levels just above those recommended in Design Guide 11 for indoor footbridges to levels just above those recommended for offices. Comparing the before and after acceleration traces of Figures 3 and 5 illustrates the relatively huge increase in damping. Responses to single jumps, which initially rang for 20 seconds and longer, were reduced to less than a second.

CASE STUDY 2: RETROFIT OF AN EXISTING OFFICE BUILDING

KJWW was retained when non-structural renovations to an existing office building resulted in floor vibrations noticeable to the occupants. The floor design of the existing office building is divisible into a row of 30x45 foot bays on each side (north and south) of a center hallway. The floor is a 3-inch deep steel form deck with concrete poured to 2.5 inches above the steel. The floor is supported by 10W29 joists spaced nine feet apart. The joists are supported by 21W82 girders connected to either side of columns spaced 30 feet apart. As part of the renovation of the building, the original three-quarter height glass and metal frame office partitions were removed. The dotted lines in Figure 10 illustrate the typical placement of the original partitions. The heavy plaster panel hallway wall (represented in Figure 10 by the wide black line) was left intact. Of special concern is the fact that the curtain wall rests on its own joist, and, therefore, the floor is not connected to the sides of the building. As renovations continued, office workers began complaining of excessive floor vibration.

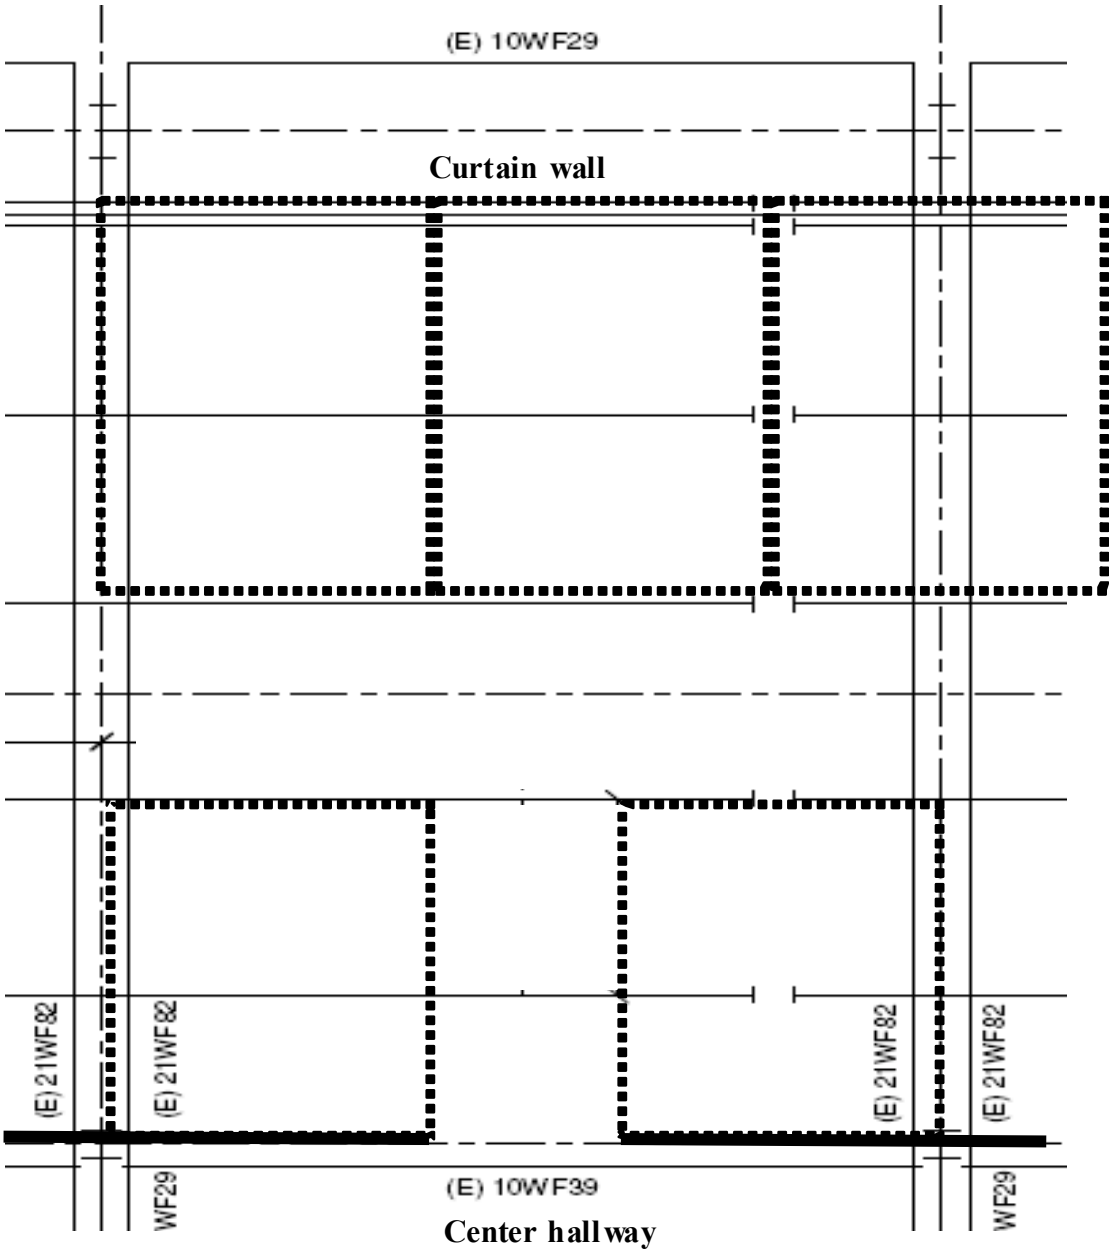

Figure 10. Diagram of Office Bay Showing Placement of Original Partitions (Dotted Lines)

Table 4 lists the results of each Design Guide 11 calculation step for the floor before and after removing the partitions. Since the floor edge is not supported by the exterior wall, the effective width for the joist panel vibration mode was reduced 50%. The removal of the original partitions had two effects: reducing the floor loading by 19 psf and decreasing the floor damping ratio from 0.05 to 0.02. Possible reduction in joist mode moment of inertia was suspected but not pursued.

Table 4: Results of Design Guide #11 Calculation Steps for Floor		
Calculation	**Before renovation**	**After renovation**
Joist mode bending moment of inertia (in^4)	660	660
Joist mode running load (lbf/ft)	783	614
Joist mode deflection (in)	0.746	0.585
Joist mode frequency (Hz)	4.10	4.62
Joist mode effective panel weight (lbm)	69,296	54,339
Girder mode bending moment of inertia (in^4)	5833	5833
Girder mode running load (lbf/ft)	2692	2129
Girder mode deflection (in)	1.468	1.161
Girder mode frequency (Hz)	2.92	3.28
Girder mode effective panel weight (lbm)	227,743	180,113
Combined natural frequency (Hz)	2.38	2.68
Combined effective weight (lbm)	174,355	137,972
Damping Ratio	0.05	0.02
Peak acceleration (G)	0.0032	0.0092
Maximum acceptable peak acceleration [150% DG#11 offices] (G)	0.0097	`0.0092

Vibration testing of the floors showed primary level peaks at 4.4 Hz corresponding to the joist mode vibration, and a secondary level peak at 2.5 Hz corresponding to the combined mode vibration. Measured vibration levels varied with floor, bay, and time of day, ranging from "slightly perceptible" to "distinctly perceptible" on the Reiher-Meister scale.

Since complaints centered on vibrations traveling from bay to bay, the investigation focused on joist mode vibration. Finite element modeling of the bay was used to determine the effect of various options to stiffen the bay. The addition of column supports was not considered feasible since this required a minimum of three columns per bay and would require considerable adjustment to the open plan office design. The model suggested that adding bracing at each joist/girder intersection would add enough stiffness to the joist mode vibration to put the floor well within the recommended vibration limits for office spaces. This was done in two bays by adding two 6-foot long L6x6x3/8 kickers to each joist/girder intersection. Ambient vibration measurements made after this installation showed peak levels of 0.0014 G @ 4.4 Hz, and complaints from this section of the building were significantly reduced.

The high installation costs of adding kickers to the joists prompted a search for a less expensive solution to handle complaints of excessive vibration in other

parts of the building. Since the seating locations of the complainants did not necessarily coincide with the locations of measured maximum vibration, a tuned mass damper was considered a good option to reduce vibrations local to the complaint. Figure 11 shows the tuned mass damper, designed to hang between joists, mounted on a test dolly that was used to tune and test the damper on various locations of the bay. Tests of a bay after installation of the tuned mass damper in the second joist interstice from the center hall measured vibration levels of 0.0006 G @ 4 Hz, with no identifiable peak at the position directly above the damper. Vibration levels at the fourth joist interstice measured 0.0013 G @ 4 Hz, with no identifiable peak with periodic (one per hour) brief (40 second) duration events of 0.0195 G @ 4 Hz. These results suggest the tuned mass damper is only locally effective for this application. At the time of writing, an additional damper was scheduled to be installed at the fourth joist interstice.

Figure 11. Tuned Mass Damper Mounted on Test Dolly

CONCLUSIONS

Test results suggest that, when using Design Guide 11, Equation 2.3 to evaluate the vibration acceptability of a stair, the designer may consider increasing P0 to a value of 157 pounds to 314 pounds to account for the added vertical kinetic energy of a person descending the stair. This is analogous to increasing the value of dynamic coefficient in Equation 2.4 of the Design Guide when considering the

response of floors to rhythmic activity. Since the tests were not designed to study this hypothesis, this is a suggestion for further study rather than a recommendation.

When the vibration acceptability of a floor is marginally acceptable, the seating locations of the complainants may not necessarily coincide with the locations of measured maximum vibration. Placing a tuned mass damper at the location of the complainant demonstrated a significant local reduction in vibration. Vibration levels at other locations in the same bay remained relatively unchanged.

Title: The Feature Stair at Louis Vuitton in Crystals at CityCenter

Authors: Crispin Howes, PEng, Associate, Halcrow Yolles Toronto
Michal Krynski, PEng, Design Engineer, Halcrow Yolles Toronto
Stephan Kordt, SE, PE, Principal, Halcrow Yolles Las Vegas

Abstract: *In December 2009, Louis Vuitton opened their largest North American store in the retail component of the CityCenter development in Las Vegas. The three retail floors of the flagship store are interconnected with an elegant feature staircase clad in polished stainless steel, glass, and exotic hardwood.*

The steel structure is comprised of stepped stringers with folded plate to form the treads and risers. The staircases finishes are closely fitted to three sides of each stringer\. The slender profile of the staircase was achieved by minimizing the depth of the stringer to 8 in even though the mi-landing is cantilevered 20' from the supporting landings. Extensive structural and vibration analyses and precise detailing of the integral glass guard ensure the performance of this monumental staircase.

This paper presents a review of the analysis, design, and detailing of this feature stair steel structure and integral glass guard.

1.0 Introduction

Louis Vuitton opened their largest North American store in the retail component of the CityCenter development in Las Vegas in 2009. The program for the store included 14,000 sq. ft of luxury retail space over 3 floors with additional area for administration services. The architects for the project were the New York based firm of Gertler & Wente Architects. As one of the key tenants on Las Vegas Boulevard, the design and construction of the store was realized with a fast track schedule to meet the opening date of the overall CityCenter development.

As the flagship store for North America, the design of the store has several features befitting the luxury brand. On the exterior of the store is clad with embossed stainless steel panels embedded with 4000 programmable LEDs. Interior features include a 31ft diameter chandelier, a two story high luggage display unit, and a 103in. plasma screen display.

One of the most prominent interior design elements is the elegant feature stair which is clad with polished stainless steel, hardwood and glass. The stair interconnects the 3 retail floors of store. The first leg of stair spans from street level to mezzanine level with a height of 12ft between floors. The next two legs connect the mezzanine level to Level 1, also with a floor to floor height of 12 ft. A mid-height landing is provided between these two legs. At the outside edge of the mid-landing, the stair is cantilevered 20ft from the supporting floor structure.

2.0 Design Concepts

The architectural design intent for this stair was to maintain an overall expression of a slender stepped plate with the soffit of the stair as a direct offset from the treads and risers. As is sometimes the case, the architectural concept was developed prior to the opportunity to prove the structural concept. The overall depth of stair assembly was to limited to 8in to maintain the appropriate slender envisioned in the architectural concept. Allowances for the cladding finishes, hardwood flooring on top and polished stainless steel panels on the soffit, were included within total depth. After the allowances for the finishes were subtracted from 8in depth only 6in was available for the structural framing.

The plate-like expression for the stair might suggest a similar type of structural solution, a cast-in-place structural slab, for example. However, such as solution would not have been feasible for several reasons. The cost of custom formwork and shoring would have been substantial. The 6in available for slab depth would have required considerable cambering to control self-weight deflection. The stepped slab profile does not allow for continuous rebar in the direction of the slab span so rebar would need to be cranked with tension splices at each step to maintain continuity moment resistance in the slab. Therefore, the appropriate choice of material was structural steel.

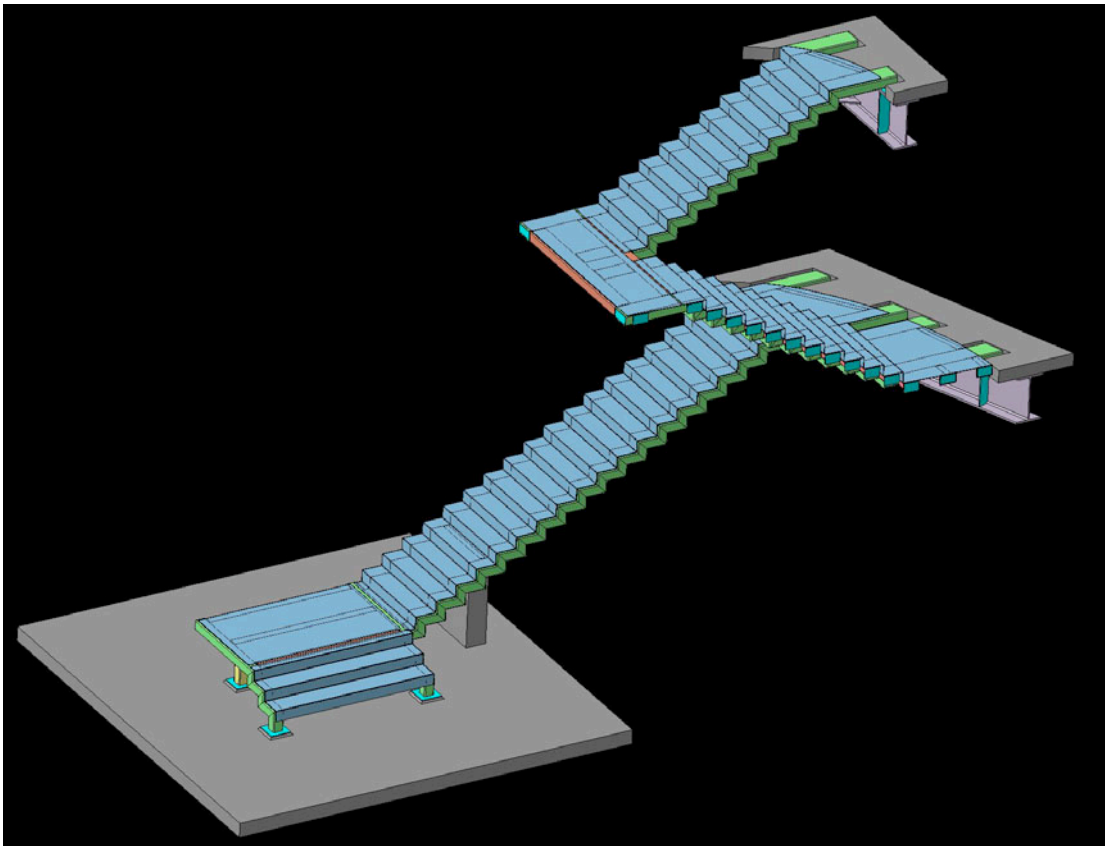

Figure 1: Structural Coordination Model of Stair Framing in CATIA

3.0 Structural Solution

The initial underlying structural solution was similar to many stairs beginning with two exterior stringers. Hollow Structural Section (HSS) were utilized for framing to maximize the capacity in the available structural depth. However, the stepped profile of the stair assembly required the stringer to be stepped as well. At each step, the HSS had to be cut and mitred with corresponding horizontal and vertical pieces. To help mitigate the extent of the required welding all the wall thickness of the HSS were increased by at least 1/8" above required so partial penetration welds could be used to achieve the needed capacity rather than specifying full penetration welds at all the mitres.

The sizes used for stringers were HSS 6x12 and HSS 6x10. The HSS were oriented with the long leg horizontally. This horizontal orientation was not the most structurally efficient but was necessary to fit within the space requirements of the stair assembly while meeting the structural requirements for strength and serviceability. The cantilever mid-landing between the two upper legs was framed by providing two HSS 6x10 members that span between the exterior stingers. The interior stringers are moment connected to the interior landing member providing moment continuity between the two stringers via torsion in the landing member. Refer to Figure 2 for a plan of mid-landing framing.

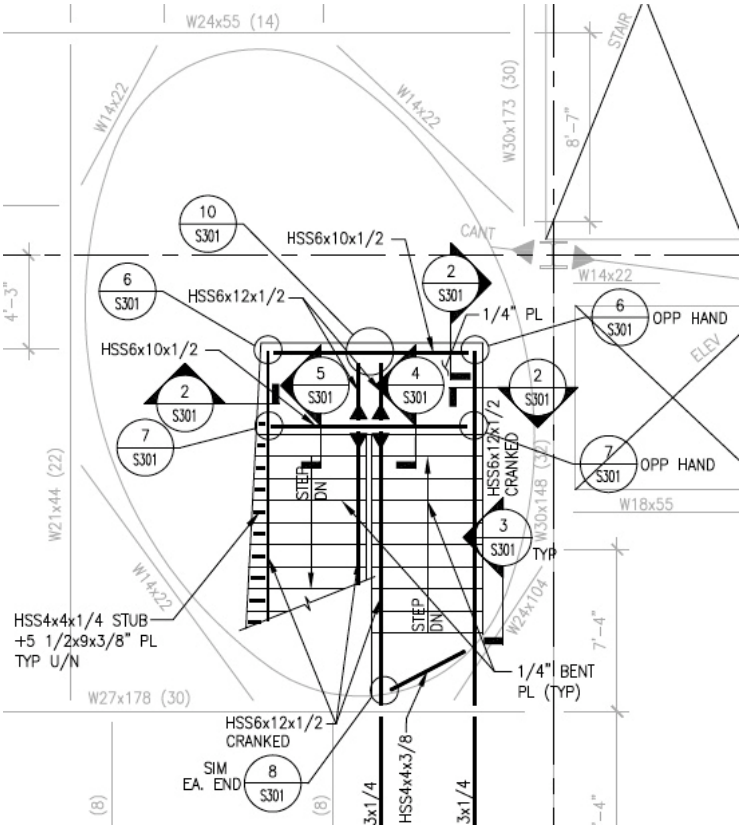

Figure 2: Cantilever Mid-Landing Framing Plan

Spanning between the two stringers, ¼" bent steel plate provides supports for the treads and risers. Concrete slab on steel deck was another option initially considered. However, the slab on deck assembly could not have been placed on top of the stringers and would have been required to fit between the stringers. Bent steel plate was a more appropriate choice, as it could be placed on top of the stringer within a minimal increase to structural depth. In addition to supporting the direct gravity loads of stair users, the bent plate provides a continuous diaphragm to maintain the horizontal stability of the overall stair structure. The connection of the bent plate to the stringer with welds near the interior and exterior faces of the HSS, provides additional stability to the stringer allowing torsion generated by loads on the glass guard to be resisted as mend moments in the bent plate profile.

4.0 Analysis

The analysis and design of the overall stair structure utilized SAP2000 Non-Linear. Per figure 3, the analysis model consisted of the entire stair structure including the glass guards and the local supporting floor framing of the base building. Plates, slabs, and glass guards were modeled as area elements while steel beams were modelled as frame elements. The glass guards were included in the model to assess the resulting internal stress distribution under the stairs loads. The supporting base building framing was included in the model to account for its stiffness under stair and floor loads and to capture the internal force re-distribution resulting from varying stiffness between supporting members.

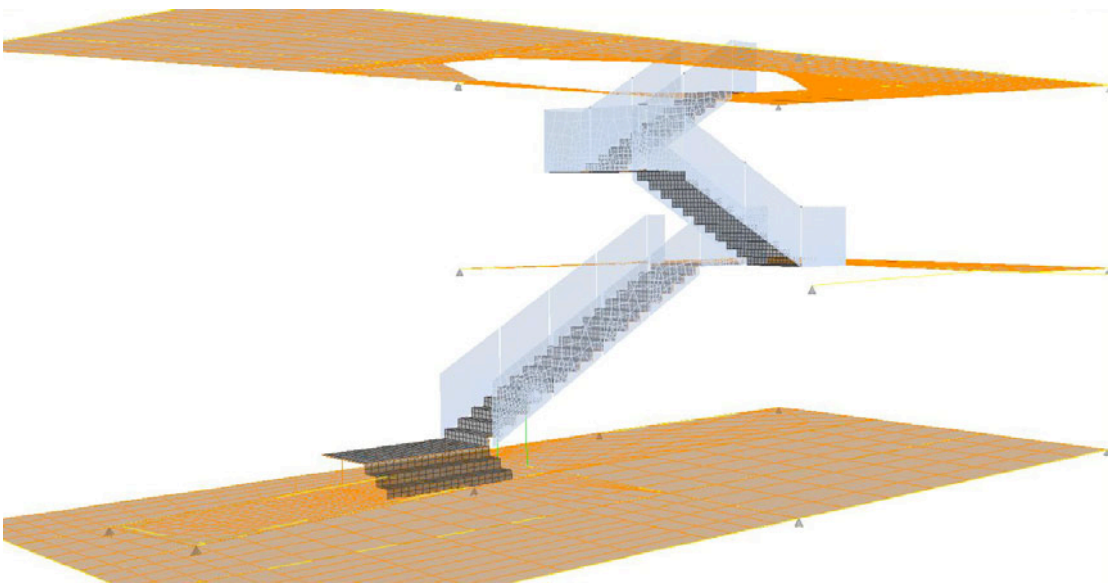

Figure 3: SAP2000 Non-Linear analysis model of stair framing

5.0 Detailing

Although the structural steel is not exposed to view, the detailing of steel connection needed to be mindful of the architectural expression. With cladding finishes fitting tight to the structural framing, welded connections were necessary as there was no opportunity to allow for connection plates that would project beyond the member profile.

6.0 Connections to Base Building

Connections to the base building floor framing were provided by sawcutting into the existing slab edge to create a trench in which to install the stair stringers. A series of field-welded stepped shims filled the gap between the as-built top of floor beam and the underside of the stringer and provided a connection capable of transferring shear and axial forces from the stinger to base building floor framing. At the each connection point, the base building beams were local stiffened and an HSS 3x3 was connected from the supporting floor beam to the next adjacent floor beam to act as a dragline to distribute the axial force deeper into the floor slab diaphragm. Figure 4 illustrates a typical connection to base building.

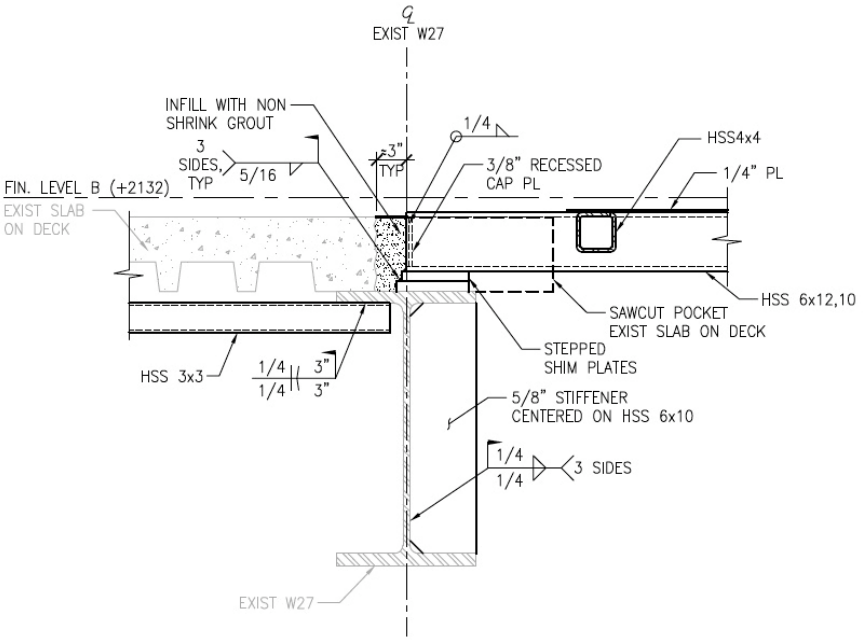

Figure 4: Typical connection of stair stringer to base building floor framing

7.0 Vibration Analysis

As with almost all slender stair structures, an evaluation of the dynamic response of structure under walking excitation is a necessary step in the design process. Our analysis indicated that, horizontally, the combination of the wide HSS stringer with the continuous steel bent plate diaphragm comfortably met our limits for acceleration limit of 0.5%g with 1.0% damping

Vertically, the reference criteria was an acceleration of 1.5%g with 1% damping as recommended for indoor footbridges in the AISC Steel Design Guide for Floor Vibrations due to Human Activity. Due to the limited structural depth in the vertical direction, the structural steel framing was unable to meet the limit. However, by engaging the glass guard in combination with the steel framing, the limit was met. The detailing of this connection between the steel and glass needed to be carefully considered to be able to transfer the required in-plane shear forces and out of plane moment from the glass guard to the steel stringer while avoiding excessive confinement that could lead to internal stress concentrations.

7.0 Glass Guard Connections

Connections between the glass guard and the stair stringer, as shown in Figure 5, were provided at every second tread. The arrangement of two connectors per connection location resisted out of plane moment due to lateral loads on the glass guard by providing a push-pull couple. The in-plane shear is transferred through friction at the two connectors. A ¾” bolt centered in an oversized hole within the glass is used to pre-compress the connection assembly clamping the glass against the stringer providing sufficient friction to transfer the shear while avoiding stress concentrations by transferring shear over a relatively large area. Refer to Figure 6 for a typical section through the glass connection.

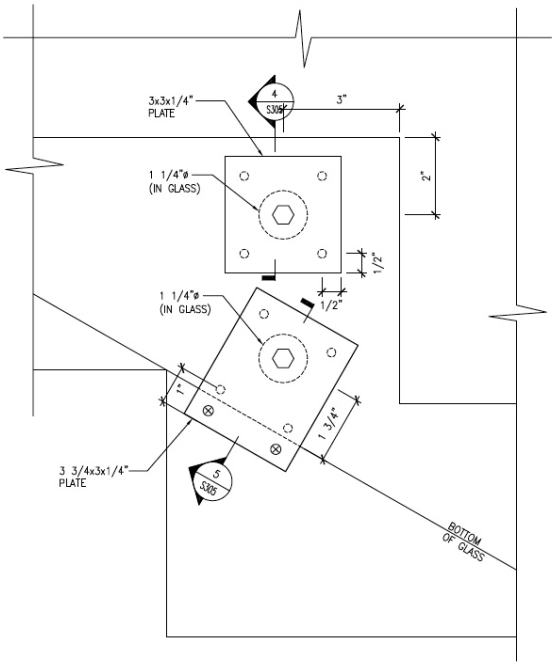

Figure 5: Elevation of glass guard connection to stair stringer

Figure 7: Erection of cantilever mid-landing,

Figure 8: Erection of Stair Framing, photo courtesy of Gertler & Wente Architects

Figure 9: Finished Feature Stair, photo courtesy of Gertler & Wente Architects

8.0 Conclusions

Although the structural steel framing is not exposed to view, it has been carefully sized and detailed with consideration for the architectural expression. In addition, a subtle and economical connection between the glass and steel helps minimize the depth of structure. With the structure in a supporting role, the architectural vision is maintained contributing to the overall shopping of experience of the clientele of Louis Vuitton.

Title: The Spiral Stairs at the Art Gallery of Ontario

Authors: Crispin Howes, PEng, Associate, Halcrow Yolles Toronto
Eric Gordon, PEng, Senior Principal, Halcrow Yolles Toronto

Transformation AGO is the recently completed renovation of the Art Gallery of Ontario by Frank Gehry.

Within the building, visitors are intuitively drawn to Walker Court, the heart of the AGO bathed in natural light. The focal point of Walker Court is the Feature Spiral Staircase. From the ground floor the stair is experienced as a sculptural form clad in douglas fir panels. Upon entering the staircase at the 2nd floor level, visitors travel through the roof of Walker Court and upward 90 ft on the north elevation of the new Contemporary Tower with landings on the 3rd, 4th, and 5th floors.

On the south elevation, an enclosed staircase, clad in stainless steel and glass, cantilevers 30 ft from the face of the building directly above the 4th oldest surviving building in Toronto. The staircase has been dubbed the "Barnacle Stair" for the manner in which it appears to cling to the face of the Contemporary Tower.

This paper will provide an overview of the design and construction processes related to the two monumental stairs.

1.0 Project Introduction

The Art Gallery of Ontario (AGO), located in Toronto, Ontario, Canada has existed for over 100 years. Over that time the building has been renovated and expanded numerous times. Transformation AGO was the latest completed and most dramatic renovation\expansion. Completed in 2008, the total cost was $276 million CDN. The design by Frank Gehry involved extensive renovations to the existing galleries, the addition of a new tower for contemporary art, and the addition of several feature elements. In addition to the two monumental stairs, other feature elements of Transformation AGO included a 300ft long glulam and glass façade, a serpentine ramp, and skylights angled to control direct sunlight but still providing the opportunity to view light under natural light.

2.0 The Feature Stair

2.1 Introduction

One of the highlights of touring Transformation AGO is the experience of entering the Walker Court from the north, looking to the south and taking pause to reflect upon the sensuous curves of the feature staircase. Clad in douglas fir panels, the stair traces a path that starts above the south entrance of Walker Court, curves towards west wall,

back to the east wall and reaches to the new glazed roof above. Moving further to the south and looking upward reveals the staircase actually penetrates through roof and climbs up the north face of the new Contemporary Tower.

From the ground floor, the stair can only be experienced as a sculptural form. Visitors access the stair from the new second floor walkway that encompasses the exterior of Walker Court. Above the second floor, the stair links the 3rd, 4th and 5th floors of the Contemporary Tower. Below the new roof of Walker Court the stair is interior with a U-shaped cross-section, while above the roof the stair is exterior and enclosed with a roof and stainless steel and glass cladding.

2.2 Structural Solution

Two steel plate girders, concealed within the balustrade finishes, run parallel to each other for the entire length of the stair. The exterior plate girder is interrupted by the floor landings which provide support to the stair with two wide flange beams cantilevered from the tower floor framing. The interior plate girder is continuous from 2nd floor to 5th floor, a total distance of 180ft. The balustrade plate girders are comprised of 6 5/8in XXS pipe for the top and bottom flanges and a 5/8in curved steel plate for the web. Along the length of the stair the height of the balustrade varies in a non-linear fashion. With top and bottom of the balustrade curving in both plan and elevation, the flange pipes were required to be bent into 3D splines. The two plate girders are interconnected at regular intervals with integral U-shaped frames of 5 9/16in XXS pipes. The rigid welded connections of the U frames ensure that the two plate girders work in unison. Pipe bracing which zigzags between the bottom pipes of the plate girders provides horizontal stiffness. ¼" bent plates were used to form the tread and riser assembly which were then topped with a 2" concrete infill.

Above the roof of Walker Court, vertical 5 9/16in XXS pipes were positioned to align with joints in the curved glazing. These pipes support the roof above which encloses the stair. Framing of the roof maintained the solution developed for the Barnacle Stair where 3/8" x 2 1.2" straight bars were located on ruling lines in the curved roof surfaces. A 1/4in plate was installed to conform to the surface dictated by the ruling lines.

Being a conditioned environment, there were multiple requirements for the structural framing to accommodate the mechanical distribution systems. At floors 3, 4 and 5, the mechanical ducts enter stair below the landing framing. This is also the zone required for the structural support of the stair. To minimize the overall depth of the landing, large plated web openings were introduced to feed the ducts through the structure. These ducts supply a plenum which runs in the zone between the stair soffit and the under side of the tread and riser assembly. At regular intervals, this under stair plenum connects to vertical plenums with the balustrade on each inside of the stair. To facilitate this connection, 6"x4" openings were cut into the curved web of the plate girder.

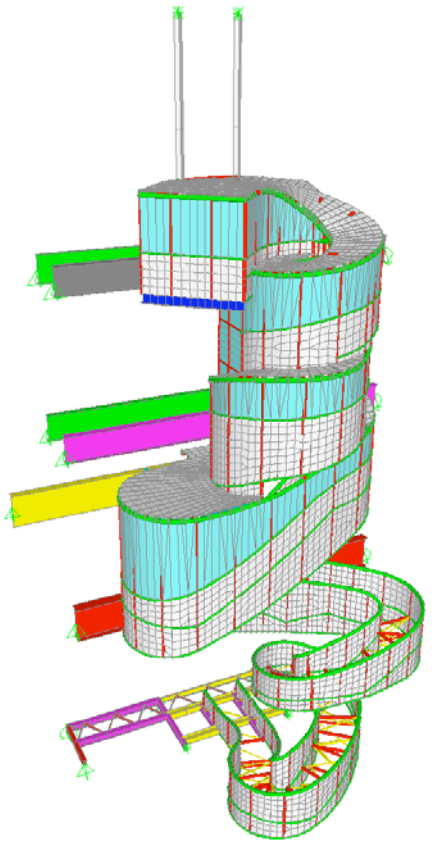

Figure 1: SAP2000 analysis model of the Feature Stair

Figure 2: Structural CATIA Model of the Barnacle Stair

3.0 The Barnacle Stair

3.1 Introduction

Visitors viewing the new Contemporary Tower of the Art Gallery of Ontario from the south in historic Grange park, will identify the Barnacle Stair as a prominent feature. The stainless steel and glass clad sculptural form softens the appearance of the rectilinear tower. The stair, nicknamed the barnacle for the manner in which it appears to "clings" to the tower, interconnects the 4th and 5th floors. Visitors in Grange Park will also notice that the stair is located directly above the Grange House. A Georgian-style manor, the Grange House was constructed in 1817 and is the fourth oldest surviving building in Toronto. Within the stair, visitors are treated to number of spectacular views to the south as they walk up and down the stair. The most prominent view comes at the tip of the stair, 30 feet from south tower and aligned with the centre of Grange park, where observers can look south along John Street down to Lake Ontario.

Achieving such a daring sculptural form that also must function as fully condition enclosed space requires a unique structural solution. From a large scale viewpoint, the framing of the stair can be viewed as a steel tube, with material distributed around the perimeter of the stair cross-section to resist bending and twist as the stair cantilevers out and curves back on itself. The interior of the tube is hollow achieving the function of the stair, to allow visitors to move between the galleries of the 4th and 5th floors.

3.2 Structural Solution

From a component level viewpoint, there are a number of requirements that shape the exact layout of the framing. A key requirement is a band of curved that runs on both sides of the stair for its entire length. This zone of transparency severs the top of the tube from the bottom. However, structurally, framing between the top and the bottom is essential for the overall structural action, so 5 9/16" XXS vertical pipes were provided which align directly with the joints in the glazing. By adding corresponding 5 9/16" XXS pipes transversely at the top and bottom of the stair cross section and aligned with the vertical pipes, a series of strong hoops was created along the entire length of the stair. These hoops are interconnected with 6 5/8" XXS pipe located at the four corners of the stair cross-section and at the top of the balustrade. As the interconnecting pipes had to be concealed within the interior and exterior finishes of the balustrade, the pipes were curved to fit within the structural "zone".

Welded rigid connections between pipes were provided to resist racking of the stair cross-section as well as to act as a vertical Veerindeel truss. The truss was further stiffened with curved ½" steel plates located within balustrade zone.

On the roof of the stair, a requirement was to provide a continuous surface to support and set out the geometry for the roof cladding. Analyzing the curvature of the surface within CATIA, ruling lines, which are straight lines which lie on curved surfaces,

were identified. 3/8" x 2 1/2" steel bars were placed on these ruling lines spaced at approximately 12" c/c. On top of these bars, a ¼" steel plate could be warped to conform to the geometry set out by the ruling lines. This ¼" plate provided the required continuous surfaces but also acted as a diaphragm to stiffen the roof of the stair horizontally. On the soffit of stair, there was no requirement to support cladding, so bracing pipes sawtooth between hoops for the entire length of the stair providing horizontal stiffening.

At the 4th and 5th floors, the stair framing is anchored to portal frame comprised of built-up the face of the building.

Beneath the oak flooring, ¼" steel bent plate topped with concrete provides support for the treads and riser of the stair. While at landings, 1 ½" composite steel deck spans across the stair as formwork for a 2 ½" concrete slab. A plenum is contained within the zone between the stair soffit and tread and riser assembly. This plenum is interconnected at regularly intervals to a vertical plenum located within the balustrade assembly. To facilitate this interconnection, corresponding 6"x4" openings in steel box sections. Two vertical box sections extend from the 4th floor to 5th floor and from the 5th floor to the Roof to resist pushing into the building or pulling away from the building. A horizontal box section, located at the stair roof level, rigidly connects to the vertical to resist loading parallel to the ½" curved plates were required. Additional requirements to accommodate mechanical systems were encountered at the connection to 4th and 5th floors. Connections in these areas are the most critical for the stair framing. Large openings for ductwork had to be carefully integrated to maintain structural integrity while allowing proper conditioning of the stair.

4.0 Tuned Mass Damper

Early in design process of the stairs, the dynamic response of the structure to walking excitation was evaluated in both vertical and horizontal modes. The evaluation limit for vertical acceleration was 1.5% g with 2% damping based in the AISC Design Guide for Floor Vibrations due to Human Activity. The limit for horizontal acceleration was 0.5% with 2% damping. The robust structure of the Feature Stair was well within the acceptable limits. The Barnacle Stair on the other hand could not meet the specified limits. Stiffening the structure by adding additional steel was not an option has it would increase the overturning moment needed to be resisted by the supporting framing. Instead, a Tuned Mass Damper (TMD) was specified to control the dynamic response of the structure.

Below the mid-landing furthest away from the tower, a pie shaped volume was allocated for the TMD. Refer to Figures 3 and 4 The specified properties of the TMD were a mass of 4850 lbs, damping of 6%, and a tuned frequency of 2.40Hz. The TMD was designed, manufactured, and installed by GERB GmbH. Third party testing following the installation verified the TMD was performing to the specified requirements.

Figure 3: TMD prior to stair erection

Figure 4: TMD after stair erection

5.0 Erection of the Stairs

A modular approach was utilized in the erection of the stair which provided a balance of efficient shop welding with field adjustability. The overall framing was subdivided into modules that would fit within shipping requirements. Each of the modules was fabricated on a jig in the shop and subsequently test-fitted to the modules directly above and below. Once in the field the modules were connected with field welds.

The Barnacle was erected in eight modules starting at both the 4th and 5th floors with modules added in succession until meeting in the middle. The presence of the Grange House, the fourth oldest surviving building in Toronto, precluded to possibility of providing temporary shoring. The Feature Stair, on the other hand, was erected temporary shoring cantilevered of the Contemporary Tower structure. Once the erection was complete from 2nd to 3rd floor the shoring was released and the as-built structure support the erection of the remainder of the framing up to the 5th.

6.0 3D Model Documentation

All of the feature elements on the Transformation AGO project were structurally and architecturally coordinated with CATIA\Digital Project. The models were subsequently issued as construction documents in combination with traditional 2D documentation. 2D documents provided members sizes, connection forces and other

connection requirements. Geometry was specified by the CATIA master models and dimension information was removed from 2D documents.

Two models were issued for each element. The master models contained only wireframe and surfaces that represented framing members, plates, and slabs. The contractor was directed to use the master models as the basis for structural detailing by extruding the member sizes specified on the 2D documents about the specified wireframes. The second type of model was the reference model which contained many of the elements modeled for coordination during the design phase. Modeled elements included member extrusions or sample connection details. The contactor was directed not to use the reference models as the basis for structural detailing as there was a possibility that modeled elements may not corresponded to information specified on the 2D documentation. These models were provided to aid the contractor in early visualization prior to developing their detailing model.

The list of submittals required by specifications was updated to include models in CATIA\Digital Project format. Prior to the production of shop drawings models were submitted to by the consultants for geometry review and to the General Contractor for interference review with the adjacent trades. The subsequent advantage of this approach was that once the 2D shop drawings were submitted for review they could reviewed and returned to the contractor substantially quicker than with a traditional approach.

7.0 Conclusions

The Feature and Barnacle Stairs, as well as other feature elements, at the Art Gallery of Ontario were a challenge to design, coordinate, fabricate, and erect. However, the overall project was realized on budget and within a month of the original opening date. Much of the success was attributable to the use of 3D modeling through out the design and construction process. While pre-dating the current Building Information Modeling (BIM), the process used on the Transformation AGO provided proof of the claimed benefits including clash detection and a reduction in the number of Requests for Information.

Large Temporary Structure for Special Event

M. G. Paschetto[1], T. D. Heidersdorf[2], and D. M. Campbell[1]

ABSTRACT

As the entertainment industry continues its efforts to attract audiences and audiences search for ever more dramatic events, engineers are being asked to design and analyze a widening variety of temporary entertainment structures. Whereas concert tours and music festivals typically employ a standard range of modular stages, some events have started using stage structures that are unique and used for one event only. Wrestlemania XXVI in the spring of 2010 at University of Phoenix Stadium is an especially interesting example of this. Standard Stageco rental equipment was combined with several custom-built pieces to create a four-legged pyramid over the main event wrestling ring. In all, 40,000 lbs' worth of truss supported rigging loads equaling 63,000 lb.

Unique, one-off entertainment structures present specific challenges for the engineer, not least because of the normally tight schedules. The loads and structure dimensions can be significant despite the temporary nature of the installations. And it is most often not feasible when problems arise to take the time to determine the cause(s). Usually, issues must simply be worked around if the event is to take place safely and on time. In working on entertainment projects, engineers need to be flexible and creative.

BACKGROUND

The Stageco Group, headquartered in Tildonk, Belgium, has been in operation since 1985. The traditional part of Stageco's business is providing modular truss systems for temporary structures to be installed at a wide variety of entertainment, sporting, and promotional events. However, Stageco also works with production designers to create unique "one-off" structures that will be used only as part of a specific tour or even just a single event.

Beginning in 2003 with Wrestlemania XIX, Stageco has been involved in the staging of World Wrestling Entertainment's (WWE) signature annual event. The WWE wanted a large pyramid structure to support the lighting and audio equipment and video screens above the ring for Wrestlemania XXVI held in the spring of 2010.

THE PYRAMID

The structure envisioned for Wrestlemania XXVI was a straightforward assembly of four trussed legs angled to meet at a point and thereby forming the outline of a

pyramid. The pyramid would be 185 feet per side at ground level and 105 feet high. The base perimeter would be formed by cables tying the legs together. Figure 1 shows the pyramid during erection.

A 70'-6" square rigging grid was incorporated into the structure at a height of 58 feet. The rigging grid was constructed of one of Stageco's larger stage roof trusses from their standard equipment inventory. All told the equipment rigged from the pyramid amounted to 63,000 pounds.

The overall structure's size and large payload required that Stageco ship their heaviest-duty truss from Belgium so it could be used for the pyramid's four legs. This steel triangular truss has a depth of 5'-11" with 3.5" diameter chords. The overall strong axis moment capacity is 235,000 ft-lb.

Stage roof truss towers and buttresses in the Stageco system are founded on 6.5' square, steel encased concrete block bases. Each base weighs 4,840 lbs. One of these bases was employed at the bottom of each pyramid leg.

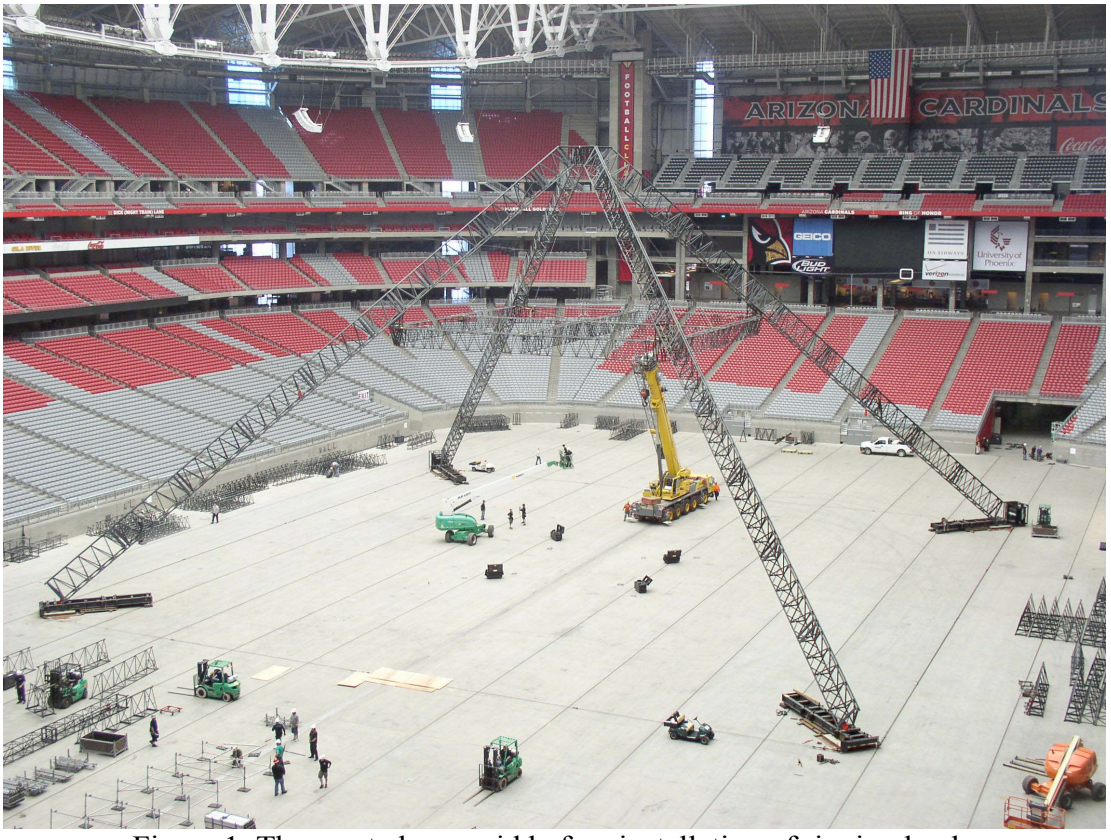

Figure 1. The erected pyramid before installation of rigging loads.

THE VENUE

A state of the art structure with both the roof and natural grass field being retractable, the University of Phoenix Stadium opened in August 2006. The dimensions of the retractable roof opening are 360' x 120'. During Wrestlemania XXVI, the roof was to be open and the grass field was to be in its outdoor location.

Planning to have the stadium roof open during the event engendered much discussion because there was no data available on the wind effects inside the stadium when the roof was retracted. No provisions had been made for wind ballast because the pyramid was being installed indoors. However, the WWE was firm in its decision to keep the roof open. Therefore it was not an option to specify that the roof be closed in the event of the outside wind reaching a certain speed.

For analysis purposes, it was finally agreed that a basic wind speed of 40 mph would be used. Any air turbulence around the roof opening would not have a significant impact on the pyramid because its height was well below the stadium's roof. So in this instance, the Engineer of Record was confident that 40 mph was conservative for a design wind speed. The maximum lateral design force from 40 mph wind on the pyramid was calculated to be 15,200 lb.

THE PYRAMID'S BASE REACTIONS

As with any structure of this type, there was significant outward thrust at the leg bases. When the pyramid was fully loaded, the thrust was 33,000 lbs per leg. Handling forces this large especially from a temporary structure presented quite a challenge. Entertainment projects almost always have a very short lead time and the schedule must be maintained if the event is to occur.

Computer analysis of the pyramid showed that creating a pinned condition at the leg bases would cause some truss members to become overstressed when all loads were applied. At the other extreme, allowing the leg bases to slide freely under load caused the trusses to become even more overstressed than in the pinned configuration. Further computer analysis of the pyramid with intermediate amounts of restraint at the bases found that allowing some spreading reduced all trusses' internal forces to allowable levels.

There was no ability to follow any design path except this last one, allowing the bases to spread a specified distance. Stageco's most heavy duty truss was already being used so the legs could not be made stronger. The rigging loads could not be significantly reduced because the client would be left with a lackluster show. The issues associated with partially restraining the bases would have to be dealt with, namely how to stabilize the bases once the desired displacements have occurred and how to ensure the bases' sliding will take place in a controlled manner.

Leg Base Restraint Methods. Two ways the bases could have been secured once they had moved the correct distance were quickly dismissed - anchoring the bases to the stadium floor or adding more ballast to them to maintain their positions. There was no doubt that neither the University of Phoenix nor Stageco would be interested in drilling into the stadium's concrete floor for anchorage. Similarly, from an engineering perspective it was considered inadvisable to rely on ballast alone to keep the bases in their proper locations because if the they spread too much the entire structure would fail.

Clearly, the base cables that were part of the original designer's concept would be a suitable alternative. These base perimeter cables that tied the legs together would be sized not just for strength but also for the right amount of stretch.

The elongation of the cables would partially release the legs and allow them to spread the desired distances. Beyond that, the cables would restrain the bases from any further spread. The final cable force was 22,000 lbs with the bases each displaced a total of 7 inches outwards.

Once the pyramid reached the desired deflected shape, gravity loads would provide enough friction at the bases to resist sliding forces that might arise from wind forces. The maximum lateral force for 40 mph wind was calculated to be 15,200 lbs. A 3,000 lb water tank was attached to each base to bring the total normal force up to a safe level for sliding resistance assuming a friction coefficient of 0.3 and including a factor of safety of 1.5.

Base Sliding. It was crucial that the bases spread a specified amount in order to keep the structure from being overstressed when fully loaded. Implied in this is that the bases needed to displace equally and in a straight outward line. See Figure 2 for the idealized displaced pyramid shape.

One fear was that a base which had not moved far enough under dead load might suddenly and violently release when rigging loads were being applied. Also, unequal movement of the bases would put additional, undesirable stress on the structure. The truss legs were strong in major axis bending and axial loading but they were not intended to resist any significant amount of weak axis bending. Although in theory the normal loads on the bases would not be high enough to create adequate frictional force to resist the thrust, in practice each base would see different floor conditions and one could easily get stuck. See Figure 3 for the expected displaced shape for this particular problem.

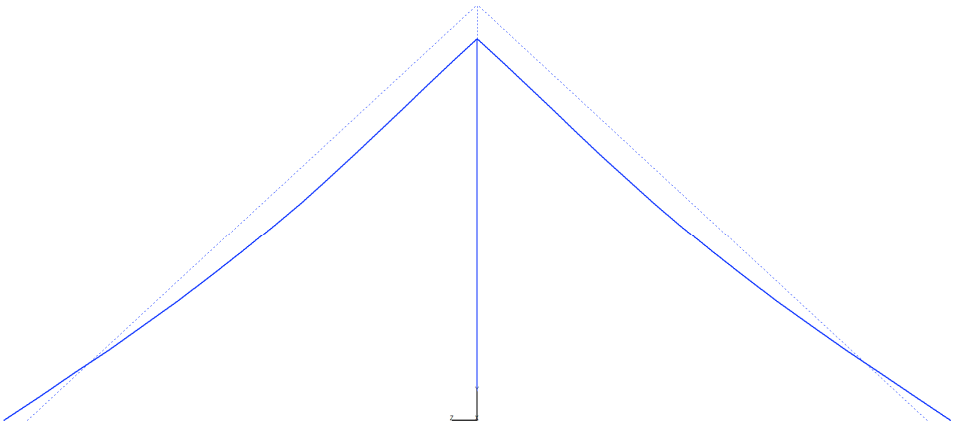

Figure 2. The desired deflected shape for the pyramid.

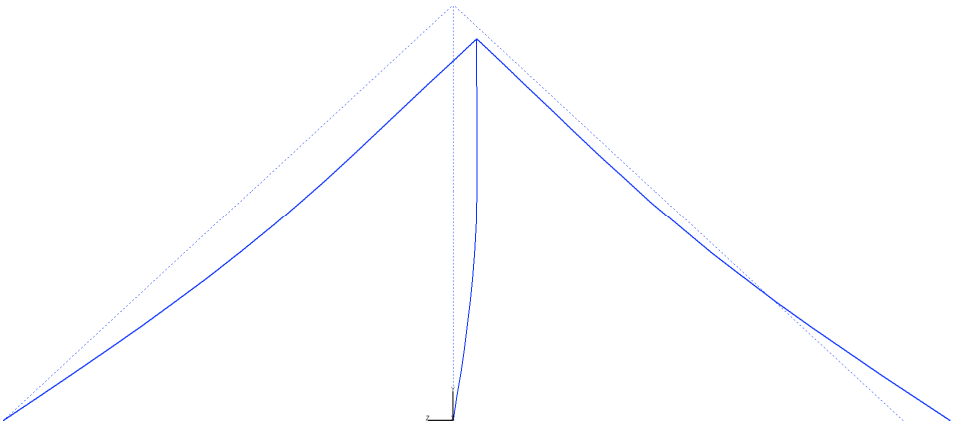

Figure 3. The deflected pyramid if the left hand base does not slide and the other three bases slide as needed.

Overall Sliding Resistance. The pyramid legs must slide during loading. However, they must also not be allowed to slide under wind forces once the structure has been completed and fully rigged. Whatever was designed to guide the legs during sliding, it would have to include a method for removing, at the appropriate point during installation, the ability to slide.

SLIDE BEARINGS

It was clear that some form of slide bearing would have to be designed for the pyramid bases. This was the only viable choice despite the attendant challenges. The remaining questions then were how to design something that could be quickly fabricated, easily installed on site, and safely used by the rigging crew.

When these decisions were being made, time and budget had become very short. The slide bearing design was therefore focused on using wood products. They were available at local DIY stores, easy to work with, lightweight, and inexpensive. Essentially, large wooden sleds were envisioned to receive and guide the pyramid's concrete bases. A plywood pad would be laid on the concrete floor of the stadium with another plywood pad on top of it and the concrete base on top of that. The plywood to plywood interface material would be selected to have a very low coefficient of friction. Blocks of wood would be nailed to the bottom pad to ensure that the legs did not slide sideways. And when the time came, the two plywood pads would simply be nailed together to secure the bearing pad assembly.

Below is provided for reference the equipment list and set of instructions given to the Stageco crew for the slide bearings. See Figure 4 for a photo of an assembled slide bearing.

Equipment:
8x4' sheet of ¾" plywood, 16 required
8x4' masonite sheet, approx. 3/16-1/4" thick, 16 required
250 ct. ¼" x 1-3/4" lag bolts

250 ct. ¼" x ¾" long flathead wood screws
lithium grease

Steps:

1. Assemble the slide bearing pads. One pad is to be made up of 4 panels in two layers – two plywood sheets in one layer and the masonite sheets in the other layer. It is important that the rougher side of the masonite, if there is one, is placed against the plywood. The smoothest face of the masonite should be the sliding surface. The bottom two sheets run in the perpendicular direction of the top sheets. The top and bottom layers are to be glued and screwed together.
2. Half of the slide bearing pads are to be cut down to 7' square overall dim's. These will be the top layers of the slide bearings.
3. Screw a guide block onto each offstage side of the exposed masonite surface of each of the 8' x 8' bottom slide bearing pads.
4. Place the 8' x 8' bottom slide bearing pads in the stadium with the masonite surface up and the masonite seam running parallel to the direction of slide. Proper alignment of the bottom pad along the direction that the base will move is critical.
5. Liberally grease the entire top masonite surface of each bottom slider bearing pad as well as the inner faces of the guide blocks.
6. Place the 7' x 7' top slide bearing pads on top of the bottom pads with the masonite surface down.
7. Place the concrete base on the slide bearing.
8. Put together the base cube assembly with the ground perimeter cables. Do not yet attach the base frames to the base cubes.
9. Tighten the perimeter cables to remove any slack.
10. Mark the current, unloaded location of the slide bearings' top pads relative to the bottom pads. Continue with assembly of the pyramid structure.
11. Once the pyramid is pinned to the base cubes, have the crane operator slowly release the load. The slide bearings should all move outwards approximately the same distance at each base – the concrete base and top pad moving together over the bottom pad – as the pyramid "settles". The guide blocks will prevent unintentional side to side movement. Note should be made of how far each base moves under self weight and also under self weight plus full rigging loads.
12. Check that each slide bearing seems to be moving properly. If there is any binding up, stop and resolve the issue. A strong hammer hit may be sufficient.
13. Once the entire self weight of the pyramid has been released from the crane, check the amount of overall movement in the slide bearing at each base. The distances should be approximately 4" and all about the same.
14. Rig the structure. The slide bearings will continue to move outwards as load is added to the pyramid.
15. Once all of the live load is in place, make one final check that each slide bearing moved a total of approximately 7" outwards.

16. Screw each slide bearing top pad to the bottom pad with 60 screws evenly spaced around the perimeter of the concrete base.
17. Attach the base frames.
18. For strike, reverse the above steps.

Figure 4. Assembled slide bearing shown with concrete base and steel base frame on top awaiting pyramid leg attachment.

IMPLEMENTATION

Challenges continued to crop up when the pyramid with its slide bearings was erected. The pyramid was assembled, still suspended from the crane, and pinned into the bases. As the crane released its load, the turnbuckle in one of the perimeter ground cables unwound, one of the bases did not slide, and the opposing base moved twice the distance it should have.

Work was halted and the structure was inspected. There was clear warping of the pyramid truss legs, as illustrated in Figure 3. It was decided that the crane operator should re-engage the pyramid in the hopes that the bases would return to their original positions. As the crane picked up load, there was some amount of rebound but not enough. Forklifts were used to "encourage" each slide bearing to return to its starting location. After several impacts from the forklifts, the slide bearings were acceptably close to where they should have been.

The turnbuckles were checked and tightened as necessary so that each perimeter cable was, as nearly as possible, under the same amount of tension. The

crane operator was again directed to start releasing the pyramid structure. This time a forklift was stationed at the previously stuck base so that it could be pushed if it still did not move.

The bases moved the correct distances after some prodding. However, there was a great deal of concern over whether the bases would slide evenly when the rigging loads were applied to the structure. It was thought that the best way forward was to add pre-stress to the perimeter ground cables. This would put inwards force on the bases which would be counteracted as the live load outward thrust started to act. Accordingly, the turnbuckles were tightened an amount that corresponded to the desired cable length decrease necessary to match the tension that would arise from the live load thrust. The pyramid was rigged without further problems and Wrestlemania went off without a hitch. The above steps were reversed for strike and went smoothly.

In hindsight, it was thought that two things were the most to blame for the stuck bearings. One was that the lithium grease seeped into the masonite and either caused it to swell or somehow become sticky. By the time the event was over and the structure was being taken down, the bearings had completely dried out and loosened up. And indeed the bearings behaved as they should have during strike. The other factor was a pair of guide blocks that had been attached too closely to the sides of the upper bearing pad of the slide bearing assembly that had caused the most problems during installation.

CONCLUSION

Unique, one-off entertainment structures present specific challenges for the engineer, not least because of the tight schedule constraints. The loads and structure dimensions can be significant in light of the temporary nature of the installations. And as with anything that is only designed and built once, there are always unforeseen issues that arise and must be addressed.

The slide bearings for the Wrestlemania pyramid are a case in point. In particular, one of the four slide bearings did not behave as expected and there was no time to disassemble the pieces to find the cause. The problem simply had to be worked around if the WWE event was going to take place safely and on time. In working on entertainment projects, engineers must be willing to deal with this type of situation on a regular basis if their clients are to be well served.

Assessing Existing Theater Structures and Rigging Infrastructure for Large Production Demands

ABSTRACT

The ever increasing load demands placed on existing theaters by modern live entertainment pose unique challenges for the structural engineer. One of the more difficult aspects for the engineer is the fact that many of the older theaters have limited, or no, design/construction documentation in existence. In the absence of drawings, investigations must be based solely on surveys of the existing conditions of the stage supporting structures and the grid-iron and fly systems. Typically, one finds that structural modifications have been made over the years for various shows without the benefit of engineering reviews. The Hammerstein Ballroom Theater (circa 1906) and the Howard Gilman Opera House at the Brooklyn Academy of Music (circa 1908) are two particularly interesting examples of old theaters requiring structural reviews for recent productions of new shows whose loads would impose a high demand on the existing structures.

BACKGROUND

Theater stagehouses provide an area over the stage for the rigging of hanging show elements. A stagehouse of a typical theater with a seating capacity of 1300 would usually have clear dimensions (with no obstructions from beams, columns, floors, etc.) of 50 ft x 90ft wide x 90ft high. Within the stagehouse is a counterweighted hanging system called a *Fly System* that allows technicians to move scenic elements such as lighting, video, audio, scenic flats and special effects vertically between the show's visible performance area behind the stage proscenium opening to the large stagehouse directly above. A schematic of a single manually operated lineset in a typical theater Fly System is depicted in Figure 1.

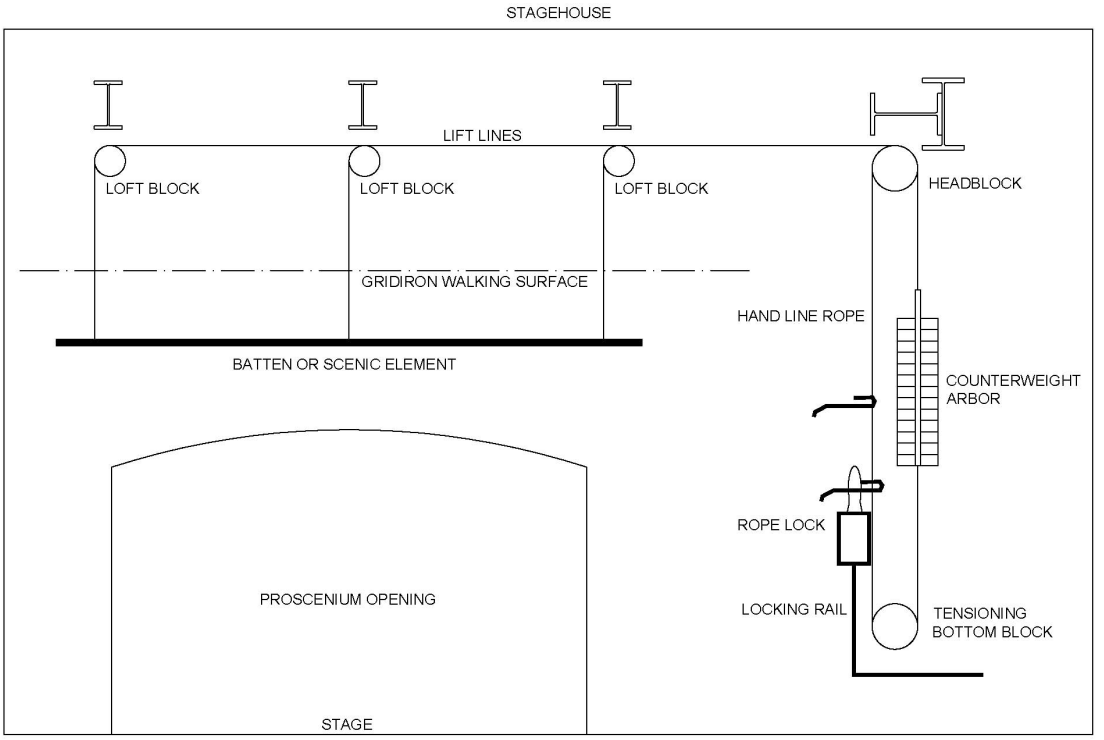

Figure 1 – Schematic of a Typical Manual Lineset in a Fly System

The counterweight arbor is brought into balance with the scenic load by adding and removing arbor weight plates. The average small theater, such as found in a high school, has 10 to 40 of these linesets. Theater facilities such as performing arts centers, and commercial Broadway and local theaters can have hundreds of linesets with multiple catwalk 'bridges' located along the side of the stagehouse wall to facilitate the loading and unloading of counterweight plates. A single lineset can have a lifting capacity of as much as 1600 lbs. The linesets range across the ceiling of the stagehouse spaced at 4 to 12 inches on center. Larger theaters typically employ a lattice grid of structural steel (called the *flygrid* or *Gridiron*) which is used as a walking surface to service the loft blocks and to support other rigging. The narrow spaces between the grid steel members allow the lift lines to pass through. The loft blocks may be attached to the gridiron itself or the stagehouse ceiling above. Figure 2 shows these two most common configurations.

(a) Gridiron Mounted Loft Blocks (b) Ceiling Mounted Loft Block

Figure 2 – Typical Stagehouses with a Gridiron (a) or without a Gridiron (b)

Occasionally, temporary rigging may be employed where chain hoists are attached to the gridiron or ceiling of the stagehouse. Typical chain hoists used in the entertainment industry have lifting capacities of 1 and 2 tons. It is not uncommon for productions to use more than 100 of these units to rig the scenic elements of a show.

Recent advances over the last 20 years have added automated, computerized rigging systems to theaters which provide accuracy of timing and positioning of scenery and special effects. As a consequence of going to motorized systems, operating speeds have increased along with the attendant dynamic loads. Automated rigging systems typically use a grooved drum wire rope hoist, which eliminates the need for counterweights and consequently lowers the gravity loads on the stagehouse structure.

Modern theaters are designed using recent code criteria where previously there were no or only limited provisions for stagehouse rigging loads. The NYC Building Code requires stage structures that support rigging to carry 100% of the rigging loads plus a 25% impact factor as well as a 50 psf live load on the gridiron. The International Building Code and the State of California also now have minimum design criteria for theater stagehouse rigging loads. For automated systems, there are also provisions in the International Building Code and ASCE for machinery impact loads.

Typically, gridirons are supported by the stagehouse roof structure. Therefore, design criteria for rigging loads are usually considered as an additional live load and used within load combinations that include environmental loads. Since there is a remote possibility that 100% of the rigging loads would be acting simultaneously over the entire gridiron, a reduction factor is typically employed. In practice, many engineers will reduce the load over the entire area, often by up to 25%.

Older theater fly systems were designed to hang simple wood-frame and painted scenery flats and other light weight loads. Although one finds that the early gridirons were built conservatively for the loads of yesteryear, modern productions push the limits of the gridiron and stagehouse structure's capacity. Making matters worse, one finds that structural modifications

have been made over the years for various shows without the benefit of engineering reviews or guidance.

Two interesting examples of old turn-of-the-century theaters requiring structural reviews for new shows whose loads would impose a high demand on the existing structures are presented herein.

HOWARD GILMAN OPERA HOUSE AT THE BROOKLYN ACADEMY OF MUSIC

Built around 1908, the Howard Gilman Opera House at the Brooklyn Academy of Music (BAM) is one of the oldest theaters in New York City and is a typical example of a large playhouse with a full stagehouse gridiron and loft blocks attached to the ceiling structure – see Figure 3.

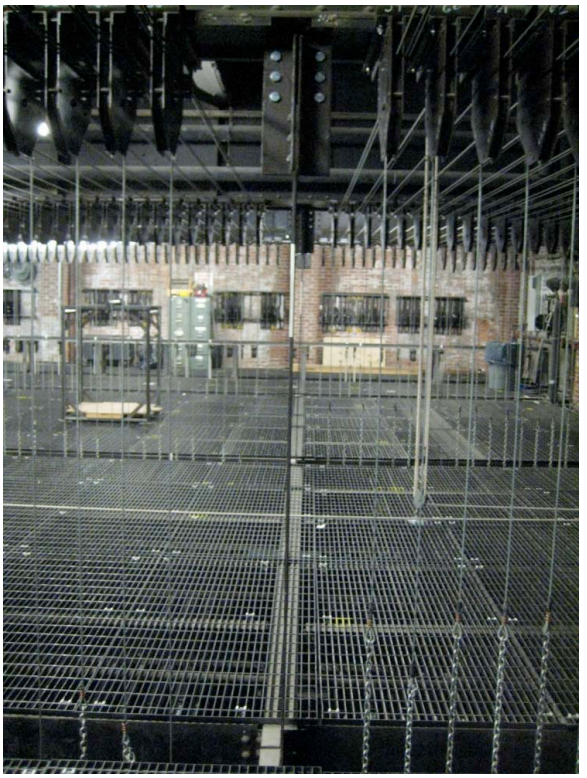

Figure 3 –Brooklyn Academy of Music Stagehouse Gridiron

In the summer of 2009, VH1's Diva/HHH show was engaged by BAM for a one-time event. The show wanted to rig fifty one (51) 1-ton chain motors to the gridiron of BAM's stagehouse. See Figure 4.

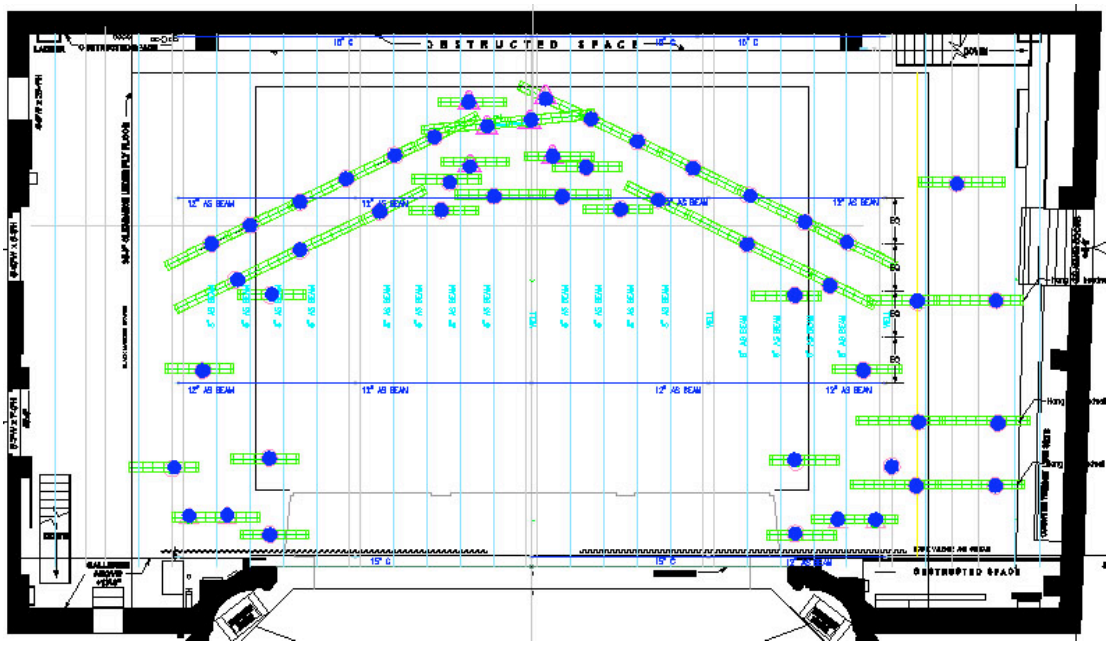

Figure 4 – VH1 Divas/HHH Show Rigging Points on Brooklyn Academy of Music Gridiron

As is common with most gridiron structures, BAM's gridiron is hung from the roof structure and is approximately 76' feet above the stage deck in the stagehouse. All loft blocks are hung from the roof structure, so the gridiron does not support loads from the permanent fly system. As a consequence, the gridiron steel structure is only used to support small hung loads and loads from the bar grating walking surface.

The Divas/HHH show required rigging from the gridiron's steel structure, so the engineering review concentrated on the capacity of the gridiron support structure. Since the Divas/HHH show did not take place in winter, the fly house roof structure was not reviewed because the roof's snow load capacity was assumed to be greater than the Divas/HHH show loads.

Based upon on-site inspections, it was found that the gridiron's original walking surface of 2" x ¼" steel slats had been replaced by modern bar grating sometime in the 1980s. It is easy to understand why the facility replaced the slats; they were bouncy and had 'dished' over the years as riggers walked on it. This left the slatted surface across the gridiron wavy with hills over the beams and valleys in between. Evidence was found of the original slats' attachments along all of the tops of the gridiron support beams. The original attachments consisted of clamping bars that grabbed both edges of the top flanges of the beams of the gridiron support structure. A small area containing some of the original slats as can be seen in figure 5.

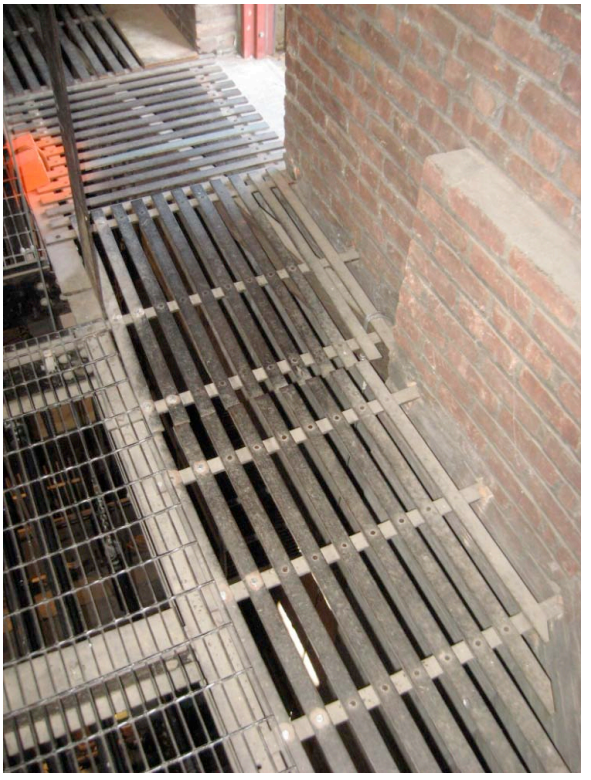

Figure 5 – Section of Original Slat Walking Surface of Gridiron (note modern bar grating to left)

The original slats provided continuous lateral beam bracing to most of the gridiron support structure. However the new bar grating with four hold-down clips at each corner of each grating panel did not provide the same level of lateral bracing for the beams. See Figure 6.

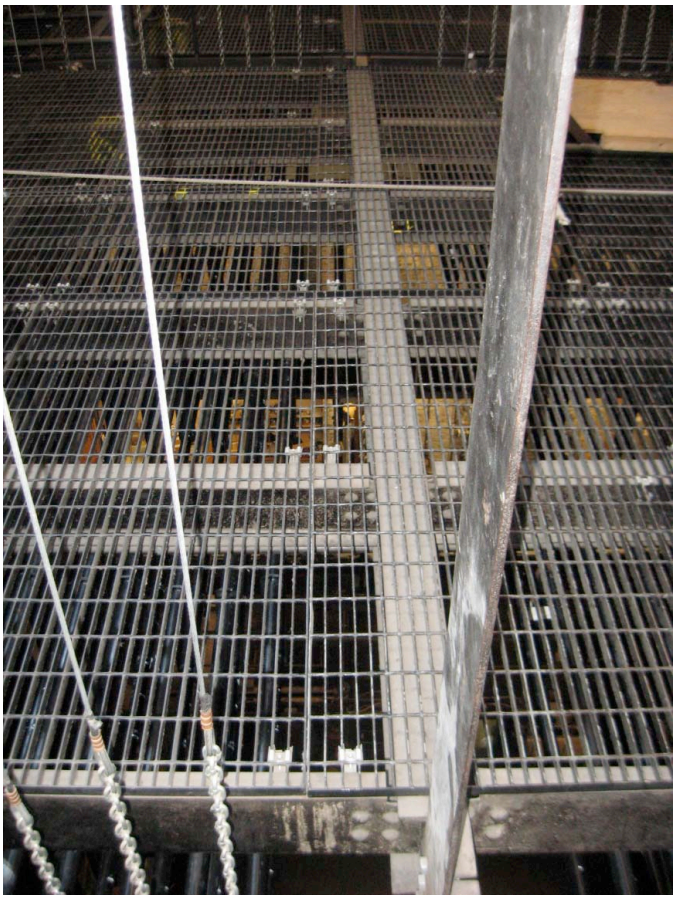

Figure 6 – Bar Grating Panels with Each Panel Secured With a Clip at Each Corner

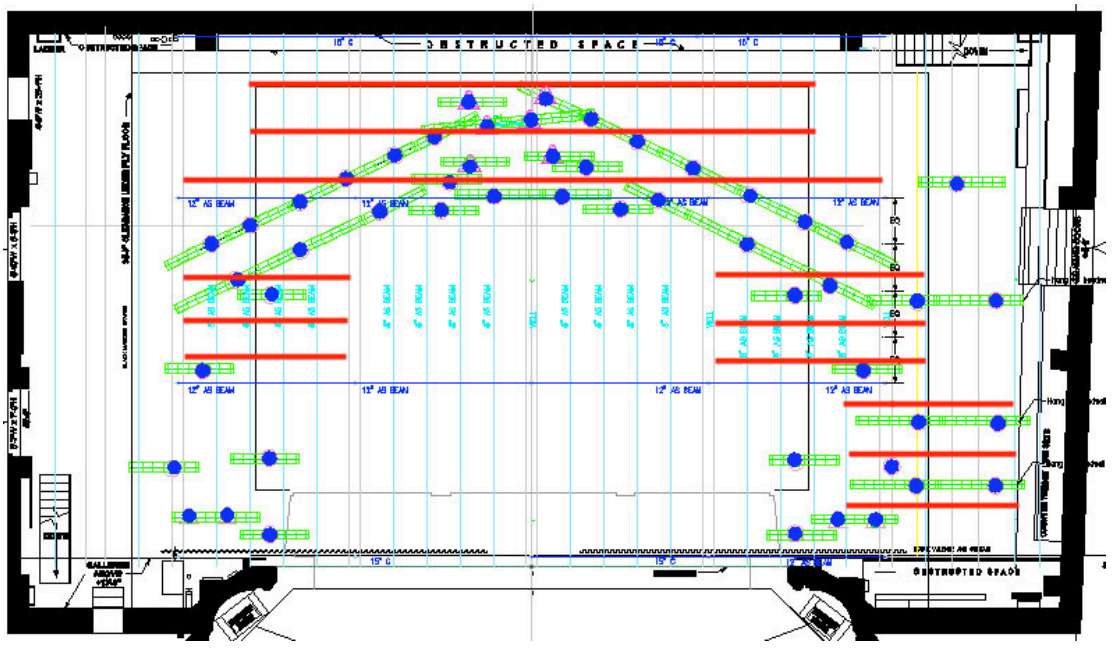
The reduction in the amount of lateral bracing meant that the gridiron structure had very low rigging load capacity above the minimum required loads for the grating surface. To rig the Divas/HHH show, the production was required to remove the bar grating panels in the affected areas and add temporary blocking/bracing between the beams. The bracing had to be installed between the webs of the beams so as not to protrude above the tops of the flanges which would prevent the bar grating panels from being replaced. See Figure 7



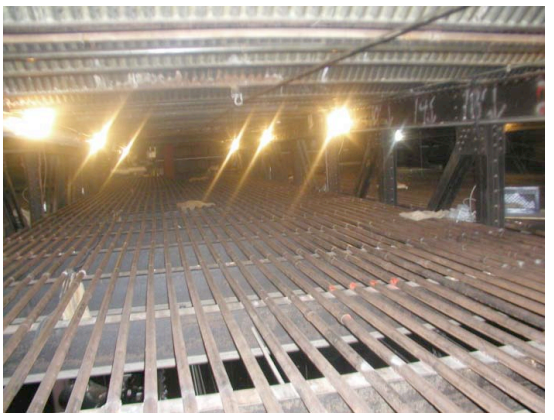


Figure 7 – Divas/HHH Show Gridiron Beam Bracing Plan

By replacing the original gridiron slats, the theater unwittingly had drastically reduced the load capacity of their gridiron. Unless and until they install permanent beam bracing, any show that desires to rig from the gridiron must now have temporary bracing added to the structure. This situation is typical of structural modifications made in theaters without the benefit of engineering guidance. This type of occurrence is possible because theaters are able to install shows and make modifications without building permits. Over the years a mindset develops where it is thought that theater rigging alterations do not warrant engineering review.

THE HAMMERSTEIN BALLROOM

Built around 1906, the Hammerstein Ballroom may be the oldest theater in New York City. Sometime in the 1970s, major renovations of the Ballroom were undertaken. The renovation included the construction of an addition to the original Hammerstein Ballroom structure. This newer structure is called the Grand Ballroom. The Grand Ballroom's stage was built on top of the Hammerstein Ballroom's original stagehouse roof. See Figure 8.

(a) Hammerstein Gridiron and Original Stagehouse Roof

(b) Grand Ballroom Stage Added to Hammerstein Stagehouse Roof

Figure 8 – Renovated Hammerstein Stagehouse with Added Stage Structure

Three Hammerstein stagehouse trusses help support the Grand Ballroom's stage. The fly house trusses are supported by deep plate girders at the stagehouse's left and right walls. See Figure 9.

(a) A Hammerstein Stagehouse Truss

(b) Hammerstein Plate Girders

Figure 9 –Hammerstein Stagehouse Gridiron and Grand Ballroom Support Structure

The original fly system had loft blocks attached to the stagehouse roof but this fly system was removed so there was a reduction of rigging loads on the stagehouse roof. While the Hammerstein stagehouse trusses were originally designed to carry gridiron and roof loads that include snow and wind, the addition of the Grand Ballroom stage has caused a net increase in the loads the trusses must support despite the removal of the snow, wind, and fly system loads. The engineering evaluation was to determine by how much the added loads from the Grand Ballroom stage reduced the capacity of the fly house trusses and how that impacted the rigging capacity of these trusses for shows in the Hammerstein Ballroom.

Computer analysis models were created for the three typical fly house trusses and the plate girder based on the site visit sketches and notes. Site visit sketches were compared to existing drawings and calculations from previous renovations to the structure. Note that while the existing documentation found was incomplete regarding the stagehouse, enough information was obtained to properly evaluate the stagehouse trusses and plate girder (but not the plate girder connections hidden within the masonry of the proscenium and stagehouse walls).

Loads applied to the computer analysis models were determined from the site visit notes, knowledge of typical construction material weights, and AISC reference materials pertaining to turn of the 20th century steel construction. Many steel mills at that time had their own steel shapes and identification of sections and materials were made from the manufacturer's markings on beams. See Figure 10.

Figure 10 – Turn of the 20th Century Steel Beam Manufactured by Steel Mill 'PHOENIX'

Codes require a 150 psf live load for stage structures. However, in determining a realistic tributary load for the three main structural elements, 100 psf was chosen since it is highly unlikely that the full 150 psf would be reached over the entire stage area all at once.

Initial findings indicated that the stagehouse trusses' top chords were at 110% of capacity per allowable AISC code stresses when a 100 psf load was applied to the Grand Ballroom stage which directly loads these trusses. This overstress condition precluded additional capacity for handling any rigging over the Hammerstein stage which would be tributary to these same trusses. Essentially, no rigging should occur in the Hammerstein stagehouse if there is any event occurring at the same time in the Grand Ballroom. Indeed, any Hammerstein Ballroom rigging should be evaluated with the stagehouse trusses' limited capacities in mind, whether there was a concurrent event in the Grand Ballroom or not.

Further investigation also found that the plate girders supporting the stagehouse trusses would be over capacity if a 100 psf live load is applied to the Grand Ballroom stage at the same time as rigging loads for the Hammerstein Ballroom. There was no exploration of possible solutions for reinforcing the stagehouse trusses and plate girders.

CONCLUSION

It is common to find that significant renovations have been made to theaters' structural components that are involved in supporting show loads. Because theatrical productions have historically been outside the purview of building departments, these renovations were often implemented without engineering oversight. For this reason, extra care should be taken to capture the structural ramifications of previous, perhaps undocumented changes when one is inspecting and evaluating existing theater structures.

Touring Stages for Outdoor Concert Productions

ABSTRACT

This paper presents the experience of the authors engineering stages for touring productions for outdoor concerts in stadia and other large outdoor venues. Stage structures spanning as much as 30m (100 ft) capable of supporting as much as 50 tons of entertainment equipment are regularly erected, dismantled, trucked and re-erected dozens of times in a major tour. Structures assembled in three days from modular steel components and platforms supported on scaffold systems are employed to create large stages often for a single performance at a venue. Most structures are designed to be supported at grade, often on sports turf fields, creating unique engineering challenges.

INTRODUCTION

Each year dozens of rock bands, country music artists, and other performers spend the summer travelling across North America and around the world playing night after night to stadiums packed with adoring fans. In addition to the musical talent a key component of every successful show is the stage structure which supports the sound, lighting, and video as well as the performers. The stage structure is comprised of many modular elements that can readily be erected, dismantled, trucked, and re-erected dozens of times in a major tour.

STAGE CONFIGURATION

A typical concert stage is 25600mm (84ft) wide by 19500mm (64ft) deep. With sound wings and additional video display on either side of the main stage, the overall width may be as much as 63700mm (209ft). The stage itself is comprised of a deck

on 1900mm (6'-3") high scaffolding. The roof over the main stage is 15600mm (51'-6") high supported on eight or ten trussed tower legs. (Figure 1) Additional trussed tower legs support the wings. Though various components of the stage and roof are pre-engineered, the entire system still must be evaluated for the specific loads for the show and for the code required environmental loads for every venue.

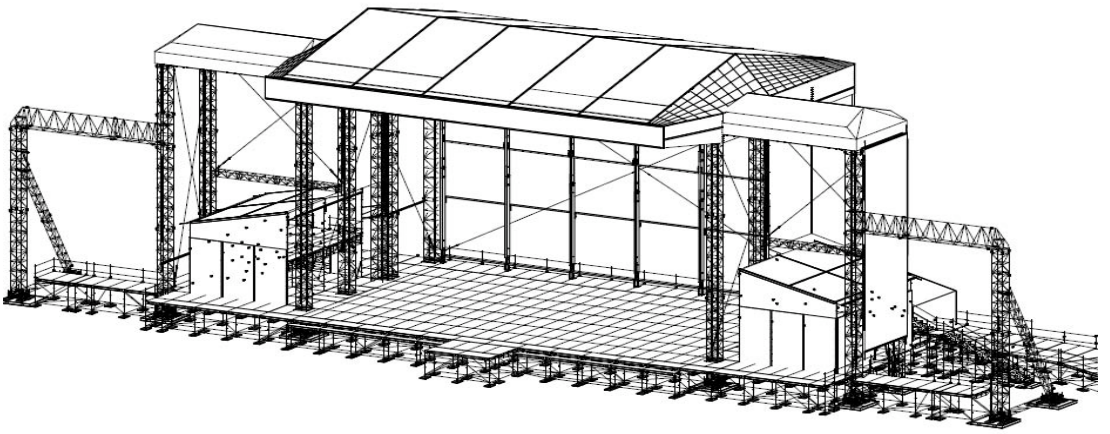

Figure 1. Touring Stage- Isometric View

LOADING

These touring stage structures are subject to the same load requirements as all other structures. However, these structures are used in multiple locations, so they must meet the load requirements of many different jurisdictions. Design loads should be determined from the building code in the structure's jurisdiction and per the reference standard ASCE 7.

The dead load of the structure is extremely light because the components must be quickly assembled and disassembled by a road crew without the benefit of heavy lifting equipment. The weight of the system is also minimized in order to reduce the transportation cost. The primary gravity load comes from the sound, lighting, and video equipment. These components are highly concentrated in a small space and so pose unique loading problems.

ROOF RIGGING LOAD

The main roof supports lighting, video, and other suspended show effects. The hung effects are usually well distributed over the roof. However, a major effect that has been incorporated in many events in recent years is the video wall. The video wall is located towards the upstage edge of the roof (the back wall of the stage) and generally spans the entire 24380mm (80ft) width of the stage. The weight of the wall, varying between 44 and 71kN (10 and 16k), must be shared between two cross-stage roof trusses since the video wall alone nearly loads a truss to its limit.

Many of the lights are located at the downstage edge of the roof (front of stage) in order to illuminate at the act on stage. This edge of the roof is a cantilever so the load at the outer edge is limited.

WIND LOAD

Wind load is the primary concern in evaluating touring stages. The main stage is covered by a roof and enclosed by semi-permeable walls (known as skin or scrim) on three sides. Large stacks of hung speakers fill the sound wings, and video walls fill the outer wings. This complete system does not conform to any of the structural systems defined in ASCE 7. Consequently, the structure has to be evaluated as several individual systems and then the resulting forces combined.

The main stage system can be evaluated as a Building Structure because it has a roof with three closed sides. However, in high wind conditions, the walls need to be lowered, creating a "Roof Only" Structure. The sound and video wings need to be evaluated as Non-Building Solid Freestanding Walls. Often there are other sub-structures located within the main stage system. Additionally, the wind load on the truss tower legs must be computed. The loads from these various components are transmitted to the 750mm x 750mm (30.5in x 30.5in) truss tower legs and then to grade.

In the upstage/downstage direction, the wind exposure of the fully rigged touring stage is approximately 1078m^2 (11,610ft^2) with a distance between the upstage and downstage tower legs of only 14400mm (47'-3"). Figure 2 and Figure 3 illustrate the front elevation and side elevation respectively. As shown in Figure 3, the lateral load on the structure is transferred to the stage level through diagonal bracing cables. The narrow footprint in the upstage/downstage direction and the limited number of truss towers lead to high vertical reactions from lateral loads.

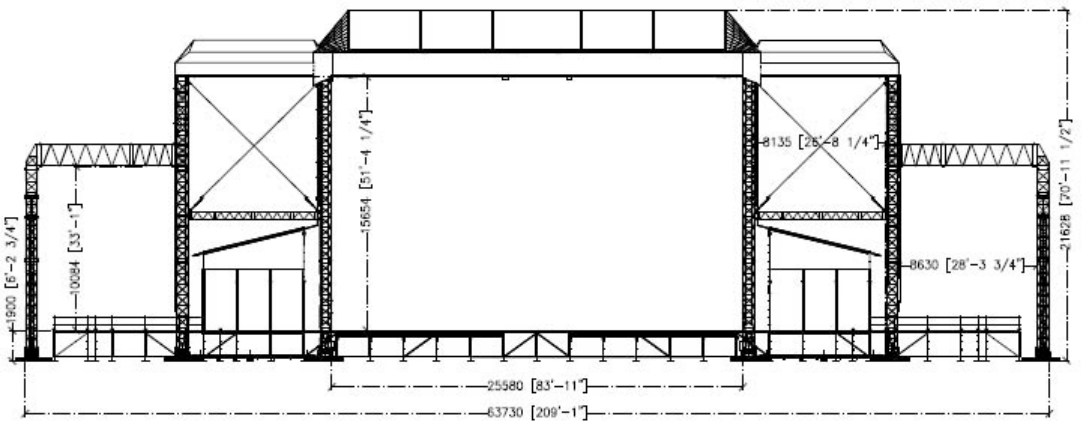

Figure 2. Touring Stage- Front Elevation

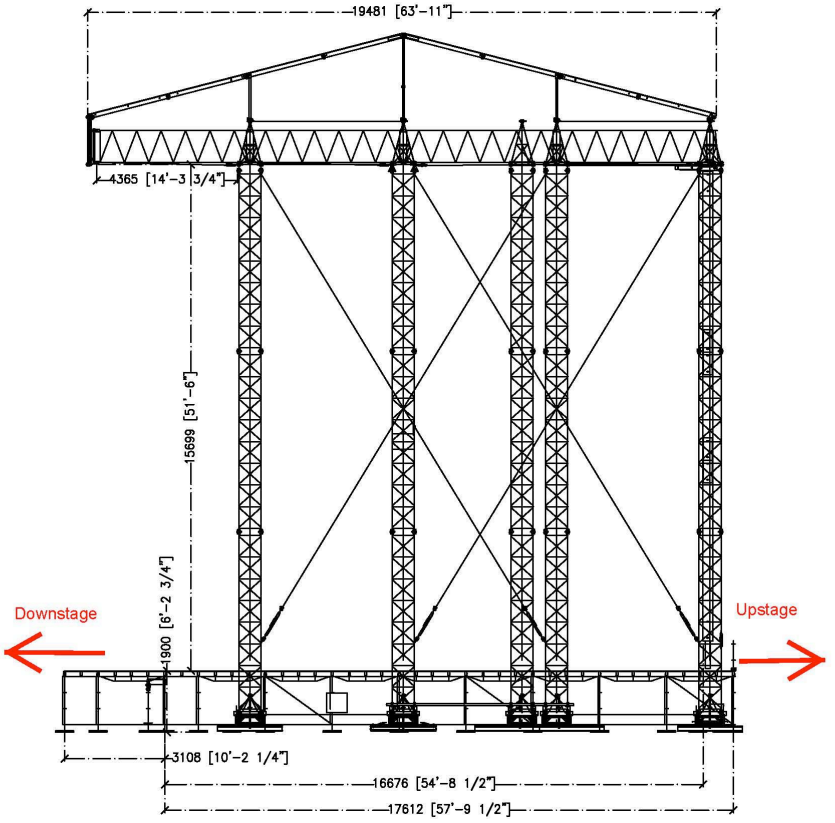

Figure 3. Touring Stage- Side Elevation

The stage is a temporary structure that is not in one venue for more than a week. SEI/ASCE 37-02, "Design Loads on Structures during Construction" provides reduction factors for "construction periods". For a "construction period" of less than 6 weeks the basic wind speed from ASCE/SEI 7 is multiplied by 0.75. Occasionally, stage structures are erected as a seasonal venue to be used for performances by different acts over the period of several months. The factor for these structures is 0.8. The reduced construction load is considered to have the same probability for a temporary structure as the non-hurricane 1 in 50 year return storm. However, the structure must be evaluated for the rigging load for each show.

BRACING

The trussed tower legs are slender elements and provide negligible lateral resistance. A pair of 16mm (5/8in) or 20mm (3/4in) diameter X-bracing cables is provided in the upstage face of the structure and multiple sets are provided in the upstage/downstage walls. These deliver the lateral load to the stage deck level. Similarly, the scaffolding legs are too slender to provide lateral resistance so an array of diagonals in the stage scaffolding delivers the load to grade.

SLIDING & OVERTURNING

The rigging loads are not distributed uniformly over the structure. The majority of the loads are hung from the downstage third of the structure with the speakers and often video walls on the downstage face. Additionally, the roof cantilevers over the downstage legs, so lighting trusses and effects hung on the front edge add substantial load to the downstage legs. With wind from upstage, the compression load on the downstage legs can reach 170kN (38k), with uplift forces on the upstage legs. To resist these vertical reactions, coupled with the lateral loads that are delivered primarily to the upstage and downstage legs poses an interesting challenge.

Often ballast is required to resist both sliding and uplift. A factor of safety of 1.5 is used in calculating the required ballast, however the coefficient of friction, μ, used for calculating sliding resistance varies depending on the surface conditions. Additionally, since the structures are supported on grade on either natural or artificial turf, the load has to be distributed so that the soil capacity is not exceeded. Therefore the tower loads and the ballast loads need to be distributed among the tower legs. Ballast is generally provided by concrete road barriers, concrete blocks, or tanks of water. Steel frames or beams are often required at grade to connect the tower bases and distribute load. In lieu of ballast, soil anchors are also employed.

Several stage systems have water tanks integrated into the base frame design. Other systems have heavy steel base frames. The lightweight tanks are shipped with the structure and filled with water during assembly. Concrete ballast is usually procured locally at each venue to eliminate shipping costs. Ballast required for an event varies between 40 and 196kN (9 and 44k).

Touring stages are used inside of stadia as well as in open outdoor venues. Although a stadium provides a measure of protection against wind, each condition is unique and requires analysis of wind from all directions.

WIND MANAGEMENT PLAN

Touring stages are primarily used during the summer months. On the east coast, however, the summer months coincide with hurricane season. Per ASCE/SEI 7, the design wind speed along most of the coast is as high as 150mph. Numerous major east coast cities including Miami, Washington DC, New York, and Boston are along this hurricane coastline and are popular destinations for concert tours.

A fully clad structure (See Photo 1 and Photo 2) is not capable of resisting hurricane force winds. Fortunately, current technology and weather forecasting are able to provide early warning of impending hurricanes. Various measures can be taken in anticipation of an extreme wind event in order to mitigate the effects on the structure. We provide the production team with a “Wind Management Plan” which defines

measures to be taken at various increasing wind speeds to protect the structure, the equipment, the personnel, and the audience.

Photo 1. Touring Stage- Fully Clad Stage with Sound and Video Wings

In addition to hurricanes, major thunder storms with strong winds are very common in the summer months. These storms often come with very little warning. The use of an anemometer, strategically placed at the top of the structure, provides accurate wind speed readings which are necessary for properly implementing the plan.

The structure is analyzed for the service condition, with all enclosure "skins", scenic panels, and suspended equipment in place, for wind gusts of up to 40mph. For the maximum design wind speed of 67.5mph (0.75x90mph) the structure is analyzed with only its self weight and significantly reduced rigging load.

The Wind Management Plan is outlined specifically for each show and each site and accounts for the rigging load distribution and the ballast. An example from one show is as follows:

Elements and components must be removed, stowed or secured as wind speed increases. The following must occur to maintain a safe condition. Items are listed in order of importance.

<u>Wind gusts approach 35 mph:</u>

Back wall skins or scrim in the PA wings are to be lowered and removed.
Main stage back wall skins are to be lowered and removed.
All side wall skins or scrim are to be lowered and removed.

Wind gusts approach 40 mph:

All video walls are to be lowered to the stage deck and secured.
All scenic trusses are to be lowered to the stage deck and secured.
PA stacks should be lowered to the deck and secured.
LED walls should be lowered to the deck, dismantled, and secured.

Storms with wind gusts expected in excess of 67.5 mph:

The stage structure without sidewalls and suspended equipment can resist design wind events with gusts to 67.5 mph. In the event of a severe storm forecast with potential winds in excess of 67.5 mph, the stage structure should be dismantled. In the event that it is impractical to dismantle the structure, efforts should be undertaken to secure whatever structure cannot be removed against severe wind. In no instance should the structure be occupied during a severe wind event. To the greatest extent feasible all cladding, skins, roof, and decking should be removed and stowed inside a building. The structures should be temporarily guyed or secured as is feasible.

Photo 2. Touring Stage- Fully Clad Stage with Sound Wings

Fortunately, in the event of an impending hurricane concerts are customarily cancelled. Above a wind speed of about 67.5mph (0.75 x 90mph) the concern is for protecting and securing the stage and equipment. The structure should not be occupied during a severe wind event. The structure is analyzed at each of these wind speeds to account for the different clad area and load for each condition.

CONCLUSION

Stages and show configurations vary widely and must be analyzed individually for the jurisdiction in which they are employed. Resulting forces from overturning from wind is a critical load case for these structures and often requires the addition of ballast. The monitoring of environmental loads, especially wind, is a design requirement necessary to define measures to be implemented to prevent overstress of the structure.

UNDERSTANDING WALL/SLAB BENDING MOMENT AND SHEAR TRANSFER IN LIQUID CONTAINING STRUCTURES

Almanzar-Micheli, Leonel I. PhD, PE[1]
Morris, Jordan MSCE, EIT[2]

[1]CDM, 4835 East Cactus Road, Suite 360, Phoenix, AZ 85254. PH (602)281-7856, email: almanzarli@cdm.com

[2]CDM, 4835 East Cactus Road, Suite 360, Phoenix, AZ 85254. PH (602)281-7924, email: morrisjl@cdm.com

ABSTRACT

During structural design of reinforced concrete liquid containing structures, it is very important to visualize how shear and moments are transferred from the wall to the foundation slab. This article presents simple explanations to understand the behavior of the shear/moment connection in reinforced concrete tanks. This includes figures and sketches to aid engineers in properly locating reinforcement, splices, and hook requirements. The proper reinforcement location, taking into account the development of the stresses transferred, is one of the most important detailing challenges in liquid containing structures in order to avoid crack formation and potential leaking. Using the tips and explanations presented, the engineers will be able to minimize cracking in the connection, as well as to understand the structural behavior of the wall/slab joint of liquid containing structures.

INTRODUCTION

Liquid containing structures' joints shall be designed to transfer loads through joint while remaining water tight. Specifically, the joint between the wall and the slab shall be properly detailed in order to obtain these objectives. Detailing mistakes at this location are commonly made and can easily be avoided. For the entirety of this paper the boundary condition between the wall and slab will transfer both shear and bending (fix connection) stresses.

Two scenarios are often encountered, interior water loading (opening moment) and exterior soil loading (closing moment). Each of these scenarios poses similar detailing challenges. In order to meet these challenges understanding stress transfer is critical. To gain insight to the behavior of these stresses a simple three dimensional solids elastic finite element model was developed in ANSYS 11.0. The wall and slab were modeling using SOLID65 solid elements. Both, opening and closing moment were applied to the joint and the stresses contours are shown in Figures 1, 2 & 3. This model represents un-cracked concrete condition at low stresses. When the concrete cracks, the strain field is disrupted, causing redistribution of the internal forces. Using finite element model to understand where the elastic internal

forces are developed, a simple truss analogy system has been developed for the cracked concrete (Figure 4). By using this truss analogy, it is assumed that the stress does not vary linearly through the joint.

The Y & Z normal stresses in Figure 1 & 2 illustrate the tension and compression regions within the concrete. Y normal stress illustrates the location for the wall reinforcement. Z normal stress illustrates the location for the base slab reinforcement. The YZ shear stress illustrates the transition of normal and shear stresses within the joint. As the normal stress propagate toward the center of the joint, they are transformed into shear stress, as the shear stress propagates away from the center of the joint, the stress are transformed into orthogonal normal stress.

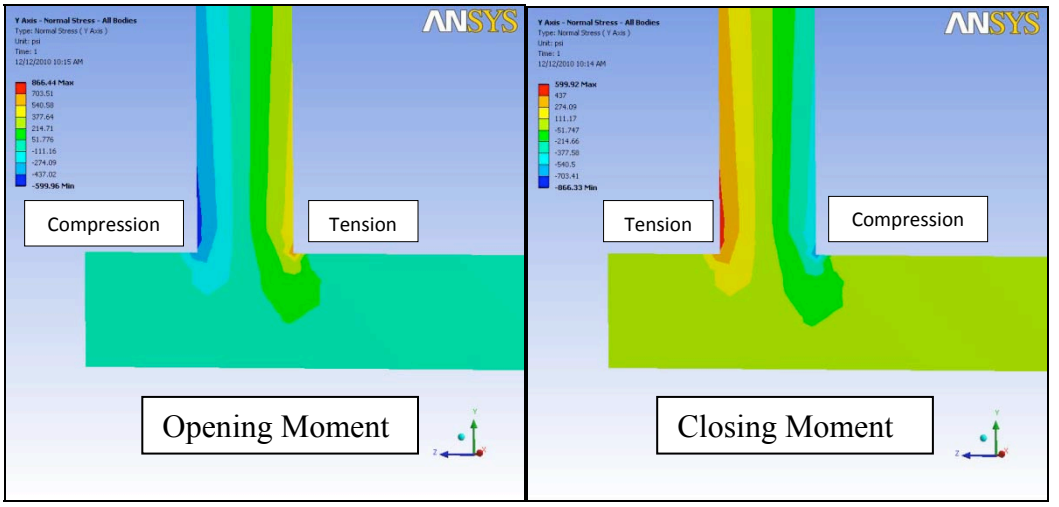

Figure 1. Y Normal Stresses

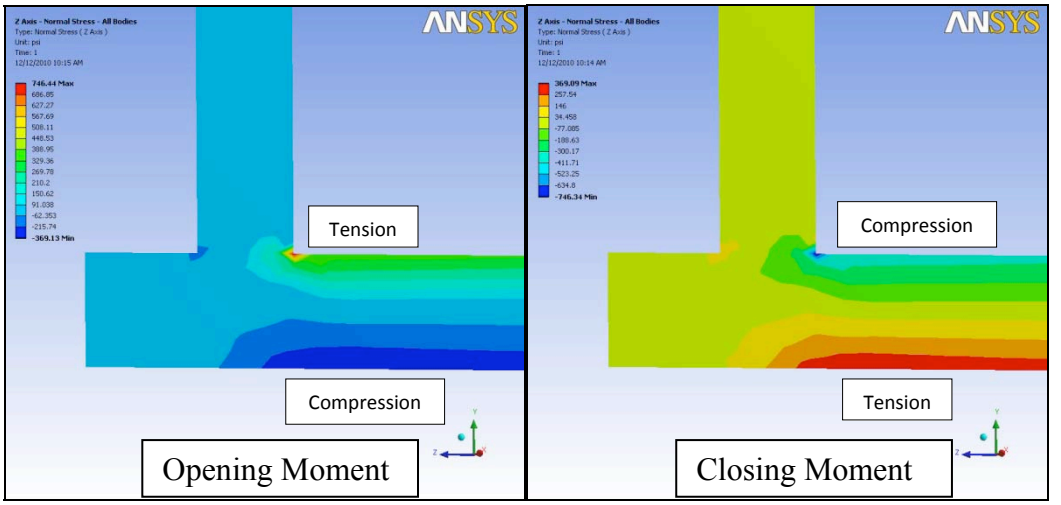

Figure 2. Z Normal Stresses

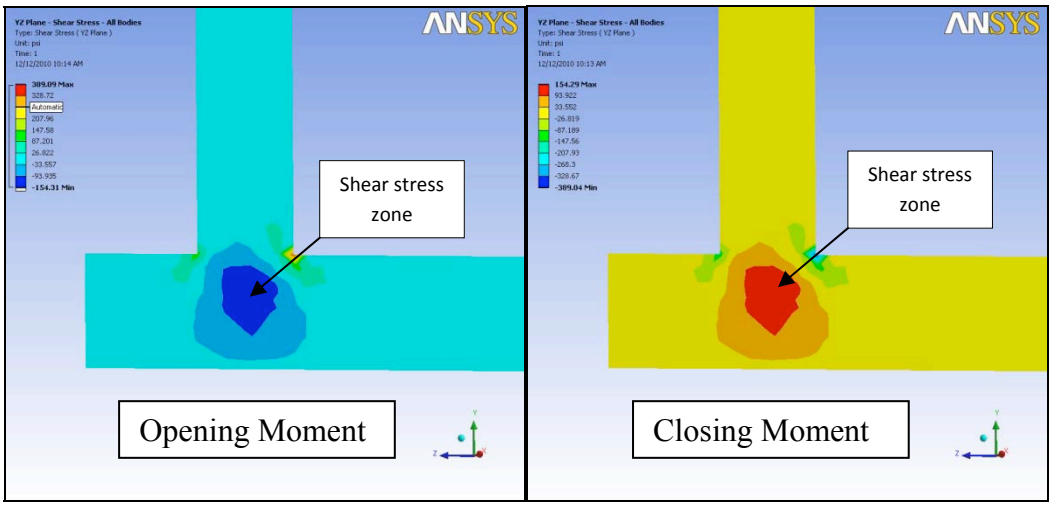

Figure 3. Shear Stress

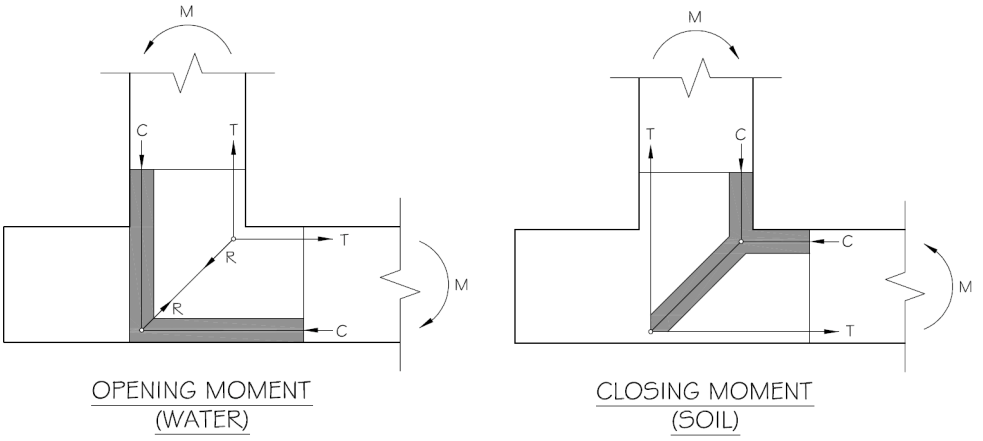

Figure 4. Truss Models

MOMENT AND SHEAR TRANSFER

Strength requirements for transfer of forces to the base slab through the joint shall be satisfied, rotation and deflection shall be minimized in order to prevent non desirable cracks, and bearing pressure shall be minimized to prevent excessive settlement. To investigate how some of these parameters affect the design, several finite element plate models were developed (Figure 5). The height of the wall and applied lateral load were held constant. In each of the models the toe length was then

varied. The results for the opening and closing moments in the slab are shown in (Figures 6 & 7). These plots clearly show that the moment that is transferred to the slab when there is no toe is approximately equal in magnitude to the base moment of the wall. For both scenarios the moment decreases as the toe is increased. This distribution is a function of both the wall/slab stiffness and the soil stiffness. Once the toe length reaches some distance the moment in the base slab should be approximately one half of the wall moment. A second advantage of toe length increase is a decrease in wall rotation and deflection (Figure 8). This decrease in rotation and deflection is also accompanied by a decrease in bearing pressure.

Often the wall and slab are casted in two separate pours that create a construction joint. Conventional shears capacities per ACI 350-06§11.3 are analyzed at a distance "d" from the joint in order to verify whether the wall has adequate shear capacity. The base shear is checked using the shear friction equation in accordance with ACI 350-06§11.7.4. There is often confusion on how the bending affects the shear friction, detailed explanation is included in ACI 350-06§R11.7.7. Usually, it is not necessary to provide additional reinforcement to resist the shear by friction. The flexural tension reinforcement is located in one face of the wall and the compression reinforcement located in the other face can be used for the shear friction transfer. Once the base shear is transferred through the joint it is transferred to the base slab as either a tension or compression. Globally this shear is satisfied by an equal and opposite lateral force from the opposite wall. Internally, in order for the global equilibrium to be satisfied the tension is resisted by the slab reinforcement. Often two mats of reinforcement are placed in the base slab and only one face of the mats is being utilized for bending. Therefore the other mat can resist the tension values, so that these tension and compression values are often ignored.

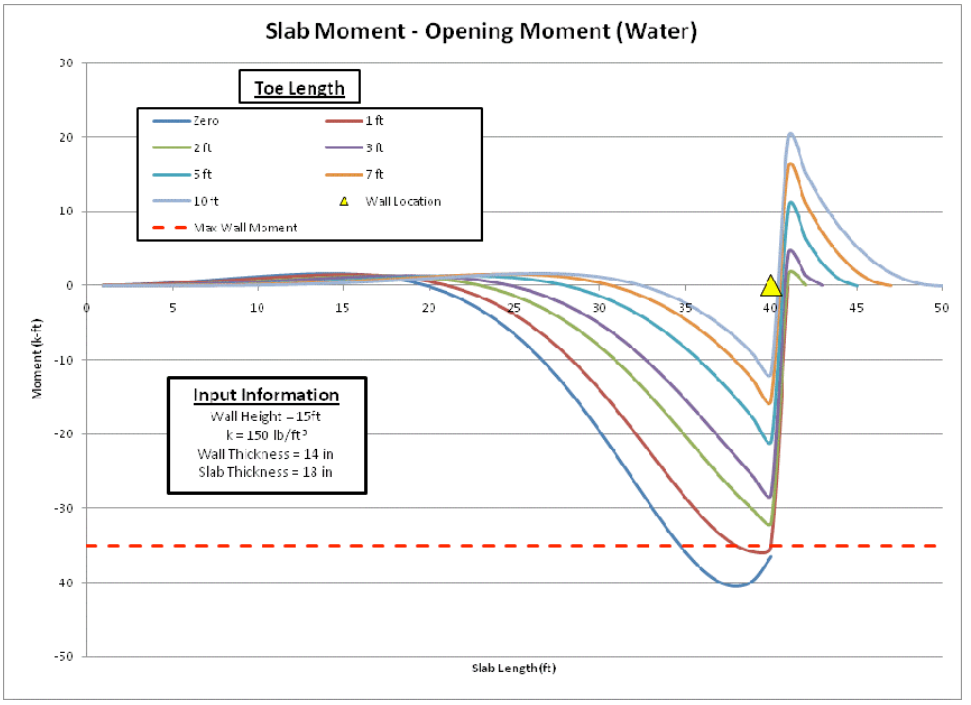

Figure 7. Slab Moment (Water)

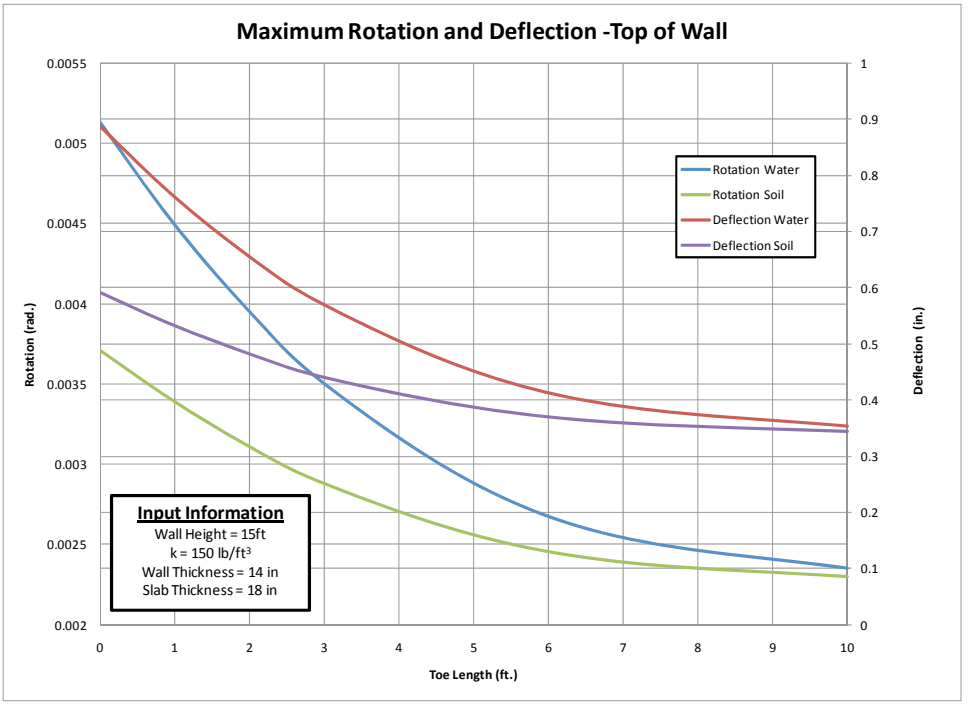

Figure 8. Maximum Rotation and Deflection

JOINT DETAILING

When detailing the reinforcement of the joint the designer's primary objective is to provide reinforcement for strength and cracking control. The design includes determining wall and slab thicknesses and reinforcement. Having done the design, the next objective is to insure proper reinforcement and anchorage detailing. Proper detailing includes reinforcement development and hook requirements for anchorage of reinforcement. All development and hook lengths shall be determined in accordance with ACI 350-06 Chapter 12. See Figure 9 for typical reinforcement details for opening and closing moments.

Using Figure 4, reinforcement is laid out in the tension zones of the wall and slab. This reinforcement is sized and spaced based on the bending moments at the base of the wall. When determining the reinforcement required in the base slab, it was shown in Figures 6 & 7 that the bending moment transferred to the base is approximately equal to the bending moment in the wall (this applies for most scenarios). The bending moment capacity of the base slab shall not be less than moment capacity of the wall. Reinforcement spacing shall be minimized to minimize cracking formation; ACI 350-06 has stringent stress limits and uses a durability factor (ACI 350-06§9.2.6) to account for the serviceability requirements in water containing structures. It is common practice to space smaller bars at a tighter spacing.

The tension reinforcement must have adequate anchorage /development. It is critical when determining the development length to understand where the

development starts. Development typical begins at the cracked section or the joint face. In Figure 9, it is assumed that the development for the reinforcement begins where the orthogonal reinforcement will first intersect the crack. The cracked section is assumed to be 45 degrees across the joint. The base slab thickness needs to at least be thick enough to develop the wall reinforcement and the toe shall be long enough to develop the base slab reinforcement.

The use of starter wall in figure 9 is to serve as a means to avoid conflict between the base slab reinforcement and the waterstop. Typical the starter wall height is between 1.5-3.0 inches, waterstop height is 4-9 inches and clear cover 2-3 inch. In lieu of a starter wall there are several other options, e.g., shear key, mounded base (used for thicker walls), or increased clear cover on base slab reinforcement.

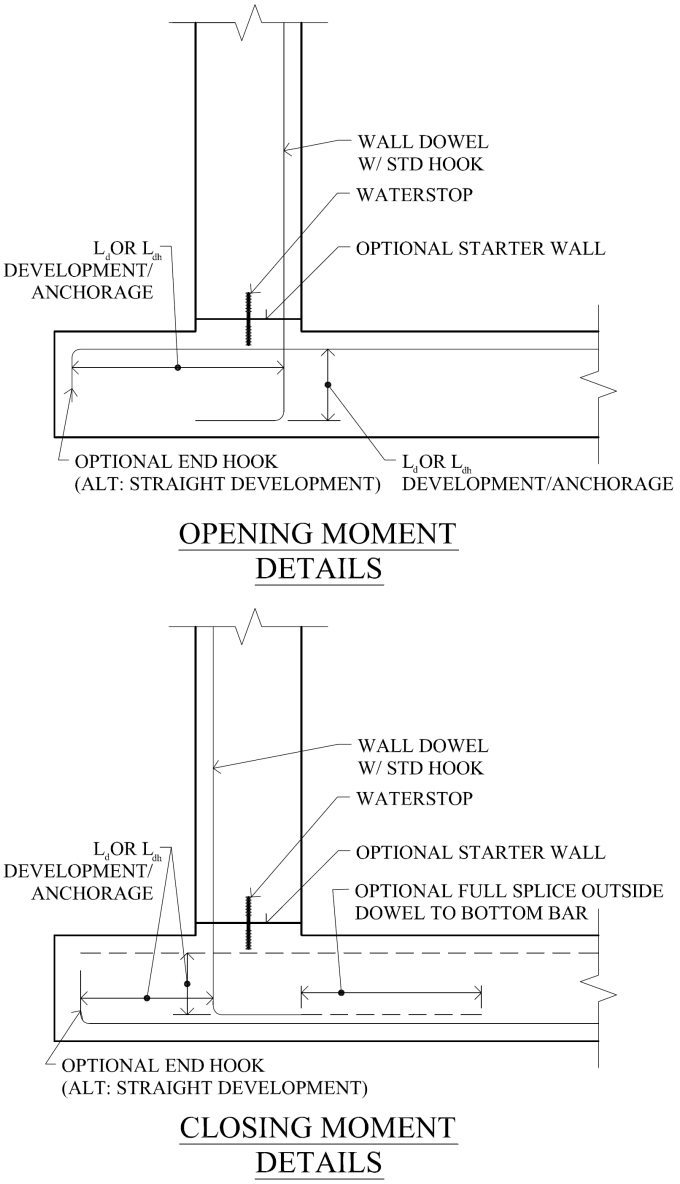

Figure 9. Typical Reinforcement Details

SUMMARY

One of the most critical tasks in water containment structures is preventing cracking. It is concretes nature to crack. By understanding how the bending moment and shear are transferred through the base slab and wall connection allows for proper detailing and analyses which lead to fewer failures. The presented details provided are example only; each structure shall be carefully analyzed for its associated loading conditions. It is also important to consider that there are several slab/wall connections used throughout the industry with success.

Typical guidelines for joint detailing:

1. Assume the opening or closing moment transferred from the wall to the base slab is at least the same in magnitude as the wall base moment.
2. Thickness of base slab and toe lengths must accommodate development lengths, hooks and clear covers.
3. The thickness of the base slab shall be no thinner than the wall thickness.
4. The toe width shall be at least the wall thickness or longer.
5. Check clearances for waterstops.
6. Space smaller bars at closer spacing.

The designer shall account for the stiffness interaction between the wall, base slab and soil, in order to properly predict the stresses transferred from the wall to the slab. The designer shall also carefully select the proper loading conditions in the structure, leading to an opening moment design, closing moment design, or both.

On the Application of the Meck Plot in Elastic Buckling

Tadeh Zirakian

Ph.D. Student, Department of Civil and Environmental Engineering, University of California, Los Angeles, CA 90095-1593; PH (818) 522-5997; email: tzirakian@ucla.edu

ABSTRACT

The Meck Plot is an adapted version of the well-known Southwell method for determining experimentally the critical load of a structure undergoing lateral-torsional buckling. It has been demonstrated that lateral displacement and rotation are directly coupled when lateral-torsional buckling occurs. Recently, it has also been interestingly shown that lateral displacement of an I-beam undergoing lateral-distortional mode of buckling is directly coupled with the web transverse strain, and satisfactory results have been obtained as a result of application of the Meck's method on these deformation variables. In this paper, one further step is taken in this regard and it is shown that web transverse strain may even be used with either web longitudinal strain, vertical deflection, or angles of twist of top and bottom flanges of an I-beam undergoing lateral-distortional buckling and still good results be obtained as a result of application of the Meck Plot on each pair of these deformation variables.

INTRODUCTION

In 1977, Meck (Meck 1977) proposed an extrapolation technique for experimental determination of the buckling load in problems of lateral-torsional buckling. He believed that it is necessary to consider both lateral displacement (δ_L) and rotation (ϕ) of the section in lateral-torsional buckling mode. Of course, later on, Mandal and Calladine (Mandal and Calladine 2002) showed that lateral displacement tends to be proportional to rotation as deformations increase in case of lateral-torsional buckling. Meck suggested to make a plot of (ϕ/M) against δ_L, and another of (δ_L/M) against ϕ; and that the respective slopes of the straight-line portions of these two plots will be $1/\alpha$ and $1/\beta$, and consequently M_{cr} will be the geometric mean of the slopes of the two plots (Eq. (1)).

$$M_{cr} = (\alpha\beta)^{0.5} \tag{1}$$

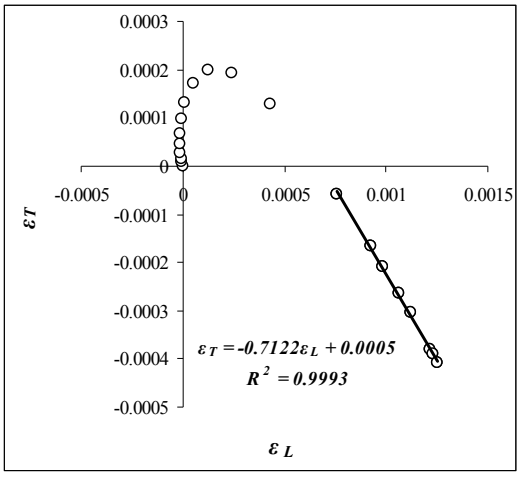
Recently, in an experimental study on the lateral-distortional buckling of I-beams (Zirakian 2008), it was revealed that in this mode of buckling, lateral displacement tends to be proportional to web transverse strain as deformations increase, and on the basis of this finding, reliable predictions were obtained for the critical buckling load as a result of application of Meck's method on δ_L and ε_T.

In this paper, a further step is taken in this regard and the possibility of application of the web transverse strain in I-beams undergoing lateral-distortional buckling with other deformation variables such as web longitudinal strain (ε_L), vertical deflection (δ_V), and angles of twist of top and bottom flanges (θ_{TF} and θ_{BF}) is explored. Accordingly, the relationship between web transverse strain (ε_T) and the aforementioned deformation variables is initially investigated, and subsequently the Meck Plot method is applied on each pair of these deformation variables which are also shown in Table 1.

Table 1. Case studies and the deformation variables.

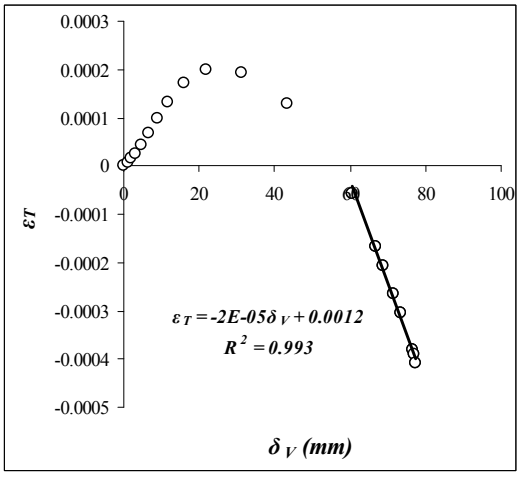
Case	$d.v.1$ *(first deformation variable)*	$d.v.2$ *(second deformation variable)*
1	web transverse strain (ε_T)	web longitudinal strain (ε_L)
2	web transverse strain (ε_T)	vertical deflection (δ_V)
3	web transverse strain (ε_T)	angle of twist of top flange (θ_{TF})
4	web transverse strain (ε_T)	angle of twist of bottom flange (θ_{BF})

DETAILS OF ANALYSIS



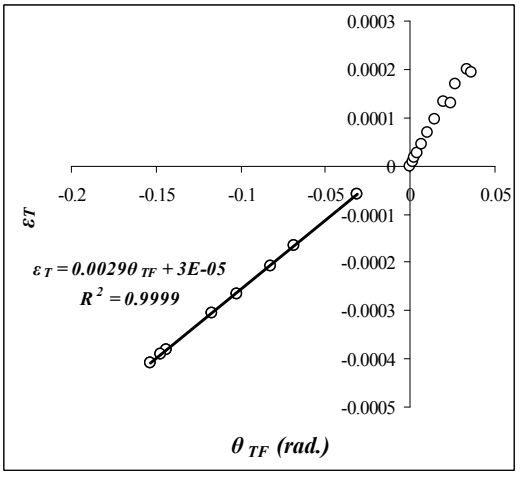
ABAQUS software (ABAQUS 2005) is used to develop lateral-distortional buckling solution and the cross-section components of the I-beam are modeled using the S4R5 shell element. The various deformation variables are captured at the midspan of a simply-supported I-beam loaded in uniform bending with dimensions $h_w = 900$ mm, $b_f = 240$ mm, $t_w = 5$ mm, $t_f = 20$ mm, and $L = 7000$ mm.

In addition, geometric nonlinear and linear elastic material analysis solutions are conducted on the beam with half sinusoidal curvature and twist as initial geometrical imperfections. The initial lateral crookedness and twist at the center of the beam are chosen as follows: (1) $\delta_{Loc} = 20$ mm and $\delta_{Voc} = 20$ mm; and (2) $\phi_{oc} =$ 0.04363 rad.

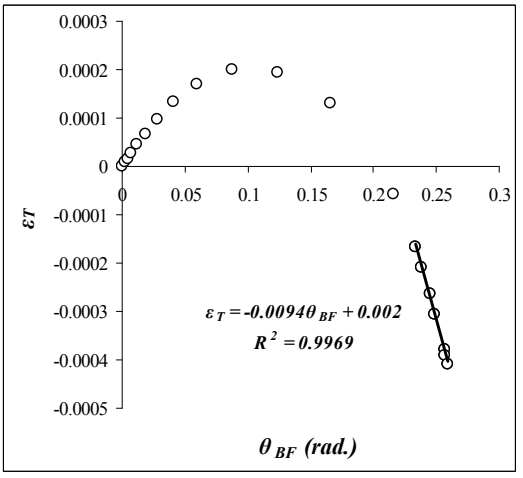


RELATIONSHIP BETWEEN DEFORMATION VARIABLES

In this part of the study, web transverse strain ($d.v.1$) is straightforwardly plotted against other deformation variables ($d.v.2$) and the respective plots of the four considered cases are provided in Figure 1. The linear equations obtained using



the least squares method as well as the respective R-squared values are also displayed in the figures.



(a) ε_T vs. ε_L

(b) ε_T vs. δ_V

(c) ε_T vs. θ_{TF}

(d) ε_T vs. θ_{BF}

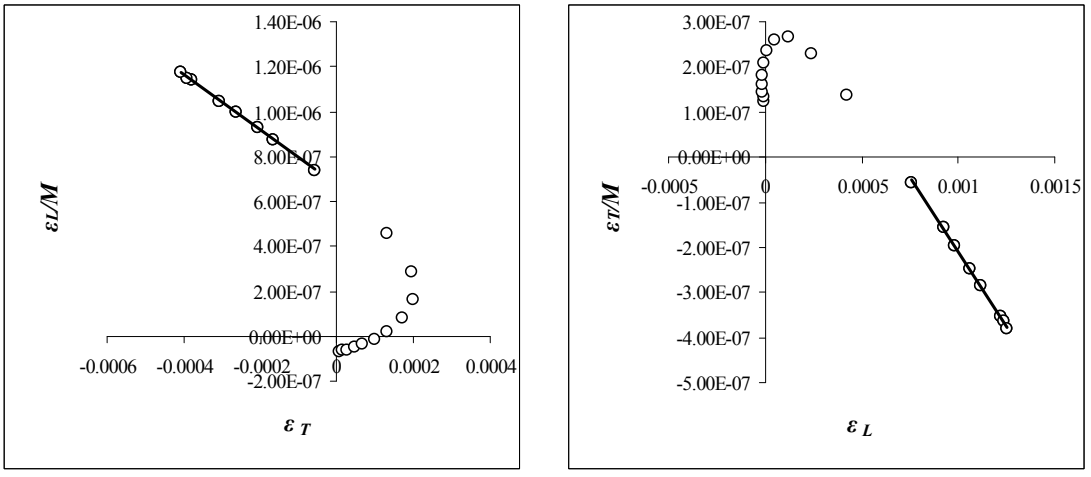


Figure 1. Relationship between deformation variables.

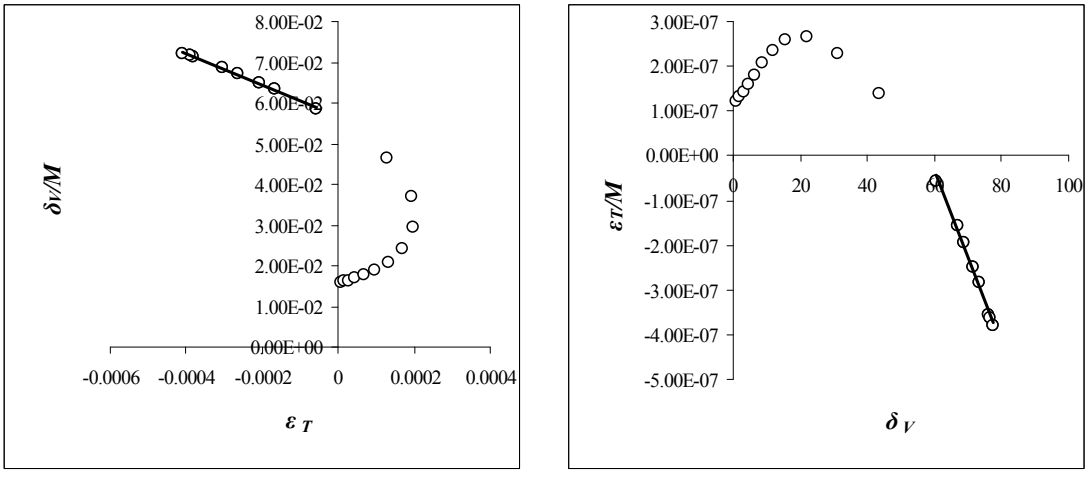
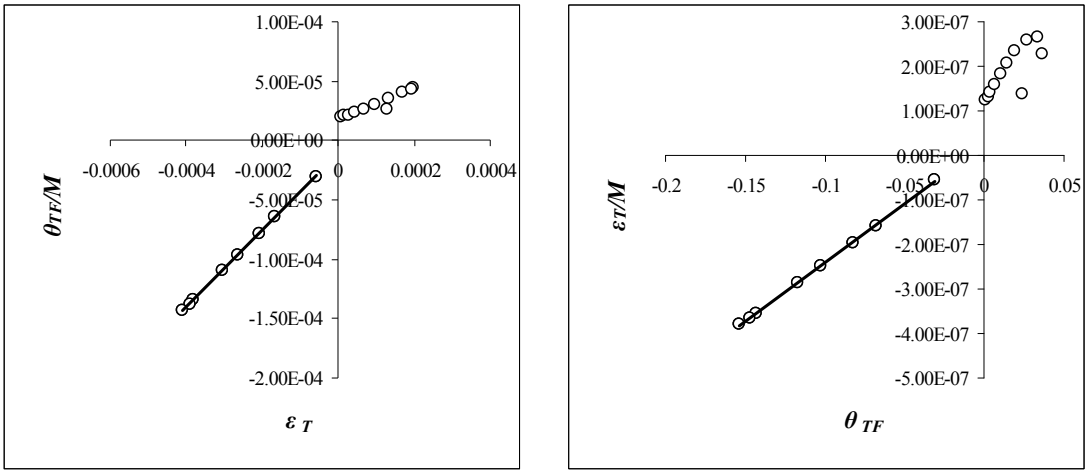
As it is seen in the figures, the data points in all cases, apart from the initial few, eventually lie on straight lines, which is indicative of proportionality between web transverse strain and the other considered deformation variables.

Based on these proportionality findings, it is now logical to apply the Meck Plot method and confidently expect to obtain reliable predictions for the critical buckling moment.



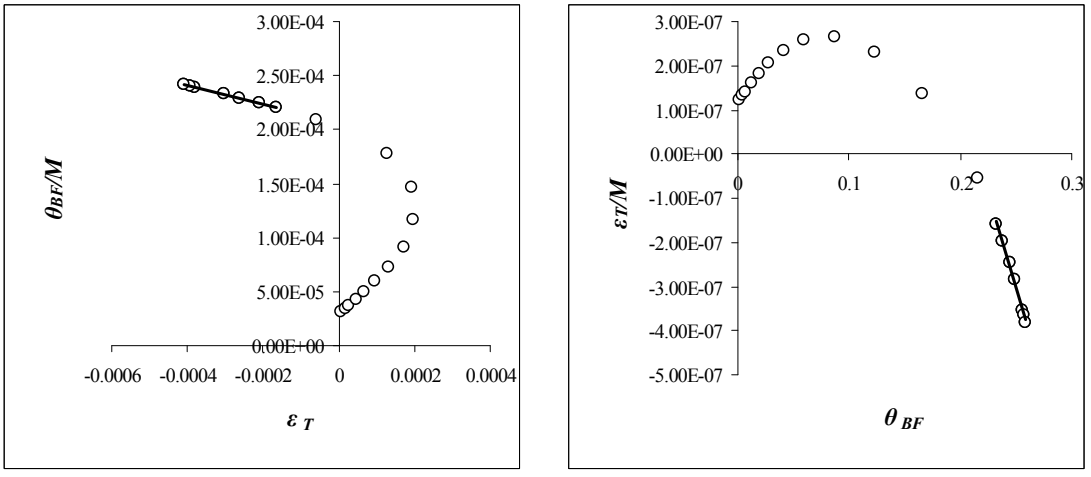
APPLICATION

In accordance with Meck's prescription, plots are made of $d.v.2/M$ versus $d.v.1$ and of $d.v.1/M$ versus $d.v.2$ for the four considered cases, which are shown in Figures 2 to 5.



(a) *(b)*

Figure 2. Plots of ε_L/M against ε_T and ε_T/M against ε_L.



(a) *(b)*

Figure 3. Plots of δ_V/M against ε_T and ε_T/M against δ_V.

(a) *(b)*

Figure 4. Plots of θ_{TF}/M against ε_T and ε_T/M against θ_{TF}.

(a) *(b)*

Figure 5. Plots of θ_{BF}/M against ε_T and ε_T/M against θ_{BF}.

As it is seen in the figures, the points in all cases tend to eventually lie on a straight line, and according to Eq. (1), the product of the inverse slopes of the straight-line portions in the two aforementioned plots is equal to the square of the critical moment. The values of α and β, Meck Plot predictions as well as the ultimate failure moment are summarized in Table 2.

Table 2. Values of α and β, Meck Plot predictions, and the ultimate failure moment.

Case	α	β	M_{Meck} (kN.m)	M_u (kN.m)
1	-833.3	-1,428.571	1091.09	1072.63
2	-0.026	-50,000,000	1146.05	1072.63
3	3.105	333,333.3	1017.29	1072.63
4	-11.834	-111,111.1	1146.70	1072.63

In spite of some scatter in the results due to application of various deformation variables, it can be seen from the table that the extrapolated moments are in good agreement with the ultimate failure moment. These findings indicate that the applicability of the Meck Plot method for experimental determination of the critical buckling loads of structures does not really need to be limited to the use of certain deformation variables, since other *directly-coupled* deformation variables may yield similar and acceptable predictions as well.

CONCLUSION

It was demonstrated that web transverse strain in I-beams undergoing lateral-distortional mode of buckling is linearly related with other deformation variables including the web longitudinal strain, vertical deflection, and angles of twist of top and bottom flanges. On this basis, Meck's plotting method proposed for lateral-torsional buckling mode was extended to the lateral-distortional mode, and consequently good predictions were obtained in all considered cases as a result of application of Meck Plot on the two deformation variables of each individual case.

ABSTRACT:

The new Deacero Headquarters in Monterrey, Mexico is a building focused on the changing world. The building was designed and engineered in a holistic fashion around two central tenents- flexibility and sustainability- while presenting it in a cutting edge architectural form.

The structure was developed to maximize flexibility of the space. The structure was designed on a 17m x 17m (56 ft. x 56 ft.) column grid without the use of internal columns or bracing. All bracing is accomplished through a unique Vierendeel Truss framing system.

The dry, hot environment of Monterrey presented a number of challenges to the façade system. To minimize heat gain on the structure, a sophisticated façade and louver system was developed.

Some of the interior architectural features, namely a very slender elevator support frame, presented a challenging structural problem. These features required careful consideration of the analysis and the design to fully capture its architectural intent.

The building has an extensive and sophisticated water management system that allows the building to be highly sustainable in a hot, dry environment. The system employs on-site water reclamation, bio-treatment and water recycling strategies. All of this results in a surplus of water which can be returned to the city.

INTRODUCTION:

After the successful completion of the Museo de Acerco in Monterrey, Mexico, Deacero S.A. de C.V. retained Grimshaw Architects of New York to design a new headquarters building for them. Grimshaw in turn retained Dewhurst Macfarlane and Partners, also of New York, to provide structural and façade engineering services.

Dewhurst Macfarlane worked closely with Grimshaw to develop a concept scheme and design criteria for the main structure as well as design development level drawings for some of the architecturally demanding elements. Dewhurst Macfarlane stayed involved in a design assist capacity through the completion of construction documents to ensure that that the engineer of record, GPI y Asociados of Mexico City, maintained the design intent laid out by the Grimshaw-Dewhurst Macfarlane team. Additionally, the construction documents of the façade were prepared by Dewhurst Macfarlane.

Figure1 – ExteriorView

Deacero is one the leading producers of steel wire and wire products in the world. The company, which is increasing their environmental stewardship, wanted their new building to reflect this growing commitment and be a showcase of sustainable building design in Mexico. The new building would form a new addition to their expanding corporate campus on the outskirts of Monterrey.

The new buildings would occupy a 68m x 68m (225-ft x 225-ft) footprint with 4 levels of subgrade parking and a 4-story, 10,500m^2 (120,000 SF). U-shaped building above grade. The program also included a 1,150m^2 (12,500 SF), enclosed atrium.

THE STRUCTURE:

To facilitate a modern office environment and allow for the possibility of leasing the building in the future, the offices needed to be as flexible as possible. Dewhurst Macfarlane was involved with Grimshaw at the earliest stages of concept design to

provide engineering and design input to vet and refine the architectural concepts as they were developed by the architects.

The design team quickly migrated towards a design which displayed many of the aspects of a classic modernist style in the tradition of Ludwig Mies van der Rohe. Interestingly, Dewhurst Macfarlane had completed the design for a much smaller structure with similar proportions for the Boston Logan 9-11 Memorial several months earlier.

The Logan 9-11 Memorial was a 6m (20 ft) cube. The architect for that project, Moskow Linn Architects of Boston, Massachusetts, wanted a structure that had very slender columns with no cross bracing. The small scale of that project allowed Dewhurst Macfarlane to investigate a large number of possible design solutions that would fit within the architectural desire. In the end, a Vierendeel frame was recommended for the memorial structure. For a variety of reasons, the memorial structure was completed using a different structural system, but it did give Dewhurst Macfarlane valuable insight into alternative framing systems, one of which would be used on the Deacero Headquarters.

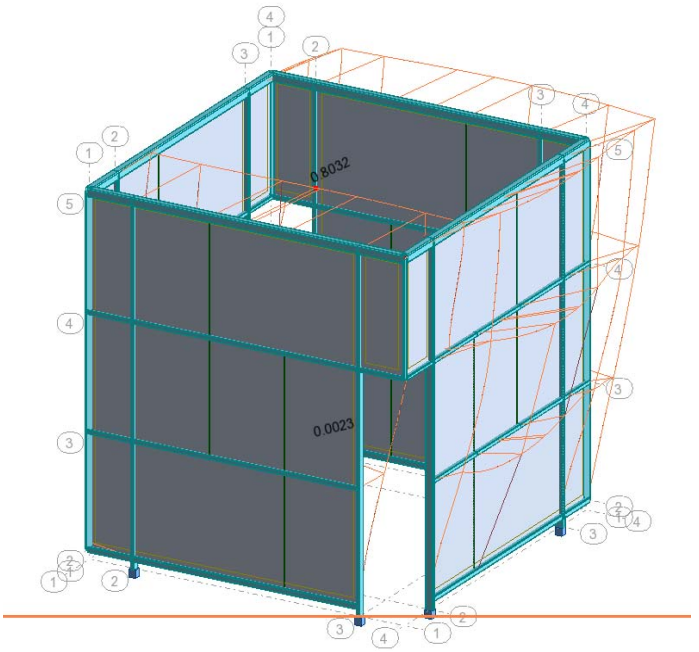

Figure 2 - Model of Logan 9-11 Memorial Model

Like the Logan 9-11 Memorial design (Figure 1), Dewhurst Macfarlane was privileged to work with an architect who was looking for an innovative design solution. Looking back on our recent experience, Dewhurst Macfarlane recommended an external Vierendeel frame for the bracing of the upper three floors and a traditional shear wall for the ground level. Besides providing lateral bracing, the Vierendeel frame also helped reduce the weight of the edge girders which carried the floor beams.

The Vierendeel frame allowed for a structure which was laid out on a 17m by 17m (55-ft x 55-ft) grid with no internal columns. This is one of the inherent and least pronounced sustainable aspects of the building. The large open floor plate allows for maximum flexibility in future use and planning. Floor beams where spaced at 3.4m which allows for future stairs and elevators to be cut in with a minimum amount of

structural modification in the future. The lack of internal bracing and a pronounced core allows for rooms with required fixed walls such as bathrooms and conferences rooms to be rearranged in the future without impacting occupiable space and architectural layout. In the end, the office floors exhibited a near 100% floor utilization factor and a 100% floor utilization factor if the full flexibility in installation of fixed rooms is taken into account.

To verify that the building performed adequately compared to a traditional structure, a number of parametric studies were done to compare the Vierendeel frame to a traditional structure with braced and moment frames. This comparison was not based purely on building performance but also on structural weight savings. As can be seen in Table 1, the Vierendeel system is comparable or superior in performance to other structural systems. Additionally, based on preliminary estimates, there was about a 50% steel reduction in using the Vierendeel scheme over a traditional moment frame.

Table 1. Comparison of different framing options examined. Framing options are shown in Figure 3.

	Deflection mm (in)	H/XXX
DHQ-Baseline	29.7 (1.169)	354
DHQ-X Brace	20.7 (0.815)	508
DHQ-1	28.4 (1.118)	370
DHQ-2	18.5 (0.731)	566
DHQ-3 (preferred scheme)	14.3 (0.562)	737

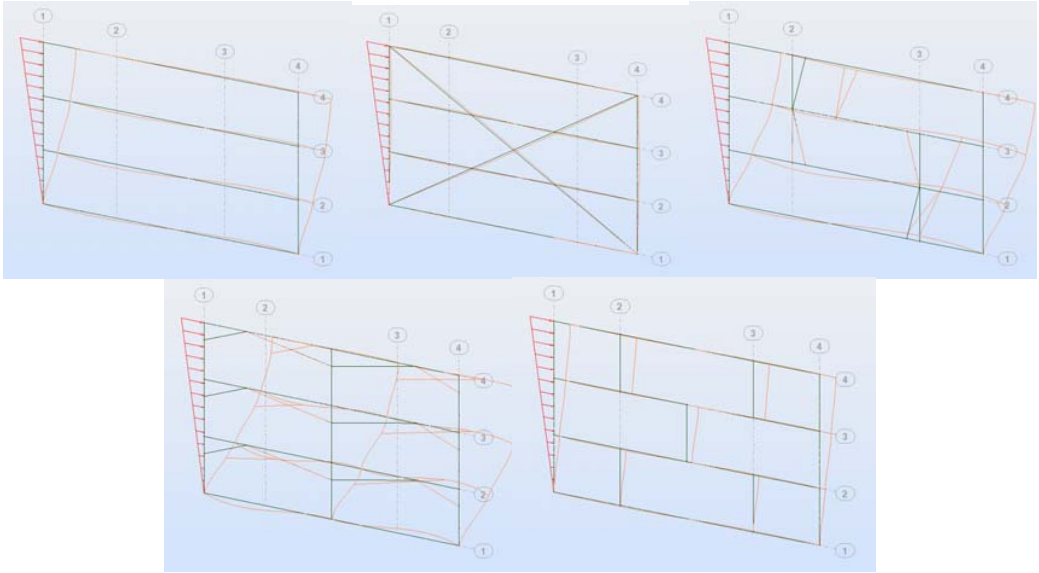

Figure 3. Five framing options compared in Table 1. Clockwise from top left: DHQ-Baseline, DHQ-X Brace, DHQ-1, DHQ-2, DHQ-3

The hardest aspect of designing the Vierendeel frame is a problem inherent in all frame structures- in order not to overstress the structural elements, they need to get larger, and as they get larger, they become stiffer and hence attract more load, which in turn causes them to get even larger, and the cycles continues until you have a

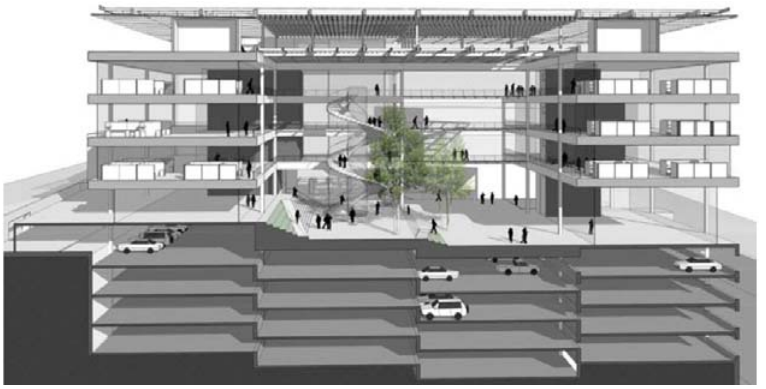

Figure 4 – Building Section

structure which is very stiff but also has a large aesthetic impact. This runs contrary to the architectural intent of the building which was to have as minimal a structure as possible, maximizing the amount of natural daylight. This required Dewhurst Macfarlane to look for elements which were strong but not stiff. While this is somewhat counterintuitive, small heavy sections, in this case a W10x60, (later changed to built-up 300mm by 300mm sections) were used. The highly compact shape with large cross-sectional area allowed Dewhurst Macfarlane to "cut the feedback loop" of strength and stiffness. The resulting stiffness was 16mm (5/8 in), H/1500, more than adequate for the structure.

What made this structural scheme even more attractive to Dewhurst Macfarlane was that the Vierendeel elements became a key part of the building's aesthetic with the architects from Grimshaw arguing just as vigorously for them as the engineers from Dewhurst Macfarlane and Partners when the scheme was first presented to the engineers of record- GPI. In the end, GPI came to understand and appreciate the scheme which was developed by Dewhurst Macfarlane and Grimshaw, but without the support of the architect, it may have been a harder sell.

One last note on the Vierendeel frame which was not fully realized when it was first proposed, but came up as the design was progressing, was the degree of structural redundancy this scheme provided. The Vierendeel frame allows for the loss of an

Figure 5– Typical office floor with conference room

edge beam connection on one floor or the loss of a column without a structural collapse via load sharing through the frame. A traditional moment frame would not have this kind of redundancy. The particular aspect of the frame's beneficial nature was realized in the extensive discussion the design team had on fire protection of the exposed steel frame.

Early in the design process it was realized that traditional notions of structural efficiency were different in Mexico than in the United States. In the U.S, it is standard practice to develop structures and details which favor labor efficiency over material efficiency, while in Mexico the opposite is true. In many ways this makes the design process more interesting to the engineer.

This logic was explored along a number of avenues in the development of the structural concept. Rather than using rolled section for the long span floor beams, a specialized steel truss was designed. This truss was design so that the top and bottom flanges would be steel plated rather than employing a steel shape and the diagonal

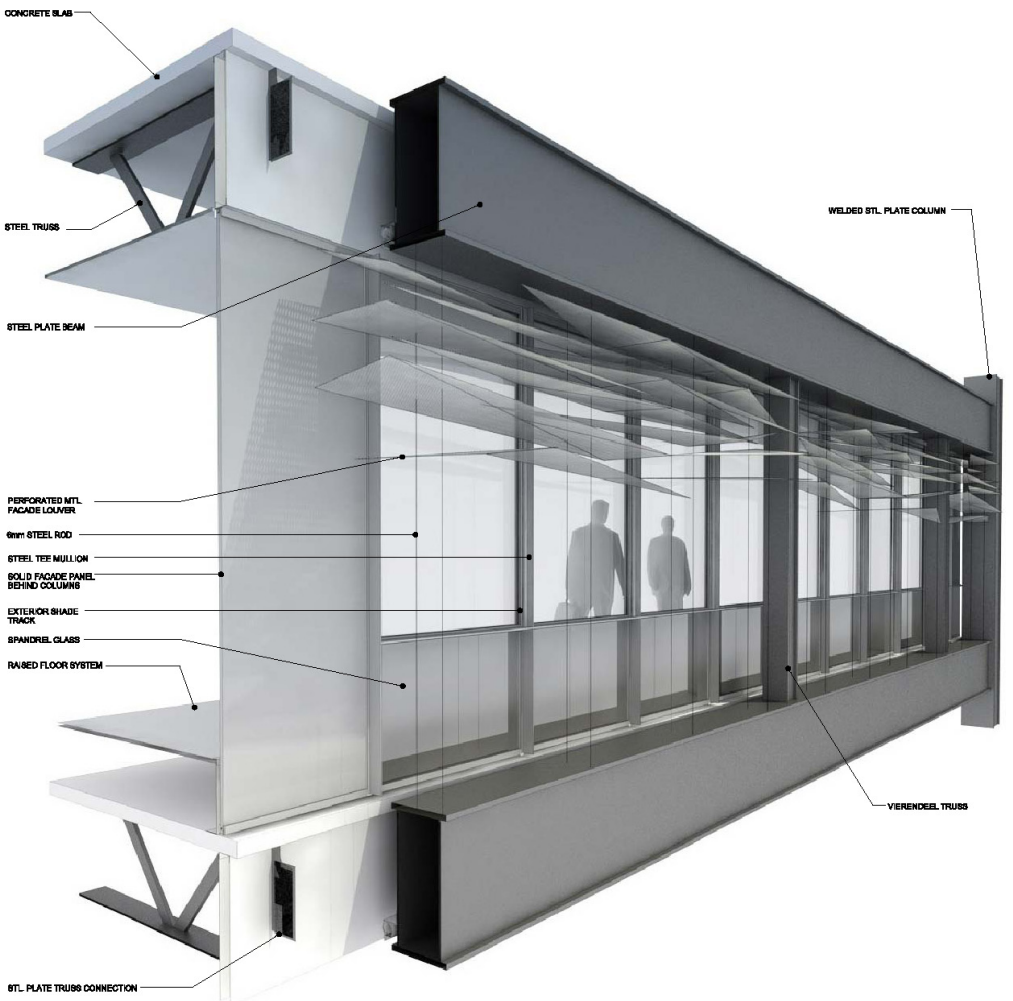

Figure 6 – Wall Section

members were made sufficiently large so that air ducts and plumbing could be run under the floor without having to drop the ceiling or create a web penetration in the floor beams, again adding to the structures' future flexibility. Additionally the floor beams were made composite with the floor slabs. These floor beams framed into box edge beams. The box shape was purely for architectural reasons since the frame of the structure was to be exposed.

The columns, and later the Vierendeel members, were designed as welded box sections 600mm (24 in) square. Along two sides the plates were recessed 50mm (2 in), to ease fabrication. This, like the Vierendeel frames, was embraced by the architect as an architectural element.

THE FAÇADE:

The environmental features of the building extended to the façade. We worked with the architect to provide completely custom designed thermally broken and insulated facades. The window wall system is a fabricated steel tee mullion system with insulated glazing, with low-e coating, and insulated panel infill.

Figure 7 – Interior Courtyard Looking towards Entrance Facade

To provide additional shading to the façade, a series of bent metal louvers made from expanded metal were employed. The louvers were cut and folded to a variety of shapes, each one analyzed using finite element software. We experimented with possible details to fix the louvers to the building. Several variations of the louver system were mocked up by local fabricators to assist in visualizing the finished product. There are 2730m^2 (29400 SF) of the standard window wall system on the building, presenting the bulk of the façade.

Another façade element it the skylight which is an integral part of the open atrium design by the architect. The skylight is supported from structural steel trusses and hung from above. The skylight structure itself is comprised of standard aluminum skylight framing members and fixed by hung rods to the structure above. The skylight itself is made from insulated glazing and uses structural silicone to connect to the

framing members. The node where the hanger rod connects to the skylight framing is thermally broken to ensure minimum heat transfer.

The main entrance to the building is through an impressive 4 story high glass wall. The wall is approximately 22m high x 34m wide (72 ft x 112 ft). The curtainwall is a custom designed system that provides support to bridges at each level that allows building users to cross the atrium space. The mullions are steel fabricated box sections at 1.85m (6-ft) centers and span vertically between the bridges and provide the lateral stiffness to the curtain wall system.

We selected materials to suit the local construction industry, but pushed for stricter usage of insulation and thermal performance than the standard requirements of Mexico in detailed drawings and specification. Together, the façade systems provide a uniquely green approach to building construction in Mexico and would be respected as an eco-friendly solution anywhere in the world.

BRISE SOLEIL:

Included in Grimshaw's design was a rooftop brise soleil. The brise soleil would help shade and lower the energy costs of the building by using mesh manufactured by the client attached to the framing. The brise soleil was supported by the interior columns of the building only, so that no support structure for the brise soleil was visible from the ground. This meant that the structural steel for the brise soleil cantilevered 17m (55 ft). The primary members for the framing were steel trusses with a depth of 2m (6 ft-6 in), but tapering to 600mm (2 ft) at the edges, giving this rooftop structure a lighter feeling.

ELEVATOR FRAMING SYSTEM:

Figure 8 – Elevator Enclosure

The architect desired an elevator core rising from open atrium below, nearly detached from the rest of the structure. Following the eco-friendly nature of the building, the decision was made to use the new Otis Gen2 elevator, a highly efficient machine roomless elevator. Grimshaw was interested in keeping the elevator structure open, with the only main framing being the elevator columns, and the elevator shaft clad in architectural mesh.

There were two challenges associated with the structural framing for the elevator. First was that the base floor for the elevator serving the office floors would be at the plaza, meaning that the base of the core rested above several levels of the subgrade parking structure. Additionally, the installation tolerance and allowable stiffness for the elevator framing are significantly higher than for a normal structure.

The first problem was dealt with by running a 1.2m (4 ft) deep truss beneath the elevator shafts. This truss needed to be strong enough to withstand the loads imparted by the elevators, but also stiff enough to be able to control the overall deflection for the elevator framing columns.

The second challenge was ensuring the proper deflection criteria to meet Otis' requirements- a maximum deflection of 6mm (¼ in). These columns were braced at every floor, but in their strong direction. In order to ensure the deflection of the elevator columns was kept within the allowable tolerances, we designed columns to be 800mm x 200mm (32 in x 8 in) steel columns with 25mm (1 in) thick plates.

The bracing of the columns at each floor level did not lead to an obvious choice of a "k" value for column design. Instead the *Direct Analysis Method* from the AISC Steel Construction Manual was used to capture the architectural intent of the columns. The columns were analyzed assuming that the columns were out of plumb by H/500 in each direction. In this case, this would be a very conservative assumption, since the elevator columns must be installed to a higher tolerance to ensure proper functioning of the elevator. The result of this analysis was a column which had minimal bracing back to the existing structure and had a very slender profile exposed to the atrium, which met the intent of the architect.

ENVIRONMENTAL FEATURES:

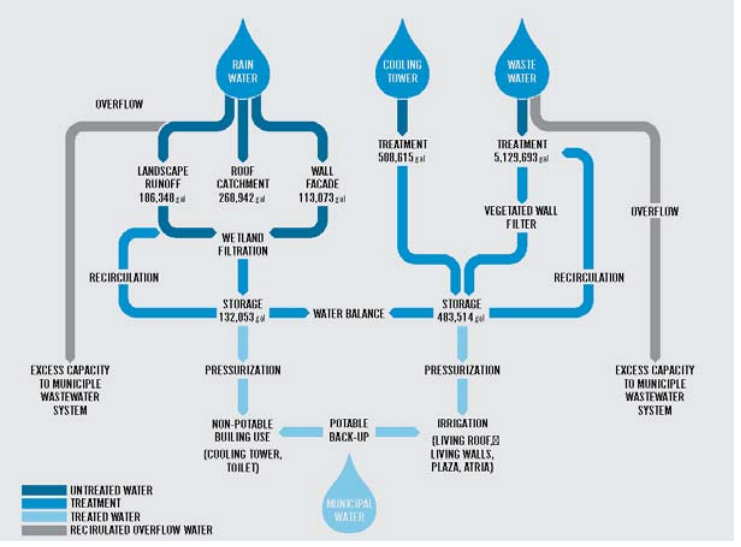

Figure 9 – Process Flow Diagram

Another very important and resonating project goal emerged more gradually in the design process and encompassed a holistic approach to the valuable and scarce resource of water. Monterrey has very limited freshwater resources and with a combined sewer system flash flooding is a dangerous and common problem. On-site water reuse addresses these

issues by providing resource efficiency, reducing sewage loads, minimizing infrastructure improvements and realizing financial return on investment. Project goals related to water include minimising potable water use for non-potable uses and a significantly reducing the volume of wastewater discharged into the municipal system. Deacero could not ignore the many benefits that these goals added to the project and so a water treatment and reuse system became an integral component of the building design.

Local code dictates that municipal water is used to supply potable demand including sinks, lavatories, janitorial uses and pantries. This is roughly 29% of the building's total consumption. The remaining 71% of consumption is non-potable demand for mechanical equipment, irrigation and toilets and can be supplied from on-site treated sources. In-depth analysis of building needs and water supply show that treatment and reuse of all building wastewater including both gray and blackwater was the most economic and efficient strategy. Initially, a system treating only graywater was considered, but this system was discarded because it required double plumbing throughout the building. This was a significant cost and resulted in the treatment and reuse of a small quantity of water compared to the current design. An integrated gray and blackwater treatment and reuse system uses a combination of biological and mechanical processes to treat 100% of building wastewater. The system manifests itself externally via significant water purification wetland terraces. This engineered wetland lines the entrance of the building from underground parking levels. Throughout the building, water features and green walls complete the circuit and highlight the story of water.

Wastewater treatment is the biological, physical, and mechanical removal of water contaminants. Each of these treatment processes occurs at different stages within the system at Deacero Headquarters. By using these processes in succession, wastewater can be treated to a level considered safe by regulatory agencies for reuse. The essential functions of the wastewater treatment system are to reduce Biological Oxygen Demand (BOD), destroy pathogens, filter particulates, reduce

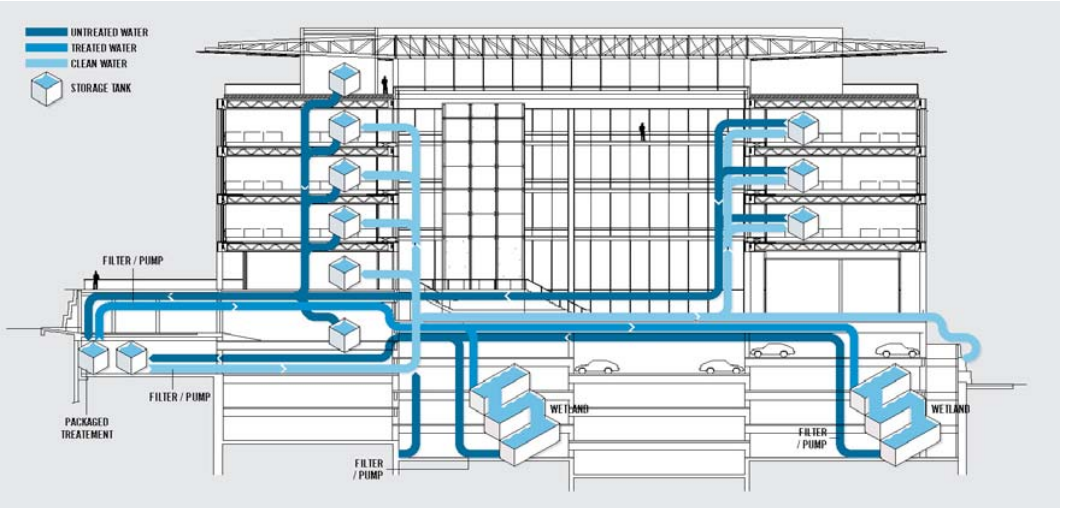

Figure 10 – Diagram of Complete Wetland System

nitrogen, phosphorous and Volatile Organic Compounds (VOCs) and stabilise or dispose of toxins. These treatment functions occur faster in constructed wetlands and biological systems than in conventional treatment systems.

Constructed wetlands are biologically complex systems, which adapt and respond to varying wastewater concentrations and changes in climate. The system is designed to emulate the systems that have naturally treated water in nature for millions of years. Naturally occurring wetlands encompass large areas and may treat water for an entire drainage basin. Studying how these systems function enables their re-creation for use in built environments. These urban wetlands are highly engineered, more efficient and able to function with less space than their natural counterparts.

The system at the new Deacero building, combines packaged biological treatment (a membrane bioreactor) with a constructed wetland to purify the water. All wastewater produced in the building is collected and directed to the membrane bioreactor (MBR) where pathogens, VOCs, most toxins and large particles are removed. The MBR is sourced locally from one of the various companies that compete in this emerging market. Water is then disinfected with ultraviolet light. From there, water is collected in a storage tank and pumped to the terraced wetlands in the parking garage. Since pathogens are removed by the MBR, water can be free flowing across the surface of the wetland without any unpleasant sights or smells. The wetland provides 'polishing treatment.' After water emerges from the bioreactor it is 'lifeless' and still contains high nutrient levels. Plants and microbes in the wetland remove excess nutrients and breathe life back into the water improving the quality for irrigation use. The recirculation of the water from storage to wetlands and through the atrium water feature prevents bacteria from developing in the tank and the water from getting stagnant. After treatment in the wetlands, water is pumped back to storage and then re-circulated throughout the building for reuse in toilets, mechanical equipment and irrigation of all indoor and outdoor vegetated features. The volume of clean water saved from non-potable uses is up to 3.6 million gallons per year- 750,000 gallons more than the building’s demand.

Two terraced planting areas which provide circulation up from the parking levels quickly evolved into the treatment wetlands, integral to the gray and blackwater treatment system. The sound of water streaming down multiple waterfalls over four stories, together with smells from the fragrant planting and the colors of seasonal foliage and flowers, feed the senses as one enters the building at the beginning of the day, or exits on the way home. Different textures in materials used to create the terracing can also be touched or viewed, completing the response to all of the senses. These wetlands are the only part of the water treatment system that is visible to staff and visitors alike. The wetlands manifest Deacero’s stewardship of natural resources in a prominent way, enrich the experience of approaching and leaving the building and perform the more mundane task of masking the sounds from the parking garage and the busy adjacent highway.

A return on investment analysis showed net savings on up-front water costs and discharge fees of some $35,000 per annum, which is about the capital cost of the blackwater treatment system. Therefore the system effectively pays for itself after one year. Continued annual savings will also cover wetland installation and system maintenance costs.

CONCLUSION:

The focus of the architect's design philosophy for this project was providing a new headquarters with a limited impact on the physical world around it. This was evident in the environmental features of the building, but Dewhurst Macfarlane and Partners, as the structural engineer, was able to expand on this vision and carry some of the same concepts to the engineering of the structure.

We were able to use a design that uses the efficiency and strength in the Vierendeel Truss framing system. The use of the Vierendeel trusses increased the stiffness of the structure, lowered the amount of steel required, and lent itself to Grimshaw's aesthetic vision for the structure. The remainder of the building's framing elements are very efficient since they make use of the approach in Mexico, where the focus is on the efficiency in materials instead of an efficiency of labor.

Additionally, the louvers, skylight, and brise soleil all have a limited visual impact, but with the shading mechanisms attached, they provide great insulating values and lower the cooling requirements for the structure. The spacing of the framing members is also an environmentally-friendly design, requiring less construction and waste when internal fit-out features are added, removed, or moved.

Working as a cohesive team, Dewhurst Macfarlane and Partners, Grimshaw Architects and GPI y Asociados were able to deliver an efficient structure to the client that was designed with each part of the design team working in unison.

ACKNOWLEDGEMENTS:

Dewhurst Macfarlane and Partners would like to acknowledge Richard Yoo, the project architect, from Grimshaw Architects in New York for the help in preparing this paper. We would also like to thank Vincent Chang, the partner in charge, and the whole design team from Grimshaw for their work on this project.

Dewhurst Macfarlane and Partners would also like to acknowledge that the section of this paper on *Environmental Features* was adapted from the article "Living Systems at the Deacero Headquarters" by Juan Porral, in collaboration with Gabrielle Fladd, published in Grimshaw's in-house journal "Blue".

CityCenter's Long Span Porte Cochères

ABSTRACT

Welcoming guests to Aria, CityCenter's 4,004 room hotel and casino, are two feature porte cochères: the Harmon Canopy to the north at the Aria Hotel lobby, and the Casino Circle Canopy to the east at the City Center Casino entrance.

The canopies, with heights of 102' and lengths of 157', are large, three dimensional structures that use their geometry to resist loads and integrate into the surrounding program. The primary system to create the canopies' cantilevers are a series of cable stayed box girders on a radial grid attached to box columns. A single cable between the box beam and column is tensioned against pairs of compression struts to resist uplift forces in the canopy.

Perpendicular to the frame of the box beam and column is a lattice work of stayed girts that support the inverted glass roof hung below. A series of in plane rods, bracing and radial struts create a diaphragm between the box girders to resist both seismic and wind lateral loading. In addition, the diaphragm stiffens the frames to reduce both periods and deflections.

The extreme fast-track nature of the CityCenter construction schedule led to unique problems and solutions in executing the design and construction of the two canopies.

INTRODUCTION

City Center is the largest privately financed construction project ever completed in the United States at a cost of $8.5 billion (Karlinsky 2009). Construction of the 76 acre development began in June of 2006 with the pour of Aria Hotel's mat foundation. The grand opening was just 42 months later in December of 2009.

As one of the largest and grandest resorts and casinos on the Las Vegas Strip an entry befitting of the project was required. Pelli Clarke Pelli Architects (PCP), the design architect of Block A, which included the 61 story Aria Hotel, the West Podium, housing the spa, pool deck, restaurants, back of house storage and parking; the East Podium, housing the casino, restaurants, valet parking and taxi cues; the Convention Center at Aria and the Cirque du Soleil theater, designed two large porte cochères for the major entrances to the Aria Complex.

Harmon Avenue provides direct access by car from Las Vegas Boulevard, also known as "the Strip," to the lobby of the Aria Hotel. Guests enter the multi-level lobby with a hybrid cable supported glass wall that is suspended from the porte cochère which provides a canopy 29' above the roadway, 84' wide and 280' in length. The Harmon Canopy is grand in both size and design.

At the opposite side of the Aria Hotel is the larger of the two porte cochères, Casino Circle Canopy, providing cover to guests as they enter the casino by both car and foot. The porte cochère at Casino Circle shares similar design elements with the Harmon Drive Canopy but with a very different layout. The canopy varies from 31' to 37' above the roadway, up to 137' wide and 604' in length.

Each of the porte cochères provided different structural design challenges based on their size, location and sequence of construction. Because of the fast-track nature of the job and compressed construction schedule, structural components were being fabricated and built in sequences that often preceded the final architectural design.

The structural design of both canopies began at the same time, shortly after ground breaking in July of 2006. Construction of the Aria Hotel was already underway, introducing complexities of integrating the Harmon Canopy with existing conditions. The design of the East Podium where the Casino Circle Canopy is located would not be released for another two months, allowing for the integration of that canopy into the surrounding structure.

HARMON CANOPY – The Aria Hotel Porte Cochère

The Harmon Canopy has a fan shape in plan with nine radial frames (Figure 1). Each frame consists of one built-up, inclined, steel plate box column and one cantilevered built-up steel plate box beam (Figure 2). The canopy spans the 75' of the three level lobby from its foundations on grade at Level S to the roof on Level 3 and then cantilevers an additional 27' past the top of the roof for a total height of 102'-5".

The canopy structure's nine radial frames form eight equal bays 36' apart at the widest point and integrates into the lobby of the Aria Hotel. Of the eight bays, six have an inclined glass wall supported by cables suspended from the canopy which run the entire height of the lobby. Two of these bays also support the vestibule into the lobby at Level 1, 25' above the base of the canopy. At the remaining two bays the lobby wall pulls away from the canopy, providing clear column spans from the foundation to the roof.

Because of the lead time required to build the Aria Hotel, construction of the tower was already at Level 1 before the Harmon Canopy design was finalized. This required any lateral loading from the canopy due to seismic wind or gravity induced lateral loads from sloping columns, which would ultimately be resolved in the tower core, to be transferred through the tower's concrete slab. It was therefore not possible to transmit the required lateral load into the existing slab at Level 1. The slab at Level 2 was a mezzanine that did not attach to the canopy, therefore all lateral loads would have to be transferred to the tower's core through a roof diaphragm at Level 3.

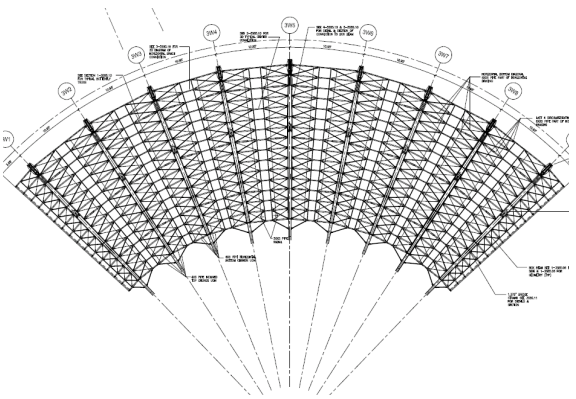

Figure 1. Harmon Canopy Plan

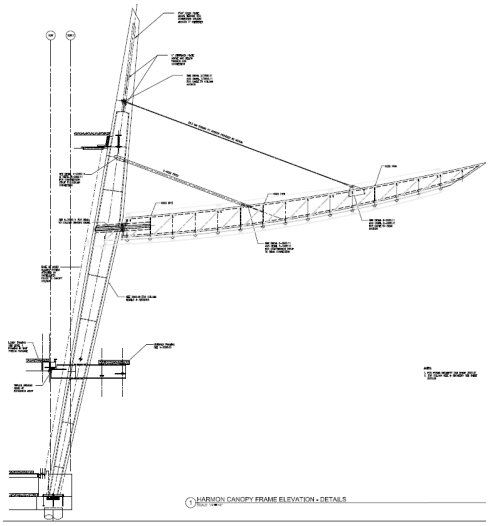

Figure 2. Harmon Canopy Section

Harmon Canopy Loading

The CityCenter site is in an area of high seismicity. Based on the site specific geotechnical report the site class was C, more favorable than the code required site class of D. The report provided a site specific spectral response which was used in the design of all components of the project. An importance factor of 1.25 was used because of the high occupancy of the structure.

Due to the complex nature of the connections of the Harmon Canopy, which are often architecturally driven, it would have been difficult to detail as required for seismic design. It was therefore decided to use a Response Modification Factor (R) of 3, "Structural Steel Systems Not Specifically Detailed for Seismic Resistance" (IBC 2000). The choice would increase lateral forces in the design from 7.4% of W, 126 kips to 12.4%, 210 kips, but would allow the most versatility in detailing of the structure. The lateral forces, however, were very small compared to sizes required by the large spans of the structure. The increased lateral forces therefore came at a negligible premium to the steel sizes and tonnage.

The wind analysis for the entire block A was conducted by Rowan Williams Davies and Irwin Inc. (RWDI). Both canopies were tested in a wind tunnel with the surrounding structures modeled. Particular attention was given to the harmonic excitation of the cantilevered canopy to prevent fluttering in the wind between adjacent frames. Infill butterfly trusses linked adjacent box columns to minimize differential movements. The first period that induced fluttering in the canopy in the form of a 1/2 sine wave occurred at .74 seconds. It was advised by RWDI that periods less than 1 second would not be excitable by wind induced excitations.

The RWDI report provided a uniform wind pressure of +/- 25 psf with peak pressures up to +30 psf. In addition, unbalanced loading was provided on the canopy both globally across all nine frames and locally for each frame. The unbalanced load induced torsion within the box beams and additional bending stresses in the infill butterfly trusses. The differential unbalance loading was a maximum of 15 psf.

At the lobby on Level 1 a cantilevered elevated exterior sidewalk from the box columns was provided that linked all nine frames. The sidewalk, part of the canopy Block A structure, adjoined the elevated roadway of Block B for guest drop-off, which had a separate design team. A 6" expansion joint was provided between the sidewalk and roadway to allow for differential seismic movement. Because of the sidewalk's location adjacent the roadway it was required to design the sidewalk for vehicular loads, in particular for emergency vehicles and equipment that may jump the curb onto the sidewalk. A 600 psf live load was used to design for the loading of emergency vehicles in addition to the weight of the sidewalk slab and finish.

Harmon Canopy Components

The main support for the canopy and the adjoining lobby are nine 106'-11" box columns on a radial grid spaced 36'-6" apart at the footing. The columns slope away from the hotel lobby at 10 degrees with a glass wall following the slope of the column attached on the back side. The columns provide gravity support for the lobby steel framing at Level 1 and the roof at Level 3. In addition the column supports a cantilevered sidewalk at Level 1 and a stayed box beams of the canopy at level 2.

The columns are unbraced for 75' between Level S and Level 3 and therefore are best suited as a box to increase the buckling capacity. The major axis of the column is radial from the hotel lobby and varies from 3'-3" in depth at the base to 6'-0" at the highest moment at the beam intersection. The column has a constant width of 1'-4" and is fabricated from 1" thick webs and 2" thick flanges, all grade 50 steel plate. Flanges are recessed 6" from the webs allowing for continuous 3/8" fillet welds at the intersection. Internal stiffeners are used at 10' centers to keep the column square during fabrication and erection.

The columns are keyed at their base into 5' square caisson caps on single 4' diameter drilled caisson. Caissons are tied together with grade beams in both directions to form fixed caps. At Level 3 the columns are tied into the roof structure of the lobby. The canopy column provides the gravity support for the roof steel but the roof steel provides lateral support for the canopy column through a network of in plane double angle braces. The braces tie back to the tower's concrete edge beam which transfers the load to the tower core walls.

At Level 1 the box columns support W36 beams which pass in between the webs of the column supporting a 6'-9" cantilevered sidewalk outside the lobby as well as the steel floor framing inside the lobby. Below the sidewalk, which connects all nine box columns together, double angle bracing was installed to provide overall lateral stability by coupling the columns at their mid-point. Because of the design and construction sequence lateral loads could not be transmitted to the tower core at Level 1. It was therefore necessary to introduce slide bearings fabricated by Fabreeka between the W36 and lobby steel to allow translational movement of the canopy columns both in and out of plane while still supporting the gravity load of the lobby floor (Figure 3).

At 29' above the sidewalk and 54' above the ground is the attachment of the canopy box beam to the box column. The box beam extends 81' beyond the column and is stayed two thirds down the length of the beam by a post tensioned 36mm cable fabricated by Pfeifer that ties back to the cantilevered portion of the box column above the lobby roof. The cable is tensioned against a pair of 6" double extra strong pipes acting as compression struts that connect the box beam at its third point back to the box column slightly below the lobby roof.

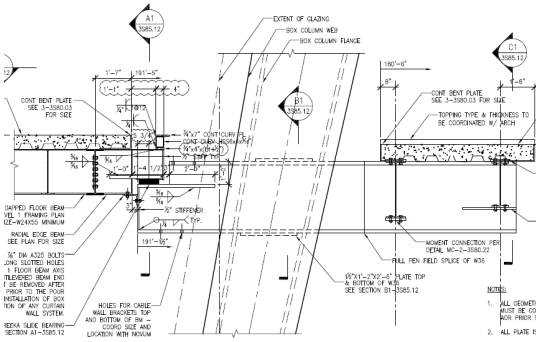

Figure 3. Slide Bearing Connection

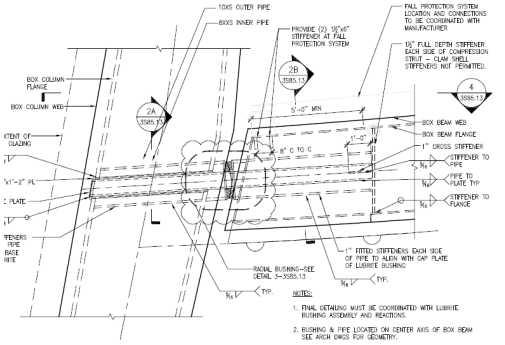

Figure 4. Harmon Canopy Radial Bearing

The box beam's geometry tapers in section from 4'-6" at the column interface to a point at its end. The beam also flares and tapers in plan, from 1'-4" wide at the column to 2'-0" wide at the compressions strut connection and down to 1'-0" in width at the tip. Both the webs and flanges of the beam are constructed of ¾" grade 50 steel plate. The flanges of the beam are recessed 4" from the web allowing for a continuous 5/16" fillet weld.

The architectural design required a reveal at the connection between the box beam and box column. To create the reveal all plates of the box beam had to stop 7" from the column, the point of highest moment in a cantilever. To make the connection work it was necessary to ensure that no moment was transferred across the joint by forming a true pin at the interface. A radial bearing, manufactured by Lubrite Technologies, was introduced between the column and beam. To ensure that the beam and column maintained in contact in the event of uplift on the canopy, therefore maintaining shear transfer from the beam to the column, an 8" double extra strong pipe was threaded through the center of the bushing tying together the column and beam (Figure 4). The connection allowed vertical rotation without vertical translation.

The cable and compression strut along with shear transfer at the radial bearing provide for the required resistance against the vertical forces of wind and gravity. To stabilize the canopy structure against the lateral forces of wind and seismic a dual purposed infill truss was used connecting each of the box beams. The infill trusses, referred to as butterfly trusses because of their shape, provided a three dimensional diaphragm in the plane of the roof allowing lateral loads to be taken as a couple between the outer box columns as well as providing attachment locations for under hung glass which formed the cover of the canopy.

The butterfly trusses spaced 5'-0" on center, matching the segmentation of the hung glass panels, were comprised of four elements. The first element, which the glass panels were directly hung from, were 6" diameter pipes hung below the box

beams from 1" fin plates. The 6" pipes were horizontal and segmented radially in plan between the box beams. At the midpoint between box beams the architect desired the pipes to reduce in section, forming a 5' long reveal. It was necessary to maintain full moment capacity across the reveal, therefore a thicker walled but reduced diameter pipe was sleeved inside the 6" pipe maintaining the section modulus.

The 6" horizontal pipe alone was not capable of spanning the required 34' without buckling under compressive loads or excessive deflection from the hung glass weight. A second element, a diagonal strut in both elevation and plan, was added forming a cantilevered truss from the box beam to brace the 6" pipe and remove shear force through tension and compression. Three and a half inch diameter pipes were used on either side of the reveal connecting back to the top of the box beams. The architect requested tapered fittings at each end of the strut to stop the connections from looking bulky. Thirteen hundred custom tapered cone cast fittings were fabricated to attach to the ends of the struts that would provide a single pin connection to gusset plates welded to the box beam.

All of the diagonal struts were inclined in the same planar direction away from the lobby. This created a force component in plan from the gravity load that needed to be resolved. A third element, in plane rod bracing in a zig-zag pattern, was added to resolve this force. The rods were stainless steel, 16 mm in diameter with pinned stainless steel fittings on each end. The rods connected alternate nodes at the reveal to the 6" horizontal pipe intersection with the box beam.

The final element was a pair of 2 3/8" struts that spanned 5' between trusses on either side of the reveal. The struts had a dual purpose. Every other connection of the strut to the horizontal pipe had no resolution to the in plane force because of the alternating connection of the zig-zag rods. The force could be accumulated in the pair of struts and then transferred where the zig-zag rods connected. The second use was to tie all of butterfly trusses together at their midpoint alleviating differential deformations in plane that could induce excessive compression forces in the attached glass below.

The butterfly trusses resolved the lateral force in the canopy back to the outer box columns which could then transfer the load to the Level 3 lobby roof and ultimately to Aria's tower core. This system prevented the need for any bracing in elevation between the box columns, a major criterion of the architects. A similar structural system was employed at the Casino Circle, except that there was no tie back at the top of the columns to resolve the lateral force.

CASINO CIRCLE CANOPY – City Center's Casino Porte Cochère

Unlike the Harmon Canopy the Casino Circle Canopy had no connection at the top of its box columns to resolve lateral load. Instead the Casino Circle Canopy cantilevers from a partially fixed base at Level 1, the drop off to the casino, 42'-6" above its foundations. A system of moment frames and braced frames, continuing three levels below Level 1, allows the box columns to act as propped cantilevers between Level S and Level 1. Because the construction of the East Podium where the Casino Circle Canopy is located lagged that of the Aria Hotel it was possible to fully integrate the canopy's required support structure into the East Podium framing.

The Casino Circle Canopy, which covers over half the circumference of the drop-off circle, is comprised of thirteen radial frames (Figure 5). Eight of the frames are made up of one inclined steel box column, 69' in height, and one cantilevered steel box beam 79' in length (Figure 6). These frames comprise the Small Canopy. Four of the frames are made up of two inclined steel box columns, 89' and 99' in height, and one cantilevered steel box beam, 157' in length, that intersects both columns (Figure 7). These frames comprise the Large Canopy. At the intersection of the Small and Large Canopies is one hybrid frame that combines the beams of both the Small and Large Canopies into the two box columns of the Large Canopy (Figure 8).

The columns of the Small Canopy and the back columns of the Large Canopy slope 12 degrees towards the entrance of the casino following a feature water wall that slopes the same angle. The beams of both Small and Large Canopies extend over the casino with the Small Canopy beams being tied vertically to building columns to reduce lateral deflections. The Large Canopy, with a second set of columns at the front slopping 8.5 degrees towards the center of the circle, has no ties between its box beam and the building below.

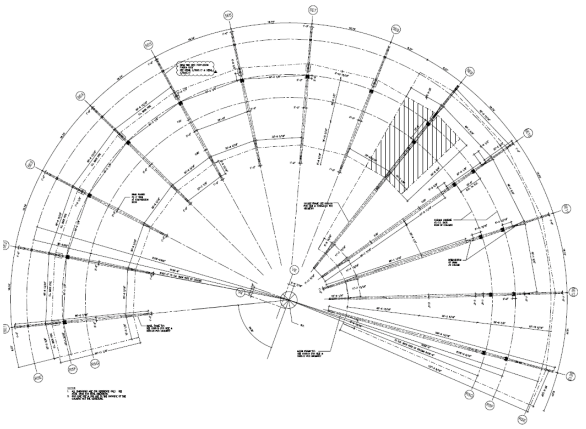

Figure 5. Casino Circle Canopy Plan

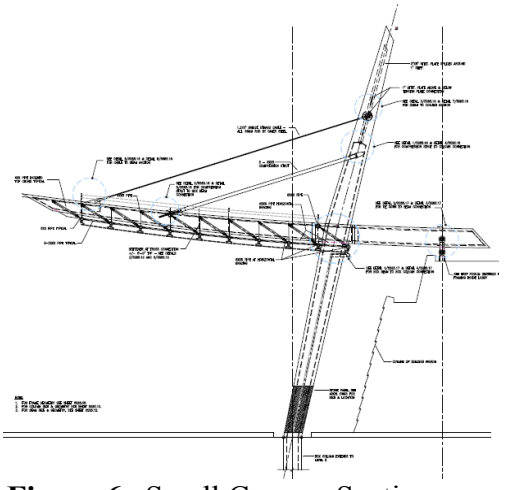

Figure 6. Small Canopy Section

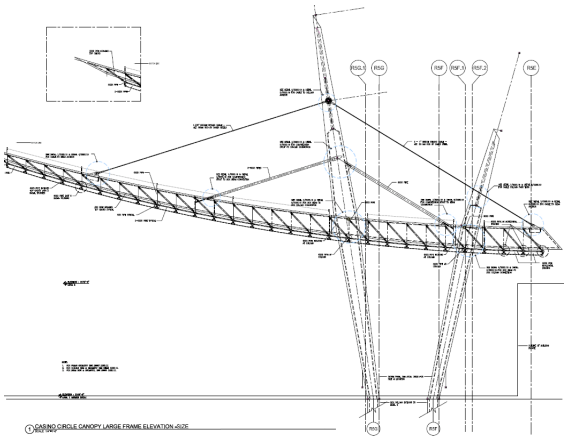

Figure 7. Large Canopy Section

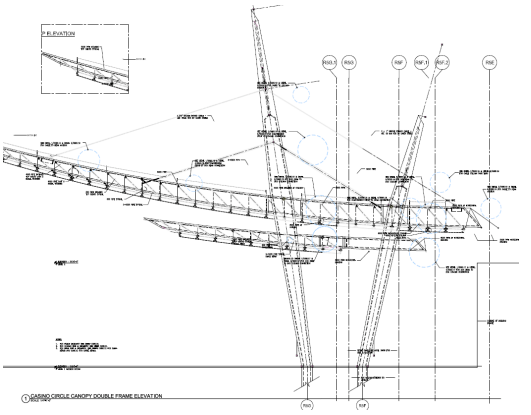

Figure 8. Hybrid Canopy Section

Casino Circle Canopy Loading

The Casino Circle Canopy shared the same seismic design criteria as the Harmon Canopy. Using a Response Modification Factor (R) of 3 the total lateral forces for seismic design was 349 kips, 14.9% of W. Lateral loads from the canopy level are transferred to the base building at Level 1 through strong and weak axis bending of the box column taking shear force and strong axis bending of the box column taking torsion in a couple through the outer columns.

Harmonic excitation of the canopy structure from wind induced fluttering was also a concern at Casino Circle. It was found in the Large Canopy that the first mode that induced oscillations in the form of a 1/2 sine wave occurred at 1.09 seconds. This exceeded the RWDI recommended maximum of 1 second, but was determined to be acceptable. For the Small Canopy the same behavior occurred at .73 seconds, under the recommended value.

The RWDI report provided a uniform wind pressure of +/- 25 psf with peak uplift pressures up to -35 psf. In addition, unbalanced loading was provided on the canopy, both globally and locally for each frame, of the Small and Large Canopies. The differential unbalanced load, inducing torsion within the box beams and additional bending stresses in the infill butterfly trusses, was a maximum of 14 psf at the Small Canopy and 18 psf at the Large.

Casino Circle Canopy Components

The main support of the Large and Small Canopies are their eighteen box columns on a radial grid spaced 44’ apart at their base. The columns are un-braced for their entire length ranging from 69’ to 99’and are best suited as boxes to resist

buckling. The major axis of the column is radial from the casino and varies from 3'-0" in depth at the base to 4'-3" at the intersection of the box beam for the Small Canopy and 6'-0" at the intersection of the box beam for the Large Canopy. Both canopies' box columns taper to a point at their tips. The width of all columns is a constant 1'-4". The webs and flanges of the column are constructed of 2" thick grade 50 steel plate. The flanges of the column are recessed 6" from the webs allowing for a continuous 3/8" fillet weld.

The canopy box columns transition at Level 1 to a three level steel structure below (Figure 9). To allow for erection tolerance in the field a 4" thick transition plate caps the building columns directly below the location of the canopy columns. The transition plate provided a surface to full penetration weld the canopy box column to. To provide the greatest fixity at the column connection a box column identical to that of the canopy was extended 26' below Level 1 transitioning 3'-0" above Level S to heavy W14 columns which continue down to caisson caps sitting on 4' diameter drilled caissons at Level S2.

The columns under the Small Canopy sit centered on a caisson cap over a pair of caissons. Each set of columns at the Large Canopy sit on a caisson cap over three caissons in line. The front and heavier loaded Large Canopy column straddles two caissons and the back column sits over one caisson, all sharing the same cap. All caissons are tied together with grade beams in both directions to form fixed caps.

At Level 1, 2' below the transition plate, beams that frame into the box columns are upsized and moment connected in both directions to provide increased stiffness for the canopy column connections above. Braced frames are also provided between the pairs of columns at the Large Canopy between Level S2 and Level 1. The propped cantilever, moment connected beams and braced frames were all required to provide sufficient stiffness at the canopy column connections to minimize the canopy's period and deflection.

The box beams are similar in construction at the Casino Circle Canopy as the Harmon Circle Canopy. Both webs and flanges are constructed of ¾" grade 50 steel plate. Unlike the Harmon Canopy the beams are moment connected to the box columns. At approximately 18" from the moment connection to the box column flange plates of the box beam are increased to 2" thick. At the Large Canopy columns the flanges are increased to 2" thick as well.

The Small Canopy shares a similar design to the Harmon Canopy with 36 mm post-tensioned cables and a pair of 6" double extra strong compression struts connecting the box beam at its two thirds and one third points respectively back to the box column. To reduce vertical translation of the Small Canopy an additional connection was required at the back of the box beam to the casino roof columns. The requirement for an open floor plan at the casino prevented the introduction of braces

in the casino. It was therefore desired to only load the building columns in tension and compression while inducing minimal lateral forces.

A pair of 2 13/16" thick dog bone shackles 30" in length were introduced, one on each side of the box beam, to allow lateral translation of the canopy while still transferring vertical loads (Figure 10). Each dog bone was fitted with two spherical bearings, one on each end, with a 3 ¾" 62 ksi solid steel pin connecting the box beam and building columns to the spherical bearings. The spherical bearings allowed the dog bone to rotate in both directions with lateral translation of the canopy box beam.

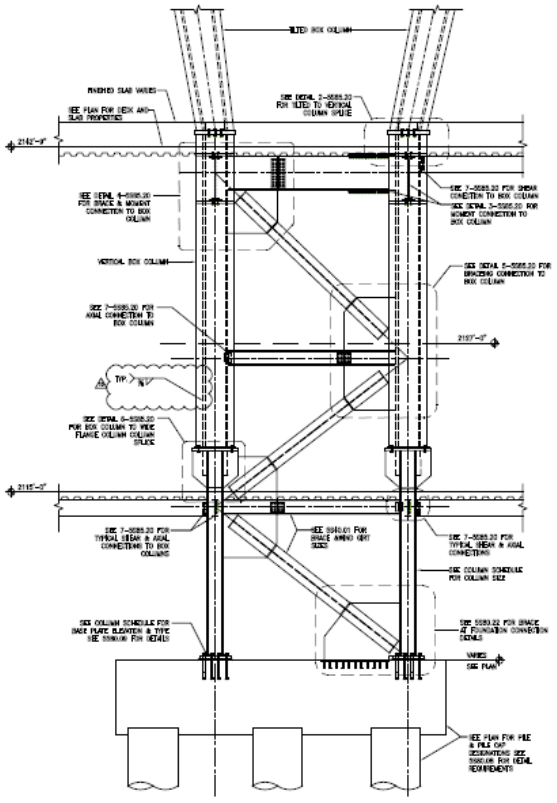

Figure 9. Large Canopy Transition

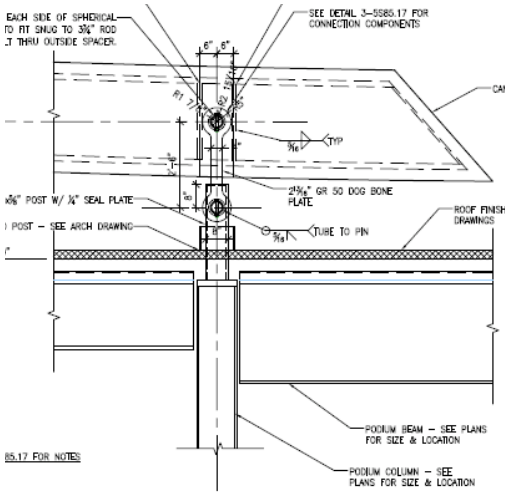

Figure 10. Dog Bone Connection

The Large Canopy, similar to the Small Canopy, has a 36 mm post-tensioned cable and pair of 6" double extra strong compression struts between the cantilevered beam and front box column. In addition aligning in elevation with the cable and struts from the front of the box column are a pair of 28 mm post-tensioned cables and a single 8" double extra strong compression strut between the front column and the back span of the cantilevered beam, with the back cables passing though the rear box column. The symmetric loading of the front column helps to reduce unbalanced loading, induced bending and deflection into the column.

A series of butterfly trusses spaced 5'-0" on center, similar to the Harmon Canopy, span between the box beams of both the Small and Large Canopies. The trusses provide a three dimensional diaphragm allowing lateral loads to be taken as a couple between the outer box columns at both the Large and Small Canopy as well as providing attachment locations for the glass hung below. The trusses comprised the same four elements as the Harmon Canopy; segmented horizontal radial chords to the bottom of the box beam, inclined struts to the top of the box beam, zig-zag steel rods, and a pair of struts linking the midpoint of the radial chords.

CONCLUSION

The porte cochères at CityCenter provided unique engineering problems in their size and complexity. A similar architectural and structural design ties all the canopies together while three different layouts required three individual solutions.

By using the geometry of the structure effectively a clean and rational approach to the design could provide simple yet elegant entries to the hotel. By integrating the canopies into the surrounding structure, structural elements could be minimized or eliminated.

A collaborative effort between the architect, structural engineer, fabricators, erectors, project manager and contractors led to successfully executing the design and installation of the large and complex canopies.

Accuracy of Applying "Stiff-Girder" Approach in Reinforced Concrete Bridges

M. AbdElLatef

Graduate Student, Department of Civil and Environmental Engineering, Washington State University, Phone (509) 432-4032; email: mohammed.abdellatef@email.wsu.edu

Abstract:

It is very common to consider the cross girder of a slab-girder bridge as a stiff-*Rigid*-girder rested on springs while distributing loads to main girders for simplification. This approach gives suitable results for primary manual analysis for bridges that have cross girder depth almost equal to main girder depth, small spacing between main girders, large spans of the bridge vent, and monolithically casted elements.

Two simplified models were studied in this paper: an infinitely rigid beam rested on springs having an applied concentrated load, and an *imaginary* very flexible beam rested on springs having the same loading condition. These two models were studied to indicate the extreme conditions of the cross girder. An approximate governing equation is proposed to correlate the bridge geometry to the accuracy of applying the stiff girder approach. Concrete sections of main and stiff girders were considered to be cracked sections in either working or ultimate stages.

It was obvious from the results that the bridge deformation) which is calculated by the stiff girder approach) is changing dramatically while changing bridge geometry. But the straining action of the bridge may not exceed the resistance values, before or after plastic hinges deformation.

Slab-Girder Reinforced concrete bridge:

One of the most common reinforced concrete bridges is the slab-girder bridge. This type of bridge consists of: slab, cross girders and main girders (figure 1). Usually this type of bridge is used to cover medium spans.

For primary analysis of this kind of bridge, the cross section could be considered as a rigid or semi rigid beam supported by the main girders as elastic supports. This approach is commonly used to estimate the straining actions in the cross girder, as well as determining the design traffic loads distribution for each main girder.

Assuming that cross girder is a rigid beam simplifies the calculations for load distribution as will be mentioned later. The main reason to simplify the cross girder as a rigid beam is that it has almost the same depth of the main girders. Also it has a very short span compared to that of the main girder.

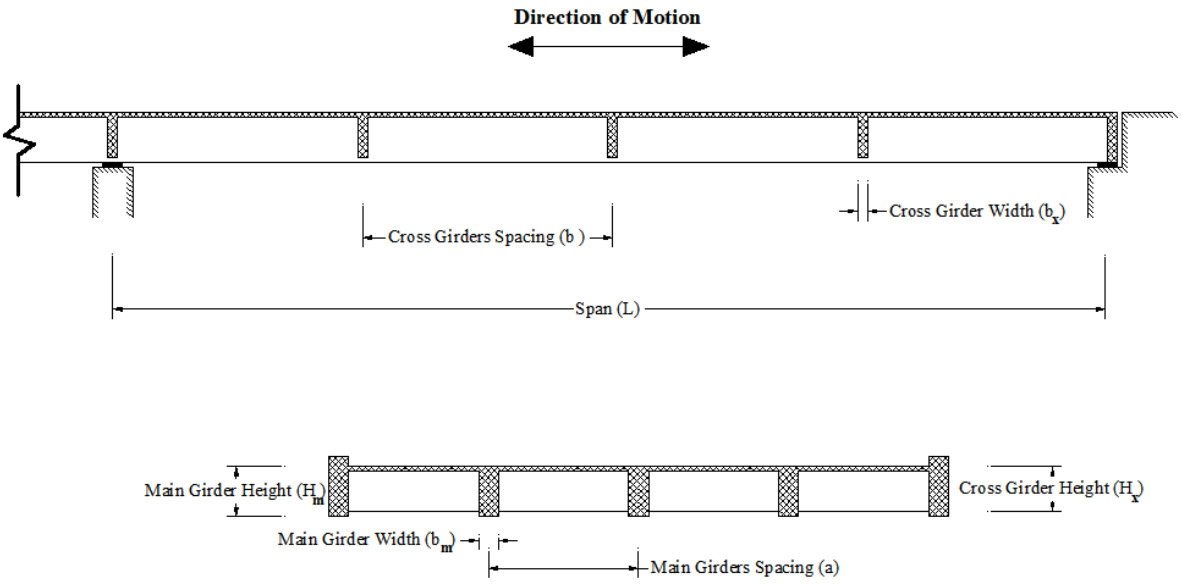

Figure 1. Typical components of concrete slab-girder bridge.

Objectives:

The main objective for this paper is to present the effect of reducing the cross girder depth or increasing its span (by increasing the spacing of main girders) on the accuracy of calculating the distributed loads on each main girder.

Two extreme approaches will be considered: the rigid approach for the cross girder and an imaginary approach for much more flexible cross girder. From the limits obtained from these two cases, a general trend will be concluded for any other case.

Also, the effect of using the effective moment of inertia of the reinforced concrete sections instead of the gross moment of inertia on the calculations will be considered.

Rigid Approach

In this approach, the stiffness of the cross girder was considered infinite compared to the stiffness of main the girders, so that it deforms as a rigid body (Figure 2). Assuming that the main girders are spaced at distance a and the springs represent n main girders with stiffness k, the force acting on each main girder R_i and the deflection δ_i will be:

$$R_i = \frac{p}{n} \pm \frac{Pe}{\sum_{i-1}^{n} r_i^2} r_i \quad [1] \quad , \quad \delta_i = \frac{R_i}{k} \quad [2]$$

where p is a concentrated load applied on the cross girder, e is the eccentricity of the load p from the center of supports and r_i is the absolute distance between support i and center of supports. "*Center of supports* is defined as the position of loading which causes the same displacement at all supports"

This case will be considered the datum for other cases, so the sum of the absolute value of errors in calculation of support reactions (displacements) and the standard deviation of these values in this case are equal to zero.

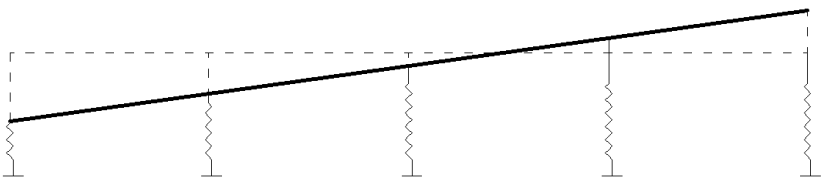

Figure 2. Structure system and deformations for stiff cross girder.

Imaginary flexible Approach

In this approach, the cross girder was assumed to be a member with no stiffness such that the entire load is transferred to adjacent supports. The goal of this approach was to calculate the maximum *sum of absolute value of errors in calculation of support reactions* (displacements) and the maximum standard deviation of these values for a unit load (displacement).

Consider the case of an odd number of supports with the load at the center of supports (figure 3). The general formula for calculating the sum of absolute value of errors and the standard deviation are:

$$e_o = \frac{1}{n}(n-1) + (1-\frac{1}{n}) \qquad [3] \quad , \quad s_o = \sqrt{\frac{\frac{1}{n^2}(n-1) + (1-\frac{1}{n})^2}{n}} \qquad [4]$$

These two equations can be simplified to:

$$e_o = \frac{2n-2}{n} \qquad [5]$$

$$s_o = \frac{1}{n}\sqrt{n-1} \qquad [6]$$

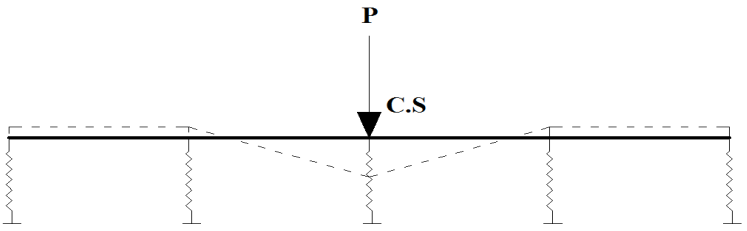

Figure 3. Cross girder with odd number of supports and loaded at the center of supports.

Consider the case of an odd number of supports with the load at the edge of the cross girder (figure 4). First, it is important to find the position where the stiff approach will have no displacement η in order to calculate the absolute value of errors. η can be calculated by solving the following equation

$$\frac{1}{n} - \frac{a(n-1)/2}{2\sum_{i=1}^{(n-1)/2}(ia)^2}\eta a = 0 \qquad [7]$$

For summation, it is required to find the last support that will have the same direction of displacement as the load. This support will be numbered as I from the center of supports.

The general formula for calculating the sum of absolute value of errors and the standard deviation of the errors are:

$$e_o = (\frac{p}{n}) - \sum_{i=1}^{I}(\frac{1}{n} - \frac{(n-1)/2}{\sum_{j=1}^{(n-1)/2} j^2} i) - \sum_{i=I}^{(n-1)/2}(\frac{1}{n} - \frac{(n-1)/2}{\sum_{j=1}^{(n-1)/2} j^2} i) + \sum_{i=1}^{[(n-1)/2]-1}(\frac{1}{n} + \frac{(n-1)/2}{\sum_{j=1}^{(n-1)/2} j^2} i) + (1 - (\frac{1}{n} + \frac{(n-1)/2}{\sum_{j=1}^{(n-1)/2} j^2} \times \frac{n-1}{2})) \qquad [8]$$

$$s_o = \sqrt{\frac{(\frac{p}{n})^2 + \sum_{i=1}^{(n-1)/2}(\frac{1}{n} - \frac{(n-1)/2}{2\sum_{j=1}^{(n-1)/2} j^2} i)^2 + \sum_{i=1}^{(n-1)/2-1}(\frac{1}{n} + \frac{(n-1)/2}{2\sum_{j=1}^{(n-1)/2} j^2} i)^2 + (1 - (\frac{1}{n} + \frac{(n-1)/2}{2\sum_{j=1}^{(n-1)/2} j^2} \times \frac{n-1}{2}))^2}{n}} \qquad [9]$$

These equations can be simplified to:

$$\eta = \frac{n+1}{6} \qquad [10] \qquad , \quad I = \text{int}\,ger(\eta) \qquad [11]$$

$$e_o = \frac{(n-1)(5n-7) + 4I(n-3I-2)}{2n(n+1)} \qquad [12]$$

$$s_o = \frac{1}{n}\sqrt{\frac{(n-1)(n-2)}{(n+1)}} \qquad [13]$$

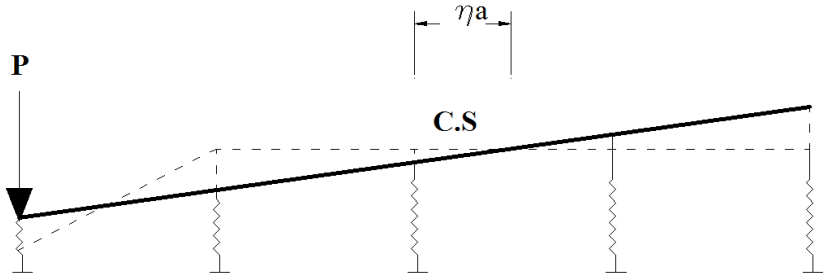

Figure 4. Cross girder with odd number of supports and loaded at the edge.

Consider the case of odd number of supports loaded at a support with eccentricity of βa (figure 5). First, it is important to find the position where the stiff approach will have no displacement η in order to calculate the absolute value of errors. η can be calculated by solving the following equation:

$$\frac{1}{n} - \frac{\beta a}{2\sum_{i=1}^{(n-1)/2}(ia)^2}\eta a = 0 \qquad [14]$$

For summation, it is required to find the last support that will have the same direction of displacement as the load. This support will be numbered as I from the center of supports.

The general formula for calculating the sum of absolute value of errors and the standard deviation of the errors are:

$$e_o = (\frac{p}{n}) - \sum_{i=1}^{I}(\frac{1}{n} - \frac{\beta}{\sum_{j=1}^{(n-1)/2} j^2} i) - \sum_{i=I}^{(n-1)/2}(\frac{1}{n} - \frac{\beta}{\sum_{j=1}^{(n-1)/2} j^2} i) + \sum_{i=1}^{\beta-1}(\frac{1}{n} + \frac{\beta}{\sum_{j=1}^{(n-1)/2} j^2} i) + \sum_{i=\beta+1}^{(n-1)/2}(\frac{1}{n} + \frac{\beta}{\sum_{j=1}^{(n-1)/2} j^2} i) + (1 - (\frac{1}{n} + \frac{\beta}{\sum_{j=1}^{(n-1)/2} j^2} \times \beta)) \qquad [15]$$

$$s_o = \sqrt{\frac{(\frac{p}{n})^2 + \sum_{i=1}^{(n-1)/2}(\frac{1}{n} - \frac{\beta}{2\sum_{j=1}^{(n-1)/2} j^2} i)^2 + \sum_{i=1}^{\beta-1}(\frac{1}{n} + \frac{\beta}{2\sum_{j=1}^{(n-1)/2} j^2} i)^2 + \sum_{i=\beta+1}^{(n-1)/2}(\frac{1}{n} + \frac{\beta}{2\sum_{j=1}^{(n-1)/2} j^2} i)^2 + (1 - (\frac{1}{n} + \frac{\beta}{2\sum_{j=1}^{(n-1)/2} j^2} \times \beta))^2}{n}} \qquad [16]$$

These equations can be simplified to:

$$\eta = \frac{n^2 - 1}{12\beta} \qquad [17] \quad , \; I = \text{int}\, ger(\eta) \le \frac{n-1}{2} \qquad [18]$$

$$e_o = \frac{2I[(n^2-1)-6\beta(I+1)]+(n^2-1)(n-1)-24\beta^2+3\beta n^2-3\beta}{2n(n^2-1)} \quad [19]$$

$$s_o = \frac{1}{n}\sqrt{\frac{n^3-n^2-n+1-12\beta^2}{(n^2-1)}} \quad [20]$$

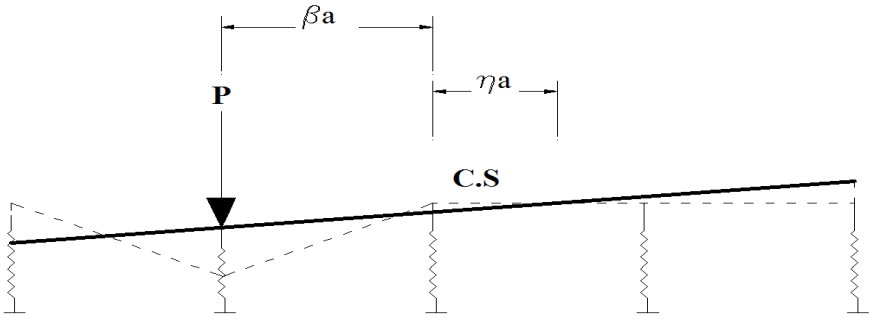

Figure 5. Cross girder with odd number of supports and loaded at any support.

Consider the case of an even number of supports with the load at the center of supports. The load will be applied to the two intermediate supports directly as an approximation because it is meaningless theoretically to but it on a member has no stiffness (figure 6). The general formula for calculating the sum of absolute value of errors and the standard deviation are:

$$e_o = \frac{1}{n}(n-2)+2(\frac{1}{2}-\frac{1}{n}) \quad [21] \quad , \quad s_o = \sqrt{\frac{\frac{1}{n^2}(n-2)+2(\frac{1}{2}-\frac{1}{n})^2}{n}} \quad [22]$$

These two equations can be simplified to:

$$e_o = \frac{2n-4}{n} \quad [23]$$

$$s_o = \frac{1}{n}\sqrt{\frac{n-2}{2}} \quad [24]$$

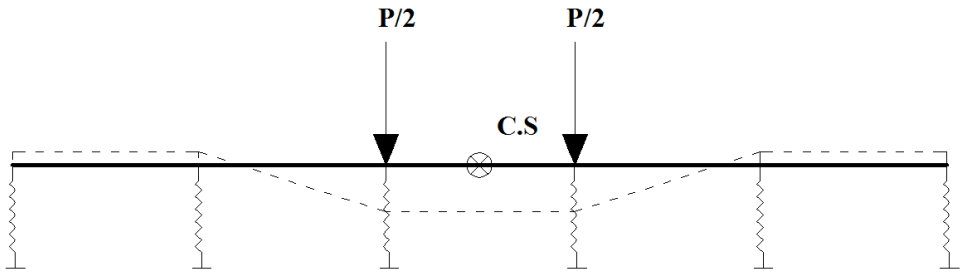

Figure 6. Cross girder with even number of supports and loaded at the middle supports.

Consider the case of even number of supports with the load at the edge of the cross girder (figure 7). First, it is important to find the position where the stiff approach will have no displacement η in order to calculate the absolute value of errors. η can be calculated by solving the following equation:

$$\frac{1}{n} - \frac{a(n-1)/2}{2\sum_{i=1}^{n/2}[(i-0.5)a]^2}\eta a = 0 \qquad [25]$$

For summation, it is required to find the last support that will have the same direction of displacement as the load. This support will be numbered as I from the center of supports.

The general formula for calculating the sum of absolute value of errors and the standard deviation of the errors are:

$$e_o = \sum_{i=1}^{I}[\frac{1}{n} - \frac{(n-1)/2}{2\sum_{j=1}^{n/2}(j-0.5)^2}(i-0.5)] - \sum_{i=I}^{n/2}[\frac{1}{n} - \frac{(n-1)/2}{2\sum_{j=1}^{n/2}(j-0.5)^2}(i-0.5)] + \sum_{i=1}^{[n/2]-1}[\frac{1}{n} + \frac{(n-1)/2}{2\sum_{j=1}^{n/2}(j-0.5)^2}(i-0.5)] + [1-(\frac{1}{n} + \frac{(n-1)/2}{2\sum_{j=1}^{n/2}(j-0.5)^2} \times \frac{n-1}{2})] \qquad [26]$$

$$s_o = \sqrt{\frac{\sum_{i=1}^{n/2}[\frac{1}{n} - \frac{(n-1)/2}{2\sum_{j=1}^{n/2}(j-0.5)^2}(i-0.5)]^2 + \sum_{i=1}^{(n-1)/2-1}[\frac{1}{n} + \frac{(n-1)/2}{2\sum_{j=1}^{n/2}(j-0.5)^2}(i-0.5)]^2 + [1-(\frac{1}{n} + \frac{(n-1)/2}{\sum_{j=1}^{n/2}(j-0.5)^2} \times \frac{n-1}{2})]^2}{n}} \qquad [27]$$

These equations can be simplified to:

$$\eta = \frac{n+1}{6} \qquad [28] \quad , \; I = \text{int}\, ger(\eta + 0.5) \qquad [29]$$

$$e_o = \frac{(n-2)(5n-4) + 4I(n-3I+1)}{2n(n+1)} \qquad [30]$$

$$s_o = \frac{1}{n}\sqrt{\frac{(n-1)(n-2)}{(n+1)}} \qquad [31]$$

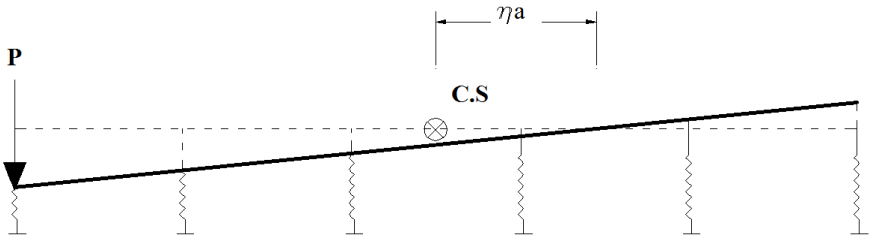

Figure 7. Cross girder with even number of supports and loaded at the edge.

Consider a case of even number of supports loaded at a support with eccentricity of $[(\gamma - 0.5)a]$ (figure 5). First, it is important to find the position where the stiff approach will have no displacement η in order to calculate the absolute values of errors. η can be calculated by solving the following equation

$$\frac{1}{n} - \frac{(\gamma - 0.5)a}{2\sum_{i=1}^{n/2}[(i-0.5)a]^2}\eta a = 0 \qquad [32]$$

For summation, it is required to find the last support that will have the same direction of displacement as the load. This support will be numbered as I from the center of supports.

The general formula for calculating the sum of absolute value of errors and the standard deviation of the errors are:

$$e_o = \sum_{i=1}^{I}[\frac{1}{n} - \frac{(\gamma-0.5)}{2\sum_{j=1}^{n/2}(j-0.5)^2}(i-0.5)] - \sum_{i=I}^{n/2}[\frac{1}{n} - \frac{(\gamma-0.5)}{2\sum_{j=1}^{n/2}(j-0.5)^2}(i-0.5)] + \sum_{i=1}^{\gamma-1}[\frac{1}{n} + \frac{(\gamma-0.5)}{2\sum_{j=1}^{n/2}(j-0.5)^2}(i-0.5)] + \sum_{i=\gamma+1}^{n/2}[\frac{1}{n} + \frac{(\gamma-0.5)}{2\sum_{j=1}^{n/2}(j-0.5)^2}(i-0.5)] + [1-(\frac{1}{n} + \frac{(\gamma-0.5)}{2\sum_{j=1}^{n/2}(j-0.5)^2} \times (\gamma-0.5))] \qquad [33]$$

$$s_o = \sqrt{\frac{\sum_{i=1}^{n/2}[\frac{1}{n} - \frac{(\gamma-0.5)}{2\sum_{j=1}^{n/2}(j-0.5)^2}(i-0.5)]^2 + \sum_{i=1}^{\gamma-1}[\frac{1}{n} + \frac{(\gamma-0.5)}{2\sum_{j=1}^{n/2}(j-0.5)^2}(i-0.5)]^2 + \sum_{i=\gamma+1}^{n/2}[\frac{1}{n} + \frac{(\gamma-0.5)}{2\sum_{j=1}^{n/2}(j-0.5)^2}(i-0.5)]^2 + [1-(\frac{1}{n} + \frac{(\gamma-0.5)}{\sum_{j=1}^{n/2}(j-0.5)^2} \times (\gamma-0.5))]^2}{n}} \qquad [34]$$

These equations can be simplified to:

$$\eta = \frac{n^2 - 1}{6(2\gamma - 1)} \qquad [35] \quad , \; I = \text{int}\,ger(\eta + 0.5) \le \frac{n}{2} \qquad [36]$$

$$e_o = \frac{2n^3 - 7n^2 - 2n - 48\gamma^2 + 48\gamma - 8 + 6\gamma^2 n + 4I[n^2 - 1 - 3I(2\gamma - 1)]}{2n(n^2 - 1)} \qquad [37]$$

$$s_o = \frac{1}{n}\sqrt{\frac{n^3 - n^2 - n - 3(2\gamma - 1)^2 + 1}{(n^2 - 1)}} \qquad [38]$$

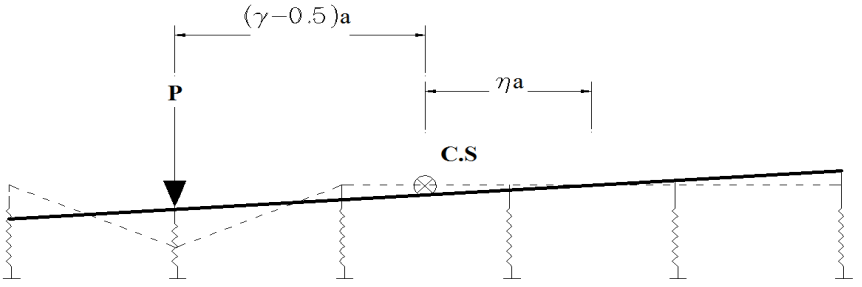

Figure 8. Cross girder with even number of supports and loaded at any support.

General Case for Main and Cross Girder Stiffness

It is extremely difficult to reproduce the previous equations for arbitrary relative stiffness of the cross girder and main girder. In that case, it is required to invert a stiffness matrix with order of $(2nX2n)$, and then do the previous operations on the values representing displacements in the column affected by load P.

The basic idea of this paper is that the extreme limits were studied, and the values of absolute error sum and standard deviation were calculated. By solving as many numerical problems as possible, a suitable approximation for the trend could be produced as follows

$$e_x[s] = \frac{e_o[s_0]}{\alpha k' + 1} \qquad [39]$$

$$k' = \frac{EI_x}{K_m a^3} \qquad [40]$$

	even	odd
e_x	$\alpha = \frac{237.25}{n^{3.43}}$ [41]	$\alpha = \frac{557.1}{n^{3.78}}$ [43]
S	$\alpha = \frac{211.35}{n^{3.38}}$ [42]	$\alpha = \frac{418.65}{n^{3.5}}$ [44]

where E is the modulus of elasticity, I_x is the moment of inertia of the cross girder, and K_m is the stiffness for the equivalent spring of the main girder.

Effective stiffness of Main and Cross Girder Concrete Moment of Inertia

It is obvious at this point that it is necessary to calculate the effective moment inertia for the considered concrete sections to get the true results. Loading codes consider the concrete section to be in the working stage of "linear stress strain relation for concrete" while it is under working loads (figure 9).

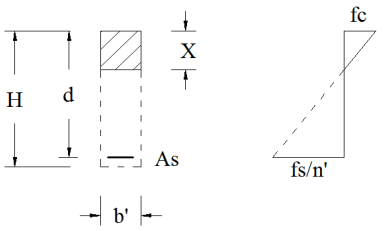

Figure 9. Effective concrete section in the working stage.

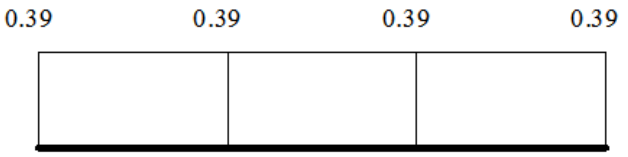
From the moment of effective areas about the neutral axis, where the tensile reinforcement ratio $\mu = \frac{A_s}{b'd}$, and $n' = \frac{E_s}{E_c}$ is the ratio between the steel and concrete modulus of elasticity : $b'\frac{x^2}{2} = n'(\mu b'd)(d-x)$ [45]

It could be concluded that: $x = (\sqrt{n'^2\mu^2 + 2n'\mu} - n'\mu)d = \alpha' d$ [46]

And by substituting in equation $I_{NA} = \frac{b'x^3}{3} + n(\mu b'd)(d-x)^2$ [47], it could be derived that:

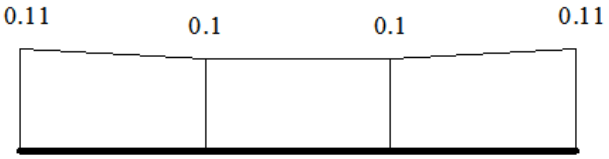
$$I_{NA} = \frac{b'd^3}{12}[4(\alpha'^3 + 3n'\mu(1-\alpha')^2] \quad [48]$$

Note that, in some cases the moment of inertia of the attached slab increases the total inertia with significant value.



Numerical example

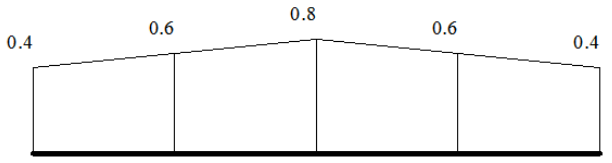
Consider a single span bridge with 5 cross girders, and the ratio of $\frac{b}{a}=2$. For design purposes, the following values could be assumed ($H_m=\frac{L}{10}$, $H_x=0.9H_m$, $d=0.9H$, $b_m=2b_x$, $n'=10$) . Usually, cross girder reinforcement ratio is close to the minimum reinforcement ratio and the main girder reinforcement ratio is close to the maximum reinforcement ratio , so it could be assumed that ($\mu_m=1.5\%$, $\mu_x=0.15\%$). From this data, $\frac{I_x}{I_m}=0.117$ which is much smaller than the value would be calculated using the gross moment of inertia.



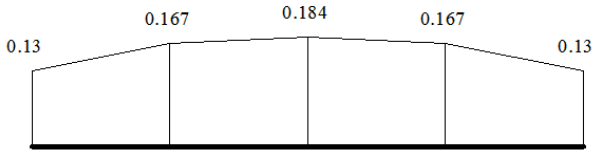
For the middle cross girder, the equivalent spring stiffness for the main girder is $K_m=\frac{p}{\delta}=\frac{384EI_m}{5L^3}$.

Consider two cases of 4 cross girders and five cross girders respectively. The influence lines for sum of absolute errors and standard deviation are drawn.

For 4 supports:



I.L. e_x



I.L. s

For 5 supports:

I.L. e_x

I.L. s

"Note that the equations were derived for loaded supports only, so it is an approximation to use straight line to describe the values between supports."

CONCLUSION

1-Applying the stiff approach to the cross girder of slab girder bridges has a significant amount of error, even in the most common geometry of the bridge. But it could be used for preliminary design under conservative conditions.

2- Considering the gross moment of inertia of the concrete thickness changes the results dramatically.

ABSTRACT

The Alabama Department of Transportation (ALDOT) is in the process of transitioning from the AASHTO Standard Specification for Highway Bridges to the LRFD Bridge Design Specifications. One significant difference between the two specifications is the seismic design provisions. From a practical point of view, the desire is that typical details can be developed for the worst case scenarios which can be implemented for bridges throughout the state without a significant cost premium. To determine the effects of the updated seismic provisions on current practice, an initial study of existing bridges was completed. Three typical, multi-span, prestressed concrete I-girder bridges were selected for the study. In order to bracket the demands for typical bridges, the primary bridge geometry variables were span length, pier height and pier configuration.

The bridges' Earthquake Resisting Systems were re-designed for the worst conditions for the state of Alabama. After doing the initial calculations with Site Class D as the soil condition, it was found that the Seismic Design Catergory B was the worst case for Alabama. The AASHTO Guide Specifications for LRFD Seismic Bridge Design was used for analysis and design of the three bridges. This paper discusses the changes made to two of the bridges in order to meet the requirements. The reinforcing detailing requirements in the pier for the hinge location were increased, the pier cap and drilled shaft were designed in accordance with capacity-based design, and the connection between the pier cap and girder was re-designed.

PROBLEM STATEMENT

Alabama Department of Transportation (ALDOT) has been designing bridges using the AASHTO Standard Specification for Highway Bridges (Standard Specification); however, due to Federal Highways Administration (FHWA) requirements, ALDOT will be required to begin designing bridges in accordance with AASHTO LRFD Bridge Design Specifications (LRFD Specification). Under the Standard Specifications most of the state was classified as Seismic Performance Category A which required minimal seismic detailing and no additional analysis. The new requirements will influence future bridge design. Specifically, the

substructure elements, the superstructure-to-substructure connections, and the foundations will see the most change. From a practical point of view, ALDOT Bridge Bureau's desire is that typical details can be developed for the worst case scenarios which can be implemented for bridges throughout the state without a significant cost premium.

This study was done to update the seismic bridge design in the state of Alabama. Three existing standard, multi-span, prestressed concrete I-girder bridges were selected to be redesigned according to the specifications in the AASHTO Guide Specifications for LRFD Seismic Bridge Design (Guide Specification). The results of two of those bridges are reported here. The main objectives were the following:

1. To determine the effects of LRFD seismic provisions on design and detailing and
2. To determine if typical, economically feasible details can be utilized for all the selected bridges.

INTRODUCTION

The major differences between the Guide Specification and the Standard Specification are described in the following section. The differences can be broken down into the following categories:

- New Ground Acceleration Maps

The Standard Specification currently uses ground acceleration maps created by the United States Geological Survey (USGS) in 2002. The map assumes the soil condition to be rock. The seismic loads represented by the acceleration coefficients have a 10% probability of exceedance in 50 years which corresponds to a return period of approximately 475 years. For the Guide Specifications, the ground acceleration maps depict probabilistic ground motion and spectral response for 7% probability of exceedance in 75 years which corresponds to a return period of approximately 1000 years. Also, the Guide Specification has maps for peak ground acceleration (PGA), 0.2 second spectral response acceleration (S_S), and 1.0 second spectral response acceleration (S_1) instead of just one map. The change in the ground acceleration maps generates an increase in design earthquake load for a bridge. These changes are due to larger return period for the design earthquake and the significant amount of research completed on the New Madrid and East Tennessee faults.

- New Design Spectral Shape

In the AASHTO Standard Specification, the spectral acceleration maximum is 2.5*Acceleration coefficient, A. Unless the ground acceleration is greater than or equal to 0.3, then the maximum spectral acceleration is 2.0*A. The equation for the elastic seismic response coefficient can be seen in Equation 1. The response coefficient is decaying a rate of $1/T^{2/3}$. However, the response spectrum decreases at a rate of 1/T, but because of the concerns associated with inelastic response of

longer period bridges it was decided that the ordinates of the design coefficients and spectra should not decrease as rapidly as 1/T but should be proportional to $1/T^{2/3}$ (AASHTO 2002). The response spectrum in the Guide Specification decreases at a rate of 1/T. In Figure 1, the response spectrum for the Guide Specification and Standard Specification is compared. The Guide Specification design response spectrum includes the short-period transition from the acceleration coefficient, A_S, to the peak response region, S_{DS}, unlike the Standard Specification. This transition is effective for all modes, including the fundamental vibration modes. Use of the peak response down to zero period is felt to overly conservative, particularly for a displacement-based design. (AASHTO 2008)

$$Cs = \frac{1.2 * A * S}{T^{2/3}} \qquad \textbf{Equation 1}$$

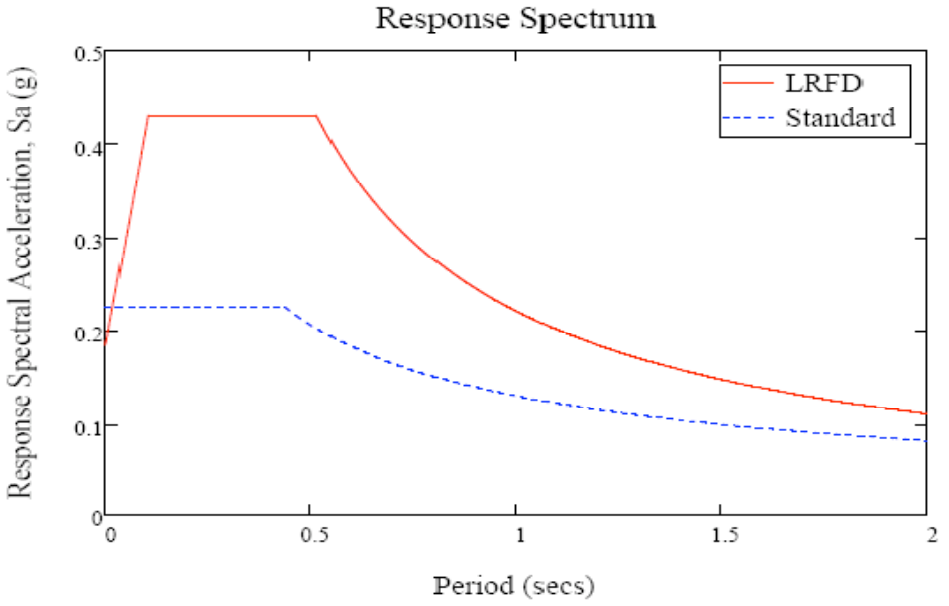

Figure 1 Comparison of the response spectrum for the Standard Specification and Guide Specification

- Site Factors

The Standard Specification has four different soil profiles which correspond to four site factors. The seismic performance category is first chosen, and then according the soil condition, the elastic seismic response coefficient is amplified. The Guide Specification has six soil profiles which correspond to six soil factors. The site class is chosen before the seismic design category is selected in contrast with the Standard Specification. These factors affect the spectral response coefficients which in turn affects the seismic design category.

GENERAL SEISMIC BRIDGE DESIGN

The initial seismic calculations and checks were the same for all of the three bridges. This is the case because the worst case for seismic design in Alabama was chosen for this project. Therefore, the location of the bridges given for redesign is irrelevant. The steps, checks and calculations described in this section are the same for the three bridges designed for this project.

A design worksheet for concrete bridges in SDC B was created using Mathcad to facilitate the design (Parametric Technology Corportation 2007). The design worksheet allows the user to input data that is required for design. The designer will have to make some changes to the worksheet as a new bridge is being designed. Mathcad is set up in a way where the input data and output can be seen easily. The checks for design are already in the worksheet; therefore, the designer must only verify that they are satisfied. This worksheet will decrease the amount of time it takes to seismically design a bridge.

The Guide Specification supplies flowcharts which can be followed to ensure all the requirements for seismic design are checked. First of all, the initial sizing of columns should be done for strength and service load combinations defined in the LRFD Specification (AASHTO 2007). The first thing to be done is to check and verify that the Guide Specification can be used for the bridge design. The Guide Specification applies to the design and construction of conventional bridges to resist the effects of earthquake motions. Critical and Essential bridges are not specifically addressed in the Guide Specification (AASHTO 2008). The bridges that were analyzed and design are classified as conventional bridges.

The next item to be investigated is under what performance criteria will be used. According to the Guide Specification, "Bridges shall be designed for life safety performance objective considering a seismic hazard corresponding to a 7% probability of exceedance in 75 years. Life Safety for the design event shall be taken to imply that the bridge has a low probability of collapse but may suffer significant damage and that significant disruption to service is possible. Partial or complete replacement may be required." (AASHTO 2008)

A foundation investigation needs to be done in the location the bridge will be built. For bridges in SDC B and where loose to very loose saturated sands are in the subsurface profile, the potential of liquefaction should be considered since the liquefaction of these soils could affect the stability of the structure. The commentary of the Guide Specification discusses when liquefaction needs to be considered for SDC B. It was assumed that the structures in this paper would not be affected by liquefaction.

For SDC B, the identification of an earthquake resisting system (ERS) should be considered. For the bridges in the study, a Type 1 earthquake resisting system was chosen. Type 1 structures have "ductile substructures with essentially elastic superstructure: This category includes conventional plastic hinging in columns and walls and abutments that limits inertial forces by full mobilization of passive soil resistance. Also included are foundations that may limit inertial forces by in-ground hinging, such as pile bents and integral abutments on piles" (AASHTO 2008).

A response spectrum should be created for the bridge being designed. The response spectrum is created by using the seismic hazard maps and the site classification. The USGS seismic parameters CD-ROM accompanying the Guide

Specification with the seismic hazard maps will calculate the accelerations based on the longitude and latitude. After determining these values, a response spectrum can be created by using a series of equations. The next step in the design process is to select the seismic design category. This is based on the 1-second period spectral acceleration which is dependent on location and site classification. For all the bridges in this project, the seismic design category is B. After this step in the process, the design will change depending on the bridge.

Introduction to the Bridges

ALDOT has chosen three existing bridges to be redesigned according to the Guide Specification. The bridges selected were standard concrete bridges. Below, two of the bridges which were redesigned are discussed. The expected changes in the transverse reinforcing and connection of the substructure and superstructure were seen in these bridges.

Bridge 1

Bridge 1 consists of three 80 ft, simple spans. The concrete bridge is 240 ft long and 32 ft 9 in. wide. The substructure has a 7 in. concrete deck supported by four AASHTO Type III girders that are equally spaced. The bridge has two bents which are made of a bent cap beam that is 4 ft x 5 ft x 30 ft, two 42 in. circular concrete columns, and two 42 in. circular drilled shafts. The abutments, which are 3 ft x 3.5 ft x 35 ft, are supported by two 42 in. circular drilled shafts. The columns have an average above ground height of 9 ft. Currently, the column and drilled shaft reinforcing are 12 number 11 bars for the longitudinal reinforcing and No. 5 hoops at 12 in. on center for the transverse reinforcing.

The first step in the seismic design process was to input all the information about the bridge into the design worksheet. An equivalent static analysis was used to analyze the bridge. Both uniform load method and single mode spectral method was completed for this bridge, but since the results were similar, the easiest method was selected. In order to do a seismic analysis, a bridge model was created in SAP 2000 Bridge Modeler (Computer & Structures 2007). A uniform load of 1 kip/ft was converted into joint loads and applied to the bridge in both the transverse and longitudinal direction. The maximum joint deflection was used to calculate the equivalent stiffness in both the transverse and longitudinal direction. The weight of the bridge was then calculated. An equivalent lateral load was created by multiplying the spectral acceleration by the weight and dividing it by the length of the bridge for both directions. Instead of re-inputting the loads into the bridge model, the designer is allowed to scale the deflection from the 1 kip/ft load by the equivalent lateral load. The bridge had maximum deflections in the longitudinal and transverse directions of 0.201 in. and 0.904 in., respectively.

Next, the displacement capacity of the columns had to be verified. For SDC B, simplified equations can be used. When the simplified equations were checked for the above ground height, the columns failed the capacity equations. Therefore after discussing this with ALDOT, it was decided to allow hinging to occur below ground. The point of fixity was assumed at the rock line. After allowing below ground

hinging, Bent 3 satisfied the simplified equations; however, Bent 2 still did not satisfy the equations because of the length-to-diameter ratio was too large. It was determined that in order to satisfy the equations with a 42 in. diameter column the clear column height would have to be 20 ft. The Bent 2 clear column height was 18 ft, and Bent 3 column height was nearly 26 ft. According to the Guide Specification, a pushover analysis can be done to verify the displacement capacity of the bridge. The bridge satisfied the pushover analysis. After completing the displacement capacity check, the seat widths were calculated to around 18 in. for the bents and abutments.

According to the Guide Specifications, the shear demand for columns in SDC B can be designed for force obtained from a linear elastic seismic analysis or the force corresponding to plastic hinging of the column including the overstrength factor (AASHTO 2008). For Bridge 1 the plastic hinging force of the column was used in design. PCA Column (PCA 2004) was used to create an interaction diagram which was used to calculate the moment capacity of the column and to ensure the column had sufficient strength to resist the applied moments from the dead load and seismic loads. The moment capacity was then amplified by an overstrength factor of 1.4. The plastic hinge zone for the columns in both Bents 2 and 3 was controlled by 1.5 times the column diameter, which is equal to 63 in. The maximum spacing of seismic hoops within the hinge zone is set at 6 in., and this is what controlled the design of these columns. Therefore within the plastic hinge zone, the columns are reinforced with No. 5 seismic hoops at 6 in. on center. The hoops within the hinge zone require 135 degree hooks or must be welded. The close spacing of the hoops provides confinement of the core which is critical during a seismic event. The shear strength of the columns was more than adequate. Also, a requirement for an extension of the hinge zone reinforcing into the bent cap beam and drilled shaft out of the LRFD Specification was used in the design. The extension zone reinforcing for these columns is 21 in. which is governed by half the diameter of the column. This is not specifically required for SDC B in the Guide Specification, but in order to avoid a plane of weakness at the joint, it has been considered important to have the extension in the design. Outside the plastic hinge zone, the columns are designed according to the LRFD Specification. Currently, outside the plastic hinge zone the No. 5 hoops were spaced a 12 in. on center, and this proved to be adequate to resist the shear force. The hoops outside the hinge zone can have tension lap splices. The drilled shafts' lateral reinforcing was designed like the column's lateral reinforcing outside the hinge zone. Hence, the drilled shaft's lateral reinforcing is No. 5 hoops at 12 in. on center. A comparison of the increase in column design can be seen in Table 1. Figures 2 and 3 compare the transverse reinforcing from the Standard Specifications and the Guide Specification for Bent 3 and Bent 2, respectively.

The change from the Standard Specification to the Guide Specification not only affects the column reinforcing but also the connection of the girder to the bent cap. The shear load the connection must be designed for has increased which in turn has affected design. Currently ALDOT is using an L6x6x1/2 by 12 in. long for the connection between the girder and bent cap beam. An anchor bolt is used to connect the angle to the bent cap beam and precast screw inserts are used to connect the vertical leg of the angle to the girder. However, a through bolt in the girder has been proposed as an option instead of the precast screw inserts. The anchor bolts and

through bolts will be designed for the same forces. Also, other types of connections are being investigated in order to avoid the construction problems with the anchor bolt locations not matching the plans. For the connection between the bents and the girders, two 1.25 in. diameter anchor bolts had to be used versus one anchor bolt, but for the connection between the abutment and girder, the same anchor bolt as before can be used. The change in the connection can be attributed to the increase in shear force demand. The increase in shear force from the previous design causes a necessary increase of the bending strength of the angle. The bending criteria for the angle could be met by lengthening the angle, adding stiffeners, or increasing the angle thickness. For this bridge, the angle thickness has been increased to 0.875 in. and 0.75 in. for the bents and abutments, respectively.

Category	Standard Specification	Guide Specification
	Bent 2 &3	**Bent 2 &3**
Stirrup Size	#5	#5
Stirrup Spacing Outside Plastic Hinging Region	12 in. o.c.	12in. o.c.
Stirrup Spacing Inside Plastic Hinging Region	12 in. o.c.	6.0 in. o.c.
Length Plastic Hinge Region	0	63 in.
Number of Stirrups per Column	34	51
% Increase in Stirrups	0	33%

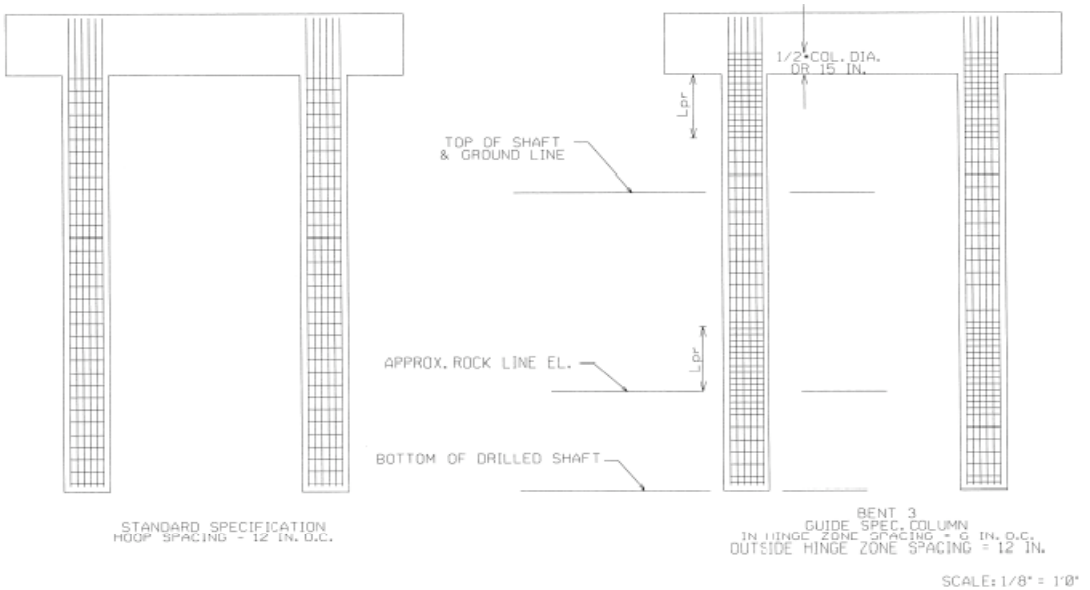

Figure 2: Column Transverse Reinforcing for Bent 3

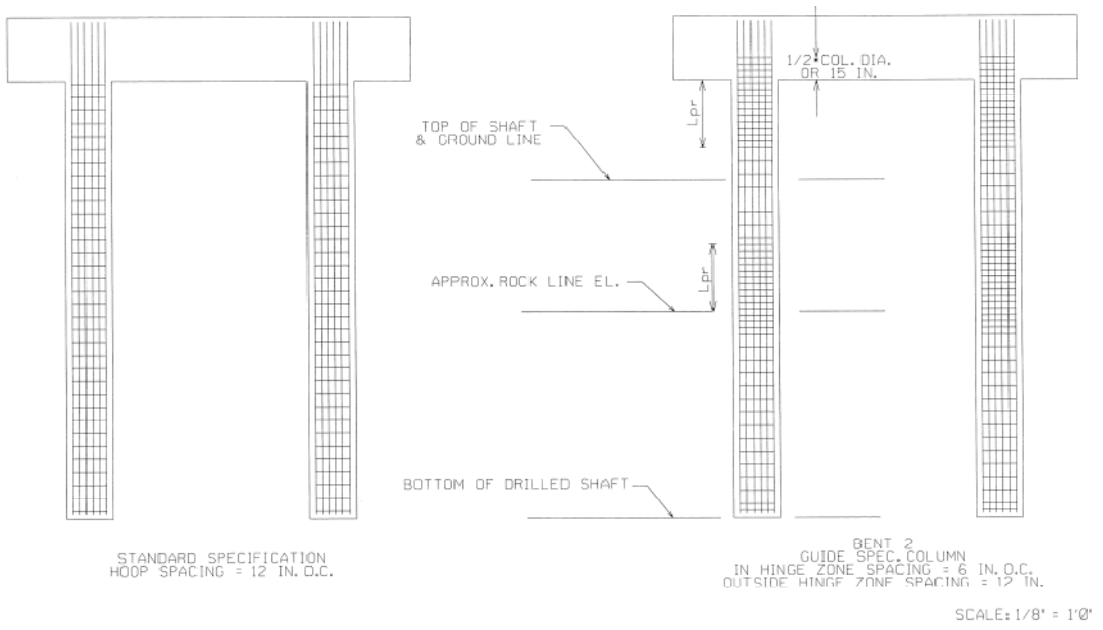

Figure 3: Column Transverse Reinforcing for Bent 2

Bridge 2

Bridge 2 is a three span concrete prestressed I-girder bridge with side spans 85 ft long and the middle span 130 ft. The total length and width of the bridge is 300 ft and 42 ft 9 in., respectively. The short span's superstructure consists of a 7 in. concrete deck supported by six AASHTO Type III girders spaced equally. The long span's superstructure consists of a 7 in. concrete deck supported by six BT-72 girders equally spaced. There are two bents which consist of a cap beam and two 54 in. circular columns which are supported by 60 in. circular drilled shafts. The columns and drilled shafts longitudinal reinforcing is 24 No. 11 bars. The bent cap beam allows for the change in size for the girders and has a total depth of 9 ft 4 in., width of 5 ft. and length of 40 ft. Bent 2 has an above ground height of 12 ft, and Bent 3 has an above ground height of 16 ft 8 in. Abutment 1, which is 3 ft x 3.5 ft x 45 ft, is supported by three 42 in. circular drilled shafts. Abutment 2 has the same dimension of Abutment 1, but it is not supported by drilled shafts.

The same procedure used to design the Bridge 1 was used to design Bridge 2. A model was built in SAP, and then the uniform loads were applied to the bridge in both transverse and longitudinal directions. When the abutment that is not supported by drilled shafts was modeled, it was only restrained in the vertical direction; therefore, the max deflection in the transverse direction is at this end of the bridge. The maximum displacements in the transverse and longitudinal direction are 1.486 in. and 0.448 in.

When designing this bridge, it was determined that it was not practical to design it for the capacity of the column, but to design it for the elastic forces from a linear elastic seismic analysis. PCA Column was used to create interaction diagrams for the columns and drilled shafts in each bent. After looking at the interaction diagrams for the column and drilled shaft for Bent 3, it was concluded that the longitudinal reinforcing needed to be increased because the combination of the uplift

case for the earthquake load and the dead load was so small. The column longitudinal reinforcing was increased to 28 No. 11 bars, and the drilled shaft reinforcing was increased to 32 No. 11 bars. This is not a problem in the design or construction process because the volumetric ratio was still small.

When the simplified displacement capacity equations were calculated, the columns failed this check; therefore, a pushover analysis was done on the bridge, and it satisfied the displacement demands. The shear forces for the design of the columns and drilled shafts were taken from the bridge model. Tables 2 and 3 display the difference in design between the Standard Specification and the Guide Specification. Figures 4 and 5 compare the transverse reinforcing from the Standard Specifications and the Guide Specification for Bent 3 and Bent 2, respectively. The plastic hinge zone is control by 1.5 times the column diameter. The spacing within the hinge zone is 6 in. on center. The spacing outside the hinge did change from 12 in. to 10.5 in. on center because the minimum transverse reinforcement specification was not met. The drilled shafts are reinforced with No. 6 hoops at 12 in. on center. The drilled shafts had a slight increase in transverse reinforcing, but this was due to the extension of the seismic hoop reinforcing. The extension into the drilled shaft and bent cap beam is 27 in. which is controlled by half the column diameter.

Table 2 Column design comparison for Bent 2

Number of Stirrups per Column	17	36
% Increase in Stirrups	0	53%

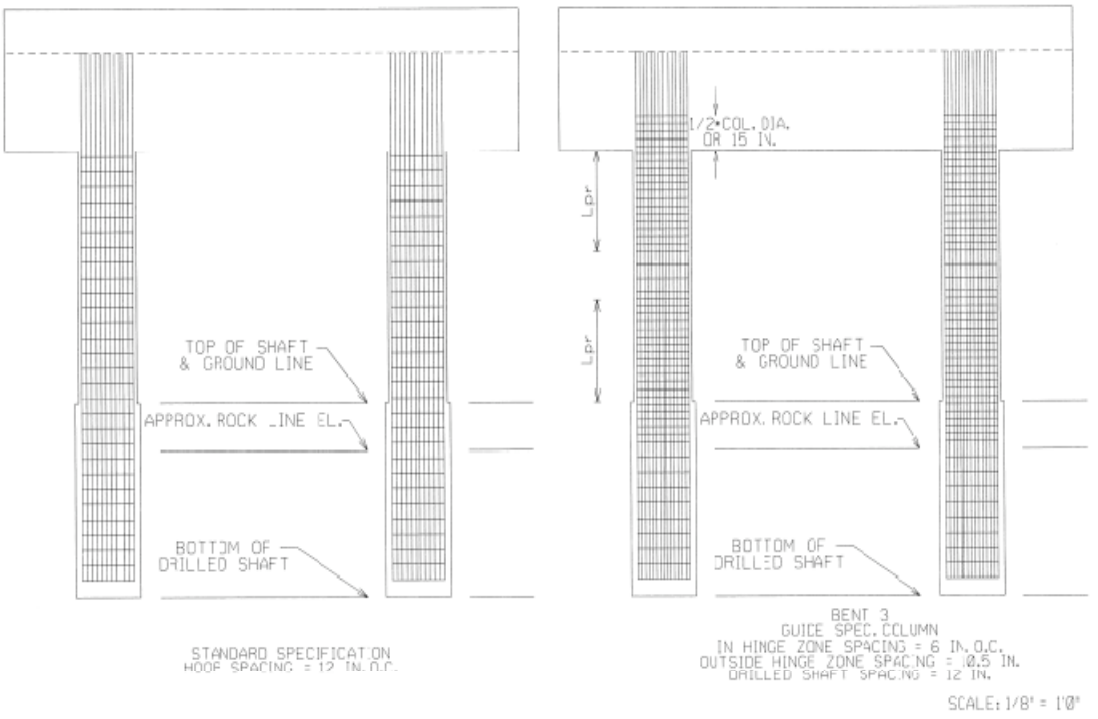

Figure 4: Column Transverse Reinforcing for Bent 3

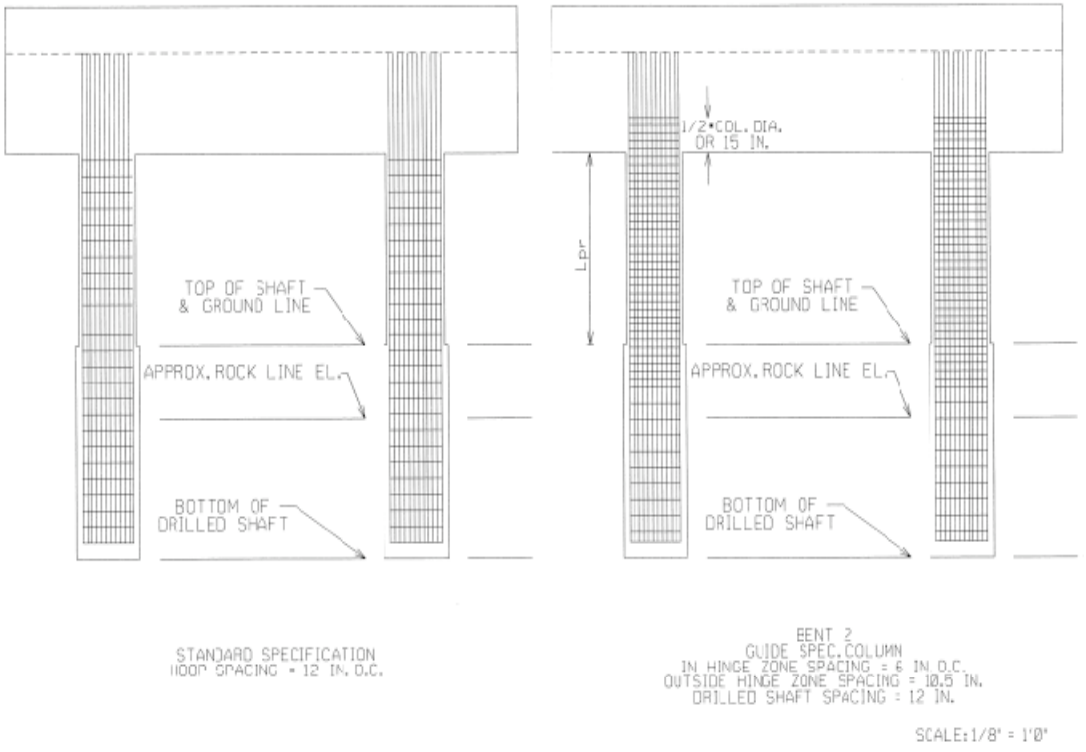

Figure 5: Column Transverse Reinforcing for Bent 2

For the Bridge 2, the connection between the superstructure and substructure had to be changed. For this bridge, the connection between the girder and bent cap beam is still an L6x6x1/2 by 12 in. long angle. For the Guide Specification, the same

connection was able to be used for both the Type III girder and the BT-72 girder. The diameter of the anchor bolt had to be increased to 1.5 in. The increase in shear force from the previous design causes a necessary increase of the bending strength of the angle. The thickness of the angle has been increased in this case.

CONCLUSIONS

Valuable information has been discovered from the two bridges whose substructures have been redesigned. From these two bridges, it is concluded that there is no problem in meeting the displacement capacity qualifications set by the Guide Specification. The shear force in the bridges has increased since the ground hazard maps have changed from the Standard Specifications. Since the bridges currently being designed do not take into account plastic hinge zones, it is concluded that there will be an increase in hoop reinforcing in most of the bridges in Alabama as seen with these two bridges. There also will be an increase in the anchor bolt diameter or number in order to carry the shear force. The angle must be strengthened in some manner in order satisfy the bending force. The redesign of the two bridges has aided in the understanding of what significant changes will need to be made in the state of Alabama.

ALDOT's goal was to develop standard details for the worst case seismic scenario in the state. From the results of these two bridges, it seems to be unlikely that will happen. In the plastic hinge zone, it can be assumed the spacing of the reinforcing will be 6 in. on center for most bridges in Alabama. Mostly likely, it can be concluded that the plastic hinge zone length will be controlled by 1.5 times the column diameter. However, the plastic hinge zone length and spacing need to be checked. If more bridges are investigated, it may be concluded that plastic hinge zone length and spacing can be assumed to be 1.5 times the column diameter and 6 in., respectively. Even though standard details may not be developed, the design worksheet that has been created for seismic design of concrete bridges in SDC B will ease the process of seismically designing bridges.

ABSTRACT

A new component-based, two-node, simplified, semi-rigid beam-to-column-connection element than can easily be used in conjunction with many available structural-engineering software products is proposed for computer-oriented structural analysis. Relevant connection element properties, such as its stiffness matrices, have been established. The proposed model circumvents the iterative procedure proposed by several code standards for determining the resistance capacity and rotational stiffness of beam-to-column connections while at the same time it also alleviates the inapplicability of four-node elements that have been proposed by several researchers for use in commonly available high-end structural engineering software products.

In the process of formulating the analytical model, panel shear deformation of the joint has been taken care of by allowing the joint region of the column to undergo shear deformation.

Numerical experience has been gained by processing several frame structural models. Application will be demonstrated using the general purpose finite element package ANSYS by way of applying to study a typical frame. Results have also been compared with those obtained by other researchers and a high-quality correlation between and among results have been obtained. In all cases, values obtained by the proposed two-node connection model have been acceptable for design purpose.

1. INTRODUCTION

The study of the behavioral response of semi-rigid joints, characterized by non-full fixity or unconstrained free rotation of the connected members, has been a research topic since the last couple of decades. Extensive studies have been carried out over the past three decades to establish the actual behavioral response of semi-rigid joints. A large number of findings have been produced on composite- and steel semi-rigid connections, covering the state of the art (Bjorhovde *et al*, 1996), numerical studies and experimental tests [such as, for example, Chen and Toma (1994), Bayo *et al* (2006), among many others] which lead to code specifications.

Most design codes also address methods and procedures for the determination of their resistance capacity and rotational stiffness. The European Code Standards

EC3 (CEN, 2004), for example, allows the use of the so called *component method* to simulate the semi-rigid behavior of such joints. In order to account for the panel shear deformation, the Code allows the use of an interaction parameter which is defined based on the internal forces at the joint thereby calling for a computationally demanding iterative process during global analysis. However, this later approach is quite inefficient and, thus, it is not generally accepted in practical design environments.

In order to avoid this iterative process Bayo *et al* (2006) proposed a new four-node element that accounts for various deformation modes in its formulation. These four-node elements, however, could not easily be practiced in commonly available structural engineering software.

Despite the fact that a large knowledge-base now exist with regard to semi-rigid connections, the design of such connection is barely practiced in several instances. This phenomenon is explained in part by the lack of effective tools for the analysis of such frames, and insufficient experimental data and the sizable cost involved in organizing such experiments. Apart from this, many available structural-engineering software products do not accommodate some of the available semi-rigid joint modeling findings.

In this paper a new component-based, two-node connection element is proposed to alleviate shortcomings of the four-node elements with particular emphasis on their computerized implementation. The local deformation of the column panel zone is accounted for by allowing shear deformation. General purpose finite element package ANSYS (2004) been used to study a series of frames under several loading and geometric conditions.

2. CONNECTION CLASSIFICATION

Realizing the potential influence of connections on frame performance, various design codes, among which Eurocode 3 is one (CEN, 2004), have introduced provisions to allow designers to consider explicitly the behavior of connections in the design of structural steel frames.

Most design codes tend to identify three types of connections for designing multistory frames: Type I (rigid framing), Type II (simple framing), and Type III (semi rigid framing). To be pertinent, the rigidity of the connection should be defined with respect to the rigidity of the connecting members. For general application to a wide range of beam-to-column connections, Bjorhorde *et al* (1996) introduced a non-dimensional system of classification that compares the connection stiffness to the beam stiffness. With particular reference to semi-rigid connections, they have used the following expression as their range of definition; viz.

$$\begin{cases} 0.2 \le \overline{m} \le 0.7 & \text{in terms of strength} \\ 0.5\overline{\theta} \le \overline{m} \le 2.5\overline{\theta} & \text{in terms of stiffness} \end{cases} \tag{1a}$$

where the non-dimensional parameters $\overline{m}$ and $\overline{\theta}$ used in the classification of connections are given by:

$$\bar{m} = \frac{M}{M_p}, \qquad \bar{\theta} = \frac{\theta_r}{\theta_p} \tag{1b}$$

where again,

θ_r is the relative deformation angle of the connection,

$\theta_p = \frac{M_p}{(EI_b/5d)}$ in which I_b denotes the moment of inertia of the beam

M_p represents the full plastic moment capacity of the beam.

3. MODELING OF SEMI-RIGID CONNECTIONS

There have been developed various approaches for modeling semi-rigid connections. The summary of the various approaches with fairly reasonable discussion on component-based methods is provided subsequently.

3.1 *Existing Models*

Several analytical models have been developed to represent connection flexibility using available experimental test data. Semi-rigid connections have been modeled on available experimental test data through curve-fitting techniques. Indeed, the most commonly used approach to describe M-θ_r curve is to simulate the experimental data with simple expressions. Such models include the Frye-Morris Polynomial model, the Modified Exponential Model developed by Kishi and Chen as a refinement of Chen-Lie exponential model, and the Three Parameter Power Model proposed by Chen *et al* [all referred to in Chen and Toma (1994)], and finally the Four Parameter Power Model of Richard and Abbott [referred to in Scott and Burns (2003)].

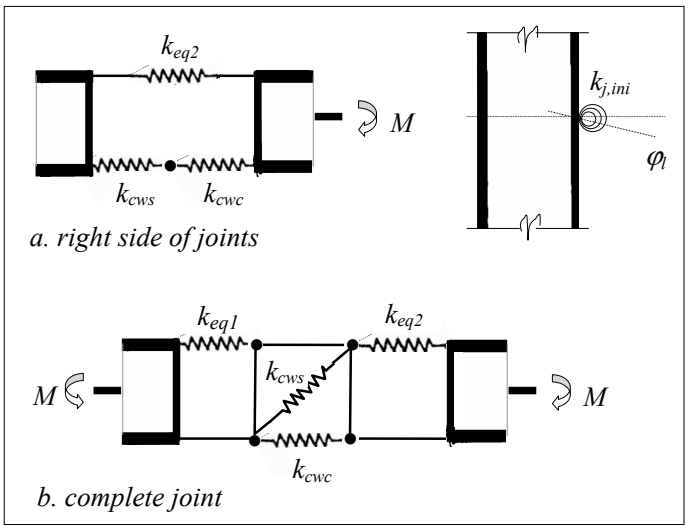

Figure 1. Spring model for the semi-rigid joint.

The finite element representation of semi-rigidly connections has also been explored. One such proposal has been by Xu [referred to in Scott and Burns (2003)]. In this modeling approach, a member is assumed to be consisting of the originally fully rigidly connected member and zero length spring elements (with spring constant equal to the appropriate secant stiffness of the semi-rigid connection it

simulates) attached to each member end. The relationship between end-moments and end-rotations of a beam can be developed. Finally, the elastic element stiffness matrix of a semi-rigidly connected member can be formulated.

The finite element modeling of semi-rigid connection takes into account geometrical non-linearity as well. The geometrical stiffness matrix has been developed by Xu [referred to in Scott and Burns (2003)] and it is specifically suited for semi rigidly connected members. The main drawback associated with this modeling approach, however, is that one needs to write an analysis program accounting for semi-rigid behavior. The other shortcoming of this model is its inability to account for the panel shear deformation.

An alternative for modeling semi-rigid connections is the so-called component-based joint modeling which is the main subject of this paper. This is a mechanical model joint in which each component is modeled by an equivalent linear spring (CEN, 2004).

Figure 1 shows a condensed model of the right side connections in which K_{eq2} is the resultant of the stiffness originating from a number of contributing parts consisting of column-web in tension, column right flange in bending, end plate in bending, angles, and bolts in tension. The springs K_{cws} and K_{cwc} represent the stiffness of the panel zone (column web) under shear and compression, respectively.

These springs are assembled to form a single bi-linear (elastic-plastic) rotational spring that models the connection and this later one is attached at the intersection of beams and columns for global analysis. The bilinear model is characterized by an initial stiffness $K_{j,ini}$ (resultant of all the components) and moment resistance $M_{j,Rd}$ which are defined, respectively, by the following expressions:

$$K_{j,ini} = \frac{h^2}{\frac{1}{K_{cws}} + \frac{1}{K_{cwc}} + \frac{1}{K_{eq}}} \tag{2a}$$

$$M_{j,Rd} = \sum F_{lt,i,Rd} h_i \tag{2b}$$

where h is the lever arm and $F_{Lt,i,Rd}$ is the resistance of each component (CEN, 2004)] (details are shown later in Figure 3).

Shear stresses in the column panel zone of the beam-column connection joint play significant role influencing the nature of the connection itself. The shear force acting on the panel zone is defined as (Bayou *et al*, 2006):

$$V_{cw} = \frac{M_1}{h}\left[\left(1 + \frac{M_2}{M_1}\right) - \frac{h}{2M_1}\left(V_{c1} + V_{c2}\right)\right] = \frac{M_1}{h}\beta_1 \tag{3a}$$

$$V_{cw} = \frac{M_2}{h}\left[\left(1 + \frac{M_1}{M_2}\right) - \frac{h}{2M_2}\left(V_{c1} + V_{c2}\right)\right] = \frac{M_2}{h}\beta_2 \quad) \tag{3b}$$

where M_1 and M_2 are the bending moments acting at the left and right side of the joint, and V_{c1} and $V_{c2,}$ are the shear forces in the upper and lower columns, respectively.

The expressions in brackets of Eqs. (3a, b) constitute the interaction factors β that are used in EC3 to define the shear forces acting on the panel zone. EC3 further simplifies Eq. (3) by omitting the beneficial effect of the shear forces V_{c1} and V_{c2} (CEN, 2004), and by limiting β to positive values less than 2.0, as in the following equation:

$$\beta_1 = \left| 1 + \frac{M_2}{M_1} \right| \leq 2 \qquad \text{and} \qquad \beta_2 = \left| 1 + \frac{M_1}{M_2} \right| \leq 2 \tag{4}$$

These β factors affect the values of the joint stiffness $K_{j,ini}$ and moment resistance $M_{j,Rd}$. However, the bending moments M_1 and M_2 and shear forces V_{c1} and V_{c2} coming from different elements (beams and columns) can only be established after a global analysis. Therefore, an initial guess of these values and a subsequent iteration procedure are needed to update the joint characteristics and to obtain the final distribution of internal forces and moments.

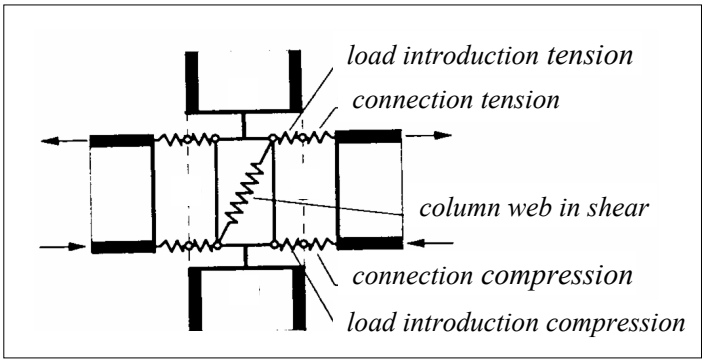

Figure 2. General model for steel joints [3]

Bayo *et al* (2006) proposed an EC3 component-based finite dimensioned elastic-plastic 4-node joint element which takes into account the actual size of the joint, its deformation characteristics (components) including those of the panel zone, local phenomenon and all the internal forces that concur at the joint. As a consequence, this new element avoids the use of the β-factor and the inherent initial guessing and iterative process that it requires. Since the element is attached to the adjacent beams and columns, the eccentricities of the internal forces coming from them are also taken into account.

For an interior joint the components are shown in Figure 1. The springs K_{eq1} and K_{eq2} represent the left and right connection stiffness, respectively. The springs K_{cws} and K_{cwc} represent the stiffness of the panel zone (column web) under shear and compression, respectively; which are usually the most critical components of the joint. All these values may be obtained by means of formulas described in EC3. Figure 3 shows the new base element with 4 nodes and 9 degrees of freedom, proposed by Bayo, *et al* in which the rigid body modes have been restrained.

The dimension *d* noted in Figure 3a is that of the width of the column, and the height *h* corresponds to the lever arm defined in EC3, Part 1.8 (CEN, 2004).

This base element will be used to obtain the basic flexibility and stiffness matrices. Afterwards, the contribution of the rigid body modes will be added to obtain the complete stiffness matrix in terms of the 12 degrees of freedom shown in Figure 3b.

In order to develop the flexibility matrix the following deformation modes are considered:

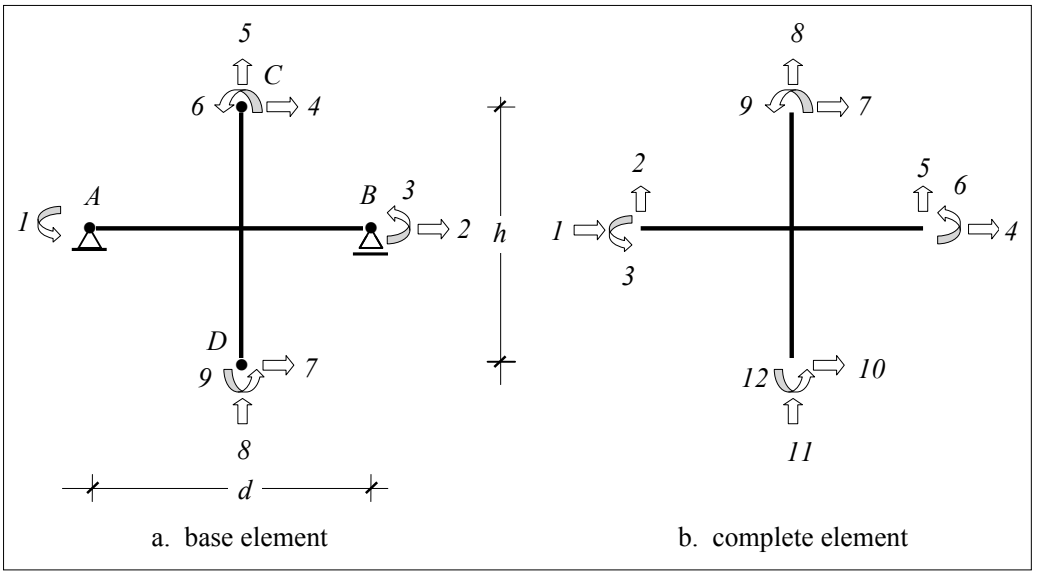

Figure 3. Degrees of freedom of the base element and complete element

- Shear deformation of the panel zone
- Tension and compression of the panel zone
- Column flange and end-plate under bending
- Elasticity and configuration of the bolts
- Bending deformation of the column
- Axial deformation of the column

Due to the stiffening effect of the column flanges the segment AB (see Figure 3) is assumed to be rigid under the shear forces coming from the beams. Thus, considering the remaining 9 degrees of freedom of element of Figure 3a and the deformation modes, the resulting non-zero elements of the upper triangular part of the flexibility matrix are derived and these are given by the various terms as in Eq. (5) in which A_c and I_c represent the area and moment of inertia of the column, respectively. All other terms F_{ij} not shown in Eq. (5) are of zero value.. The bilinear behavior of the springs is defined according to the values given by EC3.

Once the flexibility matrix has been obtained, the *basic stiffness matrix* may be calculated through matrix inversion as in $\mathbf{K}_b = \mathbf{F}^{-1}$**.** Following standard procedures in matrix structural analysis, the rigid body modes may be added by means of a transformation matrix ***T*,** which is shown in Eq. (6).

Thus, the basic stiffness $\boldsymbol{K}_b$ may be transformed to obtain the general stiffness matrix in terms of the twelve degrees of freedom (Figure 3b) as $\mathbf{K} = \mathbf{T}\mathbf{K}_\mathbf{b}\mathbf{T}^{\mathrm{T}}$.

3.2 *Simplified Two-Node Component-Based Joint Model*

The four node element proposed in the previous section is not suitable to use in many commercial software systems available to practicing or research engineers. In order to use the standard element library MATRIX27 of ANSYS (2005), for example, a two node element is proposed as shown in Figure 4. The shear spring introduced represents the web panel deformation of the column web. This shear spring is assumed to be rigid in the horizontal direction but flexible in the vertical and rotational directions.

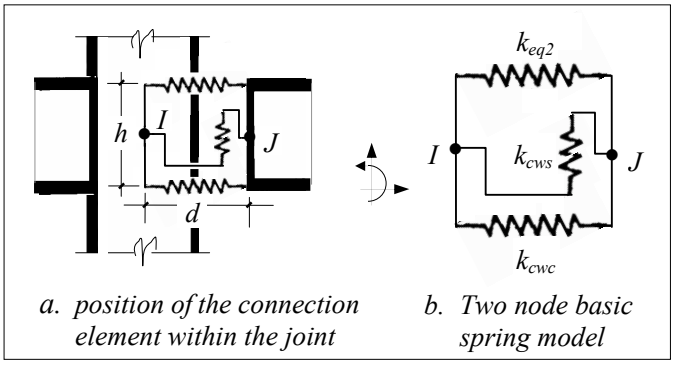

Figure 4 Position and simplified effective modeling of semi-rigid connections.

In order to derive the stiffness matrix of the connection element, the simplest case of the element with only three springs is considered, as shown in Figure 4b. As in the original component method it is assumed that a joint will primarily deform in its plane, and all other out of plane and torsional degrees of freedom (DOF) are assumed to be rigidly connected. This reduces the problem to a two node element with three DOF per node, suitable to use available routines already implemented in high-end structural-engineering products such as, for example, the stiffness matrix element MATRIX27 in the ANSYS library. If now each of these DOF is activated individually, as shown in Figure 5, and the resulting spring forces are calculated, it is possible, with the help of some geometrical considerations and the spring characteristics, to derive the stiffness matrix of the basic connection element.

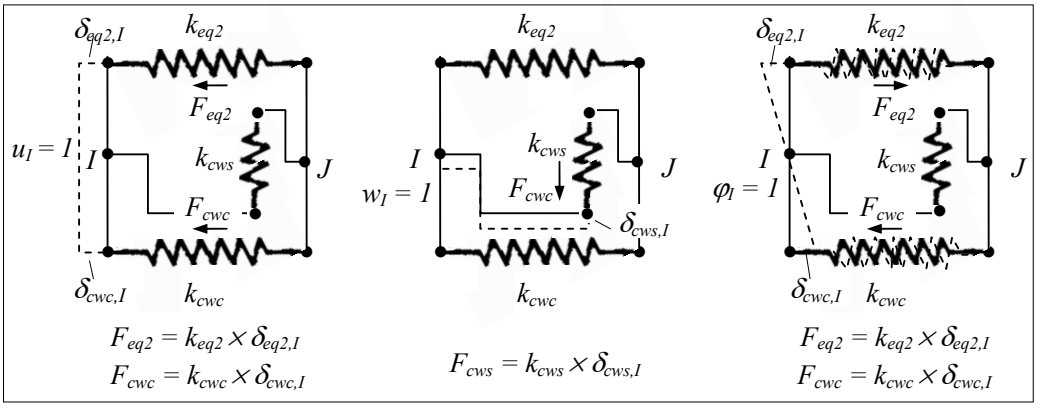

Figure 5. Derivation of stiffness terms for Node I of the basic connection element.

The stiffness matrix, generated in the manner, for the *basic* two-dimensional connection element is shown in Eq. (7).

$$\boldsymbol{K}_{el} = \begin{bmatrix} K_1 & 0 & -\frac{h}{2}K_2 & -K_1 & 0 & \frac{h}{2}K_2 \\ 0 & K_{cwc} & 0 & 0 & -K_{cwc} & 0 \\ -\frac{h}{2}K_2 & 0 & h^2K_3 & \frac{h}{2}K_2 & 0 & -h^2K_3 \\ -K_1 & 0 & \frac{h}{2}K_2 & K_1 & 0 & -\frac{h}{2}K_2 \\ 0 & -K_{cwc} & 0 & 0 & K_{cwc} & 0 \\ \frac{h}{2}K_2 & 0 & -h^2K_3 & -\frac{h}{2}K_2 & 0 & h^2K \end{bmatrix} \tag{7}$$

where, for brevity, the following substitutions have been used:

$$K_1 = K_{cwc} + K_{eq2} \qquad K_2 = K_{eq2} - K_{cwc} \qquad K_3 = \frac{1}{\frac{1}{K_{cwc}} + \frac{1}{K_{cws}} + \frac{1}{K_{eq2}}}$$

This is the desired stiffness matrix for the simplified, two-nodes semi-rigid beam-to-column connection model. The computational quality of this element matrix has been verified and validated on a series of frame models (Aure, 2007).

3.1 NUMERICAL EXPERIENCE

An extensive set of plane frames have been investigated among which the fairly simple two-story frame shown in Figure 6 is presented herewith in order to verify and validate the proposed two-node element formulation of semi-rigid joints.

The characteristics of the connections, computed based on EC3 component-based method, are provided in Table 1 and the locations of the joints are illustrated in Figure 6. ANSYS library element MATRIX 27 has been used to model the proposed two node element.

The connection region of the column has been allowed for shear deformation. The output result is given in Table 3.3. Comparison of moments (kNm) at the joints and beam mid-spans is shown. The results indicate that the moments at the semi rigid joints reduced significantly (which will reduce the cost of connection detailing).
The results are tabulated in Table 3.1. As can be seen from the table the proposed model provides comparably good result as compared to EC3 approximate analysis and the four node accurate element proposed by Bayo *et al.*

CONCLUDING REMARKS

In this study a two-node simplified connection element is proposed. The panel shear deformation of the joint has been taken care of by allowing the joint region of the column to undergo shear deformation.

The proposed model has given a good result as compared to the EC3 component method, using the interaction parameter $\beta-$factor. Though there are some discrepancies between the results obtained by Bayo *et al* and the proposed model at some locations, findings are generally within ranges acceptable for design purposes. The analysis response of the frames has indicated that a reduction in the joint moment is accompanied by an increase in the span moments. Reducing joint moments is advantageous as detailing, modeling and design of joints is the most cumbersome part of steel frame design.

Though there is an increase in moment at mid spans, usually steel sections, especially if laterally restrained, will be capable of resisting these moments as compared to the support region.

ABSTRACT

In mid-to-high rise structures, dual systems (DS) enable a structural designer to satisfy the stringent drift limitations of current codes without compromising ductility. Currently, ASCE 7-05 permits a variety of structural systems to be used in combination as a dual system yet the design requirements are limited to the following: Moment frames must be capable of resisting 25% of the seismic forces while the moment frames and braced frames or shear walls must be capable of resisting the entire seismic forces in proportion to their relative rigidities.

This paper assesses the significance of the 25% design requirement for the secondary moment frames (SMF) in dual systems with consideration of current structural engineering practice. Three 20-story buckling-restrained braced frame (BRBF) dual system structures have been designed with varying relative strengths between the braced and special moment frame systems. The SMF system has been designed for 15%, 25%, and 40% of seismic demands and the BRBF system design has been adjusted accordingly based on its relative stiffness with respect to the moment frame. These structures have been examined with nonlinear static and nonlinear dynamic procedures with guidance from ASCE 41-06.

The drift, displacement and ductility demands, and the base shear distribution results of this study show similar responses of the three prototype structures. These results indicate a secondary moment frame designed to less than 25% of seismic demands may be adequate for consideration as a dual system regardless of the 25% rule.

INTRODUCTION

Design requirements for dual systems were first written into code in the 1959 SEAOC Blue Book and the 1961 UBC. Currently, ASCE 7-05 permits a variety of structural systems to be used in combination as a dual system yet the system specific design requirements are still limited to the following: “For a dual system, the moment frames shall be capable of resisting at least 25% of the design seismic forces. The

total seismic force resistance is to be provided by the combination of the moment frames and the shear walls or braced frames in proportion to their rigidities" (ASCE 2006).

Specifically, dual systems comprised of steel moment resisting frames (MRF) with reduced beam sections (RBS) and buckling-restrained braced frames (BRBF) provide benefits from both an architectural as well as a structural standpoint. While the MRFs maintain space flexibility and architectural openness, the BRBFs help provide stiffness and control interstory drifts in mid-to-high rise structures (SEAOC Seismology Committee 2007). This drift control by the BRBFs is particularly apparent in the lower levels. In the upper levels, the MRFs will be a more effective system for drift control. This behavior is illustrated in Figure 1 where the idealized resultant DS displaced shape is linear with respect to the buildings height (Maley et al. 2010).

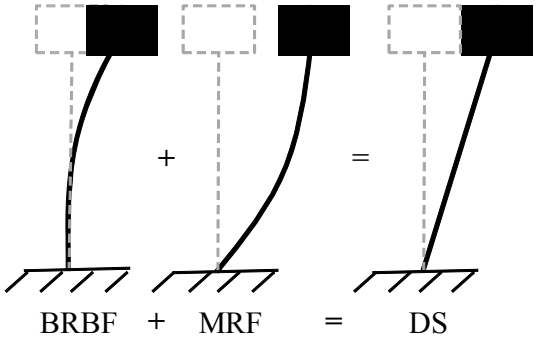

Figure 1: Simplified displaced shape of respective systems in tall buildings

Buckling-restrained braces (BRBs) provide damping to a structure in the event of the earthquake due to their low post-yield stiffness and hysteretic behavior. Typically, while dissipating energy, this behavior causes relatively large residual displacements after a large earthquake. Providing a MRF to remain elastic until after the BRBF yields allows force re-distribution from the BRBFs to the MRFs to restrict these large displacements and protect the structure. Using both MRFs and BRBFs together in a dual system allows the benefits of both systems to be utilized and the short-comings of both the BRBFs and MRFs to be mitigated by the other (EERI 1994).

The purpose of this paper is to compare the inelastic behavior of three dual system models specifically designed for this analysis. The effect of designing a secondary system for 15% (not meeting code requirements), 25%, and 40% (exceeding code requirements) of the base shear has been examined through nonlinear static pushover (NSP) and response history analysis (RHA) and conclusions are drawn from the effects of the backup system strength on the behavior and intent of a the dual system.

PROTOTYPE MODELS

A 20 story building was chosen to be examined for this study, with a rectangular plan of dimensions 144′ by 100′. The 2-dimensional analysis represented

the lateral force resisting system of the structure in one direction. One exterior braced frame line was modeled in series with an interior moment frame line connected by a rigid diaphragm. The typical bay sizes in the direction modeled are 24′-0″ with story heights of 13′-0″ and an 18′-0″ first floor lobby (Figure 2). The alternating pattern of the braces on the building elevation helps reduce column sizes by coupling the tension and compression braces.

Similar gravity loading criteria was used from the SAC project for assessment of moment frames in response to the 1994 Northridge Earthquake (FEMA 355C).

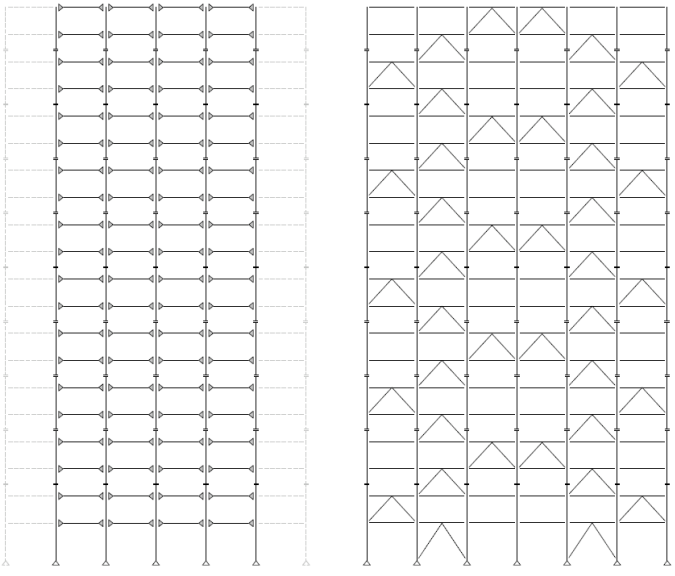

Figure 2: Elevation of dual system

The prototype structures were designed for a theoretical location of Los Angeles, California. Per the United States Geological Survey (USGS), the maximum spectral acceleration seen at the site is approximately 2*g* for short period buildings, and attains around 0.25g for long period structures. Based on ASCE 7-05 including supplement II, the upper limit fundamental period (1.8 seconds) and the minimum base shear governed the design of the structure. For an overall building weight of 29,000 kips distributed evenly among the floors, the total calculated base shear of the structure is approximately 6% of the total building weight. A Response Modification Coefficient of R= 8 was adopted per ASCE 7-05 Table 12.2-1.

Three separate buildings were designed for this analysis. The baseline model is a dual system with a backup special moment-resisting frame (SMRF) designed for 25% capacity of the seismic demands on the structure. Results reported are bound by two other models with a backup SMRF designed to 15% and 40% strength.

DESIGN PROCEDURE

The three step design procedure below was used for the prototype models in this analysis as described by Magnusson, 1997:

1. Design BRBF for full lateral resistance based on the equivalent static force procedure given in ASCE 7-05 §12.8.

2. Design SMRF for 15%, 25%, and 40% of demands per ASCE 7-05 §12.8.
3. Combine systems and reduce BRBF designs based on the relative rigidity of the BRBF to SMRF using modal response spectrum analysis as described in ASCE 7-05 §12.9.

The design utilized ASTM A992 Grade 50 steel (yield stress of 50 ksi) for all beams and columns. The BRB core yield stress was taken as 38 ksi for design. In order to develop an anticipated yielding sequence from the top of the structure down, demand-capacity-ratio (DCR) values were most conservative at the bottom levels and near unity at the top of the structure.

Typical brace core areas in Models 15, 25, and 40 are 2.0 in^2 at the roof for all structures, and 10.75 in^2, 10.5 in^2, and 10.25 in^2 at the first floor, respectively. SMRF beams used are W21x44, W21x44, and W21x50 at the roof and W21x50, W24x76, and W24x94 at the first level for Models 15, 25, and 40, respectively. Columns at the first floor are W14x455 and W14x550 for the interior braced frame and moment frames respectively in Models 15 and 25 and W14x455 and W14x605 for the interior braced frame and moment frames respectively of Model 40. W14x53 columns are used at the roof of each braced frame and the SMRF of all three models uses W14x132 columns. Additional member sizes and model information is provided in Aukeman, 2011.

Static analysis of the design forces show the stiffness ratio of the MF to BF of Model 15, 25, and 40 is 17%, 19% and 22% respectively.

MODELING FOR NONLINEAR ANALYSIS

Nonlinear elements used in Perform 3D are BRB element compounds, moment-rotation hinges for reduced beam sections and BRBF beams outside gusset connections, P-M2-M3 (PMM) Rotation Hinges for columns to consider the axial moment interaction. In addition, elastic section properties were assigned to beams and columns where nonlinear behavior was not expected and rigid elements at beam-column intersections and gusset locations in the BRBF.

The base of the SMRF elevation was assumed to be pinned with a large steel grade beam while the BRBF columns were fixed where the braces are located at the foundation and pinned elsewhere. All elements were modeled with expected yield stresses (55 ksi for beams and columns and 46 ksi for braces).

NONLINEAR ANALYSIS

The nonlinear response of the building was assessed by means of nonlinear static (pushover) and nonlinear dynamic analyses.

Nonlinear Static Analysis. A modal pushover was executed to reveal the relative behavior between the BF and MF for each model. Loading was applied based on the first mode force distribution where story forces vary with respect to story elevation as calculated in the linear static procedure.

The total base shear and the base shears in the braced frame and moment frame are shown below in Figure 3 as a function of the roof drift angle. For each model, the target displacement δ_t was calculated based on the modal pushover analyses for the design earthquake values using ASCE 41-06 §3.3.3.3.2 and is indicated in Figure 3 around 0.0068 radians or 22 inches roof displacement.

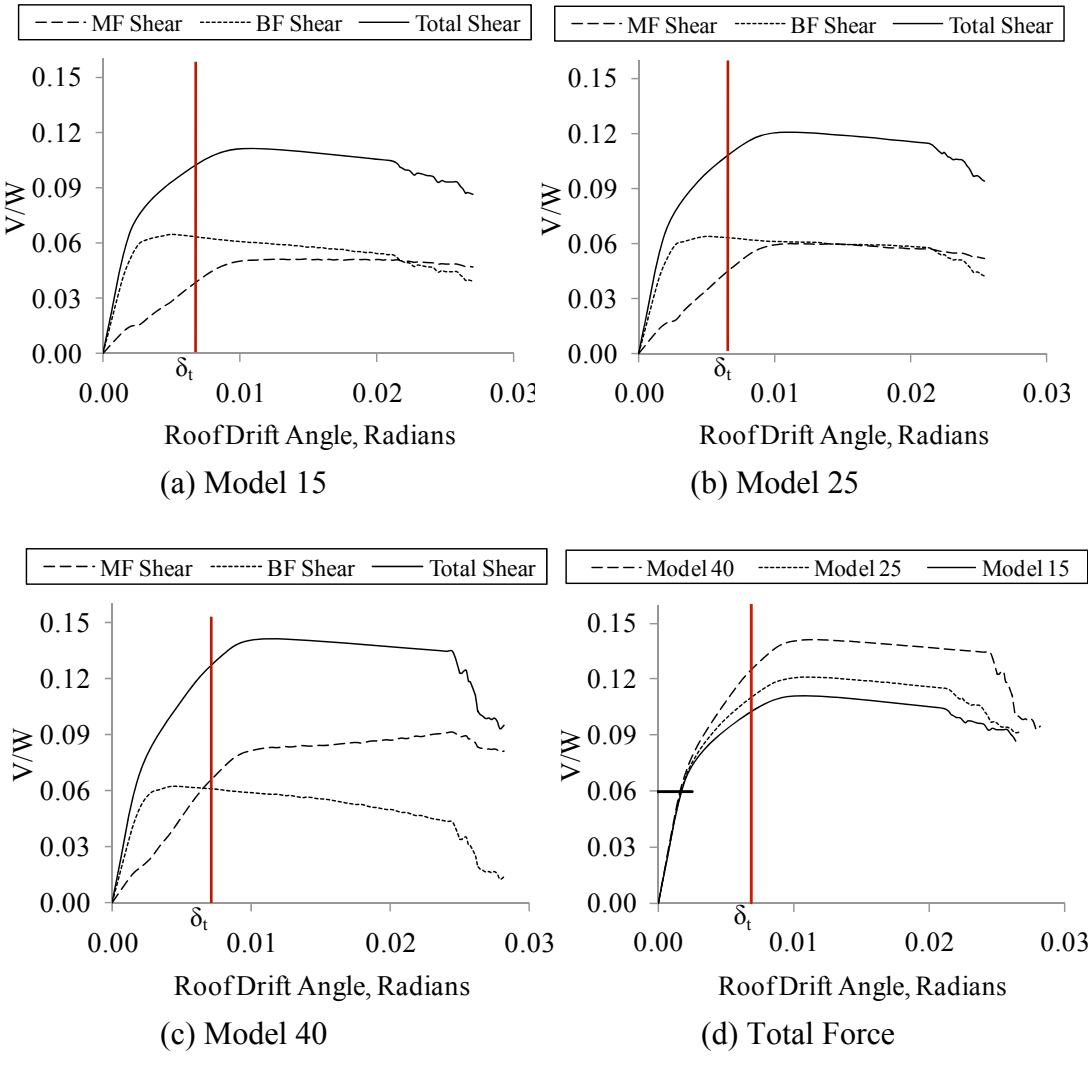

Figure 3: Modal Pushover Force Displacement Curves

The base shear value that causes first yield is approximately equal to the design base shear of 0.06W (see Figure 3 (d)). In the figures below the yielding of the braces at the upper levels cause the initial change in stiffness; however the capacity continues to increase as the conservatism of design is apparent as a result of safety factors, the gradual propagation of yielding and strain hardening. For all three models, failure is caused by a lower level column being loaded beyond its allowable axial-flexure interaction envelope and the pushover analysis is stopped. While this is not a desirable failure mechanism, the structure has been loaded well beyond its design force and has displaced to beyond 0.025 radians (6'-8") or almost four times the target displacement, δ_t, as described in ASCE 41-06.

Figure 3 (c) shows the uniqueness of Model 40 and the MF has a significantly higher capacity than the BRBF. Since ASCE 7-05 allows a reduction in strength of the braced frame (based on stiffness), the overall force displacement relationships of the different models were compared for each load pattern. Small strength reductions were made to the braced frames due to the small relative stiffness of the MF to the BF. With these reductions, the largest difference in force-displacement relationship was seen as a result of the moment frame strength rather than the reduced braced frame strength. This can be observed in Figure 3 as each BRBF has approximately the same maximum strength equal to 0.06W.

Nonlinear Dynamic Analysis. To explore the variability of seismic ground motions, a suite of 7 earthquakes were selected and the median and 84th percentile response quantities are reported below. The 7 records were scaled to the design spectrum using the amplitude scaling procedure according to ASCE 41 1.6.2.2. A list of ground motions, their unscaled peak ground accelerations and the amplitude scale factors used for this analysis is shown in Table 1. The response spectrum for the suite is shown below in Figure 4.

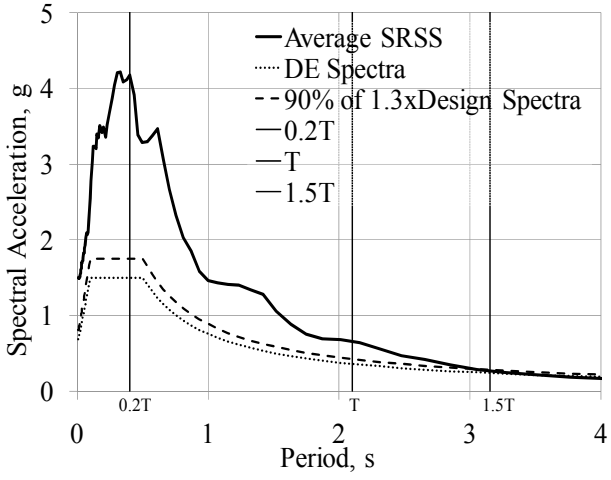

Table 1: Earthquake record data

Earthquake	Record Station	PGA (g)	Scale Factor
Northridge	Canoga Park	0.36	2.15
Loma Prieta	Capitola	0.53	2.55
Imperial Valley	Bonds Corner	0.78	2.03
Imperial Valley	El Centro	0.35	2.18
Kalamata	Kalamata	0.25	3.88
Coalinga	Pleasant Valley	0.38	3.52
Northridge	Saticoy Station	0.37	1.77

Figure 4: Earthquake spectral scaling for response spectrum

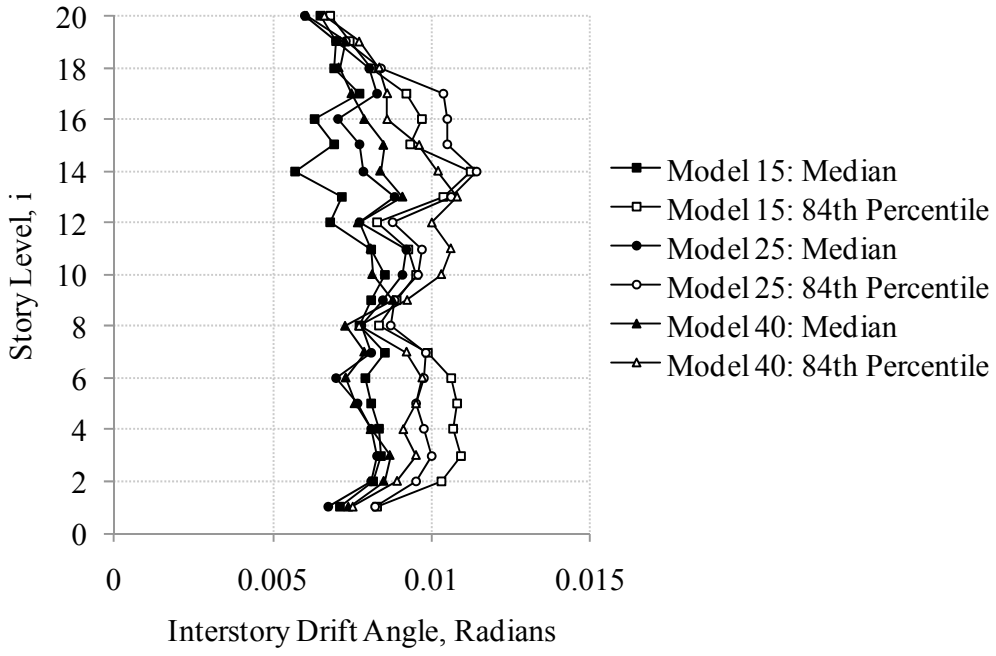
BRB hysteresis properties and modal damping of 1.9% has been assigned in Perform 3D along with a small 0.1% Raleigh damping at 0.5T and 1.5T (varying at other periods) to account for additional damping in short period modes.

For all three models, only the El Centro record induced deformations high enough to terminate the analysis. This ground motion exhibited a large pulse around 6.0 sec into the record causing large roof displacement and high ductility demands in the BRB elements that cause termination. All data from the El Centro record includes only building response data for the first 6.5 seconds (or until the maximum allowable BRB deformation of 15 times the yield displacement is reached). The remaining 6 records did not cause deformations beyond the elements maximum deformations.

For the results presented from the response history analysis, the median and 84th percentile values have been indicated. The median is reported as the value of the 4th highest result of the 7 records while the 84th percentile result is approximated as

data point 6 (since 6/7=0.86 which is nearest 0.84). The 84th percentile value can be regarded as the median response plus one standard deviation. This method was used in FEMA 355C for the SAC project when one or more earthquake records caused failure of the structure

Interstory Drift. The median and 84th percentile values for the maximum interstory drift angle for each level (not concurrent) are shown in Figure 5.



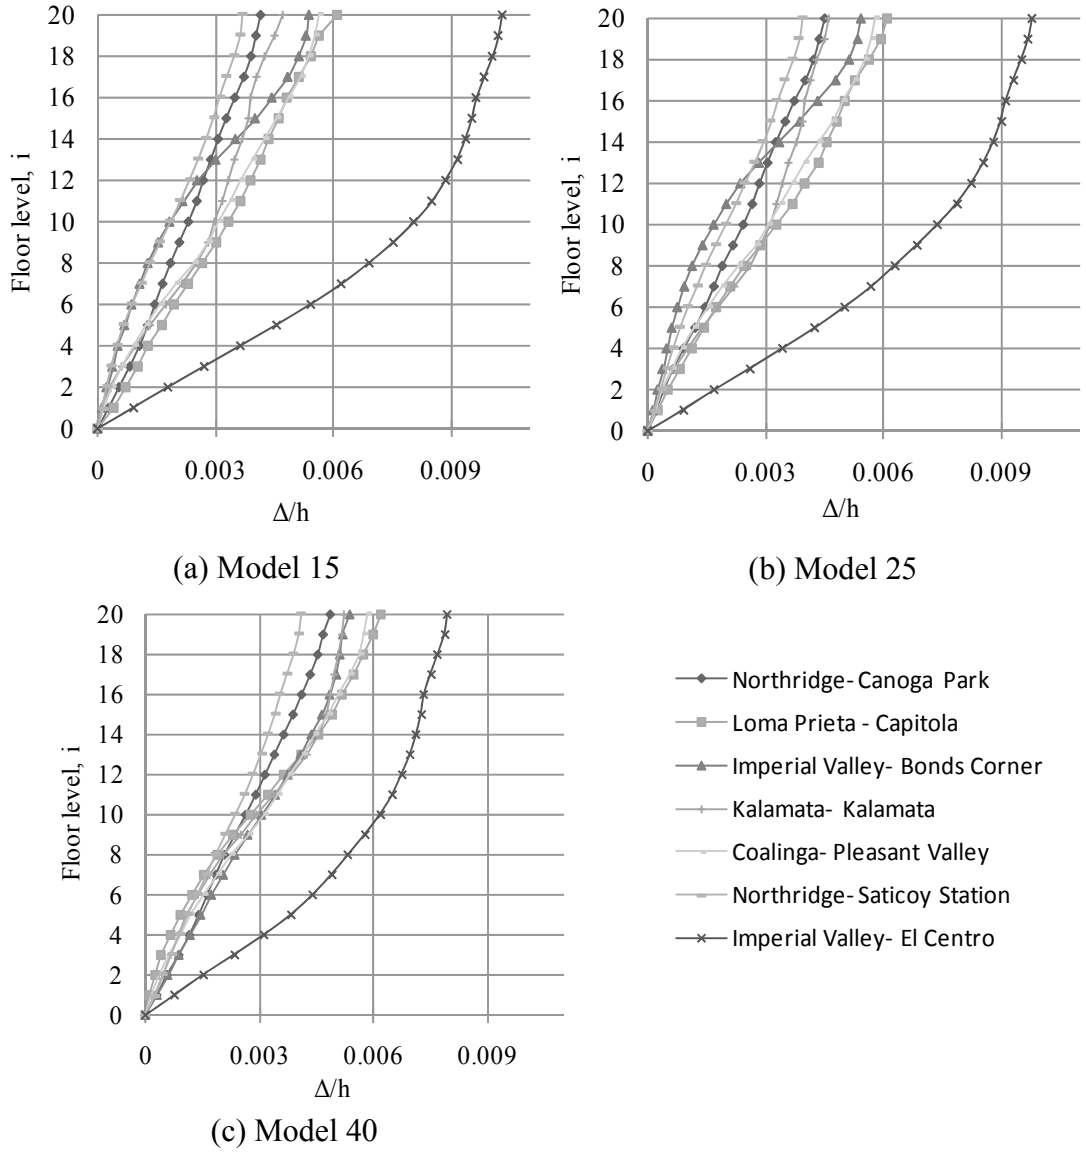


Figure 5: Nonlinear dynamic interstory drift results

The varying design criteria between models results in unique interstory drift demands. Model 25 experiences the overall highest 84th percentile interstory drift ratio equal to 0.012 radians at level 14. Model 15 experiences the largest range of drift values as the difference between the median and 84th percentile results is the highest. As the moment frame strength increases in the models, the range between the median and 84th percentile results decrease. Different trends can be observed for the upper and lower portions of the structure as an inflection point is observed near level 9. This behavior corresponds to the way the BF and MF engage each other as shown in Figure 1. These results show that no conclusive statement can be made about which design is optimal for minimizing interstory drift. ASCE 7-05 provides a limit of $0.020h_{sx}$ for drift in Table 12.12-1. Figure 5 shows that all three models performed well within the code limits for interstory drift. If a stricter drift limit of $0.010\ h_{sx}$ is used, only Model 40 would pass. Such a drift limit could be applied to high performance structures and hospitals.

Displacements. The displaced shape corresponding to the maximum roof displacement normalized by the roof height is displayed in Figure 6. Similar behavior is observed between the three models. The magnitude of the median roof drift is

approximately 0.005 for each model which is less than the target displacement roof drift of 0.0068 radians.

The displacement data of Model 40 shows the least variability between earthquake records while Model 15 demonstrates more scattered results at the lower levels. For all three structures the El Centro record induced the highest roof displacements. For the El Centro ground motion specifically, the stronger moment frame structures underwent less roof displacement at the time the lowest level braces reached their maximum allowable ductility.

(a) Model 15

(b) Model 25

(c) Model 40

Figure 6: Nonlinear Dynamic Maximum Roof Displacement

Ductility. For each structure, the ductility ratios have been calculated as the ratio of element demand to yield capacity. As shown below in Figure 7, the 84th percentile RBS ductility ratio for all three models ranges from 1.25 to 1.75 which classified by

ASCE 41-06 as the Immediate Occupancy performance category. This means that only mild plastic behavior was seen from the RHA. The 84th percentile results also show Model 40 is likely to see the least ductility demand in an earthquake.

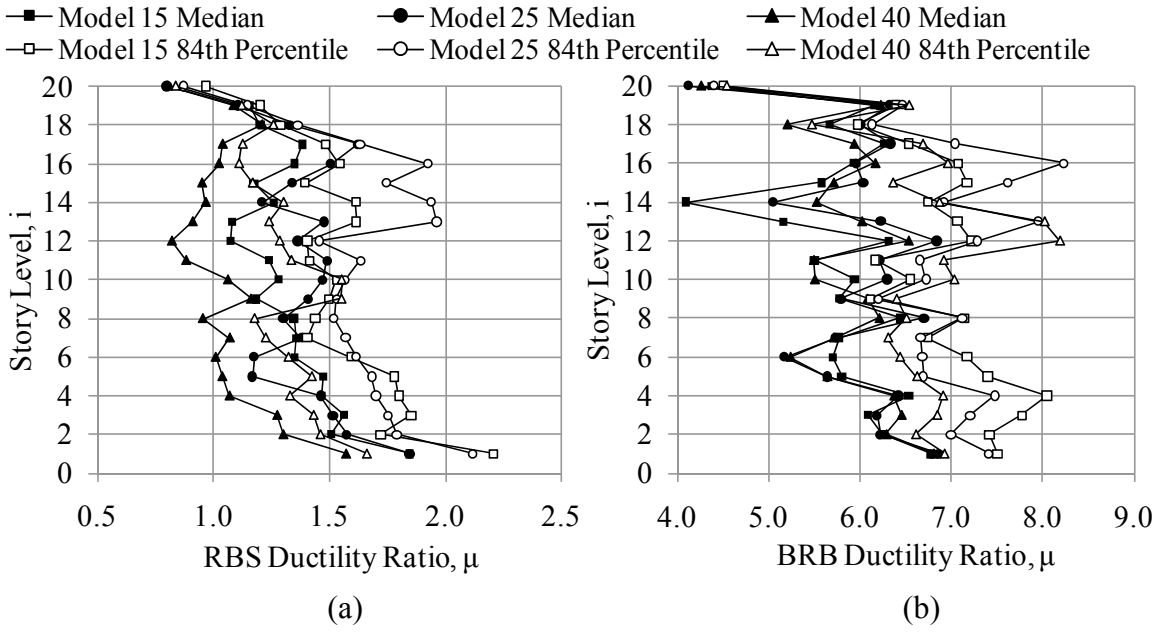

Figure 7: Nonlinear Dynamic Ductility Ratios

The results for maximum BRB ductility demands reported in Figure 7 for levels 1 through 9 show a clear trend in the 84th percentile data as Model 40 experiences the least ductility and Model 15 experiences the most. 84th percentile ductility values at levels 12 through 16 correspond to relatively higher interstory drifts in Figure 5. In the case of model 25, where BRB ductility is highest, the RBS ductility is also higher as demands shed from the BRBF into the MF as intended.

The 84th percentile results of all three models for BRB ductility in Figure 7 (b) range from 6.5 to 8.0. BRB element testing shows core yielding beyond 15 times the yield displacement is unsafe. For all BRB elements in the three models, the 84th percentile data presented above is also within the Immediate Occupancy to Life Safety range. Both RBS and BRB ductility responses show the 3 prototype structures behave similarly.

Base Shear. The median values for the base shear distribution is shown below for the instant at which the total base shear was a maximum in the Nonlinear Dynamic (ND) analysis (Figure 8 (a)) and the instant at which the MF shear was a maximum (Figure 8 (b)). These results show the total ND base shear demands far exceed the overall design base shear of 0.06W. Also, the nonlinear force distribution shows the MF appropriately take on more load as the structure yields to maintain drift control during the ND analysis. For all three models, the MF shear demands are approximately 50% or more of the overall shear. In Figure 8 (b), when the MF resists the maximum load, the shear distribution ratio is greater than 50%. The maximum total base shear imposed on Model 25 (and similarly Models 15 and 40) exceeds the ultimate capacity

shown in Figure 3. Aside from the difference in procedure, the hysteretic behavior of the BRB elements has been modeled explicitly based on test data. Due to cyclic strain hardening the capacities of the BRB elements increase as the members cycle back and forth.

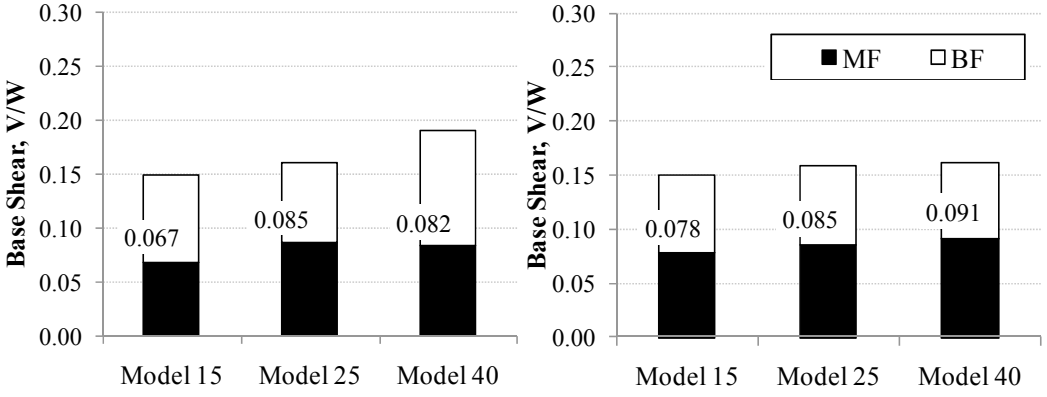

Figure 8: (a) Median ND total base shear. (b) Median ND base shear at maximum MF base shear.

CONCLUSION

Drift and displacement demands did not show one model as performing significantly better than another. The MF designed to 40% of the design base shear resulted in the least scatter of results from the 7 ground motions, however all models performed adequately based on ASCE 7-05. The general displacement profile for each structure was close to linear as expected for a BRBF and MF Dual System.
In terms of 84th percentile demands from the RHA, the interstory drift demands remained below 0.012. The ductility demands for the BRBs remained below 8.3, well within the acceptable range. The RBS ductility demands attained by the MF are approximately 2—only mildly inelastic.

As expected, the story shear results showed that the stronger moment frames resisted the highest base shear in the nonlinear pushover as well as the response history analyses in general.

Shear reversal (MF and BRBF working against each other) was observed in levels where braces occurred in adjacent interior bays. The implications of such shear reversal are unclear and should be examined further. This is related to the alternating brace patterns.

ASCE 7-05 requires a secondary system to be designed for a minimum of 25% of the seismic base shear; however the results show that the Model 15 performs similar to the Model 25. Thus there appears to be no clear argument to not categorize it as a dual system. Clearly, the design technique presented here for a dual seismic force resisting system provides a high performance structure. This paper shows that advanced analysis is required in order to fully quantify the system performance and required MF strength with respect to the performance criteria, and to quantify the added cost of the backup MF system.

This paper shows that the 25% design rule at best is arbitrary. It should be investigated if a better design rule could be based purely on strength distribution between the BRBF and MF, e.g. 75%/25%. Otherwise the BRBF design hardly changes with varying MF strength causing uneven levels of conservatism.

The allowed strength reduction of the BRBF (step 3 in design procedure) was relatively small for these systems and did not cause any deficiencies in the dual system performance.

Overall, all models were found to easily satisfy the drift and ductility limitations. However, for a more complete picture of the dual system performance, an additional study should be completed for a pure BRBF to quantify the MF contribution to the overall dual system behavior.

The results presented above may vary dramatically between dual system types as well as building layouts. It is suggested that this research may be continued with additional variations to better understand the design implications of mixing stiff and flexible systems in a dual seismic force resisting system.

Abstract: Tampa international airport interchange consists of two sub-interchanges: Courtney Campbell Causeway (CCC) and Spruce Street/S.R. 60 sub-interchanges. The objective of this paper is to present the unique and economic design of the steel bridges in the CCC sub-interchange. First, a brief description of the whole project is given. Then, a detailed discussion is presented of the most important bridge design issues influencing the selection of the best bridge alternative. Finally, some unique and innovative designs are discussed. The information presented in this paper is of benefit to both the novice and experienced bridge engineers.

INTRODUCTION

Tampa international airport interchange includes 10 steel bridges, 9 concrete bridges, and 43 permanent retaining walls. All of the steel bridges are curved I-girder bridges with a total length of over 2734.1 m (8,970 ft), many of them with very sharp skew angles and difficult site and geometric constraints. The interchange was designed in 2004; the construction of this mega project was started in 2005 and finished in 2010, at a cost of approximately $230 million. The interchange consists of two sub-interchanges: Courtney Campbell Causeway (CCC) and Spruce Street/S.R. 60 sub-interchanges. The CCC interchange improvements consist of major reconstruction replacing the existing interchange at SR 60 (Memorial Highway) and the Courtney

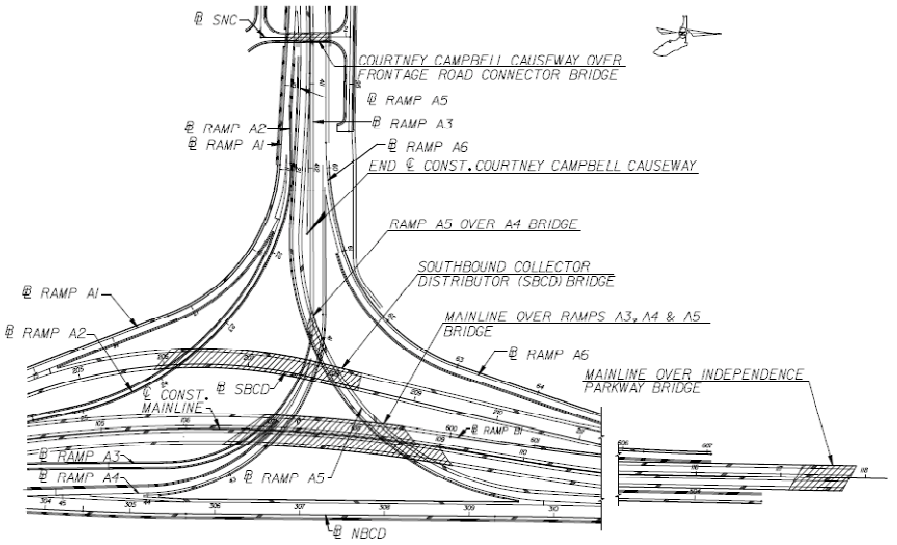

Fig.1. Bridges Layout

Campbell Causeway (CCC) with a three leg multi-level directional interchange (Fig. 1). Changes to increase traffic capacity and safety of the interchange included geometric revisions, an increase in the number of travel lanes and the elimination of two traffic signals. The project limits extend from Courtney Campbell Causeway at approximately Sta. 400+50 to the Express Lane Centerline Sta. 100+00 (South of Fish Creek). Improvements also included construction of the Mainline Express Lanes and Collector-Distributor (CD) roads from Sta. 100+00 to approximately Sta. 117+80. The Mainline Express Lanes provide a connection to the Veterans Expressway which begins at the northern terminus of this project. This project was coordinated with, and designed to match the SR60/Spruce Street Interchange at the Southern Terminus; the Veterans Expressway at the North Terminus; and the existing Courtney Campbell Causeway which consists of a 6-lane divided roadway at the Western Terminus. There are five bridges within the limits of this project. The paper focuses on the discussion of unique and innovative designs of three bridges: Southbound CD Bridge, Ramp A5 over A4 Bridge and SR 589 Mainline over Ramps A3, A4 and A5 Bridge.

SOUTHBOUND CD BRIDGE

The baselines of Southbound CD and all the ramps are on curved alignments. The minimum vertical clearance is 5.05 m and the total bridge width is 22.55 m with four travel lanes and two shoulders (see Fig. 2).

There was a partial overlap between the existing and proposed SBCD movements. Therefore, the bridge design proceeded with a staged construction scenario. Stage 1 construction (toward the outside of the curve) was 12.485 meters followed by a 8.615 meter wide Stage 2 construction (toward the inside of the curve). Stage 3 construction was a 1.45 meter closurepour.

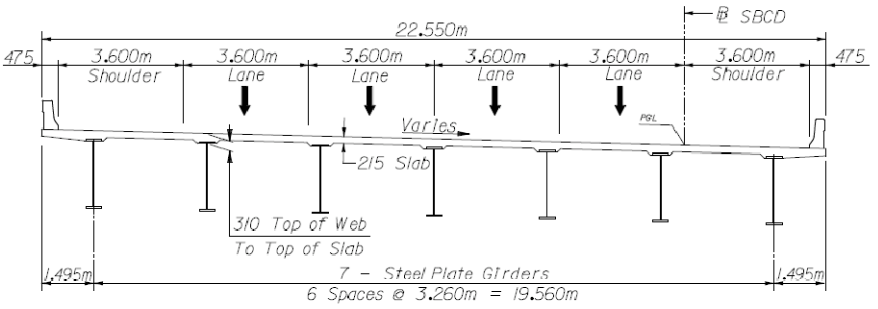

Fig.2. Southbound CD Bridge Section

Five alternatives were investigated during the project development phase and four of them will be discussed.

Alternative 1

The span arrangement for Alternative 1 consists of four spans with a steel plate girder superstructure and radial substructure (Fig. 3 (a)). End bents and piers are placed normal to the baseline of Southbound CD. The required clear zone of 4.2 meters to

the south end bent of the bridge has been provided on the south side of Ramp A2. Similarly, a clear zone of 5.7 meters has been provided on the north side of Ramp A2. A pier is located between Ramps A4 and A5 and a barrier was provided on both sides of the pier in lieu of the clear zone. A barrier is also provided on the north side of Ramp A5. This barrier, on the north side of Ramp A5 is required for the span arrangements of the bridges immediately to the east (SR 589 Mainline over Ramps A3, A4 and A5 Bridges) and the MSE wall and bridge immediately to the west (Ramp A5 over A4 Bridge), and therefore, is provided for the Southbound CD bridge for purposes of continuity. The barrier is provided just outside the sight distance line which is 4.4 meters from the edge of the lane. The resulting span arrangement is a four span structure with spans of 71.880 m + 71.870 m + 68.220 m + 45.630 m with a total bridge length of 257.600 m along the Southbound CD baseline.

Alternative 2

The span arrangement for Alternative 2 consists of four spans with a steel plate girder superstructure and skewed substructure (Fig. 3(b)). The skews are limited to a maximum of 45 degrees for this alternative. The horizontal clearances are similar to those of Alternative 1. The resulting span arrangement is a four span structure with spans of 57.610 m + 70.268 m + 70.285 m + 49.007 m for a total bridge length of 247.170 m along the Southbound CD baseline.

Alternative 3

The span arrangement for Alternative 3 consists of five spans with a steel plate girder superstructure and skewed substructure (Fig. 3 (c)). The skews are limited to a maximum of 30 degrees for this alternative. The horizontal clearances are similar to those of Alternative 1. The resulting span arrangement is a five span structure with spans of 62.040 m + 63.280 m + 49.360 m + 36.410 m + 42.260 m for a total bridge length of 255.350 m along the Southbound CD baseline. The alternative with two superstructure units (Span 1 and 2 as Unit 1 and Spans 3, 4 and 5 as Unit 2 was considered. The advantage of having two units would be the ability to optimize the structure depths for the larger spans in Unit 1 and the smaller spans in Unit 2 separately. The disadvantage would be the compromised aesthetics (with the variable structure depths within one bridge) and the introduction of an additional expansion joint. Considering that the cost advantage for the two unit arrangement is likely to be minimal, it was proposed to construct the five spans as one continuous unit.

Alternative 4

The span arrangement for Alternative 4 consists of five spans with a steel plate girder superstructure and normal substructure (Fig. 3(d)). A five-span single-unit superstructure is used as discussed for Alternative 3. The horizontal clearances are similar to those of Alternative 1. The span arrangement is a five span structure with spans of 63.380 m + 57.000 m + 47.960 m + 36.410 m + 44.350 m for a total bridge length of 249.100 m along the Southbound CD baseline.

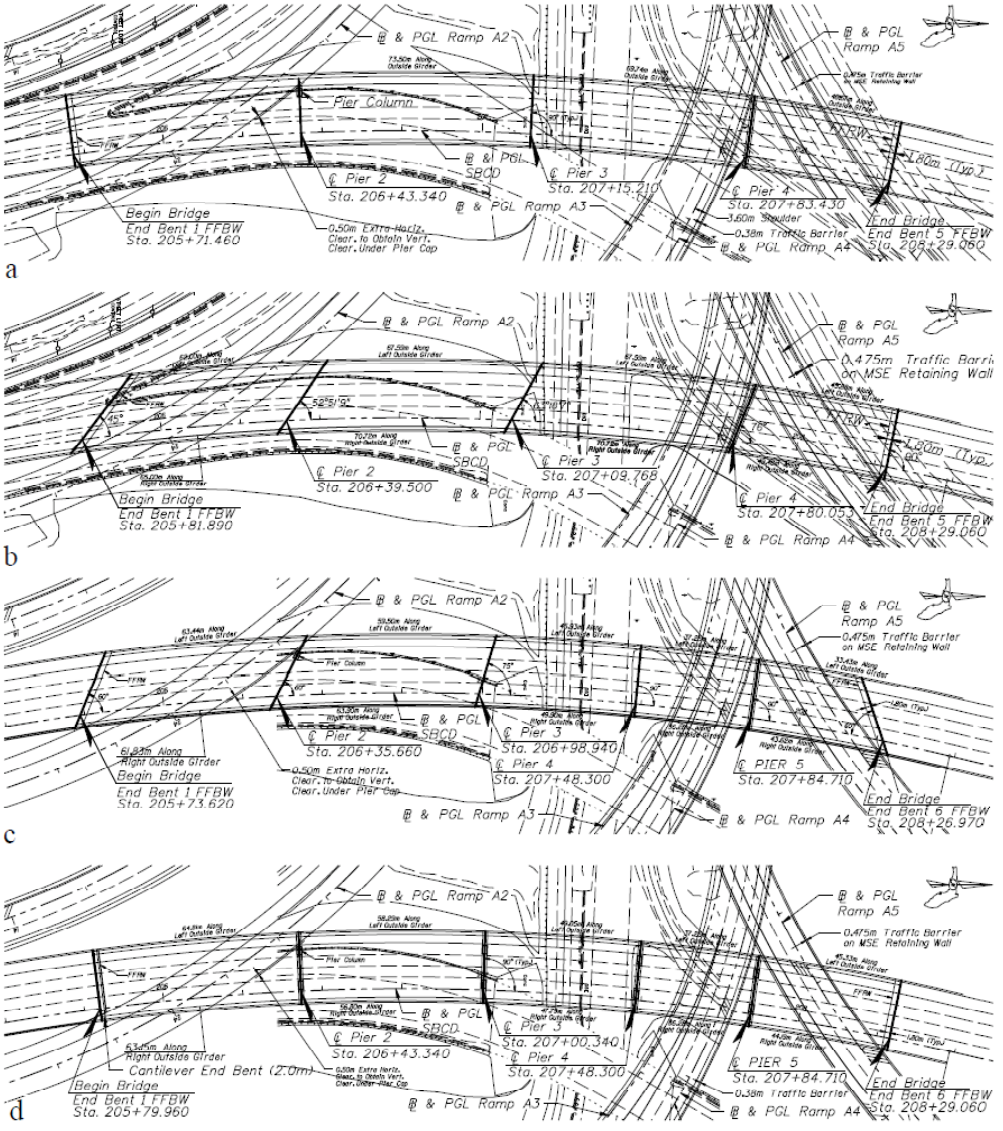

Fig.3. Southbound CD Bridge Alternatives, (a) Alternative 1, (b) Alternative 2, (c) Alternative 3, (d) Alternative 4

Unique Design Features

Of special interest in Alternative 4 is the southeast corner of the bridge. It can be seen that the crossing angle of the alignments of the Southbound CD and Ramp A2 are highly skewed. For a normal bent arrangement, this results in an unusually long end span, about 73.5 meters to cross over a relatively narrow ramp. As a means of shortening the length of Span 1, the southeast corner of the end bent was clipped such that a portion of the end bent and the approach slab would cantilever over the clear zone area. The fascia beam would not be supported on the traditional end bent pile and cap system but rather on a special foundation system integrated into the end bent.

This results in a substantial reduction in the end span length. Vertical clearance requirements would be maintained. The arrangement and details of this corner, as explained above, are shown in Figs. 4 and 5.

Substructure System

The two column hammerhead type pier was adopted for the piers on this bridge. A single column hammerhead pier may be structurally feasible with bulky sections. However, the width of the bridge makes the two column pier better suited for this

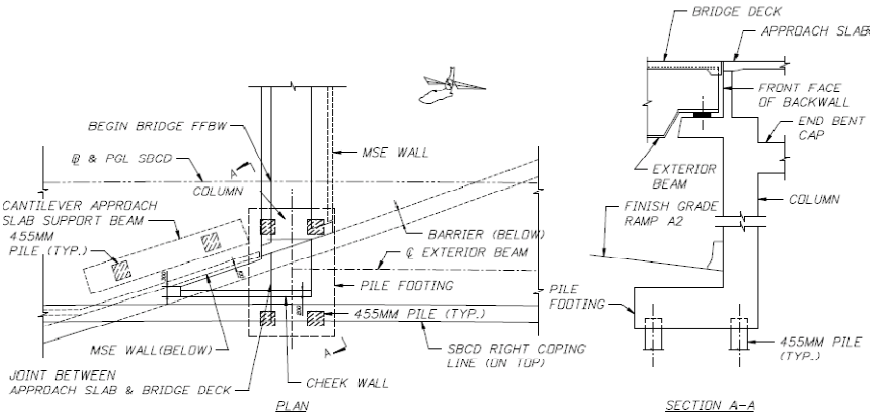

Fig.4. End Bent Details of Southbound CD Bridge

bridge. The piers have chamfered columns and caps. The wider face of the columns have vertical striations to provide a perception of a more slender appearance (see Fig. 5).

Fig.5 Southbound CD Bridge

Recommended and Constructed Alternative

In order to select the best alternative, the estimated costs for the alternatives evaluated are summarized in the Table 1. The most cost effective 4-span arrangement (Alternative 1) costs about $730K (18%) more than the most cost effective 5-span arrangement (Alternative 4). Therefore, the three 4-span arrangements were not pursued further. Alternatives 3 and 4 were the remaining alternatives requiring further consideration.

One consideration in the selection of the recommended alternative was that the bridge would require lateral staging for maintenance of traffic. The first stage of construction was 12.485 m wide, and then Stage 2 construction was 8.615 m. Stage 3

Table. 1 Estimated Costs for Southbound CD Bridge

Alternative	Est. Total Construction Cost	Cost Ratio*	Construction Cost per Square Meter
1	$4,883,312	1.18	$841
2	$4,892,690	1.18	$854
3	$4,356,454	1.05	$763
4	$4,153,411	1.00	$739

*Using the estimated cost of Alternative 4 as the base cost.

construction was a 1.45 meter closure pour. It is important to minimize any differential deflections, twisting, dead load deflections, and racking (due to skew, curvature, etc.) in order to lower the potential for erection and constructability problems during steel girder erection and concrete deck pouring. One example of a potential construction problem is after Stage 1 is constructed, the Stage 2 girders will be erected in the cambered position (before Stage 2 concrete pour). There will be a large vertical differential between stages until the Stage 2 concrete is poured. Predicting accurate deflections is critical, and large deviations for any reason could be a problem during construction. The simpler the layout, the less potential there is for construction problems. Skewed substructures cause differential deflections, twisting and racking. Therefore, the skew of the substructures should be minimized as much as possible. In addition, Alternative 3, with a skewed substructure, costs more ($203K) than Alternative 4 with the radial substructures. Therefore, Alternative 4 with all radial substructures was recommended for the Southbound CD Bridge. It should be noted that during construction the contractor eliminated the lateral construction staging and built the bridge in one stage.

RAMP A5 OVER A4 BRIDGE

The baseline of Ramp A5 crosses over the baseline of Ramp A4 at Station 54+10.176 of Ramp A5. Also, the baseline of Ramp A5 crosses over the baseline of Ramp A3 at Station 53+87.112 of Ramp A5. At this location, both Ramp A5 and A4 are on

curved alignments. The minimum vertical clearance is 5.05 m and the total bridge width is 14.7 m with two travel lanes and two shoulders (see Fig.6).

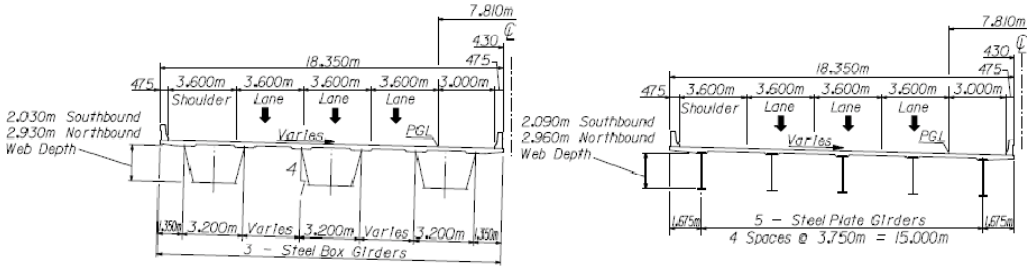

Fig.6. Ramp A5 over A4 Section, (a) Box Girder Alternative, (b) I-Girder Alternative

Four alternatives were investigated during the project development phase. Alternative 1 and 2 consist of one span and Alternative 3 and 4 consists of two spans. The two-span Alternatives, 3 and 4, were not recommended due to the higher cost and reduced aesthetics as compared to the single span alternative. Therefore, only the single-span alternative was considered and described as follows.

Alternative 1

Alternative 1 consists of a single span with a steel box girder superstructure (see Fig. 7 a). End bents are placed normal to the baseline of Ramp A5. Providing full clear zone for Ramps A3 and A4 results in a span length in excess of 85 m. This span length is not considered practical from a structure depth, cost and aesthetics point of view. Therefore, barriers are provided on Ramps A3 and A4 to result in a more practical span length. The resulting span length is 68.68 m. On the north side of Ramp A4, the barrier is placed just outside the 3.6 m wide shoulder. On the south side of Ramp A3, the barrier is placed just outside the horizontal sight distance line.

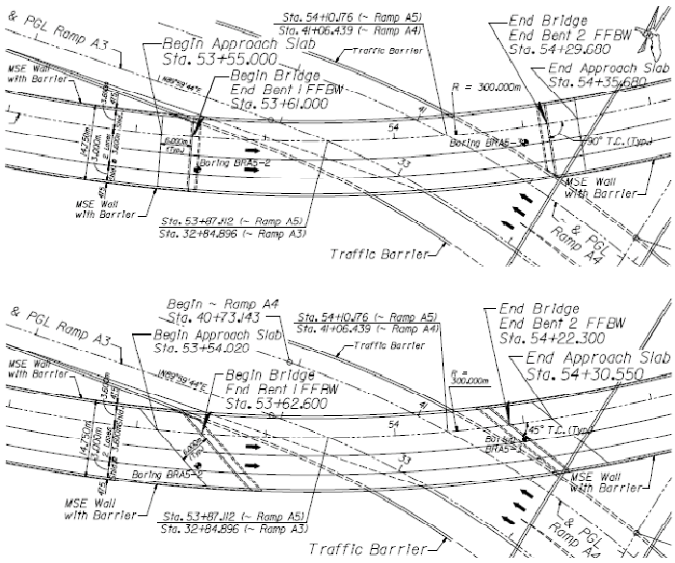

Fig.7. Ramp A5 over A4 Bridge Alternatives, (a) Alternative 1, (b) Alternative 2

Alternative 2

Alternative 2 consists of a single span with a steel plate girder superstructure (see Fig. 7(b)). End bents are skewed at 45 degrees to the baseline of Ramp A5. Providing full clear zone for Ramps A3 and A4 results in a span length in excess of 75 m. This span length is not considered practical from a structure depth, cost and aesthetics point of view. Therefore, as in Alternative 1, barriers are provided on Ramps A3 and A4 to result in a more practical span length. The resulting span length is 59.70 m. On the north side of Ramp A4 the barrier is placed just outside the 3.6 m wide shoulder. On the south side of Ramp A3, the barrier is placed just outside the horizontal sight distance line.

Unique Design Features

The crossing angle of the alignments of A5 and A4 are not close to normal. This results in an unusually long span for the A5 Bridge to cross over a relatively narrow ramp. As a means of shortening the bridge length, the corners of the end bents are clipped such that a portion of the approach slab will cantilever over the traffic shoulder (see Fig. 8). This relatively inexpensive modification results in a reduction in span lengths of 7.96 and 7.5 meters for Alternatives 1 and 2 respectively.

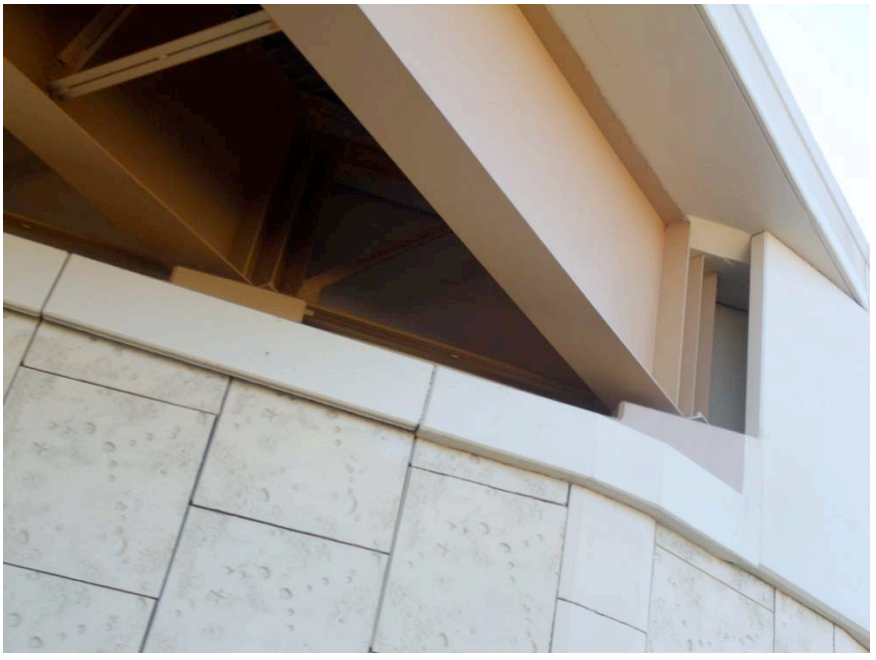

Fig.8. Clipped Corners of End Bents

Recommended and Constructed Alternative

Alternative 2 was the most cost effective alternative (refer to Table 2) and was recommended and constructed (see Fig. 9)

Table 2. Estimated Costs for Ramp A5 over A4 Bridge

Alternative	Est. Total Construction Cost	Cost Ratio *	Construction Cost per Square Meter
1	$1,083,267	1.22	$981
2	$885,819	1.00	$819

*Using the estimated cost of Alternative 2 as the base cost.

Fig.9. Ramp A5 over A4 Bridge

SR 589 MAINLINE OVER RAMPS A3, A4 AND A5 BRIDGE

At the bridge location the baselines of SR 589 and all the ramps are on curved alignments. The bridge is separated into northbound and southbound structures with an 860 mm "gap" between them (see Fig. 10). The gap is required because the superelevation of the northbound and southbound structures are in the same direction with independent PGL's, creating a step at the centerline of construction. The gap was determined using the 7.810 m distance between the PGL's, the 3.00 m shoulders, and the 475 mm traffic barriers.

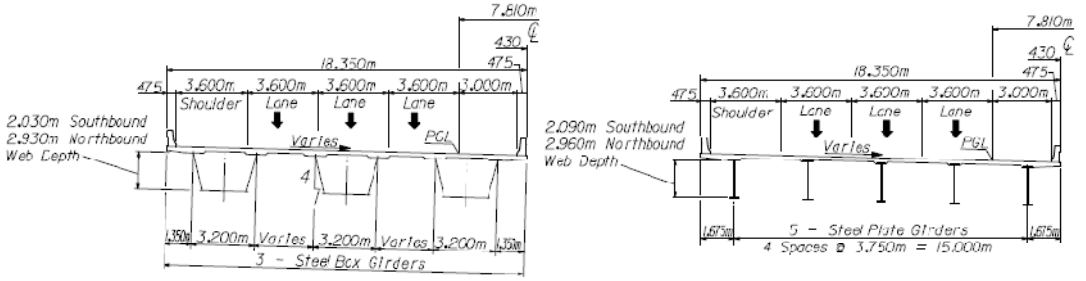

Fig. 10. SR 589 Mainline over Ramps A3, A4 and A5 Bridge, (a) Box Girder Alternative, (b) I-girder Alternative

Alternative 1

The span arrangement for Alternative 1 consists of a steel box girder superstructure (see Fig. 11 (a)). End bents are placed normal to the baseline of SR 589. A clear zone of 4.2 meters to the south end bent of the bridge is required on the south side of Ramp A3. However, at this location the horizontal sight distance requirement is 6.67 meters and is provided as a minimum. A horizontal clearance of 7.3 meters adjusted to 10.3 meters for curvature is required and provided on the north side of Ramp A4. On the south side of Ramp A5, a barrier is provided just outside the shoulder width in lieu of a clear zone of 9.5 meters adjusted for curvature from 7.3 meters. Similarly, on the north side of Ramp A5 a barrier is provided just outside the sight distance line of 4.4 meters in lieu of a clear zone of 7.3 meters. Eliminating these barriers and providing clear zones around Ramp A5 results in the north end span being greater than 82 meters which is not considered practical especially for the end span. A variance was obtained for not providing the full clear zone on the north side of Ramp A5. The end bents and piers of the northbound bridge are staggered from the end bents and piers of the southbound bridge, to provide as close to a balanced span arrangement as possible. The crossing angle of the alignments of Ramps A3 and A5 with the SR 589 mainline are not close to 90 degrees. This results in an unusually long end span, especially for the northbound bridge. The resulting span arrangement for the northbound bridge is a four span structure with spans of 71.000 m + 55.710 m + 55.710 m + 73.420 m for a total bridge length of 255.840 m long the SR 579 baseline. The resulting span arrangement for the southbound bridge is a three span structure with a span arrangement of 56.810 m + 73.140 m + 57.300 m for a total bridge length of 187.250 m along the SR 589 baseline.

Unique Design Features

As a means of shortening the bridge length for this alternative, the corners of the end bents are clipped such that a portion of the approach slab will cantilever over the traffic shoulder.

Alternative 2

The span arrangement for Alternative 2 consists of a steel plate girder superstructure (see Fig. 11 b). The span arrangement and horizontal clearances are similar to Alternative 1 except that the bents have a skew of 45 degrees. Another difference is that the piers for the northbound and southbound bridge are not staggered as in Alternative 1 but are lined up. The resulting span arrangement for the northbound bridge is a four span structure with a span arrangement of 62.610 m + 48.640 m + 48.640 m + 68.980 m for a total bridge length of 228.870 m along the SR 589 baseline. The resulting span arrangement for the southbound bridge is also a four span structure with a span arrangement of 50.810 m + 48.640 m + 48.640 m + 41.260 m for a total bridge length of 189.350 m along the SR 589 baseline.

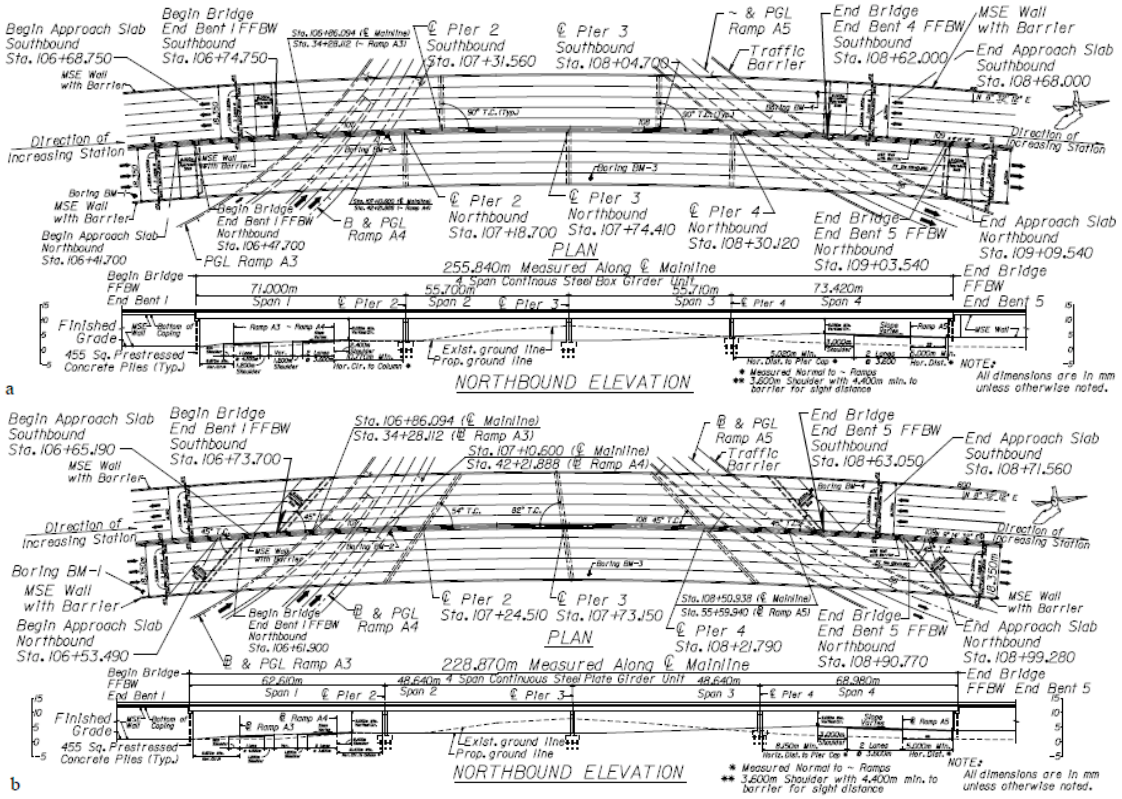

Fig.11. SR 589 Mainline over Ramps A3, A4 and A5 Bridge Alternatives, (a) Alternative 1, (b) Alternative 2

Recommended and Constructed Alternative

An estimate of probable construction costs was prepared for the two alternatives evaluated. Since the alternatives have a different amount of deck area, the cost estimates have been modified to reflect the additional embankment and wall area required for the shorter bridges. The results are summarized in the Table 3. Alternative 2 was the most cost effective alternative and was recommended. It should be noted that only the northbound roadway and bridge was constructed in this contract. The southbound roadway and bridge is planned for future construction (see Fig. 12).

Table 3. Estimated Costs for SR 589 Mainline over Ramps A3, A4 and A5 Bridge

Alternative	Est. Total Construction Cost	Cost Ratio *
1	$7,228,661	1.16
2	$6,206,427	1.00

*Using the estimated cost of Alternative 2 as the base cost.

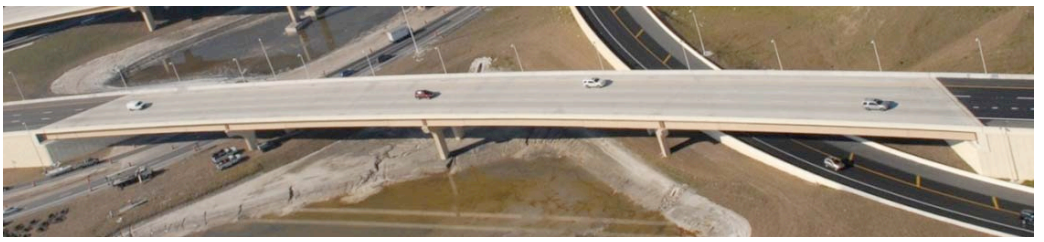

Fig.12. SR 589 Mainline over Ramps A3, A4 and A5 Bridge

CONCLUSION

Though there are many steel bridges that have successfully been built, each bridge has its unique geometric, geologic, and other site features. How to design an economic and aesthetic bridge is still a great challenge to bridge engineers. This paper presented how to select the most cost effective alternative while maintaining the required aesthetic level for three different site conditions. For phased construction, it is important to minimize the skew of the substructures as much as possible to reduce differential deflections, twisting, racking, and potential construction problems. As a means of shortening the bridge length, the corners of the end bents can be clipped such that a portion of the approach slab will cantilever over the traffic shoulder. Proper use of barriers can significantly reduce the construction costs.

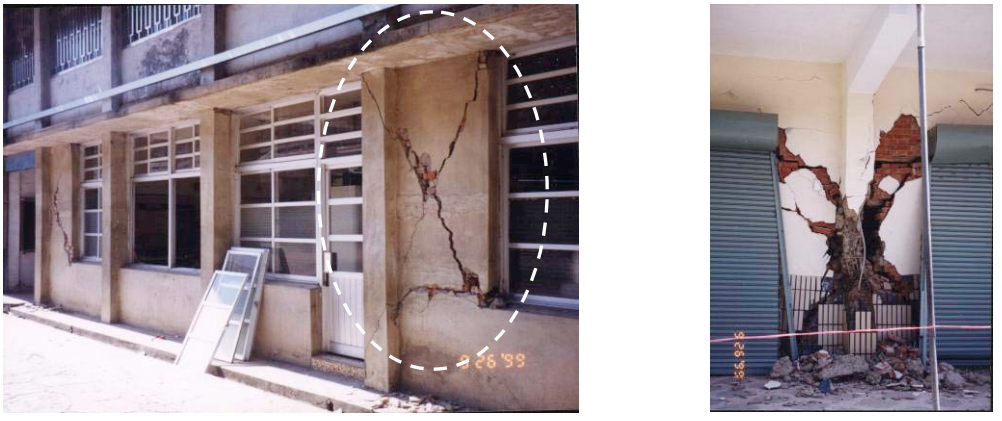
ABSTRACT



Confined masonry (CM) consists of masonry panels surrounded by cast-in-place RC boundary frames that provide confinement to the panels. When a CM panel is perforated for the needs of opening, the confining effect becomes questionable. This research is aimed at the slender CM panel segments between openings and tie columns. A series of test was carried out to study the failing behavior of this type of panels under in-plane loading. The main variables are the position of tie columns, the number of panels, and the loading pattern. Three specimens were tested under monotonic loading, including two single wing-walls with a tie column placed at the tensile and compressive side respectively and one twin wing-wall with the tie column place at the middle. Another single wing-wall and twin wing-wall specimens were tested under cyclic loading for comparison. The test result indicated that the failing behavior of the specimens was considerably affected by the position of tie column but not by the loading pattern.

INTRODUCTION

Confined masonry (CM) panels are commonly used as infill walls and partitions in low-rise RC buildings in Asian countries such as China [Hori et al. 2006], Indonesia [Sanada et al. 2009], India [Sivarama Sarma et al. 2003], and Taiwan [Tu et al. 2010]. It is also widely used in most Latin-American countries like Mexico [Tena-Colunga et al. 2009] and Chile [Gent Franch et al. 2008]. Seismic assessments for these buildings are complicated, since they combine the behaviors of RC frames and masonry panels and the interactions between frames and panels. Practical guidance for the seismic evaluation of concrete buildings with masonry infill panels can be found in FEMA 356 [FEMA 2000], where solidly infilled masonry panels are considered to be equivalent to compression struts. However, no adequate guidance is provided for partially infilled masonry panels or panels with openings. Most engineers tend to neglect the strength and stiffness of perforated masonry infill panels when designing a new building. In the commentary for section 7.5.2.1 of FEMA 356, it is suggested that a perforated infill panel can provide load-resisting system through the panel segments between openings, as proposed by Hamburger (1993). However, theoretical studies and experimental data

are insufficient for establishing reliable guidelines; the use of this approach requires judgment on a case-by-case basis.

Typical low-rise RC school buildings and street side buildings in Taiwan have a common structural system, where adjacent classrooms or street side buildings are divided by fully infilled CM partitions and the elevations normal to the partitions are opened with doors and windows. This results in an obvious weakness in seismic capacity along the corridor direction for school buildings and street direction for street side buildings. Therefore, the seismic behavior and strength of the perforated CM panels become rather important for these buildings. Figure 1 shows the two regular types of partially infilled CM panels used in typical school buildings in Taiwan, including a single wing-wall with an opening on one side and a boundary column on the other side (Figure 1(a)), and twin wing-walls with a column clamped between them (Figure 1(b)). Slenderness is a common factor in the three types, whereas the condition of the vertical boundaries is the main difference between them.

(a) Single wing-wall (b) Twin wing-wall

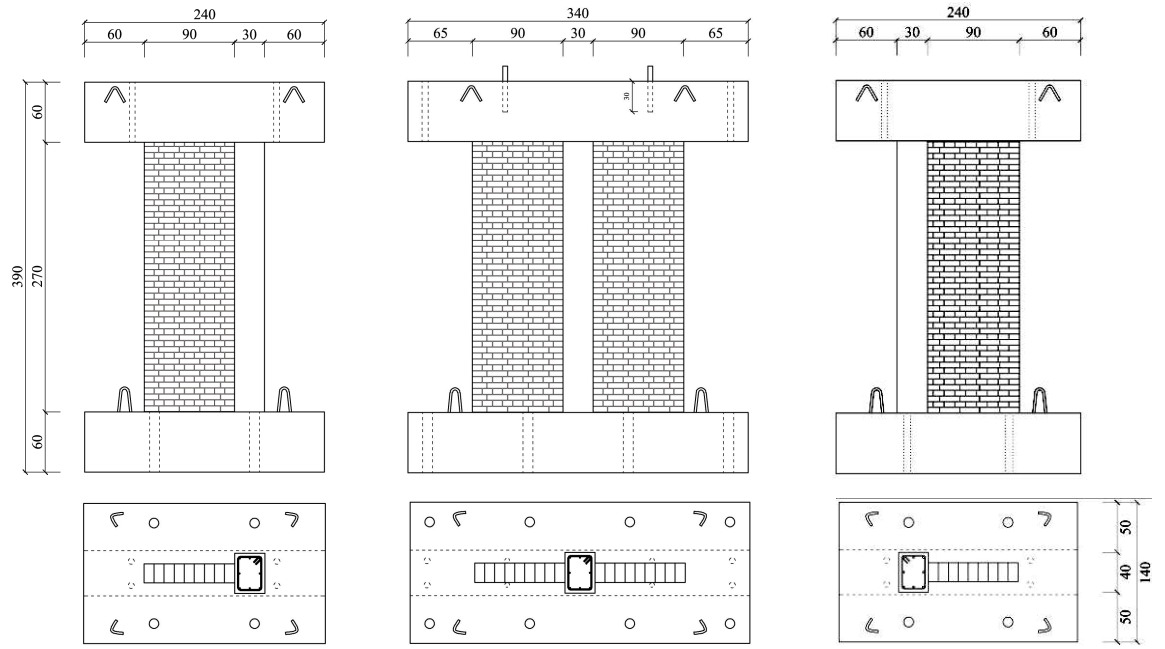


Figure 1. Regular types of partially infilled CM panels in Taiwan

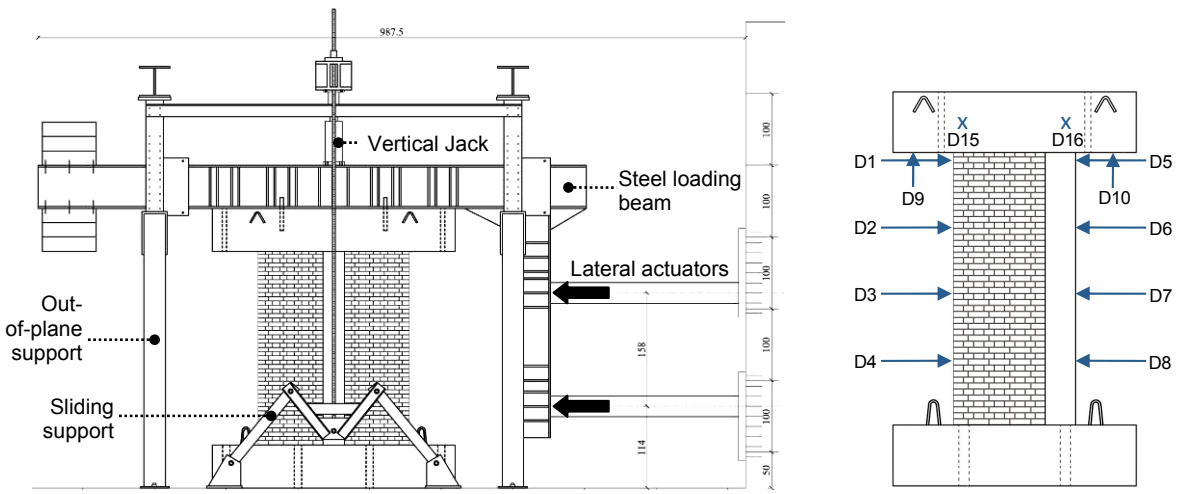
Usually, a wing-wall is 900 mm wide with a clear aspect ratio exceeding 2.0, but in the examples shown in Figure 1, the failure modes are different and affected by the presence of the boundary column. In order to elucidate the capacity and the factors that affect the behavior of slender CM panels subjected to lateral load, a series of experiments were planned. The first phase of the experiment [Tu et al. 2009] included four specimens: two piers, one single wing-wall, and one twin wing-wall. Each specimen was subjected to monotonic lateral loading and constant axial force. For further study on the effect of tie column and loading pattern, the second phase of the experiment was finished in 2010. It included a single wing-wall and a twin wing-wall, both subjected to cyclic loading, and another single wing-wall subjected to monotonic loading with the tie columns positioned reversely. The test results of five wing-wall specimens are presented and discussed in this paper.

EXPERIMENTAL PROGRAM

Test specimens. A four-story existing typical school building was selected as the prototype structure. The most common section details from a damage databank for school buildings [Tu et al. 2011] were chosen to represent the existing buildings that do not meet the current design requirements.

The test specimens were full-scale, having weak columns and strong beams, as shown in Figure 2. Specimens A, AC, and C were identical single wing-walls, where specimen C was placed reversely in the test setup. Specimens B and BC were twin wing-walls with identical masonry panels used for single wing-walls. The clear height, length, and width of each panel were 2700 mm, 900 mm, and 200 mm, respectively. 200mm × 95mm × 53mm solid clay bricks were used and laid in English bond (one stretcher to one header, alternating). The panels were constructed in confined masonry; that is, the boundary beams and columns were cast after the bricks were laid. The panels have their vertical edges adjacent to the columns toothed for shear connections with the columns. The top beams were cast in place with the panels inserted in the beam base for 10~20 mm, so that the specimens could exhibit a fixed-fixed behavior, as is the case in regular CM structures. The columns had a 300 mm × 400 mm cross section, with eight #6 reinforcing bars and #3 hoops at 250 mm of spacing to represent non-ductile design details. The top beams were 400 mm × 600 mm with eight #6 reinforcing bars and #3 hoops at 100 mm of spacing.



(a) Specimens A / AC (b) Specimens B / BC (c) Specimen C

Figure 2. Elevations and plans of the test specimens (unit:cm)

Test setup and instrumentation. Figure 3(a) shows the test setup. In order to ensure a fixed-fixed behavior and to maintain the top beam horizontal during the test, the lateral load was applied through an L-shaped steel loading beam by two actuators. Vertical load was applied by a jack fixed at the midline of each specimen top and connected to sliding reaction supports developed by Kuang and Wong (2005), so that no horizontal force component was produced.

Eight lateral gauges for measuring in-plane displacement were installed at different heights along the leeward (D1~D4) and windward (D5~D8) vertical edges, as shown in Figure 3(b). Four additional gauges were installed on the middle column of twin wing-wall specimens. Another two vertical gauges (D9 and D10) and two out-of-plane gauges (D15 and D16) were installed on the top beam to monitor its levelness and out-of-plane stability. Strain gauges were attached to every hoop and to both ends of the longitudinal tension and compression steel.

(a) Test setup (b) Displacement gauges

Figure 3. Test setup and arrangement of displacement gauges

Table 1. Test specimens

Specimen	Type	Lateral load	Vertical load* (kN)
A	Single wing-wall	Monotonic	313.6
B	Twin wing-wall	Monotonic	313.6
C	Single wing-wall (reversed)	Monotonic	313.6
AC	Single wing-wall	Cyclic	313.6
BC	Twin wing-wall	Cyclic	313.6

*: The weight of loading beam and jack are included.

Load patterns. As shown in Table 1, a constant vertical force of 313.6 kN (32 t) that represented the dead load was applied to each specimen during the test. Two types of in-

plane lateral loading were selected: monotonically increasing and cyclic. The cyclic load was applied with the displacement amplitudes gradually increased in each cycle. Usually, a test was terminated when severe damage was observed in the masonry panels or the residual strength was below 85% of the maximum strength.

Material properties. Material tests were conducted on the reinforcing steel, concrete, and masonry samples. These included the compression tests of standard 150 mm diameter concrete cylinders, the compression tests of brick units (Figure 4(a)), the compression tests of 50 mm mortar cubes (Figure 4(b)), and the compression tests of double wythe × double wythe × 8-course masonry prisms (Figure 4(c)). The main results are presented in Table 2.

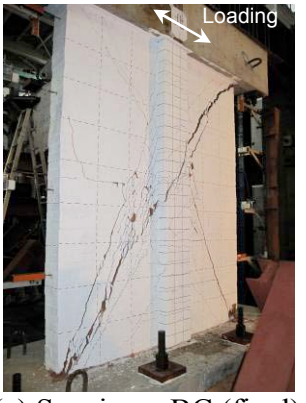
Specimen	Steel Yield stress (MPa)		Concrete Compressive strength (MPa)	Masonry Compressive strength (MPa)		
	#3	#6		Brick	Mortar	Masonry prism
A, B	318.9	439.2	30.4	43.6	15.5	17.4
C	400.3	490.5	30.9	44.5	13.9	19.4
AC	400.3	490.5	33.6	44.5	13.9	19.4
BC	400.3	490.5	32.4	44.5	13.9	19.4

EXPERIMENTAL RESULTS

Overall behaviors. Magenes and Calvi (1997) presented three possible failure modes for masonry walls: rocking, bed-joint sliding, and shear cracking. Rocking means that the wall rotates with flexural cracks occurring at the lower windward and upper leeward corners, ending with toe crushing at the compressed corners. Bed-joint sliding occurs along a tensile horizontal crack when the vertical load is low. Shear cracking mode is identified when the strength is governed by the formation and development of inclined diagonal cracks. In this experiment, shear cracking failure occurred in single wing-wall

specimens A, C, and AC, but the tie columns didn't fail when the panels failed. The twin wing-wall specimens B and BC had a composite behavior combining rocking and shear cracking failure, and the tie columns failed simultaneously with the panels. In all specimens, uniform tensile cracks appeared at the tie columns, suggesting that the columns acted as tension chords while the panels acted as equivalent compression struts. Figure 5 shows the photographs of the failed specimens, the value in the brackets means the drift. Figure 6 shows the lateral force-displacement curves. In some of the curves, slight load degradation happened when the actuators were paused for recording the damage condition. The damage progress of each specimen is as follows.

(a) Specimen A (1.49%)



(b) Specimen B (0.51%)

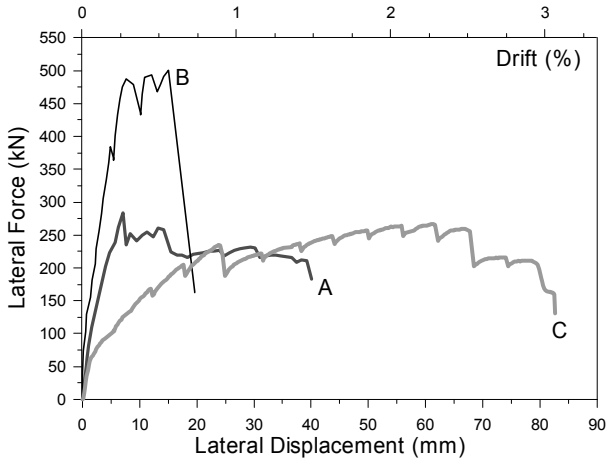
(c) Specimen C (3.15%)

(d) Specimen AC (+1.48%)

(e) Specimen BC (final)

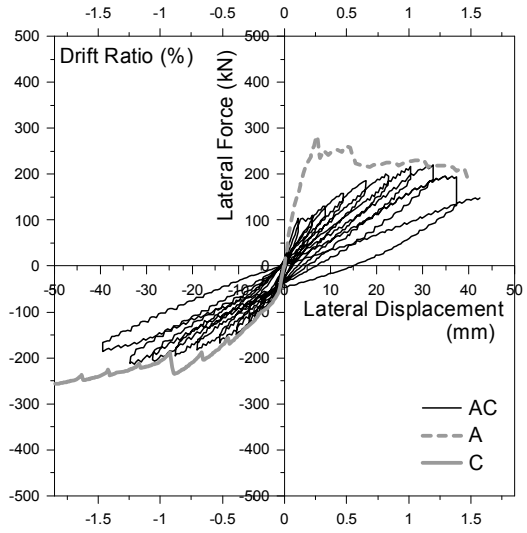
Figure 5. Photographs of failed specimens

Specimen A. This specimen exhibited asymmetric behavior due to the eccentrically placed boundary column. Uniform tensile cracks occurred in the lower portion of the column at 0.18% drift. A diagonal crack occurred in the panel and extended to the column at 0.26% drift, where the specimen also reached its peak strength, which was followed by strength degradation. The diagonal crack extended to two compression corners at 0.39% drift; it did not cause the column to fail but resulted in an



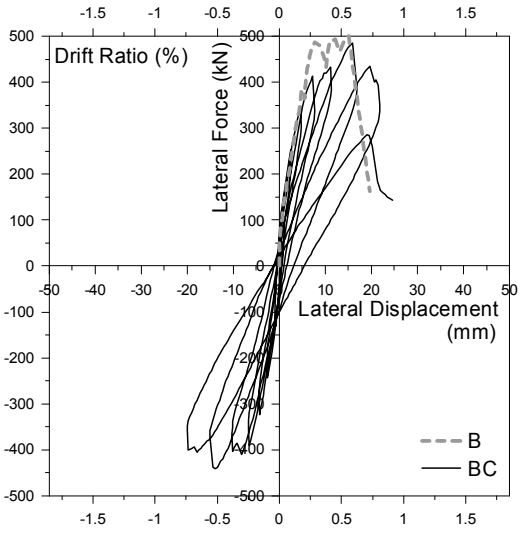
increase in the strain in the hoop passing through the crack. Toe crushing occurred at the lower leeward corner of the panel, accompanied by widening of the diagonal crack and further strength degradation at 0.53% drift. After that, brick pieces started to spall from the crack. The shear crack at the column became wider and finally caused the column to fail at 1.49% drift.

Specimen B. This specimen was slightly damaged before the experiment. When it was fixed to the floor before testing, flexural cracks appeared at its four corners due to uneven prestress in the tie-downs. These cracks closed after the prestress in the tie-downs was adjusted. Therefore, it was difficult to identify when the flexural cracks re-opened due to the lateral load. Uniform tensile cracks showed in the middle of the column soon after loading began. Flexural cracks at the upper leeward and lower windward corners started to extend at 0.08% drift, showing that the specimen was rocking as one united panel. Rocking behavior continued until 0.18% drift, when the specimen reached its first peak strength. It was followed by a diagonal crack appearing and extending to two compression corners. No obvious strength degradation occurred, but the specimen suddenly failed at 0.56% drift. The diagonal crack that extended across the both panels and the column was responsible for the sudden failure.



Specimen C. Usually, this type of wing-wall is considered to be invalid since the panel is located at the tensile side. However, its loading condition is actually the same with specimen A, if the top and bottom boundary conditions are completely identical. This specimen showed a cracking pattern similar to that of specimen A but upside-down. At 0.52% drift, tensile cracks occurred in the upper portion of the column and many small inclined cracks showed at the panel along its edge adjacent to the column. Longer inclined shear cracks appeared at the panel and the column bottom at 0.74% drift. The shear crack widened at 0.89% drift and a horizontal crack suddenly occurred at 1/3 height of the panel, where the first peak on the load-displacement curve also showed. The strength dropped about 20% after the peak, but returned to rising state again. After that, brick spalling kept happening along the cracks at the column-panel boundary. The specimen had the maximum strength at 2.27% drift. At 2.63% drift, a diagonal shear crack that extended across the panel suddenly appeared and divided the panel into two pieces. The failure of panel resulted in another strength degradation. Since the column was not severely damaged, the test was continued. The test was terminated at 3.15% drift, when brick crushing happened at the bottom compressive corner of the panel. At that time, only shear cracking was observed at the column.

Specimen AC. An unexpected vertical crack showed at the middle of the upper portion of the panel when the specimen was installed. It affected the initial cracking pattern of the specimen but did not change the final failure mode. At ± 0.3% drift cycle, inclined shear cracks extended from the bottom end of the vertical crack and tensile cracks started to appear at the column. A horizontal crack similar to the one of specimen C occurred at 1/3 height of the panel at –0.3%. After that, all cracks kept extended and more inclined cracks showed at the bottom 1/3 portion of the panel. The maximum strength showed at +1.19% drift. At +1.48% drift, a new diagonal crack that extended across the panel but did not extended to the column suddenly appeared and divided the



panel into two pieces. The bottom compressive corner crushed. During the next cycle, the panel broke into several segments and fell. The test was terminated when the column remained only cracked.

(a) Monotonically loaded specimens

(b) Single wing-wall specimens

(c) Twin wing-wall specimens

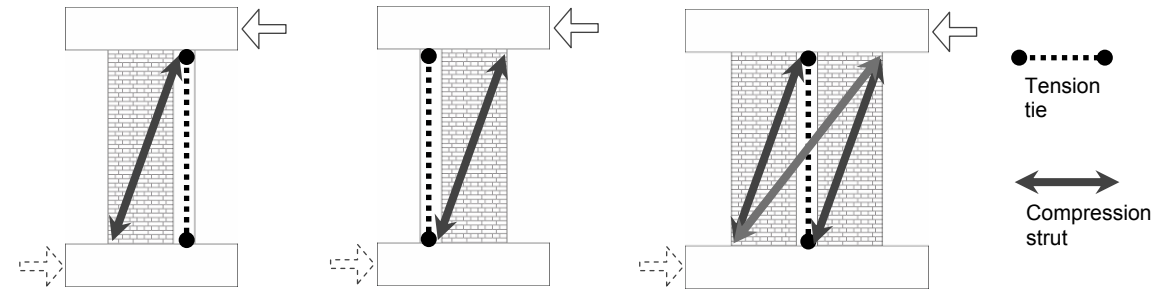


Figure 6. Lateral force-displacement curves and comparison

Specimen BC. This specimen showed quite symmetrical cracking pattern under cyclic loading. Flexural cracks appeared at the top and bottom edges of the panel at ± 0.10% drift cycle and extended to the column soon after. Inclined cracks at the panels and tensile cracks at the column showed at ± 0.25% drift cycle. At +0.56% drift, a new diagonal shear cracks showed at the panel at the compressive side. Slight toe crushing happened and the specimen showed maximum strength. At +0.75% drift, a shear crack appeared at the mid-height of the column and connected with the inclined cracks at both

panels, forming a diagonal crack extended across the entire specimen. During the next cycle, obvious sliding occurred along the diagonal crack and caused simultaneous shear failure of the panels and the column.

Effects of tie column. Figure 6(a) shows a comparison between the lateral force-displacement curves of the three specimens subjected to monotonic loading. The observation on the damage progress indicates that even though the specimens were not fully constrained in closed frames, strut-and-tie mechanism still can be developed between the panels and single tie columns. As shown in Figure 7, the lateral-load-resisting system in specimen A and specimen C should be basically the same. However, the observed behaviors of the two specimens were not identical. The difference might be due to the effect of the self-weight of panels and the asymmetry between top and bottom boundary conditions. Although the value was very small, the top beams of these specimens rotated slightly during the test. The higher yield strength of steel used for specimen C might also result in a relatively stronger column that caused the difference in failing behavior.

The failing behavior of specimen B showed that the twin panels were not independent but united with the column as a squat panel. Its cracking pattern also suggests that there might be a double layered compression stress field. As shown in Figure 7(c), one layer lies between the two extreme compressive corners of the specimen, whereas the other lies along the diagonal of each panel. In this experiment, the failure of the specimen was governed by the former layer. The comparison between specimens A, B, and C suggests that the estimation of lateral force and deformation capacities might be affected by the relationship between the individual strength of the column and the panel.

(a) Single wing-wall (b) Single wing-wall (reversed) (c) Twin wing-wall

Figure 7. Lateral-load-resisting system

Effects of loading pattern. Figure 6(b) and (c) show the comparison between the specimens subjected to monotonic and cyclic loading. In general, the monotonic load-displacement curves show good agreement with the cyclic ones. Between single wing-wall specimens, the curves of specimen A and specimen C fit well to the positive and

negative portions of the curve of specimen AC, respectively. Specimen A showed higher differences in stiffness and strength initially, but the final strength and drift at failure point agreed with specimen AC. The asymmetry between positive and negative portions of the curve of specimen AC suggests that the type of wing-wall shows different behavior when the lateral load comes from different directions and the failure is controlled by the positive case (specimen A) since the failure deformation is smaller.

The curves of specimen B and BC show good agreement in both stiffness and strength. This suggests that the loading pattern does not cause considerable influence on the test result.

CONCLUSIONS

Five confined masonry wing-wall specimens were tested with in-plane lateral load while also being subjected to a vertical compression force. In order to study the effect of the position of tie columns, the specimens included three single wing-walls with the tie columns placed eccentrically and two twin wing-walls with the tie columns placed in the middle. One twin wing-wall and two single wing-walls, where one of them was installed reversely, were tested with monotonically increasing load. The other twin wing-wall and single wing-wall were tested with cyclic loading to study the effect of loading pattern. The following conclusions can be drawn.

1. Shear cracking failure occurred in single wing-wall specimens, but the tie columns didn't fail when the panels failed. The twin wing-wall specimens had a composite behavior combining rocking and shear cracking failure, and the tie columns failed simultaneously with the panels. This suggests that the failing behavior might be affected by the position of tie column and the relationship between the individual strength of the column and the panel.
2. In all specimens, uniform tensile cracks appeared at the tie columns, suggesting that the columns acted as tension chords while the panels acted as equivalent compression struts. However, the twin wing-wall specimen acted as a united squat panel instead of two divided slender panels. This suggests that strut-and-tie models might be applied to the analysis for wing-walls, but case-by-case consideration is needed.
3. In general, the load-displacement curves of the monotonically loaded specimens showed good agreement with the curves of the cyclically loaded specimens. This suggests that the loading pattern does not cause considerable influence on the test result.

ACKNOWLEDGEMENT

ABSTRACT

As engineers are being guided with greater frequency to ASCE 31, *Seismic Evaluation of Existing Buildings*, and ASCE 41, *Seismic Rehabilitation of Existing Buildings*, by state and federal government requirements as well as model building codes, greater numbers of buildings are being evaluated, upgraded, and even designed in accordance with the methodologies and criteria prescribed therein. By using these flawed standards, harm is being inflicted by the structural engineering profession on society-at-large. While the contributors to the original documents have been well aware of major technical problems with these documents since long before publication, efforts to mitigate the problems have been slow, and engineering studies of buildings across the country -- including all buildings considered for lease by the Federal Government -- are being impacted by these problems. To our knowledge, no formal efforts have yet been put forth to warn anyone -- not engineers, not building owners, not government officials, and not building officials -- that reliance on the documents can easily lead to wrong results -- even though engineers most familiar with ASCE 31 and 41 acknowledge that in their own practice, use of the documents often entails modifying or ignoring major components of the published methodologies. In fact, despite the recent renewal of efforts by the associated ASCE committees to improve these standards as much as seven years after publication (and much more than a decade after the bases of these documents, FEMA 310 and 356, were published), these so-called standards remain highly flawed and continue to adversely affect the public interest.

This paper discusses a selection of mind-boggling problems with ASCE 31 and 41, focusing on some aspects about which every engineer planning to use the documents ought to be aware.

INTRODUCTION

The American Society of Civil Engineers publishes the two standards addressed herein: ASCE 31, *Seismic Evaluation of Existing Buildings* (2003), and ASCE 41, *Seismic Rehabilitation of Existing Buildings* (2006), as well as a more recently released *Supplement No. 1* (2007). Both of these standards purportedly represent the consensus knowledge of a large number of engineers and are touted as major advances in earthquake engineering. ASCE 31 and ASCE 41 were developed from

FEMA 310 (1998) and FEMA 356 (2000), respectively, with the goal of providing a set of rules, regulations, and procedures dealing with seismic assessment and strengthening of existing structures, with each set of rules, regulations, and procedures organized by basic building type, and written like a recipe. Unfortunately, however, both are evidence of the ongoing "standardization" and "cookbook-ization" of earthquake engineering (Searer *et al*., April 2008) and both dramatize the risks of disseminating performance-based earthquake engineering on a "how-to" basis. Although both documents represent a tremendous quantity of effort and contain a great deal of valuable material for reference purposes, performance-based earthquake engineering for existing buildings does not lend itself to a "how-to" formulation, and attempts to address and standardize it that way disrespect its premise, the engineering projects that are its product, and the societal stakeholders in its product.

SEAONC SURVEY

To assess how ASCE 41 is currently being used by the profession, the Structural Engineers Association of Northern California (SEAONC) conducted a non-scientific Internet survey of engineers (2010). Although the results were heavily skewed by participants from Northern California (53 percent of respondents), the results were illuminating to say the least.

Why Use ASCE 41?

When engineers were asked to select from a list of reasons why they use ASCE 41 (with multiple selections allowed) only 33 percent selected the option "provides a clear, step-by-step procedure." Other decidedly less inspiring reasons for using ASCE 41 included "industry trend" (48 percent), "required by law for California state-owned buildings" (39 percent), "company policy" (36 percent), "requested by owner" (24 percent), and "requested by building official" (16 percent). Clearly, ASCE 41 is not being used because engineers feel that it is the right tool for the job; overwhelmingly, they are required or pressured into using it.

Why NOT Use ASCE 41?

When engineers were asked why they *don't* ASCE 41 (with multiple reasons again allowed), the most frequent reason given was that most projects do not require the use of ASCE 41. Because most of the engineers who participated in the survey were California structural engineers, who presumably conduct more seismic assessments and design more seismic strengthening projects than almost any other group, the extent to which these standards appear to be manufacturing a bureaucratic need -- as opposed to filling a legitimate engineering need -- begins to be made clear. Other reasons provided for not using ASCE are equally disappointing, but of interest: "too complicated to use" (22 percent), "overly conservative results, leading to undesirable outcomes" (18 percent), "not familiar with its use" (17 percent), and "reluctant to migrate from prior practices that are satisfactory" (9 percent).

When Is a Standard Not a Standard?

In our view, and despite our predilection toward the exercise of engineering judgment when engaged in the practice of performance-based earthquake engineering, the most frightening statistic revealed by the survey was the fact that approximately 70 percent of surveyed engineers admitted to modifying or ignoring specific provisions of ASCE 41. Given this admission, ASCE 41 may be the most non-standard standard, ever. Certainly, if a greater than two-thirds majority of engineers surveyed feel that ASCE 41 gives incorrect results or requires unjustifiable amounts of analysis to the point where the same engineers admit that they have to modify or ignore portions of the standard, there must be major problems with it. Moreover, given the apparent frequency with which provisions of the standard are being modified or ignored, we seriously doubt that the structural engineering products that ostensibly rely on ASCE 41 provide anywhere near consistent standard-compliant performance -- and we challenge the profession to provide statistics demonstrating otherwise. It is therefore ethically incumbent upon the professional organizations that actively promote the use of these standards to formally notify those less knowledgeable than themselves (i.e., municipalities, government agencies and the general public who no doubt all rely on the representations of the profession that buildings "conforming" to these standards are somehow "better") that these standards leave a lot to be desired and that the hoped-for promise of these standards may be little more than false advertising or structural engineering "snake oil". To our knowledge, however, no such warnings have yet been given.

Just How Inaccurate Is It?

When the accuracy of ASCE 41 was polled, engineers were quick to point out that the results are often not accurate at all. A full 74 percent of engineers surveyed felt that ASCE 41 needs to be calibrated with the new construction provisions of the building code (e.g., some perfectly acceptable new designs are condemned by ASCE 41, and all the while, designs according to ASCE 41 are by definition less conservative than typical new construction). And when it comes to the various analysis options covered by ASCE 41 (i.e., linear static, nonlinear static, linear dynamic, and nonlinear dynamic), despite the fact that the vast majority of engineers using ASCE 41 rely on the linear static procedures therein, 64 percent of the engineers surveyed believe that the linear procedures (linear static and linear dynamic) produce results that are "too conservative", leading to excessive upgrades, and that results from the nonlinear dynamic procedure are often at odds with the results from the nonlinear static procedure. In this light, it is simply not appropriate for the engineering profession to promulgate engineering requirements that we acknowledge (but only within our little circle, with a wink and a nod) can be overly conservative and/or give conflicting or nonsensical results -- in effect selling something that consumers of our services are falsely led to believe is good engineering science and, in any case, may not really need. At the same time, of concern to us is the fact that 36 percent of engineers using the standard appear not to have recognized that the results from the linear procedures don't agree with the results from the nonlinear procedures, and that the two nonlinear procedures give results that often don't agree with each other!

ASCE 41 IS NOT EQUIVALENT TO THE BUILDING CODE

We have seen increasing evidence that ASCE 41 is being used by the engineering community to justify "equal or better" performance relative to that obtained from strict conformance to the prescriptive requirements of the building code; is being accepted by jurisdictions as equivalent to legally required code compliance; and is being pushed by the structural engineering community as a means to justify code equivalence for any work associated with existing buildings -- even the construction of additions. In fact, in states that have adopted the *International Existing Building Code*, a path now exists explicitly and legally to rely entirely on ASCE 41 to justify alterations, additions, repairs, and changes of occupancy (SEAONC, October 2010). Such uses of ASCE 41, however, are ill-advised, ill-informed, and misguided because the seismic performance obtained from ASCE 41 is in no way equivalent to that obtained from designs based on the building code. ASCE 41 itself does not even posit equivalence and expressly points out the opposite: "The level of damage and potential economic loss experienced by buildings rehabilitated to the BSO [Basic Safety Objective] may be greater than that expected in properly designed and constructed new buildings." We wonder, therefore, how exactly does that imply any equivalence between ASCE 41 and the seismic design requirements in the current building code and why exactly the structural engineering profession is pushing ASCE 41 as equivalent?

We have also long found it astonishing that the leaders of a profession that has for so long swathed itself in the mantle of public safety would suddenly reverse course and actively promote a methodology that was recognized by many of its contributors as inherently flawed -- even before it was made into a standard. But now that the profession has been told outright by the engineering community that the standard has major provisions that are regularly ignored, and that the standards lead to inconsistent and only sometimes overly-conservative results, we are floored that the *only* response of the profession has been to convene another committee to try and address the problems. When will the organizations that have brought these standards into being inform the public, local jurisdictions, and other government agencies about the problems with them? When will the organizations that developed these standards rally against allowing these standards to be used as an equivalent to the prescriptive requirements of the building code? Based on the current evidence, it appears that these organizations will never own up to what they have done; instead, and to cover their mistakes, they will create new and "improved" versions of the standards, all the while promoting continued use of the existing standards and extending their use into yet more areas for which they are inappropriate. What better way to never have to admit that buildings throughout the country are every day being evaluated and strengthened, added to, and altered, using methodologies that do not work, but can still be said to be engineered in accordance with a state-of-the art "standard"!

We hope that the following examples will illustrate the point.

Example #1

Consider the 12-story, non-ductile perimeter lightweight concrete frame / perforated shear wall structure that was designed in 1967 and is located a stone's throw away from a major California fault (Figure 1). The building had been abandoned for approximately two decades after reportedly being damaged during the Loma Prieta earthquake; because it had forfeited legal occupancy, a municipal ordinance required that the structure be brought up to current code before it could be reoccupied. In addition, the owner wanted to add another story to the top, increasing the occupant load of the structure. Based on the input of the owner's engineer to the building department, however, that ASCE 41 qualified as an alternative method under the *International Building Code*, ASCE 41 was used to justify the assessment and strengthening of the structure. The engineer-of-record evaluating the structure according to ASCE 41 determined that only relatively minor strengthening was needed beyond that required to address the soft, weak story; the engineer's design relied on the existing perimeter non-ductile concrete columns to resist a large percentage of the lateral load in the transverse direction and nearly all of the lateral load in the longitudinal direction.

Figure 1: Twelve-story non-ductile concrete frame.

The original drawings indicate that the lightweight concrete columns are shear critical -- typically with #3 hoops spaced at 10 to 12 inches on center -- or approximately "d" in the minor axis direction -- and lacking appropriate hooks. Further, an in-situ load test conducted after Loma Prieta showed that the columns are also splice/development critical -- largely the result of the #8 to #10 longitudinal reinforcement bars being spliced with compression-only mechanical couplers. The splices are staggered (but only by 30 inches), are not located at the column point of inflection, have a much shorter lap splice length than required by ACI, and are without confinement. Essentially, when the splices go into tension, the columns start to come apart. Axial loads on the perimeter columns are fairly low, and overturning of the perimeter frame can easily result in tension that overcomes the dead load pre-

compression. Bending of the columns results in further tension in the splices, and the fact that the columns are eccentric to the spandrel beams creates torsion in the column members as well. Figure 2 shows the unconventional shape and reinforcing of a typical column.

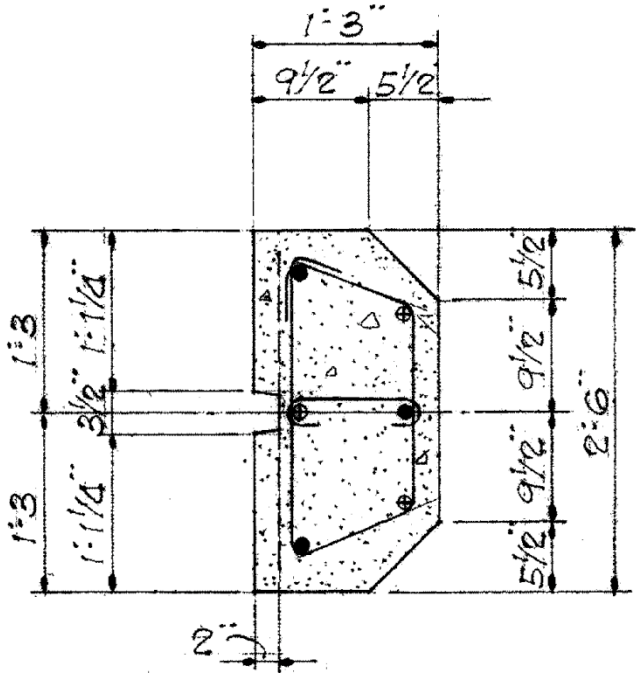

Figure 2: Typical non-ductile detailing of a column, with #3 hoops at 10- to 12-inches on center.

Even assuming that the non-ductile detailing "acceptable" to ASCE 41 would somehow preclude catastrophic failure in the event of a design-level earthquake (which the authors seriously doubt), it should be immediately obvious that these non-ductile details will not have the same *likelihood* of providing life safety or collapse prevention as a ductile design that complies with current code. Indeed, in the case of time history analysis, ASCE 41 requires only that the columns be capable of withstanding the *average* shear demand from the seven simulations required -- in effect allowing the columns to fail one-half the time under design level events. While the authors understand that in some cases, it ought to be possible to justify the use of less-than-ductile detailing, we believe that neither the owner nor the City knew what ASCE 41 was really doing, particularly that safety and resiliency were being compromised relative to what a new code-compliant design would have provided, and that the spirit and intent of the municipal ordinance in requiring code-compliance was being compromised as well. This is not a problem that can be pinned solely on the engineer; the entire profession is at fault because it has made insufficient efforts to advise the people who need to know that ASCE 41 does not provide performance equivalent to that of the code. Most unfortunately, projects like this continue to move forward and be occupied, with everyone thinking they are in seismically safe structures -- even "better than code" -- because the latest greatest "standards" were used.

Example #2

As another example, consider a proposed four-story vertical addition to an existing eight-story concrete perimeter moment-frame building (Figure 3) designed in the early 1970s located in an area of very high seismicity (Searer *et al*., October, 2008). To be permitted to add the new stories, the lateral resistance of the entire building was explicitly required by the municipal code of this major city to comply with *all* the structural design provisions applicable to new buildings in the current code. Although the concrete moment frames were apparently designed with the intent to conform to the ductile detailing requirements of the very early 1970s code, the structural drawings depict classic non-ductile detailing, including typical column hoops at greater than d/2 spacing, longitudinal reinforcing splices located outside the middle third of the column and with no confinement other than the typical widely spaced hoops, and plastic hinge confinement of heavy longitudinal steel relying on #3 cross ties. Worse still, a typical 17-inch (42-cm) thick brick-faced reinforced concrete-filled kneewall reduced the clear height of the typical columns, forcing the column hinge region up into the portion of the column with widely-spaced column hoops, creating classic "short" or captive column conditions throughout the building height, creating shear-critical columns, and increasing the flexural depth of the beams, thus creating strong-beam-weak-column conditions.

Figure 3: Photo of non-ductile concrete moment frame structure designed in the early 1970s.

Since the original building was constructed in the early 1970s with non-ductile details, bringing the building up to current code would have required substantial expense and disruption to tenants if the building could not be shown to be "conforming". The engineer initially released a report stating that the building complied with *every* detailing and strength requirement in the current code, even

considering the effect of the addition and without any strengthening whatsoever, and attempted to show "by code" that the existing building could support the four-story addition. After a peer review challenged the conformance of the existing detailing to current code requirements, the engineer selected ASCE 41 as the methodology of choice for demonstrating "equivalence", and that choice was accepted by the peer review panel and the municipality. Unnoticed and unmentioned was the brief advisement in ASCE 41 itself that it does not provide code-equivalent performance.

Using ASCE 41, and taking a few liberties with the design ground motions (which were 30% smaller than those used for code-complaint adjacent construction) and the structural analysis model (which did not include any of the kneewalls because they were so-called "architectural elements"), the engineer demonstrated via ASCE 41 that the performance of the building would provide for collapse prevention during the deterministic Maximum Considered Earthquake (MCE). As in the prior example, the ability of the columns to withstand shear was satisfied by relying on ASCE 41's provision that only the average shear from seven simulations need be considered, and based on the engineer's ASCE 41 analyses of the structure without the kneewalls modeled, the four-story vertical addition was actually approved for construction by the municipality without requiring any strengthening of the existing building!

As bizarre as this seems, but as this example clearly shows, ASCE 41 is being used to demonstrate compliance and equivalence of non-ductile detailing with the ductile detailing requirements of modern building code. Unfortunately, literally decades of learning from earthquakes about the importance of ductile detailing in concrete structures are being stripped away and dismissed by the "performance-based" analyses permitted by ASCE 41. While it may be true that a structure with limited ductility may survive a postulated design-level earthquake, it is not in the least realistic that the *confidence* that the structure will survive such an earthquake can be equated with that provided by a structure that complies with the ductile detailing requirements of the code. In no way should ASCE 41 be considered to provide the same performance or the same level of confidence that the desired performance will be achieved. Of note, ASCE 41 expressly states that ASCE 31 is understood to be even less conservative than ASCE 41 because it employs a 0.75 factor on demands when conducting a Tier 3 evaluation, which begs the question of just how many existing buildings, and projects involving additions, alterations, and changes of occupancy are being found to be "code-equivalent" on the basis of ASCE 31 Tier 3 analyses.

ASCE 31 AND ASCE 41 GIVE ANSWERS THAT ARE NONSENSICAL

The examples above notwithstanding, ASCE 31 and 41 are not always less conservative than current code; in fact, they can be far more conservative than current code, can force the performance of unnecessary calculations, and can give nonsensical results, as these next examples show.

Example #3

This structure is a one-story prefabricated steel-framed warehouse (Figure 5). Rectangular in plan, measuring 205 feet by 60 feet, and weighing just 0.4 pounds per cubic foot, this is one of the lightest structures we've ever studied.

Figure 4: Prefabricated steel-framed warehouse.

Lateral loads are resisted by steel moment frames, by diagonal cable bracing, and by the corrugated steel cladding. This building, which is in an area of moderate seismicity, was being considered for lease by the US Federal Government, which requires all buildings it leases to meet ASCE 31. With some back-of-the-envelope calculations and engineering judgment, it is possible to show not only that this structure has sufficient lengths of exterior wall that it meets the intent of current code with respect to seismic provisions, but also that hurricane-level design wind loads will govern the actual performance of the structure. Unfortunately, ASCE 31 permits neither back-of-the-envelope calculations nor engineering judgment.

Although most experienced engineers would probably consider a site with a 2475-year earthquake peak ground acceleration of 0.21g and a maximum spectral acceleration of 0.52g to be an area of moderate seismicity, the peak spectral acceleration is just 4 percent above the ASCE 31 cutoff for "moderate" seismicity.

No engineering judgment being permitted, the site is considered to have a high level of seismicity per ASCE 31. ASCE 31 then sets forth 11 pages of checklists that must be investigated to prove that the building is seismically adequate -- something that any experienced earthquake engineer should know after just a few minutes of reviewing of the structure. ASCE 31, being a cookbook, requires that torsion be checked, even though the structure is torsionally stable by inspection; several pages of calculations were required to show that torsion is adequately resisted by the structure. Further, ASCE requires that the axial stress in the cable bracing be checked but fails to require that the end connections of the cables be checked. In this case, the actual connections in this structure are so poorly engineered and constructed (Figure 5), they would be unable to develop the axial strength of the cables. ASCE 31, being a cookbook, failed to identify this potential weakness, and any inexperienced engineer relying on ASCE 31 would consequently miss this weakness as well.

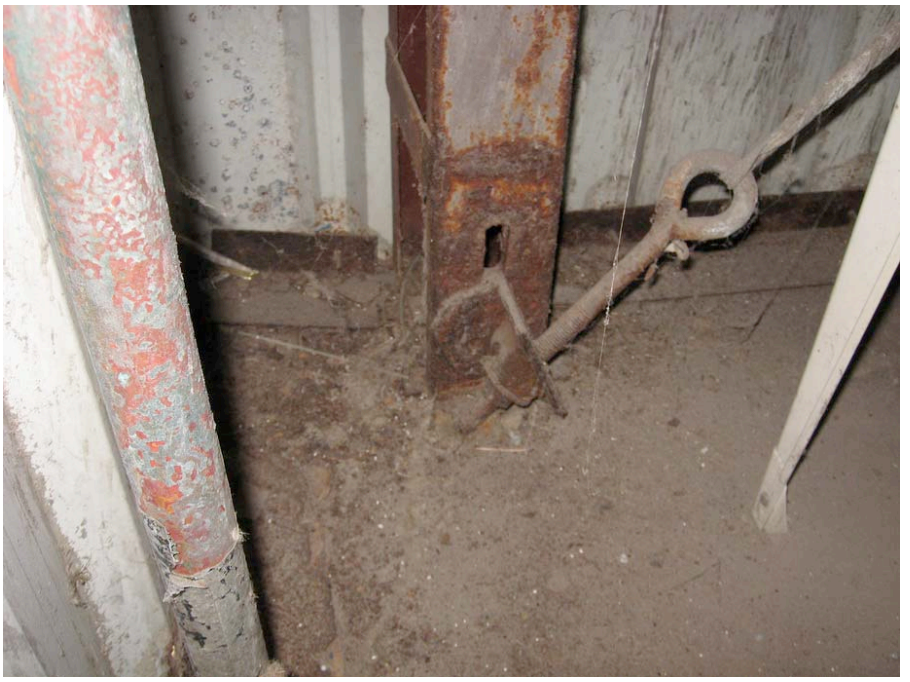

Figure 5: The connections of the cable bracing are highly eccentric and are clearly inadequate to develop the strength of the cables.

In the end, the structure "passed" ASCE 31, but for the wrong reasons. ASCE 31 required checks of elements that were clearly adequate for a structure that is likely to be unoccupied if a significant earthquake ever occurs, and failed to identify potential problems with other elements. In the end, ASCE 31 required more than 25 hours of fieldwork and analysis to prove what an hour of review by an experienced structural engineer should have been able to determine.

Example #4

ASCE 31 also fails to work properly in areas that most engineers would classify as having low seismicity. Consider the four-story unreinforced masonry structure that was originally used for manufacturing (Figure 6). The structure has since been

converted to office space and is being considered for occupancy by the U.S. Government, which requires the structure meet the requirements of ASCE 31.

Figure 6: This four story structure failed to meet the requirements of ASCE 31, despite being located in an area of relatively low seismicity.

Located on the east coast of the United States, this site has an effective peak ground acceleration of 14 percent, a peak spectral acceleration of 36 percent, and a one-second spectral acceleration of 15 percent, based on the 2475-year earthquake -- a return period that is, in the opinion of the authors, typically not appropriate for evaluation of existing buildings. A discussion of the problems with using such a long return period earthquake to evaluate existing structures is beyond the scope of this paper but can be found in Searer *et al*. (2007). In this case, the building is located in what used to be a Seismic Zone 2A in the Uniform Building Code (ICBO, 1994), and is located approximately 25 miles from an old Seismic Zone 1 -- hardly a portion of the country where earthquakes are a significant concern for well-built structures, even unreinforced masonry structures. Consequently, to occupy a portion of the structure, compliance with ASCE 31 requires that the entire building be upgraded via addition of floor- and roof-to-wall tension ties and shear transfer details -- a fairly expensive impediment to leasing space within the structure, and one that, in the authors' opinion, does not appear to be justified given the low level of seismicity to which this historic structure is exposed.

A FEW SELECTED TECHNICAL PROBLEMS WITH ASCE 31 AND 41

The ASCE standards have a myriad of technical problems, arguably enough to fill a book-length document longer than the standards themselves. A sampling of these was discussed in Searer *et al*. (April 2008); a few other head-scratchers are touched on herein.

Concrete Shear Wall Provisions

ASCE 41 provides "Numerical Acceptance Criteria for Nonlinear Procedures" for, among other things "Reinforced Concrete Shear Walls and Associated Components Controlled by Shear". The criteria are provided for, among other things, Life Safety (LS) and Collapse Prevention (CP) limit states in terms of an "Acceptable Total Drift (%)", determined using the full unreduced earthquake demands and the softening of the structure resulting from member nonlinearities. The drift criteria provided therein, which may not be exceeded without the entire structure failing the test, are 0.60 percent for LS and 0.75 percent for CP -- which makes us ask the following questions: What are the physical facts that led the authors of the document to conclude that a building -- for the sake of having an easy-to-visualize example, say a one-story concrete shear wall structure with a roof height of 10 feet -- would be a risk to the life safety of anyone when its lateral displacement at the roof during a design 475-year event was predicted to be less than ¾ inches, or would present a risk of collapse too great to accept when its lateral displacement at the roof during a 2,475-year event was predicted to be less than 1 inch? What physical facts could possibly have persuaded everyone involved that such a building was required to be seismically improved in order to make that building seismically adequate?

The provisions for reinforced concrete coupling beams have similar problems; we are not aware of any case where coupling beam damage itself resulted in the collapse of a building. What basis is there for a Collapse Prevention limit on coupling beam damage such that the safety of an entire building could be found deficient? Shouldn't the seismic adequacy of any building with coupling beams depend on whether the coupling beams are critical to the stability of the structure?

Steel Braced Frame Provisions

ASCE 41 also provides "Numerical Acceptance Criteria for Nonlinear Procedures" for, among other things "Structural Steel Components - Axial Actions" which are specifically applicable to braces. Similar to the concrete shear wall example above, the criteria provided for a primary "slender" brace in compression, say for an HSS section, which may not be exceeded without the entire structure failing the test are $5*\Delta_c$ for LS and $7*\Delta_c$ for CP, where Δ_c is the axial deformation expected at buckling load. Even a simple hand calculation, however, demonstrates that a slender brace in a bay of typical proportions could buckle at something around $^1/_{10}$ inches of axial deformation, meaning that the brace -- and thus the entire building in which the brace resided -- would fail the ASCE 41 Life Safety test if the story drift computed for the design event was short of ½ inch, and would fail the ASCE 41 Collapse Prevention test if the story drift computed for the design event was around ¾ inch. Given this,

questions similar to those raised in the preceding paragraph are certainly relevant: What are the physical facts that led the authors of this document to conclude that a building -- for the sake of having an easy to visualize example, say a one-story structure with a roof height of 15 feet -- would be a risk to the life safety of anyone when its lateral displacement at the roof during a design event was predicted to be less than ½ inch, or would present a risk of collapse too great to accept when its lateral displacement at the roof during a design event was predicted to be less than ¾ inch? What physical facts could possibly have persuaded everyone involved that such a building was required to be seismically improved in order to make that building seismically adequate? In developing these criteria, did anyone notice that these Life Safety and Collapse Prevention drift criteria are not particularly different from the drift levels used for decades to provide serviceability for wind design?

P-Delta Effects

These simple examples bring to light an underlying fundamental flaw that pervades the ASCE 41 approach; namely, that nonlinear assessment of Life Safety and Collapse Prevention limit states is typically viewed for "deformation-controlled" elements through the lens of drift-dependent element-specific criterion alone, rather than through a lens which explicitly accounts for local P-Delta effects and the structural context in which the element resides. This lapse is made clear in part by examination of the ASCE 41 acceptance criteria for structural steel columns, subject to nonlinear analysis, which are expressed in terms of "Plastic Rotation Angle, Radians". Being "plastic hinge rotations", these criteria are in some respects independent or relatively independent of the magnitude of the axial load in the column, meaning that according to ASCE 41, it does not matter whether the particular column being assessed is supporting only one story of tributary load or 100 stories -- the column being assessed is deemed to present essentially identical risk to life safety and the essentially identical collapse hazard. To our mind, however, the risk associated with any column is inextricably linked to the axial load on that column and no drift criterion alone -- such as provided by ASCE 41 -- can appropriately identify when that column will approach collapse conditions; the axial load in the column simply must be considered in tandem with the drift.

Equally, if not more, important is the subject of structural context. One criterion by which the seismic safety columns might have been judged in a pre-ASCE 41 world would have related to global buckling of the column, and the propensity of a column to buckle would have been related to whether it was located in a structure such that is either was or was not braced against sidesway. Should not the safety of a column located in a building that has shear walls be judged somewhat differently from a column located in a frame structure? Should not the safety of a column in a frame structure also be judged relative to the bracing provided by other frames in the structure? Yet this simple concept seems to not be relevant to any of the seismic safety checks in ASCE 41; in other words, the structural context of the element being evaluated does not appear to matter anymore. This is particularly ironic given that the safety of the element has, in ASCE 41, been given such weight that entire buildings

can be condemned based on the evaluation of a single element, as discussed in the following section.

Ignoring the Big Picture

As a last example, we will dwell for just a moment on the obvious -- the aspect of the ASCE methodologies that condemns entire buildings on the basis of the computed behavior of a single element. As we read the standards, assessment of the seismic adequacy of buildings is to be done on a member-by-member basis; the demands on each member in the lateral force resisting system is to be compared to the acceptance criteria applicable to that member. According to the standards, if a single primary member in a building fails the tests (including the Secondary Acceptance Criteria) the entire building fails the test, regardless of the level of redundancy and excess capacity in its remaining members and regardless of the ability or inability of the structure to redistribute loads. Unfortunately, this approach directly conflicts with what we believe are the fundamental elements and benefits of true performance-based engineering assessments, which, by employment of nonlinear analysis procedures are able to directly consider the consequences on the structure as a whole of excessive demands on individual members in a structure. The very simplistic approach required by the ASCE standards stands the intent of performance-based engineering on its head -- which it ought not to do if for no reason other than it sets itself forth as a performance-based standard. It is also simply wrong -- both in a technical sense and from an ethical one -- to automatically condemn the seismic performance of a building on the basis of the predicted response of a single element and to require that an engineer conclude on that basis that the building requires seismic strengthening.

CONCLUSIONS

While engineers familiar with ASCE 31 and 41 are well aware of the problems with these two documents, no apparent efforts have been made by either ASCE or structural engineers associations to inform other engineers, government officials, building officials, or the public with the myriad problems with these documents. Instead, these documents are being used indiscriminately by the engineering profession, resulting in inconsistent, illogical, useless, and sometimes even unsafe results. Although these documents are currently in the process of being revised, with revisions due in the fairly distant future, we are not hopeful that these documents can be improved to the point where they do more good than harm.

ABSTRACT

Force-based seismic evaluation techniques for low ductility braced frame buildings generally will classify a braced frame structure as a potential collapse hazard if the brace connections are not capable of developing the force capacity of the associated braces. However, anecdotal evidence from major earthquakes has shown that most steel braced frame buildings have performed to a life safety or better performance level, even when brace connections have fractured. One reason for this lies with the contribution of the gravity framing participating as partially restrained moment frames. This paper discusses the seismic evaluation of a two-story 1980's braced frame building located in California. A nonlinear static analysis in accordance with *ASCE 41-06 Seismic Rehabilitation of Existing Buildings* was performed, with brace connection fracture and all the gravity frames modeled as partially restrained moment frames. The analysis showed that the building was very stiff, until the brace connections fractured. Following the connection fracture, the building became more flexible, but the gravity frames had sufficient flexibility to accommodate the earthquake induced drifts without compromising the stability of the building. The analysis showed that the building met the Life Safety performance level.

INTRODUCTION

Steel braced frame structures have been a common choice for low-rise buildings since the 1960's in many parts of California. New steel braced frame buildings in regions of high seismicity, such as coastal California, are required to either be Special Concentrically Braced Frames, Eccentrically Braced Frames, or Buckling Restrained Braced Frames (ASCE/SEI, 2006). All three of these types of braced frames have very specific design and detailing provisions that are intended to force the nonlinear response into actions that can dissipate energy such as brace yielding or buckling. Sudden failures, such as those that could occur at a connection, are prevented by requiring the connections to be designed for the capacity of the brace.

Explicit capacity based design provisions for braced frame connections were only instituted in the 1990's. Prior to the 1990's the most common type of braced frame used in low and midrise construction in California would likely be classified as a low ductility braced frame because its connections were not explicitly designed for the capacity of the braces.

The objective of this paper is to present the investigation of the seismic performance of a low ductility steel braced frame building via a nonlinear static procedure, while modeling the gravity beam to column connections as partially restrained moment frames. The purpose is to demonstrate that even though typical force based analysis procedures would show that the brace connections could not develop the capacity of the brace, and therefore would result in a classification of the building as a potential collapse hazard; the non-linear analysis indicated that the building met the Life Safety performance level.

The impetus for the assumption that the low-rise braced frame building was not a collapse hazard came first from observations of the behavior of braced frame building in major earthquakes and from some research conducted on the contribution of the steel gravity framing system behaving as a partially restrained moment frame system.

HISTORIC PERFORMANCE OF STEEL BRACED FRAMES

Past earthquakes have illustrated the susceptibility of low ductility steel braced frames to brittle failure mechanisms. These failures have typically been categorized as: i) net section fracture of the brace ii) failure of the brace to gusset connection via inadequate bolts or welds or iii) failure of the gusset plate or its connection to the beam or column. Although the documented number of brace and brace connection failures is quite extensive, the actual number of recorded building collapses due to these failures is limited, and typically only associated with older buildings with slender elements.

The 1978 Miyagi-ken Oki earthquake was one of the earliest earthquakes to illustrate potential weaknesses of modern braced-frame connections and detailing. Researchers Kato, Tanaka, and Yamanouchi (Kato, Tanaka, and Yamanouchi 1980) surveyed 454 steel buildings after the event and indicated that 107 buildings (with varying degrees of damage) had fractures of the brace elements and/or their connections. Of these 107 buildings only 6 had either collapsed or had lost their residual strength. It should be noted that a significant number of the braced frame buildings in Japan at this time consisted of slender tension-only bars or straps and light gauge steel elements, and most likely were the buildings that were categorized as collapsed. The steel building stock affected by this earthquake is not consistent with the braced frame building analyzed in this paper, and therefore, calculating probabilities of collapse from this pool and applying them to this building is unwarranted.

The 1985 Michoacan, Mexico earthquakes struck off the coast of Lazaro Cardenas on September 19th and 20th and were of magnitude 8.1 and 7.5, respectively. Investigator Martinez-Romero (Martinez-Romero 1986) surveyed 102 engineered steel buildings and reported that 10 of these had either totally collapsed or partially collapsed. Of these 10, only 3 were built after 1957 and contained diagonal braces. These 3 failures all occurred at the Pino Suarez complex, and are attributed to overstressing of slender columns, P-delta effects, and the long duration of shaking (Krawinkler and Martinez-Romero 1989). In addition, one of the 3 failures occurred

because the adjacent 21-story building collapsed onto the adjacent 14-story building. Although there was extensive damage to braced steel buildings in these earthquakes, the brace members and their connections are not representative of current detailing practices in United States, nor are they consistent with the building type investigated in this paper.

The 1994 Northridge earthquake is typically associated with having exposed the potential for brittle fractures in "ductile" moment frames and prompting investigations into various issues related to welded steel moment frame buildings; however, it also revealed the susceptibility of braced frames to non-ductile component failures. Kelly, Bonneville, and Bartoletti (Kelly, Bonneville, and Bartoletti 2000) describe damage found to a four story concentrically braced frame building that was designed to the 1980 Los Angeles building code. This building was reported to have only minor damage to its exterior; however, the interior braced bays experienced significant damage via twisting of beams at brace mid-spans, failure of brace connections to gusset plates, and fracture of bracing members at mid-spans due to local buckling. Most of the damage was concentrated at the second floor and was a result of softening that occurred to that level after initial brace failures began. It is unclear how many braced frame buildings experienced brace and component failures after the Northridge earthquake; however, there were no collapses of steel buildings.

The 1995 Hyogo-ken Nanbu earthquake caused damage very similar to the 1978 Miyagi-ken Oki earthquake, highlighting the weaknesses of slender tension-only straps and poor detailing of brace connections. Tremblay et al. (Tremblay, R. et al. 1996) summarizes a survey performed by the Architectural Institute of Japan (AIJ 1995) of 982 steel buildings. It is reported that of 452 *damaged* steel braced frame buildings, 29 had collapsed; however, 148 had only minor damage. All of these collapses were associated with slender bracing systems such as angles, flat bars and rods. Although not specifically quantified, these smaller cross sections would correlate with older building types, and therefore, as mentioned previously, are not representative of current detailing practices in United States, nor are they consistent with the building type investigated in this paper.

PARTIALLY RESTRAINED MOMENT FRAME CONTRIBUTION

After the Northridge earthquake, January 17, 1994, it was discovered that many steel welded moment frames exhibited brittle fractures in their welded moment connections; however, the performance of these buildings suggested the actual contribution of simple shear connections at the beam column joints was greater than previously thought. Liu and Astaneh-Asl (Liu and Astaneh-Asl 2000a-2000d), as part of the SAC Joint Venture Steel Project, conducted multiple full-scale cyclic tests of typical simple shear connections to very large drifts in order to establish their strength, stiffness, and ductility. These tests indicated that typical moment capacities ranged from about 20% of the plastic moment capacity of the beam (Mp) for the bare steel condition, to about 50% Mp if a concrete slab was present, and up to 80% Mp for the shear connection with a bottom seat angle and concrete slab.

ASCE 41-06 considers these types of shear connections as partially restrained (PR) moment frames and recommends modeling parameters and acceptance criteria limit states for nonlinear analysis procedures, and states that these gravity load-carrying elements could be used in the analytical model to reduce the demands on the moment frame elements. It is reasonable that specific modeling of the gravity shear connections can also be applied to non-ductile steel braced frame buildings, and therefore, act as a backup system to the non-ductile primary lateral force resisting system.

BUILDING DESCRIPTION

The existing building investigated is a two story steel braced frame building with a plan aspect ratio of approximately 3 to 1, as seen in Figure 1 and Figure 2, and a floor to floor height of 14 feet. Its design was performed in accordance with the 1976 Uniform Building Code. The gravity system is comprised of 2-inch metal deck with 3.25-inches of lightweight concrete fill spanning to steel beams, girders and columns. The beams and girders are composite members with shear studs spaced typically at 24 inches on center at gravity beams, and 12 inches on center at collector lines. The gravity beam connections are simple bolted connections with a single shear plate welded to the column as seen in Figure 3, and in some cases seat angle connections are also provided as seen in Figure 4. The foundation consists of reinforced concrete drilled piers and pier caps interconnected to each other with reinforced concrete grade beams.

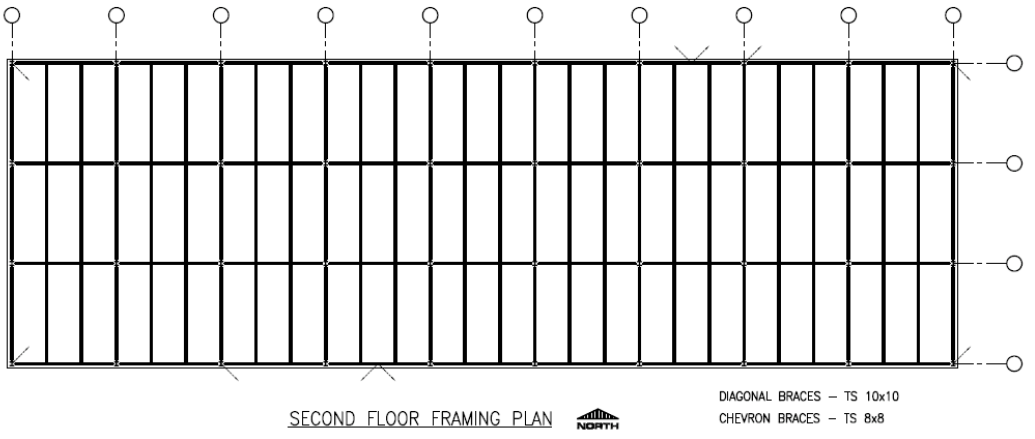

Figure 1. Second Floor Framing Plan

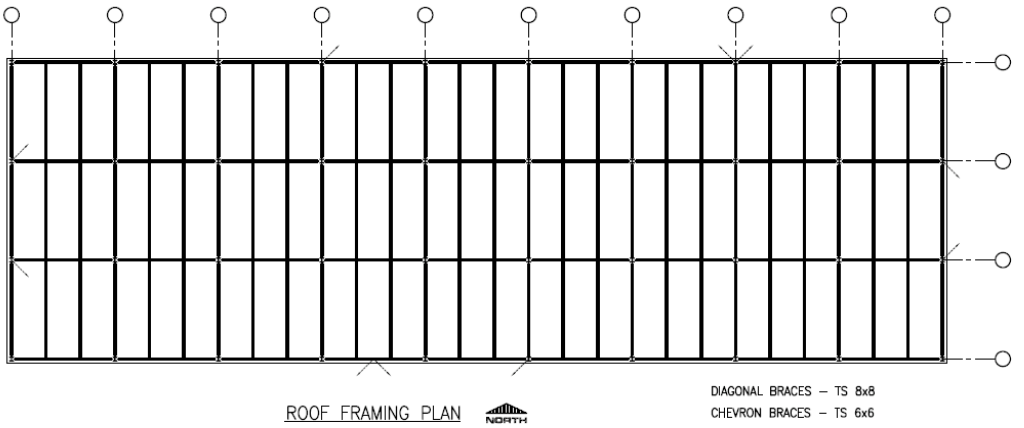

Figure 2. Roof Framing Plan

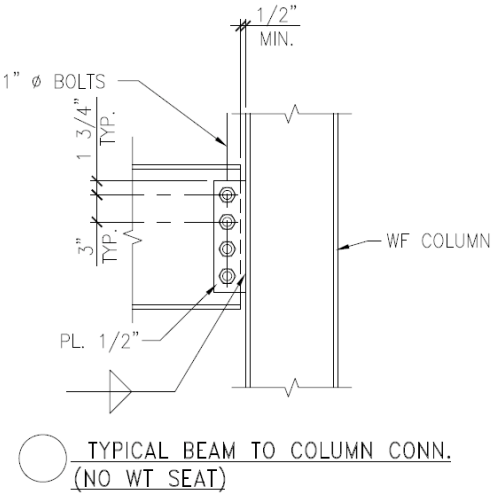

Figure 3. Typical Beam to Column Conn. (No Seat)

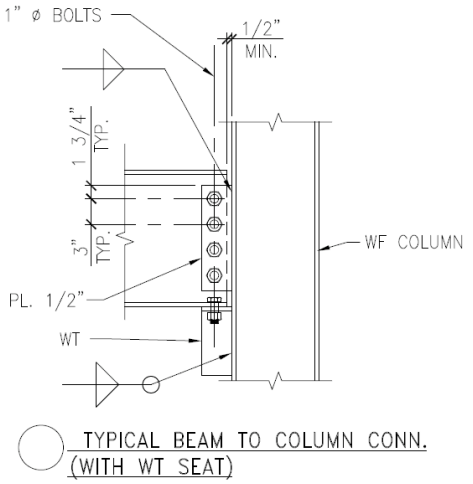

Figure 4. Typical Beam to Column Conn. (With Seat)

The lateral braces are located at each of the four exterior sides of the building, and are arranged in both diagonal and chevron bracing configurations. The diagonal braces are TS 10x10 structural sections and the chevron braces are TS 8x8 sections at the first floor. At the second floor the diagonal braces are TS 8x8 and the chevron braces are TS 6x6. The difference in brace sizes between the diagonal and chevron braces can be attributed to the longer pin-to-pin length of the diagonal brace relative to the chevron brace. The typical brace connection is depicted in Figure 5, and consists of a single gusset plate that receives the slotted tube steel brace. The absence of reinforcing plates at the net section of the brace, the short weld length of the brace to gusset connection, and the absence of detailing for ductile hinging in the gusset plate are all indicators of the potential brittleness of this connection.

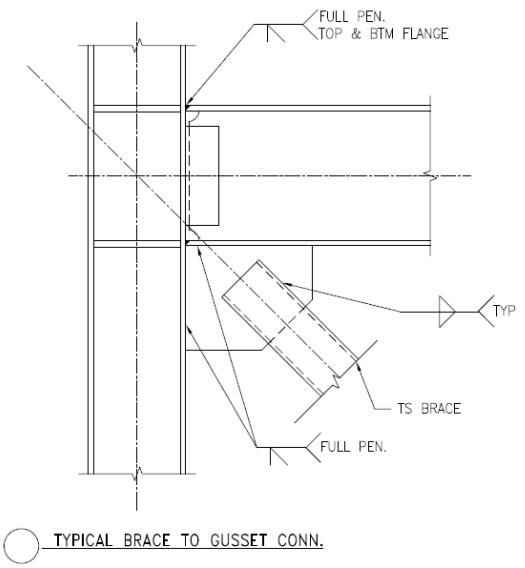

Figure 5. Typical Brace Connection

LINEAR ANALYSIS

A typical linear analysis of a braced frame building will assume the entire lateral seismic load is resisted by the brace elements, and all of the beam to column connections are assumed to have no rotational strength and stiffness (i.e. pinned connections). The compressive and tensile capacities of the braces are then checked against axial loads induced by the seismic demands. In an ASCE 7-05 procedure, the seismic demands on the braces are reduced by the system Response Modification Factor, R, and the brace capacities are based on nominal strengths (Rn) and resistance factors (phi) (AISC 360-05 and AISC 341-05). In an ASCE 41-06 procedure, the seismic demands for a particular earthquake hazard level are evaluated, and the brace capacities are based upon the expected strength of the component and the component demand modification factor (m). In both procedures, the connections of the braced frame system must be strong enough to withstand the expected yield strength of the brace in tension or the maximum load that can be delivered to the braces.

For the building considered in this paper, and true of many braced frame buildings designed and constructed prior to the code changes of the 1990's, the brace connection capacities are calculated to be insufficient to withstand the force capacity of the associated braces. Therefore, the linear analysis would classify the building as a potential collapse hazard, and costly seismic retrofitting would be required.

NON-LINEAR ANALYSIS

Simple linear analysis cannot accurately model building performance, and therefore, its inherent conservatism is more appropriate for new building design, not existing building evaluation; especially, when the existing building is a low ductility braced frame building. Therefore a nonlinear analysis of the building was performed.

As is common with ASCE 41-06 analyses, two seismic hazards were considered in this assessment. The BSE-2 seismic hazard is based on the Maximum Considered Earthquake at the building site. The BSE-1 seismic hazard is similar to a design level earthquake that would be used in new building design. Different structural performance states are assessed at each seismic hazard. In ASCE 41-06, the Basic Safety Objective (BSO) is a level which is intended to be consistent with the accepted level of seismic risk a new building would be designed to (ASCE/SEI 2007). For a building to conform to the BSO, it must meet the Life Safety performance level at the BSE-1 hazard and the Collapse Prevention performance level at the BSE-2 hazard.

The nonlinear static analysis procedure (NSP) outlined in ASCE 41-06 was used. The NSP provides a more detailed assessment of structural performance than the linear procedures contained in the building codes and ASCE 7 because it explicitly permits structural members to be stressed beyond their elastic limits and allows forces

to redistribute as they would in an actual earthquake.

In a pushover analysis, the displacement of a user-specified node is tracked against the force at the structure's base. Target displacements for the control node are calculated based on the seismic response spectrum for the site. These displacements are estimates of the maximum displacement the structure will undergo in a seismic event. Deformations in all the nonlinear hinges are then evaluated at the target displacement and checked against limits set forth in ASCE 41-06 or determined based on other rational methods. The structural elements that do not have nonlinear hinges assigned to them must then be checked to verify they have not been overstressed.

To perform the nonlinear static analysis, a three-dimensional model of the structure was created using ETABS v.9. The model included the braced frames, the concrete floor and roof diaphragms, and the main gravity framing – all the columns and all the beams along the gridlines. Because the initial assessment showed that the brace connections would not permit the braces to buckle and yield, which is the ideal way for braced frame structures to absorb seismic demands, the back-up system created by the gravity framing was included with the beam-column connections modeled as partially-restrained moment connections. Additionally, the explicit deformation characteristics of the concrete floor and roof diaphragms were modeled.

Nonlinear hinges were placed at all locations where there was a potential for the respective element to be stressed beyond its elastic limits. The hinge backbone curves were developed based on PR moment frame modeling parameters of ASCE 41-06. For the braces, ductile hinges representing the brace yielding in tension and buckling in compression were added, as were brittle hinges to represent the sudden loss of load carrying capacity in a brace when its connection is overstressed. The beams in the braced frames that had brace gusset plates attached to them were given ductile flexural hinges. The partially-restrained beam-column connections of the gravity framing had flexural hinges placed at each end to represent the behavior of their connection yielding in accordance with ASCE 41-06 and procedures developed by Liu and Astaneh-Asl (Liu and Astaneh-Asl 2004). The flexibility of the structure's foundation was explicitly modeled by placing three-dimensional springs at each drilled pier location, using upper bound stiffness values.

The model was then "pushed" in the transverse or north-south direction using a load pattern that displaces the structure elastically based on its first mode of vibration. Figure 6 shows a plot of the control node displacement, which was taken as a point on the roof near its center-of-mass, versus the base shear force (known as a pushover curve). In the analysis, the curve displays the pushover curves between zero and 150% of the BSE-2 target displacement, as ASCE 41-06 requires pushovers be carried out to. No analysis of the structure in the longitudinal, east-west direction was performed.

The structure is elastic until the point at which the connections of the second story western braces reach their limit. At that point, those connections are assumed to

fracture and render the braces ineffective, as seen in the large drop in base shear in the pushover curve. That creates a severe stiffness imbalance between the east and west sides of the second story since the eastern braces are still elastic. The roof then begins to rotate, engaging the resistance of the gravity framing and the perpendicular braced frames, which act to resist the rotation. As the roof continues to displace and rotate, the gravity framing beam-column connections yield and the perpendicular braces along the south face either buckle or fracture their connections. Those events are represented by the smaller sawtooth patterns on the pushover curves. All the while, the eastern braced frames at the second story and all the braces at the first story remain elastic.

The failure of the braced frame connections at the second story western frame creates a pronounced difference in strength and stiffness between the two stories. Because of that all the nonlinear yielding of elements occurs at the second story and the first story remains essentially elastic. At the BSE-1 target displacement, the western brace connections fracture and one of the southern braces buckle. Also, several of the gravity frame connections yield and reach their Immediate Occupancy limit. At the BSE-2 target displacement the southern brace connections fracture because of the forces imposed upon them as they resist the rotation of the roof. Most of the gravity frame connections yield. Because a significant number of the gravity connections in the roof were detailed to have a welded steel seat in addition to the standard shear-tab, those connections are capable of undergoing very large displacements without collapse and those are the connections that have the greatest rotational demand on them.

The non-linear analysis for this building indicates that when the simple shear connections are modeled as PR moment connections, these elements can have sufficient strength, stiffness, and ductility to act as a backup lateral system to the non-ductile braced frame building. The pushover curve shows that despite the fracture and/or buckling of the braces, the building can still displace well beyond the target displacement, while continuing to show increased strength in its force-displacement curve.

At the BSE-1 target displacement all the PR connections were found to have rotational demands well below the specified rotation limits for the life safety performance. Additional at the BSE-2 target displacement all the connection rotation demands were below the collapse prevention performance limits. Therefore the building met the Basic Safety Objective of ASCE 41-06.

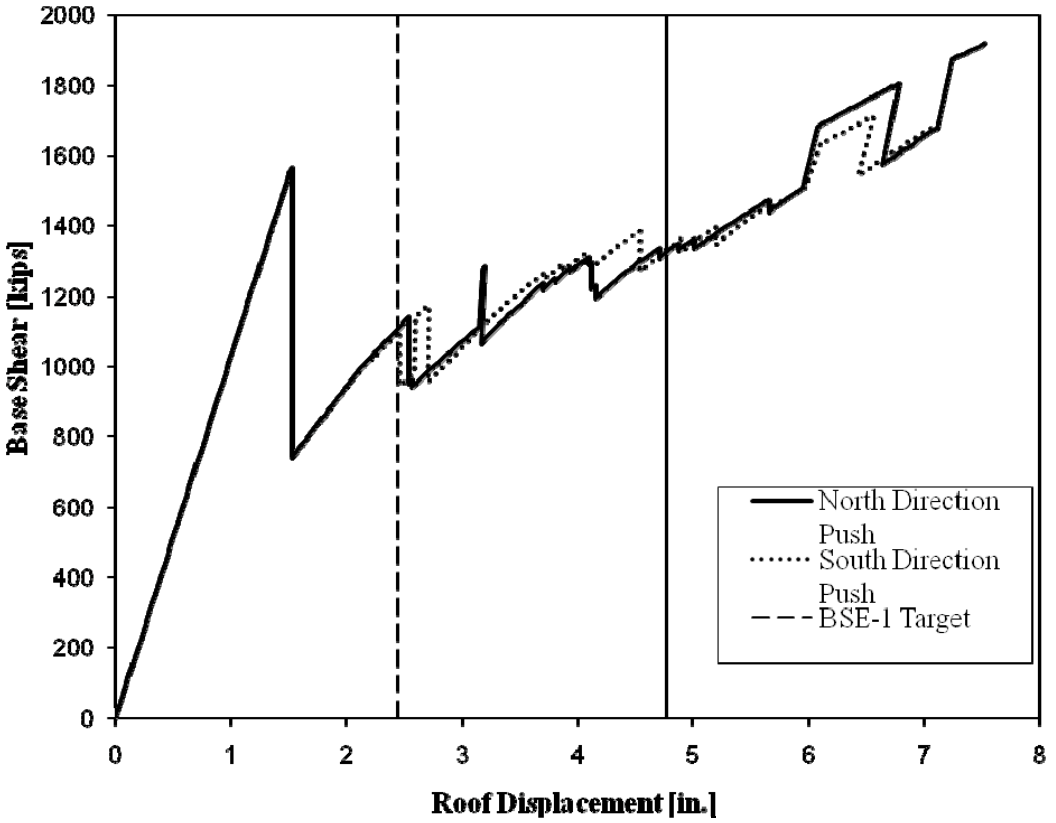

Figure 6. Nonlinear Static Pushover Curves

CONCLUSIONS

Force based or linear analysis seismic evaluations methods for low ductility braced frames will indicate that a building is a potential collapse hazard due to the inability of the brace connections to develop the capacity of the brace. As suggested by anecdotal evidence of past building performance, cyclic testing, and non-linear static modeling, the contribution of simple gravity connections in steel buildings can provide a backup system of strength, stiffness, and ductility to a building utilizing low ductility lateral braces. This contribution is significant enough that when considered in seismic evaluations, they may provide a cost-effective alternative to seismic retrofitting. This paper only considers a non-linear static procedure; however, it is expected that a non-linear dynamic procedure would yield the same conclusions, as the refinements of the non-linear response history procedure would remove any conservatism inherent in all other analysis methods.

ABSTRACT

Firstly, a plastic-damage constitutive model for concrete complying with the laws of thermodynamics is proposed based on continuum damage mechanics theory. The damage constitutive equations, damage evolution equations and plastic deformation of concrete are derived. Secondly, Fiber damage analysis model(FDAM) for RC beam-column member is established by analyzing section of fiber beam column element, which was developed with VUEL subroutine based on ABAQUS/Explicit platform, with the uniaxial damage constitutive relations of concrete proposed in present paper being used. The member damage index is defined, which can describe the nonlinear damage behavior of RC members under any loadings. Accuracy of the model is identified preliminarily by comparing with the analysis results of solid element. Finally, a numerical analysis model based on finite element program ABAQUS combined with the proposed damage model is built to analyze the seismic damage of a high-rise structure, and the structure analysis results are compared to the data from shaking table test.

INTRODUCTION

In recent years, the seismic damage model that based on the plasticity and damage mechanics theories has attracted many attentions(e.g. Lee and Fenves, 1998; Wang and Liu, 2001; Li and Wu,2005; Teng and Li, 2006; Wu and Li, 2006). Theoretically, this approach could provide a more robust and broad basis for the research and application of structure seismic analysis. The reinforced concrete members are the

most widely used in structural engineering, so it is more crucial to develop corresponding damage model based on material damage mechanics to understand its mechanical behavior and damage evolution under monotonic/cyclic loadings.

On the other hand, at the aspect of finite element model, the so-called 'fiber method' is currently believed as a promising 'finer' strategy for inelastic structure analysis. The key points of fiber method are, firstly, subdivide member element into longitudinal fibers, and then determine the strains of section points with plan section assumption. After introducing corresponding uniaxial damage constitutive relation for each concrete and rebar fiber (i.e. each section point), the inelastic relation between section resultant forces and section deformations can be derived by integration of the response of the fibers. An especial advantage of the fiber method is that, the inelastic behavior of member section will be simulated at strain-stress level, which provides a practicable way for seismic damage analysis that based on material damage model.

From above considerations, a new energy release rate-based plastic-damage model for concrete, which accounts for the interaction of the damage and plastic deformation, can predict the concrete primary behavior in tension and compression is formulated comply with the basic principles of thermodynamics, and the fiber damage analysis model(FDAM) using fiber method for reinforced concrete members is developed, with uniaxial damage consitutive model for concrete fibers. The task is accomplished by the way of secondary development on ABAQUS/Explicit, which is a famous powerful explicit solver. The member damage index is defined, which can describe the nonlinear damage behavior of RC members under any loadings, and a numerical example of fiber damage analysis model for RC member is given in this paper, with their results compared with results from solid model. Finally, The present model is adopted to analyze seismic damage of a real structure, with their results compared with data from shake table test and which proved the effectiveness of the proposed model and strategy.

DAMAGE ANALYSIS MODEL

Plastic-damage constitutive model for concrete material. A plastic-damage constitutive model for concrete complying with the laws of thermodynamics is proposed based on continuum damage mechanics theory(e.g. Yu and Qian,1993). In order to describe the deformation process resulted from internal energy dissipation and micro change of the structure, the independent internal state variables related with irreversible thermodynamic processes are introduced. The Helmholtz free energy takes the form(Coleman and Gurtin,1967):

$$\psi\left(\boldsymbol{\varepsilon}^e, \boldsymbol{\varepsilon}^p, \boldsymbol{D}\right) = \psi^e\left(\boldsymbol{\varepsilon}^e, \boldsymbol{D}\right) + \psi^p\left(\boldsymbol{\varepsilon}^p, \boldsymbol{D}\right) \tag{1}$$

where $\boldsymbol{D}$ is damage tensor, $\psi^e\left(\boldsymbol{\varepsilon}^e, \boldsymbol{D}\right)$ is elastic Helmholtz free energy, $\psi^p\left(\boldsymbol{\varepsilon}^p, \boldsymbol{D}\right)$

and is plastic Helmholtz free energy.
In the present model, the damage tensor in (1) is substituted by scalar damage variable , which can consider the stiffness degradation of the material, one obtains the following expression for $\psi^e\left(\boldsymbol{\varepsilon}^e, \boldsymbol{D}\right)$:

$$\psi^e\left(\boldsymbol{\varepsilon}^e, D\right) = \frac{1}{2\rho}\boldsymbol{\varepsilon}^e : (1-D)\,\boldsymbol{E}_0 : \boldsymbol{\varepsilon}^e \tag{2}$$

where $\boldsymbol{E}$ is the stiffness tensor, $\boldsymbol{E}_0$ is the initial stiffness tensor, and ρ is the material density.

Based on the Clausius–Duhem inequality (Coleman et al., 1967) for the isothermal case, the damage constitutive equation is given as follows:

$$\boldsymbol{\sigma} = \rho\,\partial\psi^e\left(\boldsymbol{\varepsilon}^e, D\right)\big/\partial\boldsymbol{\varepsilon}^e \tag{3}$$

Generally for the state without damage, there is no plastic deformation occur in the concrete material. In other words, the damage and the plastic deformation will always coexist. The plastic Helmholtz free energy will not be zero when damage appears. But, even up to date, it is difficult to define the expression of plastic Helmholtz free energy directly. In this paper the expression of plastic Helmholtz free energy is given indirectly through a function that is defined using internal variables and elastic Helmholtz free energy, and its expression assumed taking the form as:

$$\psi^p\left(\boldsymbol{\varepsilon}^p, D\right) = F\left(\boldsymbol{\varepsilon}^e, \boldsymbol{\varepsilon}^p\right)\psi^e\left(\boldsymbol{\varepsilon}^e, D\right) \tag{4}$$

where $F\left(\boldsymbol{\varepsilon}^e, \boldsymbol{\varepsilon}^p\right)$ is a function of internal variables.

The damage energy release rate Y may be written in the form:

$$Y = -\rho\frac{\partial\psi}{\partial D} = -\rho\left[\frac{\partial\psi^e\left(\boldsymbol{\varepsilon}^e, D\right)}{\partial D} + \frac{\partial\psi^p\left(\boldsymbol{\varepsilon}^p, D\right)}{\partial D}\right] \tag{5}$$

By substituting (4) into (5), one gets Y expressed by $\psi^e\left(\boldsymbol{\varepsilon}^e, D\right)$ as follows:

$$Y = -\rho\left[1 + F\left(\boldsymbol{\varepsilon}^e, \boldsymbol{\varepsilon}^p\right)\right]\frac{\partial\psi^e\left(\boldsymbol{\varepsilon}^e, D\right)}{\partial D} \tag{6}$$

Thus, Eq. (6) is the control equation of material damage evolution. In this paper $F\left(\varepsilon^e, \varepsilon^p\right) = k\,\varepsilon^p/\varepsilon^e + l$, where k and l are constants.

On the other hand, for the material damage, the Weibull distribution is widely used to describe the distributing rule of the damage and fracture in the rock and the concrete material (e.g. Gao, 1993). In this paper the Weibull distribution hypothesis is also adopted in the determination of the damage variable and damage energy release rate. Therefore, one obtains expressions of D and Y as follows:

$$D = 1 - \exp\left(-\frac{\left(Y - Y_0\right)^a}{b} \right) \tag{7}$$

where Y_0 is initial damage energy release rate, a and b are constants. By substituting (6) into (7), one gets the evolution equation of damage.

The experimental tests show that there a surface (yield surface) in the stress space, where a failure or damage state can be determined. The yield function of Lubliner et al. (1989), with the modifications proposed by Lee and Fenves (1998) that accounts for both tension and compression plasticity is adopted in this work. In terms of effective stresses, the yield function takes the form

$$F = \frac{1}{1-\alpha}\left[\alpha \bar{I}_1 + \sqrt{3\bar{J}_2} + \beta(\tilde{\varepsilon}^p)\left\langle \hat{\bar{\sigma}}_{\max} \right\rangle \right] - c(\tilde{\varepsilon}_c^{\,p}) \tag{8}$$

where $\bar{I}_1 = \mathrm{tr}\,(\bar{\boldsymbol{\sigma}})$ is the first-invariant of the effective stress, $\bar{J}_2 = 1/2\,\bar{\mathbf{s}}:\bar{\mathbf{s}}$ is the second-invariant of the effective deviatoric stress, $\hat{\bar{\sigma}}_{\max}$ is the maximum principal effective stress, $\tilde{\varepsilon}_c^{\,p}$ is the equivalent plastic strain in compression.

The parameters α and β are dimensionless constants which are defined by Lubliner et al. (1989) as follows:

$$\alpha = \frac{\left(f_{b0}/f_0^-\right) - 1}{2\left(f_{b0}/f_0^-\right) - 1} \tag{9}$$

$$\beta(\tilde{\varepsilon}^p) = \left(1-\alpha\right)\frac{c(\tilde{\varepsilon}_c^{\,p})}{c(\tilde{\varepsilon}_t^{\,p})} - \left(1+\alpha\right) \tag{10}$$

where f_{b0} is the biaxial initial yield stress, f_0^- is uniaxial initial compressive yield stress, $\tilde{\varepsilon}_t^{\,p}$ is the equivalent plastic strain in tension.

The shape of the concrete loading surface will be obtained by using a non-associative plasticity flow rule. When the current yield surface F is reached, the material is considered to be in plastic flow state upon increase of the loading. In this work, the flow rule is given as a function of the effective stress $\bar{\boldsymbol{\sigma}}$ by

$$\dot{\boldsymbol{\varepsilon}}^p = \dot{\lambda}^p \frac{\partial F^p}{\partial \bar{\boldsymbol{\sigma}}} \tag{11}$$

where $\dot{\lambda}^p$ is the plastic loading factor, which can be obtained using the plasticity consistency condition, such that

$$F \le 0, \quad \dot{\lambda}^p \ge 0, \quad \dot{\lambda}^p F = 0, \quad \dot{\lambda}^p \dot{F} = 0 \tag{12}$$

Plastic potential F^p adopted in the present model is the Drucker-Prager function expressed as:

$$F^p = \sqrt{2\bar{J}_2} + \alpha^p \bar{I}_1 \tag{13}$$

where is α^p the dilation constant.
By substituting (13) into (11), the evolution law for the plastic strains is obtained

$$\dot{\boldsymbol{\varepsilon}}^p = \dot{\lambda}^p \left(\frac{\bar{\mathbf{s}}}{\|\bar{\mathbf{s}}\|} + \alpha^p \mathbf{I} \right) \tag{14}$$

where $\|\bar{\mathbf{s}}\| = \sqrt{\bar{\mathbf{s}} : \bar{\mathbf{s}}} = \sqrt{2J_2}$, $\mathbf{I}$ is the identity tensor.

Fiber Dmamge Analysis Model(FDAM). The general system equation of structure dynamics can be written in the form

$$\mathbf{M}\ddot{\mathbf{u}} = \mathbf{F} - \mathbf{F}^{\text{int}} \tag{15}$$

where $\mathbf{M}$ is mass matrix, $\mathbf{F}$ is external load vector, and $\mathbf{F}^{\text{int}}$ is defined as internal force at time t. Thus the acceleration, $\ddot{\mathbf{u}}$ can simply obtained by

$$\ddot{\mathbf{u}} = \mathbf{M}^{-1}(\mathbf{F} - \mathbf{F}^{\text{int}}) \tag{16}$$

In practice, the above equation does not usually require solving of the matrix equation, if lumped masses were used, which will derive a diagonal or nearly diagonal mass matrix. Moreover, $\ddot{\mathbf{u}}$ is usually discretized by explicit second order central difference scheme. Therefore, the most important tasks of secondary development in ABAQUS/Explicit are to define the element mass $\mathbf{M}_e$ and element internal force $\mathbf{F}_e^{\text{int}}$, and the global solution is left to the solver itself.

Consider the three dimensional beam-column model in local coordinate system $\bar{x}$-$\bar{y}$-$\bar{z}$, show as in Figure 1, where longitudinal axis $\bar{x}$ is the union of geometric centroids of each section, and $\bar{y}$, $\bar{z}$ are two directions of the section. There are six displacement components and six resultant force components at arbitrary section

$$\bar{\mathbf{u}} = [\bar{u} \quad \bar{w} \quad \bar{v} \quad \bar{\varphi}_x \quad \bar{\varphi}_y \quad \bar{\varphi}_z]^{\mathrm{T}} \tag{17}$$

$$\bar{\mathbf{F}}_s = [\bar{N} \quad \bar{Q}_y \quad \bar{Q}_z \quad \bar{M}_x \quad \bar{M}_y \quad \bar{M}_z]^{\mathrm{T}} \tag{18}$$

where, $\bar{u}$ is axial displacement, $\bar{w}$, $\bar{v}$ are transverse deflections, $\bar{\varphi}_x$ is torsional rotation, and $\bar{\varphi}_y$, $\bar{\varphi}_z$ are bending rotations. Correspondingly, $\bar{N}$ is axial force, $\bar{Q}_y$, $\bar{Q}_z$ are transverse shearing forces, $\bar{M}_x$ is torsional moment, and $\bar{M}_y$, $\bar{M}_z$ are bending moments.

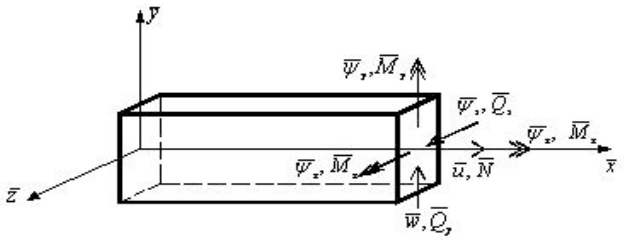

Figure 1. 3D Beam-column model.

Based on Timoshenko Beam Theory and small deformation assumption, we introduce the generalized geometrical relation of the section formulated in vector form

$$\boldsymbol{\varepsilon} = [\,\varepsilon \quad \gamma_y \quad \gamma_z \quad \chi_x \quad \chi_y \quad \chi_z\,]^{\mathrm{T}} = \mathbf{L}\bar{\mathbf{u}} \tag{19}$$

In the section deformation vector $\boldsymbol{\varepsilon}$, the component ε is axial extension, γ_y , γ_z are transverse shearing deformations, χ_x is torsion deformation, χ_y , χ_z are bending curvature. $\mathbf{L}$ denotes the geometrical differential operator matrix. Thus, the generalized section constitutive relation could be formally written as

$$\bar{\mathbf{F}}_s = \bar{\mathbf{K}}_s \boldsymbol{\varepsilon} \tag{20}$$

where $\bar{\mathbf{K}}_s$ is the section stiffness matrix.

For the above model of beam-column, we establish a finite element model that contains two nodes with their local axial coordinates denoted by $\bar{x}_1$ and $\bar{x}_2$, show as Figure 2.

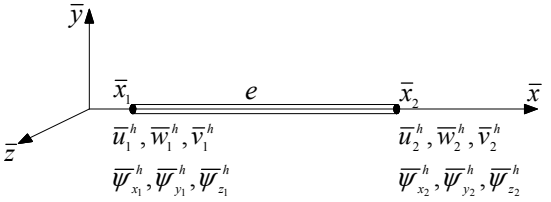

Figure 2. Finite element model.

Therefore, the nodal displacement vector of each element could be written as

$$\bar{\mathbf{u}}_e^h = [\bar{u}_1^h \quad \bar{w}_1^h \quad \bar{v}_1^h \quad \bar{\psi}_{\bar{x}_1}^h \quad \bar{\psi}_{\bar{y}_1}^h \quad \bar{\psi}_{\bar{z}_1}^h \quad \bar{u}_2^h \quad \bar{w}_2^h \quad \bar{v}_2^h \quad \bar{\psi}_{\bar{x}_2}^h \quad \bar{\psi}_{\bar{y}_2}^h \quad \bar{\psi}_{\bar{z}_2}^h]^{\mathrm{T}} \tag{21}$$

Moreover, finite displacement of arbitrary local section

$$\bar{\mathbf{u}}^h = [\bar{u}^h \quad \bar{w}^h \quad \bar{v}^h \quad \bar{\psi}_{\bar{x}}^h \quad \bar{\psi}_{\bar{y}}^h \quad \bar{\psi}_{\bar{z}}^h]^{\mathrm{T}} \tag{22}$$

Obviously, there will be the following interpolating relation between $\bar{\mathbf{u}}_e^h$ and $\bar{\mathbf{u}}^h$

$$\bar{\mathbf{u}}^h = \mathbf{N}\bar{\mathbf{u}}_e^h \tag{23}$$

where $\mathbf{N}$ is formally the displacement interpolating matrix, respectively, the transverse deflections are cubic, bending rotation are quadratic. All of them contain

condensed internal freedoms, and the so-called 'shearing locking' has been avoided. Moreover, both axial displacement and torsional rotation are linear. From Eq.19~Eq.23, the finite deformation and internal force of sections can be written as

$$\bar{\boldsymbol{\varepsilon}}^h = \mathbf{B}\bar{\mathbf{u}}_e^h \tag{24}$$

$$\bar{\mathbf{F}}_S^h = \bar{\mathbf{K}}_s \mathbf{B}\bar{\mathbf{u}}_e^h \tag{25}$$

where geometric matrix $\mathbf{B} = \mathbf{LN}$, which results from $\mathbf{L}$ acting on $\mathbf{N}$. Then, the element internal force vector $\bar{\mathbf{F}}_e^{\text{int}}$ will be derived by virtual displacement theorem

$$\bar{\mathbf{F}}_e^{\text{int}} = \int_{\bar{x}_1}^{\bar{x}_2} \mathbf{B}^{\mathrm{T}} \bar{\mathbf{F}}_S^h \mathrm{d}\bar{x} \tag{26}$$

Besides, the element lumped mass $\bar{\mathbf{M}}_e$ is easy to be formulated for two nodes element model and its formula abbreviated here. But, it should be noted that, in the whole above process, '$\bar{\ }$' means definition in local coordinates system $\bar{x}$-$\bar{y}$-$\bar{z}$, so coordinates transformation should be implemented before the global integrating phase.

In nonlinear explicit dynamic analysis, the main target of 'fiber method' is to calculate section internal force $\bar{\mathbf{F}}_S^h$, and $\bar{\mathbf{F}}_e^{\text{int}}$ will be calculated by integration show as Eq.26.

Take a reinforced concrete beam-column show in Figure 3 as example, the member is longitudinally discretized into *nfib* fibers. The configuration of fibers on sections is displayed in Figure 4, where $(\bar{y}_{ifib}, \bar{z}_{ifib})$ refers to the fiber position in cross section and A_{ifib} is the section area of fiber. Following the plane section assumption, the strain of each fiber can be derived as

$$\varepsilon_{ifib} = \varepsilon + \bar{z}_{ifib}\chi_y - \bar{y}_{ifib}\chi_z = \mathbf{l}_{ifib}^{\mathrm{T}} \bar{\boldsymbol{\varepsilon}}^h \tag{27}$$

where, $\mathbf{l}_{ifib} = [\mathbf{1} \quad \mathbf{0} \quad \mathbf{0} \quad \mathbf{0} \quad \bar{z}_{ifib} \quad -\bar{y}_{ifib}]^{\mathrm{T}}$ Introducing particular uniaxial constitutive relation $\sigma = f(\varepsilon)$ for each fiber respectively, there derived the axial stress of fibers

$$\sigma_{ifib} = f(\varepsilon_{ifib}) \tag{28}$$

Summing all stresses of fibers together, $\bar{\mathbf{F}}_S^h$ will be deduced by virtual displacement theorem

$$\bar{\mathbf{F}}_S^h = (\sum_{ifib=1}^{nfib} \mathbf{l}_{ifib}\sigma_{ifib}A_{ifib}) + \mathbf{l}_{\bar{M}_x}(GJ\chi_x) + \mathbf{l}_{\bar{Q}_y}(GA\gamma_y) + \mathbf{l}_{\bar{Q}_z}(GA\gamma_z) \tag{29}$$

where A is the section area, G is the section shearing modulus, J is the section torsional moment of inertia.

In Eq.29, the effects of torsion and shearing are macroscopically considered at section level, and they are usually assumed to keep elastic in inelastic analysis.

In order to evaluate the nonlinear behavior of RC beam-column member subjected to

arbitrary loading, extreme section damage index of RC member is defined as

$$D_{MC} = \frac{\sum_{i}^{k} D_{ci} A_{cifib}}{\sum_{i}^{k} A_{cifib}}, \quad D_{MT} = \frac{\sum_{i}^{m} D_{ti} A_{tifib}}{\sum_{i}^{m} A_{tifib}} \tag{30}$$

where A_{cifib} is the section area of compressive fiber, A_{tifib} is the section area of tensive fiber.

The last important aspect of our fiber strategy is, the uniaxial constitutive relation of fibers, i.e. the determination of $\sigma = f(\varepsilon)$. Here we adopted uniaxial damage constitutive relation deduced from Eq.3 and its hysterical rule deduced from Eq.15~Eq.16. For steel material in real structure members, we adopted bilinear kinematic hardening model, which is simple but practically effective. The more numerical details will be abbreviated in present paper.

Numerical Exampel For FDAM. In this section, a numerical example of the present fiber damage analysis model for RC beam-column member is presented, the following properties(see Figure 5) are used: the length is 4m, the cocrete material is C30, the section size is 500mm×600mm. The subdivision of cross section is shown in Figure 9(c). The displacement loading is used: $Dx = -5mm$, $Dy = 20mm$, $Dz = 20mm$.

Figure 5. RC beam-column member.

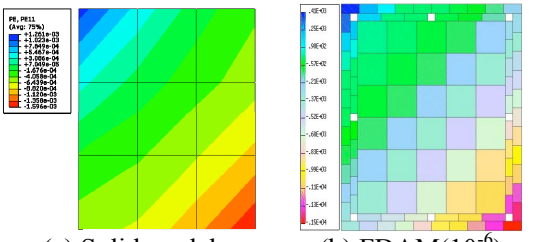

Figure 6~Figure 9 show the stress, the plastic strain and damge distribution of extreme

section for RC member compared with the results of solid model. The results show that the response of fiber damage analysis model for displacement loading is close to the results of solid model. The extreme section damage index of RC member D_{MC}=0.319, D_{MT}=0.0258, the damage evolution of RC member is shown in Figure 10. This example shows that the fiber damage analysis model based on material is reasonable and reliable to evaluate the damage behavior of RC beam-column.

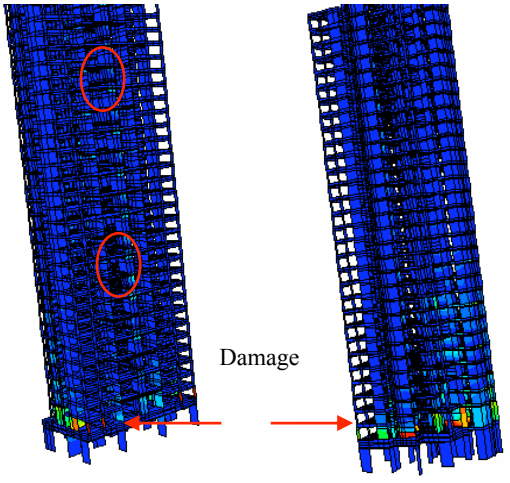
APPLICATION OF STRUCTURAL SEISMIC DAMAGE ASSESSMENT

Based all above proposed models and strategies, the inelastic dynamic analysis

numerical solutions of a high-rise RC structure are given in this section respectively. The structure is the split-level shear wall structure (98.8m), whose girder transfer floor is set on the top of the first floor. The proposed plastic-damage model for concrete is adopted to model the concrete material, and FDAM was adopted to model RC members. Kinematic hardening model is used to model for rebar.



Dynamic elastoplastic analysis and test comparison. Typical earthquake waves including El Centro wave and Taft wave are used as the input data of the earthquake motions, and the excitation in X direction and Y direction is considered respectively. The peak value of acceleration is 220gal.

Theoretically speaking, the dynamic analysis method based on the material damage model can describe the whole damage evolution process and the exact final damage of structure, depending on the degree of finess and exactness of the analysis model. Figure 11 and Figure 12 show the weak portion and the final damage degree of the structure under strong earthquake excitations. The damages are mainly located at the vertical members of upper story of transfer floor, and some coupling beams are also damaged. For many vertical members of the upper story of the transfer floor are destroyed, the structure cannot meet the requirement of No Collapsing Under Strong Earthquake. Figure 13 shows that the seismic damage assessment results closely agree with the shaking table test results. Therefore the seismic damage model based on material damage model can judge the yielding mechanism, weak positions and damaged degree exactly of structures under strong earthquake excitations.

CONCLUSION

A plastic-damage constitutive model based on continuum damage mechanics theory is presented in this paper. The formulas of the elastic and plastic Helmholtz free energy are defined to describe the plasticity and damage degradation behavior of concrete. The constitutive relations are validated using the second law of thermodynamics, and the Weibull distribution hypothesis is introduced to simulate the process of damage evolution. The damage constitutive equations, the damage evolution equations and plastic deformation of concrete are presented respectively.

The fiber damage analysis model developed on ABAQUS/Explicit that combined with the proposed uniaxial damage constitutive relations is effective in the damage analysis of RC beam-column. Comparing to the results of solid model, the fiber damage analysis model based on material is reasonable and reliable to evaluate the damage behavior, and can describe the damage evolution process for RC bema-column under loading.

Comparing to the data from shaking table test, the seismic damage assessment of high-rise RC structures based on material damage model is more reasonable and more reliable, to evaluate the seismic performance comprehensively, find out the weak parts effectively and understand the seismic damage evolution process explicitly.

ABSTRACT

Wall-type precast reinforced concrete (WPC) residential buildings, which are assembled using prefabricated concrete panels for the slabs and walls, were widely constructed during the 1960-70s in Japan. The number of existing WPC residential units constructed before 1980 is approximately 470,000. Although these buildings are of high quality in terms of structural condition, they are not fully utilized due to their small and uniform unit plans that do not suit modern living styles. Creating new openings in the walls could widen the possibility of plan changes during renovation; however, a design methodology for new openings, including the addition of structural reinforcement, has not been developed for this unique structural system. In this research, reinforcement design for new openings was developed and improvement of seismic performance was examined in half-scale cyclic loading tests. Numerical analysis models were also developed and the behavior of the walls was well simulated.

INTRODUCTION

Wall-type precast reinforced concrete (WPC) residential buildings (Figure 1) were widely constructed in Japan from the middle of the 1960s to counter the serious

shortage of housing. Figure 2 shows the annual and accumulative number of WPC units constructed. Approximately 470,000 units were built before 1980. Most of them still exist and maintain good physical condition with precast (PCa) concrete slab and wall panels. Also, their high seismic performance was confirmed from the limited damage observed after the Hanshin-Awaji Earthquake in 1995 (AIJ, 1998). The unit plans for this type of residential building were highly standardized, and each unit area is rather small for modern family use. The buildings typically have five stories without elevators. Stairs were constructed between every two units in the plan and there are no corridors connecting floors, providing both privacy and natural ventilation during summer. With its inconveniences, this housing stock has not been fully utilized despite its good structural condition.

Figure 1. WPC residential buildings

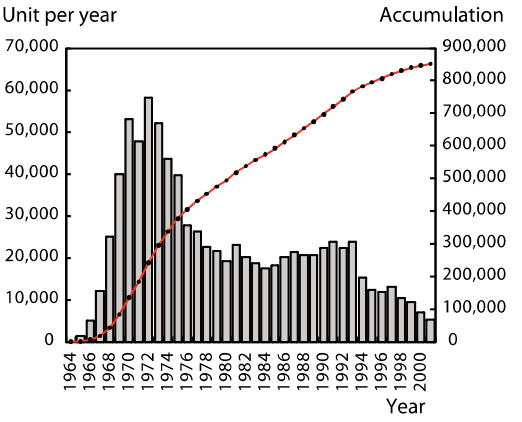

Figure 2. Number of WPC units

In order to activate the housing stock, a renovation design study team in which the authors participated was organized. Barrier-free schemes are proposed considering various aspects including financial feasibility and legal restrictions (Figure 3). In order to provide various unit plans suiting modern life styles, new openings in existing walls are needed in the schemes. However, a methodology for reinforcing the openings in this unique structural system has not yet been developed.

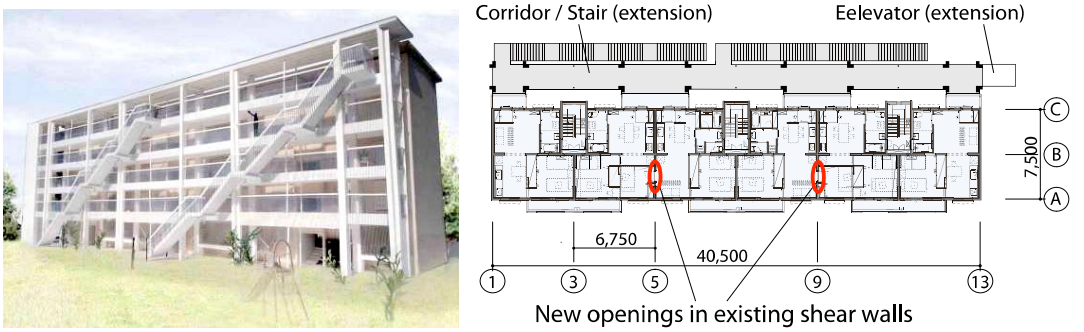

Figure 3. Renovation scheme

In this research, reinforcement design schemes for the new openings in the existing wall panels are developed, and their seismic performance is experimentally evaluated. Also, numerical analysis models for the wall tests are created using inelastic springs for the connections between wall panels.

WPC RESIDENTIAL BUILDINGS

As shown in Figure 4, prefabricated wall and slab panels are assembled for the construction of WPC residential buildings. For the connections between the wall panels, steel plates and welded reinforcements are embedded in the upper and lower sides of the panels (Figure 5). The embedded steel plates are field-welded, and these connections are called "setting bases (SBs)." In addition, there are connections with shear connectors on the vertical sides of the wall panels (vertical connections) as shown in Figure 6. The extended reinforcement is welded to the reinforcement of the horizontally adjacent wall panels, and the gaps between the panels are filled with concrete on site. In the gaps, reinforcement is vertically placed penetrating the slab levels. This reinforcement is called "vertically connecting reinforcement (VCR)," and this works to connect vertically adjacent walls.

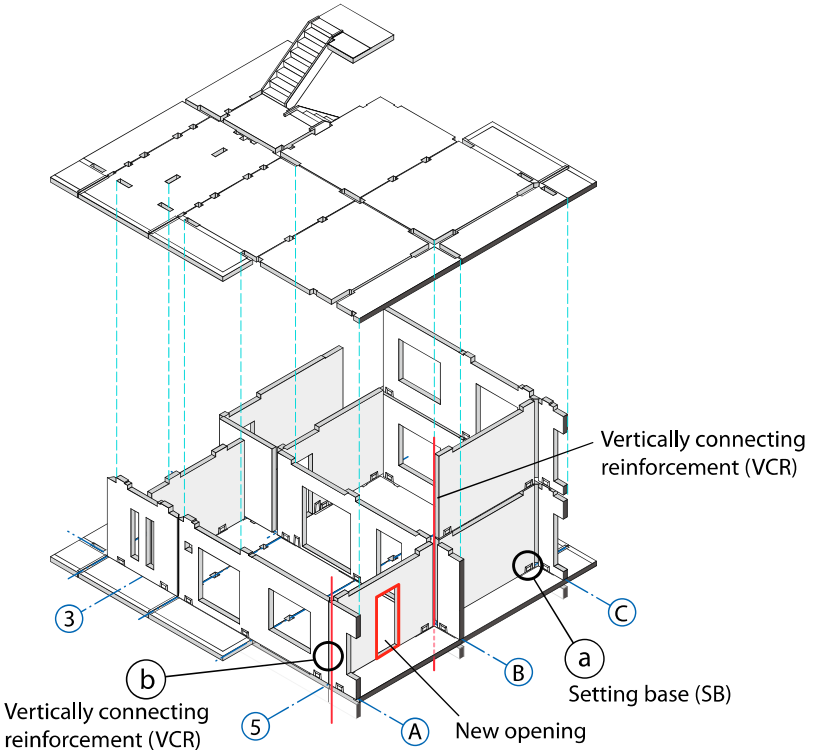

Figure 4. WPC structure

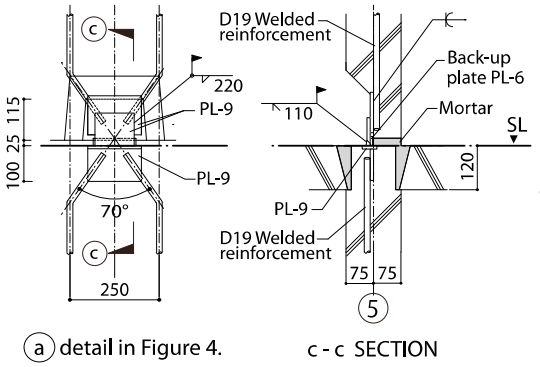

Figure 5. Setting base (SB)

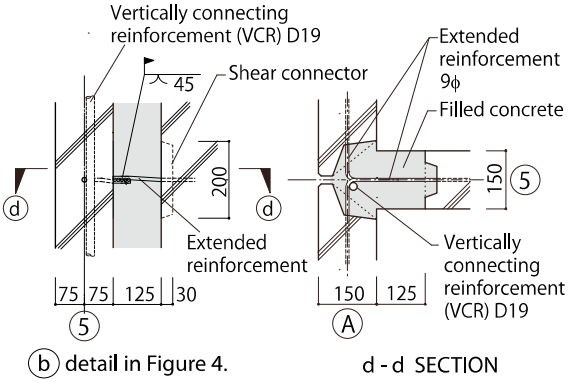

Figure 6. Vertical joint

REINFORCEMENT FOR NEW OPENINGS

Experiencing a significant number of major earthquakes, Japanese seismic design codes have been developed with revisions to design specifications. Consequently, not every existing building necessarily meets all of the current specifications. These existing buildings are not illegal; however, structural reinforcement to meet requirements is needed in the case of major renovation. Generally, this reinforcement is technically difficult and significantly costly. On the other hand, if the renovation is relatively minor, where the number of (partially) structural members demolished is limited, the current design specifications do not apply under the condition that each member (or part of the building) maintains equal or greater structural performance due to the reinforcement involved in the renovation.

Because the seismic performance of the existing WPC residential buildings is generally high, creating new openings in some of the wall panels may not be essential. Depending on the target seismic performance criteria, no reinforcement may be needed. Studying the seismic performance of WPC buildings with new openings is an interesting subject (and this is our future work), and with much consideration given to rapid practical application of the research outcome, our first research objective was to develop reinforcement design schemes for the walls as required by most jurisdictions. (A performance-based design approach, including evaluation of the whole building, takes more time as several issues such as research development, design review, and authorization must be tackled.)

In WPC shear wall panels, there are more than two SBs on the upper and lower sides. The SBs carry pull-up force induced by the overturning moment (OTM) under the seismic lateral load. In the renovation schemes, new openings are placed at

the center of walls, not disturbing the SBs, as shown in Figure 7. The new opening subdivides the wall panel into two. If rocking of these wall panels is the major deformation mode as shown in Figure 7, the resistance capacity of the wall can be significantly reduced. Also, a part of the wall above the new opening is not strong enough to be a coupling beam. Using reinforced concrete (RC) or steel (S) members, reinforcement design schemes are developed by strengthening connections to the walls in the lower story and coupling beams above the new openings.

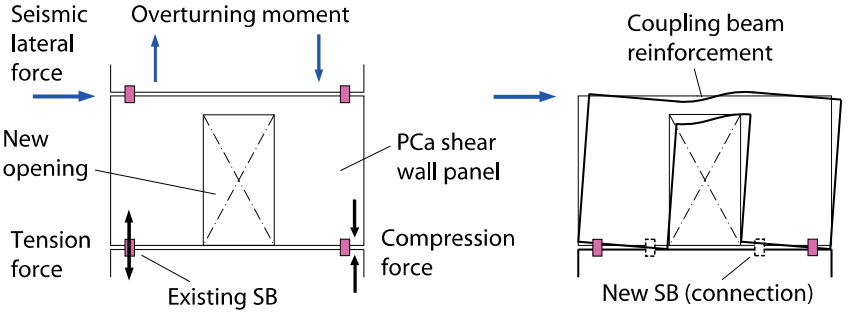

Figure 7. Seismic load resisting system in WPC shear walls

TESTING PROCEDURE

A half-scale experiment was conducted for the shear wall panel on the second floor in the five-story building shown in Figure 3, where there are PCa wall panels on the upper and lower stories and where the seismic lateral load is the greatest. The specimens are composed of a shear wall, part of the walls of the first and third stories, flange walls, and slabs. Stubs are also created at the top and bottom of the specimens for loading. The test parameters are openings in the shear wall, shear-span ratio (H/W), and RC or S reinforcement. Specimens with a small H/W have openings in the first and third stories, while those with a large H/W do not. Eight specimens were created: one with no opening, two with no reinforcement, two with RC reinforcement, and three with S reinforcement. Figure 8 shows the C5S specimen (RC reinforcement with a large H/W) and N5M (no reinforcement with a small H/W). The new RC columns are placed on the side of the new opening in C5S. The columns connect to the new beams under the existing PCa slab panels. A list of specimens with fundamental information is shown in Table 1.

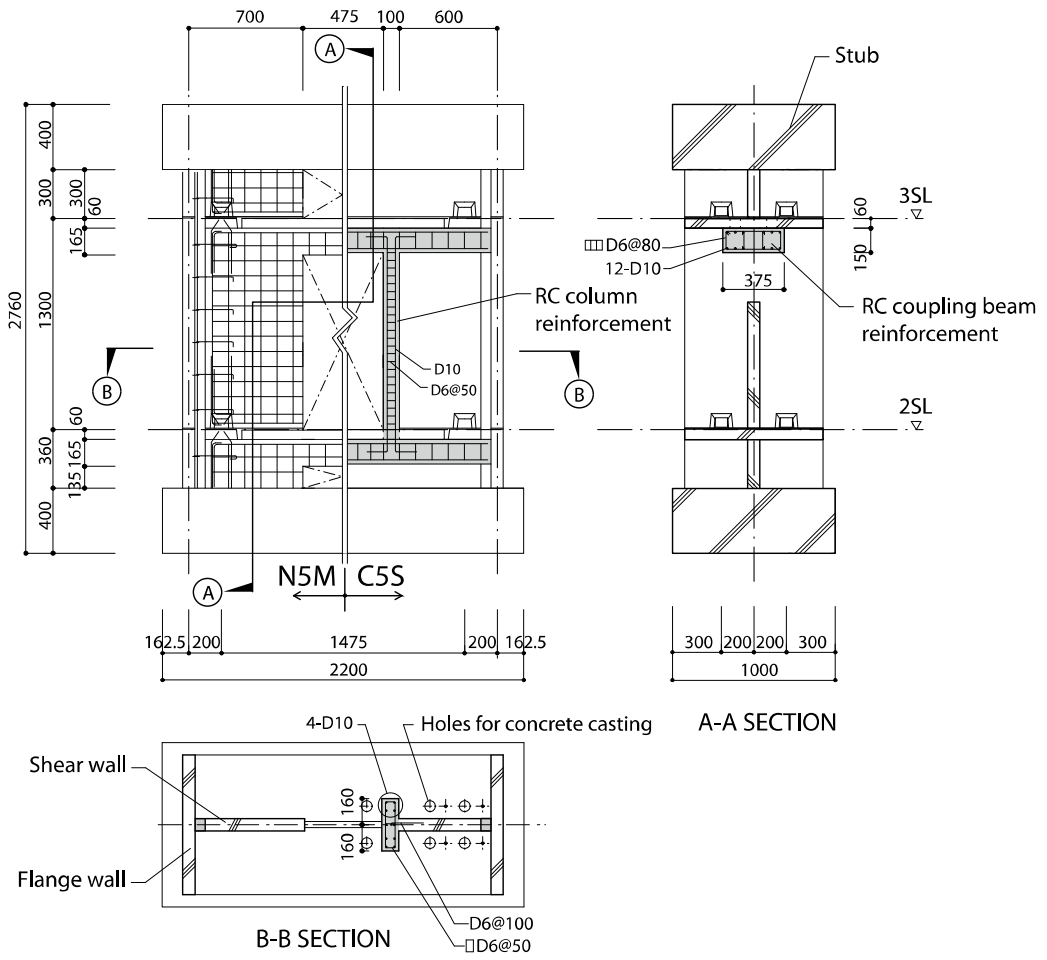

Figure 8. Shear wall test specimens (N5M and C5S)

Table 1. Specimens and fundamental information

Specimen	H/W	Reinforcement	Concrete strength *1) (N/mm^2)			Maximum strength *2) (kN)		Initial stiffness *3) (kN/mm)	Failure mode *4)	Description
			${}_P\sigma_B$	${}_J\sigma_B$	${}_C\sigma_B$	+dir.	-dir.			
W5	1.85 (large)	none	58.6	44.8	-	101	103	166	F	Damage around 2SL SBs
N5S			67.0	48.0	-	105	110	53	F	Failure of 3SL SBs
C5S		RC	58.0	55.2	74.4	154	139	190	F	Damage to first-floor walls under reinforcing columns
S5S		S	66.3	45.7	-	124	117	97	F	
B5S			50.2	59.5	-	113	106	64	F	Damage around 2SL SBs
N5M	1.17 (small)	none	60.8	57.8	-	136	132	40	F	
C5M		RC	52.8	78.8	74.3	289	271	189	F/S	Shear failure (significant damage) of shear walls
S5M		S	51.1	52.4	-	220	235	101	S	

*1) Concrete strength (N/mm^2) on the test day (${}_P\sigma_B$: PCa panels, ${}_J\sigma_B$: joint concrete, and ${}_C\sigma_B$: reinforcing members); *2) Maximum lateral strength (kN) (+dir: positive direction, and -dir: negative direction); *3) Initial stiffness defined as secant stiffness with the origin and strength at R=+0.025%; *4) Failure mode (F: SB failure, and S: shear failure of wall)

Figure 9 shows the loading system of the specimens. Under a constant vertical load, which represents the dead and live load (shown as D in Figure 9), static incremental cyclic load Q (=Q1+Q2) is applied. Coupled vertical force V, which is equivalent to the OTM, is also loaded in proportion to lateral force Q. In order to investigate the influence of the OTM on the behavior of the wall, two shear span ratios (shown as H/W in Figure 9) were prepared: 1.85 (large) and 1.17 (small).

Controlled cyclic lateral displacement is applied to the specimens for rotational deformation, R =0.025%, 0.05%, 0.1%, 0.2%, 0.33%, 0.5%, 0.67%, 1.0%, and 2.0%, with two cycles each except R =0.025% with one cycle, where R is defined as the lateral displacement of the center of the upper stub divided by the height from the top of the bottom stub.

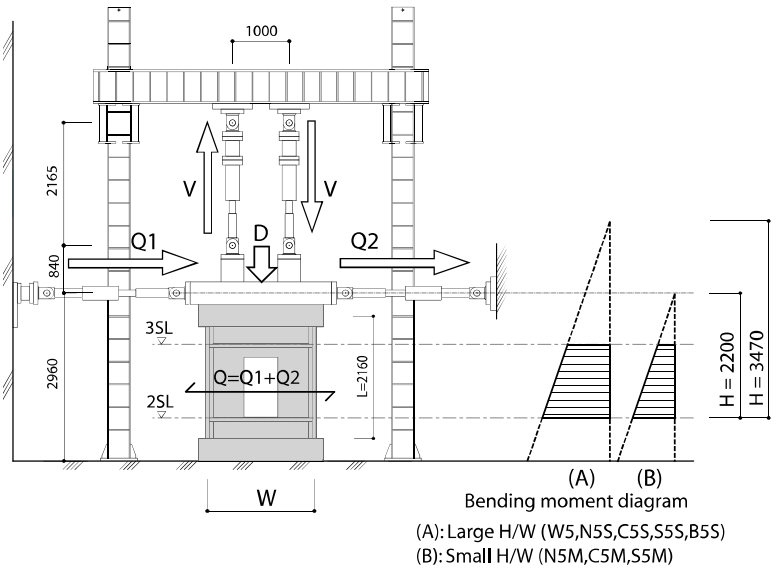

Figure 9. Loading system

TEST RESULTS

Shown in Figure 10 are the crack patterns in the shear walls after loading in W5, N5S, C5S, and C5M, out of the eight specimens. In W5 and N5S, minor cracks were observed in the wall panels and damage is concentrated around the horizontal connections (the SBs and VCRs). Rocking of the wall with failure of the horizontal connections is the overall failure mode in these tests. In N5S, shear cracks were observed; however, they did not directly trigger strength degradation. Regarding behavior of the flange walls, damage was limited to the panels and was observed only at the connections on the upper and lower sides of the panels in all cases.

In C5S, where the new opening is reinforced with RC members and the

H/W is large, several shear cracks were observed in the shear wall panels. Major horizontal cracks were also generated in the wall panel on the first floor. The pull-out force transferred to the wall from the new RC column via the new connected beam was large enough to cause cracks in the wall under the new column. Thus, the connection detail between the wall and the new beam needs to be improved. Although shear cracks were observed in C5S, the primary failure mode is also rocking of the shear wall with failure of the horizontal connections. In C5M, where the new RC columns on the side of the opening penetrate the floor slabs and are embedded in the upper and lower stubs, the walls failed in shear. Because the new columns vertically tighten the wall panels and the H/W is relatively small, failure of the horizontal connections was less significant compared with other tests with a large H/W.

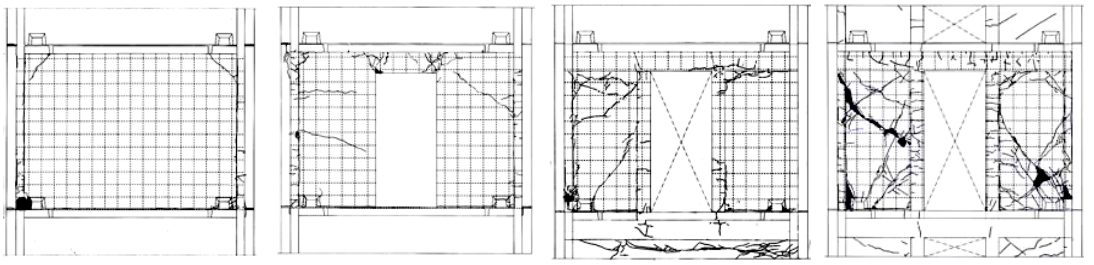

Figure 10. Crack patterns in shear walls

Figure 11 compares the relationships between the lateral force and rotational deformation in the three tests on W5, N5S, and C5S. The difference in the maximum lateral strength of W5 (no opening) and N5S (no reinforcement for the opening) is limited. This is because the failure mode in these tests is rocking with failure of the SBs under a large H/W. Shear failure of the wall was not critical and, consequently, the opening in the wall did not reduce the maximum lateral strength. Contrarily, the initial lateral stiffness and equivalent viscous damping ratio of N5S is approximately 30% and 50% those of W5, respectively; therefore, the difference in their energy dissipation capability is significant.

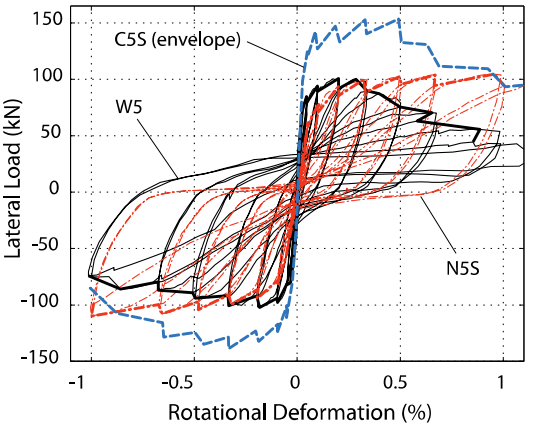

Figure 11. Test results

In C5S, the maximum lateral strength was 140-150% that of W5 and N5S. Similarly, enhancement of seismic lateral strength was observed in other test cases with reinforcement. Although further improvement is needed such as for the connection of the reinforcing and the existing members, the reinforcement design was able to provide equal or greater seismic performance compared to WPC walls without openings.

NUMERICAL SIMULATIONS

In order to simulate the behavior of the WPC wall in the test, numerical analysis models were created. Figure 12 shows two-dimensional models of W5, C5S, and C5M. The models are composed of elastic line elements for the wall panels and inelastic springs for the connections. Shear springs in the shear walls were also included in the models for the small H/W test, where shear failure was observed. The elastic modulus of the concrete was calculated based on the tested concrete strength according to AIJ (2010). In some wall tests, it is observed that rocking of the shear walls is the primary failure mode and behavior of SBs significantly influences the overall behavior of the wall.

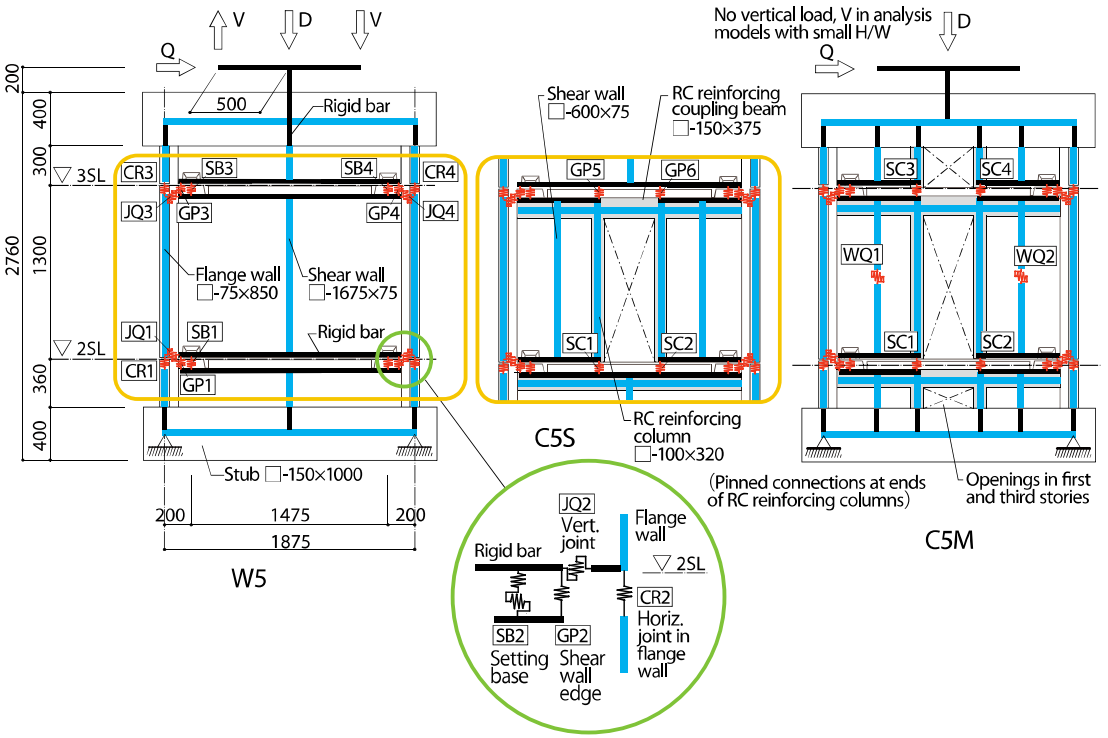

Figure 12. Analysis models

In order to investigate the SB properties, especially pullout tension force and vertical displacement relationships, additional tests were conducted. Shown in Figure 13 is the half-scale specimen of the SB test. Vertical displacement of the specimen composed of an SB and its vicinity in the WPC wall panels on two stories was enforced. The test was performed under two types of loading: one-way tension and cyclic tension-compression. In order to separate the wall panels into two stories, a steel plate was inserted at their boundary. It was expected that the plate would minimize the vertically connecting tensile strength between the concrete panels using a potential manufacturing process.

Shown in figure 14 are the relationships between the controlled vertical displacement and load on the specimens. Peak strength was observed at approximately 8 mm from the vertical displacement with yielding of the reinforcement and fracture of the plate welding. As shown in Figure 14, a tri-linear tensile property of SBs is defined for the analysis models. Calibrating the shear wall simulation with the test, the peak strength is reduced to 75% of the more accurately approximated tri-linear model. A possible physical reason for this reduction is the combination of lateral and vertical force in the wall test.

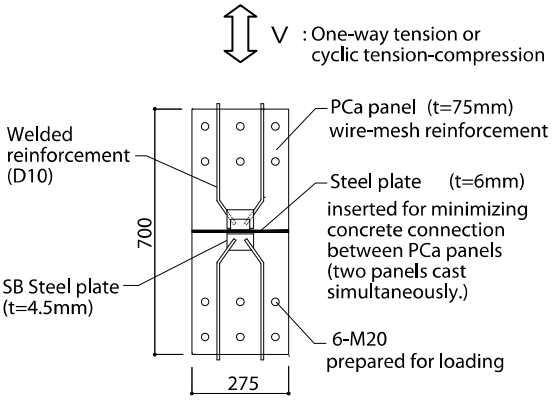

Figure 13. Specimen of SB tests

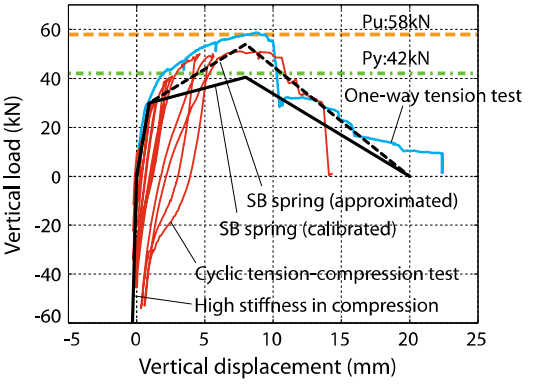

Figure 14. SB test and spring

Other properties of the inelastic springs in the analysis models of the walls are summarized in Table 2. The SB, CR, GP, and JQ spring properties are consistent in the analysis models, while the SC and WQ properties are evaluated for each test with opening reinforcement. Using these simulation models, displacement control static pushover analyses were conducted (MIDAS). Figure 15 shows the analytical results superimposed on the test data. The analyses reasonably simulate the envelope of the cyclic loading test. It is noteworthy that the analyses simulate the failure mode of the WPC walls with reasonable order and accuracy, as well as the strength.

Table 2. Inelastic springs in analysis models

Spring	Direction*	Description
SB	X	Represents sway deformation of shear walls at slab levels Perfect elastic-plastic bi-linear curve with high elastic stiffness and ultimate strength based on Mattock (1972)
	Y+	Represents the tension force and displacement relationships at SBs Tri-linear curve as shown in Figure 14
	Y-	Sufficient strength for compression at SBs Rigid elastic spring
CR	Y+	Represents the tension force and displacement relationships at slab levels at flange walls Tri-linear curve with twice the SB (Y+) curve added to the perfect elastic-plastic curve for VCR
	Y-	Rigid elastic spring
GP	Y-	Rigid elastic spring
JQ	X	Rigid elastic spring, representing condensed horizontal displacement at the shear wall and adjacent flange wall
	Y	Represents shear displacement at vertical connectors between the shear wall and flange wall Perfect elastic-plastic bi-linear curve with rigid elastic stiffness and ultimate strength based on Nakano (2001)
SC	Y+	Represents tension force and displacement relationships at slab levels at new reinforcing columns Perfect elastic-plastic curve with calibrated strength and rigid elastic stiffness
	Y-	Rigid elastic spring
WQ	X	Represents shear deformation of shear walls Quad-linear curve with rigid elastic stiffness (elastic shear deformation simulated by line elements of the walls), shear strength at cracking as 1/3 of the peak strength, which is defined through calibration with the test, R=0.4% for the peak displacement, negative post-peak stiffness (0.5% of the elastic shear stiffness), and 1/2 of the peak strength for the residual strength
	Y	Rigid elastic spring
	R	Rigid elastic spring

* X: horizontal transition, Y: vertical transition (Y+: tension, Y-: compression), and R: rotation
Local coordinate axes of the springs are parallel to the global axes. Freedoms not shown in the table are not constrained.

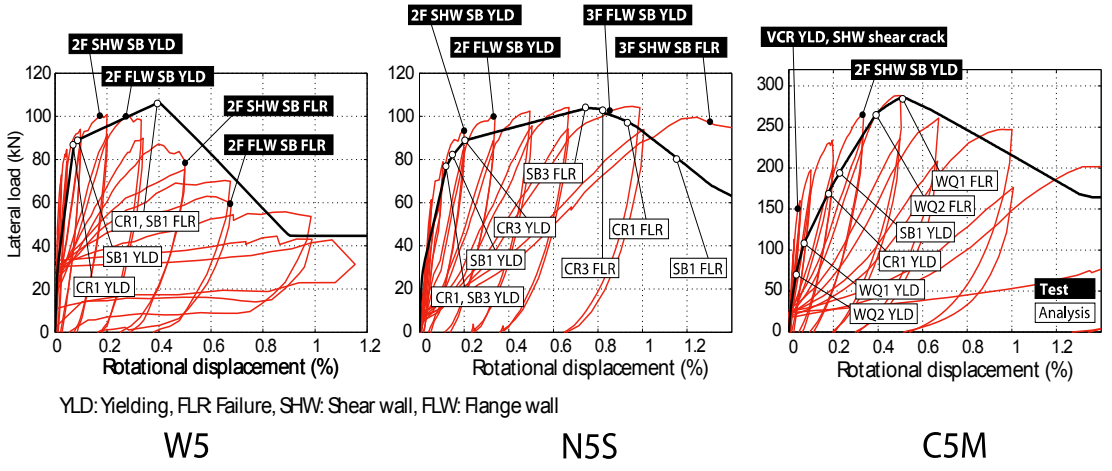

Figure 15. Analysis and test results

CONCLUSIONS AND FUTURE WORK

In this research, reinforcement design for new openings in existing shear walls in wall-type precast reinforced concrete (WPC) residential buildings was developed and improvement of seismic performance was examined through half-scale cyclic loading tests. Furthermore, two-dimensional numerical analysis models, which are composed of line elements for the wall panels and inelastic springs for the connections and shear behavior of the walls, were created. Using the models, the behavior of the tested walls was well simulated. As future work, analysis models are to be further developed for the evaluation of whole building seismic performance.

ABSTRACT

A hexagonal space dome was analyzed to investigate the relationship between structural vulnerability and failure mechanism. The analysis of stress ratios under design loads has shown that the bars that have greater stresses are closely correlated to the deteriorating bars in structural vulnerability. This provides a new approach for structural vulnerability analysis. By calculating the vulnerability parameters of bars of greater stresses, a variety of failure modes can be found and the structural vulnerability can be estimated. Moreover, the relationship between vulnerability characteristic parameters and design ultimate load was discussed by analyzing the structural failure modes under El Centro and artificial earthquake ground motions.

INTRODUCTION

The structural vulnerability theory was introduced by Blockley and others of University of Bristol (Wu, et al, 1993a, 1993b; Blockley 1999; Agarwal, et al, 2001a, 2001b). The structure is vulnerable if the structure fails to a disproportional extent or even collapses under some local destructive effects.

Shen and Zhi (2005) showed that with the increase of load, every latticed shell would collapse finally due to dynamic instability. Some of the latticed shells become instable, while their displacement and internal plastic deformation are very limited, and the collapse due to dynamic instability is abrupt. Other structures undergo large plastic deformations and significant softening before collapsing. They are categorized as strength failure since structures attain large displacements and bars reach their ultimate strengths at failure.

Nodal load-displacement curves can be used to distinguish between structural

dynamic instability and strength failure, as well as other characteristic response indices such as the curve of total load vs. maximum nodal displacement, the proportion of bars entering plasticity, the relative strain of bars, and the total strain energy in the structure.

Under earthquakes, the mechanical behavior of the structure and the damage and collapse modes of the elements are complicated. Strength failure is preferred over dynamic instability to ensure greater structural robustness. For latticed shells, preliminary studies have shown that the differences in height-span ratios, element sections, span lengths, structure forms and connections can lead the structures to different failure mechanisms, namely, strength failure, or dynamic instability. Furthermore, these different parameters can cause the differences in characteristic parameters of structural vulnerability, and subsequently, the results of vulnerability analysis differ. Determining structural failure mechanism involves large amounts of analysis and calculations, resources and time. This paper attempts to find the correlation between the structural vulnerability theory and the structural failure mechanisms by determining structural failure mechanisms from structural vulnerability analysis. The classical 24-bar hexagonal space dome is chosen as the benchmark structure in this preliminary analysis.

VULNERABILITY ANALYSIS OF HEXAGONAL SPACE DOME

The structure of a hexagonal space dome is shown in Figure 1, with geometric and physical parameters as follows: elastic modulus E = 3030 MPa, shear modulus G = 1095 MPa, element cross-section area A = 317 mm^2, R1 = 25 cm, R2 = 43.3 cm, a = 2.0 cm, b = 6.216 cm. The structure is composed of 24 bar elements, and has been used as benchmark structure in many studies. Papadrakakis et al (1986) studied the performance of load-displacement of the structure as a truss system by using two-vector iteration method. Meek and Tan (1984) studied the mechanical behavior of the structure as a frame system by arc-length method. Shen and Chen (1999) analyzed the structure using their nonlinear analysis program SNAP.

Also shown in Figure 1 are the numbering of the nodes and elements of the structure. The structure is clustered in accordance with principles of vulnerability theory, and the results are shown in Figure 2. In the course of clustering, the connection ability of the joints increases until all elements are included. The ultimate value of the connection ability of structural joints is Q = 5.98E18, and the maximum requirement of damage value is 1.65E+008. The results of de-clustering are shown in Table 1. Among all of the failure modes, the resolution is one for the failure mode that is composed of failure event 5, 6, 4 and 3. The index of vulnerability reaches maximum, so this mode is overall collapse.

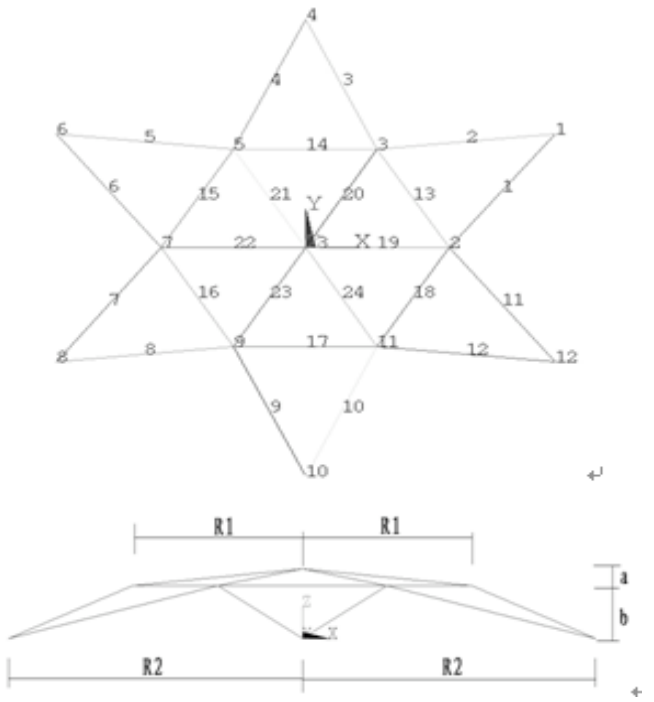

Figure 1. Hexagonal space dome

COMPARISON OF DETERIORATING BARS UNDER STATIC ACTION

In calculating the structural stresses in the bars, two load combinations were considered, one with 1.2 dead load + 1.4 live load, and the other with 1.35 earthquake load by response spectrum analysis + 1.2 gravity load. The results are shown in Table 2. It can be shown that, when the structure is intact, stresses in the deteriorating bars of the overall failure mode are higher than that of other bars. For instance, the bar 6 has the largest stresses in both combinations. In the process of de-clustering, internal forces redistribute with the failure of elements occurs. After bar 5 fails first, deteriorating bars in the structure are bars 6, 4, and 3, and their stresses are relatively high. In the intact structure or the structures with damaged elements, stresses in deteriorating bars from vulnerability analysis are always higher, among the top 50%. Typically, vulnerability analysis does not account for the loading and is only based on the configuration of the structure. The aforementioned observation leads to a new idea in vulnerability analysis – combing the characteristic parameters in vulnerability analysis with the stress determination under actual loading in the structure. Firstly, find elements with high stresses, and then calculate their characteristic parameters and determine the structural vulnerability. Choose the deteriorating bars from the high stressed bars, by trial and error, until the structure becomes mechanism. Based on the characteristic parameters of structural vulnerability, failure modes of overall collapse in different combinations can be determined.

The process of vulnerability analysis of complex structures with a large number of bars is tedious and calculation intensive. This presented method neglects elements of low stresses, therefore reduces the amount of calculation significantly, and in addition, considers the effects of loading.

ANALYSIS UNDER DYNAMIC LOADING

By changing element cross-section area and height-span ratio, seventeen different structures were generated for parametric study. Structural vulnerability analysis was conducted to determine the values of joint connection ability and requirement of damage. Three dimensional earthquake excitations are imposed to the structures with the El Centro record and a response spectrum-compatible artificial wave, as shown in Figure 3. Incremental dynamic analysis was conducted, while the maximum nodal displacements were recorded. From the curve of amplitude of ground motion vs. maximum nodal displacement, the ultimate strengths of structures against instability can be found.

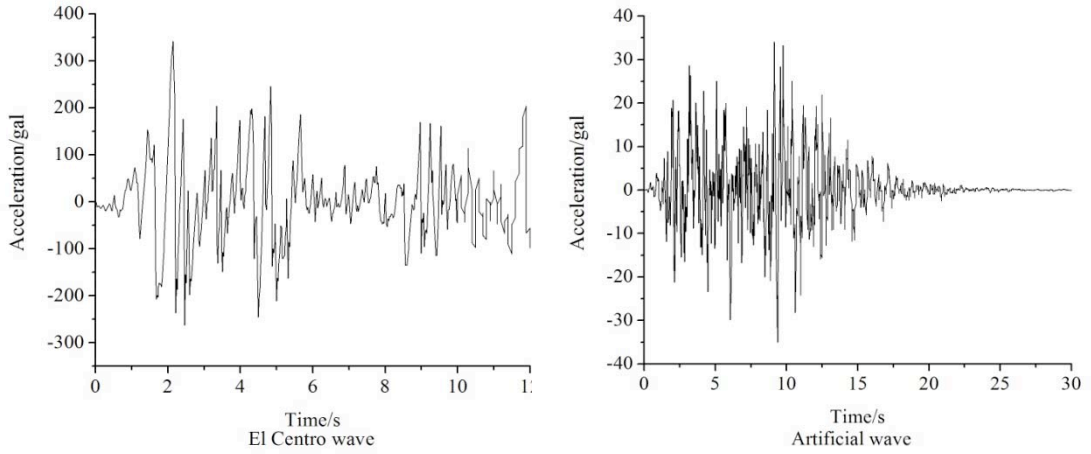

Figure 3. Earthquake ground motions

Joint connection ability vs. ultimate peak acceleration. The values of joint connection ability and requirement of damage were calculated on seven selected models of different element cross-sections, as shown in Table 3. Also shown in Figure 5 are the peak ground acceleration-displacement curves, and in Figure 6 the nodal displacement response-history curves. The peak values for ground acceleration and the ultimate displacements at structural failure can be obtained from figures. For example, in Structure 1, when the peak ground acceleration reaches 1023 gal, some structural elements enter the plastic stage, while the structure retains some bearing capacity at this point. When the amplitude reaches 1074 gal, displacement is much larger. When the amplitude reaches 1091 gal, displacement becomes very large abruptly. The structural stiffness matrix no longer converges. It can be judged that the structure fails completely and no longer has bearing capacity. Therefore, the ultimate strength of the structure in terms of peak ground acceleration is 1074 gal and the corresponding ultimate displacement is 5.68mm. Connection ability values, ground motion peak values and ultimate displacements of different structures are shown in Table 3.

Figure 4 illustrates the relationship between structural joint connection ability and the peak ground acceleration. From Figure 4, it can be observed that the peak ground acceleration increases with the structural joint connection ability, with a nonlinear correlation. As the value of structural joint connection ability increases every 5E18, the peak value of seismic wave increases 3000cm/s^2,1100cm/s^2, 800cm/s^2 and 600cm/s^2, respectively. When joint connection ability value increases to 2E19, the peak value of seismic wave reaches 5500cm/s^2. Therefore, as the same as concentrated load, when the connection ability increases to a certain extent, the peak value of ground motion increases minimally. Connection ability should be chosen rationally to make the structure reach optimal peak value of seismic wave.

Table 3. Parameters of different cross-sections

No.	A cm^2	Con. abil. Q	Req. dam. D_{max}	Vul. ind. φ	El Centro wave			Artificial wave (response spectrum-compatible)

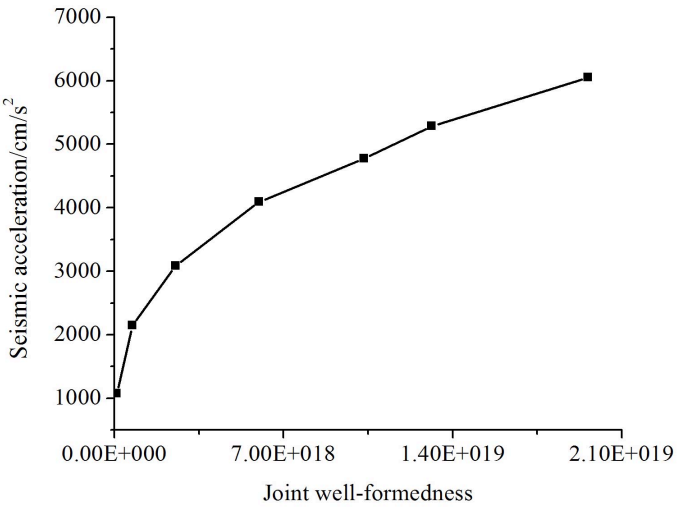

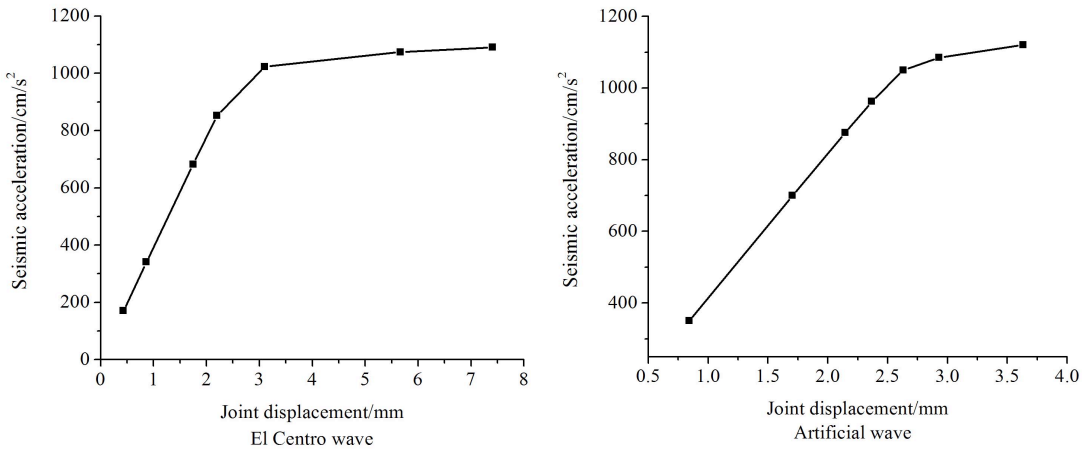

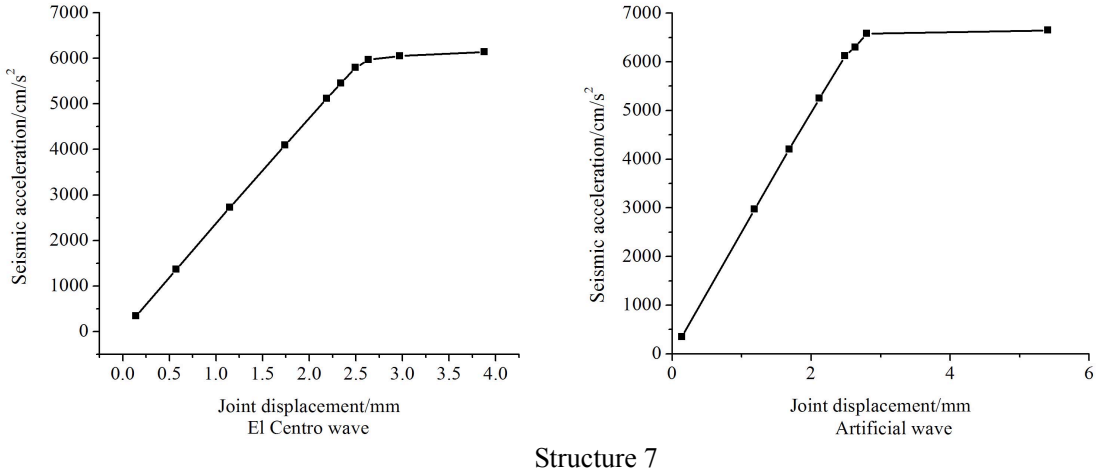

Figure 4. Joint connection ability vs. ultimate peak accel.

Structure 1

Structure 7

Figure 5. Peak ground accel. vs. max. joint displacement

Failure mode and characteristic parameters of structural vulnerability. It can be seen from Table 3, Figures 5 and 6 that the ultimate displacements of Structures 1 and 2 can reach 5.68 mm and 7.90 mm, respectively, under El Centro record, and 3.03 mm and 5.03 mm under the artificial wave. With the increasing amplitude of seismic motion, significant plastic deformations develop in the yielded bars. At the time when the structure collapses, the displacements are comparatively large. So one can judge that Structures 1 and 2 are of strength failure, and corresponding structural connection ability and requirement of damage values are relatively small at this time (see Figures 5 and 6). But the ultimate displacements of Structures 3, 4, 5, 6 and 7 at collapse are comparatively small. It indicates that these structures are of dynamic failure, while corresponding structural connection ability and requirement of damage are relatively large. In case of the same structural configuration, increasing element cross-section is equivalent to increasing grid density. Structural connection ability

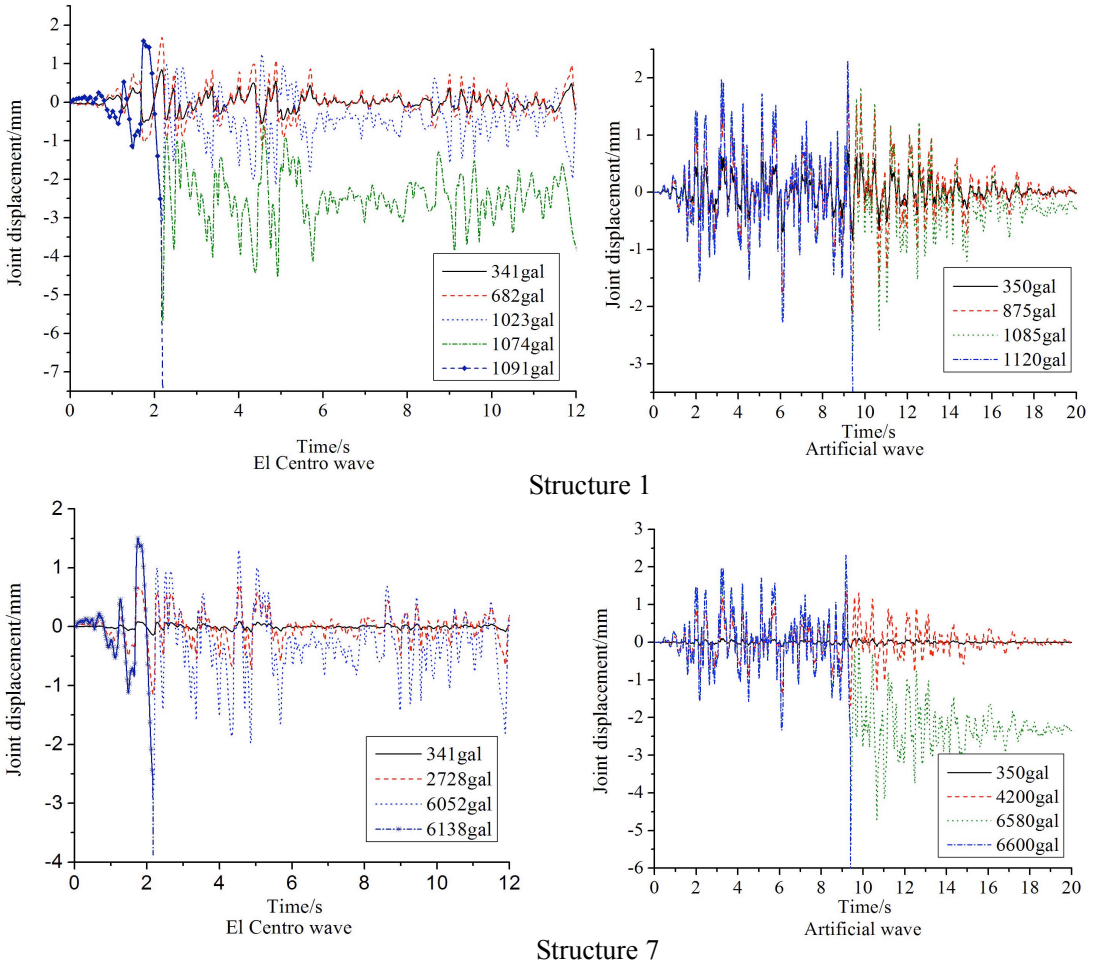

Figure 6. Joint displacement response history

and requirement of damage will change accordingly, and the failure mode changes from strength failure to dynamic instability.

It can be seen that the peak ground acceleration-maximum joint displacement curve has a obvious turning point. This is due to the fact that some of bars in the structure reach inelastic buckling and enter plastic stage under certain peak values of ground motion. Through checking the proportion of the plastic bars, it is found that the hexagonal space dome has a simple form, a small number of elements and most of the bars enter plastic stage simultaneously at a peak ground acceleration, causing an evident turning point in the curve.

Now we change the structural height-span ratio and conduct the structural vulnerability analysis to obtain the joint connection ability and requirement of damage. Similarly the ultimate load and ultimate displacement of the structure can be obtained from the load-displacement curve (see Figures 7 and 8). Failure mode can be determined from the load-displacement curve and response-history curve, as shown in Table 4. Different height-span ratios cause different failure modes. Under El Centro ground motion, structrues with height-span ratios of 1/13, 1/14, and 1/15

are of strength failure mode while ultimate displacements are of large values. Structural failure mode is strength failure under the artificial wave when the span ratio is 1/14 and 1/15.

From analysis above, it can be shown that the structures will fail in strength when values of the connection ability and vulnerability index are small. With the increase of the vulnerability index, the failure mode changes from strength failure to dynamic instability. Structure 15 shows different failure modes under different seismic ground motions.

SUMMARY

This paper uses the theory of dynamic instability and failure mechanism to investigate the relationship between failure mechanism and vulnerability theory. A new idea of using vulnerability analysis to determine structural failure mechanism is introduced.

A hexagonal space dome was used as benchmark structure in vulnerability analysis. The relationship between bars of high stresses under load and deteriorating bars with failure mode of overall collapse was studied by calculating stresses in elements under different load combinations. Whether in intact structure or in structure of partial failure, the stresses of deteriorating bars by vulnerability analysis are relatively high. Structural vulnerability analysis provides a new idea of directly

calculating high stress elements' characteristic parameters of vulnerability, finding all failure modes and judging structural vulnerability. The presented method neglects elements with low stresses, which can reduce amount of calculation and account for the effects of loading.

Structural ultimate load and connection ability are nonlinearly correlated. Connection ability should be chosen rationally to ensure the structure reach optimal peak ground acceleration values.

Different member cross-sections and different height-span ratios were studied using incremental dynamic analysis under El Centro record and an artificial ground motion. Different structural failure modes were presented with different element cross-sections and different height-span ratios. Through vulnerability analysis failure mechanisms of different structures are discussed, which reveals strength failure is likely when the connection ability and vulnerability index are small. With the increase of the vulnerability index, the failure mode changes from strength failure to dynamic instability.

ABSTRACT

The dynamic characteristics of the long-span corridor in a stadium are usually very complicated. The vibration may be significant when subjected to heavy walking excitations, which requires vibration control systems, such as dampers, to be implemented. In this paper, a stadium corridor using Tuned Mass Dampers (TMDs) for vibration control was studied. The eigenvalue analysis of the corridor showed that a vertical vibration mode is prominent, and the frequency of this mode is close to human fast-walking frequency, which can cause resonance in the corridor. Simulated walking excitation loads were applied to the finite element model. A variety of walking scenarios, and different TMD frequencies and distributions were investigated in order to optimize the frequencies and layout of the TMDs. The analysis results indicated that TMDs can significantly reduce the vibration response of the corridor due to walking, particularly near the resonance frequency. Though the TMDs were tuned to or near the resonance frequency, when subjected to other walking frequencies, the corridor's responses with TMDs also reduced substantially. The sensitivity of TMDs to structural frequency necessitates the field dynamic tests before fine tuning the dampers to optimize the vibration control effects.

INTRODUCTION

Contemporary architectural design evolves with radical changes in functionality, aesthetics, and space arrangement, and brings irregular and unique building configurations. It poses challenges to structural engineers in achieving structural

design to meet the safety and comfort requirements. Shown in Figure 1 is the 3-D model of a stadium, an example of such a challenging structure.

As shown in Figure 1, the bowl is hung at the outer rim by cables to the space trusses at the top. There is no support from the bottom except a few diagonal braces to the giant lattice columns on the left side. The top of the bowl is partially connected to the space trusses. The vertical vibration may be significant because of the low vertical stiffness of the bowl. The ring corridor inside the bowl is supported by vertical posts on the latticed shells of the bowl structure (Figure 2). As a result of the long span, and being supported on the locations where the vertical vibration mode is pronounced, the corridor's vibration may be substantial under human walking excitation, causing discomfort of the occupants and affecting the use of the structure. Therefore, it is necessary to control the vibration of the corridor.

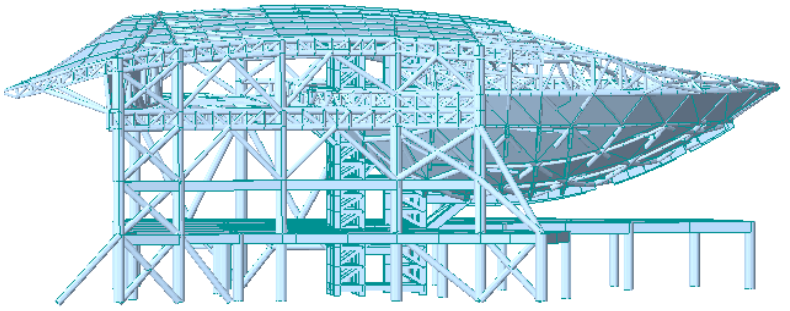

Figure 1. 3-D model of the stadium

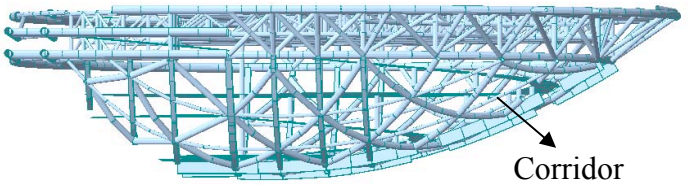

Figure 2. Bowl section and corridor

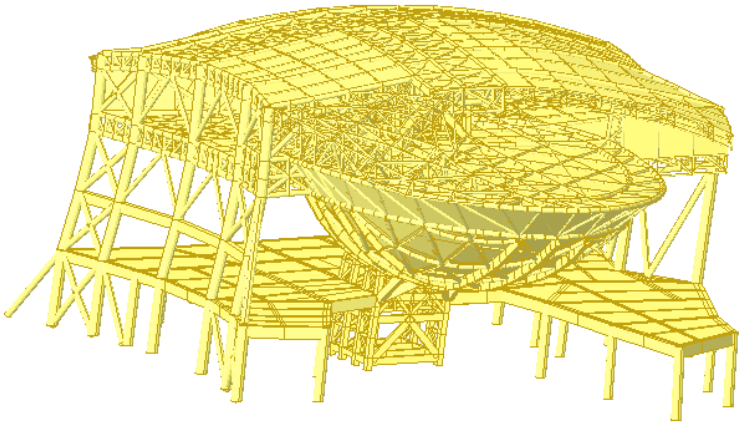
DYNAMIC ANALYSIS OF THE STRUCTURE

A 3-D finite element model (Figure 1) was developed in MIDAS in order to study the dynamic behavior of the structure, and to provide a basis for the settings of the damper parameters. The space beam element is used to model concrete and steel beams and columns. The shell element is used to model floor slabs, taking account of in-plane and out-of-plane deformations. The cable element is used for the cables

hanging the bowl. Modal analysis is performed using the Ritz vector method by Wilson and others.

The damping ratio varies among different modes for a steel-concrete composite structure like this. To ensure the accuracy of subsequent response history analysis, the method provided by MIDAS is used to calculate the damping ratios of the structure's different modes. The theoretical base is the Stain Energy Weighted Average Method, which averages the strain energy of members of different materials in a mode, weighted by their damping ratios, to obtain the damping ratio of that mode. The damping ratios of the first ten modes are shown in Table 1.

Table 1. Frequencies and damping ratios of the first 10 modes



Mode No.	1	2	3	4	5	6	7	8	9	10
Frequency (Hz)	2.34	3.21	3.47	4.53	4.89	6.32	7.20	7.38	7.41	7.48
Damping ratio	0.031	0.027	0.036	0.033	0.044	0.036	0.021	0.025	0.047	0.024

The results of the modal analysis reveal that the vertical vibration mode of the structure is prominent. The second vibration mode turns out to be a vertical mode of the bowl (see Figure 3) and the third mode is a torsion mode. Meanwhile, the corridor shows significant vertical vibration in every mode. Therefore, the vertical vibration is significant for the corridor. The first two modal frequencies of the structure are 2.3Hz and 3.2Hz. Though the first mode is mainly translational, the corridor exhibits certain vertical vibration. The frequencies of 2.3Hz and 3.2Hz are very close to human walking frequencies ranging from 1.8Hz to 2.5Hz, leading to potential resonance in the structure. The structure is adequate in strength. However, the excessive vibration beyond the acceleration tolerance of human comfort may cause psychological panic. Therefore, it is necessary to take measures to damp the vertical vibration of the corridor. The modal periods and vertical participating mass ratios of the top 20 modes are shown in Table 2.

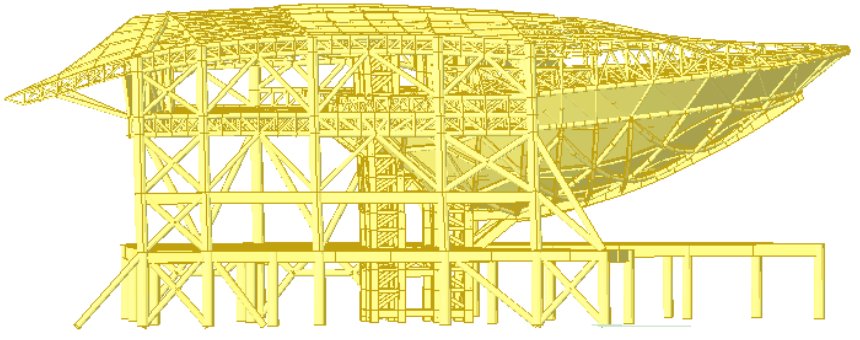


Table 2. Modal properties of first 20 modes

Mode No.	1	2	3	4	5	6	7	8	9	10
Freq. (Hz)	2.34	3.21	3.47	4.53	4.89	6.32	7.20	7.38	7.41	7.48
Vert. parti. mass ratios (%)	0.14	7.90	0.01	2.00	0.51	0.10	1.53	6.62	3.03	3.70
Mode No.	11	12	13	14	15	16	17	18	19	20
Freq. (Hz)	8.07	8.50	8.83	9.56	9.88	10.22	10.39	10.67	10.86	10.95
Vert. parti. mass ratios (%)	3.86	0.01	2.12	4.31	1.26	0.14	1.16	0.14	0	0.42

It can be seen from Table 2 that the 2nd, 8th, 9th and 10th modes are primarily vertical vibration modes, of which the vertical participating mass ratio of the 2nd mode is the largest. The vertical vibration modes are distributed. However, almost every mode has some vertical participating mass. It's observed that significant vertical vibration occurs in every mode in the corridor. With regard to higher order modes, their vibration frequencies are far away from that of the walking excitation, and are less likely to cause resonance. Hence, the vibration control is performed mainly on the first two modal frequencies. Figure 3 shows the first two mode shape.

Mode 1

Mode 2

Figure 3. First two structural vibration modes

During the response history analysis, sixty modes were included for combing. The damping ratios for the first ten modes are shown in Table 1, while the other modes having a uniform damping ratio of 0.035, 0.04, and 0.05, respectively, by input. The analysis demonstrated that the results of using the above three values are almost the same. This indicates that the damping ratios for the upper fifty modes have little

effects on the analysis.

PRINCIPLES AND DESIGN PROCEDURES OF TMD

The main task of controlling the vibration of the corridor under walking excitation is to reduce vertical vibrations. Tuned mass damper (TMD), as a passive control technology, has been successfully used in control of wind-excited vibration in high-rise structures. Numerical studies have shown that TMD can also effectively reduce the vertical vibration of long-span structures.

To maximize the effect of vibration control, the frequency of TMD shall be set near the free vibration frequency of the structure to be controlled. However, the damping effect of TMD is very sensitive to the fluctuations of the free vibration frequency, and there are always discrepancies between the actual free vibration frequencies of the structure and the calculated ones as a result of structural analysis errors and construction variations. Damping effect of TMD will be affected by these factors. More importantly, for the vibration modes lower than the mode being controlled, TMD has a good curbing effect to their response. For the modes higher than the one being controlled, TMD has little damping effect or may even amplify them. Given these characteristics, Clark (1988) proposed the concept of MTMD, which aims at a certain range of frequencies to be controlled, resolving the TMD system of a certain frequency bandwidth into multiple sub-TMD systems to improve the stability of the control system.

With MTMD attached, the dynamic equations of the multi-degree of freedom system under vertical load become:

$$[\mathbf{M}]\{\ddot{\mathbf{x}}\} + [\mathbf{C}]\{\dot{\mathbf{x}}\} + [\mathbf{K}]\{\mathbf{x}\} = \{\mathbf{F}\}$$

Where:

$$[\mathbf{M}] = \begin{bmatrix} \mathbf{M}_S & \mathbf{0} \\ \mathbf{E}^T\mathbf{M}_d & \mathbf{M}_d \end{bmatrix}, \quad [\mathbf{C}] = \begin{bmatrix} \mathbf{C}_S & -\mathbf{E}\mathbf{C}_d \\ \mathbf{0} & \mathbf{C}_d \end{bmatrix}, \quad [\mathbf{K}] = \begin{bmatrix} \mathbf{K}_S & -\mathbf{E}\mathbf{K}_d \\ \mathbf{0} & \mathbf{K}_d \end{bmatrix}$$

$$\{\mathbf{x}\} = \begin{Bmatrix} \mathbf{x}_S \\ \mathbf{x}_d \end{Bmatrix}, \quad \{\mathbf{F}\} = \begin{Bmatrix} f(t) \\ \mathbf{0} \end{Bmatrix}$$

$\mathbf{M_S}$, $\mathbf{C_S}$, and $\mathbf{K_S}$ denote the mass, damping and the stiffness matrices of the main structure, respectively. $\mathbf{M_d}$, $\mathbf{C_d}$, and $\mathbf{K_d}$ denote the mass, damping and the stiffness matrices of the TMD system. $\{\mathbf{x}_d\}$ stands for the displacement vector of each TMD relative to the main structure, only with the vertical component, while horizontal components being zero. $\mathbf{E}$ is the acting position matrix of TMD, where, the j^{th} column vector (with i^{th} element being unity, all others zero) represents that j^{th} TMD is set at the i^{th} node of the structure. *f(t)* is the time history of the walking load, which was obtained by the standard of IABSE.

To reduce the vertical vibration of the corridor, the primary vertical modes must be controlled. In this project, the second mode is the primary vertical mode. Considering the sensitivity of TMD systems to the frequencies, the TMD frequencies need to be fine tuned within the range of frequencies being controlled, to prevent the amplification of other walking frequencies and enhance the stability of the structure. The following are the basic steps of the method.

1. Analyze the structure's dynamic properties. Obtain the vertical vibration mode of the structure and the distribution of the corridor's vertical vibration.
2. Determine the frequency that needs to be controlled according to the results of modal analysis.
3. Locate the TMDs. Generally speaking, installing TMDs targeting a vibration frequency at the peak(s) of the mode shape appears to provide the most damping effect.
4. Add TMDs to the structure, and fine tune the controlling frequency of TMD in a certain spectrum. With the consideration of period change due to the additional masses of TMDs and variations of the walking excitations, determine the most appropriate frequency value(s), to enhance the stability of the system.

COMPARISON OF TMD DESIGNS AND ANALYSIS ON DAMPING

To find out the maximum response locations under the walking load, a group of 30 people were considering walking along the corridor on two floors from Endpoint A to Endpoint B. With two people in a row and the length of the group on the corridor being 14m, that is equivalent to a uniform load of to 0.7kN/m^2, when taking the weight of a person as 70kg, referring to Section 2.2.1 in American Institute of Steel Construction (AISC) Steel Design Guide Series 11 – *Floor Vibrations Due to Human Activity* (Murray et al 1997). The acceleration response was calculated every time the group moving forward by three sections. Then the maximum response was found, which occurred at the exterior on the upper and lower levels, i.e., Node 4999 and Node 5015. Therefore, the locations near these two nodes are the major spots to set TMDs.

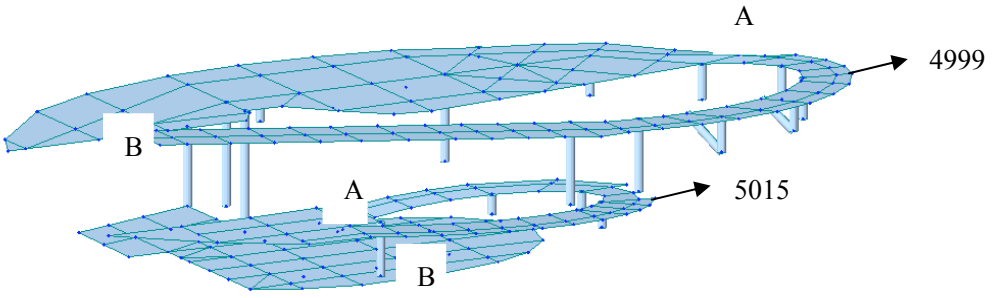

Figure 4. Sketch of the corridor

According to the analysis above, more TMDs are set at the curved segment on the exterior side of the corridor, and fewer near the end points A and B. TMDs are also located on the entrance platforms of the corridor. There are a total of 33 sets of TMD systems over the two corridors. Since the frequencies of walking excitation range from 1.8Hz to 2.5Hz, and the first two natural frequencies of the structure are 2.3Hz and 3.2Hz, the following vibration control schemes are compared: 1) TMDs at 2.5Hz; 2) TMDs at 2.8Hz; 3) TMDs at 3.2Hz. After finding the most effective damping frequency, the TMDs are divided into three groups having different frequencies within the narrow band around that frequency. The damping effects of the above schemes are compared under different loading conditions. The following loading conditions were considered: 1) slow walking, 50 people stretching 20m on the corridor, at the most unfavorable location (i.e., the outermost arc), with a uniform load of 0.7 kN/m^2, and exciting frequency of 1.8Hz, 2.0Hz and 2.2Hz, respectively; 2) fast walking, 30 people stretching 14m on the outermost arc, with a uniform load of 0.7 kN/m^2, and exciting frequency of 2.5Hz and 3.2Hz, respectively. The walking excitation curves are shown in Figure 5.

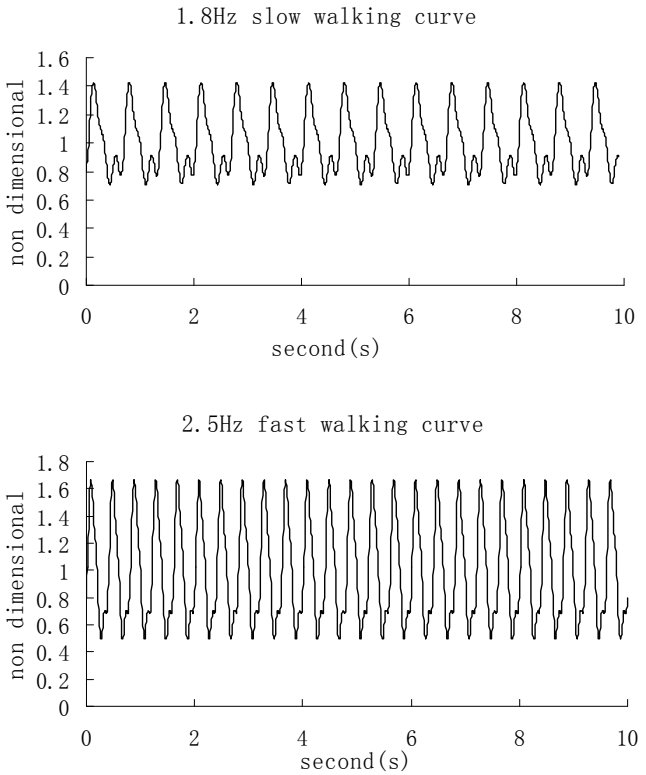

Figure 5. Walking excitations

The comparisons between the acceleration responses of Node 4999 and Node 5015 under each loading condition in three TMD schemes are shown in Table 3.

The following was observed from the analysis, as shown in Table 3. 1) The second vibration mode of the structure plays a decisive role in the response of the corridor, with the frequency of 3.2Hz. 2) The resonance is significant under the walking frequency of 3.2Hz. 3) The responses are much less under the walking frequencies ranging from 1.8Hz to 2.5Hz than that of 3.2Hz, since the resonance frequency is outside this range. 4) As TMDs' tuning frequency increases, the damping effects under different conditions vary. The tuning frequency of 3.2Hz has the best effects on restraining the resonance. But under low excitation frequencies, the damping effects are limited. The tuning frequencies of 2.5Hz and 2.8Hz better restrain vibrations of the lower modes, less effective at 3.2Hz excitation.

Table 3. Acceleration responses of Nodes 4999 and 5015 (mm/s^2)

Tuning frequency		Excitation frequency									
		1.8Hz		2.0Hz		2.2Hz		2.5Hz		3.2Hz	
		Node		Node		Node		Node		Node	
		4999	5015	4999	5015	4999	5015	4999	5015	4999	5015
Before TMD		182	142	207	163	200	160	160	135	665	531
After TMD	2.5Hz	168	128	179	138	176	137	132	101	464	323
	2.8Hz	169	128	179	135	176	133	132	100	353	251
	3.2Hz	175	138	187	145	183	143	143	124	201	183

In order to avoid the resonance, the tuning frequency should be set around 3.2Hz. Table 3 indicates that TMD with one single frequency cannot behave well on both cases of slow and fast walking. Using the concept of MTMD, the whole system of TMDs is divided into three groups. Considering that 3.2Hz is about the upper bound for walking, the groups have the frequencies ranging from 2.8Hz to 3.2Hz. These groups are mostly laid around the peaks of the second mode shape, at the outer side of the arc. TMD with different frequencies are laid in alternative pattern. Doing so reduces TMDs' sensitivity to the excitation frequency, and makes the system to gain damping effects in a wider frequency range. The parameters of the three groups of TMDs are shown in Table 4.

Table 4. TMD system parameters

Number	Mass (kg)	Tuning frequency (Hz)	Period (s)	Stiffness (kN/m)
TMD1	500	3.0	0.333	177.5
TMD2	500	3.1	0.322	189.5
TMD5	500	3.2	0.313	201.9

With the MTMD systems in place, the response accelerations of Nodes 4999 and 5015 under each operating condition are shown in Table 5.

Compared with results in Table 3 and Table 5, it can be seen that after grouping TMDs with separate frequencies within a small range, the responses changed little under the resonance, with significant damping effects. It improved damping effects under slow walking.

Figure 6 shows the comparison of acceleration responses of Nodes 4999 and 5015 before and after TMD installation under the excitation of the frequency of 3.2Hz. It can be seen from Figure 6, before installing TMDs, the structure's acceleration response is of resonance characteristics. After the installation of TMDs, the resonance phenomenon diminishes. At the resonance frequency of 3.2Hz, the damping effect on the acceleration reaches nearly 65%.

Table 5. Max acceleration responses under MTMD (mm/s^2)

Excitation frequency	Node	Before TMD	After TMD	Damping ratios
1.8Hz	4999	182	169	7.14%
	5015	142	129	9.15%
2.0Hz	4999	207	181	12.56%
	5015	163	141	13.50%
2.2Hz	4999	200	175	12.50%
	5015	160	135	15.63%
2.5Hz	4999	160	135	15.63%
	5015	135	110	18.52%
3.2Hz	4999	665	235	64.66%
	5015	531	212	60.08%

CONCLUSIONS

Based on the damping analysis using MTMD on the corridor in a stadium under walking excitations, the following conclusions can be drawn.

1. When the vertical natural frequency of the structure is close to the walking frequency, the resonance response is significant. In order to meet the human comfort requirements, the vibration control should be implemented.
2. TMDs need to be deployed in the vicinity of the peaks of the mode shape corresponding to the frequency to be controlled to achieve the most vibration control effects.
3. TMDs perform the best when tuned to the excitation frequencies. They are less effective to other vibration modes. To control more vibration modes, each group of TMDs should be located at the peaks of the corresponding mode shape.
4. Grouping TMDs into different frequencies within the controlling frequency range

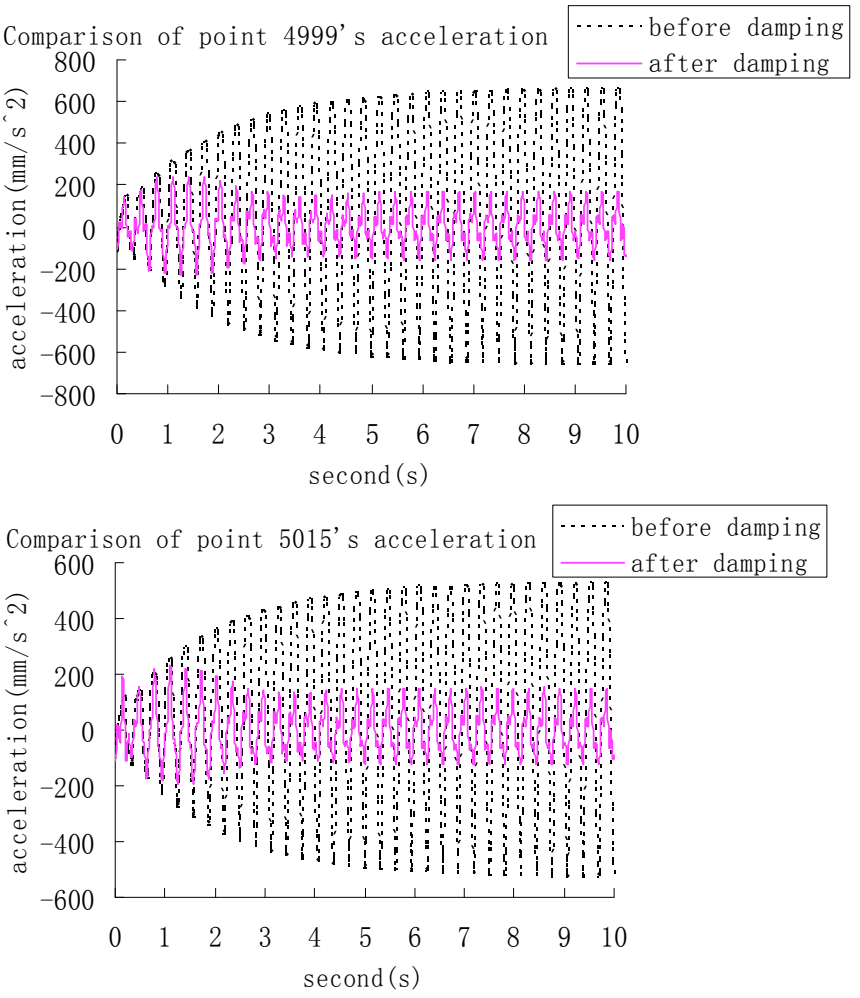

Figure 6. Acceleration responses of Nodes 4999 and 5015 before and after TMD installation

can reduce the amplification of the structure's vibration under other modes.

5. Due to TMDs' sensitivity to the structural free vibration frequencies, it is necessary to conduct field measurements of the dynamic properties of the structures before setting the final damper parameters.

The Road Less Traveled – Middlebury, Vermont's Design-Build Cross Street Bridge Project

Gregory S. Goodrich, PE

Vanasse Hangen Brustlin, Inc., 6 Bedford Farms Drive, Suite 607, Bedford, NH 03110; PH (603) 644-0888; FAX (603) 644-2385; email: ggoodrich@vhb.com

Abstract:

From funding to design and construction, the Cross Street Bridge in Middlebury, Vermont is an infrastructure accomplishment that can serve as both inspiration and a blueprint others desiring to integrate infrastructure improvements into the fabric of the community. This paper discusses the development of the bridge —the longest simple span spliced girder known in the US—from conceptual design through final design and construction, providing detail on the team's design-build approach and the challenges faced and overcome.

Background/History:

Middlebury is in the heart of Vermont and home to Middlebury College, one of the country's elite liberal arts schools. The College and the charming New England town both have a rich history but were separated by river with only one narrow crossing. For 60 years the town has wrestled with the issues of funding, location, and consensus about this dilemma while traffic and frustration increased.

The three span Cross Street Bridge is the first major design-build transportation project in the State of Vermont, and with a center span of 240-feet, it boasts the longest simple span precast post-tensioned, spliced concrete girder bridge span known in the United States.

Residents of Middlebury will attest that the idea of a second river crossing was anything but a new initiative. The plan for a new bridge crossing was originally proposed in the 1960's, prompted by the burning of the town's second crossing, the Three Mile Bridge in 1952. Otter Creek bisects the town, separating the downtown shopping district and the college from the emergency services and Route 7, the major north/south highway in the region. The lone crossing for the past 50 years is the Battell Bridge, a narrow stone arch bridge built in the late 1800's. The need for a second bridge to alleviate traffic for residents and visitors and provide additional pedestrian and bicycle facilities was became more urgent as the Battell Bridge aged.

The new bridge, in addition to being the first major transportation design-build project in Vermont required a main span that is now the longest simple span concrete girder in the country, What makes this project even more unique is that the $16 million project received no funding from Federal or State sources; it was funded

entirely by the Town of Middlebury and Middlebury College. Ground breaking was in April 2009 and the bridge opened to the public with great fanfare in October 2010.

Conceptual Design Development:

At the outset of the project, the Town assembled a Bridge Committee comprised of ten local citizens including Town officials, members of the Department of Public Works, , and local volunteers. The committee met regularly with the design-build team to provide feedback on conceptual bridge drawings, graphics, product samples, and other key information pertinent to the development of the project.

Once the project funding was secured by the Town and the VHB/Kubricky Construction design-build team was officially selected and approved, the first challenge was to determine how to deliver a structure with aesthetic significance that would integrate seamlessly into the landscape of this beautiful and historic New England community while also staying within the $16 million project budget. Several goals and considerations were presented by members of the Bridge Committee and the design-build team. Having the Contractor on board from the beginning of design proved to be invaluable to quickly narrow the range of options that would fit within the project budget.

Through engineering studies conducted prior to selection of the design-build team, the location and preliminary layout of the bridge was presented. This layout was expanded upon once the Town determined it would take a design-build approach. The project budget was established first, followed by another important priority for the Town – involving local resources as much as possible. A major regional precast concrete supplier, J.P. Carrara and Sons, based in Middlebury, was brought on board. Carrara specializes in precast, prestressed concrete bridge construction, so the team focused on designing a crossing that would incorporate these materials.

The bridge crossing spans three features: Bakery Lane on the west side, the Otter Creek, and the active Vermont Railway (VTR) on the east side. These features limited the placement of the substructure components. The primary challenge was crossing the Otter Creek at approximately 160-feet between each toe of slope. Crossing Bakery Lane on the west side required 160-feet of superstructure length, as did the railroad crossing on the east side, for a total required superstructure length of 480-feet.

Bridge Concept 1

The first bridge layout proposed two piers placed approximately at the toe of each embankment slope, requiring three span lengths of 160-feet each. This concept utilized 2000 mm tall (6’-6”) 160-foot long precast prestressed New England Bulb Tee (NEBT) girders. At 160- feet long, the NEBT 2000 shape would have maximized J.P. Carrara’s picking weight and transporting length. Another hurdle with this concept was hydraulics. The proposed crossing location for the Cross Street

Bridge is at a bow in the Otter Creek, making it economically impractical to geometrically align each pier with its respective river bank while. This substructure layout proved to be less than ideal from a hydraulic standpoint, and upon further review it was expected that the Vermont Agency of Natural Resources (ANR) would not likely approve of two substructures placed at the toe of each slope in such a configuration.

Bridge Concept 2

The second configuration placed two piers at the top of each river bank, and placed one pier directly in the middle of the channel, creating a bridge crossing with four equal spans of 120-feet long. This configuration incorporated an additional pier and reduced the total number of in-water substructures from two piers to one, requiring fewer cofferdams, reducing the individual precast span lengths from 160-feet to a more reasonable 120-foot span using 42" deep box beams. The design-build team thought that this alternative would be more attractive to the permitting agencies because it only placed one substructure unit in the channel, thereby reducing the overall impacts to the river. Vermont ANR pushed-back challenging the team to find a way to completely span the Otter Creek without permanent channel impact. From this request, the final bridge configuration was born.

Final Bridge Concept: Designing the longest simple span spliced girder known in the US

The third and final bridge configuration presented some significant engineering hurdles. The challenge: span the Otter Creek without permanent channel impacts. The solution: remove the middle support and create a record breaking, 240-foot simply supported center span using precast concrete.

The design team looked at alternatives, one of which was precast, post-tensioned, spliced concrete girder construction. With 120-foot end spans the span ratio of 2:1 would not economically or geometrically accommodate making the bridge continuous for live load, particularly given the close proximity of the railroad on the east side. The vertical clearance required by the railroad, coupled with the profile grade tie-in elevation at the intersection of Pleasant Street at the end of the bridge, made superstructure depths for the east end span relatively shallow, and did not allow for a gradual superstructure depth transition on the east side of the pier in order to effectively establish continuity over the pier. The solution was to create the longest simple span spliced girder known in the US. Through close coordination with Kubricky Construction (the Prime Contractor), and J.P. Carrara, the team began preliminary design on the center span.

Establishing the capabilities of the precast fabricator was critical. J.P. Carrara's maximum crane capacity was 95 tons. Their casting plant configuration could accommodate up to a 10-foot tall girder. J.P. Carrara already owned forms for the NEBT shape; therefore this would be the most economical girder shape for this

application. The team reached out to Corven Engineering, a nationally renowned specialist in post-tensioning construction, for due diligence. Corven conducted a review of the proposed bridge configuration and agreed that it was the most appropriate given the site constraints. They also reviewed the preliminary design and agreed that the proposed girder size and shape was within acceptable design limits. Kubricky and Carrara reviewed the preliminary design and determined that they could build the span within the proposed budget and schedule.

The team scheduled a follow-up meeting with ANR to present the revised bridge layout. The team designed a crossing that would completely span the Otter Creek without permanent channel impacts, however one question remained: would the Agency permit temporary channel impacts in the form of temporary erection towers in order to support the massive girder segments until the post-tensioning could be completed? ANR agreed to permit the temporary channel impacts, and with that, the concept drew one step closer to fruition.

With a viable bridge layout in-hand, the team presented the configuration to the Bridge Committee for approval. From there, the team and the committee presented the layout to the Town Selectboard for final approval, and it passed without exception.

Simultaneously, the team coordinated with the Bridge Committee to develop pier concepts and aesthetic features. Several pier configurations were considered: column bents, wall piers with voided recesses to provide a "window" through the pier, solid wall piers with various arched and vertical recesses, and flared piers. The Town challenged the team to develop a pier that would be unique in its own right and be true to itself– a concrete pier with its own historic significance.

Victor Nuovo, a member of the Bridge Committee and professor emeritus of philosophy at Middlebury College, was a proponent of creating a pier with unique character. He presented photos of a few historic bridges, the Brooklyn Bridge in particular, citing its distinctive visual appeal. These photos provided the initial inspiration for the piers. The team developed a pier concept with telescoping octagonal-shaped end caps, along with two full-height vertical recesses centered on each pier face. The features fit seamlessly with the height-to-width ratio of the piers and visually anchored the massive center span. Extending the ends of the piers beyond the superstructure fascia, and continuing the pier ends above the bridge seats proved to be an effective way of shielding the difference in superstructure depth, which stepped at the pier from a 42-inch deep box beam end span to a 10-foot deep center span NEBT. The pier "end cap" also served to visually break up the sight line along the bridge fascia, thereby providing a graceful and nearly seamless transition from the end span to the center span.

The Town also expressed an interest in visually marking the ends of the channel to motorists on the bridge in an effort to break up the long "viaduct" nature of the bridge and to add aesthetic interest. The Town originally proposed adding "spires" at the pier

locations, which would extend above the roadway to mark the location of the channel. Once the pier shape was developed, the pier end caps were temporarily terminated at the top of sidewalk elevation while alternatives were considered. The design team proposed adding overlooks at the pier location. Since the Cross Street Bridge was intended to serve both motorists and pedestrians, the overlook concept was a natural way to provide pedestrians a place to rest and converse on the bridge while allowing others to pass by. Additionally, the overlooks break up the long superstructure and also serve as a distinguishing feature of the bridge.

Once approved, the final bridge design concept proceeded to the final design phase. The final approved concept was presented to the public at a Town Meeting for direct input prior to beginning final design. There were no bridge design changes or requests from the public meetings as the feedback was overwhelmingly positive. Final bridge design was in full swing by March 2009.

Final Design Development:

The design-build team immediately kicked-off the final design phase of the project, beginning with foundations.

Preliminary bridge borings were taken as part of an engineering feasibility study that had been conducted prior to selection of the design-build team. These select borings were used to develop preliminary foundation concepts in order to project which types of foundations would be suitable at each substructure location. The preliminary geotechnical evaluation suggested that the substructure units on the west side of the Otter Creek would be best supported on piles. The east side required more in-depth discussions due to the presence of a seven to 10 foot deep layer of silt and organic matter on top of very dense and boney glacial till that was thought to be unsuitable for driving piles.

Once the final bridge layout was approved, the team initiated a final subsurface exploration and evaluation program at each proposed substructure location. At the same time, the team began a series of initial coordination meetings between the contractor, geotechnical consultant, and the design engineers to prioritize the design schedule. The team broke-down the bridge components into discrete construction document packages in order to meet the contractor's preferred order of construction sequence.

Expecting that the west abutment and west pier would be founded on piles, the contractor preferred to begin construction there. This decision was aided by the fact that access to the east pier location required a formal Railroad Agreements between the Railroad, the State of Vermont, and the contractor in order to construct the pier on railroad right-of-way, and a superstructure over the railroad corridor. The layout and clearance envelope was subject to Railroad approval prior to the start of construction on the east side.

With the conceptual pier design approved on March 2009 and the ground breaking ceremony scheduled for April 14, 2009, the team worked quickly to produce construction documents for the west pier foundation.

Establishing a Communication Protocol

The team recognized the need for establishing a well-defined "construction communication protocol" for use throughout the project. Given the aggressive schedule and amount of work to be accomplished, the project team defined a process that would guide the project to completion. The project team agreed on a hierarchy of communication that would efficiently channel information between the field and the office while keeping key staff informed without creating unnecessary delays.

To ensure an open flow of communication during the design phase, the team employed weekly scheduled progress conference calls between the contractor, geotechnical consultant, design engineers, and others as needed. This practice proved pivotal in keeping the foundation design and subsurface evaluation on-schedule and in-tune with the contractor's expectations during the early stages of design and construction. The meetings also allowed the design team to explore foundation options on the fly with the contractor available for immediate feedback.

Substructure Construction

As is common for most design-build projects, the substructure is typically designed and constructed prior to final design of the superstructure. The final superstructure configuration had been approved as part of the conceptual design phase, which called for two, 11-foot travel lanes, 4-foot shoulders, 6-foot sidewalks on each side, and three rail anodized aluminum bridge rail with balusters, for a total out-to-out bridge width of 44-feet 8-inches. The spans were set at 120-feet, 240-feet, and 120-feet. These criteria, with the preliminary superstructure design, the preliminary superstructure dead and live loads were calculated and used in the final design of the substructure units, beginning with the west pier.

Due to the advanced construction schedule and the quick turnaround required between approval of the conceptual bridge design and the groundbreaking, the first construction document deliverable was the west pier foundation. This allowed the contractor to order piles and reinforcing steel for the footing prior to releasing construction documents for the intricate pier stem. Since the contractor was to begin pile installation at the west pier, for efficiency he chose to immediately follow with pile installation at the west abutment.

The west pier pile group consists of 30 HP 14x89 piles driven to bedrock, arranged in three rows of 10 vertical piles, each pile approximately 40-feet long. The geotechnical engineer determined that battered piles would not be required given the design loading.

Horizontal loads on the pier were minimized and distributed evenly to each pier by fixing the end spans at the abutments and by releasing both ends of the center span, thereby allowing the longitudinal breaking, thermal, and shrinkage forces to be distributed evenly between both piers ("expansion" style elastomeric bearings were used on each end of the center span, and over the piers on the end spans). Lateral superstructure earthquake loads were transmitted to the piers via cast-in-place "keeper blocks" that were built into each pier bridge seat.

The west abutment pile group consists of a single row of nine vertical HP14x89 piles driven to bedrock, each pile approximately 60-feet long. The pile group was designed to support a continuous stub abutment cap perched atop a wrap-around Mechanically Stabilized Earth (MSE) wall bridge approach. The abutment pile group layout construction documents were broken-out in similar fashion to the west pier foundation in order to allow the contractor to continue pile driving operations prior to the completion of the final abutment cap design. The piles extended through the MSE engineered fill, through a layer of unclassified fill, into glacial till and ultimately set-up on bedrock. The geotechnical engineer was concerned that the unclassified fill would be susceptible to settlement, mostly during construction of the MSE wall, and since the piles had to be driven prior to construction of the MSE wall, the team needed to isolate the piles from potential down-drag induced by the settlement of the MSE wall. This was accomplished by encasing the piles in a 24-inch diameter smooth-wall High Density Polyethylene (HDPE) sleeve that was filled with sand prior to casting the abutment cap.

The abutments were designed to accommodate the longitudinal loads transmitted to them through the fixed bearings. Since the west abutment single row of h-piles were too flexible to resist the longitudinal loads (these loads were not resisted at the piers as the beam ends were placed on expansion bearings over the piers) the loads were resisted via two layers of MSE straps spaced at one foot fastened to the abutment backwall. The straps resist the longitudinal loads traveling away from the abutment (toward the pier). Soil resistance against the cap and backwall was used to resist loads toward the abutment.

The east pier foundation was constructed next. It was initially expected to utilize drilled shafts due to 100+ blow count glacial till under a 10-foot layer of loose silt and alluvial fill material. The contractor preferred to use pile foundations as he could utilize his own labor force instead of hiring a specialty contractor for drilled shaft construction, however, the design team was concerned that the piles would reach refusal without achieving the minimum desired depth of 10-feet. The depth of the loose alluvial fill layer was too deep to consider over-excavating down to the top of the glacial till layer. Over-excavating would require extensive dewatering and cofferdams capable of supporting railroad live load.

The contractor proposed an experimental "test pile" program to evaluate drivability at the east pier. Dynamic pile load tests were completed on each test pile with re-strike in order to confirm proper bearing had been achieved. The test pile program was

successful and h-piles were used at the east pier en lieu of drilled shafts, saving significant project costs.

Upon completion of the east pier stem, the focus turned to the east abutment, which is a traditional spread footing abutment with u-back wingwalls. With firm glacial till only four to seven feet below bottom of footing, and with the water table well below bottom of footing, the contractor elected to simply over excavate the unsuitable material and replace it with a layer of engineered structural backfill.

While the east abutment was being constructed, a second crew began construction on the west abutment MSE wall. The construction of the west abutment MSE wall was relatively routine with the exception of localized over-excavation required to remove pockets of unsuitable organic matter that were found during a series of shallow supplemental field borings taken along the proposed face of MSE wall. The uncontrolled nature of the fill made it imperative that the wall be able to accommodate minor amounts of differential settlement. The approach was isolated from the west abutment by installing 24-inch diameter sleeves over abutment piles to eliminate down drag on the piles in the event that the approach settles. MSE wall construction was ideal for the approach because it can accommodate small amounts of differential settlement since it is relatively flexible in nature.

Final Design Development: (Superstructure)

The keystone of the project was the design and construction of the 240-foot precast, post-tensioned, spliced concrete girder center span. A simple span of this size and type had never been constructed before, and at nearly 10-feet tall, it was also the tallest precast NEBT girder ever constructed in the northeast.

In order to accomplish this engineering feat, VHB teamed with Corven Engineering, post-tensioning design specialists, to perform the final design of the record breaking span. Corven Engineering was initially brought in to provide a peer review of the design concept, and was ultimately engaged to provide final design and construction support during fabrication, erection, and post-tensioning of the span.

Close coordination was required between J.P. Carrara, the precast fabricators, the contractor, and the design team in order to meet the tight schedule and stay on budget for both design and construction.

J.P. Carrara had three initial requirements crucial to the success of fabrication: the girder had to be less than 10-feet tall in order to be able to pick the girder out of the casting bed and load it onto the transport vehicles; the pick weight of each of the girders segments had to be less than 95 tons, the maximum capacity of the cranes in the fabrication plant; and to achieve economical fabrication costs, the design team needed to utilize the NEBT top and bottom flange configuration and configure the girder segment geometry in a way that was compatible with their fabrication beds.

The girder weight and geometry parameters pushed the design capabilities of the girder shape to the absolute maximum of its potential. The girder geometry was tweaked through a series of intermittent reviews by the design team and the fabricator. One of the most significant challenges posed to the design team was the final location of the girder splices. The girders had to be fabricated in three segments. Ideally the splices are located as far from the middle of the span as possible, in order to reduce the applied stress on the splice. The ideal location for the splice was at the quarter-point of the span, or 60-feet from the centerline of bearing. However at 1,700 pounds per linear foot the center segment would weigh over 100 tons. Therefore the final splices were located 65 feet from each pier, making the center segment a total of 108-feet long (accounting for a two-foot splice width), yielding a center segment weight of 92-tons. Each end segment weighed approximately 66-tons, including the massive eight-foot long end blocks.

The girders required five post-tensioning tendons per girder. The top two tendons consist of 19-0.6 inch diameter 270 ksi low-relaxation strands, each requiring approximately 835 kips of jacking force per tendon. The three lower tendons consist of 22-0.6 inch diameter strands, requiring approximately 967 kip of jacking force per tendon. The VSL PT-Plus™ post-tensioning system was selected for use in the girders because it uses corrugated polypropylene plastic ducts, which facilitate tendon installation, increase durability, and enhance corrosion protection of the tendon.

The high post-tensioning anchorage stresses at the end of the girders required heavily reinforced end blocks, the design of which demanded additional coordination between the designers and fabricators. Bar size, spacing, and placement considerations were of critical importance. Through a series of design reviews and interactive comment periods the team swiftly produced a design acceptable to the fabricator.

The balance between fabrication parameters, efficiency, economics, and design performance requirements meant that the design team had to push the envelope by using high performance concrete with a 28-day compressive strength of 10,000 psi. The team was concerned with the ability to place such high-performance concrete in large quantities while achieving proper consolidation in highly congested areas such as the end blocks. The solution was a self-consolidating concrete design mix. The design team requested trial batches to demonstrate the ability to produce a consistent mix with the proper design capabilities. A rigorous quality control program was employed by the fabricator, with independent testing, and additional oversight from the concrete admixture representative throughout the casting process.

The concrete results were incredibly consistent throughout. Proper design strength was achieved in 7-10 days, while the proper release strength was achieved in just less than two days in order to facilitate resetting the casting beds to keep production on-schedule.

The fabricator's casting bed was 270-feet long, which was ideal for casting one entire girder line at a time. Five total casting runs were required (one for each girder line). With a turnover rate of just over a week between castings it took approximately a month and a half to fabricate all five girder lines.

Once on-site, the girder segments were hoisted onto two temporary supports that were erected in the channel. A single 350-ton Manitowoc crane was used to erect the segments, starting with the 64-foot long segments on the east end of the channel, progressing to the 108-foot long center segments, and finishing with the west segments.

Two-foot field closure splices were cast using the same 10,000 psi self-consolidating concrete mix. The close proximity of the concrete plant to the project site made it possible to use such a high-strength mix without compromising the consistency of the mix. One challenge during construction was that the splices had to be cast during the winter, requiring heated curing. The contractor addressed heated curing by threading a two-inch diameter tube with glycol circulating at 180 degrees around each of the splices, covering them with thermal blankets. Continuous recording thermal sensors were strategically placed around each splice to monitor the temperature of the concrete. The sensors were monitored regularly so that adjustments could be made as necessary.

The 240-foot center span was post-tensioned in February 2010. Despite the sub-freezing temperatures of central Vermont, the weather did not significantly slow stressing operations. The crew installed and tensioned nearly 24-miles of post-tensioning strand in approximately three weeks. Upon completion of the stressing operation, the girders lifted off of their temporary supports by approximately 1 inch. The temporary supports were then removed from the channel, and the Otter Creek was finally traversed unobstructed.

The weather did play a role in the progress of the bridge construction, however. Since the tendon stressing operation was completed in mid-winter, it was too cold to initiate grouting of the tendons. The ends of the girders had to be accessible in order to grout, therefore the end spans could not be erected until the grouting was completed. A corrosion inhibitor was installed in the ducts upon completion of stressing operations. The inhibitor was blown out of the ducts in April 2010 in preparation for grouting.

The 120-foot long, 42-inch deep box beams for the end spans were fabricated during the winter months of 2009-2010. Similar to the center span, the box beams also utilized a self-consolidating concrete mix; however, the required design 28-day compressive strength of the box beams was 8,000 psi. Each box beam required 56-0.6 inch diameter 270 ksi low-relaxation prestressing strands, 50 straight strands in the bottom flange, and six straight strands in the top flange. The large number of strands in the box beams created high stress concentrations in the end blocks, and therefore the concrete required release strength of 6,000 psi.

The erection of the box beams on the east side was a carefully coordinated process. The east abutment is perched at the top of a 3:1 spill slope which extends to the railroad at the base of the slope. The location of the railroad and the length of the spill slope limited the contractor's available staging locations for the cranes. Instead of erecting a launching truss to erect the box beams, the contractor elected to utilize a series of three cranes in a choreographed box beam hand-off.

The first crane was placed directly behind the east abutment; the second crane was located at the base of the spill slope, to the east of the railroad, and a third crane adjacent to the pier. The second crane began by picking the west end of the box beam off of the transport dolly by using a sling instead of the lifting loops embedded in the end of the box beam. The transport backed up towards the pier while the crane rotated to the west, walking the end of the beam towards the pier. Once the east end of the box beam was in reach of the crane behind the abutment, the crane finally lifted the east end of the box beam off the transport. At this point, the third crane was in range of the west end of the box beam. This crane engaged lifting loops, which then relieved the middle crane from duty. Finally, the first and the third crane would rotate the box beam over to the abutment and the pier respectively and place the beam on the supports. This process was repeated for each of the 10 box beams on the east end span. The west end span was placed by utilizing two cranes in a conventional manner.

Upon completion of box beam erection, the crew focused on forming and placing the concrete bridge deck. The concrete deck was placed in one continuous operation starting at the west end (the low side) and proceeding to the east. The center span deck slab consists of an eight- inch thick concrete deck with a 28-day compressive strength of 5,000 psi. Each of the two end spans has five- inch minimum thick topping slabs with a required 28-day compressive strength of 4,000 psi. To utilize a single concrete mix design during the continuous deck placement operation, the contractor opted to use the 5,000 psi mix design for each of the three spans. Once cured, the six foot concrete sidewalks and a waterproofing membrane were installed and the deck was paved with three inches of bituminous asphalt.

With the bridge deck complete, one of the more defining features of the bridge was constructed— the overlooks. Four 11-foot wide octagonal shaped overlooks were constructed; one perched on top of each end of each pier, reflecting the shape of the pier ends. With the overlooks complete and the three-rail anodized aluminum bridge rail installed, the bridge was ready for its historic October 30, 2010 ribbon cutting.

Conclusion:

From initial concept through final design, the Cross Street Bridge was a welcomed addition to its unique New England Town. The innovative approach to funding, cutting edge design, and aesthetic detailing, make the Cross Street Bridge truly one of a kind.

Three-Dimensional Effects in Progressive Collapse Modeling

Honghao Li[1] and Sherif El-Tawil[2]

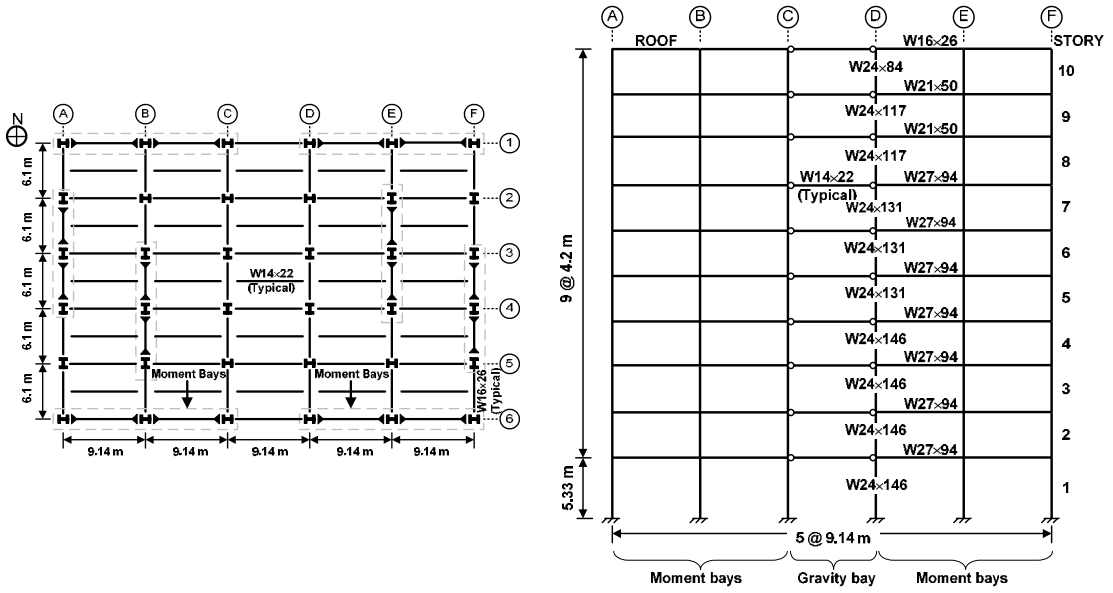
ABSTRACT

This paper highlights the importance of accounting for three dimensional effects when modeling progressive collapse behavior. Two types of nonlinear, inelastic models are first presented: 1) a planar comprised of beam-column elements to represent key structural members, and 2) a 3-D model that accounts for the most important components of the building. After validation, the simulation models are exercised to investigate system robustness when columns are forcibly removed. The importance of 3-D effects is quantitatively investigated through comparisons of system responses captured by the planar and 3-D models. In addition, the effect of modeling the slabs is demonstrated by comparing the responses of a 3-D model without slabs and the same 3-D model, but with slabs. It is shown that the slab plays a crucial role in progressive collapse response.

INTRODUCTION

Planar approximations of system response are made for convenience, because solving such models requires much less computational effort that solving corresponding 3-D models. As such, many of the models in the literature that have been used to study progressive collapse are planar. Planar models typically represent a single frame extracted from a structure, examples of which can be found in Kaewkulchai et al. (2003), Khandelwal and El-Tawil (2007), Khandelwal et al. (2008) Bao et al. (2008), Kim et al. (2009) and Khandelwal et al. (2009). By definition, these models do not explicitly address three dimensional effects, although they could be calibrated to account for some types of 3-D effects in an implicit manner.

It is only recently that 3-D models have come to be used for investigating progressive collapse. One of the earliest examples can be found in Ruth et al (2006), who used 3-D macro-models to show that the dynamic increase factor provided by the then-existing DoD and GSA guidelines is too conservative. However, the Ruth et al. (2006) study did not account for the effect of slabs, which can play a large role in 3-D behavior. Sasani et al. (2008), Szyniszewki (2009) and Mohamed et al. (2009) also used 3-D models to investigate the response of structures under events that could trigger progressive collapse. Other examples can be found in Main (2009), Fu (2009), Fu (2010) and Masoero (2010). Kwasniewski (2009) developed a detailed 3-D model, which was verified and validated by applying a hierarchical approach that included four levels of complexity. Alashker et al (2010) compared the responses of a 3-D



detailed finite element model and a 3-D macro-model subjected to loss of exterior columns. All of the previously discussed efforts to address 3-D behavior were conducted using the finite element method, albeit employing different types of elements. Other approaches for modeling 3-D response can be found in Galal et al (2009), for example, who developed a 3-D model using the Applied Element Method to investigate effect of retrofit strategies on mitigating progressive collapse of steel frame structures.

While it is becoming more clear from accumulating evidence in the literature that accounting for 3-D effects could be significant in progressive collapse modeling, there has not been a systematic study to show how important those effects are. This limitation is addressed herein by comparing between the responses of various types of models. Specifically, the collapse responses of planar and 3-D models of the same system are compared to gain insight into the effects of the various modeling assumptions made and to quantify: 1) the effect of planar versus 3-D models, and 2) the effect of modeling the slab in 3-D systems.

PROTOTYPE STRUCTURE

The National Institute of Standards and Technology (NIST) designed prototype steel framed buildings for the purpose of studying their response to an event which may cause progressive collapse (Liang et al., 2007). The buildings are 10-story office buildings with plan dimensions of 45.7 x 30.5 m and utilize moment-resisting frames as the lateral load resisting system. One of buildings designed by NIST is selected for the study in this paper: namely Building 3, located in Seattle, WA, and categorized as Seismic Design Category D, i.e. SDC-D. The building employs Special Moment Frames (SMF) for lateral force resistance. Design details can be found in Liang et al. (2007) and Khandelwal et al. (2008).

The selected building has a structural system comprised of both moment frames and a gravity system. There are 36 columns, of which 24 belong to moment-resisting bays, while the rest are gravity columns. Beams in the gravity system are connected to columns through shear connections which are comprised of single plate shear tabs that are 9.5 mm thick, made of A36 steel and filet welded to the columns. The beams are bolted to the tabs using 22 mm, A325 high strength bolts. In the moment frames, reduced beam sections (RBS) are used with 50% reduction in RBS flanges. In all moment connections, beams are assumed fully welded to the columns to simplify the modeling process. The structural steel used for all beams and columns is A992 (F_y = 345 Mpa). The plan of Building 3 is shown in Figure 1-a, while the elevation of the E-W frame on axis 6 is shown in Figure 1-b.

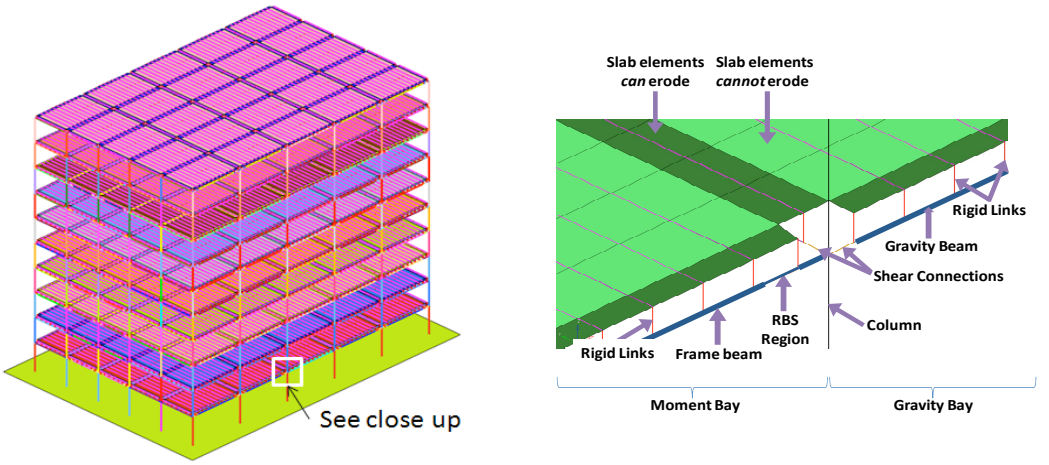
MODELING APPROACH

The general modeling approach adopted in this study is to model all primary structural elements in the system, within the specific limitations of each model, including all structural members and the connections between them. Since the focus of the study is on nonlinear response, each element's representation permits inelastic response to occur including fracture and separation, where appropriate. To enable realistic simulations of collapse, interpenetration between the various components of each model is prohibited. Therefore, falling components can introduce impact forces on the components with which they come in contact. The simulations are conducted with 5% mass proportional damping and are carried out using the explicit finite element code LS-DYNA (Hallquist 2006).

In both planar and 3-D models, beams and columns are represented using a Hughes-Liu beam-column element formulation, which was shown to be capable of reasonably representing structural response by Khandelwal and El-Tawil (2007). The radius cut reduced beam sections are modeled with a beam element whose cross section is set to the minimum cross section in the reduced section. The failure strain in the macro elements, which triggers deletion of the elements, is based on the work in Khandelwal and El-Tawil (2008).

The composite floor is comprised of a RC slab of thickness 82.5mm sitting on a steel deck with 76 mm depth and connected to the underlying steel beams via shear studs. Steel reinforcement in the RC slab is 0.05927 mm^2/mm in both directions. To avoid the complexity of modeling such a system in detail in the 3-D model, e.g. as in Sadek et al. (2008), a reduced model is employed in this study. The RC floor slab is modeled using fully integrated four-node, isotropic shell elements. A J_2 plasticity



model that can accommodate different tensile and compressive yield responses is used to model the RC slab. Since the steel deck can only develop resistance along the directions of the flutes, its effect is represented using steel bars attached directly to the shell elements. The area of the equivalent steel bars is taken to be 50% of the area of the steel deck based on calibration to Alashker and El-Tawil (2010). To preserve the mass of the slab as it collapses, only peripheral elements are permitted to be deleted while all other slab elements are not allowed to be eliminated. The composite slabs are connected to the steel beams through rigid links to model the composite effect. The model is therefore not purely a macro or micro model, but rather a hybrid, although it is referred to herein as a macro model because of the predominant effect of the macro-elements on collapse response. The total number of the elements used in this model is 63,600. Figure 2-a, shows an overview of the model, while Figure 2-b shows a close up of the shear connections and moment resisting connections. The shear tab is modeled by a single beam element, which has integration points that correspond to the local of individual bolts, as specified in Khandelwal and El-Tawil (2007).

The planar model is essentially a subset of the 3-D model and is a representation of the frame on axis 6 or axis E depending on the column in question. The planar model is extracted from the 3-D model by deleting all but the pertinent elements associated with the pertinent frame. The gravity load from the floor system acting on the frame is computed using the tributary area associated with the frame. To assure that the frame behaves in a reasonable manner, the top flanges of the beams are prevented from moving out of plane to model the stabilizing influence of the slabs.

The 3-D model runs for only 15 minutes to simulate 6-seconds of real time on an AMD Opteron 2435 cluster with 12 CPUs and 24 GB of RAM. The high speed of the model is primarily due to the careful sizing of elements to ensure that they yield as large a time step as possible without compromising accuracy. Since the solution scheme is explicit, the solution time is linked to element characteristics, specifically element size and density.

The proposed models are validated through comparisons to disparate experimental data and the results of more refined models. More details about the material models and validation studies can be found in Alashker et al (2010).

The models employed in this study are designated M2 for the 3-D models and M4 for the planar model. The naming scheme used is selected to match that employed by Alashker et al. (2011). In this paper, simulations were conduct using model M2, but without the slab. The modified M2 model is designated M2-NS (where NS stands for no slab). In M2-NS, it is necessary to keep a small set of peripheral slab elements in each panel in order to maintain the stability of the beams, which tend to undergo lateral torsional buckling when they are left completely unsupported. The slab elements employed in M2-NS are deemed to contribute minimally to the overall structural resistance attributed to the slab system, a fact that was confirmed through sensitivity studies involving subassemblages.

SIMULATION SETUP

The Alternate Path Method (APM) is used to study collapse potential. Gravity loads (i.e. dead load plus 25% of the live loads) are applied gradually within 1 second, followed by a wait period of 0.5 seconds, in order to eliminate dynamic effects. After that, a key element, such as a column is forcibly removed by deleting it instantaneously. It was been shown in Alashker et al (2010) that the proposed loading period is able to yield a reasonable compromise between computational time of the model and prevention of unwanted dynamic effects. The structural system's response to the new boundary conditions is then investigated.

THE COMPARISON BETWEEN RESPONSES OF PLANAR AND 3-D MODELS SUBJECTED TO LOSS OF COLUMNS

A series of nonlinear dynamic analysis are performed with the proposed models. Three first floor column loss cases, which are removal of column at D6, removal of columns D6 and E6 simultaneously and removal of column E5 are carried out and the responses of the planar and 3-D models are compared.

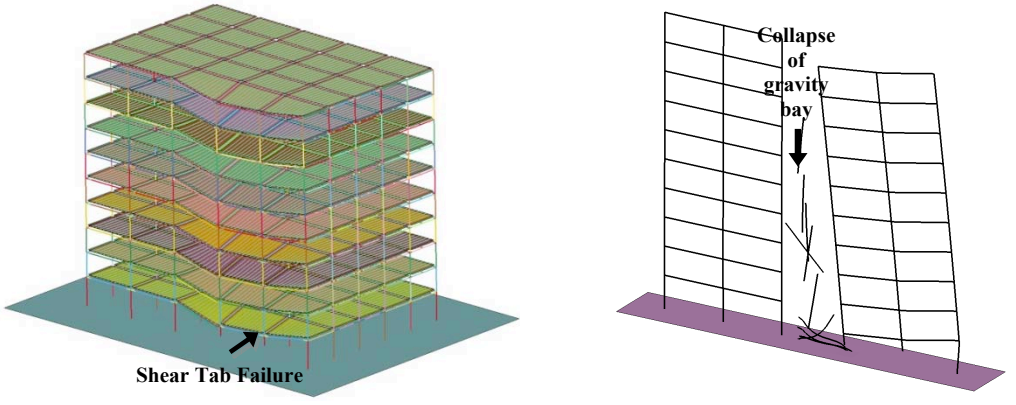

Figure 3 shows a comparison of system responses of M2 and M4 (representing the frame on axis 6) after sudden loss of the exterior column at D6. Cleary, there are substantial differences between the responses of the two models, which are attributed to the slab and other 3-D effects captured by M2 but not M4. These effects appear to play a key role in reducing the overall deflections and promoting load redistribution. For example, the vertical deflection of the node corresponding to the top of the removed column reduces from 128.6 mm in the planar model to 68.3 mm in the 3-D, a 47% reduction. The compressive force in Column C6 is less affected by column removal, losing only 70 kN in M2 versus 479 kN in M4, which highlights again the role of 3-D effects in promoting load redistribution.

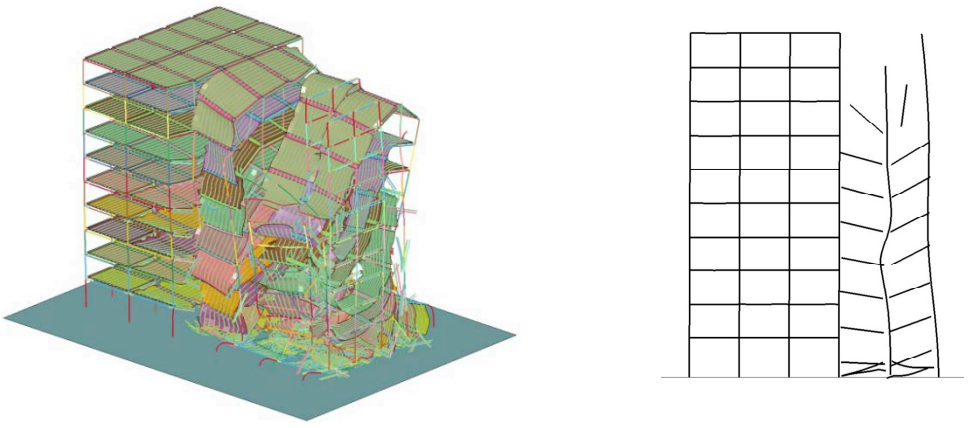
(a) Column axial forces **(b) Vertical displacement**

Figure 3. Comparison between the responses of models M2 and M4



Great differences can be seen between M2 and M4 (representing the frame on axis 6) when exterior columns D6 and E6 are simultaneously removed. As shown in Figure 4, model M4 predicts failure of the system, while M2 shows a controlled response in spite of failure of one of the shear tab connections in bay CD at the first floor. Like the response of M2, failure in M4 initiated at the shear tab connection in bay CD, adjacent to column D6, at the first floor. However, unlike what was captured by M2, shear tab connection failures propagated rapidly upwards all the way to the top floor. At that point, the moment frame spanning columns D6-E6-F6 became unbalanced because it was effectively supported on only one intact column, i.e. F6, and the frame collapsed.

(a) 3-D model response (displacement magnification factor=5) **(b) 2-D model response (displacement magnification factor=1)**

Figure 4. Responses of M2 and M4 subjected to loss of columns D6 and E6 simultaneously

The comparison between the responses captured by M2 and M4 (representing the frame on axis E) after column E5 is removed is shown in Figure 5. It can be seen that system failure occurs in both of the models. In M4, after removal of the column, the shear connections joining the gravity beams to the columns in bays 4-5 and 5-6 failed rapidly and the failures propagated up to the top floor, which induced collapse of these two bays. However, the other three bays remained undamaged. In contrast, widespread collapse occurred in M2. The failures initiates in the slab panels adjacent to the removed column and radiated upwards and outwards to adversely influence the rest of the structure.

(a) 3-D model response **(b) 2-D model response**

Figure 5. Responses of M2 and M4 subjected to loss of columns E5

The 3-D models are considered more realistic than the planar models in that they can capture the effects of the slab and its interaction with the other frame members. The column loss cases discussed above show that there are distinct differences between the results of the planar and 3-D models. When failure is not imminent, e.g. as shown in the case when column D6 is removed, it appears that the slab reduces the deformations that occur and leads to a reduction in the forces that are redistributed to adjacent columns. This can be clearly seen in Figure 3(a), where column E6 in M4 sees a larger increase in load than in M2, whereas Column C6 sees a larger decrease in M4 than in M2. In other words, the slab collaborates with the moment frames to temper the force redistribution that happens when members are removed.

When failure is predicted by model M4, it is not possible to say whether the vulnerability of the structure is overestimated or underestimated. In the studies presented herein, M4 predicted failure when columns D6 and E6 were simultaneously removed, whereas M2 showed that the failure was arrested and did not propagate. On the other hand, when column E5 was removed, M4 predicted failure of the 2 adjacent bays only, whereas M2 showed much more widespread failure. Therefore it is not possible to state with certainty that 2-D models are generally conservative.

EFFECT OF THE SLAB

The previous discussions show that there are substantial differences between the response of planar and 3-D models. It is hypothesized that the slabs are the source of this difference, however that cannot be clearly discerned from the simulations conducted. To clarify the role of the slab in 3-D response, comparisons are made between models M2 and M2-NS. Tables 1 and 2 illustrate these comparisons. Table 1 lists all cases in which collapse is mitigated in the 3-D models. In it, the steady state displacements of the node corresponding to the top of the removed column, computed from both various models, are compared. Table 2 presents cases in which collapse could not be arrested in 3-D models and describes how the models responded during collapse.

An examination of Table 1 shows that the deformations captured by M2-NS are always larger than those captured by M2 and, in fact, are very close to those captured by M4. The only exception is when column E4 is removed, which leads to collapse in M4 (representing the frame on axis E), but not in M2 or M2-NS. However, the displacement in N2-NS reaches 196 mm, which is 3 times the value in M2. Clearly, the slab is exerting much 3-D influence. However, there appear to be other significant sources of 3-D resistance, e.g. coming from out-of-plane structural members, which helped arrest collapse in M2-NS when column E4 was eliminated.

Table 2 reveals that the existence of the slabs is not always beneficial. In cases where D5 or E5 are individually removed, full progressive structural collapse occurs in M2, but not M2-NS, which suffers only partial collapse around the eliminated column. Clearly, the presence of the slab helped promote progressive collapse in these cases. In contrast, when D6/E6 are removed simultaneously, partial collapse also occurs in M2-NS, but collapse is mitigated in M2.

Table 1. Comparison between the responses of the 3D models with and without slabs: progressive collapse is prevented

Column-loss case	Deformation after column loss (steady state)		
	Model M2 (mm)	Model M2-NS (mm)	Model M4 (mm)
D6	69.3	108.1	109.0
E6	26.4	32.1	33.3
F6	45.7	51.8	53.3
E4	65.5	196.1	collapse

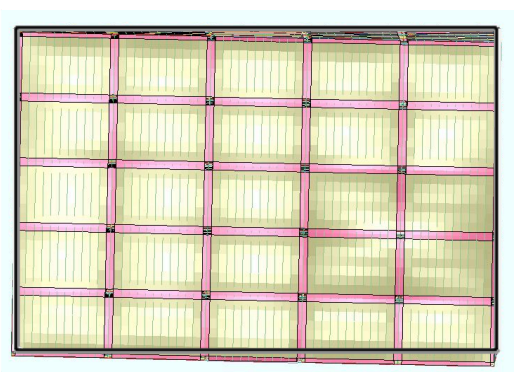


Table 2. Comparison between the responses of the 3D models with and without slabs: progressive collapse occurs

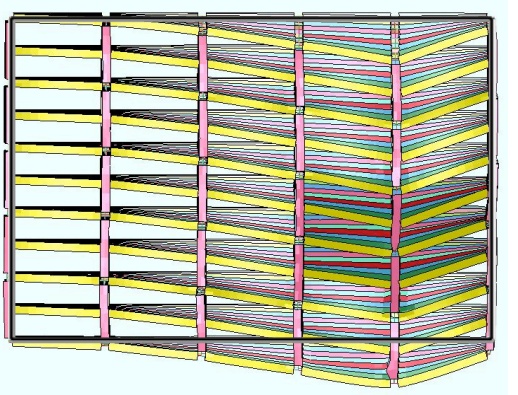
Column-loss case	Response of the model	
	Model M2	Model M2-NS
D5	Full structure collapse	Partial collapse
E5	Full structure collapse	Partial collapse
D6/E6	Collapse mitigated	Partial collapse



The simulation results shed light on the complex role of the slab in resisting collapse. The results show that when a column in a moment bay is lost and the structure does not collapse, the moment bay containing the removed column will lean towards the location of the removed column. The moment bay will therefore push or pull on adjacent bays in the plane containing the affected moment bay causing the entire frame to also lean in that direction. This effect is equivalent to apply an additional lateral force on to the frame, which results in force redistribution in the columns in the moment. In addition, since the slabs are so stiff in plane, they tend to maintain their rectangular shape, which can lead to global torsional effects.

Figure 6 shows the comparison between the top views of the deformed shape of the models with and without the slabs after loss of E4. The dark lines indicate the outline of the undamaged structure. The global torsional effect is evident in Figure 6(a) and it is clear that the slabs force other moment bays in the system to be mobilized to resist collapse, e.g. the frame on axis F. It can also be seen that the greatest lateral displacement demands may not occur in the frame containing the removed column. In this particular case, the frame on axis F experiences the largest lateral displacement leading to substantial force redistribution in that frame. For example, after loss of E4, the steady state axial force in F5 increases from 1470 kN to 1980 kN, whereas the force in F3 decreases from 1470 kN to 935 kN.

Figure 6(b) shows that for model M2-NS, the frame containing E4 suffers the greatest lateral deformation. Other frames are also being mobilized, but force redistribution in surrounding frames is not as severe as when the slab is present because the other three frames containing moment bays in N-S direction hardly deform laterally. Also evident from a comparison between Figures 6(a) and 6(b) is that a much larger lateral displacement occurs in the frame on axis E in M2 versus M2-NS, which clearly demonstrates the effective role of the slab in this situation.

CONCLUSION

In this paper, planar and 3-D validated models representing the same structure are used to investigate the influence of three dimensional effects on the responses of the structure under column-loss scenarios. Three different models were employed, M2 which is a 3-D model that accounts for the slab, M4, which is derived from M2 but only represent a frame along a single axis, and M2-NS, which is similar to M2, but does not account for the presence of the slab. From the limited simulations presented herein, the following main conclusions can be drawn: (1) 3-D effects are significant and play an important role in determining the response of the structure subjected to sudden column loss; (2) When failure is not imminent, 2-D models can represent the structure reasonably, although they are conservative. However, when failure is predicted, 2-D models may underestimate or overestimate the vulnerability of the structure; and (3) Slabs contributes significantly to reducing the overall deflection of the structure when columns are removed suddenly. The slabs can also help to enhance the integrity of the structure and redistribute the loads when moment columns are removed. However, slabs also lead to more widespread failure if the collapse process is not arrested early on.

ABSTRACT

The Alternate Path Method is used to examine the vulnerability of a 5-story barracks building to progressive collapse based on DoD criteria UFC-4-023-03. The building is composed of composite deck floor system and steel roof trusses, all supported by cold-formed steel stud load bearing walls. Two different wall section removal scenarios at the first story of the building were considered for the analysis. The analysis was performed using the "Extreme Loading® for Structures" software, a 3-dimensional nonlinear dynamic analysis software.

The results show the ability of the composite deck floor slabs to bridge over the removed wall sections. The slabs were able to re-distribute the gravity loads to adjacent wall components, while some of the loads were picked up in tension by the stud walls above the slabs. The study provides a good understanding of the composite deck floor-cold-formed steel stud bearing walls building system in resisting progressive collapse.

INTRODUCTION

In 2001, the Department of Defense (DoD) started to publish design guidelines for structures to resist progressive collapse resulting from an extreme loading event. The design guidelines are given in the Unified Facilities Criteria UFC 4-023-03 "Design of Buildings to Resist Progressive Collapse" (UFC, 2009). This document provides the design requirements necessary to reduce the potential of progressive collapse for new and existing DoD facilities. Since then, engineers are on the lookout for design guides that explain the implementation of DoD guidelines in conventional and new construction systems. This paper provides some guidance for implementing the DoD progressive collapse criteria in buildings constructed with cold-formed steel stud bearing wall systems.

Cold-formed steel load bearing wall systems

The use of cold-formed steel (CFS) load bearing framing in typical mid-rise construction (three to eight stories in height) brings the value of reducing associated construction cost in comparison to other structural framing systems such as reinforced masonry, structural steel and wood. A key component of the cost savings is the lighter mass of the structure, which is the key element to the design of the lateral force resisting system (shear walls) and the foundation. CFS load bearing stud walls must be braced laterally at intermediate points to restrain the studs against lateral and torsional buckling. X-brace flat straps are commonly used in this type of construction to provide the building resistance to lateral wind and seismic forces. The X-brace system provides pre-determined load path for the lateral shear forces, and therefore requires vertical stacking of the shear walls to ensure the load transfer from all floors down to the foundation. The design of cold-formed steel framing in the US is governed by the specification published by the American Iron and Steel Institute (AISI, 2007).

It is important to note that several types of floor systems can be integrated with CFS load bearing walls. Among these types are composite steel deck-concrete slabs (composite deck), CFS joists or open bar joists with a concrete or wood floor diaphragm, and precast hollowcore concrete planks. The composite deck combines the structural advantage of a flat slab with the time saving advantage of a permanent form. The steel deck furnishes the total bottom reinforcement of the composite slab, while additional top reinforcement is required. Due to the composite action between the concrete and the steel deck, the slab can support a greater floor live load compared to a typical reinforced concrete slab of the same depth. More information about CFS load bearing wall systems are given by Rahman (2006, 2007).

DoD progressive collapse design criteria

Unified Facilities Criteria 4-010-01 (UFC, 2007) requires that all new and existing military facilities of three stories or higher be designed to avoid progressive collapse. UFC 4-023-03 (UFC, 2009) offers two general design approaches to reduce the possibility of progressive collapse; Direct Design approach and Indirect Design approach. The Direct Design approach includes the “Alternate Path” method, which is based on flexural performance of the floor system, as the building must bridge across removed vertical supporting elements. The Indirect Design approach includes the “Tie Forces” method, which is based on the catenary (membrane tension) response of the structure, and is used to enhance continuity, ductility and structural redundancy of the building. The level of progressive collapse design and the selection of the design approach and method are based on the Occupancy Category (OC) of the building. This OC is specified in UFC 3-310-01 (UFC, 2005), but also allowed to be specified by the building owner. Engineers dealing with buildings with OC II have the option of using the Alternate Path Method or the Tie Forces Method for the progressive collapse analysis. However, design for buildings with OC III and above must include the Alternate Path Method for the analysis.

The Alternate Path Method follows the LRFD philosophy with load combination for extraordinary events and resistance factors to define design strengths. Three analysis procedures can be used; linear static, nonlinear static and nonlinear dynamic. The estimate of design strength varies depending on the classification of the action; either deformation-controlled or force-controlled action. The nonlinear dynamic analysis selected for this study requires the creation of a three-dimensional model for the primary framing members of the building. Inclusion of secondary framing members in the model is optional, but they must be checked with the results of the analysis if omitted. To perform the analysis, gravity loads and notional lateral loads are to be applied to the model until equilibrium is reached. Then, specified vertical load bearing components (columns or walls) shall be removed from the model and analysis shall continue until maximum displacement of slab is reached, or one cycle of vibration occurs at the location of the removed component. The acceptance criteria are dependent on the structural material. In this study, axial forces are checked as force-controlled action in CFS studs, and displacement is checked as deformation-controlled action in composite deck slab.

Applied Element Method for collapse analysis of structures

The Applied Element Method (AEM) is a nonlinear dynamic analysis method that is capable of predicting, to a high degree of accuracy, the continuum and discrete behavior of structures. The method is proved to track the structural collapse behavior passing through the stages of crack initiation and propagation in tension-weak material, yielding and formation of plastic hinges in ductile material, element separation, element re-contact, and collision with the ground or with adjacent structural components. In the AEM, a structure is modeled as an assembly of small elements. The two elements shown in Figure 1 are assumed to be connected by series of normal and shear springs located at contact points, which are distributed around the element edges. Normal and shear springs totally represent stresses and deformations of the elements. Steel bars in reinforced concrete components are modeled using continuous springs connecting elements together.

Each applied element has six degrees of freedom. These degrees of freedom represent the rigid body motion of the element. Although the element motion is as a rigid body, its internal deformations are represented by its springs' deformation. The global stiffness matrix is determined by summing up the stiffness matrices of springs around each element. Consequently, the developed stiffness matrix has total effects from all of the springs according to the stress status around the element. This technique can be used in both load and displacement control cases, and static and dynamic loads. For more details about the AEM, refer to publications by Meguro and Tagel-Din (2001 and 2002). The AEM is implemented in the Extreme Loading® for Structures (ELS) software (ASI, 2009), which is used to run the analysis in the current study.

BARRACKS BUILDING CASE STUDY

Building Description. Figure 2 shows the elevation, plan view and overall dimensions of the barracks building. The building is a 5-story structure composed of two wing areas and a core area with a typical slab-to-slab height of 3048 mm (120 inch) and first story height of 3200 mm (126 inch). The core area is constructed from structural steel framing, while cold-formed steel stud walls are used in the wing areas as the supporting structure for the gravity loads from the floor slabs and the roof. In the wing areas, the exterior walls on the short side of the building and every separation wall are gravity load bearing walls as shown in Figure 3. The figure also shows the locations of the X-brace strap system, with cold-formed steel stud boundary members, which is used as shear walls to resist lateral loads. The light weight roof trusses are supported on the corridor walls and the exterior walls of the long side of the building. Table 1 shows the schedule of the studs and top and bottom tracks of the main load bearing walls in standard nomenclature. The studs are distributed on typical 406 mm (16 inch) spacing, with weak axis bracing at mid-height. Table 2 shows the schedule of the X-brace shear walls in the longitudinal (east-west) and transverse (north-south) directions. All cold-formed steel (CFS) sections with nomenclature "S" and "T" have 228 MPa (33 ksi) yield strength, and all CFS sections with nomenclature "SG" and "C" have 345 MPa (50 ksi) yield strength. The diagonal straps also have 345 MPa (50 ksi) yield strength.

The floor slab is a composite deck system supported every 4216 mm on separation walls with 50 mm (2 inch) deep, 0.9 mm (30 mil, 20 ga) thick corrugated steel sheet and 100 mm (4 inch) concrete on top of the corrugated sheet. The slab reinforcement includes welded wire mesh 152x152 MW13.3/13.3 (6x6 W2.1/2.1) on top of the deck, and top reinforcement of 16 mm diameter (#5) bars at 150 mm (6 inch) spacing in both directions. The top reinforcement is used as part of a special design requirement for the floor slabs to resist an upward blast pressure specified in a previous version of the UFC 4-023-03. Figure 4 shows the actual cross-section of the composite deck, and the simplified cross-section used in the current numerical analysis model. In the analysis model, the composite deck was simplified into a 150 mm (6 inch) thick concrete slab with a reduced unit weight of the concrete to account for the void space created by the corrugated deck. In addition, the corrugated steel sheet was modeled as an equivalent area of rebar and spacing in the longitudinal direction only, located at the centroid of the deck profile as shown in the figure.

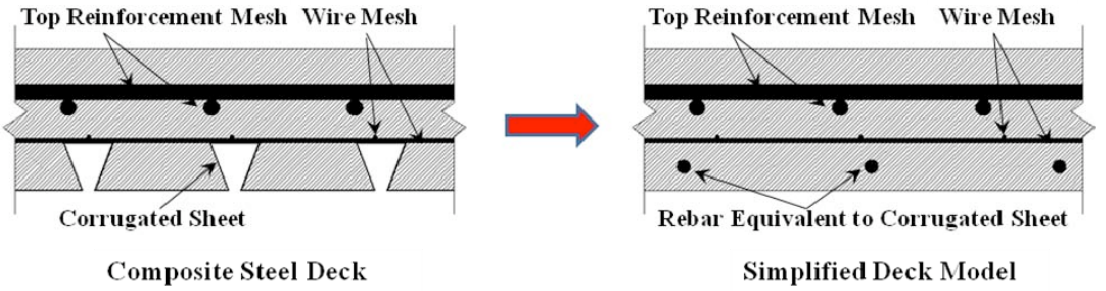

Figure 4. Cross-section of composite steel deck and the simplified model

The connection between the composite deck floor slabs and both the top track of the load bearing walls below and the bottom track of the load bearing walls above uses 4 mm (0.157 inch) diameter powder actuated fasteners. Four fasteners are used at each stud location and one fastener between studs. The steel studs are welded to the top track and the bottom track of the walls at both side of each stud.

Analysis Model. The three-dimensional model of the barracks building was created using the graphical interface and section database of the Extreme Loading® for Structures (ELS) software, Version 3.1. One part of the building, as outlined in Figure 2, and only the first four stories of the building have been considered in the model. This was decided to make the modeling time and analysis time of the building practical. The weight of the fifth story walls was uniformly distributed and added to the weight of the slab below. The weight of the roof trusses was added as line load to the locations of its supporting corridor walls and exterior walls of the long side of the building. Figure 5 shows the three-dimensional model for the part of the building used in the analysis.

All window and door openings on the exterior and the interior of the building were modeled with their appropriate dimensions and framing members. Full connections were used between these framing members attached together, and that between wall studs and their top and bottom tracks. The diagonal straps of the X-brace shear walls were modeled as long tension springs. Powder actuated fasteners for composite deck attachments were modeled as short tension and shear springs. The interface layer between the wall tracks and the composite deck was modeled as material with concrete compressive strength, but with very low shear and tension strengths. Table 3 gives the material properties and strength reduction factors for all components in the numerical model.

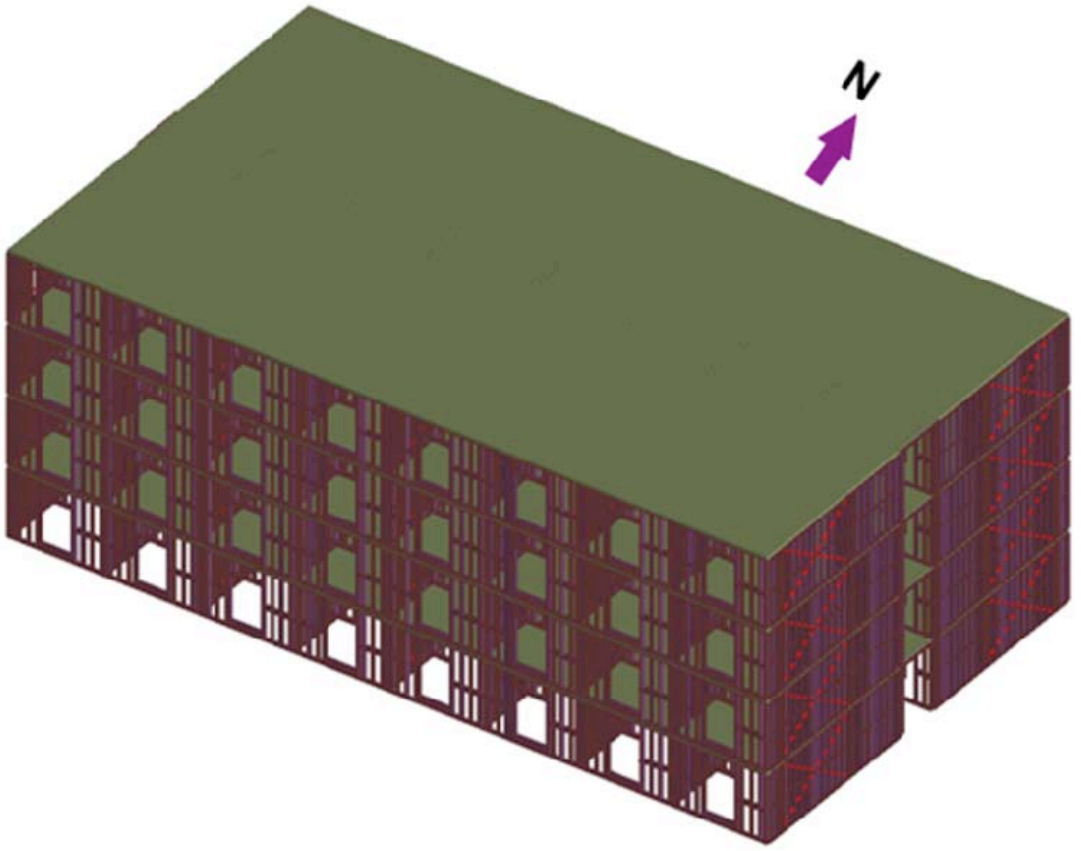

Figure 5. Three-dimensional model of the barracks building

Table 3. Lower bound material properties and strength reduction factors for components

Material	Min. Φ	Type	Young's Modulus (MPa)	Material Strength (MPa) or (kN)
Concrete (ACI 318-08)	0.90	Tension	26,000	$F_c = 27.6$ $F_t = 2.5$
	0.65	Compression and Bearing		
Reinforcement (ACI 318-08)	0.90	Wire mesh and Rebar	200,000	$F_y = 415$ $F_t = 620$
Cold-Formed Steel Framing (AISI S100-07)	0.90	Tension	200,000	$F_y = 228$ or 345 $F_t = 310$ or 450
	0.85	Compression		$F_y = 228$ or 345 $F_t = 310$ or 450
Steel Deck	0.85	Composite Concrete	200,000	$F_y = 275$ $F_t = 415$
Powder Actuated Fasteners	0.5	Deck/Track Connection	200,000	Tension = 4.3 kN Shear = 4.1 kN

Loading and wall removal. The load combination applied for the analysis was "1.2D + 0.5L", as recommend by UFC 4-023-03 for nonlinear dynamic analysis. The total load calculated for floor slabs was 6.3 kN/m^2 (132 psf) and for roof level was 3.7 kN/m^2 (78 psf). Two wall removal scenarios for the Alternate Path Method at the first story of the building were considered in this analysis. Scenario 1 was removal of an exterior wall section at the short side of the building equals to twice the first story height, or 6.4 m. Scenario 2 was removal of a corner wall section of the building equals to the first story height, or 3.2 m, in each direction. The two wall removal scenarios are illustrated in Figures 6 and 7.

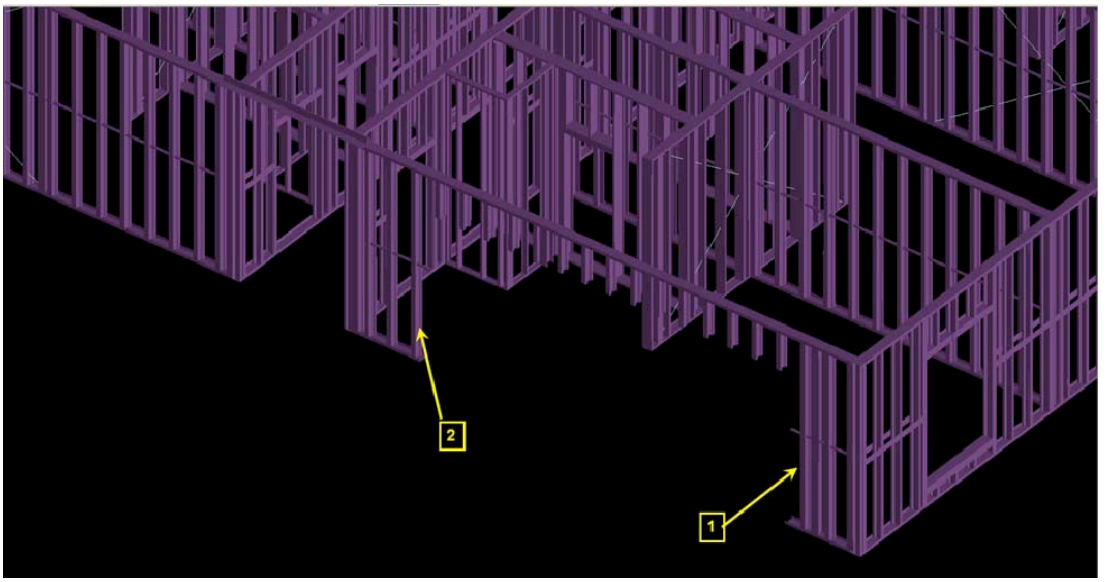

Figure 6. Removal of an exterior wall section of the building

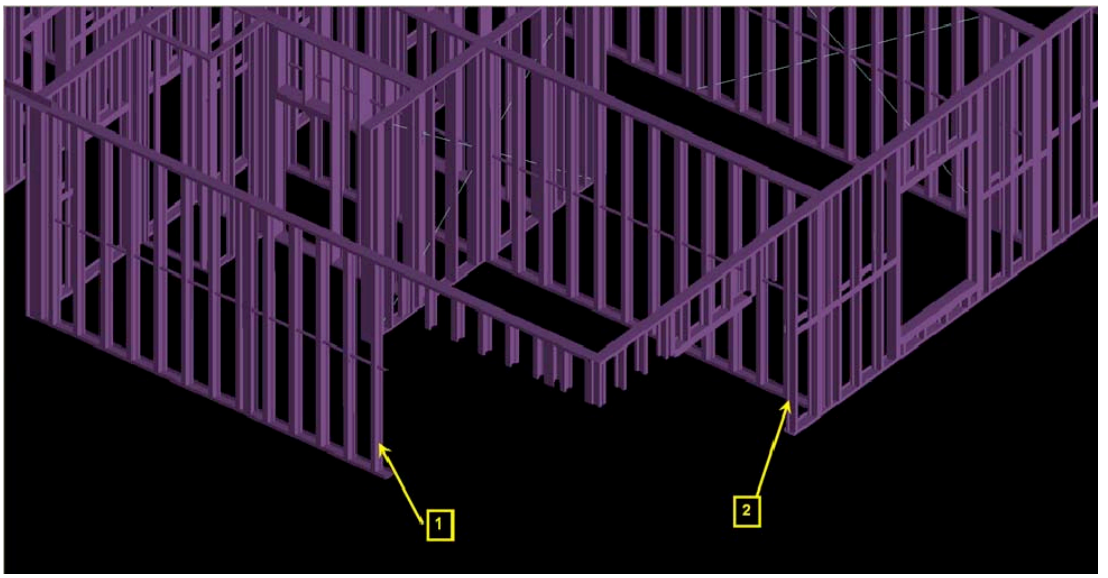

Figure 7. Removal of a corner wall section of the building

RESULTS AND DISCUSSION

There was no progressive collapse or component failure observed in the two wall removal scenarios analyzed in this study. Figure 8 show the deflection history for the floor slabs after wall removal in Scenario 1. Upon removal of the wall section in the model at this location, all the floor slabs started to deflect downward until reaching a maximum deflection of about 3 mm. The deflection stabilized for all floor slabs around an average value of 2.25 mm. Similar deflection behavior was observed for Scenario 2 wall removal with a maximum deflection of 3.5 mm. The limited deflection observed in both scenarios can be attributed to the ability of the composite deck floor slabs to distribute the load in both directions due to the existence of the relatively heavy top reinforcement mesh (16 mm bars every 150 mm). If the special upward blast pressure design requirement did not exist, the top reinforcement could be easily reduced while maintaining the integrity of the floor slabs for the progressive collapse design.

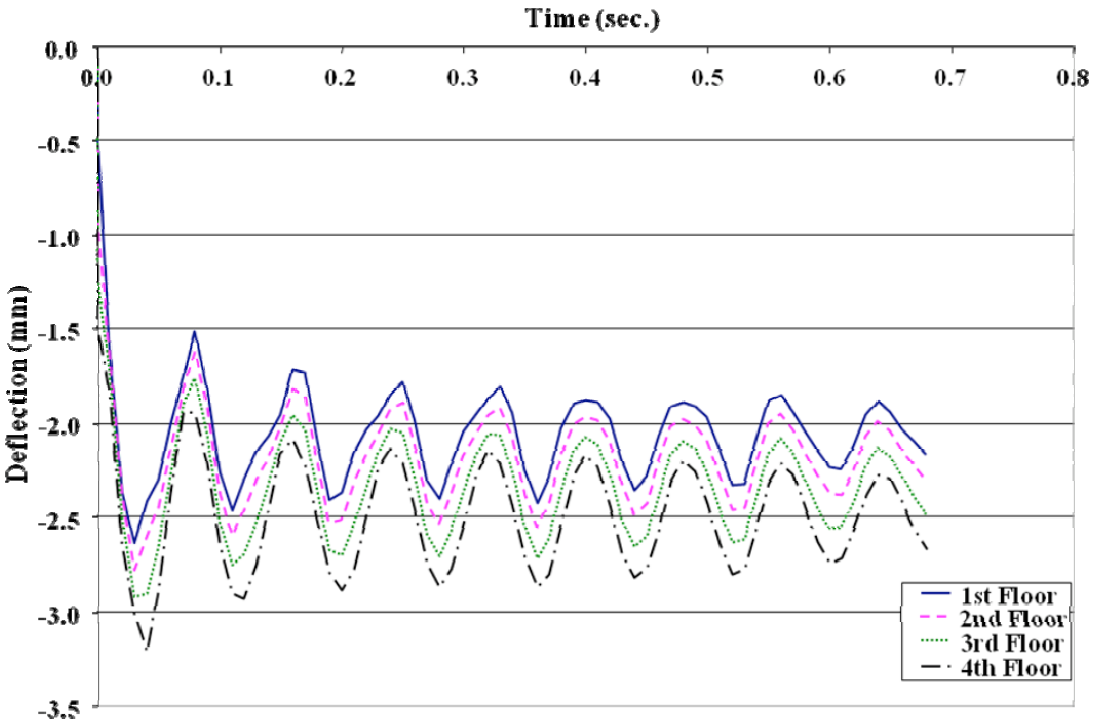

Figure 8. Deflection of floor slabs after wall removal in scenario 1

The axial forces in the adjacent studs to the removed wall sections were monitored before and after wall removal. Table 4 shows the cross sections of the numbered studs, the axial compression forces in the studs prior to wall removal, the sustained axial compression forces in the studs after wall removal, and the LRFD compression strengths of the studs calculated based on the AISI S100-07. It can be noticed that the loss of wall support of the first floor slab of the building caused the load acting on the wall to re-distribute through the slab to the nearest stud support.

The axial forces in the studs increased significantly, but still met the force-controlled acceptance criteria for compression members (ΦP_n) as shown in the table.

Table 4. Axial forces in adjacent studs for wall removals

Scenario and Stud Number	Stud Cross-section	Axial Force Before Wall Removal (kN)	Axial Force After Wall Removal (kN)	LRFD Compression, ΦP_n (kN)
Sc. 1- Stud 1	600SG300-54	8.5	33.7	88.8
Sc. 1- Stud 2	600SG300-54	5.4	24.5	88.8
Sc. 2- Stud 1	600SG300-54	16.5	49.8	88.8
Sc. 2- Stud 2	600SG162-43	5.9	20.2	27.8

The tension forces in the powder actuated fasteners connecting the composite deck floor slabs to the stud walls were also monitored. No failure was observed in these fasteners. The maximum tension force recorded after wall removal was about 0.3 kN, which is less than the acceptance criteria of the fasteners in tension. The tension strength of fasteners is controlled by the pullover strength of the steel sheet around the head of the fastener, ΦPnov, which is calculated as 0.5x4.3 = 2.15 kN.

CONCLUSION

The current study provides a good understanding of the composite deck floor-cold-formed steel stud bearing walls building system in resisting progressive collapse. The results of the study show that the Alternate Path Method coupled with the nonlinear dynamic analysis procedure can be efficiently used to examine the vulnerability of multi-story buildings to progressive collapse based on DoD criteria UFC-4-023-03. The Extreme Loading® for Structures (ELS) software, with its Applied Element Method, assisted in the application of the nonlinear dynamic analysis procedure. The study considered removal of an exterior wall section and a corner wall section at the first story of a 5-story barracks building. The results show the ability of the composite deck floor slabs to bridge over the removed wall sections at the first story of the building. The slabs were able to re-distribute the gravity loads to adjacent wall components, while some of the loads were picked up in tension by the studs above the slabs through the fasteners connecting the slabs to the walls. Although the axial compression forces in the studs adjacent to the removed wall sections increased significantly, the redundancy in the cold-formed steel wall system helped preventing overstressing these studs and exceeding the limit acceptance criteria for compression members.

ABSTRACT

The ability to perform accurate nonlinear simulations is a key component in the assessment of the behavior of seismic force resisting systems. A three-dimensional distributed plasticity formulation for composite beam-columns suitable for nonlinear static and dynamic analyses of composite seismic force resisting systems has been developed. New uniaxial constitutive relations are developed for the concrete and steel elements to simulate the cyclic response of steel reinforced concrete (SRC) members. The relations account for the salient features of each material, as well as the interaction between the two, including for concrete: varying levels of confinement within a section, cracking, crushing, and spalling, and for steel: cyclic plasticity and residual stresses. The accuracy of the formulation is validated against a comprehensive set of results from monotonically and cyclically loaded beam-column specimens. The formulation is suitable for use in parametric studies to quantify the seismic performance factors of special moment frames using steel reinforced concrete columns and structural steel beams following recommendations of the recently released FEMA P695 report.

INTRODUCTION

Steel-concrete composite columns have been shown to have high strength, stiffness, and ductility. However, there is a lack of quantitatively justified guidance for design of structures with these members. Notably, there is little data is available to justify the structural system response factors (e.g., R, C_d, and Ω_o) given in the specifications. In the current work, we strive to fill these gaps through developing system response factors; assessing beam-column strength; and establishing guidelines for the computation of equivalent composite beam-column rigidity to be used in seismic analysis and design of composite frames. Accurate nonlinear static and dynamic computational formulations are required to achieve these goals. Specifically, for developing rational system response factors, a model should directly simulate all predominate inelastic effects from the onset of yielding through strength and stiffness degradation causing collapse, while being sufficiently robust to track inelastic force redistribution without convergence problems up to the point of collapse (FEMA 2009).

Often, SRC members are modeled with constitutive relations taken directly from structural steel and reinforced concrete theory. This approach neglects the beneficial effects that the composite section provides, namely the added confinement of the concrete by the steel shape and the delay of local buckling in steel shape (although local buckling is often not modeled in structural steel). Several researchers have developed models specifically for use with SRC members (Mirza 1989, Sanz Picon 1992, Elnashai and Elghazouli 1993, El-Tawil and Deierlein 1999, Chen and Lin 2006) that do account for the beneficial effects provided by the composite section. A defining feature among all of these models is the varying levels of concrete confinement assumed throughout the cross-section. The differences between the models arise from the use of different mechanistic assumptions and empirical relations for the various aspects of section behavior (e.g., differences in determination of confining pressure and confinement model). The validity the models and thus their underlying assumptions are shown through comparisons between computation and experimental results. The model presented in this work utilizes a sophisticated finite element as well as comprehensive cyclic constitutive relations. Additionally, extensive validation is performed to ensure accuracy.

THREE-DIMENSIONAL MIXED BEAM FINITE ELEMENT

Frame analyses using distributed-plasticity beam-column elements strike a favorable balance of computational efficiency and accuracy. Additionally, mixed formulations (defined here as treating both element displacements and stress resultants as primary state variables) provide more accurate results with fewer elements as compared to either displacement- or force-based formulations (Alemdar and White 2005). Tort and Hajjar (2010) developed a three-dimensional mixed beam-column element for the analysis of composite frames that include rectangular concrete-filled steel tube members, validating against a large number of experimental tests of composite members and frames. This finite element was adapted and further validated against an additional set of experimental tests on circular concrete-filled steel tube members (Denavit 2009). The element stiffness and internal force are derived in the corotational frame using small strain assumptions. When accompanied with an exact transformation between the corotational and global frame the element is capable of capturing moderate deformation and rotation behavior. The use of independent force interpolation functions provides for a more accurate representation of the nonlinear curvature along the length of a yielded member. Implemented within the OpenSees framework (OpenSees 2011), the element can be used with the wide variety of other elements and solution algorithms available in the framework.

UNIAXIAL CYCLIC CONSTITUTIVE RELATIONS

The formulation relies on accurate constitutive relations to achieve accurate results. The constitutive relations are defined for the finite element at the section level using a fiber model. A fiber model allows the wide variety of behavior exhibited by SRC sections to be described by the integration of uniaxial constitutive relations located throughout the section.

It is desired that the fiber section be defined with minimal input from the analyst. The required input from the analyst includes: basic dimensions (depth of the composite

section, H and width of the composite section, B), dimensions of the steel section (depth, d, flange width, b_f, flange thickness, t_f, and web thickness, t_w), material properties of steel section (yield strength, F_{ys}, ultimate strength, F_{us}, and elastic modulus, E_s), concrete material properties (compressive strength, f'_c), dimensions and material properties of the longitudinal and transverse reinforcement, and fiber density. Using these parameters, the uniaxial constitutive relations and fiber section are defined. Five distinct regions are identified within the section (Figure 1). Separate constitutive relations are defined for each of these regions.

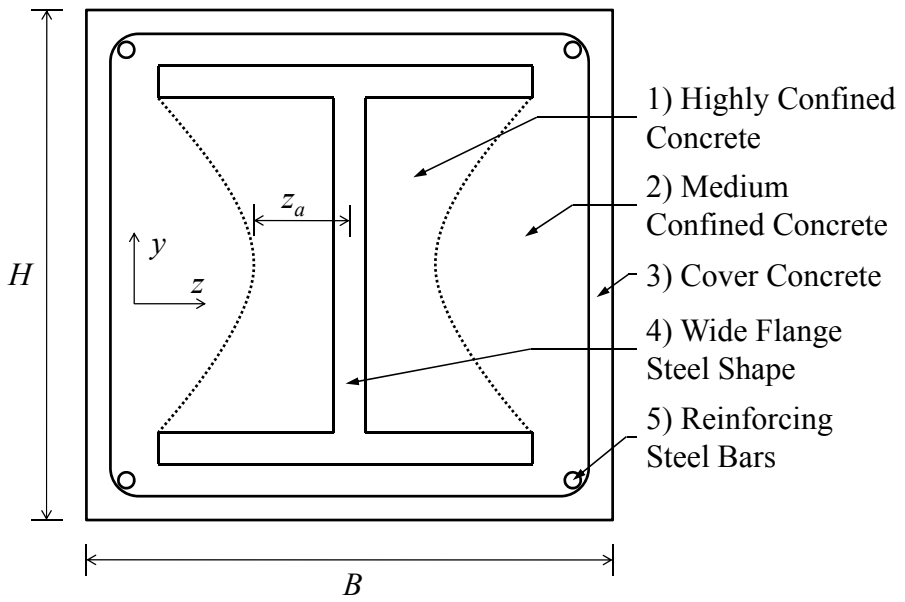

Figure 1. SRC Section

The constitutive relation used for the wide flange steel shape and the reinforcing steel bars is based on the bounding-surface plasticity model of Shen et al. (1995). Modifications were made to model the effects of residual stress within the steel section. The residual stress at a fiber is modeled explicitly as an initial elastic stress in the uniaxial constitutive relation. The Lehigh residual stress pattern (Galambos and Ketter 1958) is used to define the value of residual stress in the steel section with a maximum compressive residual stress of 30% of the yield strength occurring at the flange tips. The confined concrete is assumed to prevent flange and web local buckling and thus, these effects have not been included. In contrast, the model by Elnashai and Elghazouli (1993) is for partially encased composite columns and includes flange local buckling since the concrete only prevents inward buckling of the flange. For simplicity, the wide flange steel section is modeled with sharp corners (i.e., neglecting the fillets).

The constitutive relation for the concrete is based on the rule-based model of Chang and Mander (1994). The backbone stress-strain curve for the concrete is based on the model by Tsai, which is defined by the initial stiffness E_c, peak coordinate ($\varepsilon'_{cc}, f'_{cc}$), and r which acts as a shape factor. The confinement model developed by Mander et al. (1988) for a triaxial state of stress is utilized to determine the peak compressive

strength from the confining pressure in two orthogonal directions (Equations 1 through 5).

$$K = \frac{f'_{cc}}{f'_c} = 1 + A\bar{x}\left(0.1 + \frac{0.9}{1 + B\bar{x}}\right) \tag{1}$$

$$A = 6.8886 - \left(0.6069 + 17.275r\right)e^{-4.989r} \tag{2}$$

$$B = \frac{4.5}{\frac{5}{A}\left(0.9849 - 0.6306e^{-3.8939r}\right) - 0.1} - 5 \tag{3}$$

$$\bar{x} = \frac{f_{l1} + f_{l2}}{2f_c} \quad r = \frac{f_{l1}}{f_{l2}} \quad f_{l1} \le f_{l2} \tag{4}$$

$$\varepsilon'_{cc} = \varepsilon_c\left(1 + 5\left(K - 1\right)\right) \tag{5}$$

where, the strain at peak stress for unconfined concrete, ε_c, is given by Equation 6

$$\varepsilon_c = f_c'^{0.25} \Big/ 1150.0 \tag{6}$$

In order to accommodate low values of r necessary to model high confinement pressures, two values of r are used; one prior to the peak stress reached and one after the peak stress is reached. The value used prior to the peak is based on unconfined concrete, while the one after the peak accounts for the level of confinement and is based on a comparison of the models of Tsai and Popovics (Chang and Mander 1994). These and other parameters for the concrete model are as described in Table 1.

The outermost concrete region of concrete, also termed the cover concrete, is assumed to have zero confining pressure in either direction. Furthermore, it is allowed to spall. Spalling is modeled by modifying the nonlinear compressive backbone curve so that the stress and tangent reduce to and remain at zero after a certain strain. The concrete inside the lateral reinforcing bars is termed the medium confined concrete. In this region, confining pressure is provided by the lateral reinforcing bars. The magnitude of the confining pressure is computed in two orthogonal directions with Equations 7 and 8.

$$f_{ly,medium} = K_e \rho_y F_{yr} \tag{7}$$

$$f_{lz,medium} = K_e \rho_z F_{yr} \tag{8}$$

where, K_e is the ratio of effectively confined cross sectional area to area of the core as defined by Mander et al. (1988), ρ_y, ρ_z are the volumetric ratios of the transverse reinforce steel in either direction as defined by Mander et al. (1988), and F_{yr} is the yield strength of the longitudinal reinforcement.

The concrete between the flanges is termed highly confined concrete. In this region, confining pressure is provided by the lateral reinforcing bars and the steel shape. El-Tawil and Deierlein (1999) developed a mechanism model in which the confining pressure provided by the steel shape acts only in the y direction (Figure 1) and is

computed considering the plastic moment capacity of the flange (Equation 9). The distance between the vertex of the parabola defining the boundary between the highly and medium confined concrete (Figure 1) and the centerline of the steel section is described by Equation 10. This parabolic boundary is modeled explicitly with different constitutive relations on either side. In contrast, the parabolic boundary between the cover and medium confined concrete is implicitly modeled, utilizing the factor K_e to provide average behavior. The difference in handling these two boundaries exists to provide greater accuracy in modeling the boundary between the flanges while retaining the flexibility of different possible configurations of reinforcing steel. A comparison of the monotonic compressive response of the concrete in each of the three regions is shown in Figure 2.

$$f_{ly,high} = f_{ly,medium} + \frac{t_f^2 F_{ys}}{0.75\left(b_f - t_w\right)^2} \tag{9}$$

$$z_a = 0.50 b_f - 0.25\left(d - 2t_f\right) \geq 0.50 t_w \tag{10}$$

The discretization of the fiber section (i.e., computation of location and area of the fibers) is consistent with the geometric description of the cross section presented here. The sum of the area of the fibers for each material type and the total for the section are exact for the selected geometry and do not change with the fiber density. The moment of inertia of the section as computed from the fibers approaches the exact value with increasing fiber density. The discretization is implemented for general three-dimensional analyses as well as for two-dimensional analyses where bending is along either the strong or weak axis. The fiber discretization for two-dimensional analyses takes the form of strips allowing a significant savings in the number of fibers used. The fiber density is defined as the nominal number of fibers along the strong and weak axis with the number of fibers for individual section components (e.g., steel flanges or concrete cover) determined in proportion to their size relative to the entire section. A discretization of 20×20 (or simply 20 for two dimensional analyses) is found to be both accurate and efficient and is used for the analyses presented in this paper.

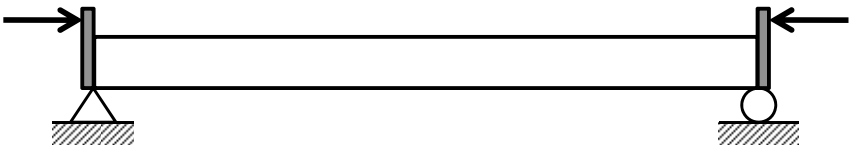
VALIDATION OF THE FINITE ELEMENT METHOD

To validate the accuracy the model, a large number of comparative analyses were performed against experimental results. A selection of the validation results for monotonic proportionally loaded beam-columns and cyclic non-proportionally loaded beam-columns is presented here.

Proportionally Loaded Beam-Columns

The most common experimental configuration for testing SRC beam-columns is monotonic proportional loading (Figure 3). Tests of this type have been performed by Virdi and Dowling (1973), Roderick and Loke (1975), Morino et al. (1984) and Wang (1999), and others. Details of four specimens from these experimental studies are presented in Table 2. The results of these experiments are compared to results from analyses conducted using the model presented in this work (Figure 4). When the eccentric of the applied load coincided with one of the principal axes of the column (i.e., strong or weak axis bending), one mid-height lateral deflection is reported. When the applied load induces biaxial bending, two mid-height lateral deflections are reported, one for each of the columns principal axes.



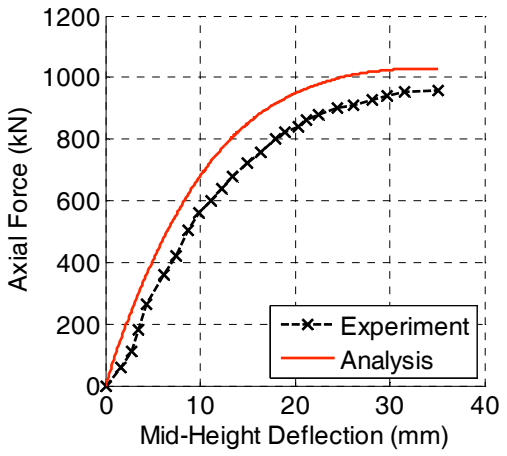


Figure 3. Proportionally Loaded Beam-Column Test Schematic

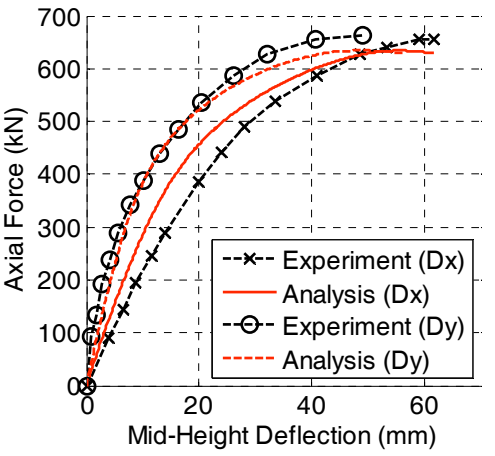
The results (Figure 4) show a good correlation between experimental and computational results. This is seen in the initial stiffness, peak load, deflection at peak



load, post-peak degradation, and ratio of strong and weak axis deflections. The two specimens by Morino et al. (1984) (Figure 4c,d) have a similar cross section and loading angle, but specimen D8-45 has approximately twice the length and eccentricity of B4-45. The higher first- and second-order moments resulted in a significantly lower peak axial load for D8-45. The model predicted the peak axial load accurately for both specimens indicating that model captures well both material and geometric nonlinearity.

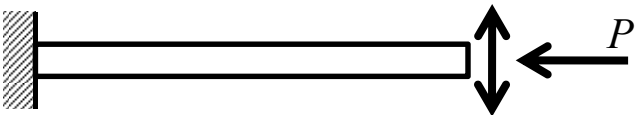
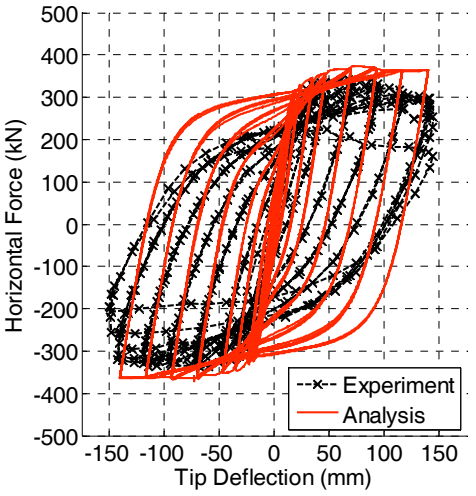
Figure 4. Proportionally Loaded Beam-Column Validation Results.

Cyclically Loaded Beam-Columns

A set of carefully controlled and well documented non-proportionally loaded cyclic SRC beam-columns tests was performed by Ricles and Paboojian (1993, 1994). The specimens were subjected to a constant axial load and cyclically increasing horizontal displacements (Figure 5) which induced strong axis bending in the column.





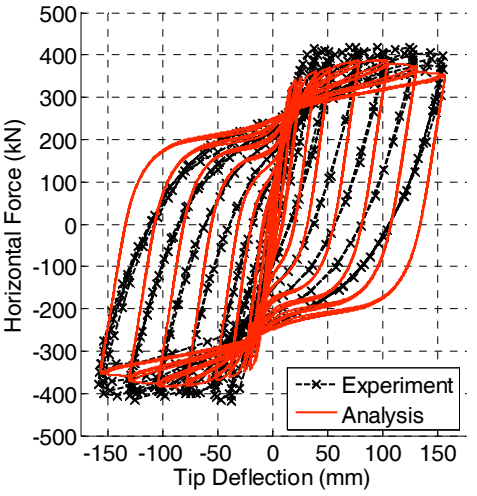


Figure 5. Cyclically Loaded Beam-Column Test Schematic

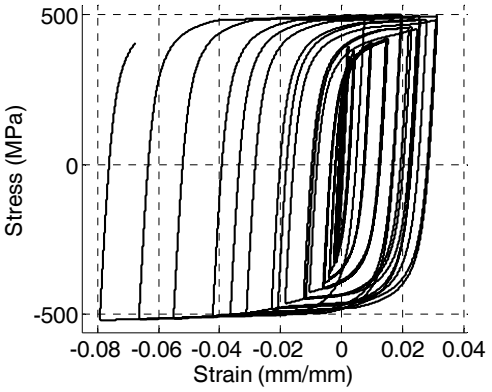

Details of two of specimens from this experimental study are presented in Table 3. The load-deformation results of these experiments are compared to those from analyses conducted using the model presented in this work (Figure 6a,b). Additionally, the stress-strain response from the extreme fiber of the steel section (Figure 6c) and the extreme fiber of the highly confined concrete (Figure 6d) as predicted from the analysis are shown.

(b) Specimen 8

(c) Specimen 6, Steel Section Fiber Stress-Strain Relationship

(d) Specimen 6, Highly Confined Concrete Fiber Stress-Strain Relationship

Figure 6. Cyclically Loaded Beam-Column Validation Results.

Table 3. Cyclically Loaded Beam-Column Specimen Data

Specimen	H (mm)	B (mm)	f'_c (MPa)	Steel Section	F_y (MPa)	d_b (mm)	F_{yr} (MPa)	L (mm)	P (kN)
6	406	406	35.8	W8x40	372	28.6	448	1,930	1,490
8	406	406	62.9	W8x40	372	22.2	434	1,930	1,490

The results (Figure 6) show a good correlation between experimental and computational results. The initial stiffness and peak strength are predicted well by the model. The unloading stiffness and yield upon unloading are less accurate, leading to the model predicting fuller hysteresis loops than observed in the experiments. Similar discrepancies between experimental and computational results have been noted in other SRC models (e.g., Elnashai and Elghazouli 1993).

CONCLUSION

A finite element formulation for analysis of SRC members and frames has been presented. The formulation included a mixed based distributed-plasticity beam element and uniaxial constitutive relations. The cyclic uniaxial constitutive relations account for the salient features of SRC behavior. The concrete constitutive relation was based on a rule based model from the literature. Three regions of concrete were defined with separate material properties based on computed levels of confinement pressure. The steel constitutive relation was based on a bounding surface plasticity model from the literature with modifications so that residual stresses could be modeled explicitly within the steel section. A validation was performed showing good correspondence between experimental and computational results for a selection of both monotonic and cyclic tests. The finite element formulation provides an accurate analysis tool for use with composite frames and is suitable for use in parametric studies such as those necessary to develop system behavior factors.

ABSTRACT

Structure-Soil-Structure Interaction (SSSI) is defined as the effect that a neighboring structure has on the dynamic response of a given structure on a common soil site. The significance of SSSI is sensitive to the characteristics of the soil, structures, and ground motion, as well as the spatial distance between structures.

The Hanford Site, a Department of Energy Facility, contains a complex of structures that exhibit significant SSSI behavior. The SSSI effect is measured in this paper by considering two models, one including the entire complex of structures and one including only the structure that exhibits the most critical SSSI response. The amplification is quanitifed through a comparison of transfer functions and seismic member demand accelerations.

A realistic study of the sensitivity of soil parameters is accomplished by replacing the Hanford Site soil parameters with those of the Savannah River Site (SRS). SRS is also a Department of Energy Facility. As this Site is located in the state of South Carolina, the soil stiffness is less rigid and provides for a practical comparison. The sensitivity of the soil stiffness is quantified by taking a ratio of the response of the combined model to the response of the individual model for both soil types.

INTRODUCTION

The Hanford Waste Treatment Plant (WTP) is a Department of Energy Facility that will vitrify radioactive and chemical tank waste stored at the Hanford Site. The Pretreatment Facility Complex (PTC) houses the first step in the vitrification process. The structures within the PTC are classified as Seismic Category I and must meet the criteria of U.S. Department of Energy Standard 1020 (U.S. Department of Energy, 2002).

The PTC (see Figure 1) is comprised of two small surface-founded structures, the Pretreatment Facility Annex (PTFA) and the Pretreatment Facility Control Building (PTCB), adjacent to one large partially embedded structure, the Pretreatment Facility (PTF). The PTFA and PTCB are separated from the PTF with a seismic gap of less than one foot.

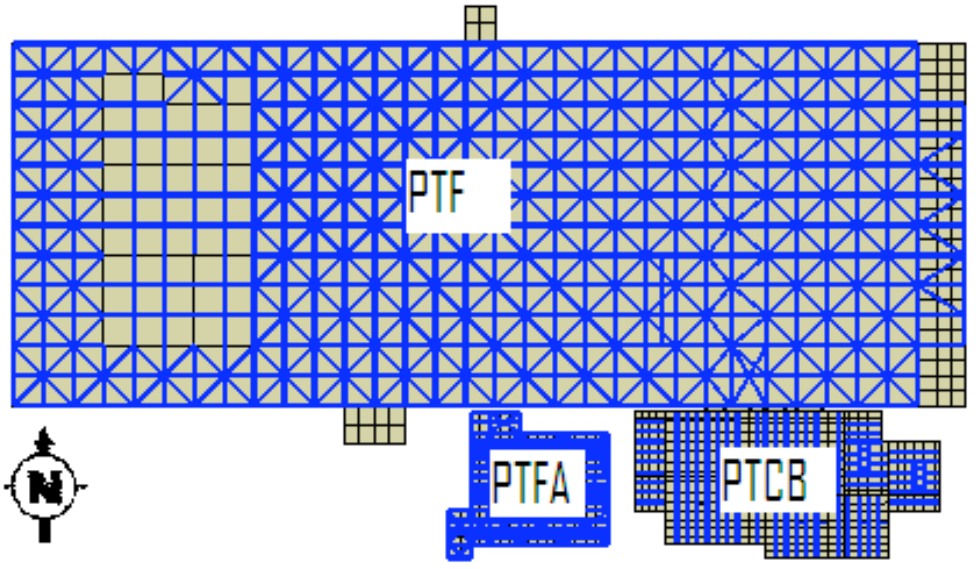

Figure 1. Pretreatment Facility Complex.

The PTF lateral load resisting system consists of concrete shear walls that extend to Elevation (EL) 98'-0" and relatively rigid concrete slab diaphragms. Above EL 98'-0", the roof is designed as a steel framing system that is supported by the concrete shear walls below EL 98'-0" and a steel framing system that surrounds the perimeter of the structure. The PTF exhibits a complex response particularly due to the interaction between the steel and concrete lateral resisting systems.

Lateral loads applied to the PTFA are resisted by a steel framing system, distributed by composite slab diaphragms and a flexible roof diaphragm.

Lateral loads applied to the PTCB are resisted by a concrete shear wall system as distributed by composite floor slab and composite roof slab diaphragms.

The PTCB exhibits a more rigid response than that of the PTFA. The Soil-Structure Interaction (SSI) and Structure-to-Soil-Structure Interaction (SSSI) response of the PTCB is shifted to a more flexible frequency range, which corresponds to a more critical portion of the input response spectra. The PTFA response is more flexible, so the frequency shift when SSI and SSSI are considered is less significant. Therefore, since the PTCB exhibits the most significant SSSI effect, this structure is the focus of the sensitivity studies discussed herein.

SSI RESPONSE OF THE PTCB

Structural Characteristics

The PTCB is a concrete shear wall structure with 1'-6" thick shear walls extending floor to roof and a 4'-0" thick mat. Contributing shear walls are shown highlighted in Figure 2.

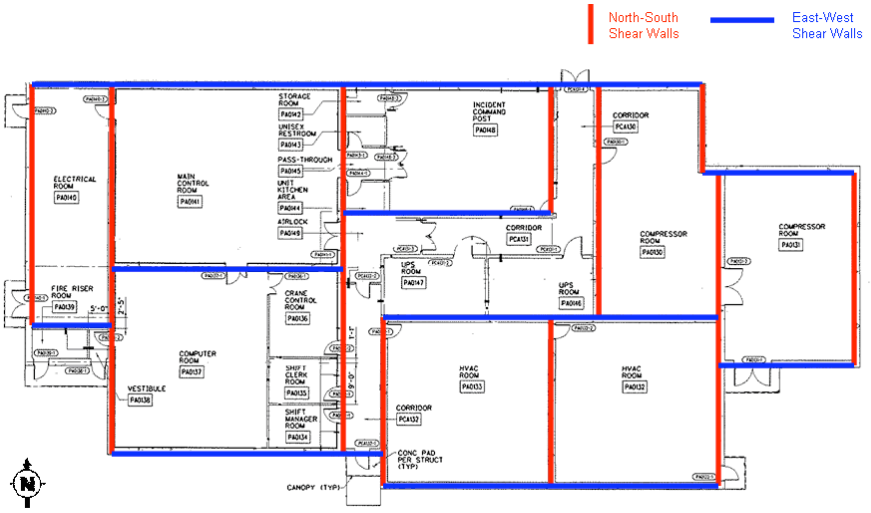

Figure 2. PTCB Shear Walls.

The roof and floors are designed as composite slabs. There are two mezzanine slabs, at EL 15'-0" that cover a small portion of the building footprint. The roof slab elevations range from EL 22'-6" to EL 37'-6".

Hard Rock Analysis

The Hard Rock (HR) analyses and subsequent SSI and SSSI analyses are completed using SASSI2000 (Lysmer et al. 1972, and Lysmer et al. 1999) which provides a linear solution to the SSI problem in the frequency domain.

First, the HR soil case is created with a shear wave velocity of 14,000 fps, to emulate the fixed base condition. Transfer functions are computed at a node on each floor elevation at the same horizontal coordinates. Transfer functions are defined as the ratio of the Fourier amplitude of the frequency dependent seismic response of a given node to that of a control node at the free field where the input seismic motion is applied. For the HR analysis case, the transfer functions provide a visual representation of the structural response.

The HR transfer functions for the EW (x) direction and the NS (y) direction are shown in Figure 3 and Figure 4, respectively.

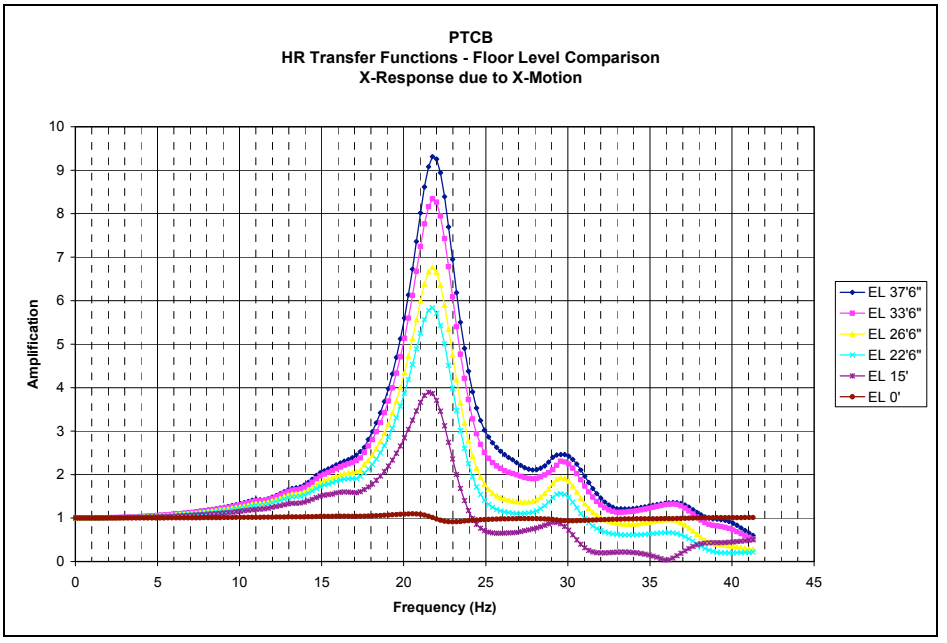

Figure 3. PTCB HR EW Transfer Functions.

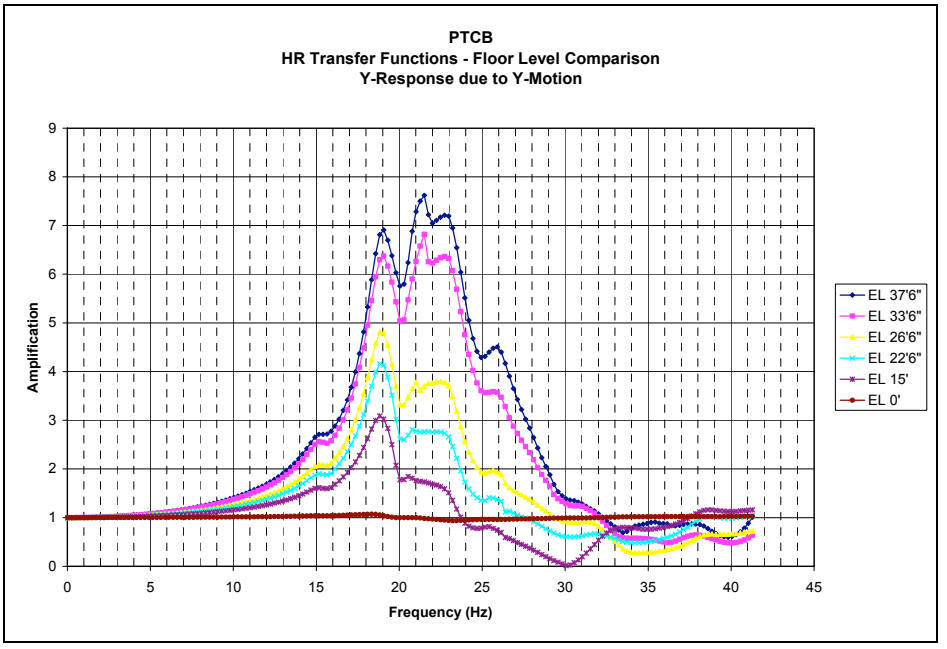

Figure 4. PTCB HR NS Transfer Functions.

The HR analyses indicate that the EW dominant structural mode occurs at approximately 22 Hz and the NS dominant structural modes occur at 19 Hz and 22 Hz. There are more than one dominant modes for the NS direction due to the layout of the NS running shear walls. As shown in Figure 2, the NS shear walls are less regular in placement and length than the EW shear walls.

SSI Analysis

SSI analysis is completed for three strain compatible soil profiles, Upper Bound (UB), Mean (M), and Lower Bound (LB) that are generated through free-field deconvolution analysis. Transfer functions are computed for each soil case and compared for a node at the highest roof elevation due to excitation in the EW and NS directions (see Figure 5 and Figure 6, respectively).

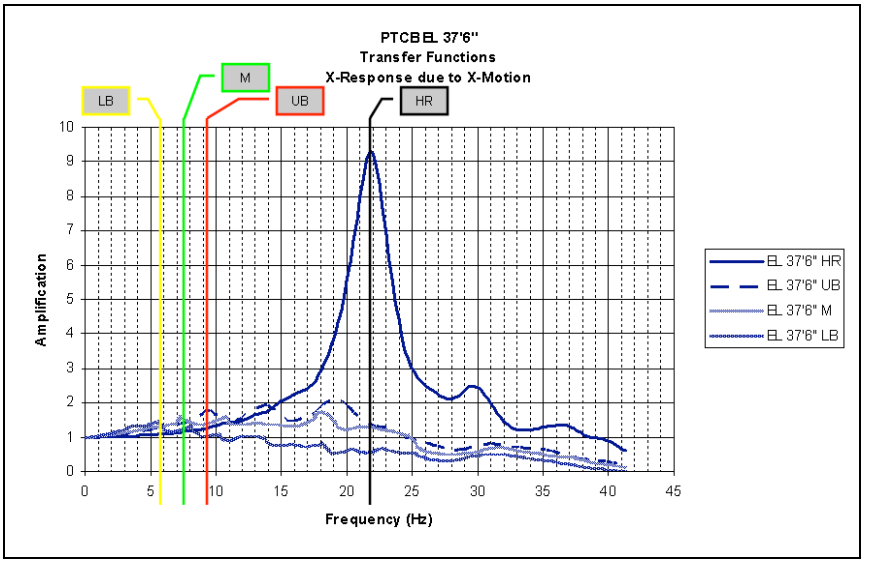

Figure 5. PTCB SSI EW Transfer Functions.

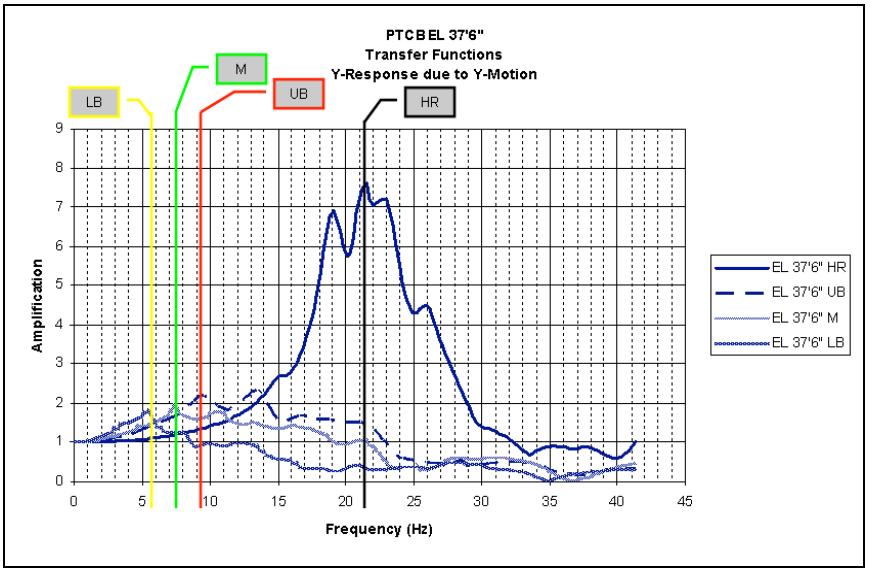

Figure 6. PTCB SSI NS Transfer Functions.

Incorporation of SSI shifts the response of the PTCB into a lower frequency range. For clarity, only the M soil case is shown in the subsequent comparisons.

SSSI RESPONSE OF THE PTCB

Two SSI models are considered for the SSSI analysis. The "combined model" contains the three structures that make up the PTC, with the separation distance of 3'-0" considered. The "individual model" contains only the PTCB without consideration of the adjacent structures in the PTC. Transfer functions are shown for a common node at the center of the PTCB mat in both the individual and combined models (see Figures 7, 8, and 9).

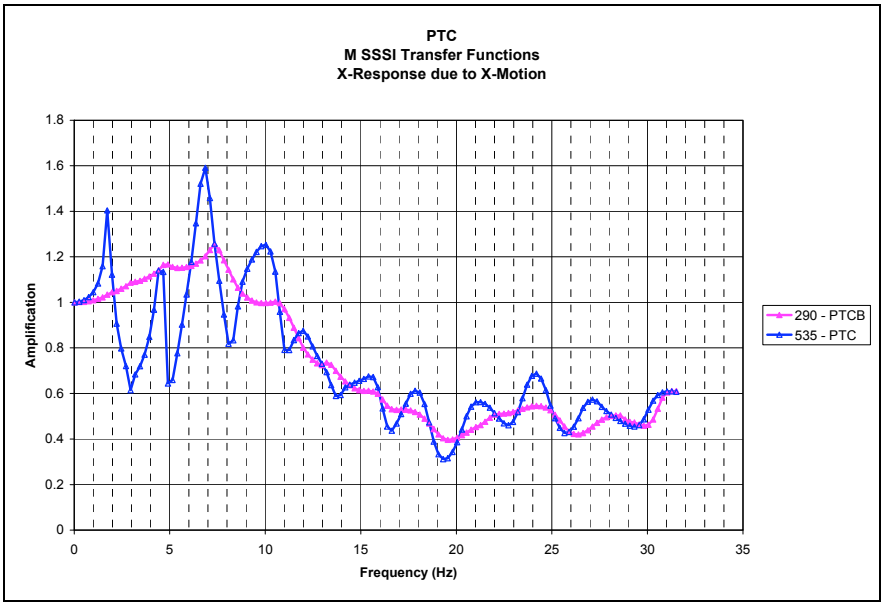

Figure 7. PTCB SSSI EW Transfer Functions.

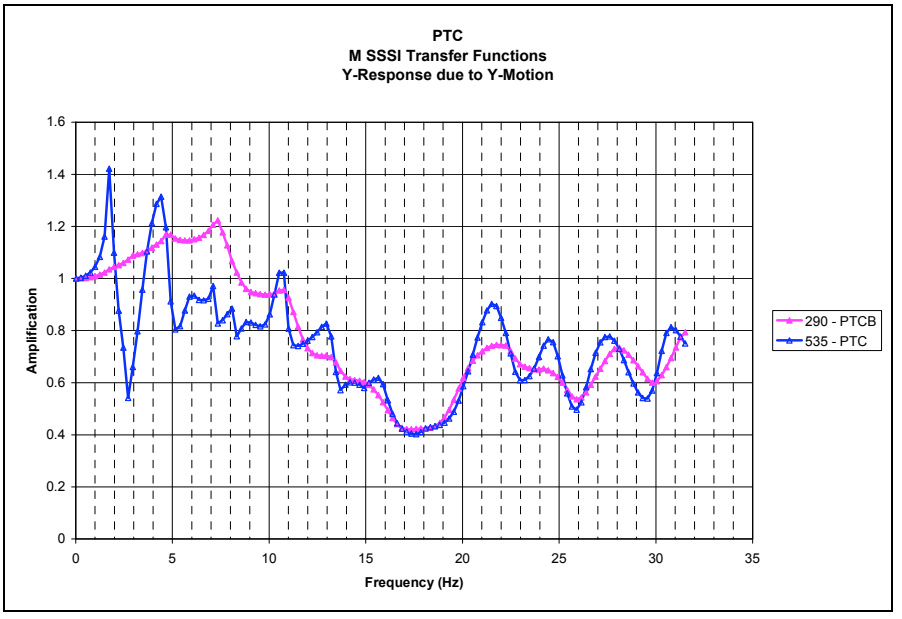

Figure 8. PTCB SSSI NS Transfer Functions.

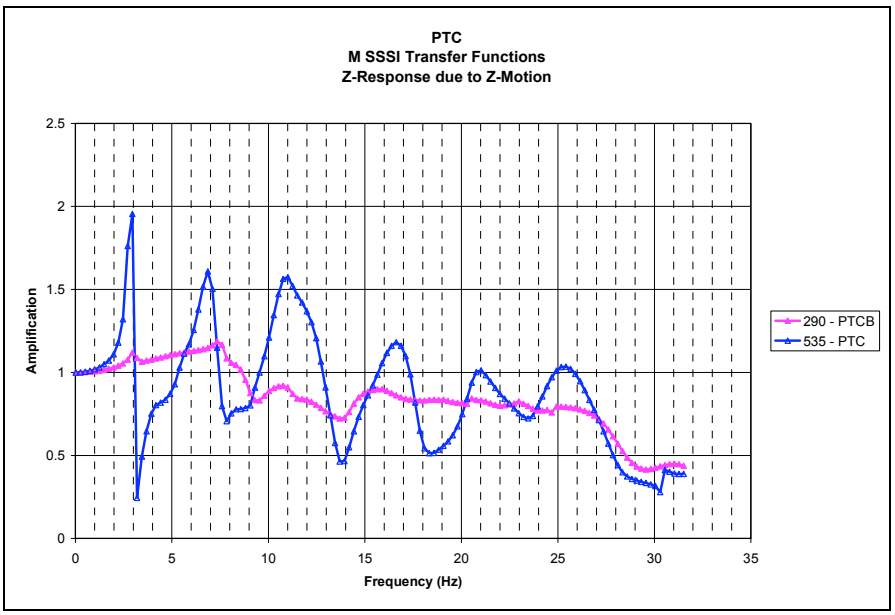

Figure 9. PTCB SSSI Vertical Transfer Functions.

The response of the PTCB in the combined model appears to oscillate about the response of the PTCB in the individual model.

Transfer functions are printed from the combined model for a node at the center of the PTCB mat (Node 535) and a node at the center of the PTF mat (Node 4547) (see Figures 10, 11, and 12).

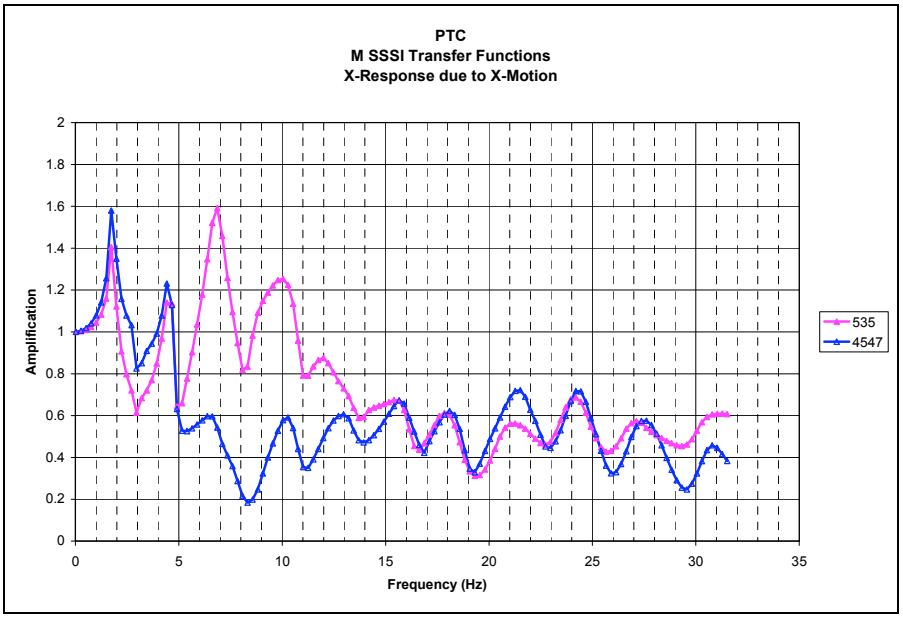

Figure 10. PTC SSSI EW Transfer Functions.

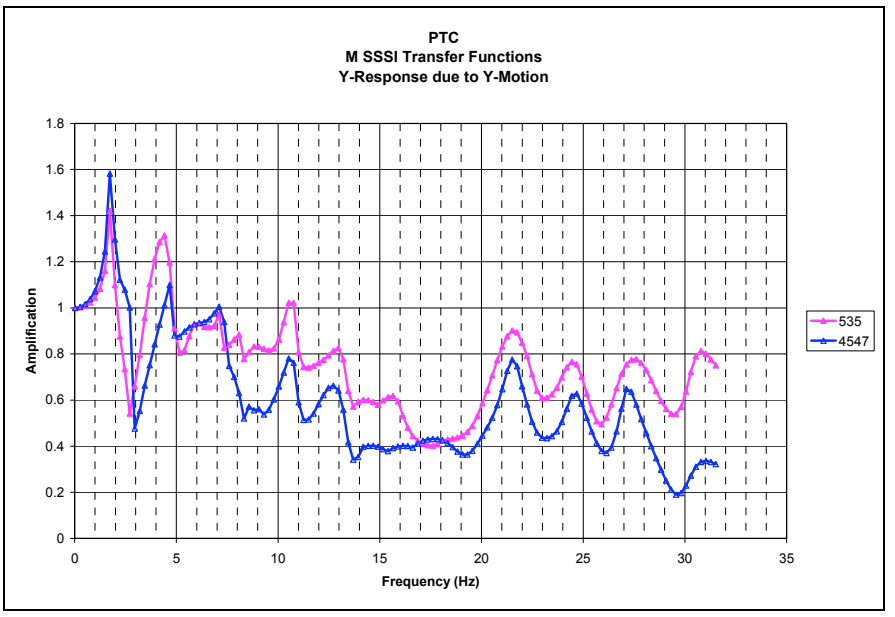

Figure 11. PTC SSSI NS Transfer Functions.

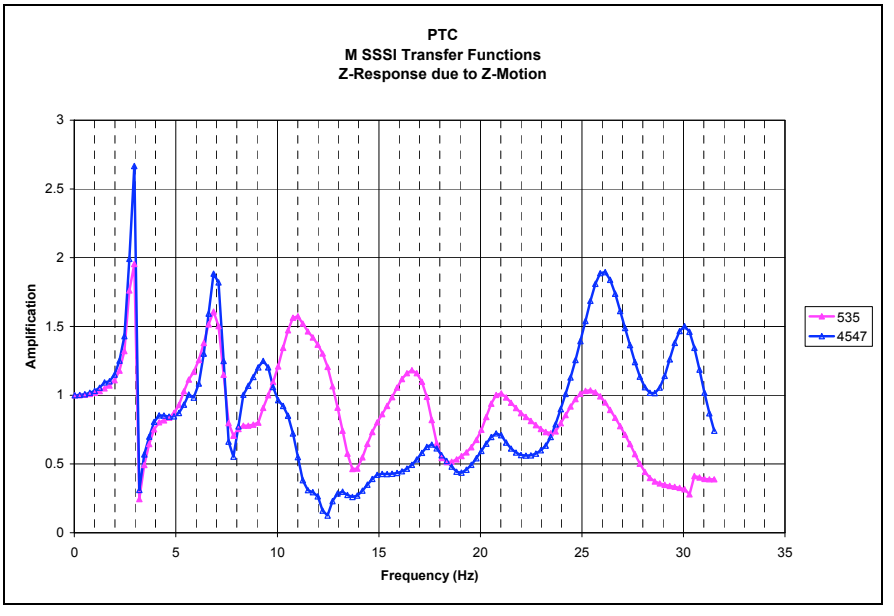

Figure 12. PTC SSSI Vertical Transfer Functions.

The response of the PTCB in the combined model follows the pattern of the PTF response while oscillating about the individual PTCB response. The PTF response exhibits higher energy than that of the PTCB.

Maximum Nodal Accelerations

The site specific input spectra at the free field for the PTC are shown in Figure 13. H1, H2, and VT, correspond to the X, Y, and Z directions, respectively. The input motion is applied to the SSI models.

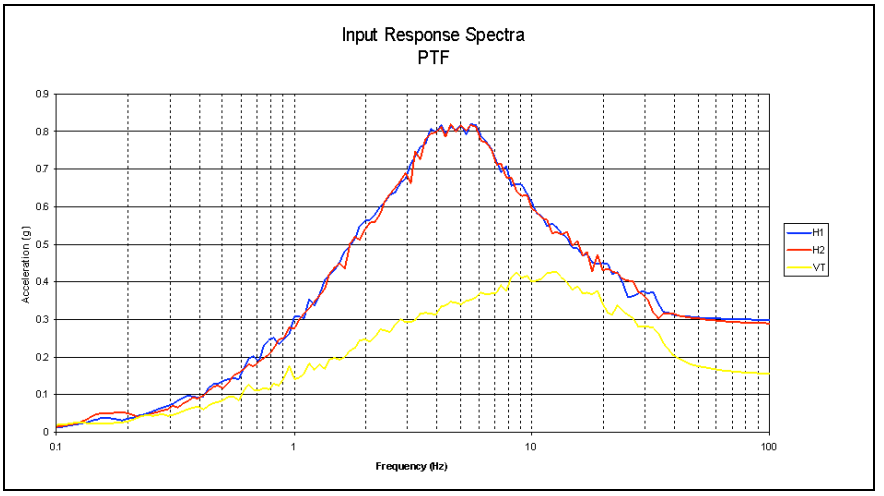

Figure 13. PTC Site Specific Free Field Input Spectra

Maximum accelerations at each node are extracted, in each response direction, due to seismic input in each of the three directions, for each of the three soil cases and then combined for each response direction and enveloped for each soil case. The result is one maximum acceleration, at each node of each model, for each direction.

The SSSI effect with consideration of seismic motion is quantified by computing a weighted average ratio. First, the ratios of the maximum nodal accelerations from the combined model to the individual model are computed for each node. Second, the ratios are weighted by the characteristic nodal mass. Then, the weighted ratios are summed and divided by the total nodal mass of the PTCB.

The weighted average ratios for each direction are shown in Table 1.

Table 1. SSSI Ratios.

X	Y	Z
1.02	1.15	1.33

On average, the incorporation of SSSI effects amplifies the maximum nodal accelerations of the PTCB. When motion is in-plane with the interface, the SSSI amplification is 2%. When motion is out-of-plane with the interface, the SSSI amplification is 15%. When motion is vertical, the SSSI amplification is 33%.

SENSITIVITY OF SOIL PARAMETERS ON SSSI RESPONSE

The sensitivity of soil parameters is studied by replacing the Hanford Site soil parameters (referred to as WTP) with those of Savannah River Site (SRS). The soil stiffness of SRS is less rigid. The Mean shear wave velocities are compared in Figure 14.

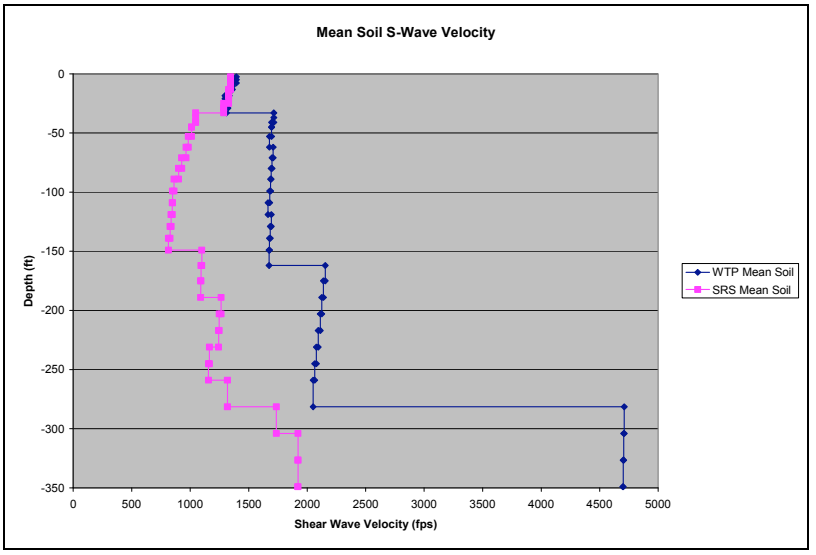

Figure 14. Comparison of Shear Wave Velocities.

Transfer functions are computed for the center node of the PTCB mat in both the combined and individual models. The results are compared for the WTP and SRS soil profiles (see Figures 15, 16, and 17).

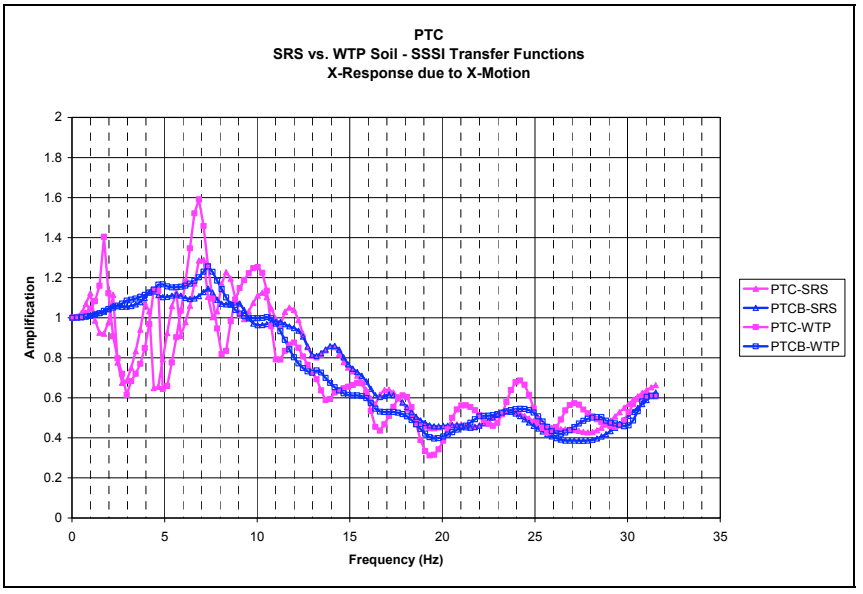

Figure 15. EW Comparison of SSSI Effect WTP vs. SRS Soil.

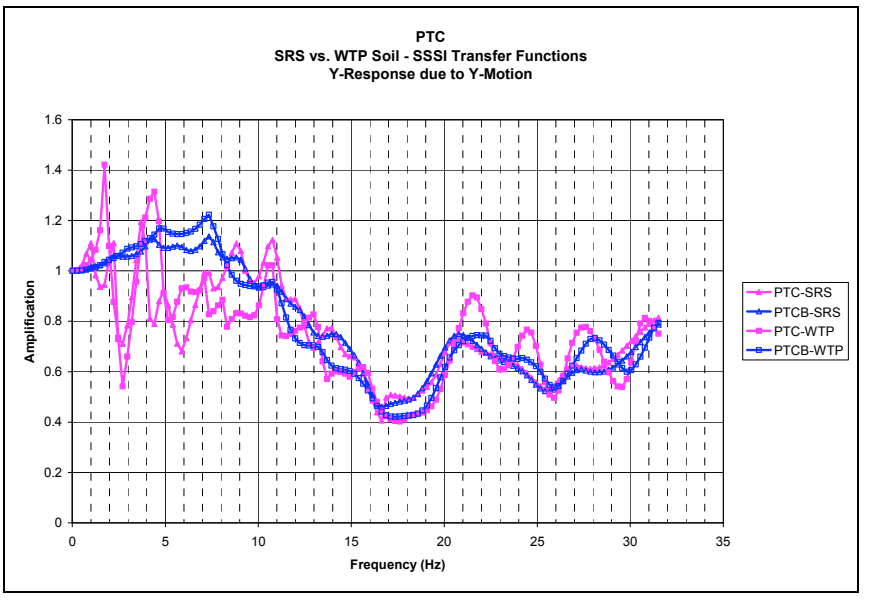

Figure 16. NS Comparison of SSSI Effect WTP vs. SRS Soil.

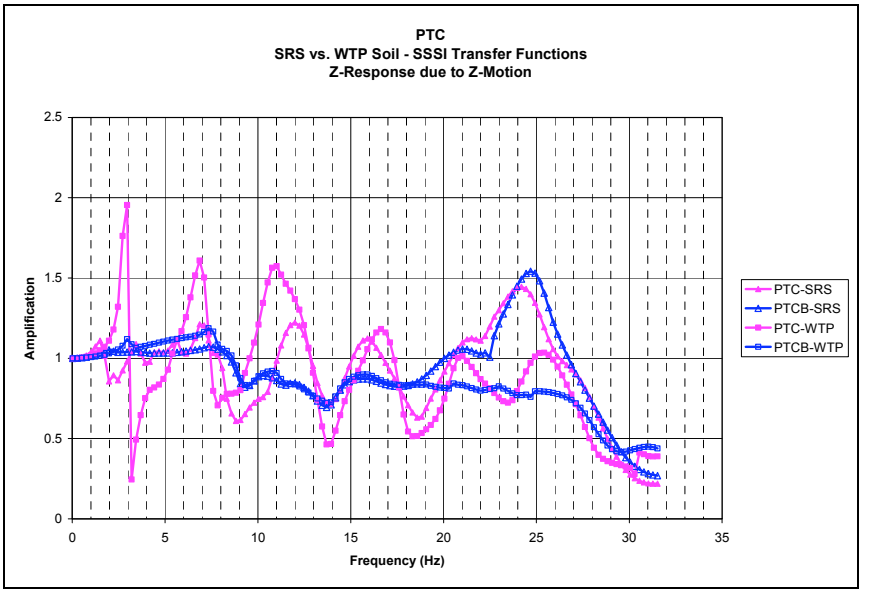

Figure 17. Vertical Comparison of SSSI Effect WTP vs. SRS Soil.

The low frequency energy that is apparent in the response of the model on Hanford Site soil is not evident in the response of the model on Savannah River Site soil. The overall pattern of the transfer functions for the WTP and SRS soil profiles are similar; however, the SRS soil profile provides less SSSI amplification.

The ratio of the combined model response to the individual model response is computed for each frequency and then averaged. The resulting ratios are shown in Table 2.

Table 2. SSSI Ratios by Soil Type.

	SRS Soil	WTP Soil
EW	1.01	1.03
NS	0.97	1.05
Vertical	0.99	1.07

The ratios show that SSSI amplifications are of lesser magnitude when considering a softer soil profile.

CONCLUSION

The Pretreatment Facility Control Building exhibits a significant amplification of seismic demand loads due to the SSSI effect of a larger adjacent structure. Weighted average ratios of maximum nodal accelerations indicate that the SSSI amplifications are most significant in the vertical direction which results in a 33% increase in seismic demand. The amplification in the response perpendicular to the building interface is also significant, resulting in a 15% increase in seismic demand. The amplification of the response parallel to the building interface is less significant, representing only a 2% increase in demand loads.

The Savannah River Site soil profile applied to the Pretreatment Facility Complex structure lowered the SSSI amplification that was apparent with the Hanford Site soil profile. The softer soil generates a smaller SSSI effect than that of the stiffer soil.

ABSTRACT

For a secondary mass damper such as tuned liquid damper (TLD) or tuned liquid column damper (TLCD), whose moving mass is liquid, it is impossible to pre-fabricate the damper in a factory for the identification of dynamic properties. Also, it is not easy to pre-fabricate a concrete tuned mass damper (TMD) in a factory whose moving mass is made of concrete. In this paper, an identification method of dynamic properties of secondary mass dampers based on the forced vibration test is presented. Decoupled equations of motion are derived from a coupled equation of motion of building and damper. The decoupled equations of motion are then applied to the system identification using the response of the damper as an input and the response of the building as an output. The proposed method is applied to numerical examples and an actual TMD and TLCD installed in buildings.

INTRODUCTION

As the design and construction of skyscrapers has increased growing in recent years, the interest in the countermeasures to reduce wind-induced motion has gradually increased. In particular, most tall buildings in construction recently have been residential buildings, and thereby the issue of residents' serviceability against wind-induced vibration has received more attention. To solve this matter, it has become a more common practice to install supplementary damping devices for dissipating the energy caused by the external load rather than to increase the lateral stiffness (Soong and Dargush, 1997).

The most typical supplementary damping devices are inter-story installation type dampers and secondary mass dampers (Kim and Adeli, 2005a, Irwin, 2009). The inter-story installation type dampers provide energy dissipation utilizing hysteretic force-displacement behavior induced by inter-story drift. The secondary mass dampers such as a tuned mass damper (TMD), a tuned liquid damper (TLD), and a

tuned liquid column damper (TLCD) are devices relying on the motion of a secondary mass, which is about 0.3 to 1.0% of the entire mass of the building, to counteract the forces acting on a building. Because the secondary mass dampers are often installed on the top floor, they provide fewer architectural constraints than inter-story installation type dampers.

When designing a secondary mass damper, the ratio of moving mass to the first modal mass, or called generalized mass, of a building is determined depending on the required reduction ratio of wind induced vibration. Then, the optimal tuning frequency and damping ratio of the secondary mass damper are calculated based on the determined mass ratio. In the case of a TMD design, the stiffness and number of springs are decided from the optimal frequency ratio, and the damping coefficient and number of oil dampers are decided from the optimal damping ratio (Rana and Soong, 1998, Ghorbani-Tanha et al., 2008).

Before installing a TMD at a site, it requires a free vibration test or human-powered vibration test to be conducted in the factory using a pre-assembled TMD in order to obtain TMD's natural frequency, damping ratio, friction coefficient, restoration force, and other dynamic properties for comparison with designed values. This is to consider discrepancy and tolerance during the fabrication and installation. Especially, the accurate identification of the natural frequency is very important because the control performance of the secondary mass dampers depends significantly on how dampers are properly tuned to the natural frequency of a building. In general, the natural frequency of the pre-assembled TMD is calculated from a spectrum analysis of the response obtained from the free vibration test or human-powered vibration test in the factory, and the damping ratio is calculated using a logarithmic decrement method or half-power method.

In the case of TLD or TLCD, however, it is impossible to perform a factory test using an actual size damper. In addition, in the case of a concrete TMD whose moving mass is composed of concrete rather than steel, the accurate identification of the dynamic properties of the pre-assembled TMD is very difficult because concrete casting at the factory is not feasible.

When the factory test is not viable, the only way to identify the natural frequency and damping ratio of a secondary mass damper is through a force vibration test after installing the damper at the site. In the case of the field test, however, it is very difficult to estimate the dynamic properties accurately using a simple spectrum analysis method and logarithmic decrement method because the responses of a building and a secondary mass damper are coupled in connection to each other. This is because the peak of each response spectrum of damper and building are split into two peaks. That is, the interaction of the building and damper causes the building mode to split into two modes and vice versa.

In this paper, an identification method of the dynamic properties of secondary mass dampers based on the force vibration test is presented. Decoupled equations of motion are derived from a coupled equation of motion of building and damper. The decoupled equations of motion are then applied to the system identification of secondary mass dampers using the response of dampers as an input and the response of the building as an output. For the verification of the proposed method, the dynamic properties of a TMD and a TLCD installed on a single-degree-of-freedom

(SDOF) system are identified through numerical examples. Further, the method is applied to the identification of an actual TMD and TLCD installed in buildings using free vibration responses.

EQUATIONS OF MOTION

TMD. A TMD is a device that increases the damping capacity of a building by installing a secondary mass body with springs and dashpots attached to the building (Figure 1). Since the TMD is installed so that the frequency of this secondary mass body is tuned or close to the natural frequency of the building, the behavior of TMD becomes out of phase to the behavior of the building when the excitation frequency matches the natural frequency of the building resulting in the energy dissipation by the inertial force of the TMD.

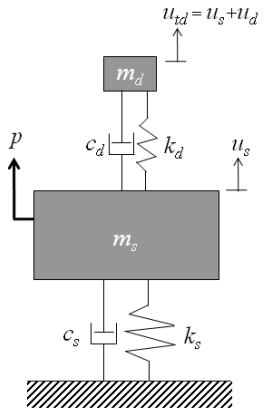

Figure 1. An SOF system with a TMD

The equation of motion of an SDOF system with a TMD can be easily constructed treating the TMD as an additional DOF added to the SODF system. Then, the consequent coupled equation of motion is given as (Den Hartog, 1956, Chopra, 1995)

$$\begin{bmatrix} m_s & 0 \\ 0 & m_d \end{bmatrix}\begin{bmatrix} \ddot{u}_d \\ \ddot{u}_{td} \end{bmatrix}+\begin{bmatrix} c_s+c_d & -c_d \\ -c_d & c_d \end{bmatrix}\begin{bmatrix} \dot{u}_d \\ \dot{u}_{td} \end{bmatrix}+\begin{bmatrix} k_s+k_d & -k_d \\ -k_d & k_d \end{bmatrix}\begin{bmatrix} u_d \\ u_{td} \end{bmatrix}=\begin{bmatrix} p \\ 0 \end{bmatrix} \quad (1)$$

where m_s, c_s, and k_s are mass, damping coefficient, and stiffness of the SODF system, respectively, and m_d, c_d, and k_d are mass, damping coefficient, and stiffness of the TMD respectively, and u_s is the displacement of the SDOF system, and u_{td} is the absolute displacement of the TMD, and p is an external load applied to the SDOF system. It can be seen from Eq. (1) that the response of SDOF system is coupled with that of TMD because there exist non-zero off-diagonal terms.

The natural frequency and damping ratio of TMD can be obtained from Eq. (1) as

$$\omega_d = \sqrt{\frac{k_d}{m_d}} \tag{2.a}$$

$$\xi_d = \frac{c_d}{2m_d\omega_d} \tag{2.b}$$

where ω_d and ξ_d are the natural frequency and damping ratio of TMD, respectively. The ratio of natural frequencies of TMD to that of SDOF system is called frequency ratio, γ, and the ratio of TMD mass to that of SDOF system is called mass ratio, μ, where

$$\gamma = \frac{\omega_d}{\omega_s} \tag{3.a}$$

$$\mu = \frac{m_d}{m_s} \tag{3.b}$$

The optimal frequency and damping ratio of TMD are functions of the mass ratio given in Eq. (3.b) as follows.

$$\gamma_{opt} = \frac{1}{1+\mu} \tag{4.a}$$

$$\xi_{opt} = \frac{1}{2}\sqrt{\frac{3\mu/2}{1+3\mu}} \tag{4.b}$$

The expressions in Eq. (4) are derived assuming free vibration or sinusoidal external loading and zero structural damping ratio. Therefore, the optimal values vary if the external loading is different or there is intrinsic non-zero structural damping ratio. For tall buildings subjected to wind load, however, it is common in practice to design a TMD using optimal parameters by Eq. (4) because the first mode governs the behavior of the tall building and the damping ratio of the building is very small.

In Figure 1, the absolute displacement of TMD is the sum of the displacement of the SDOF system, us, and the relative displacement of TMD to the SDOF system, ud, and it can be expressed as follows.

$$u_{td} = u_s + u_d \tag{5}$$

Using the relative displacement of TMD, Eq. (1) can be re-written as

$$\begin{bmatrix} m_s & 0 \\ m_d & m_d \end{bmatrix}\begin{bmatrix} \ddot{u}_d \\ \ddot{u}_d \end{bmatrix} + \begin{bmatrix} c_s & -c_d \\ 0 & c_d \end{bmatrix}\begin{bmatrix} \dot{u}_d \\ \dot{u}_d \end{bmatrix} + \begin{bmatrix} k_s & -k_d \\ 0 & k_d \end{bmatrix}\begin{bmatrix} u_d \\ u_d \end{bmatrix} = \begin{bmatrix} p \\ 0 \end{bmatrix} \tag{6}$$

The first row of Eq. (6) is

$$m_s\ddot{u}_s + c_s u_s + k_s u_s = p + k_d u_d + c_d \dot{u}_d \tag{7}$$

and the second row of Eq. (6) is

$$m_d\ddot{u}_d + m_d\ddot{u}_s = -k_d u_d - c_d \dot{u}_d \tag{8}$$

Substituting Eq. (8) into Eq. (7) yields

$$m_s\ddot{u}_s + c_s u_s + k_s u_s = p - m_d(\ddot{u}_s + \ddot{u}_d) \tag{9}$$

From Eq. (5), the sum of the absolute acceleration of the SDOF system and the relative acceleration of the TMD in Eq. (9) equals the absolute acceleration of the TMD. Consequently, the equation of motion of SDOF system and TMD can be expressed as follows.

$$m_s\ddot{u}_s + c_s u_s + k_s u_s = p - m_d\ddot{u}_{td} \tag{10.a}$$
$$m_d\ddot{u}_d + c_d \dot{u}_d + k_d u_d = -m_d\ddot{u}_s \tag{10.b}$$

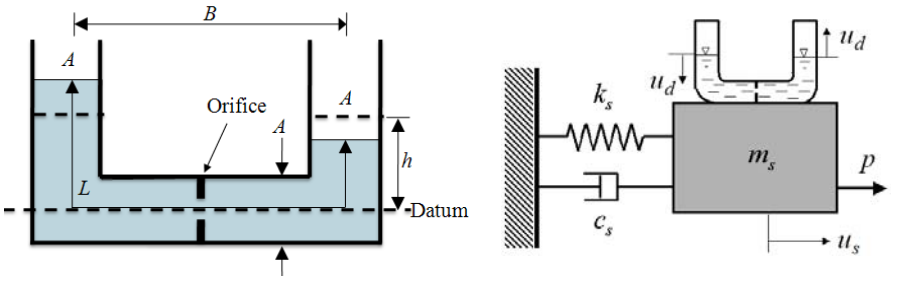
Eq. (10.b) can be further simplified as

$$\ddot{u}_d + 2\xi_d\omega_d\dot{u}_d + \omega_d^2 u_d = -\ddot{u}_s \tag{11}$$

From Eqs. (10.b) and (11), it can be seen that the equation of motion for a TMD subjected to the motion of the SDOF system is identical to that of an SDOF system subjected to an earthquake load. Moreover, it can be recognized that the external force applied to the SDOF system is not included in the equation. Therefore, it can be concluded that the natural frequency and damping ratio of TMD can be identified easily if the acceleration of SDOF system and one of the responses among relative acceleration, relative velocity, and relative displacement of the TMD are known. This can be done by applying any system identification technique using the acceleration of SDOF system as an input and the response of TMD as an output.

Meanwhile, the dynamic properties of the building can be easily obtained from a transient vibration test applying any typical system identification techniques (Ljung, 2007). In the transient vibration test, the movement of TMD should be restrained in order not to provoke any interaction with the building. This condition, however, is often difficult to satisfy in practice. Accordingly, it would be useful if the approximate dynamic properties of the building could be directly identified from an in-situ experiment.

In the in-situ TMD experiment, a free vibration test is often used. The TMD is forced by a hydraulic pump to have an initial displacement and released to move freely, which in turn causes the building to vibrate. In this case, the external force, p, in Eq. (10.a) can be ignored if the magnitude of building vibration is large enough



and the applied wind load is negligible. Then, Eq. (10.a) can be simplified as

$$\ddot{u}_s + 2\xi_s\omega_s\dot{u}_s + \omega_s^2 u_s = -\mu\ddot{u}_{td} \tag{12}$$

Similar to the identification of TMD, it can be seen from Eq. (12) that the natural frequency and damping ratio of the building can be obtained by applying any typical system identification technique using a response of TMD as an input and a response of the building as an output.

TLCD. A TLD is similar to a TMD in principle except that a TLD uses liquid (usually water) as a secondary mass body. That is, liquid acts as a moving mass and the liquid sloshing movement absorbs the building's energy if the sloshing frequency is tuned to the natural frequency of the building. In addition to this similarity, a TLD has the advantages of cheap installation cost and ease of maintenance compared to a TMD. Because the control performance of a TLD is close to that of a TMD, it has been increasingly used in practice (Kim and Adeli, 2005b, Kim et al., 2008, Shum et al, 2008).

A TLCD proposed by Sakai et al. (1989) is as one of the TLD variations and particularly designed to maximize the liquid motion energy in the TLD. It is made of a U-shaped tube and dissipates the energy acting on the building by the passage of the liquid through an orifice (Figure 2).

(a) Section of TLCD **(b) An SDOF system with a TLCD**

Figure 2. TLCD system

Unlike a TMD, there is no spring and dashpot between the U-shaped tube of a TLCD and main structure. Therefore, the liquid in the vertical tube is moving together with structure while the external force causes an additional movement of the liquid in the horizontal tube resulting in the following dynamic equilibrium (Chang and Qu, 1998).

$$m_{dh}(\ddot{u}_s + \ddot{u}_d) + m_{dv}\ddot{u}_s + m_s\ddot{u}_s + c_s\dot{u}_s + k_s u_s = p \tag{13}$$

where m_{dh} and m_{dv} are the mass of liquid in the horizontal and vertical tubes, respectively. Eq. (13) can be re-written as

$$(m_s + m_d)\ddot{u}_s + m_{dh}\ddot{u}_d + c_s\dot{u}_s + k_s u_s = p \tag{14}$$

where m_d (= m_{dh} + m_{dv}) is the total liquid mass. From Figure 2, the total liquid mass and mass of liquid in the horizontal tube are calculated as follows.

$$m_d = \rho AL \tag{15.a}$$

$$m_{dh} = m_d \frac{B}{L} \tag{15.b}$$

where ρ is the density of liquid, A is the cross-sectional area of tube, B is the center to center distance between vertical tubes, and L is the total liquid length. The total liquid length, L, is calculated as

$$L = B + 2h \tag{16}$$

where h is the height of water column from the center of the horizontal tube when the liquid is in a state of equilibrium.

When the liquid in a U-shaped tube is moved by the movement of structure, the equilibrium inside the tube is as follows.

$$m_{dh}\ddot{u}_s + m_d\ddot{u}_d + \frac{\rho A\zeta}{2}|\dot{u}_d|\dot{u}_d + 2\rho A g u_d = 0 \tag{17}$$

where g is the gravitational acceleration and ζ is the head-loss coefficient that varies depending on the orifice opening ratio. The natural frequency and damping coefficient of TLCD can be calculated from Eqs. (15) and (17) as follows.

$$\omega_d = \sqrt{\frac{2\rho Ag}{m_d}} = \sqrt{\frac{2g}{L}} \tag{18.a}$$

$$c_d = \frac{\rho A\zeta}{2}|\dot{u}_d| \tag{18.b}$$

It can be seen from Eq. (18.b) that the damping force of a TLCD is not linear unlike a TMD since the absolute value of velocity is included in the damping coefficient.

Using Eqs. (14) and (17), the equation of motion of a SDOF system with a TLCD can be constructed similar to Eq. (1) as follows.

$$\begin{bmatrix} m_s + m_d & m_{dh} \\ m_{dh} & m_d \end{bmatrix}\begin{bmatrix} \ddot{u}_s \\ \ddot{u}_d \end{bmatrix} + \begin{bmatrix} c_s & 0 \\ 0 & c_d \end{bmatrix}\begin{bmatrix} \dot{u}_s \\ \dot{u}_d \end{bmatrix} + \begin{bmatrix} k_s & 0 \\ 0 & k_d \end{bmatrix}\begin{bmatrix} u_s \\ u_d \end{bmatrix} = \begin{bmatrix} p \\ 0 \end{bmatrix} \tag{19}$$

It can be seen from Eq. (19) that the response of the SDOF system is coupled with that of the TLCD because there are non-zero off-diagonal terms in the mass matrix similar to Eq. (1) of the TMD where there are non-zero off-diagonal terms in the damping and stiffness matrix.

In order to identify the dynamic characteristics of a TLCD using the responses of structure and TLCD, the coupled equation of Eq. (17) needs to be derived into the form of Eq. (11). Eq. (17) can be simplified using Eqs. (2.b) and (18) as

$$\ddot{u}_d + 2\xi_d \omega_d \dot{u}_d + \omega_d^2 u_d = -\frac{m_{dh}}{m_d}\ddot{u}_s = -\frac{B}{L}\ddot{u}_s \tag{20}$$

where

$$\xi_d = \frac{c_d}{2m_d\omega_d} \tag{21}$$

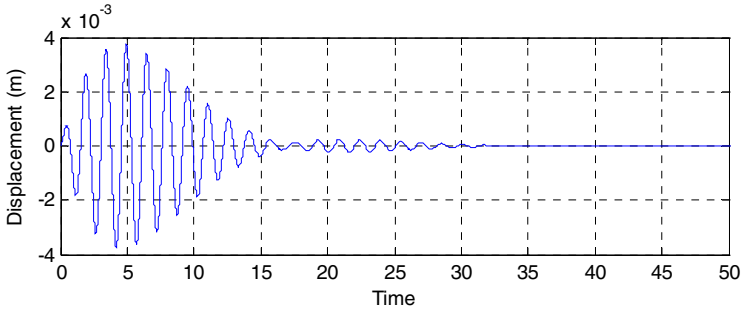
Accordingly, if the accelerations of structure and response of a TCLD are available, the natural frequency and damping ratio of a TLCD can be identified using the structural acceleration as an input and the response of a TLCD as an output from Eq. (20) similarly to a TMD. It is important to note that the identified damping ratio of a TLCD is only an equivalent damping ratio unlike a TMD because the damping ratio in Eqs. (20) and (21) includes a nonlinear term. The equivalent damping ratio has been studied by several researchers, and the optimal equivalent damping ratio for the case of sinusoidal load is given by

$$\xi_{opt} = \frac{1}{2}\sqrt{\frac{\gamma(1+\mu-\gamma/4)}{(1+\mu)(1+\mu-\gamma/4)}} \tag{22}$$

Through field experiments on a TLCD, the dynamic properties of a structure can also be approximately calculated from the responses of structure and a TLCD similar to the case of a TMD. First, Eq. (14) can be re-written as

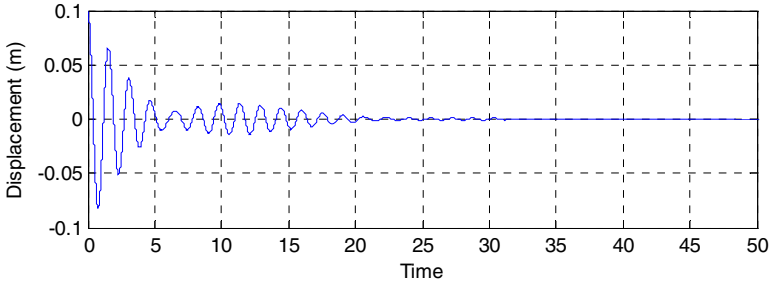
$$(m_s + m_d)\ddot{u}_s + c_s\dot{u}_s + k_s u_s = p - m_{dh}\ddot{u}_d \tag{23}$$

Similar to the free vibration test of a TMD, if the displacement caused by a TLCD is large enough compared to the displacement caused by external forces during the field test of a TLCD, it is possible to ignore the external force term. Then Eq. (23) can be simplified as follows taking into consideration that the mass of TLCD is generally less than 1% of the mass of the structure.



$$\ddot{u}_s + 2\zeta_s \omega_s \dot{u}_s + \omega_s^2 u_s = -\frac{m_{dh}}{m_s}\ddot{u}_d \tag{24}$$

It can be seen from Eq. (24) that the natural frequency and damping ratio of the building can approximately calculated by applying any typical system identification technique using the response of a TLCD as an input and the response of the building as an output in a way similar to the case of a TMD.



NUMERICAL EXAMPLES

TMD example. A numerical study of an SDOF system with a TMD is performed to investigate the validity of the proposed method for the identification of dynamic properties of TMD and structure. It is assumed that the mass, natural frequency, and damping ration of the SDOF system are 10,449 ton, 0.660 Hz, and 2%, respectively, and the mass of TMD is 100 ton. The corresponding mass ratio of TMD to SDOF system is 0.96 %. From Eq. (4), the optimal natural frequency and damping ratio of TMD are obtained as 0.6537 Hz and 5.91%, respectively.

The free vibration response of the SDOF system is calculated numerically enforcing the initial displacement on the TMD. Figures 3 and 4 present the displacement and acceleration time histories of the SDOF system and TMD, respectively, when the initial displacement of the TMD is 0.09 m. The corresponding power spectral densities (PSD) of the SDOF system and TMD accelerations are shown in Figure 5. From Figure 5, it can be seen that the peak of each PSD of the SDOF system and TMD are split into two peaks near 0.660 Hz, which is the natural frequency of the SDOF system. Consequently, it can be concluded that it is not possible to obtain the natural frequency and damping ratio from PSD using the spectrum analysis method and half-power method due to the interaction of the building and damper.

(a) SDOF system **(b) TMD**

Figure 5. PSDs of the SDOF system and TMD accelerations

Using the proposed method, the natural frequency and damping ratio of the TMD can be identified directly from the responses of the SDOF system and TMD. The identified natural frequencies and damping ratios of the TMD found using Eq. (11) are summarized and compared in Table 1. The input for the system identification is the acceleration of the SDOF system while the outputs are the relative displacement and relative acceleration of the TMD. This is to evaluate the identified results depending on the output responses because both the relative displacement and relative acceleration of the TMD can be measured during the free vibration test of the TMD.

Table 1.Identified natural frequency and damping ratio of TMD

Output response	Identified system matrix	Natural frequency (error)	Damping ratio (error)
TMD relative displacement	$\mathbf{A}=\begin{bmatrix} 999.752 & 1000.246 \\ -999.760 & -1000.237 \end{bmatrix}$	0.6538 Hz (0.02 %)	5.91 % (0.00 %)
TMD relative acceleration	$\mathbf{A}=\begin{bmatrix} 999.749 & 1000.248 \\ -999.757 & -1000.240 \end{bmatrix}$	0.6565 Hz (0.43 %)	5.95 % (0.68 %)

The system identification in this study is performed using a Matlab Box-Jenkins model and the state space equation with an order of 2 is used. The system matrix A in Table 1 represents the identified system matrix of the Box-Jenkins model, and the natural frequency and damping ratio are obtained from the eigenvalue analysis using the system matrix A. It can be seen from Table 1 that the identification using both the TMD relative displacement and the relative acceleration yields accurate results with errors of less than 1.0 %.

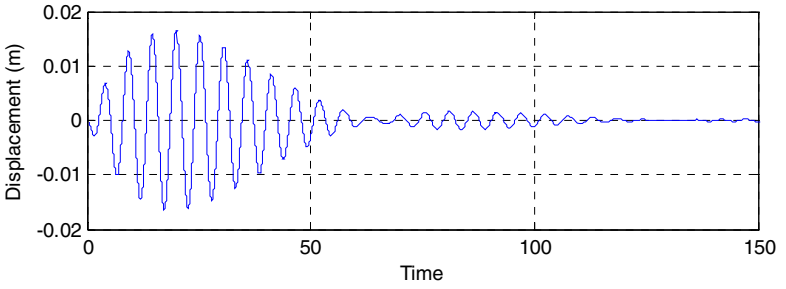

Table 2.Identified natural frequency and damping ratio of SDOF system

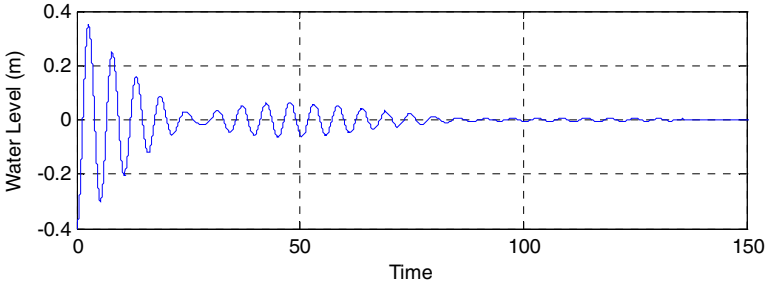
Input response	Identified system matrix	Natural frequency (error)	Damping ratio (error)
TMD relative displacement	$\mathbf{A}=\begin{bmatrix} 99.858 & 100.113 \\ -99.945 & -100.027 \end{bmatrix}$	0.6619 Hz (0.29 %)	2.02 % (1.0 %)
TMD relative acceleration	$\mathbf{A}=\begin{bmatrix} 99.861 & 100.111 \\ -99.947 & -100.025 \end{bmatrix}$	0.6604 Hz (0.06 %)	1.98 % (1.0 %)



The system identification of the SDOF system is also performed using Eq. (12) and the results are summarized in Table 2. The output for the system identification is the acceleration of the SDOF system while the inputs are the relative displacement and relative acceleration of the TMD. It can be seen from Table 2 that the results using both the TMD relative displacement and the relative acceleration are close to the assumed value. This is because the external force is not considered in the numerical analysis. In contrast, the identified results for the actual building may contain errors to some extent due to external wind load applied to the building during the field test.

TLCD example. The identification of dynamic characteristics of a TLCD and building is performed numerically using a SDOF system. For the numerical simulation, the mass, natural frequency, and damping ratio of the SDOF system are assumed to be 34,153 ton, 0.189 Hz, and 2%, respectively. Further, it is assumed that the mass ratio is 1 % and the ratio the center to center distance between vertical tubes to the total liquid length (B/L) is 0.9. The corresponding optimal natural frequency of

TLCD is 0.187 Hz and the optimal equivalent damping ratio from Eq. (22) is 4.23 %.

(b) Acceleration time history of the TLCD

Figure 7. Acceleration time histories of the SDOF system and the TLCD subjected to the initial TLCD water level of 0.4 m

(a) SDOF system **(b) TLCD**

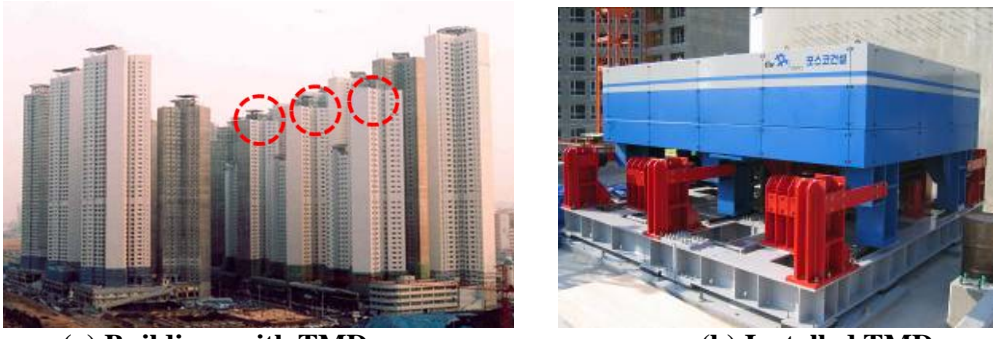
Figure 8. PSDs of the SDOF system and TLCD accelerations

The free vibration response of the SDOF system is calculated numerically enforcing the initial water level on the TMD. Figs. 6 and 7 present the displacement and acceleration time histories of the SDOF system and TLCD, respectively, when the initial water level of TLCD is 0.4 m. The corresponding PSDs of the SDOF system and TLCD accelerations are shown in Figure 8. From Figure 8, it can be seen that the peak of each PSD of the SDOF system and TMD are split into two peaks near 0.189 Hz, which is the natural frequency of the SDOF system. Consequently, it can be concluded that it is not possible to obtain the natural frequency and damping ratio from a PSD similar to how it was obtained in a TMD.

In the field test of TLCD, it is impractical to measure the acceleration of water in the TLCD, and only the water level is generally measured using an ultrasonic level probe. Accordingly, the water level in the TLCD and the acceleration of the SDOF system are only used for the system identification in this numerical example. The identified dynamic parameters of the SDOF system and TLCD using Eqs. (20) and (24) are summarized in Table 3. The input and output for the identification of the TLCD are the acceleration of the SDOF system and the TLCD water level, respectively, and the input and output for the identification of the SDOF system are the TLCD water level and acceleration of the SDOF system, respectively.

Table 3.Identified natural frequency and damping ratio of the SDOF system and TLCD

	Identified system matrix	Natural frequency (error)	Damping ratio (error)
TLCD	$\mathbf{A} = \begin{bmatrix} 199.950 & 200.049 \\ -199.954 & -200.045 \end{bmatrix}$	0.1871 Hz (0.01 %)	4.04 % (1.5 %)
SDOF system	$\mathbf{A} = \begin{bmatrix} 19.955 & 20.034 \\ -19.990 & -19.998 \end{bmatrix}$	0.1888 Hz (0.11 %)	1.84 % (8.0 %)

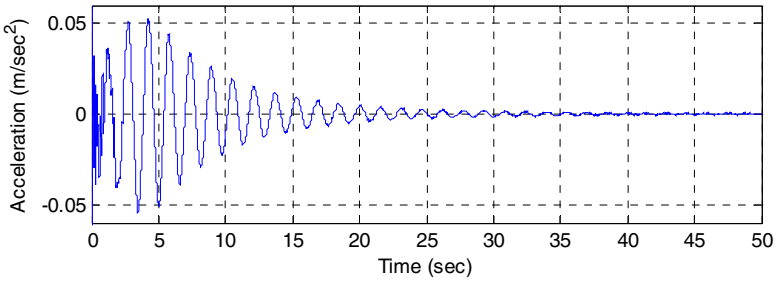


It can be seen from Table 3 that the natural frequencies are quite closely estimated while the damping ratios are identified with relatively large errors. This is

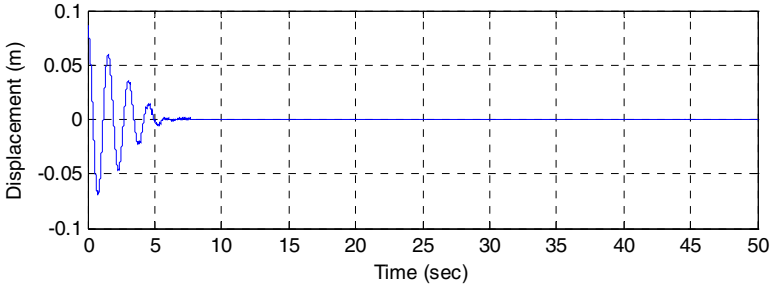
because the damping ratio of a TLCD is a nonlinear value having an absolute value of TLCD water velocity as seen in Eq. (18). Considering that the error is 1.5 % compared to the linearlized optimal equivalent damping ratio of Eq. (21) and the factory pre-assembling test is impossible for a TLCD, however, it can be concluded that the proposed method in this study is effective enough for the identification of a TLCD based on in-situ experiment.

IN-SITU FORCED VIBRATION TEST

TMD test. For the system identification of a TMD through a forced vibration test, the free vibration test was performed in a 50-story building where a TMD is installed. Figure 9(a) depicts the buildings where TMDs are installed and Figure 9(b) shows an installed TMD. The buildings are residential buildings and TMDs are installed in the three buildings marked with dotted circles in Figure 9(a).



The generalized mass and frequency of the fundamental mode of the building are 10,449 ton and 0.660 Hz, respectively, and the assumed damping ratio for wind design is 2.0 %. The mass of the TMD was designed to be 100 ton, and the natural frequency of TMD was set at 99% of that of the building. The optimal damping ratio of the TMD is 6.0%. Because the moving mass of the TMD installed in the Centum Park project is steel, a pre-assembled test was performed in the factory. The errors of the natural frequency and damping ratio obtained from the factory test were 2.5% and 3.3% respectively.



(a) Buildings with TMD **(b) Installed TMD**

Figure 9. Centum Park project, Busan, Korea

A TMD was installed on the roof floor when the concrete work of the structural frame was completed and the forced vibration test was performed at the time of completion of construction including cladding. Figure 10 shows the measured acceleration time histories of the building and the free vibration displacement of the TMD obtained from the forced vibration test on site. The forced vibration test was performed by enforcing an initial displacement of 0.09 m on TMD. It can be seen from Figure 10 that the peak acceleration of the building is about 0.05 m/sec2, which corresponds to the H-90 level according to AIJ2004. This indicates that the acceleration due to the external wind load during the field test was negligible compared to that due to TMD initial displacement.

(a) Accelearation time history of the building

(b) Displacement time history of the TMD

Figure 10. Time histories of the building and TMD obtained from the forced vibration test

The results of system identification using the TMD displacement and building acceleration presented in Figure 10 are shown in Table 4. It can be noted from Table 4 that the identified dynamic parameters of the TMD and building are close to the designed values and the results of the factory test while the natural frequency of the TMD was found to be little greater than the designed value. This is because the TMD is originally tuned to the expected natural frequency based on the testing of a partially completed building.

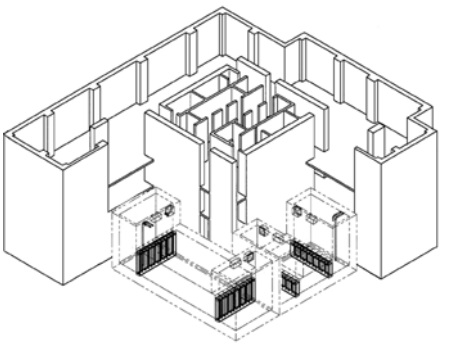


Table 4.Identified natural frequency and damping ratio of the building and TMD

	Natural frequency	Damping ratio
TMD	0.6668 Hz	8.37 %
Building	0.6623 Hz	2.60 %

TLCD test. The forced vibration test was performed for the system identification of the TLCD on a 64-story building where two TLCDs are installed. Figure 11(a) depicts the buildings where TLCDs are installed and Figure 11(b) shows an isometric view of the TLCD floor. The buildings are residential buildings and TLCDs are installed in the all four buildings.

(a) Buildings with TLCD

(b) Isometric view of TLCD floor

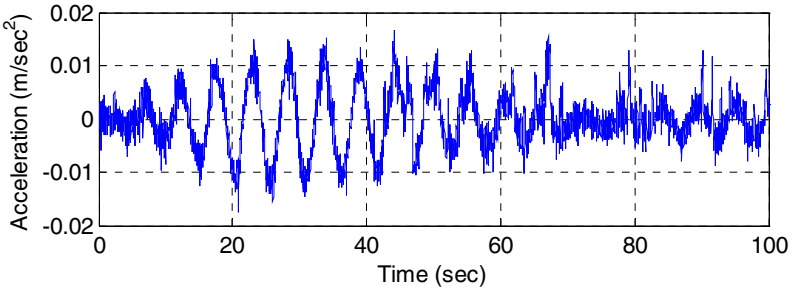
Figure 11. The First World project, Incheon, Korea

The generalized mass and frequency of the fundamental mode of the building are 31,145 ton and 0.189 Hz, respectively, and the assumed damping ratio for wind design is 2.0 %. Two perpendicular TLCDs are installed in each building, and the water mass of the larger TLCD is 450 ton. The natural frequency of TLCD is set at 97 % of that of the building. Table 5 shows the results of the building system identification based on the ambient vibration test. It can be noted from Table 5 that the natural frequency shows almost no change but the damping ratio increases significantly by adding water to the TLCD.

Table 5. Identified natural frequency and damping ratio of building based on the ambient vibration test

	Natural frequency	Damping ratio
Without TLCD water	0.188Hz	0.47%
With TLCD water	0.189Hz	1.47%

TLCDs were installed on the 66th floor when the concrete work of the structural frame was completed and the forced vibration test was performed at the time of completion of construction. The forced vibration test was performed enforcing an initial water level of 0.4 m on a TLCD. Figure 12 presents the measured TLCD water level and building acceleration obtained from the forced vibration test.



The results of system identification using the TLCD water level and building acceleration presented in Figure 12 are shown in Table 6. For the system identification, a low-pass filter of 1 Hz was used in order to minimize the effect of higher modes and noise. It can be seen from Table 4 that the identified dynamic parameters of the TMD and building are close to the designed values and the results of an ambient vibration test.

Table 6. Identified natural frequency and damping ratio of the building and TLCD

	Natural frequency	Damping ratio
TLCD	0.1788 Hz	3.65 %
Building	0.1854 Hz	1.50 %

CONCLUSIONS

In this paper, an identification method for the dynamic properties of secondary mass dampers based on the forced vibration test is presented for the case that the pre-assembled test in a factory is impractical. Decoupled equations of motion are derived from a coupled equation of motion of building and damper. These decoupled equations of motion can be applied to general system identification methods using the responses of the building and damper.

For the verification of the proposed method, the dynamic properties of a TMD and a TLCD install12345ed on a SDOF system were identified through numerical examples, and the method was applied to the identification of an actual TMD and TLCD installed in buildings using free vibration responses. The results of the numerical study and the forced vibration test show that the proposed method is effective in the identification of TMD and TLCD based on the forced vibration test.

ABSTRACT

Column forces, displacements and accelerations experienced by the structure during strong ground motions can be reduced by weakening and (or) softening the structure and adding a supplemental damper. Although this approach proved to be promising analytically, the concept of "structural strength reduction" leads to inelastic behavior and large permanent deformations in the main structural system. In this paper a new concept is developed to emulate weakening in a structural system by adding an "adaptive negative stiffness device" (NSD) and shifting the "yielding" away from the main structural system; leading, to the new idea of "apparent weakening" with reduced inelastic excursions in the main structural system. This is achieved through an adaptive negative stiffness system (ANSS), which is a combination of NSD and a damper. Engaging the NSD at an appropriate displacement (simulated yield displacement), that is well below the actual yield displacement of the structural system, will result in a composite structure-device assembly that behaves like a yielding structure. The NSD has a re-centering mechanism thereby avoiding permanent deformation in the composite structure-device assembly unless, the main structure itself yields. Essentially, a yielding-structure is "mimicked" without any, or with minimum yielding and permanent deformation in the main structure. In summary, the main structural system undergoes less acceleration, less displacements and less base shear, while the ANSS "absorbs" them. This paper presents the working principle and details on development and study of the ANSS/NSD. Through numerical simulations, the effectiveness and the superior performance of the ANSS/NSD as compared to a structural system with supplemental passive dampers is presented.

INTRODUCTION

Conventional structures designed for loads specified by codes undergo significant inelastic deformations during severe earthquakes, leading to stiffness and strength degradation, increased inter-storey drifts, and damage with residual drift. These yielding structures however keep the global forces within limited bounds dictated by the yielding levels. The inelastic effects can be reduced to some extent using passive seismic protection systems in the form of supplemental damping

devices. This approach has emerged as an efficient way to reduce response and limit damage by shifting the inelastic energy dissipation from the framing system to the dampers (Lobo *et al.*, 1993, Constantinou and Symans, 1993, Spencer and Nagarajaiah, 2003). Examples of few such passive systems are base isolation systems (Nagarajaiah et al. 1991, Nagarajaiah *et al.* 2005, 2006; Narasimhan *et al.*, 2006), fluid dampers (Constantinou and Symans, 1993,1997), adaptive tuned mass dampers (Nagarajaiah 2009), adaptive friction dampers (Fenz and Constantinou, 2008), active and semiactive control (Spencer and Nagarajaiah 2003).

Adaptive systems belong to the category of passive seismic protection systems but they are more sophisticated than the regular passive systems. An adaptive system consists of adaptive stiffness and/or damping devices which are capable of changing the stiffness and/or damping of the device depending on the displacement amplitude (Nagarajaiah 2009, Fenz and Constantinou, 2008). These devices are designed to exhibit a force-displacement behavior which upon the addition of structural properties will result in an adaptive system having superior characteristics compared to the original structure. Adaptive systems can also be classified into variable stiffness devices and variable damping devices (Nagarajaiah 2009, Spencer and Nagarajaiah, 2003).

Recently, Iemura and Pradono (2009) proposed pseudo-negative-stiffness dampers (PNSD) that are hydraulic or semiactive or active devices capable of producing negative-stiffness hysteretic loops. It has been shown in their investigations that by adding negative-stiffness hysteretic loops the total force would be lowered significantly. Common passive dampers that act in parallel with the stiffness of structure add to the total force rendering the shear force larger than that due to stiffness of the base-structure alone. Iemura and Pradono (2009) have also reported the applications of PNSD to the benchmark control problems for seismic response reduction. Effectiveness of the proposed method has been validated on three benchmark structures, cable-stayed bridges, buildings, and highway bridges, subjected to various types of recorded ground motions (Iemura and Pradono, 2009). It must be noted that the passive hydraulic dampers cannot "push" the structure is the same direction as the structural displacement; the adaptive NSD proposed in this paper can. Since the NSD has a precompressed spring, it has the ability to push the structure in the same direction as the structural displacement generating the true negative stiffness, instead of pseudo negative stiffness. A hydraulic device that is fully active or semiactive as in the case of PNSD can generate a pseudo-negative stiffness in which case feedback control would be needed to generate the negative stiffness.

All the methods described in this section thus far suffer from one or other limitation: 1) active control devices require feedback and substantial power; 2) semi-active controllers require feedback but nominal power 3) passive control devices may reduce displacement but lead to larger base shear. Combination of adaptive negative stiffness and damping device can result in reduction in base shear and displacement response of the structure. However, to date truly negative stiffness systems have received relatively little attention as compared to aforementioned semiactive or pseudo negative stiffness systems and thus represent a significant gap. Hence, development of new true negative stiffness devices is necessary to reduce the inelastic

behavior excursions in the main structural system. ANSS/NSD can reduce damage in frames by reducing the base shears and deformations and they can also eliminate residual inter-storey drifts.

Reinhorn *et al.* (2005) and Viti *et al.* (2006) introduced the concept of weakening structures (reducing strength and stiffness), while introducing added viscous damping to reduce simultaneously total accelerations and inter-story drifts. Design methodologies for softening the structure (reducing stiffness) and adding damping devices using control theory have been proposed by Cimellaro *et al.* (2009) to determine the locations and the magnitude of weakening and/or softening of structural elements and the added damping while insuring structural stability. A two-stage design procedure was suggested: (i) first using a nonlinear active control algorithm, to determine the new structural parameters while insuring stability, then (ii) determine the properties of equivalent structural parameters of passive system, which can be implemented by removing or weakening some structural elements, or connections, or reduction of stiffness of the main structural elements and by addition of energy dissipation systems. Passive dampers and weakened elements were designed using an optimization algorithm to obtain a response as close as possible to an actively controlled system.

In this study a new concept of ANSS is proposed and the idea of "adaptive weakening." The original stiffness of the main structural system is left unchanged in the proposed ANSS and the "adaptive weakening" occurs due to NSD that mimics the "yielding" thus attracting it away from the main structural system—unlike the weakening concept proposed earlier, wherein the main structural system stiffness itself is reduced.

This paper presents comprehensive details of development and study of the behavior of the ANSS/NSD. The NSD is described in detail and its force-displacement loop is presented. Through numerical simulations it is shown that the concept of ANSS/NSD is very effective in elastic and inelastic structural systems. The effectiveness and the superior performance of the ANSS/NSD as compared to a structural system with supplemental passive dampers when subjected periodic and random input ground motions is demonstrated by numerical results.

PRINCIPLE OF ADAPTIVE NEGATIVE STIFFNESS SYSTEM (ANSS)

From here on adaptive negative stiffness system (ANSS) refers to the assembly of NSD and NPD—damper, unless described otherwise. It can also be simply referred as adaptive system or adaptive stiffness system. The main objective of the adaptive system is to reduce the inelastic excursions of the main structure and reduce the base shear of the structure and at the same time limit the maximum displacement of structure. Adaptive systems belong to the category of passive seismic protection systems but they are more sophisticated than the regular passive systems. The adaptive system that is developed in this work consists of two components that are designed in a two step sequence. First a truly adaptive negative stiffness device, which is capable of changing the stiffness of the device during lateral displacement, is developed based on the properties of the structure. This NSD is designed to exhibit true negative stiffness behavior which upon the addition of structure properties will

result in reduction of the stiffness of the structure and NSD assembly or "adaptive weakening" there by resulting in the reduction of the base shear of the assembly. Then a passive damper is added to reduce the displacements that are caused due to the reduction in stiffness. It has been found through simulation studies that the deformations of the structure and NSD assembly can be reduced using a passive damper--there by reducing the base shear and displacement in a two step process. An alternate explanation to justify the need for a NSD is explained in the next part of this section.

NEGATIVE STIFFNESS DEVICE (NSD)

True negative stiffness means that the force must assist motion, not oppose it as it is in the case of a positive stiffness spring. Psuedo negative stiffness can be accomplished using active or semiactive hydraulic device. In this paper the authors develop a new device that is passive, as it does not need any feedback signal or external power supply to generate the desired force. NSD has a precompressed bar, nonlinear springs and nonlinear damper (Nagarajaiah and Reinhorn, 1994). Schematic diagram showing the configuration of ANSS is shown in Figure 1(a) and the actual NSD placed in a base isolated system is shown in Figure 1(b). The properties of precompressed vertical spring and nonlinear horizontal springs are chosen in such a way that the desired force displacement is achieved. Precompressed bar is placed vertically between the beam and the top of the chevron brace. Since this is an unstable equilibrium for the spring, any inter-storey drift will result in a lateral force that assists the motion. For complete details of the device and its experimental validation the reader is referred to Sarlis *et al*. (2011).

Working principle: Assume a perfectly-linear single degree of freedom structure with stiffness, K_e, and no damping, an NSD with stiffness K_n and a passive damper with damping coefficient C. The force displacement plots are shown in Figure 2(a) (green line is structure, magenta is viscous damper and red is negative stiffness device). By adding NSD to the structure, schematically shown in Figure 2(b), the assembly stiffness reduces to $K_a=K_e–K_n$ beyond the displacement x_1 (shown as blue line in Figure 2(b)). If, F_2 and x_2 are the maximum restoring force and maximum displacement of a perfectly-linear system (green line in Figure 2(b)) then for the same load the maximum restoring force and maximum displacement of the assembly are F_3 and x_3 (blue line in Figure 2(b)), respectively. K_n is designed to achieve the desired reduction in base shear. Force exerted by the NSD is shown as red line in Figure 2(b). Although the reduction in base shear is achieved the maximum deformation of adaptive system is increased in the process when compared with an elastic system.
Deformation of this assembly can be reduced by adding a passing damping device in parallel to the NSD. To demonstrate the concept, a linear viscous damper is used for illustration but a nonlinear damper is a more optimal choice. An optimization needs to be performed to find the best suited nonlinear passive damper (NPD). By adding the viscous damper to the structure along with NSD maximum displacement is reduced resulting in $x_3 < x_2$. Since the assembly of structure and NSD acts like a nonlinear elastic system, viscous damper even with a very small damping coefficient can be

effective. It should be noted that by adding a damper to structure and NSD assembly, base shear of the assembly is not significantly increased.

From Figure 2(a,b,c) it can be seen that there is an offset displacement, x_1, called as "simulate yield-displacement", before the negative stiffness device is engaged. This is to avoid excessive response for relatively small external excitations. For displacements x such that $|x| < |x_1|$ the NSD assembly provides zero force and the structure behaves like the original linear structure. A provision to create this initial gap can be provided in the actual device using a pair of mechanical springs.

Analytical Model: The force in the NSD is given in Eq. (1) (Nagarajaiah and Reinhorn, 1994; Sarlis *et al.*, 2011):

$$F_{NSD} = 2K_h(x)x + K_v\left[\frac{\left(\sqrt{1+\left(\frac{x}{l}\right)^2}-\left(\frac{\Delta}{l}\right)\right)}{\sqrt{1+\left(\frac{x}{l}\right)^2}}\right]x \tag{1}$$

F_{NSD} is the force exerted by the NSD device. x is the horizontal displacement of the structure. K_h and K_v are the stiffness of the nonlinear horizontal spring and linear vertical springs, respectively as shown in Figure 1(a). l is the length of the precompressed spring in the initial position and Δ is the precompression in the vertical spring. By changing the parameters $K_h(x)$, K_v, l and Δ any desired force-displacement curve can be obtained. Initial gap in the NSD can be generated by choosing an appropriate nonlinear elastic spring, $K_h(x)$. A force-displacement loop of NSD—for a particular set of parameters—is shown in Figure 3 (red line), in comparison with the elasto-plastic base-structure (green line) and the structure + NSD (blue line).

PASSIVE DAMPING DEVICE

In the previous section a detailed study on the desired characteristics of NSD was described. Since the NSD reduces the effective stiffness of the structure+NSD assembly increased deformations will result. To limit these deformations a nonlinear passive damper has to be used. Assuming that we have the design ground motion for which the adaptive system has to be designed, the first step is to find the active control force exerted by the output feedback controller to satisfy desired performance specifications. Using optimization method proposed by Cimellaro *et al.* (2009), wherein the optimal properties of the damper, that minimizes the error between the active control force and force exerted by the passive devices, can be found. In this study, with the assumed NSD properties, a linear viscous damper with 20% damping ratio is found to be very effective. Force exerted by the passive damper is given by the following equation

$$F_{NPD} = 2\xi\sqrt{K_e m}\,\dot{x} \tag{2}$$

where, F_{NPD} is the force exerted by the damper, is the damping ratio, K_e is the elastic stiffness of structure and m is the mass of the structure. As mentioned in previous section the main objective of the adaptive system is to reduce the base shear of the structure and at the same time limit the maximum displacement of structure. It will be uneconomical and unrealistic to design devices that will retain the structure in elastic state, without any yielding, after a major earthquake. So, all the studies in this paper involves structure whose properties are representative of a real building and the loading cases for which there is yielding in the structure are also considered.

Ultimate goal of this study is to prove the concept and the effectiveness of the proposed ANSS/NSD analytically and experimentally. All the simulation studies presented in this paper are for a 1:3 scale three storey frame structure developed at University at Buffalo for a study of zipper frames. In the initial phase 2^{nd} and 3rd floors of the frame are braced rendering it essentially as a single degree of freedom system, which is considered in this study. Push-over curve for the zipper frame is obtained using the commercial software with the exact detail. Sivaselvan-Reinhorn model (Sivaselvan and Reinhorn, 2001) is used to capture the bi-linear hysteresis characteristics observed in the three-storey frame. Strength degradation and pinching are ignored. Governing equation of motion for the structure is shown in Eq. 3,4. Simple parameters like K_e and ε are obtained from the push-over curve. Mass of the structure, m, is measured and the values for remaining parameters are obtained using an optimization algorithm. Description of the variables is given in Table-1.

$$m\ddot{x} + \left(2\xi\omega_n m\right)\dot{x} + \alpha\left(1-\varepsilon\right)z + \varepsilon K_e x = -m\ddot{x}_g \tag{3}$$

$$dz/dx = K_e\left(1-\left|z/K_e Y\right|^{\eta}\left(\gamma\,\mathrm{sgn}\left(z\dot{x}\right)+\beta\right)\right) \tag{4}$$

SIMULATION RESULTS

Periodic Ground Motion: For all the results, for periodic input, presented in this work, 10 cycles of sinusoidal input are considered. Excitation frequency is same as the natural frequency of the base structure, $\omega_n = \sqrt{K_e/m}$.

***Elastic Systems*:** For those systems that will remain in elastic region for the design ground motion, NSD is found to be very effective. NSD will reduce the base shear of the structure substantially. To demonstrate this fact, a periodic ground motion is applied to the zipper frame. Amplitude of the ground motion is chosen such that the structure and NSD assembly will remain in elastic region. Adaptive system here refers to the structure and NSD assembly; damper is not used. Response time histories comparing the actual structure and adaptive system (structure + NSD) are shown in Figure 4. It can be seen from results in Figure 4 that all the response characteristics i.e., displacement, velocity and acceleration of the base structure (red curve) are higher that the adaptive system (green curve). Force-displacement behavior of the actual structure and the adaptive system are shown in Figure 5; it is evident from these results that the adaptive system remains in the elastic region whereas the base structure yields. The component forces acting in the adaptive system are shown in Figure 6. "Simulated yield displacement" for the NSD is assumed at a normalized

displacement of 0.25. It should be noted that passive damper is not yet included for the results shown in Figures 4, 5 and 6. For the systems that remain in elastic region, NSD alone is effective for reducing base shear without any increased deformations. A passive damper can be added to reduce the deformation of structure along with the base shear.

Inelastic Systems: The performance of the NSD is further verified for higher input amplitudes. Amplitude of input ground motion is increased so that the adaptive system starts yielding. For yielding structures NSD alone will not improve the performance of the adaptive system. Passive damper has to be added to limit the excessive displacements caused due to reduction in the overall stiffness of the structure.

Passive viscous damper with 20% damping ratio is used in the simulations studies presented in the paper. Three systems are compared after the addition of passive viscous damper (1) Bilinear system (referred to as BS), (2) Bilinear system + passive damper (referred to as PS), and (3) Bilinear system + passive damper + NSD (referred to as ANSS).

For the same input amplitude and 10 input cycles it was found that, by adding the passive damper the deformation of the structure is reduced substantially with a slightly higher base shear (Nagarajaiah *et al.*, 2010). In addition, the acceleration of adaptive system is 40 % less--compared to passive system and base structure system. Due to the presence of NSD in adaptive system the base shear is reduced substantially, whereas in the case of passive system base shear is larger than the case with base structure alone.

To study the efficiency of the ANSS/NSD, performance of the aforementioned systems is verified for Kobe ground motion. The response histories and the force-displacement loops for Kobe earthquake excitation are shown in Figures 7 and 8 respectively. The system with NSD and damper reduces both the displacement and base shear significantly, as evident in Figures 7 and 8.

CONCLUSIONS

A novel and new adaptive negative stiffness system (ANSS) and negative stiffness device (NSD) is proposed and developed in detail in this paper along with a new concept of "adaptive weakening". The proposed NSD does not rely on structural-response feedback and external power supply—unlike previously reported pseudo-negative stiffness devices that do depend on active control—hence, is passive, and exhibits true adaptive negative stiffness behavior by possessing predesigned variations of stiffness as a function of structural displacement amplitude. Addition of NSD to the structural system will result in the reduction of stiffness in the combined system or "adaptive weakening" occurs; however, it is important to note that the stiffness of the base-structure remains unchanged in this study—unlike the concept of weakening proposed earlier wherein the stiffness of the base-structure itself is reduced. Addition of the passive damper reduces the displacements that are caused due to the reduction in effective stiffness.

Effectiveness of the proposed ANSS/NSD in elastic and inelastic structural systems has been demonstrated through the simulation studies for periodic and random input ground motions. It has been shown that the main structural system suffers less force, less displacements and less damage, while the ANSS "absorbs" them.

ABSTRACT

Shear connections in beams are conventionally designed to transfer shear forces only. It is assumed that there is no substantial moment transfer due to the fact that beam end rotation is allowable. The shear tab, or fin plate, connection is one of the simplest and most cost-effective shear connection types and, although its behavior under gravity and cyclic loading has been established, its response to the column removal scenario that is commonly considered for progressive collapse analysis is still relatively unknown. In this paper, challenges involved in numerical studies for simulating the performance of shear tab connections when a column has been compromised are discussed. Modeling definitions for performing highly nonlinear analysis are discussed and recommendations are made regarding obtaining verification by available experimental data. Shear, axial force, and moment versus chord rotation diagrams are presented for both numerical and experimental results and conclusion are made.

Introduction

Based on a definition accepted in the literature, connections with moment capacities less than 20 % of the plastic moment capacity of the connected beams are called shear connections (Astaneh-Asl 2005). Shear connections are used conventionally to transfer shear forces exclusively. It is assumed that no moment transfer occurs at simple connections since beam end rotation is permitted. There are several forms of simple connection used in steel structures. The shear tab, or fin plate, connection consists of a plate welded to the supporting column and typically bolted to the supported beam. It is easy to fabricate and is cost-efficient in terms of construction and material. A typical double-sided joint with shear tab connections is depicted in Figure 1.

Table 1 summarizes the types of material usually used in this type of connection in conventional construction.

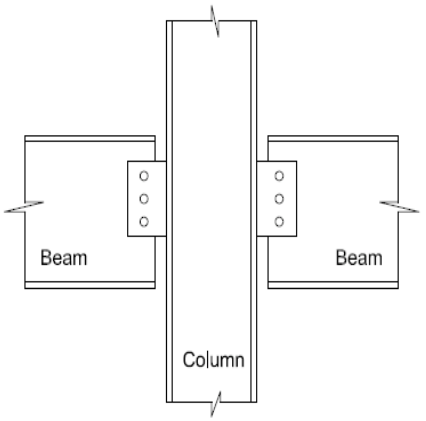

Figure 1. Typical beam-to-column shear tab connection

Table 1. Typical material used for shear tab connections

Component	Material	Description
Plate	A36	-
Bolts	ASTM A325, A490	standard/slotted hole
Welds	E70XX electrode	fillet welds

The behavior of this type of connection under gravity and cyclic load has been established over the past decades (Astaneh-Asl et al. 2002). However, its performance for the progressive collapse scenario has not been established and documented thoroughly. Differences between the behavior of steel connections based on conventional design versus progressive collapse type of design have been described in a paper by the authors (Daneshvar and Driver 2010). Since available progressive collapse guidelines ask designers for robust connections that can resist a "double span" scenario, there is a necessity to investigate this issue. In this paper, challenges involved in numerical studies for simulating the performance of shear tab connections when a column has been compromised are discussed. Various factors involved in modeling for performing highly nonlinear finite element analysis are discussed and results are verified by available appropriately-selected experimental data for the column removal scenario.

Selected Experimental Study

Unfortunately, there are few experimental studies on connection behavior for progressive collapse analysis (Daneshvar and Driver 2010). Experiments conducted by Thompson (2009) have been used to verify the numerical study. A total of nine full-scale tests were carried out at the Milwaukee School of Engineering, keeping the connection depth as the sole varying factor based on AISC's conventional configuration (AISC. 2005). In Figure 2, the test setup and specimen assembly are shown.

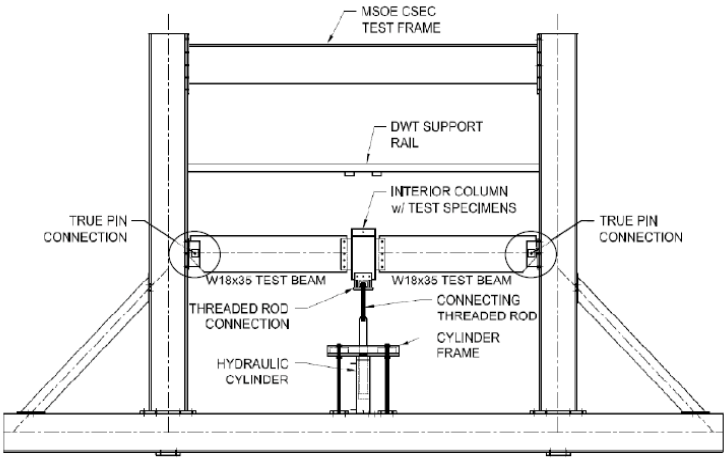

Figure 2. Test setup assembly (Thompson 2009)

The test specimen consisted of a planar two-span beam, with the beams attached to a central column stub by shear tab connections and to "true pin" connections at the far ends of the beams. A vertical displacement was applied to the central stub column in order to simulate a controlled collapse of an interior column (Thompson 2009). The main reasons that this experiment has been selected for the current research are:

- Test configuration: As shown in Figure 2, the test setup simulates a double-span scenario, as described in available progressive collapse design guidelines (e.g., DoD (2009) and GSA (2003));
- Destructive nature of the test: the assembly is pushed down to its ultimate capacity. The connection goes through large rotations, in contrast to many previous tests on the shear tab connections;
- Report of catenary force (axial force): catenary resistance is recognized as one of the main distinguishing factors in the characterization of a connection's robustness for progressive collapse prevention. It is also an alternative path for transferring loads for resisting against collapse after a column has been compromised. Catenary action is explicitly reported in the test report, which is contrary to previous tests on shear tab connections.

Modeling of Steel Connections

Abaqus/CAE (Dassault Systèmes 2009) is used for all stages in the simulation. Finite element models consist of the central column and adjacent beams, as well as the connections with complete detailing, as shown in Figure 3. Shear tabs are welded to the column flange and bolted to beam's web. Since the connection is the point of interest, all characteristic features of the connections are included in the model. The central column is pushed down, while the connection performance is monitored. Model information is summarized in Table 2.

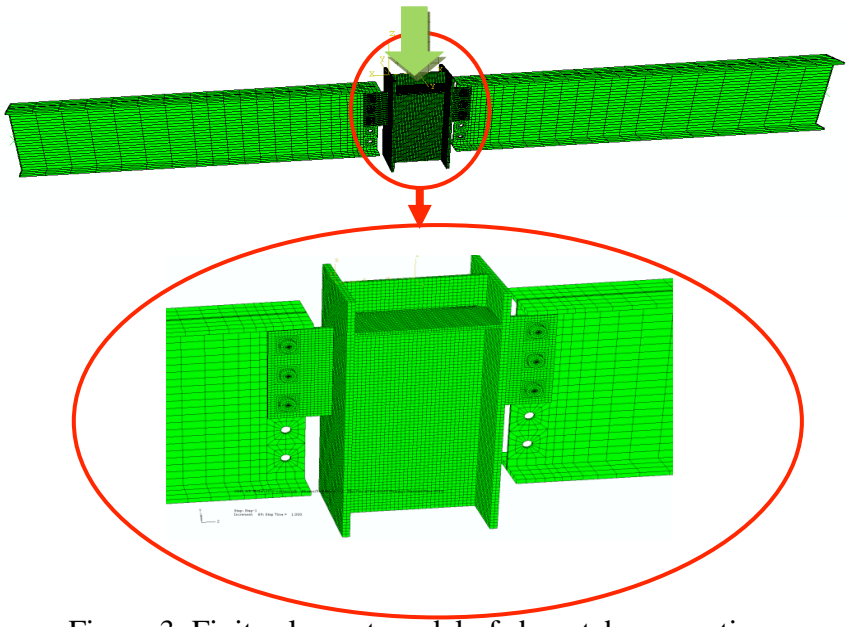

Figure 3. Finite element model of shear tab connection

Table 2. Finite element model summary

Model Summary	No.	Description
Parts	6	beam; stub column; shear tab; bolt; stiffener; rigid plane
Materials	3	A36 (shear tab); A325 (bolts); A992 (others)
Analysis Steps	2	apply pretension; apply vertical displacement
Interactions	13	refer to "boundary nonlinearity" section
Interaction Properties	1	both tangential and normal behavior included
Constraints	6	tying shear tab and stiffeners to stub column
Boundary Conditions	3	avoid out-of-plane displacement; true pin at far ends; two axial springs at far ends of the beams to simulate flexibility of the test setup

In general, the finer the mesh density, the more accurate the result. By increasing the number of elements, convergence to a unique solution can be achieved. This solution is an approximation of the physical model's response. Potential sources of error include the model's geometry, material model, boundary conditions, and loads (Dassault Systèmes 2009). In order to approach the real behavior of the physical model, performing a nonlinear simulation is necessary. Sources of nonlinearity are discussed after the sections on element selection and the mesh refinement analysis.

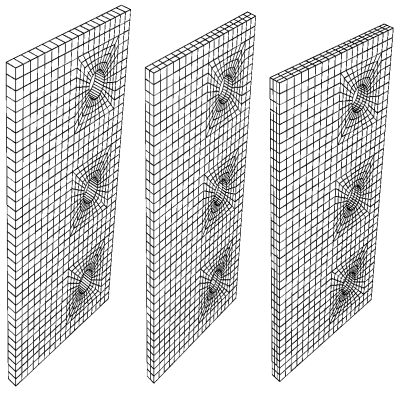
Element selection

The most comprehensive element family in finite element software is the continuum (solid) element. In this study, three-dimensional (3D) elements are adopted since the problem is 3D in nature. Some studies have established the correlation between two-dimensional and 3D modeling of steel connections (Jaspart 1997). The

incompressibility of plastic deformation in metals imposes some limitations on the types of element suitable for elastic–plastic analysis. This phenomenon may make some elements over-constrained and cause volumetric locking (Epstein and Barrett 2006). Table 3 summarises the properties of different types of continuum elements available in Abaqus.

Table 3. Element types available in Abaqus (Dassault Systèmes 2009)

Element Type	Description
First Order Elements	constant strain throughout the element that prevents mesh locking when the material is approximately incompressible
	accuracy achieved with full integration versus reduced integration depends on the nature of the problem
	recommended in cases of large strains or high strain gradients
Second Order Elements	provide higher accuracy for problems not containing contact simulations or element distortion
	better modeling geometric features, e.g., modeling a curved surface with fewer elements
	very effective in bending-dominated analysis
Reduced-integration Elements	use lower-order integration just for the element matrix, not mass and loading – No locking concern
	reduces the time of analysis, especially in 3D analysis
Full-integration Elements	may suffer from locking behavior, including both shear and volumetric locking
	volumetric locking happens when the material behavior is almost incompressible



Considering the issues mentioned in Table 2, and taking into account different factors available in the connection assembly model (e.g., presence of large strain and complex contact definition), led to the adoption of a first-order reduced-integration type of element for whole model.

Mesh convergence analysis

In order to make sure that the result of finite element simulation is adequately precise, a mesh refinement study is necessary. Increasing the mesh density leads to a unique value that represents the response of the model. Convergence is obtained when further mesh refinement causes negligible changes in the response. Basically, if the same results are produced with different meshes, it is confirmed that the solution is mathematically accurate (Dassault Systèmes 2009). For the purpose of mesh refinement analysis, the shear tab plate with three holes is isolated from the assembly,

since the main goal of the research is to determine the behavior of the shear tab. Besides, preliminary analyses and experimental evidence show that most of the nonlinear behavior is accumulated in the shear tab region. Instead of including complex bolt–plate interactions, distributed pressure over the bottom half of the holes is considered in order to load the model. In reality, the pressure magnitude varies around the hole circumference, but it is assumed to be uniform. In this study, the influences of mesh density across the thickness of the plate (Figure 4) and mesh density around the holes (Figure 5) are investigated for three particular results: maximum von Mises stress where the shear tab is attached to the stub column (assumed to be fixed), maximum von Mises stress on the bottom surface of the top hole, and vertical displacement of the bottom of the top hole. The results for these two mesh refinement studies are summarized in Tables 4 and 5, respectively.

It is observed that the "normal" mesh density is adequate for both cases, either refining through the thickness or around the hole. There is no considerable advantage in terms of more accurate results that can be obtained using the fine mesh. Besides, the time of analysis would nearly double without getting significant improvements in the results. Although the normal mesh is deemed to be sufficient, appropriate relative mesh density of different parts in the assembly is a big challenge when contact exists. Master and slave surfaces should be defined with respect to associated mesh density.

Sources of Nonlinearity

It is necessary to perform nonlinear analysis since the behavior of each component of the connection individually is highly nonlinear, as is the behavior of the whole assembly as a system. All three sources of nonlinearity that are common in structural simulations exist in connection modeling for progressive collapse, including material nonlinearity, geometric nonlinearity, and boundary nonlinearity.

Material nonlinearity

True strain and true stress must be used when plasticity data are being defined in Abaqus. However, most available generic material behavior is in the form of nominal, or engineering, stress versus strain. In order to convert nominal values to true ones, the incompressibility of plastic deformations are taken into account. The conversions are as follows:

$$\sigma_{true} = \sigma_{nom}\,(1 + \varepsilon_{nom})$$

$$\varepsilon_{true} = \ln(1 + \varepsilon_{nom})$$

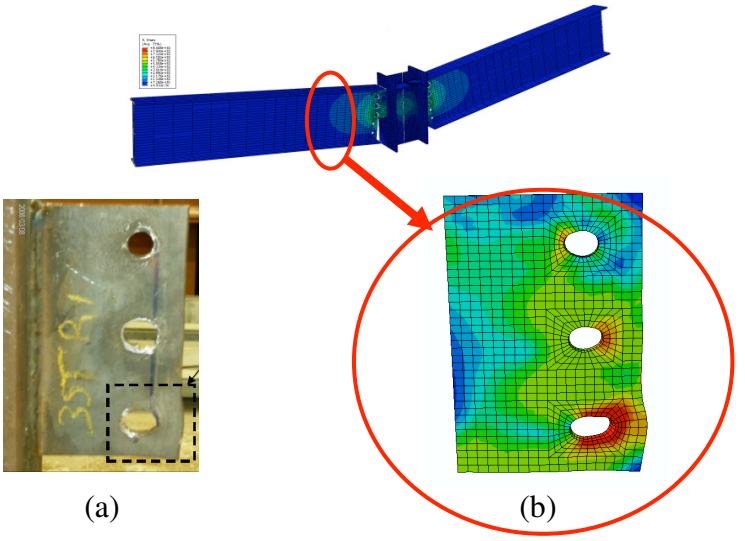
These equations are valid prior to necking. The strains provided in material test data are the total strains. In order to define the plastic strains, it is necessary to decompose these values into elastic and plastic strain components. Linear interpolation is used

between the data points provided in order to obtain the overall material response. Abaqus assumes a constant stress response outside the range of data provided (Dassault Systèmes 2009).

Geometric nonlinearity

For many structural applications, it is necessary to write the equilibrium equations based on the deformed structure. If loading on the structure causes large deformations, nonlinearity in geometry is involved and superposition cannot be applied. Due to the presence of large deformation in the model under investigation, geometric nonlinearity must be included.

Boundary nonlinearity (contact)



Connection modeling involves contact simulations of different components, allowing transmission of force from one part to another. The mere physical proximity of two surfaces in the connection assembly is not enough for contact definition. Contact behavior is highly nonlinear and causes large and instantaneous changes in the behavior of the assembly. The analysis should detect when the surfaces are separated or in contact in order to apply contact constraint correctly. Contact simulations in Abaqus can be surface-based or element-based. Surface-based contact can be general (automatic) or a contact-pair algorithm (Dassault Systèmes 2009). General contact definitions are highly automated; hence, in models like connections that are complex in terms of the number of interactions, they do not usually lead to a converged solution. Contact-pair algorithms are recommended, although they require more effort in terms of pre-processing. There are a total of six contact pairs in the shear tab connection model: bolt head and shear tab, bolt shank and shear tab, bolt shank and beam web, bolt's nut and beam web, shear tab and beam web, and shear tab and column flange. The "tie constraint" is used to model the last aforementioned contact assuming the welding is flawless.

Relative sliding of the connection's components interacting with each other is another important phenomenon that needs to be included in the model. Abaqus uses two different analysis methods to deal with this phenomenon: small sliding and finite sliding. "Small sliding" is less computationally expensive, but sliding must not exceed a fraction of a typical element dimension (Dassault Systèmes 2009). In the column-removal connection modeling scenario, sliding can be much more than what is assumed to be acceptable in for "small sliding", so the "finite sliding" method must be applied. For tangential behavior, a penalty formulation with a friction coefficient of 0.3 has been used. For normal behavior, a hard-contact formulation with a penalty constraint enforcement method is applied. Nonlinear stiffness behavior has been incorporated and all related parameters are calibrated with experimental data.

Analysis Results

Three tests were carried out on three-bolt shear tab connections (Thompson 2009). Each test produced results for two identical shear tab connections, although their responses might be different. Therefore, six different responses from experiments are available for comparison. The deformed shape of the overall test assembly and a direct comparison of the shear tab deformations observed in the model and the

experiment are shown in Figure 6. It can be seen that there is close similarity between the experiment and the numerical simulation results. Plastic deformation is mostly accumulated around the bottom hole where the failure begins. Besides, the ductility of the system is mostly provided by bearing deformation developed around the holes.

(a) (b)

Figure 6. Deformed shapes of assembly: (a) Shear tab from experiment (Thompson 2009); (b) Shear tab from finite element simulation.

The internal forces—including shear, axial force, and moment—at the bolt line location versus chord rotation of the connection assembly are shown in Figures 7 to 9. The dashed lines and solid lines represent the results of the experiments and simulations, respectively. Figures 7 and 9 verify the simulated model based on acceptable coincidence with the associated experimental results. Based on previous research, the maximum value of rotational demand on a shear connection under gravity load is about 0.03 radians. The maximum rotational demand due to seismic loading is approximately 0.05 radians (Astaneh-Asl 2005). Even the accumulative effect of both gravity and seismic forces is approximately 0.08 radians, which is much smaller than the rotational demand in the column removal scenario.

Figure 8 shows a discrepancy between the experimental and numerical results due to the presence of compression in the finite element curve. Formation of catenary action in the connection assembly is highly dependent on the boundary condition of the test assembly. In other words, the external axial restraint provided by the test setup is very influential on the axial response of the connection as the system goes through large displacements. The precise amount of this external restraint is unknown.

The external restraint provided to the beam and column-stub assembly by the surrounding frame is simulated by axial springs at the far ends of the beams, as mentioned in Table 2. Figure 10 shows the axial response of the connection with different spring stiffnesses. As the stiffness reduces, the compressive force decreases as well. Further study is needed to characterise the influence of support flexibility on the catenary behaviour of shear tab connections under the column removal scenario. Moreover, non-linear springs may be required to achieve an accurate axial response.

Conclusion

The following conclusions can be drawn from the finite element study presented:

- Finite element modeling can be used as an accurate tool to mimic the response of steel connections such as shear tabs in the column removal scenario.

- Nonlinearity definitions, including material, geometric, and boundary (contact) nonlinearities, are the most challenging part of finite element modeling of connections.

- External restraint can influence the catenary behavior of shear tab connections considerably. Axially rigid restraint of the system leads to the development of significant compressive forces before the formation of tensile action. Tensile catenary forces can be counted as an alternative path load when moment resistance has vanished.

- The resulting response curves can be used as input for shear tab connection models in full-building progressive collapse analyses.

Effect of Regular Perforation Patterns on Steel Plate Shear Wall Column Demands

Abstract

Several methods have been proposed to reduce the moment and axial force demands on the columns of steel plate shear walls. One such method is to reduce the strength of the infill plate by introducing a regular pattern of perforations in the form of circular holes. The decrease in shear strength of the system depends on the diameter of the holes and their centre-to-centre distance. It was found using a variety of finite element models that although introducing the perforations may reduce the lateral strength of the system, the total demand on the columns can in some cases actually increase. Also, the perforated system is sensitive to the pattern of holes selected in that a small change in the arrangement of the holes can have a significant effect on the moment demand on the columns. Moreover, the flexibility of the beam-to-column connections affects the column demands considerably and also influences the sensitivity of the column design forces to the pattern of holes selected. An appropriate design method is proposed and the suitability of this system is summarized.

Introduction

Experimental and numerical studies on steel plate shear walls (SPSWs) have shown that they constitute an excellent lateral force resisting system that is characterized by high shear strength and outstanding ductility and redundancy. The high inherent shear strength of the system often results in very thin infill plates being required when using steel grades commonly available in North America. In this common case, handling and welding considerations tend to govern the selection of the infill plate thickness, potentially resulting in a large panel over-strength that leads to excessive demands on the columns under capacity design. This increased demand can have a severe negative impact on the economic competitiveness of the system.

Several methods have been proposed to reduce the moment and axial force demands on the columns of SPSWs arising from the selection of infill plates that are thicker than required to resist the design story shear. These methods can be classified into

two groups. In the first group, the share of the column demands arising from the effect of frame action is reduced by using semi-rigid beam-to-column connections, using reduced beam sections at rigid beam-to-column connections, and/or using a horizontal strut at the mid-height of each story. In the second group, the share of the column demands arising from the effect of tension field action in the infill plates is reduced by decreasing the strength of the infill plates. The use of light-gauge cold-rolled or low yield point steel for the infill plates is one method. The other method is to reduce the strength of the infill plate by introducing a regular pattern of perforations in the form of circular holes. In the latter method, the decrease in shear strength of the system depends on the diameter of the holes and their centre-to-centre distance. It has been intuitively assumed that there is a direct correlation between the reduction of lateral strength of the wall associated with the perforations and the reduction in column demand. In this study, the focus is on the demands on the columns of SPSWs with regular perforation patterns in their infill plates.

Target displacement evaluation

This paper aims to investigate the lateral performance of SPSWs with perforations by comparing them with similar SPSW systems with no perforations in their infill plates. In order to compare the two systems, criteria are needed to make this comparison possible. Most recent studies on SPSW systems have used the capacity design approach as the design method and possibly also for performance checks. However, this method has some shortcomings for seismic design in low and moderate seismic regions, since it can result in very high level design forces that may not occur in the systems in these regions. The capacity design approach is a strength-based method and does not provide any information regarding the lateral deformation of the system when it is under the effect of the design earthquake. Moreover, it cannot be used when different performance objectives are to be satisfied for different seismic hazard levels.

On the other hand, the performance-based design method eliminates the shortcomings mentioned above. In this method, the performance objectives define the status of the building following a design earthquake that represents a desired seismic hazard level. Hence, this method provides a design procedure that allows for the design of lateral force resisting systems for different performance objectives under different seismic hazard levels.

In performance-based design, the target displacement, which is the maximum roof displacement under the design earthquake, δ_r, must be evaluated. Based on the Coefficient Method, the target displacement, δ_t, can be approximated as follows, in terms of the fundamental natural mode of vibration in the direction under consideration:

$$\delta_t = \delta_r = \Phi_{1,r}\, \Gamma_1\, S_d(T_{1e}, \xi_1)\, \psi \qquad (1)$$

where $\varphi_{1,r}$ is the deflection value at the roof level for the fundamental mode shape (which is equal to unity for a normalized mode shape), Γ_1 is the modal mass participation factor for the fundamental mode, $S_d(T_{1e},\xi_1)$ is the spectral displacement at the effective fundamental period (T_{1e}) and its corresponding critical damping ratio (ξ_1) in the direction under consideration, and ψ is a correction factor that takes into account the effects of nonlinear response on the maximum lateral deformation of the system.

The effective fundamental period is the fundamental period of the system, modified to account for yielding in the system (based on the idealized pushover curve) and can be evaluated from $T_{1e} = T_1\sqrt{K_i/K_e}$, where T_1 is the fundamental period, K_i is the elastic lateral stiffness and K_e is the effective lateral stiffness, which is a secant stiffness calculated at a base shear force of 60% of the effective yield strength of the system.

The correction factor ψ takes into account the effects of yielding (coefficient C_1) and pinched hysteresis cycles and cyclic strength and stiffness degradation (coefficient C_2) of the system on the maximum lateral displacement of the system. ASCE 41-06 (2007) defines this correction factor as the product of two factors as follows:

$$\psi = C_1 * C_2 = \left[1 + \frac{R_d - 1}{aT_{1e}^2}\right] * \left[1 + \frac{1}{800}\left(\frac{R_d - 1}{T_{1e}}\right)^2\right] \qquad (2)$$

where a is a site class factor, which is 60 for Site Class D. The correction factors C_1 and C_2 may be selected as unity for periods greater than 1.0 s and 0.7 s, respectively. Also, for systems with no degradation of stiffness and strength, the C_2 coefficient can be selected as 1.0. R_d is the ductility-related force modification factor, as defined in the National Building Code of Canada (NBCC 2005) and FEMA 450 (NEHRP 2004), and is a measure of the extent of nonlinearity in the system. This factor represents the capability of the system to dissipate energy through nonlinear behaviour, and can be defined as the ratio of elastic base shear demand to yield strength of the system.

Normally, for a given design case, the spectral displacement, S_d, for the effective fundamental mode of vibration is evaluated based on following equation:

$$S_d(T_{1e},\xi_1) = S_a(T_{1e},\xi_1)\, g \left(\frac{T_{1e}}{2\pi}\right)^2$$

where S_a is the design spectral acceleration for the effective fundamental period and critical damping ratio of the structure in the direction considered. However, this method is site dependant (depends on seismic hazard and site class at each location) and is not appropriate for general comparisons of different systems. In this study, a standardized seismic hazard independent target displacement has been proposed as a method of comparing different systems. Considering a multi-degree of freedom system designed for a base shear level V_D under monotonically increasing lateral loading, the pushover curve (roof displacement vs. base shear) is similar to Figure 1.

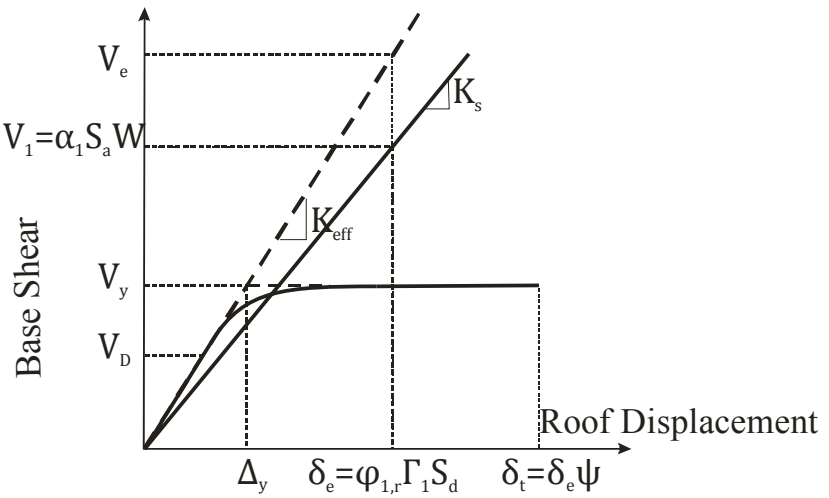

Figure 1. Pushover curve of a general MDOF system.

ASCE 41-06 (2007) defines R_d as the strength ratio of V_1 to V_y, where V_y is the effective yield strength of the system, $\alpha_1 = M_{e1}/M$ is effective mass ratio of the fundamental mode, and M_{e1} and M are the modal effective mass and total seismic mass of the system, respectively. However, defining R_d as this strength ratio does not guarantee that the displacement ratio will be proportional to the stiffness K_{eff} (Figure 1). In this study, R_d is defined as the strength ratio so that the effective stiffness of the system is maintained:

$$R_d = \frac{V_e}{V_y} = \frac{\Phi_{1,r}\Gamma_1 S_d}{\Delta_y} \quad (3)$$

Substituting Equations (2) and (3) into (1), the following equations for target displacement and ductility ratio at the target displacement are obtained:

$$\delta_t = R_d \Delta_y [C_1 C_2] \quad (4)$$

$$\mu_t = \frac{\delta_t}{\Delta_y} = R_d [C_1 C_2] \quad (5)$$

where C_1 and C_2 are defined in Equation (2). Defining R_d based on ASCE 41-06 leads to the following equation for the ductility ratio $\mu_t = [R_d \Gamma_1/\alpha_1][C_1 C_2]$, which yields about 80% larger values for the target displacement. (For a typical SPSW system, the values of Γ_1 and α_1 are fairly constant and can be selected as 1.32 and 0.72, respectively, which makes the coefficient Γ_1/α_1 equal to $1.83 \approx 1.80$).

Equation (5) defines the ductility ratio mainly as a function of R_d. In this study, for any desired level of ductility-related force modification factor, the target displacement is evaluated from Equation (4) and then the performance of the wall has been studied for the ductility ratio obtained from Equation (5).

Numerical Model of Steel Plate Shear Wall System

In order to study the performance of different SPSW systems under pushover analyses and seismic records, a system that was tested previously and proved to have very good response under cyclic loading has been selected and studied. The system is a four-story SPSW (Driver et al. 1997) that was tested under vertical load concurrent with increasing cyclic lateral displacement. The columns were spaced at 3.05 m centre-to-centre and the story height was 1.83 m for the top three story and 1.93 m for the first story. The columns were W310×118 sections, the intermediate beams were W310×60 sections, and the top beam was a W530×82 section. All cross-sections are Class 1 based on S16 (CSA 2009) (or compact based on AISC 360 (AISC 2005)), and they satisfy the stiffness requirements for boundary members of SPSWs (ω_h and ω_L requirements (CSA 2009)). The mean measured infill plate thicknesses were 4.54 mm, 4.65 mm, 3.35 mm, and 3.40 mm, respectively, for stories 1 (base) to 4 (top). Moment connections were used at the beam-to-column joints and all the materials were hot-rolled steel. In the early stages of the experiment, force control was used to control the test, and after achieving the yield lateral displacement for the first story, δ_y, the experiment switched to the displacement control method. Three full cycles were conducted at each deformation stage up to a deformation of $3\delta_y$, and two cycles were used at each deformation step afterward. The system achieved its maximum lateral strength at $5\delta_y$ and its lateral resistance then declined gradually to about 85% of the maximum value at $9\delta_y$. The roof lateral displacement at yield, maximum base shear, and maximum lateral deformation occurred at 32.0 mm, 92.5 mm, and 158 mm, respectively.

The commercial general-purpose finite element code ABAQUS is selected to model this wall. In order to verify the model, first the wall is analysed under the same loading conditions as those used in the experiment. As-built dimensions are used; however, the fish plates are not modelled and the infill plates are connected to the surrounding boundary elements. All infill plates of the wall are modelled using four-node shell elements with reduced integration (S4R element), and frame elements (beams and columns) are modelled using two-node linear beam elements (B31). Material and geometric nonlinearities are both considered. The measured material properties for the beams, columns, and infill plates are used. The von Mises yield criterion, along with the isotropic hardening rule for monotonic loading and kinematic hardening rule for dynamic loading, is used. The effect of residual stresses in the frame members is not considered in the analyses.

The story shear versus story deflection relationships of panel 1 (base) from the analyses are compared with the experimental results in Figure 2. Figure 2(a) shows the response under monotonic loading, where it can be seen that the model provides acceptable results up to the ultimate strength. However, it over-predicts the strength slightly at the early stage of yielding, which is mainly because the monotonic analysis disregards the effect of softening of material due to the cyclic nature of the loading applied to the test specimen. Also, the model does not account for the gradual

degradation of strength exhibited by the test specimen after a story drift of 5δy (lateral displacement 42.5 mm) because the local buckling of the column section and material failure due to tearing of the infill plate are not included in the model.

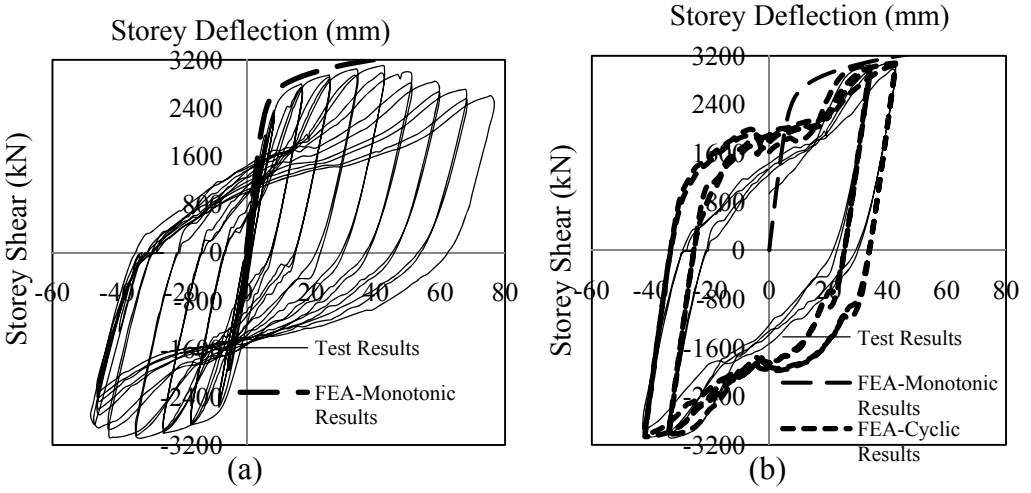

Figure 2. Comparison of test results for panel 1 with FEA results:
(a) Monotonic loading; (b) Cyclic loading.

Figure 2(b) compares experimental results with the cyclic loading analysis results for two excursions at 4δy and two excursions at 5δy. The ultimate load is accurately predicted by the model at each displacement level and even at each excursion. Also, the model predicts the loading and unloading stiffnesses and the deflection at which the tension field in the panel becomes effective well. However, it over-predicts the shear strength of the panel slightly around the zero-displacement regions. In general, the model predicts the monotonic and cyclic responses of the system up to ultimate strength very well and a similar model is used for the pushover analysis discussed in the next section.

Steel plate shear wall systems investigated

In this study, three different steel plate shear wall systems have been considered. Wall A1, shown in Figure 3(a), is the SPSW tested by Driver at al. (1997) and studied in the previous section numerically. Wall A2 is similar to Wall A1, but with simple shear beam-to column connections.

Figure 3(b) shows Wall B1, for which all the properties are similar to Wall A1 except that it contains a regular perforation pattern in all four panels, as permitted by CSA standard S16 (CSA 2009). There are 23 holes in panels 1, 2 and 3, and 18 holes in panel 4. Wall C1, shown in Figure 3(c), is the same as Wall B1, but with a different arrangement of holes; there are 22 holes in panels 1, 2 and 3, and 18 holes in panel 4. Walls B2 and C2 are the same as Walls B1 and C1, respectively, but with simple shear beam-to-column connections.

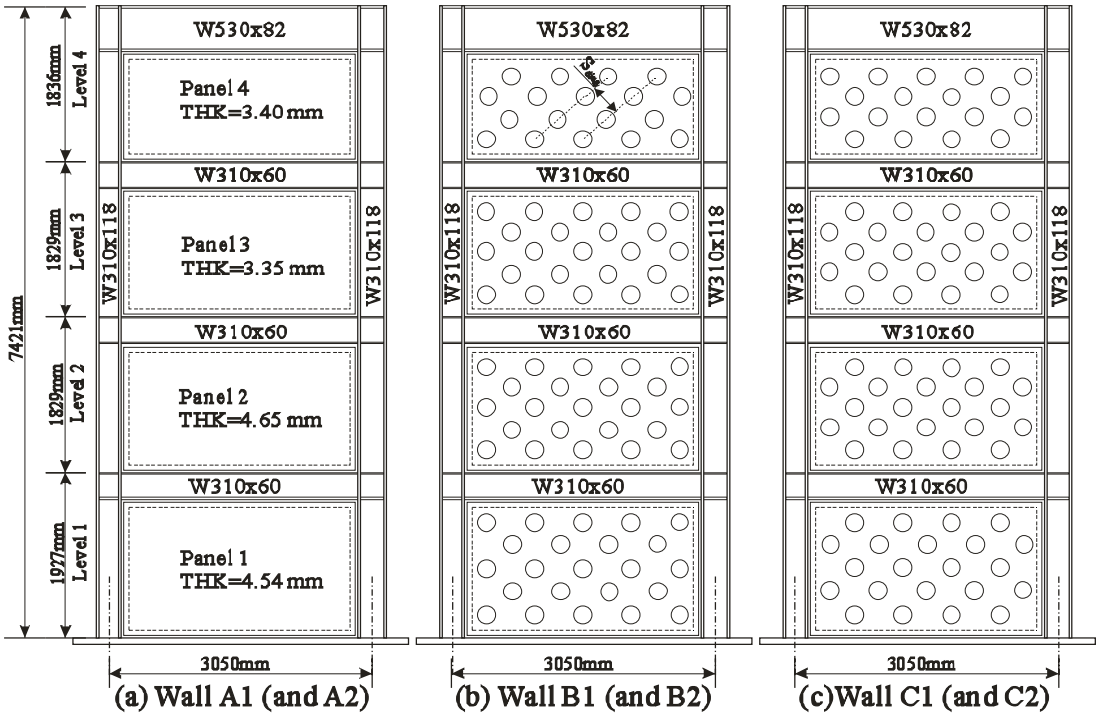

Figure 3. Different systems of SPSWs.

In all perforated walls, the holes are of equal diameter (D = 230 mm) and regularly spaced vertically and horizontally (at a distance of 280 mm) over the entire area of the infill plates. The regular grid of staggered holes allows the development of a diagonal tension field at 45°. The shortest centre-to-center distance between perforations is S_{diag} = 396 mm, which makes the ratio of $D/S_{diag} = 0.58 < 0.6$. The distance between the first hole and surrounding frame members is between D = 230 mm and D+0.7 S_{diag} = 507 mm. Hence, the two perforation patterns satisfy all the requirements of clause 27.9.2.3 of CSA S16-09 for perforated infill plates. Thus, based on this clause, the factored shear resistance of the perforated wall is equal to that of a conventional SPSW times the reduction factor $1-0.7D/S_{diag}$, which for the patterns selected is equal to 0.6.

Performance criteria

Each action is classified as deformation-controlled (ductile) or force-controlled (non-ductile), and all components of each SPSW are primary components (ASCE 2007). When a nonlinear procedure is used, the component capacity for deformation-controlled actions is taken as the permissible inelastic deformation limit considering all coexisting forces and deformations (defined in chapter 5 of the standard, and usually expressed in term of the yield displacement). Conversely, the component capacity for force-controlled actions is taken as the lower-bound strength, evaluated by code design equations and using lower-bound material properties and a strength reduction factor equal to unity.

Flexure of beams is considered to be a deformation-controlled action. Axial compression of columns is considered a force-controlled action, with the lower-bound axial compression capacity P_{CL}. Flexural loading of columns with an axial load at the target displacement less than $0.5P_{CL}$ is considered deformation-controlled. For greater axial loads, it is considered force-controlled. Steel columns subjected to axial tension or combined axial tension and bending moment are considered deformation-controlled. Walls A1, B1, and C1 all use fully restrained moment connections, while Walls A2, B2, and C2 use partially restrained moment connections.

When the criteria of ASCE 41-06 (2007) are used for new buildings, slightly higher than life safety performance levels for a BSE-1 hazard level are needed in order to achieve a system comparable with a similar system designed based on design codes.

Pushover analysis results

In the pushover analyses, a uniform lateral load distribution pattern is used and the effects of gravity loads are considered on the columns of each wall. The pushover curves for all SPSWs investigated are shown in Figure 4. The difference in the curves of Wall A1 and Wall B1 or C1 indicates that the proposed reduction factor based on S16-09 (2009), $1\text{-}0.7*D/S_{diag} \approx 0.6$, provides a conservative evaluation for shear resistance of the perforated walls.

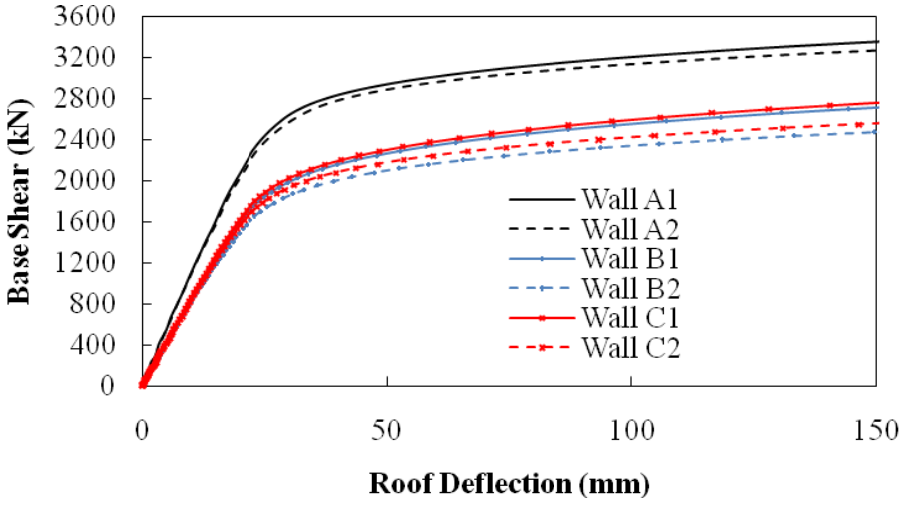

Figure 4. Pushover curves of the SPSW systems.

Previous research has shown that the demand on columns of SPSWs is complex and notably large. Column shear, moment, and axial force demands result from the frame action of the boundary frame and tension field action in the infill plates. The level of the demand depends on the geometry of the system (such as bay width and story height, number of stories, thickness of the infill plate), type of beam-to-column connection (rigid, semi-rigid, and simple), and mechanical properties of the material (especially the infill plate), and can be extremely high in the capacity design method.

In order to design robust and reliable SPSW systems, they should be studied in the context of performance-based design rather than capacity design. In this way, by assuming a desired level of R_d, the target displacement is evaluated from Equation (4). The appropriate values for R_d could be 2, 3.5, and 5, which correspond to limited-ductility (or ordinary), moderate-ductility (or intermediate), and ductile (or special) SPSWs, respectively. At the target displacement, members under deformation-controlled actions must have an expected deformation capacity not less than the maximum deformation demand, and members under force-controlled actions must have a lower-bound strength not less than the maximum force demand.

The axial load and moment internal force demands of both columns of the different walls for $R_d = 2$ and 5, are shown in Figures 5 and 6, respectively. For each level of strength ductility factor, (while the base shear is different) the target displacement for each wall is essentially the same and is equal to 54 mm and 140 mm, for R_d equal to 2 and 5, respectively. Based on the test results (Driver et al. 1997) the 54 mm roof displacement is between the Immediate Occupancy and Life Safety performance levels, and the roof displacement of 140 mm is larger than the Collapse Prevention performance level. As can be seen from Figures 5(a), 5(c), 6(a), and 6(c), the axial force demands for the perforated walls are less than for the solid walls. However, Figures 5(b), 5(d), 6(b), and 6(d) show that the column moment demands for the perforated walls for all connection types tend to be larger than for the solid walls. Also, these figures show that although the difference between Walls B and C are apparently minor, the difference in moment demand is considerable in some regions, suggesting an inherent uncertainty in the response of the perforated SPSWs.

The reason for the higher moment demand is attributed to the fact that the perforated infill plate causes the frame action in the SPSW to increase, since much of the increased demand is located in the connection regions. All in all, the column design demands for perforated walls may be increased in some cases, which is in contrast with the main idea behind the development of the system.

In order to study the actual change in the column demands, design equations are used that take into account the interaction of axial compression and moment. Table 1 shows the compression force–moment interaction results for $R_d = 2$ based on both S16-09 (2009) and AISC 360-05 (2005). The strength ratios presented are the maximum of cross-sectional strength, overall in-plane member strength, and lateral-torsional buckling strength, which in almost all cases is that of the cross-sectional strength. The first two stories of the left columns are subjected to tension loads and they are considered as fully deformation-controlled elements. Also, for the first two stories of the right columns, some of the beam-column strength ratios are greater than 1.0. The reason is attributed to the fact that the design equations are a conservative approximation of true capacities, and also the material models consider strain hardening, while all the interaction equations are checked using yield values. The results show that the perforations increase the interaction values in the upper stories and in the lower stories the improvement is mostly negligible.

Table 2 shows the deformation ductility ratios for $R_d = 2$. For the first two stories of the left columns, which are subjected to tension, the axial ductility ratios are shown. Also, all columns with an axial compressive force at the target displacement that exceeds 50 % of the lower-bound axial compressive strength are considered force-controlled for both axial load and flexure, and are identified in the table by the symbol FC. The results show that the perforations provide limited improvements to the performance of deformation-controlled elements.

Conclusion

In this paper, a standardized method has been presented to evaluate the target displacement of any lateral force resisting system in terms of the yield displacement of the system and the ductility-related force modification factor, R_d. Also, it provides a suitable method for comparing different systems with the same value of R_d.

Perforated SPSWs were introduced to alleviate the severe force demands on the columns of SPSWs by degrading the lateral shear resistance of the system. This study has shown that although the perforations reduce the shear capacity of the infill plate considerably, they may not reduce the force demands on the columns, especially at the upper stories where the perforations makes the design strength ratios worse.

ABSTRACT

One of the critical factors affecting the strength of steel columns at elevated temperatures is the influence of material creep. Under fire conditions, steel columns can exhibit creep buckling, a phenomenon in which the critical buckling load for a column depends not only on slenderness and temperature, but also on the duration of applied load. Although material creep and consequently the phenomenon of creep buckling can significantly impact the safety of steel columns subjected to fire, they have received relatively little research attention, and are not currently explicitly considered in code-based design formula for columns at elevated temperatures, such as those in the Eurocode 3 or in the AISC Specification.

This paper will propose a preliminary methodology to study the phenomenon of creep buckling in steel columns subjected to fire. Preliminary analytical solutions are presented, and compared with computational predictions for creep buckling. The analytical and computational results clearly indicate that accurate knowledge of material creep is essential in studying creep buckling phenomenon at elevated temperatures. In addition, the results show that neglecting creep effects can lead to erroneous and potentially unsafe predictions of the strength of steel columns subjected to fire.

INTRODUCTION

The essence of performance-based structural fire safety design of steel building structures is the ability to predict thermal and structural response to fire. An important aspect of such predictions is the ability to evaluate strength of columns at elevated temperatures. Columns are critical structural elements, and failure of columns can lead to collapse of a structure. One of the critical factors affecting the strength of steel columns at elevated temperatures is the influence of material creep. Under fire conditions, steel columns can exhibit creep buckling, a phenomenon in which the critical buckling load for a column depends not only on slenderness and temperature,

but also on duration of applied load. This paper presents some results of an on-going research on the phenomenon of high-temperature creep buckling of steel columns.

Creep of Steel at Elevated Temperatures

The term creep refers to time-dependent strain response of materials, or more generally to time- and rate-dependent stress-strain response. At normal temperatures, the stress-strain response of steel shows only a very mild dependence on loading rate, for typical loading rates seen in buildings. Yield stress variations on the order of 10-percent are possible as loading rates are varied (Galambos 1998). Although showing mild rate dependence, steel shows virtually no time-dependent strain (i.e., creep strain) at normal temperatures, and creep effects are normally neglected in the analysis and design of steel structures at normal temperatures. However, as temperature increases, steel exhibits increasingly significant creep effects. The temperature of structural steel members in a building fire can vary widely. However, as a point of reference, unprotected steel in building fires can reach temperatures on the order of 1000 °C (Buchanan 2002). Steel protected with insulation ("fireproofing") can reach temperatures of 550 °C (Buchanan 2002). At these temperatures, the effects of creep on the response of structural steel can be very significant. Creep tests on materials are commonly conducted by subjecting the material to constant stress and temperature, and then measuring strain (creep strain) as a function of time. A typical creep strain versus time curve is shown in Figure 1. This curve is often divided into the three phases of primary, secondary and tertiary creep. In the primary stage, the curve is nonlinear and typically exhibits a decreasing creep strain rate with increase in time. In the secondary stage, the creep strain rate is almost constant, and this stage is often referred to as steady-state creep. In the tertiary stage, the creep strain rate increases with time. For steel, the shape of the curve, the magnitude of the creep strain, and the time scale are highly dependent on temperature and stress levels.

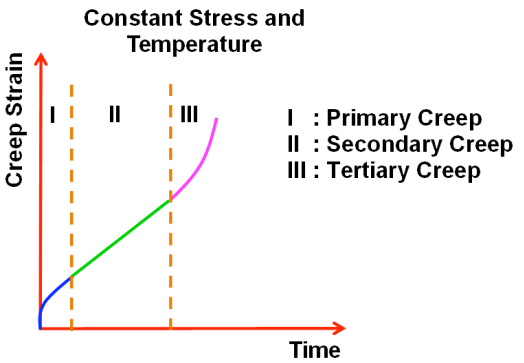

Figure 1. Typical creep strain versus time response under constant stress and temperature.

The creep behavior of steel at elevated temperatures has been studied and reported by several researchers (Norton 1929, Bailey 1930, Dorn 1954, Harmathy 1967, Knight, Skinner and Lay 1971, Williams-Leir 1983, Fields and Fields 1989, and

Luecke et al 2005). One of the simplest and most widely used creep models is the Norton-Bailey model, also known as creep power law (Norton 1929, and Bailey 1930). It should be noted that although the Norton-Bailey law is capable of modeling primary creep, it can define the steady-state or secondary stage of creep more accurately. One of the widely used creep models in structural-fire applications proposed by Fields and Fields (1989) incorporates a power law and represents creep strain, ε_c, in the form of a Norton-Bailey equation as follows:

$$\varepsilon_c = a\, t^b\, \sigma^c \tag{1}$$

In this equation, t is time and σ is stress. The parameters A, B and C are temperature-dependent material properties. Fields and Fields (1989) derived equations for these temperature-dependent material properties for ASTM A36 steel. As a result, the creep model developed by Fields and Fields (1989) were used by NIST in their analysis of the WTC 1 and 2 collapses (NIST 2005). The model developed by Fields and Fields (1989) is capable of predicting creep in the temperature range of 350 °C to 600 °C and for creep strains up to 6-percent. For initial studies of creep buckling of steel columns at elevated temperature, one of the creep models used by the authors was the Fields and Fields (1989) model. The application of this creep model together with observations will be discussed in more detail in the following sections of this paper.

Another creep model used by the authors in their study of creep buckling phenomenon at high temperatures is the one developed by Harmathy (1967). Harmathy (1967) appears to be one of the first investigators who attempted at developing creep formula for structural steels subjected to fire exposure. Harmathy proposed a creep model based on experiments on several structural and prestressing steels including ASTM A36. His model attempts to predict creep strains in both the primary and secondary stages of creep. The model proposed by Harmathy represents creep strain, ε_c, for steel as follows:

$$\varepsilon_c \approx \left(3Z\varepsilon_{c_0}{}^2\right)^{\frac{1}{3}}\theta^{\frac{1}{3}} + Z\theta \quad \text{when} \quad \frac{d\sigma}{dt} = 0 \tag{2}$$

In this equation, θ is the temperature-compensated time in Dorn's creep theory, Z is the slope of the secondary part of the creep curve, also known as the Zener-Hollomon parameter (Zener and Hollomon 1967), and ε_{c0} is the intercept obtained by extending the straight-line section (secondary part) of the $\varepsilon_c(\theta)$ curve to the ε_c axis. The parameters ε_{c_0}, and Z are stress-dependent material parameters.

Although models developed by Fields and Fields (1989) and Harmathy (1967) are referenced by many investigators in the field of structural-fire engineering, their predictions of creep strain for some applied stress levels and temperatures are quite different. As an example, predictions from these two models for ASTM A36 steel are compared and plotted in Figure 2 for an applied stress of 23 ksi at 500 °C. As can be observed from this plot, the differences in the two models are significant. This difference in creep predictions and its impact on creep buckling behavior will be discussed in the following sections and emphasized throughout this paper.

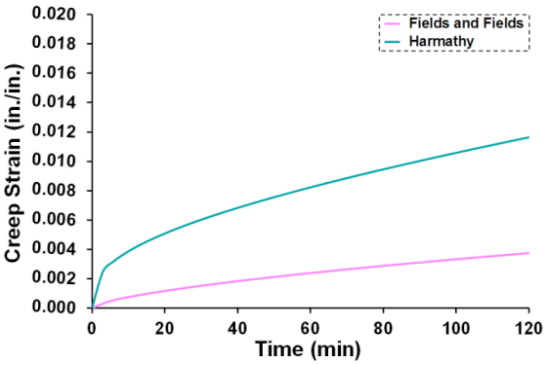

Figure 2. Comparison between Fields and Fields (1989) and Harmathy (1967) models at 23 ksi and 500 °C.

Creep Buckling of Steel Columns at Elevated Temperatures

The term *creep buckling*, as used herein, refers to the phenomenon in which the critical buckling stress for a column depends not only on slenderness and temperature of the column, but also on the duration of the applied load. The concept of creep buckling is illustrated qualitatively in Figure 3. This figure plots buckling stress for a steel column of given effective slenderness KL/r, for different temperatures. Temperature T_1 represents room temperature, for which creep effects are not significant. In this case, the buckling stress is independent of the duration of applied load.

As temperature increases, the initial buckling load (at time zero) decreases, due to the decrease in material strength, modulus and proportional limit. Consequently, the buckling capacity at initial application of load depends only on temperature. This phenomenon has been studied by a number of past investigators. But, as temperature increases and material creep becomes significant, the buckling stress depends not only on temperature, but also on the duration of load application. Thus, in a fire scenario, initially a column at elevated temperature may be safely carrying its load. However, after a period of time, even though the load and temperature have not changed, the column may buckle. This time-dependent creep buckling phenomenon has seen only very limited study in structural-fire engineering research, but is potentially of great importance.

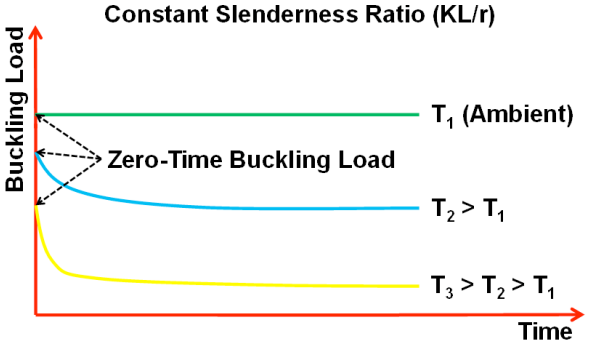

Figure 3. Qualitative representation of creep buckling.

Freudenthal (1946) was one of the first researchers who attempted to solve creep buckling analytically. One year later, Marin (1947) suggested an analytical model to predict creep deflections in columns. Shanley (1952) studied creep buckling behavior of columns for aircraft applications and came up with a model based on the concept of *time-dependent tangent modulus*. A complete account of creep buckling testing programs in the fifties and sixties is provided by Singer, Arbocz, and Weller (2002). Hoff (1957), and Eggwertez (1976) did early work on the effect of creep on high-temperature behavior of steel columns. More recently, Tan et al. (2002) incorporating Harmathy's creep model, developed a finite element program to study the buckling of steel columns at elevated temperatures.

To better evaluate the potential importance of creep buckling in structural-fire engineering applications, preliminary creep buckling analyses have been conducted by the authors. These analyses, analytical and computational, attempt to predict the elevated-temperature creep buckling strength of simply supported steel columns. For these analyses, a W12×120 section made of A36 steel is considered for both the analytical and numerical studies. Moreover, the effective slenderness ratio is kept constant by considering only one single column length of 240 inches.

For the analytical creep buckling studies, the creep buckling model proposed by Rabotnov and Shesterikov (1957) is utilized, along with the creep material models developed by Harmathy (1967) and by Fields and Fields (1989), both for ASTM A36 steel. It should be noted that the model by Rabotnov and Shesterikov (1957) has been adopted, after a fairly comprehensive review of the literature on creep buckling, due to its simple form. In developing their creep buckling model, Rabotnov and Shesterikov (1957) make the fundamental assumption that creep strain rate depends only on the stress and creep strain and not on the history of loading. In other words,

$$f(\sigma, \varepsilon_c, \dot{\varepsilon_c}) = 0 \qquad \text{or} \qquad \dot{\varepsilon}_c = F(\sigma, \varepsilon_c) \tag{3}$$

In which both f and F are functions expressing material creep, ε_c is the creep strain, and $\dot{\varepsilon_c}$ is the creep strain rate. With this assumption, the creep buckling equation can be shown to have the following form,

$$\frac{P_{cr}}{P_E} = \frac{1}{1-[E\lambda/\mu]} \tag{4}$$

in which, E is the temperature-dependent Young's modulus, P_E is the Euler buckling load at elevated temperatures, and λ and μ are material parameters defined as follows,

$$\lambda = \frac{\partial f}{\partial \sigma} \qquad \mu = \frac{\partial f}{\partial \varepsilon_c} \tag{5}$$

Using the material creep models by Harmathy (1967) and Fields and Fields (1989), equations for material parameters μ and λ can be derived according to Equation (5).

Equation (4), which again represents creep buckling capacity, has a simpler form when the material creep model by Fields and Fields (1989) is used to get parameters μ and λ. Equation (4) together with the Fields and Fields (1989) creep material model has the following form,

$$\frac{P_{cr}}{P_E} = \frac{1}{1+[a c\, t^b \sigma^{c-1}]E} \quad \text{or} \quad \frac{P_{cr}}{P_E} = \frac{1}{1+[c\, \varepsilon_c/\sigma]E} \tag{6}$$

Equation (6) clearly shows that at constant stress and temperature, creep buckling capacity is inversely proportional to creep strain. This fact is also represented graphically in Figure 4, in which equivalent creep and creep buckling capacity curves are plotted together at 400 °C. Therefore, like the creep curve at constant stress and temperature, the buckling capacity curve changes with time and ends at a failure point at which the buckling capacity is equal to the applied load. Another useful observation is that there is a specific creep strain corresponding to the buckling failure. The time to reach this specific creep strain and consequently the creep buckling load is considered to be the failure time or time-to-buckle. By considering other constant load levels, one can generate more buckling capacity curves at the same temperature. Figure 5(a) plots these curves, which will be referred to as *iso-load creep buckling capacity curves* at a constant temperature of 400 °C. Again, these curves end at creep buckling loads which are the same as the corresponding applied loads. The envelope to these curves at the buckling failure points is what we refer to as the *creep buckling curve* or the *time-dependent buckling curve* throughout this paper and is shown in Figure 5(b). It is also possible to use Equation (6) directly to solve for creep buckling load. Since at buckling $\sigma = \sigma_{cr} = P_{cr}/A$, Equation (6) can be rewritten as follows,

$$P_{cr} + \left[\frac{acE}{A^{(c-1)}}\right] t^b P_{cr}^c = P_E \tag{7}$$

in which A is the cross sectional area of the column. Equation (7) can be solved iteratively to get the P_{cr} as a function of time at constant temperature. In other words, Equation (7) can be used directly to construct the creep buckling curve at a specific temperature.

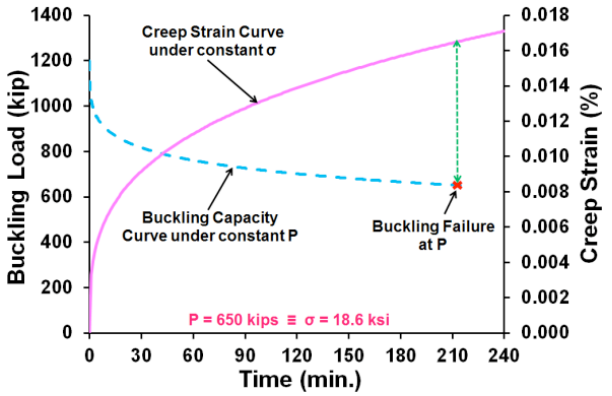

Figure 4. Graphical representation of the concept of creep buckling at 400 °C.

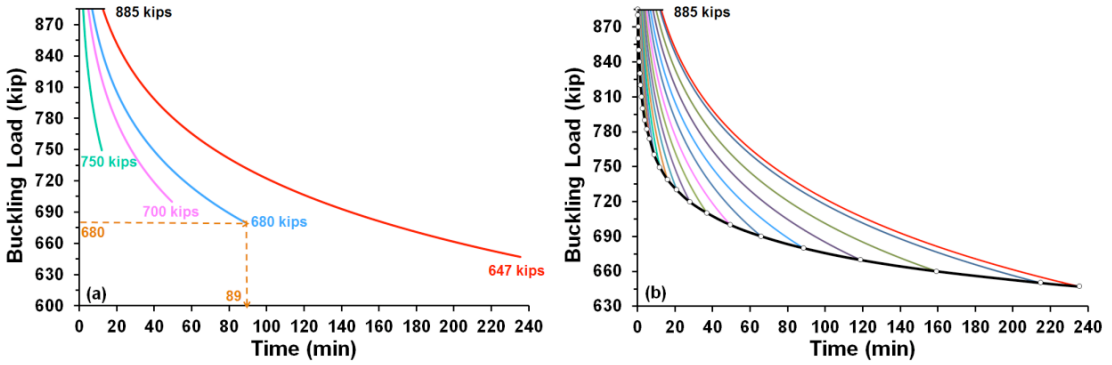

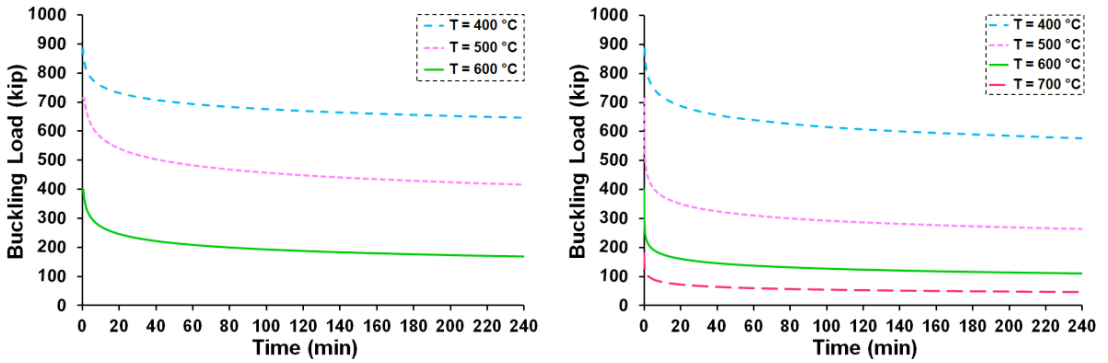

Figure 5. Iso-load buckling capacity curves and the creep buckling envelope at 400 °C.

As a final note on the analytical formulation, it should be added that this method disregards any initial imperfections and assumes a perfectly straight column. Moreover, this method predicts the Euler buckling load as the zero-time buckling load at any given temperature. To be more specific, this method only considers time-dependent inelasticity and ignores time-independent inelasticity due to the applied load at time zero. To have a more sensible model, a cap was placed on the maximum predicted buckling strength to reflect the effects of inelasticity and initial crookedness at time zero. For instance, the Euler buckling load for the column in consideration is 1198 kips at 400 °C. The results of load-deflection analysis on ABAQUS® assuming an initial imperfection of L/1000 and including material inelasticity showed a buckling load of 885 kips, which is shown in Figure 5.

Figures 6(a) and 6(b) show representative results of the analysis considering both material creep models. In these figures, plots of buckling load as a function of time are presented. Results are shown for temperatures of 400 °C to 700 °C. Although this is just a rudimentary study, these results show the potentially enormous impact of creep on buckling. At 500 °C and higher temperatures, the buckling strength of the column after just 20-minutes is reduced to about one-half of its value at initial application of load.

(a) Fields' and Fields' material model **(b) Harmathy's material model**

Figure 6. Analytical predictions of creep buckling using Rabotnov–Shesterikov method.

As a next step, computational predictions of creep buckling were developed using ABAQUS®. In order to simulate creep buckling on ABAQUS®, first, temperature is increased to the desired level, and then a fraction of the zero-time buckling load is applied to the column. No material creep is considered in these two steps. Next, the column is allowed to creep over the time period of 50 hours under the sustained load. Finally, the time-to-buckle due to creep is estimated. It should be pointed out here that to get the zero-time buckling load, an inelastic load-deflection analysis has to be performed. This has been done in ABAQUS® by using a nonlinear analysis scheme called a Riks Analysis. Moreover, to model initial geometric imperfections, an Eigen-value buckling analysis was performed. The initial shape of the column was taken as the shape of the first buckling mode, and the magnitude of the imperfection was chosen as a fraction of the column length. As far as material modeling is concerned, the inelastic material model at elevated temperatures was defined according to Eurocode 3 (2003), and the creep material model is the one proposed by Fields and Fields (1989), explained in the previous section. 3D hexahedral eight-node linear brick elements, C3D8R, have been utilized to model the columns on ABAQUS®.

As an example, the results of creep buckling simulations for the temperature of 500 °C and an initial out-of-straightness of L/1000 are presented in Figure 7 as plots of creep deflection versus time at different load levels. Figure 7 clearly shows that the rate of change of deflection with time increases very slowly up to an inflection point and then increases more rapidly until the column no longer can support its load. The time at which column becomes instable is considered as the failure time or time-to-buckle in this study.

Curves like the one presented in Figure 7 can be used to construct time-dependent column buckling curves, a sample of which is shown in Figure 8. Figure 8 simply presents buckling load as a function of time for different initial imperfections at 500 °C. To better gage the effect of temperature on time-dependent column buckling, Figure 9 compares buckling curves at three different temperatures. As can be expected, the higher the temperature, the more significant are the creep effects on column buckling behavior. It should be emphasized here that creep buckling curves like the ones shown in Figures 8 and 9, clearly show the possible danger of high-temperature design of steel columns just based on the zero-time buckling loads thereby ignoring the effect of duration of the applied load.

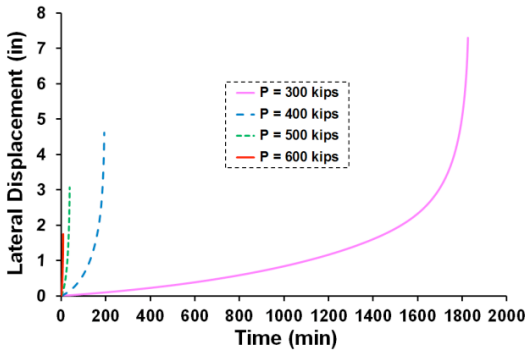

Figure 7. Lateral deflections due to creep at 500 °C and Δ_o = L/1000.

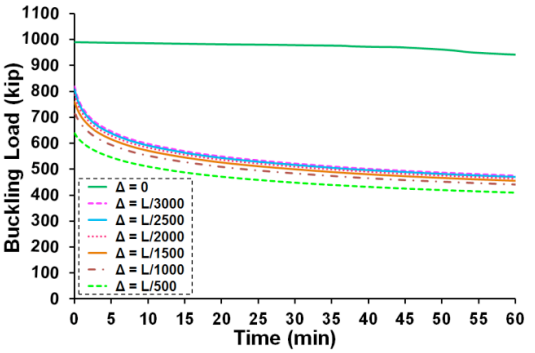

Figure 8. Creep buckling curves at 500 °C considering different initial imperfections.

Creep buckling predictions from analytical and computational methods are compared at 500 °C and presented in Figure 10. The analytical predictions are for a perfect column, while the computational one is for a column with L/1000 initial crookedness. As can be seen in Figure 10, these three curves follow the same trend after about 10 minutes. The difference between these predictions after 10 minutes is related to the difference in predictions of the material models and inclusion of time-independent inelasticity in the computational method. The interesting part though is at times of less than 10 minutes. This initial difference may be related to the effect of initial imperfection on the zero-time buckling load. On the other hand, it can probably also be related to the fact that Harmathy's and Fields' and Fields' models consider primary creep quite differently, especially at high level of stresses as shown in Figure 2. In any event, this seems to be an interesting observation and any solid conclusion requires more accurate experimental information regarding material creep behavior at elevated temperatures.

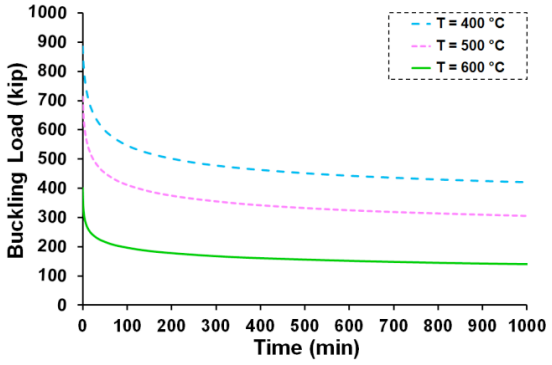

Figure 9. Computational creep buckling curves at Δ_o = L/1000.

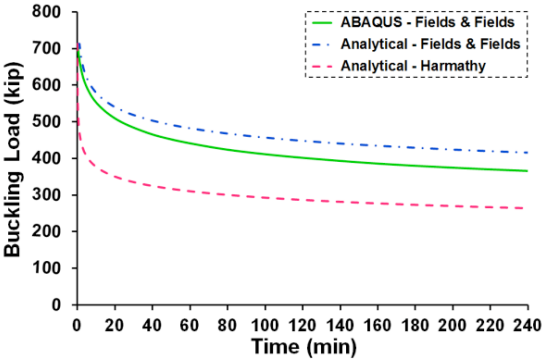

Figure 10. Comparison between analytical and computational creep buckling predictions at 500 °C.

Comparison with AISC and EC3 Predictions

In this section results obtained from analytical and computational creep buckling analyses presented in the previous sections will be compared with the corresponding elevated temperature column strength predictions of AISC (2011) and Eurocode 3 (2003).

It should be pointed out here that formula to predict column strength at high temperatures in Appendix 4 of the 2011 edition of the *AISC Specification for Structural Steel Buildings* are based on work by Takagi and Deierlein (2007). Both the Eurocode 3 column strength formula and that proposed by Takagi and Deierlein predict column strength as a function of temperature, but do not consider duration of load and temperature exposure; i.e., they do not consider creep buckling effects. These formulas are based on computational studies using elevated-temperature stress-strain curves for steel that do not explicitly include creep effects, and are verified against high-temperature column buckling experiments that also did not explicitly consider time dependent effects on buckling.

Figure 11 depicts the comparison of creep buckling predictions from ABAQUS® and Rabotnov-Shesterikov with the ones from Eurocode 3 (2006) and AISC (2011). Generally speaking, it can be observed that code-based predictions underestimate creep buckling time, especially at higher temperatures like at 600 °C as shown in Figure 11(c). The problem with code-based predictions of creep buckling becomes more evident when analytical creep buckling predictions using Harmathy's material creep model are compared against code-based ones, as shown in Figures 11(b), 11(c) and 11(d). It is also interesting to note that as temperatures get higher, analytical and computational buckling predictions using the Fields and Fields material creep model get closer, suggesting that the effect of creep is perhaps more important in overall inelastic buckling behavior at higher temperatures. Observations like these clearly show the significance of the need for more reliable creep data for structural steel.

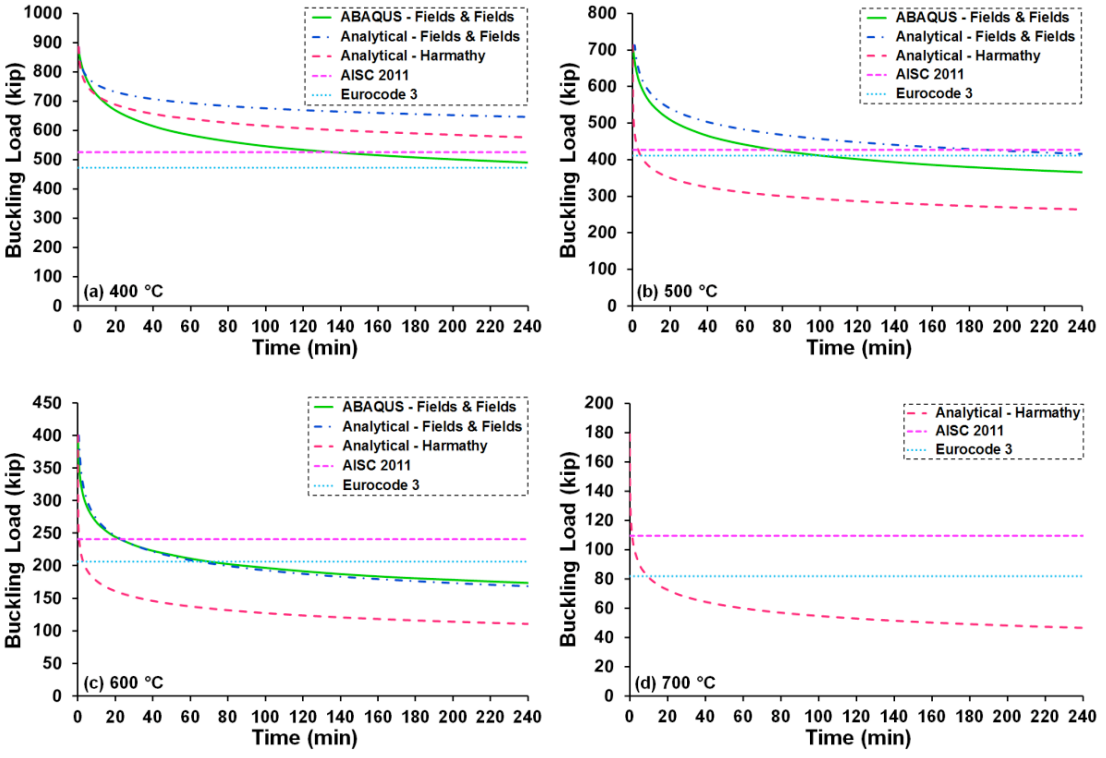

Figure 11. Comparison between computational, analytical, using both Fields and Fields and Harmathy creep models, and code-based creep buckling predictions.

CONCLUSIONS

This paper has presented some results of on-going research on the time-dependent buckling behavior of steel columns subjected to fire. Studies were conducted using a 3D finite element model incorporating both geometric and material nonlinearities. Analytical solutions were also developed to consider material creep effects on the overall time-dependent buckling. A number of factors that influence the time-dependent buckling behavior of steel columns in fire have been investigated, including the initial imperfection of columns.

It is clear from results obtained during this research that having an accurate knowledge of material creep is essential in predicting column buckling behavior at elevated temperatures. In addition, results show that neglecting creep effects can lead to erroneous and potentially unsafe predictions of the strength of steel columns subjected to fire. Columns are critical elements that affect the safety of structures during a fire. Consequently, a thorough understanding of column behavior during fire events is essential for developing appropriate analysis and design approaches. The research presented in this paper is on-going. The next stages of this research will involve a series of elevated temperature experiments on column specimens to provide further understanding of the time-dependent behavior and controlling failure modes of the column as far as creep is concerned. It will also provide further data for validation of modeling techniques.

ABSTRACT

A column failure caused by an explosion, impact, or other accidental events can propagate in a flat plate/slab structure through punching shear and lead to progressive collapse. The local post-punching behavior of flat slabs has been investigated experimentally and theoretically at the EPFL, Switzerland, and a mechanical model capable of predicting this behavior was developed. Using the mechanical model, an analytical model is developed here to estimate the initiation of punching shear failure as well as post-punching shear response of flat plates/slabs. The analytical model is used to study the system level post-punching response of structures and nonlinear dynamic finite element analyses are performed using a general purpose finite element software ABAQUS. The analytical model and the results of system level study can be of interest in assessing progressive collapse resistance of existing structures and in design of new structures.

INTRODUCTION

The term progressive collapse refers to the spreading of an initial local failure triggered by the loss of one or more load carrying members and leading to partial or total collapse of the structure in a manner analogous to the chain reaction. (ASCE/SEI 7, 2010). Following the attacks on the Murrah Federal building in 1995 and on the World Trade Center towers and the Pentagon on September 11, 2001 researchers evaluated progressive collapse resistance of structures (Sozen *et al.,* 1998, Corley *et al.,* 2004, Sasani *et al.*, 2007, Bao *et al.*, 2008) which covers both experimental and analytical studies. One approach based on direct design methods to evaluate progressive collapse of structures is to study the effects of instantaneous removal of load-bearing elements, such as columns. GSA (2003) and DOD (2010) regulations provide threat independent methods and use different scenarios for initiation of local failure to examine potential progressive collapse of structures. These regulations are meant to evaluate general integrity of structures and their capacity to redistribute the loads following removal of only one column. After column removal, the loads previously carried by the column will be dynamically redistributed to the neighboring columns, which could lead to collapse of partially or entire structure. One potential source of progressive collapse in such columns is punching shear caused by the transfer of additional loads from the removed columns. Over the past decades, several collapses due to punching shear failure occurred that resulted in human casualties and large damages. As a local punching failure can trigger progressive collapse, the study

of the post-punching behavior can help adopting constructive solutions to enhance the post-punching behavior of flat slabs and to mitigate the likelihood of the progressive collapse. In this paper, first an analytical model is developed to evaluate punching and post-punching response at a local level, i.e. slab on a single column. In developing this analytical model, experimental studies as well as a mechanical model developed in (Mirzaei Y., 2010) are used. Then to evaluate the effects of punching shear in progressive collapse analysis of structural systems, the response of a flat slab structure following loss of a column is studied leading to punching shear failure in a neighboring column.

POST-PUNCHING TESTS

The post-punching behavior a total of 24 slab specimens with various reinforcement layouts were experimentally evaluated at the EPFL, Switzerland. The effects of tensile reinforcement, integrity reinforcement passing through the column, bent-up-bars, and anchorage details were investigated. All the specimens were identical in geometry but different in reinforcement layout. Slab specimen PM-11 was a square plate with 125 mm thickness and 1500 mm width. The reinforcement ratio was 0.0082 and the concrete compressive strength was 32 MPa. Four integrity reinforcing bars with diameter 12 mm (2×2Ø12) pass through the column with the yield stress of 548 MPa and tensile strength of 625 MPa. A mechanical model was proposed, whose estimation for the PM-11 slab is compared with experimental data later in this paper. Figure 1 shows the test setup as well as the slab geometry (Mirzaei Y. and Muttoni A., 2008). Test results showed that the load-carrying mechanisms that take place after punching failure were related to the well-anchored tensile reinforcement and to the integrity reinforcement passing through the column. The post-punching strength provided by the tensile reinforcement was small because the concrete cover was thin and susceptible to spalling.

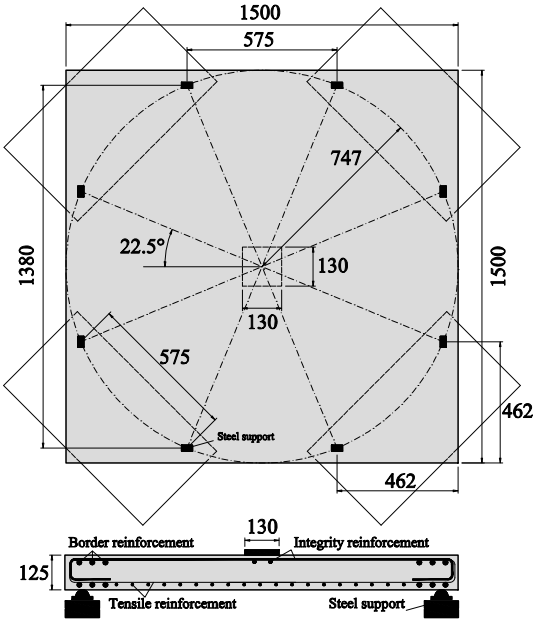

Figure 1. Typical slab plan section [mm].

POST-PUNCHING MECHANISM

Several structural collapses occurred over the past decades due to punching shear failure resulting in human casualties and large damages. These collapses revealed some shortcomings in codes of practice and the necessity of reconsidering punching provisions. The investigations of these collapses showed that the collapse initiated from a local punching failure and propagated throughout the structure likewise a chain reaction or progressive collapse (King *et al.*, 2004). The design of

reinforced concrete flat slabs is governed by deflection at the serviceability limit state and punching shear at the ultimate limit state. When no punching shear reinforcement is provided, failure develops in a brittle manner. Punching shear failure occurs with almost no warning signs, because deflections are small and cracks at the top side of the slab are usually not visible. A large amount of scientific effort has been devoted to the punching shear research and various theories and formulations have been developed. Recently, Muttoni suggested a failure criterion for slabs with and without shear reinforcement which can determine the punching strength mainly as a function of the radial rotation of the slab in the vicinity of the slab-column connection (Muttoni A., 2008). To compute the maximum punching strength, the load-rotation relationship of the slab is also needed for which a mechanical model was proposed based on a quadrilinear moment-curvature relationship for the reinforced concrete section. As a local punching failure can trigger progressive collapse, the study of the post-punching behavior can help adopting constructive solutions to avoid progressive collapse. The post-punching resistance is provided by reinforcing bars passing through the punching cone as they are the only link between the damaged area and the rest of the slab. These reinforcing bars can carry load by developing high tensile stresses accompanied by a significant inclination (Mirzaei Y., 2010).

Mirzaei (2010) developed a mechanical model which is capable of predicting the post-punching behavior of slab column connections as well as the contribution of top and bottom reinforcement to the post failure shear transfer. The model accounts for possible failure modes including the fracture of the bars and the destruction of the concrete over the integrity bars. The destruction of the concrete within and outside the punching cone is treated by considering the pullout behavior of reinforcement embedded in the concrete. The mechanical model calculates the mean axial strain and the rotation of the reinforcing bar for any given deflection. The maximum strain in the reinforcing bar developed in the curvature-influenced zone and then the maximum strain is compared to the ultimate tensile strain. This failure criterion will determine the rupture of the reinforcement.

ANALYTICAL MODEL

Figure 2 shows the geometry as well as a Finite Element Model (FEM) of the PM-11 simply supported reinforced concrete slab tested by (Mirzaei Y. and Muttoni A., 2008). Due to the symmetry and to simplify the analysis only one quarter of the slab is modeled. Because the punching shear is associated with local failure and deformation and the slab deformation away from the failure zone is negligible compared to that at this zone, the concrete is assumed to remain elastic during the analysis. The concrete modulus of elasticity is 33 GPa and its Poisson's ratio is 0.15. The reinforcing steel is modeled as a quadrilinear elastic-plastic material including strain hardening. The elasticity modulus of steel reinforcement is 201 GPa, the yield strength is 548 MPa, and the tensile strength is 625 MPa (Mirzaei Y. and Muttoni A., 2008). The slab thickness is 125 mm and can be modeled as a thin plate. Therefore, the four-node first-order quadrilateral in-plane shell S4R with reduced integration points and finite strains from the ABAQUS element library is used in the model (ABAQUS 2010).

In the load-deflection response of a slab in punching tests two different phases can be distinguished, which are pre-punching and post-punching phases. The finite element modeling of the punching phenomenon is feasible but rather complicated and time consuming. Therefore, to exclude the complexity of the punching calculation, the pre-punching load-deflection response of the slab is analytically calculated by the Critical Shear Crack Theory (Muttoni A., 2008). Then, the result is implemented into the finite element model by using nonlinear connectors. From the basic category of the connections, a Cartesian + Cardan connector has been selected. All the six components of relative motions are available for this connection. The results of the mechanical model are used as the constitutive model for these connectors. Note that the failure zone undergoes large deformations after a column failure, and thus nonlinear constitutive material laws modeling this zone should be applied to simulate the structural behavior realistically.

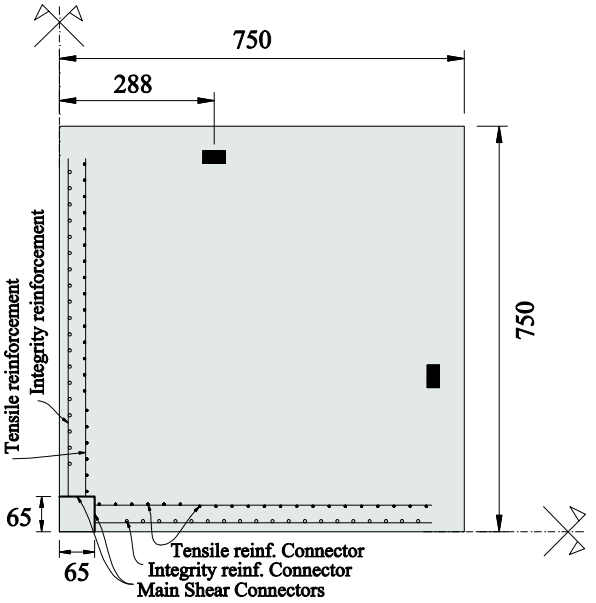

Figure 2. Geometry of the finite element model.

The post-punching strength is mainly provided by the integrity reinforcement passing through the column in the connection zone (Mirzaei Y., 2010). The connection zone shown in Figure 2 connects a rigid zone right above the column to the rest of the slab. In other words, this connection zone simulates the contribution of the reinforcing bars to the shear transfer after a punching shear failure has occurred. The two-node first-order Bernoulli beam element B33 has been chosen in order to simulate the

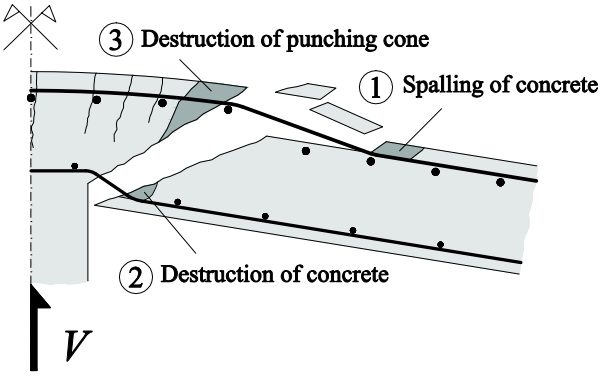

Figure 3. Various critical zones due to interaction between concrete and steel bars

integrity reinforcement passing through the column. This reinforcement will be practically activated as the column punches through the slab. The vertical component of the force developed in the reinforcing bars is the contribution of the integrity reinforcement to the post-punching shear transfer.

In order to better understand the failure process and simulate the failure zone various failure zones are illustrated in Figure 3. Depending on the direction of loading and the thickness of the concrete, three primary failure zones can be characterized in post punching shear, as shown in Figure 3. In zones 2 and 3, the reinforcing bars break the concrete because of the small concrete thickness in these zones. In other words, the thickness of the concrete over the integrity bars at the beginning of the post-punching phase is small. Therefore, reinforcing bars act against concrete with a small thickness and consequently concrete breakout occurs. The progressive destruction of concrete continues up to a certain point at which the thickness of concrete is sufficient to prevent further concrete breakout. Beyond this point, yielding of the bar and crushing of the concrete supporting the bar control the failure process. It has been reported that if the concrete thickness is larger than six to seven times the bar diameter, yielding of the bar and crushing of concrete govern the failure process.

In general, the contribution of the integrity reinforcement to the post-punching strength is governed either by the maximum breakout strength of the concrete above the bar or by the fracture of the integrity bars. For further deflections, the concrete breakout strength remains constant as the thickness of the concrete above the integrity reinforcement is constant. Thus, no further increase in the length of the exposed integrity reinforcement will occur.

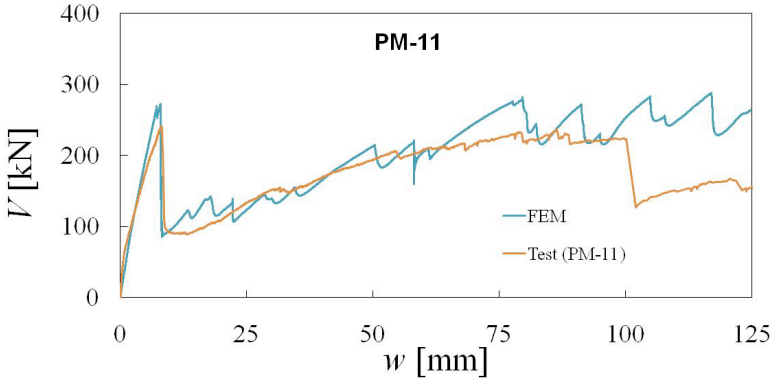

Figure 4. Comparison of analytical and experimental results.

A comparison between the results obtained by the nonlinear FEM and the experimental data is shown in Figure 4. A good agreement can be found between the measured post-punching strength and the one calculated by the nonlinear FEM. The model accounts for the contribution of both well-anchored tensile reinforcement and integrity reinforcement. In this experiment, the tensile reinforcement was well-anchored in the slab which is unlikely in practical projects because of the cut-off points around the zero bending moment areas. The contribution of the well-anchored tensile reinforcement to the post-punching strength could reach 33% of the punching strength and the contribution of the integrity reinforcement reached 65% of the punching strength (Mirzaei Y., 2010).

POST-PUNCHING SHEAR AND PROGRESSIVE COLLAPSE

The implementation of the prescribed post-punching mechanical model in an analytical model in ABAQUS is presented to illustrate the possibility of progressive collapse due to punching failure after a column explosion/removal. To investigate the effects of the post-punching resistance in a concrete slab after a column removal, a sixteen column slab model is considered. Figure 5 shows the geometry of the slab, which is 250 mm thick and has 6m × 6m panels. The column cross sections are 300 × 300 mm. The applied uniformly distributed loads are a total dead load of 8.1 kN/m^2 and a live load of 4 kN/m^2.

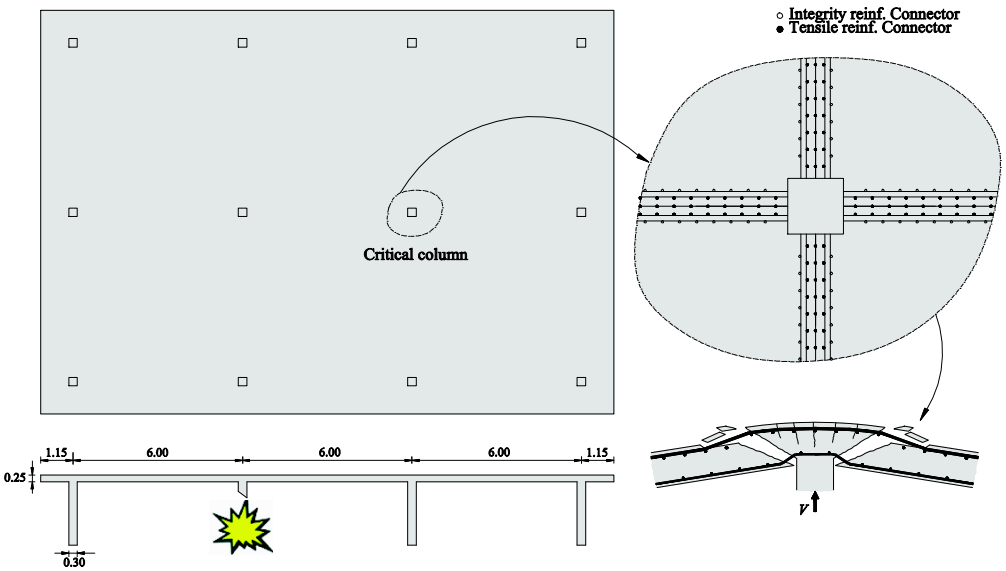

Figure 5. Analytical model of the system level study of progressive collapse due to punching shear failure.

To design the integrity reinforcement, the design load is calculated using load factors of the accidental situation according to ACI 352.1R (2002). The integrity reinforcement is designed by the following equation:

$$A_{si} = \frac{0.5 q_d \ell_1 \ell_2}{\Phi f_y} \tag{1}$$

where A_{si} is the minimum area of the integrity reinforcement in each principal direction placed over the column, q_d is the factored uniformly distributed load but not less than twice the slab service dead load, f_y is the yielding strength of steel, $\Phi = 0.9$ is a shear reduction factor, and ℓ_1 and ℓ_2 are center-to-center span in each principal direction. The quantity of reinforcement A_{si} may be reduced to two thirds of that given quantity for edge connections, and to one-half of that for corner connections.

The Critical Shear Crack Theory proposed by Muttoni (2008) has been used to calculate the up to punching response of the slab-column connection. The post-punching behavior of the slab has been calculated by the mechanical model (Mirzaei Y., 2010). The tensile reinforcement and integrity reinforcement are assumed

to be well-anchored in the slab. The punching strength and post-punching strength are 1067 kN and 899 kN for the interior columns, respectively.

The elements used in the FEM are the same as those described in the previous section for the single column model. This model aims to demonstrate the vulnerability of flat slabs against punching shear failure after a column removal. The load-deflection response of column B is obtained after the removal of column A. The removal of a column influences dynamically the rest of the slab and therefore the structure should be analyzed dynamically. The procedure is described below. The gravity load is applied and the column A top forces and moments are found. Then, the column is removed and its internal forces are applied to the column head. And finally, forces and moments in opposite directions are dynamically applied to the column head and the response of the other columns is studied.

ANALYTICAL RESULTS

The load-deflection response of column B as a result of column A removal is shown in Figure 6.a. It can be seen that the transferred load exceeds the punching strength and therefore the column punches through the slab. One important question is how much post-punching strength and in its turn integrity reinforcement is needed to provide structural safety against progressive collapse in a structure. The punching shear failure occurs at a very small deflection and activates the integrity reinforcement passing through the column. The force developed in the reinforcement increases for further defection. The vertical component of this force is the main contribution to the post-punching strength.

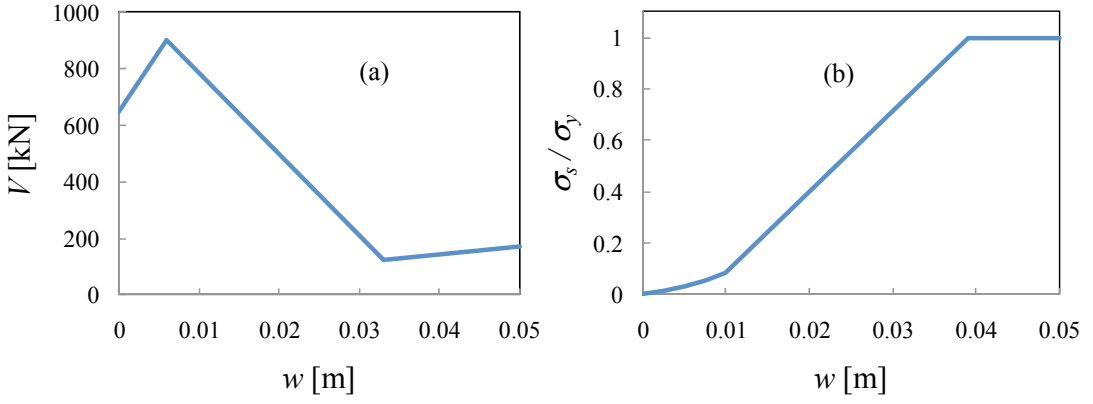

Figure 6 . a) Load-deflection response of column B after the removal of column A and b) evolution of stress in integrity reinforcing bars.

In this analysis, the structure arrived at an equilibrium position soon after the punching shear occurred. However, if the structure required deflecting more to redistribute the loads, the contribution of the integrity reinforcement in transferring load to the column could increase. This increase in the post-punching strength can be helpful in preventing the failure from propagating throughout the structure. The way that a punching shear failure of a slab-column connection can lead to progressive collapse depends not only on the post-punching behavior of the connection but also on

the overall behavior and structural characteristics of the region of the slab surrounding the damaged area and the punching strength of adjacent slab-column connections. Figures 6.b shows the evolution of the stress in reinforcing bars as a function of the vertical displacement. It clearly shows that steel reinforcement exceeds the elastic limit and enters in the plastic region for such small deflection. It has been shown that the integrity reinforcing bars could carry load by developing high tensile stresses accompanied by a significant inclination.

Figure 7 displays the slab deflection contour before and after the punching shear failure of column B. They clearly show that the maximum vertical displacement of the slab occurs at the location of punching shear. It can be seen that the column removal in flat slab structures triggers the failure to the adjacent column. The failure could propagate throughout the structure in the same way leading to the progressive collapse of a large part of the structure. It is shown that the presence of the integrity reinforcement can provide an alternative load path for the load redistribution and prevent the structure from totally collapsing.

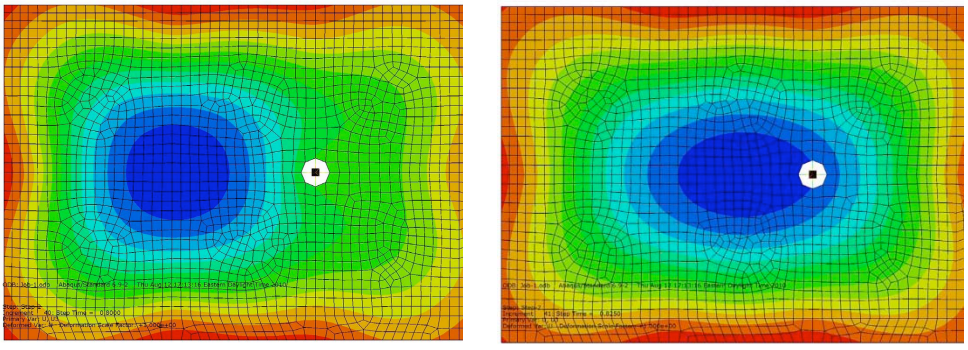

Figure 7. Slab deflection right before (w_{max}=-.00228 m) and right after the punching shear failure of column B (w_{max}=-.00408 m).

CONCLUSIONS

It has been shown experimentally that reinforcing bars play an important role in post-punching behavior as they are the only remaining link between the punching cone and the rest of the slab. Therefore, the load-carrying mechanisms that take place after punching failure are related to well-anchored tensile reinforcement and to integrity reinforcement passing through the column.

A nonlinear finite element model has been developed to simulate the post-punching behavior of flat slabs after a column removal. The performance of reinforcing bars acting against the concrete cover and against the punching cone is fundamentally different. However, a generic procedure was developed capable of predicting the behavior of all possible mechanisms. Within this scope, a series of connector elements has been used and their nonlinear constitutive laws were introduced according to a previously developed mechanical model. The mechanical model is used to determine the mechanical properties of the analytical model of the connection zone, which is between a rigid zone of slab directly above the column and the rest of the slab. The model of the connection zone simulates the contribution of the reinforcing bars to the shear transfer after a punching shear failure. The contribution of

the reinforcing bars to the post-failure shear transfer is simulated using beam element. These elements are practically activated after punching shear failure has occurred. The vertical component of the force developed in these reinforcing bars is the main contribution to the post-punching strength.

The analysis shows that a column removal in a flat slab structure can trigger a punching shear failure at the location of an adjacent column. Such failure potentially can propagate throughout the structure and a series of punching shear failure can occur leading to the progressive collapse of a large part of the structure. The presence of an adequate amount of the integrity reinforcement can provide an alternative load path for the load redistribution and help resist progressive collapse.

ABSTRACT

In a collaborative effort between NEES TIPS, NIED in Japan, and the NEES Nonstructural Grand Challenge project, a 5-story steel moment frame building will be shaken at the E-Defense facility in Japan. The specimen will be shaken both with and without triple friction pendulum isolators. Nonstructural components including interior walls, ceilings, piping, and concrete cladding panels will be constructed and in the specimen. The isolated specimen will be shaken to a suite of motions representing frequent, design/L2, and MCE/L3 level motions. The tests represent the grandest showcase of the benefit of seismic isolation technology to date, and the primary objective of the tests is to demonstrate that damage free performance can be targeted and achieved against an MCE/L3 earthquake. Limit state tests will illustrate the performance when the demands exceed the displacement capacity of the bearings. The tests will take place over a 3-week time frame in August 2011, with 4 days of shaking anticipated.

INTRODUCTION

Seismic base isolation is recognized as one of the most effective methods to protect both the structure and its contents from large earthquakes. The fundamental horizontal period of the structure is lengthened by installing flexible devices beneath the structure and the base. Lengthening the fundamental period reduces the base shear demand, and increased displacements are accommodated by the isolation system. The hysteretic force-deformation of an isolation system also contributes considerable damping to the dominant response mode so that the input energy to the structure is further reduced.

Analytical and experimental studies on base isolation systems have been carried out during the last four decades. Most research has shown that isolated structures have very good performance (Erduran et. al. 2010, Fan and Ahmadi 1992,

Kelly and Aiken 1991, Samali and Wu 2003). Some studies are concerned about the safety and performance of the isolation system or the isolated building when subjected to extreme ground motions that exceed the design ground motion. Extreme displacement demands of an isolation system subjected to very rare earthquakes may causes these problems: 1) shear failure or buckling of an elastomeric bearing, 2) exhausting the displacement capacity (hitting the rim) of a friction pendulum bearing, 3) pounding against an outer moat retaining wall, or 4) transfer of the force demand accompanied by yielding in the superstructure. Furthermore, some stakeholders (such as the nuclear industry) have become increasingly concerned about the influence of vertical ground acceleration in an isolated structure, since isolation does not specifically protect against vertical motion, and vertical accelerations exceeding 1g have been recorded in recent earthquakes (Clark et. al. 1996, Malushte and Whittaker 2003, Su and Ahmadi 1988).

Most shaking table tests on isolation systems have been conducted on reduced scale models, and lack of full scale testing to demonstrate the reliability of analytical modeling techniques for extreme motions is considered a knowledge gap. The influence of isolation on content response should also be examined, as the overall movement of the building can be considerable. In 2010, E-Defense studied the response of an R/C building isolated with different elastomeric isolator such as high damping rubber and natural rubber with steel dampers, and also with the base of the building fixed. The tests investigated the performance of hospital equipment and several different types of hospital rooms were furnished (Sato et. al. 2010).

The proposed test program will provide additional complimentary data on the response of full-scale isolated buildings. In this testing program, shake table tests of a full scale 5-story steel moment frame building will be conducted. The specimen will be examined both with and without triple friction pendulum isolators, and subjected to several ground motions of varied characteristics and intensity. U.S. style partition walls, ceiling systems, piping components, and exterior cladding panels will be built over portions of the building, and enclosed rooms will house furnishings and other contents. The isolation tests will provide realistic data for examining the response of an isolated structure and contents to extreme earthquakes and evaluating current design and modeling techniques. The response of the fixed base specimen to the same ground motions will provide data for comparing the two configurations.

The test will be performed at Hyogo Earthquake Engineering Research Center, also known as E-Defense, which is accessible to U.S researchers through the NEES/E-Defense collaborative program. This research center hosts the world's largest three dimensional shaking table. The E-Defense shaking table can reproduce the largest three-dimensional ground motions recorded in the 1995 Kobe Earthquake while supporting a test model of 1200 metric tons. At the maximum payload, the E-Defense shake table can produce motions with horizontal acceleration exceeding 0.9g and vertical acceleration exceeding 1.5g. At lower payloads, larger accelerations can be reproduced. The shake table is also capable of producing large motions with low frequency content, as exhibited by the large stroke and velocity capacity (maximum stroke is ±100 cm, maximum velocity is 200 cm/s). The 15 × 20 meter platform is sufficiently large to support a small full scale building.

TEST OBJECTIVES

This research program aims to provide a grand demonstration of effectiveness of seismic isolation for very large ground motions. An international collaboration has been developed that addresses the research concerns for both U.S. and Japan participants. The test objectives are described as follows:

1. Accelerate adoption of protective systems through a full scale, proof-of-concept test. Component tests of isolation devices suggest that scaling effects significantly alter their response trends, while most system level tests have been conducted on reduced-scale specimens. The proposed tests will fill a gap in the existing data while allowing real-life visualization of the behavior of a real building under earthquakes. In this test program, the performance of not only the structure but also nonstructural components and contents will be confirmed. To ensure the educational impact of the tests, we will publicize these tests widely to the U.S. through invited observation, workshops, and media targeted to different audiences. A blind prediction contest is planned; details will be released through NEESComm and at the Structures Congress meeting in 2011.

2. Validate new seismic isolation solutions and design/analysis methods. The proposed tests will examine the new triple friction pendulum isolator that has a limited history of commercial use. The triple pendulum isolator is conducive to a performance-based design approach, wherein the parameters of the isolation system are optimized relative to specific multi-hazard performance criteria. The overriding performance objective is to provide damage-free response against a maximum credible (MCE) or Japan L3 level earthquake. The tests will validate the ability to achieve the performance objective that is targeted in the design process.

3. Extend resiliency to challenging range of critical applications. The test program considers some additional challenges with regard to system configuration and loading conditions. The building structure is lightweight for a traditional elastomeric isolation system. With regarding to load conditions, extreme earthquakes will be applied to the system, including those with large vertical acceleration components or long period, long duration subduction motions.

4. Identify performance limits of the isolation system for extreme motions. The tests will examine the endurance of the devices under long duration motions, and the re-centering capabilities as well as the implications of not re-centering. The specimen is predicted to undergo uplift in some of the simulations. For the motions that produce the largest displacement demands that exceed the isolator capacity, the sliders are predicted to pound against the rim of the bearing, causing a large acceleration wave to propagate through the structure. The influence of this pounding on the performance and safety of the structure will be determined.

SPECIMEN

The specimen to be tested is a 5-story steel moment frame building that has already been constructed (Figure 1). The specimen is approximately 16 meters tall, and asymmetric in plan with dimension of 10 meters by 12 meters (2 bays by 2 bays). The total weight of the building is about 5000 kN, which is well below the maximum capacity of the shaking table so that extreme earthquake ground motions can be

reproduced accurately. The specimen was constructed in September 2008 and used in a test in March 2009 with several different types of inter-story dampers to provide enhanced performance (Kasai et. al. 2010).

The specimen was designed and detailed according to Japanese code and style. The beams and girders are either built-up or rolled wide flange sections, and the columns are cold-formed HSS sections. All girder-to-column and column base connections are fully restrained moment connections. Each girder was constructed in 3 pieces, and bolted together at the approximate inflection points determined by gravity loading. The flanges of the girders are widened near the connections to the column to increase the moment capacity. Floor slabs are composite slabs formed from 75 mm height corrugated steel decks covered by 80 mm normal concrete. The roof slab is a 150 mm normal concrete slab with a flat steel deck; the roof was designed to carry additional loading representative of equipment.

For preliminary analysis, finite element models of the specimen were developed both in SAP2000 and OpenSees. The modeling and analysis is not discussed in detail to preserve the integrity of a planned blind prediction contest.

INPUT GROUND MOTIONS

Design spectra. Design spectra were developed that represent both U.S. and Japan design practice. The design ground motion (DBE) in the U.S. varies as a function of regional seismicity and site conditions. To represent high seismicity, a Los Angeles (CA) location with site class D soil conditions ($V_{s30} = 180$ m/s to 360 m/s) was

selected. These assumptions are consistent with the case study buildings examined in the NEES-TIPS project (Erduran et. al. 2010). Using standard procedures, DBE and MCE design spectra were developed.

The design ground motion for Japan is based on a single "level 2" (L2) design event, where the spectrum is determined as

$$S_A(T) = Z \times G_s(T) \times S_0(T)$$

In this equation, Z is zone factor taken to be 1.0 for most area of the country, $S_0(T)$ defines the default spectrum for engineering bedrock, and $G_s(T)$ is a soil amplification factor that varies with period (Pan et. al. 2005). Soil type II was assumed to be equivalent to U.S. site class D. The U.S. and Japanese design spectra are shown in Figure 2 for damping ratios of both 5% and 15%, the latter which represents the damping in the isolation system.

Selecting ground motions. A number of ground motions have been selected to represent each of the above design spectra and evaluate potential design solutions to satisfy the performance objectives. A subset of these motions will be selected for inclusion in the final test program.

Seven ground motions were selected to represent U.S. spectra; three for the DBE and four for the MCE. The U.S. code requires that appropriate ground motions shall be selected from events having parameters consistent with those that control the MCE, and the motions are scaled to at least 1.3 times the design spectrum over a set period range. However, for the experimental program, records were selected that are rich in long period content and recorded in large earthquakes; the majority of these records are from California earthquakes; both lateral components and the vertical component have been considered. Table 1 indicates the list of records and the characteristics (peak ground acceleration, velocity and displacement of any component) for each record. The scale factor represents the factor by which the record was scaled to match the DBE or MCE spectrum using a similar scaling procedure to the U.S. code. All selected ground motions for the U.S. MCE were scaled down to match the code spectrum, which means that the unscaled motions exceed the MCE level defined by the code. Some of the unscaled records will be included in the test program to represent "beyond MCE" level motions. Figure 3(a) and 3(b) show the response spectra of the records against the 1.3 times DBE and MCE design spectra, as appropriate.

The Japanese code requires all isolated structures to be checked for three standard ground motions: El Centro NS 1940, Taft EW 1952 and Hachinohe EW 1968, scaled to the peak ground velocity of 0.5 m/s; and three additional ground motions that account for the local site effects (Becker et. al. 2010). The subset considered for the experimental program includes El Centro, JMA Kobe (commonly included in the design set for Japan), and Takatori (a strong near fault record). The synthesized Sannomaru record is a long period and long duration record, representative of the motion that would be generated by a deep subduction fault. The Sannomaru record, which has a spectral acceleration that nearly peaks at a period of 3 seconds, is of particular concern due to the large demands and potential resonance effect on long period structures. Table 1 and Figure 3(c) include the statistical information and response spectra for the selected Japanese motions.

Table 1. Parameters of Selected Ground Motions.

Ground motion	Code	Peak A (cm/s^2)	Peak V (cm/s)	Peak D (cm)	Scale Factor
Northridge – Rinaldi	U.S. DBE	809.5	160.3	29.7	0.88
Northridge – Newhall	U.S. DBE	578.6	97.8	38.2	1.32
Turkey – Erzican	U.S. DBE	505.5	84.0	27.6	0.89
Chi Chi TCU 065	U.S. MCE	798.4	126.2	92.6	0.93
Northridge - Sylmar	U.S. MCE	880.2	117.5	54.3	0.85
Loma Prieta - Los	U.S. MCE	947.9	108.7	65.8	0.99
Tabas -Tabas	U.S. MCE	835.6	121.4	95.2	1.11
El Centro N-S	Japan L2	312.8	36.3	21.1	1.38
Kobe - JMA Kobe	Japan L2	805.7	81.6	20.0	1.66

DESIGN OF ISOLATION SYSTEM

Design Strategies. The U.S. code requires that an isolated structure be designed for a force reduction factor $R \leq 2$ in the DBE event, wherein $R = 2$ is permitted for a ductile lateral system while $R = 1$ is required for some types of nonductile systems such as ordinary braced frames. However, because of the inherent overstrength, yielding typically would not be expected in the design event. The U.S. code also requires that interstory drift of the superstructure not exceed 1.5%. For a moment

frame, the drift requirement typically controls the design. The U.S. code does not limit the floor acceleration. The Japanese code permits a small level of yielding in the superstructure for an L2 earthquake event (full plastic hinge formation should be avoided). According to Pan et. al. (2005), while not specifically specified by the code, interstory drift ratio of 1% and the peak floor acceleration of $3\ \mathrm{m/s^2}$ are commonly targeted for isolated buildings in Japan.

However, the above code criteria does not directly consider nonstructural component and content response in the U.S. DBE or Japan L2, and does not consider structural response in the U.S. MCE or Japan L3. In this program, to protect the structure against damage, the isolation system will be designed such that the maximum interstory drift does not exceed 0.5% in MCE/L3. Comparable target drift for the DBE/L2 earthquake is 0.33%. An appropriate performance objective for acceleration sensitive components and contents is being sought, which could be based on floor accelerations, velocity, or floor spectra.

Behavior of Isolators. Nine identical triple friction pendulum isolators provided by EPS Inc. will be used in the test, one beneath each column. Triple friction pendulum bearings consist of two layers of sliders sandwiched between concave sliding surfaces. Static friction between the surfaces resists small lateral loads without deformation, but when the applied lateral force is large enough, the system slides. The combination of vertical force and the curvature of the concave plates provide restoring force while the friction between bearing plates and sliders dissipates the input energy. The general loading behavior of a triple pendulum bearing, which consists of several sliding stages, is described in Fenz and Constantinou (2008).

The bearings selected for the test program have relatively low friction coefficients combined with large lateral displacement capacity designed to provide optimal protection for nonstructural components and contents. The selection of identical pendulum curvature and friction coefficients for the outer sliding surfaces simplifies the force-displacement to a two stage system. The isolator dimensions are shown in Figure 4 and the backbone curve of the isolator is shown in Figure 5. The period of the isolation system depends only on the pendulum lengths and not on supported mass; thus, for each bearing the tangent period at large displacements is 5.6 sec, and the secant period is 4.6 sec at the peak displacement of 112 cm (Fig. 5).

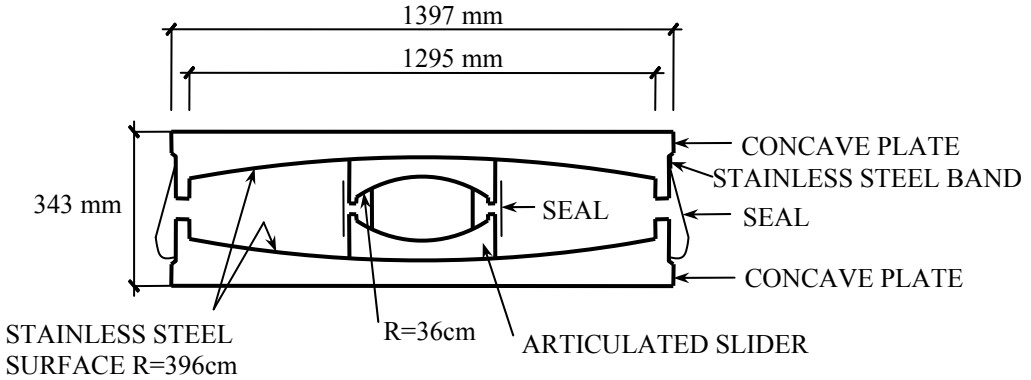

Figure 4. Section view indicating dimensions of isolation bearings

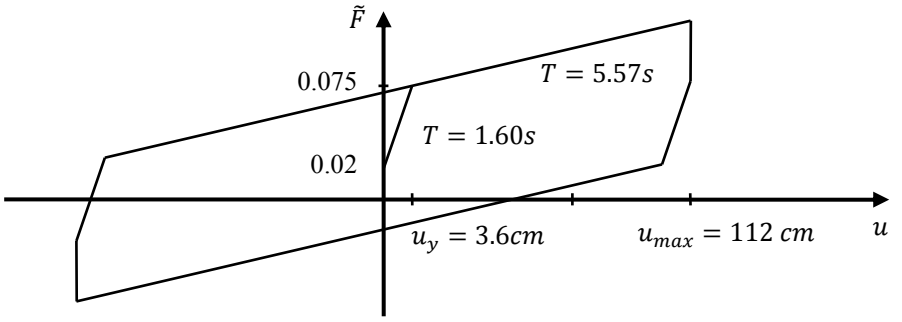

Figure 5. Backbone force displacement of selected triple pendulum isolators

CONNECTION DESIGN

To check performance objective and design the connection, peak responses of isolated structure to the selected ground motions were analyzed. The absolute peak response observed over all of the ground motions in Table 1 are shown in Table 2. The structure easily meets story drift criterion, which is 0.5% for MCE scenario. However, the peak displacement demand observed in the analysis exceeds the capacity, and the effect of sliders pounding against the bearing rims has not yet been considered. Detailed results are not presented to preserve the integrity of the planned blind prediction contest, as mentioned earlier.

For examining behavior of isolators during earthquakes, load cells will be installed beneath each isolator to measure reaction components, as schematically illustrated in Figure 6(a). Two types of load cells are available for use at E-defense. Their properties are shown in Table 3.

Table 2. Peak Responses of Isolated Structure Model to Large Ground Motions.

Peak Isolator Displ. (cm)	Peak Isolator shear (kN)	Peak isolator's vertical reaction (kN)			Peak story drift (%)	Peak floor acc. (g)
		Center isolator	Edge isolator	Corner isolator		
135.4	286.0	1742.4	1382.6	931.5	0.327	0.504

Table 3. Properties of Load Cells.

Type	Number (units)	Height (mm)	Vertical capacity (kN)	Horizontal capacity (kN)
A	44	180	400	250
B	32	195	700	400

Measuring the large forces (Table 2) with available load cells (Table 3) is challenging due to the large overturning effects distributing high axial forces to load cells in the direction of isolator displacements. Previous tests of the isolated hospital at E-Defense did not measure the isolator forces. Optimal arrangements of the load cells have been devised for center, edge, and corner isolators based on the tributary

weight carried by each (Figure 6). The hexagonal configuration distributes the forces and reduces the deformation of connecting plates while minimizing the number of load cells. This configuration possesses identical stiffness in any horizontal direction.

Finite element models were developed in SAP2000 to investigate stress and deformation of connecting plates. The connecting plates were modeled using 8-node solid elements (Figure 7). Forces distributed to load cells were computed by assuming that the connecting plates are plane and stiffness of all load cells are the same. The expected forces in the load cells were applied to the model, and top and bottom plates of load cells were modeled by 4-node shell elements to evenly distribute the forces from the load cells to connecting plates. Table 4 presents the maximum tension and compression forces induced in load cells.

Von Mises stress in the connecting plates is well below the yield stress of the steel, which is 24.82 kN/cm^2. The safety factor is greater than 1.5. The maximum deflection of the plate is 0.784 mm, which is equivalent to a relative deflection $0.96/1000$. This order of flatness is acceptable for friction pendulum bearings.

Table 4. Peak Forces Induced in Load Cells

Load cell	Max. compression (kN)	Max. tension (kN)	Max. shear (kN)	Status
Type A	388	112	41	OK
Type B	582	192	41	OK

NONSTRUCTURAL COMPONENTS

In recent earthquakes, damage to nonstructural systems resulted in loss of functionality of buildings, including critical facilities, and contributed to major economic losses. Significantly limited data is currently available that address damage

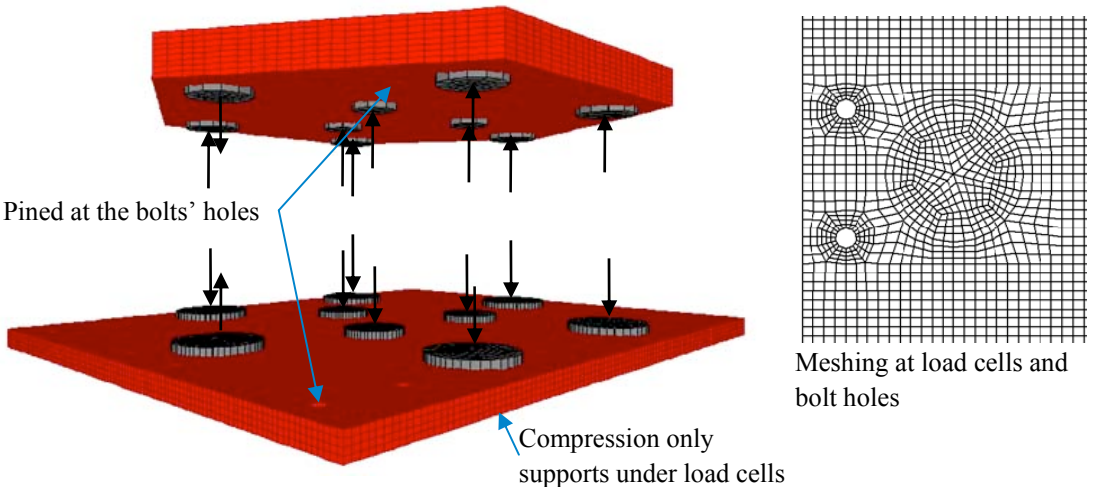

Figure 7. Finite element modeling and analysis of connecting plates.

measures of nonstructural systems that can be used to estimate downtime, repair cost, and life safety threats. In addition to the previously stated objective to demonstrate damage free performance of the building specimen, the experiment presents an excellent opportunity to investigate the seismic response of the full scale nonstructural assemblies in a realistic dynamic environment with interacting together and with the structure.

The NEESR Grand Challenge project "*Simulation of the Seismic Performance of Nonstructural Systems"*, led by PI Emmanuel Maragakis, integrates multidisciplinary system-level studies that develop, for the first time, the simulation capabilities and implementation process for enhancing the seismic performance of ceiling-piping-partition (CPP) nonstructural systems (Maragakis 2011). The Grand Challenge project has formed a collaboration with NEES TIPS and E-Defense to use the experimental setup in Japan as a testbed for installing CPP systems and enhancing the data that will contribute to the project goals.

Ceiling, piping, and partition systems were selected for inclusion in the large scale structure specimen as they account for almost 75% of the total value of critical facilities such as hospitals, schools and offices. The fourth and fifth floors of the test structure were selected to install the CPP systems. A realistic partition layout was designed that offers approximately 1000 sf of enclosed ceiling area. Figure 8 shows the plan layout of these systems. The partitions have been designed with conventional details that are currently in use in residential and commercial buildings, respectively. The ceiling in the fourth floor will be installed without a bracing system, while in the fifth floor the bracing will be included according to the seismic code requirement. Fire suppression sprinkler systems are included to capture dynamic interactions between the ceiling and sprinkler heads. The designed configurations for these systems allows for evaluation of the following effects:

- Comparative performance of CCP systems for isolated and fixed-base structural configurations.
- Interaction of the nonstructural assemblies and structural elements.
- Influence of openings (doors and windows) on response of partitions.
- Influence of corner and T-configuration partition layouts.

- Relative length of partition walls.
- Institutional versus residential partition wall detailing
- Partitions with slip tracks versus fixed tracks.
- Behavior of self-standing partial height partitions (shown as dotted line in Figure 8), which provide an enclosed room for testing furniture and other contents.
- Interaction between partition-ceiling and ceiling–sprinkler piping.
- Dynamic amplification of ceiling relative to structural accelerations.
- Effect of bracing on large areas of ceilings.
- Effect of additional masses such as lighting systems.
- Dynamic response of sprinkler piping system.

Additional plans include the construction and testing of a small section of concrete cladding panels on the building exterior. Details are omitted due to space limitations.

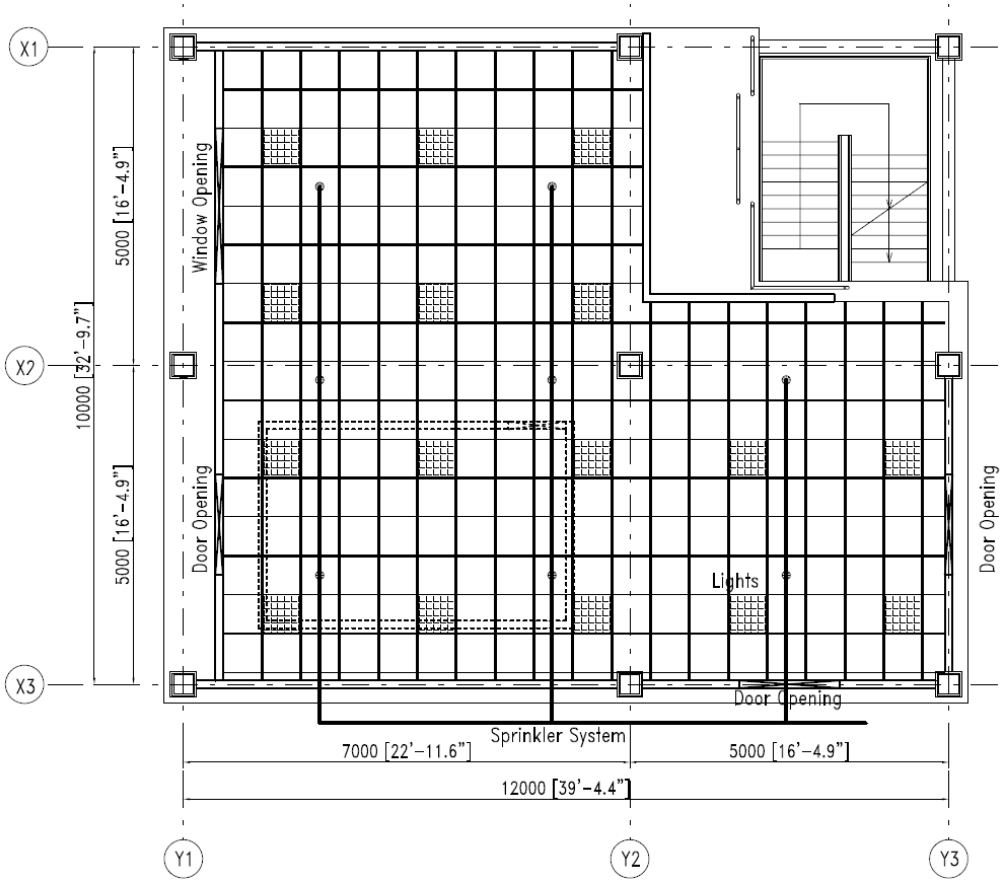

Figure 8. Plan view of interacting ceiling system, exterior wall, and piping planned for 4th and 5th floors of specimen.

CONCLUDING REMARKS

These landmark tests will take place in August/Sept. 2011, where the specimen will occupy the table for a 3 week time frame. Four days of shaking are allocated, with 3 for the isolated specimen (Day 1 = frequent and DBE/L2, Day 2 = MCE/L3, Day 3 = displacement limit tests) and one for the specimen in the fixed-base configuration.

ABSTRACT

Concrete is the most widely used construction material, and the addition of carbon-nanofibers (CNF) to concrete has many advantages in both mechanical and electrical properties such as higher strength, a higher Young's modulus, improved fatigue resistance in addition to self-monitoring behavior due to the high tensile strength and high conductivity. In this study, the Ultrasonic Pulse Velocity (UPV) method was used to characterize properties of concrete containing carbon-nanofibers. Concrete strength correlations between pulse velocity, electrical resistance variation and destructive tests were analyzed. The experimental results indicate that the compressive strength, pulse velocity and percent reduction in electrical resistance while loading concrete containing CNF are much greater than those of plain concrete.

INTRODUCTION

Concrete has been used as the major construction material for many years in the field of civil engineering because of its high compressive strength and constructability. Cement, the binding component of concrete, develops micro cracks during casting and loading which weaken the final concrete structure. Micro cracks range in size from picometers to micrometers and eventually lead to abrupt failure if not detected and repaired. In order to restrict the growth of micro cracks, carbon-nanofibers (CNFs) were added to the concrete mix. CNFs have tensile strengths over 7.0 GPa (1015 ksi) and an average length of 20 μm. These characteristics enable the nanofibers to bridge micro cracks and absorb the energy normally released during crack propagation. Addition of the carbon-nanofiber into the concrete increases the strength, ductility and transforms this material into a more robust material. Carbon-fiber concrete is gaining its acceptability during recent years due to the decrease in carbon-fiber cost and increasing demand of superior structural and fundamental properties such as strength, ductility, creep, shrinkage and ductility. Strength of the cement concrete increased with the development of the nanoscale bonding between the CSH and nanofiber which has the ability to hold the cement matrix more strongly than the CSH itself [1].

In recent years, more and more researchers are prone to use the ultrasonic pulse velocity nondestructive technique to test the materials because this technique is easier and more economical than traditional tests. Current research utilized the pulse velocity method to evaluate the properties of the carbon-nanofiber concrete. Lamb [2] analyzed the surface wave propagation for the case of impulse vertical point load with a solution valid for a point far from the source. Lamb's solution was later extended by Nakano [3] for the cases close to the source. Pulse velocity changes with many variables in concrete, including water content, mixing proportions, aggregate type and size, and age of concrete (Tanigawa et al., [4]). Okamoto and Whiting [5] studied the maturity and the pulse velocity to predict the strength of the concrete. Mantrala and Vipulanandan [6] used the pulse velocity method for the evaluation of the differences between polyesterpolymer and polymer. Frearson [7] conducted nondestructive testing and discussed the problems with concrete tests and test results in adverse weather conditions. Gao *et al* [8] indicated that some mechanical and electrical properties of CNFSCC were improved under compression stress, which is the most basic force acting on concrete in reinforced concrete structures. Especially in the aspect of electrical properties, the relationships between electrical resistance variation (ERV) and strain as well as ERV and stress can be established. Therefore, the damage evaluation and self-health monitoring of concrete structures might be easier to carry out since the concrete itself acts as a sensor, resulting in much lower cost of the infrastructure's maintenance and repair. Based on the reasons mentioned above it is feasible and attractive to develop smart high performance carbon-nanofiber concrete by adding CNF to concrete.

EXPERIMENTAL PROCEDURE

MATERIAL PROPERTIES

CNF from Pyrograf Products, Inc. [9] were used in this study. PR-19-XT-LHT-OX is the oxidized product produced by heat-treating the fiber at 1500° C. Heat treatment converts any chemically vapor deposited carbon present on the surface of the fiber to a short-range ordered structure. The inherent conductivity of the fiber is increased following heat treatment. High-range water reducer Glenium 3200 HES, a polycarboxylate admixture from BASF Chemical Co., was used to decrease the viscosity of the concrete [10]. Antifoam agent Antifoam 2210, a silicone–glycol emulsion (polypropylene glycol and polydimethylsiloxane) from Dow Corning, was used for all three kinds of CNFs to reduce the amount of foam produced during mixing and after detergent addition [11]. Low-alkali, type I/II cement was used in all specimens. Crushed limestone with a maximum size of 19 mm was used as coarse aggregate in all specimens. Natural river sand with a fineness modulus of 2.71 was used as fine aggregate in all specimens.

MIXTURE PROPORTIONS

As shown in Table 1, six mixtures were studied. The binder weight is the total weight of cement and CNF. CNFSCC07-LO, CNFSCC10- LO, CNFSCC15-LO,

CNFSCC20-LO and CNFSCC25-LO denote self-consolidating concrete containing the CNF PR-19- XT-LHT-OX in amounts of 0.7%, 1.0%, 1.5%, 2.0% and 2.5% by volume of binder, respectively.

Table 1 Mixing proportions

Mix	Carbon nanofiber (vol% binder)	Water (kg m^{-3} concrete)	Cement (kg m^{-3} concrete)	Coarse aggregate (kg m^{-3} concrete)	Fine aggregate (kg m^{-3} concrete)	High-range water reducer (fl.oz./cw)	Antifoam (fl.oz./cw)
SCC	0	191	480	901	1005	11	0
CNFSCC07-LO	0.7	191	478	902	1008	7	11
CNFSCC10-LO	1	191	478	902	1008	11	11
CNFSCC15-LO	1.5	191	478	902	1008	19	11
CNFSCC20-LO	2	191	478	902	1008	23	11
CNFSCC25-LO	2.5	191	478	902	1008	35	11

TESTING METHODS

DESTRUCTIVE TESTING

Compression tests were conducted using a Tinius Olsen Universal Material Tester with a maximum load capacity of 600 kips according to ASTM rates of 300 lbs s^{-1} in load-control mode and 0.00005" s^{-1} in strain-control mode. The specimens used were 4" by 8" cylinders. A compressometer Standard C 39M-05 load with a digital strain gauge was used to detect strain.

ULTRASONIC PULSE VELOCITY (UPV) TESTING

The device used to measure velocity is ultrasonic pulse velocity meter [12] (V-meter). The V-meter can generate compressive waves traveling along the materials and record the shortest travel time. The wave travel depends upon the amount and dispersion of the carbon-nanofibers. The transit time can be measured with three methods, which are direct, semi direct and indirect method. Direct transmission method is used in this current research because it is more reliable than the other two methods.

The pulse velocity [12] is calculated with the known distance and time as

$$V = D / T \tag{1}$$

whereas V is the pulse velocity, D is the distance between transducers across the diameter, and T is the transit time.

The pulse velocity is measured continuously along the transverse direction of the cylinder throughout the destructive testing. It eases the correlation between pulse velocity, strain and stress at different stages of loading of the cylinder.

ELECTRICAL RESISTANCE VARIATION (ERV) TESTING

The four-probe method was used to determine the volume electrical resistance of the specimens (Fig. 1). The surface of each specimen was ground in order to expose higher densities of CNFs and remove dust from the surface where the wires contact the specimen. Conductive silver epoxy was spread along the wires to hold them in place and ensure continuous contact with the concrete surface. Current was measured across the top and bottom wires using an ammeter with ±0.01 μA accuracy and voltage was measured across the two middle wires using a voltmeter with ±1.0 μV accuracy so that the electrical resistance between the two central wires could be calculated using Ohm's law. A 1.5 V AA battery was used as the voltage source. The original voltage and current readings were recorded as V_0 and A_0, and the original electrical resistance R_0 was calculated. Subsequent voltage and current values were recorded each time the load and strain were recorded during the compressive test. Each strain value, Δ_i, at every time point, i, had corresponding values of voltage and current recorded as V_i and A_i . The electrical resistance R_i and electrical resistance variation Δ_{Ri} were calculated using Eqs. (2) and (3):

$$R_i = V_i / A_i \tag{2}$$

$$\Delta_{Ri} = (R_i - R_0)/R_0 \tag{3}$$

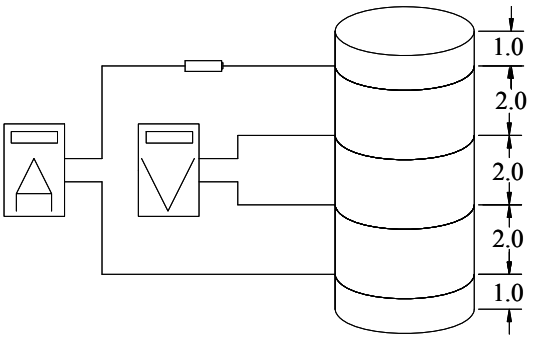

Fig. 1. Cylinder with wires and multimeters attached to measure electric resistance with four probe method.

STRENGTH AND PULSE VELOCITY (V_{PD}) VARIATIONS DURING LOADING

Pulse velocity (V_{PD}) is measured at the middle of the cylinder along the transverse direction throughout the loading and the variation of the pulse velocity (V_{PD}) was compared with stress and strain containing plain Self Consolidated Concrete (SCC) and SCC containing the PR-19-XT-PS-LHT-OX. As the loading increases, compressive strain along the longitudinal direction increases along with the increase of the compressive strength of the concrete. After reaching the peak strength of the concrete, compressive strength reduces with the increase of the compressive strain (Figs. 2 - 3). With the increase of the compressive strain of the concrete along

the longitudinal axis of the cylinder, tensile strain along the transverse direction increases because of the Poisson's effect and that causes damage of the cylinder. Pulse velocity (V_{PD}) is reduced steadily until reaching a strain of about 0.001, and, after that, it is reduced rapidly because of the increase of the damage of the specimen.

For CNFSCC containing PR-19-XT-PS-LHT-OX, the peak compressive strength and pulse velocity (V_{PD}) varies as follows (Figs. 2): CNFSCC10-LO > CNFSCC15-LO > SCC > CNFSCC07-LO > CNFSCC25-LO > CNFSCC20 -LO and is increased 21.4% compared to plain SCC when the CNF concentration is 1.0%. This indicates the threshold of the concentration is around 1.0% and gives higher energy dissipation. From Fig. 2 it is clear that the pulse velocity (V_{PD}) and ductility of CNFSCC10-LO is 20% and 45% higher than the SCC, respectively. Figure 3 shows that the ductility of SCC containing PR-19-XT-LHT-OX is greater than that of plain SCC.

From the above discussion, it is evident that the pulse velocity has a direct correlation between the strength and energy dissipation of the CNF concrete. In next section, the pulse velocity is correlated with the electrical resistance variation.

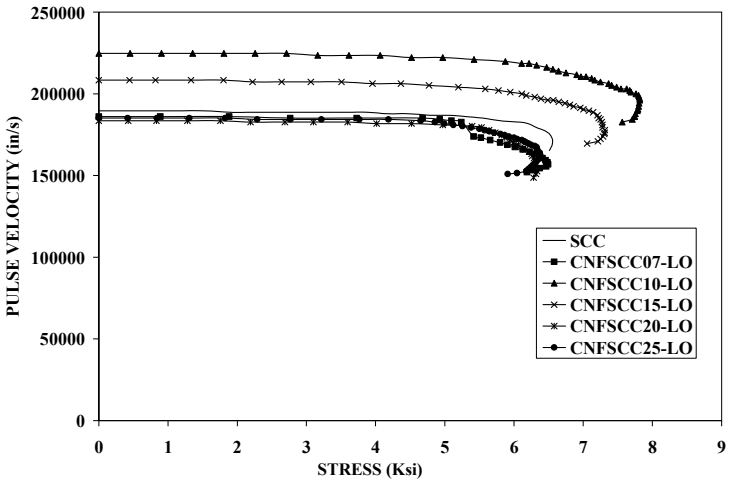

Fig. 2. CNFSCC-LO pulse velocity-stress relation

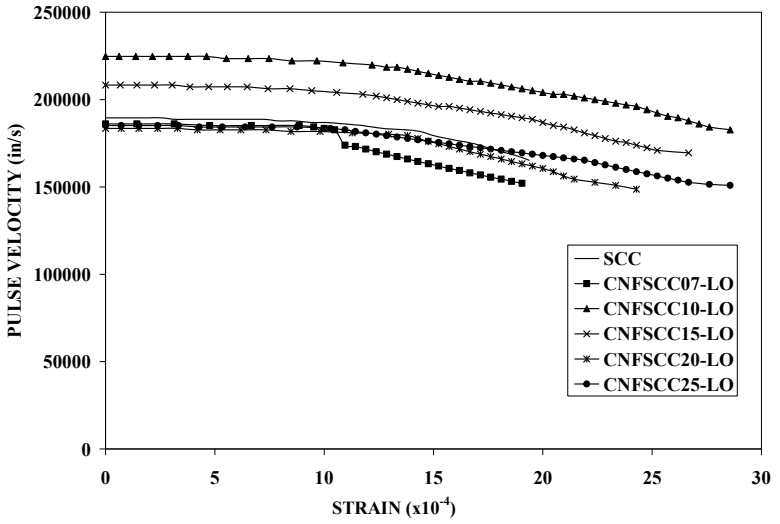

Fig. 3. CNFSCC-LO pulse velocity-strain relation.

PULSE VELOCITY (V_{PD}) *AND ELECTRICAL RESISTANCE (R) VARIATIONS DURING LOADING*

Figures 4– 5 show the relationship between electrical resistance variation Δ_{Ri}, pulse velocity (V_{PD}), stress and strain of each plain SCC and SCC containing the PR-19-XT-PS-LHT-OX. Resistance decreases for all concentrations of fiber. At 1.0% CNF concentration, CNFSCC10-LO exhibits the highest electrical sensitivity with an 80% reduction in electrical resistance. Electrical resistance variation decreases rapidly when the concentration of CNFs is increased from 1.0% to 1.5%. This trend continues at a slower rate for CNF concentrations greater than 1.5%. When the concentration of PR-19-XT-LHT-OX fibers exceeds 2.0%, the percent reduction in electrical resistance is less than 10%. From Figs. 4 and 5 it is evident that the increase of strain and stress reduces the pulse velocity (V_{PD}) and electrical resistance variation. Compared to other mixes CNFSCC10-LO exhibits the higher pulse velocity (V_{PD}) and lower electrical resistance variation.

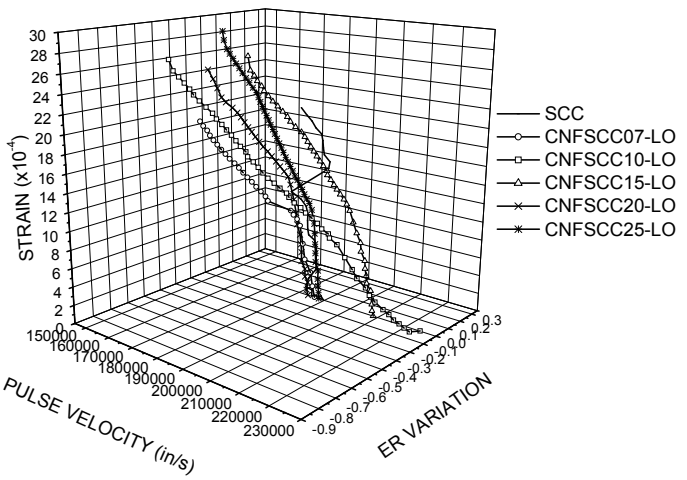

Fig. 4. CNFSCC-LO variation of electrical resistance - pulse velocity - strain

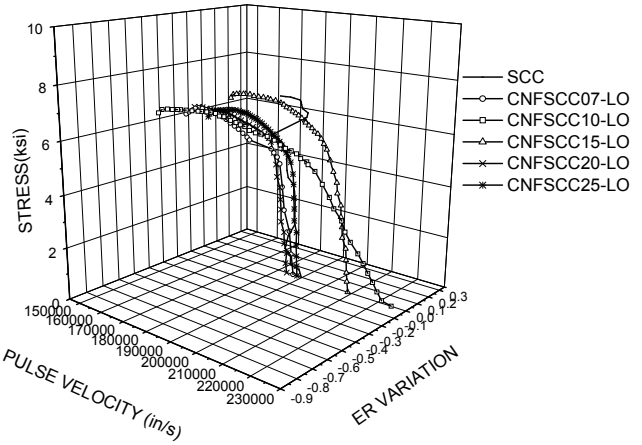

Fig. 5. CNFSCC-LO variation electrical resistance - pulse velocity – stress.

CONCLUSIONS

The results presented in this paper have articulated that the strength and ductility of carbon-nanofiber concrete can be estimated by the pulse velocity method. The ERV of plain SCC is random, so it is impossible to establish the relationship between ERV and strain/stress. Adding CNF decreases the electrical resistance of SCC because it is a semiconductor, but there is a threshold for fiber concentration. If the actual concentration is higher than the threshold, the tunnel conductivity effect of CNF will decrease and the electrical resistance does not change with increasing strain. Well-dispersed CNF in the appropriate concentration allows for the greatest pulse velocity and electrical resistance variation of concrete with increasing strain and, consequently, may be used in applications that require strain monitoring and make concrete itself a sensor. Well-dispersed CNF improves the pulse velocity and strength of concrete. Excess concentration leads to poorly dispersed CNF clumps inside the concrete and has a negative effect on pulse velocity and strength. PR-19-TLHT-OX performs best at concentrations around 1.0%.

INTRODUCTION

The California legislature originally authorized state engineering staff to design their own highways and bridges in 1923 [Caltrans 1999] (Figure 1). For approximately eighty-seven years state employees have designed bridges for the state highway and interstate system in California. There are approximately 300 award winning bridges that have been cost effectively designed by state employees and are maintained and operated by Caltrans (www.dot.ca.gov) for the taxpayers of the state of California. The Professional Engineers in California Government (PECG) (www.pecg.org) was created in 1963 as an organization to represent the interests of public employees. PECG's function was primarily to highlight the technical achievements and viewpoints of state employees. In the 1970's with the passage of the Ralph C Dills Act, PECG took over the additional role of representing engineering and related classes in bargaining with their California government employer. Thus the authors as engineers employed by the state of California Department of Transportation belong to both PECG and ASCE. Featured bridges in this short paper and poster are mainly the best known structures recognized by the bridge industry and others as state of the art in bridge engineering. Leading educators such as Professor David Billington believe that structural engineering is an art form with creative individuals due recognition by society, such as award programs (Figure 1). A Bridge Architecture Aesthetics unit has been part of Caltrans structures design since the 1930's. A licensed Architect has managed the unit of technicians, renderers and scale model makers since the 1960's. Caltrans engineers have also designed several notable tunnels and the Webster Precast Concrete Tube, which opened in 1963 (Figure 2).

ORTHOTROPIC BRIDGES DESIGNED BY CALTRANS

The origin and development of orthotropic steel deck bridges occurred over many years and has many sources [Mangus 1999 & 2005]. In the 1920's steel plates were riveted to steel girders on long span movable bridges to achieve a durable, strong and lightweight superstructure. In 1938 the AISC American Institute of Steel Construction promoted the "Battledeck Bridge System" because the superstructure was made of 100% of welded steel and built tough as a battleship. The German steel industry produced the first orthotropic bridge design manual in 1957 and patented the orthotropic system. In 1963, the American Institute of Steel Construction (AISC) funded and published the "Design Manual for Orthotropic Steel Plate Deck Bridges," authored by Roman Wolchuk [Wolchuk 1963]. Caltrans Engineers researched this technology to bring state of the art seismic resistant design solutions from Europe to California. The authors were instrumental in creating www.orthotropic-bridge.org in 2004 and 2008 for ASCE, which attracted an attendance of about 200 from eleven countries. The FHWA –Federal Highway Administration has a new Orthotropic Bridge Manual in progress which was conceived at the first international orthotropic bridge conference. Active California bridges with orthotropic or 100% steel superstructures designed by Caltrans bridge engineers are summarized in table 1 vs. well known foreign bridges [Huang 2006].

Text In Section	Bridge in Service Name [year open to traffic]	Rib Type	Deck Area (Sq. feet)	Bridge Number (by owner)
1.	Dublin 580/680 Test [1965]	closed	10,880	33-0371G
2.	Ulatis Creek Test [1966]	open	4,420	23-0052R
3.	San Mateo – Hayward [1967]	open	468,875	35-0054
4.	San Diego – Coronado [1969]	closed	122,220	57-0857
TOTAL	**Deck area of CA Orthotropic Bridges**	**both**	**606,395**	
	Akashi-Kaiyo, Japan [1998]	closed	905,093 sq. ft. = 84,086 sq. m.	
	Millau Viaduct, France [2005]	closed	1,989,168 sq. ft. = 184,800 sq.m.	

TABLE 1 CALTRANS DESIGNED ORTHOTROPIC BRIDGES COMPARED TO FOREIGN BRIDGES

WEARING SURFACE TEST BRIDGE AT DUBLIN [1965]

The North 680 to West 580 connector bridge at Dublin, CA [Br. No. 33-371G] [Dec 1965] was built as an experimental bridge to check the accuracy of Caltrans' design software **"*Orthotropic Plate Design*".** This software uses the actual capacities, various trapezoidal ribs, and deck plate thicknesses. The California Department of Transportation (Caltrans) built the I-680 over I-580 Bridge as their test structure. The four span [75-ft + 85-ft + 85-ft + 75-ft] bridge is still in use after 30 years of service, but the wearing surface has been replaced on the thin section. The bridge is 34-ft wide x 320-ft long = 10,880 sq. ft. of deck area [Davis 1964 & 1968].

WEARING SURFACE TEST BRIDGE AT ULATIS CREEK [1966]

The State of California Division of Highways (Caltrans) designed the Ulatis Creek experimental orthotropic bridge lane in 1965. Construction of Caltrans Bridge Number [Br. No. 23-0052R] was completed in 1966. It consists of the two outside lanes of a 5-span bridge for eastbound Interstate I-80. All spans are 26-ft [8-M] long and the orthotropic deck has a "Split-T" superstructure (Figure 3). The bridge design engineers

wanted to test the durability of five types of wearing surfaces. Caltrans San Francisco Bay Toll Crossing engineers supervised this testing, with the most practicable material selected for use as the wearing surface of the San Mateo- Hayward Orthotropic Bridge (Figure 4).

FIGURE. 3 TEST BRIDGE AT ULATIS CREEK [1966]
PHOTO BY ALFRED R. MANGUS

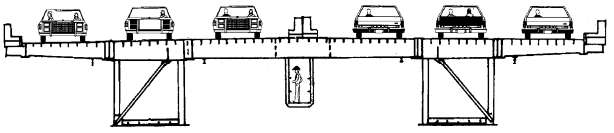

FIGURE 4 CROSS-SECTION SAN MATEO HAYWARD [1967]
DRAWING BY ALFRED R. MANGUS

The Ulatis Creek bridge is 34-ft wide x 130-ft long = 4,420 sq. ft. of Orthotropic steel deck area. The original wearing surface which was selected based upon in service performance at this location for the San Mateo Hayward Bridge is still in place after 43-years, so this bridge has been successful in several ways.

SAN MATEO HAYWARD BRIDGE ACROSS SAN FRANCISCO BAY [1967]

The San Francisco Bay Toll Crossings office (now part of Caltrans) was the designer and owner of the San Mateo – Hayward Bridge. It opened on Oct 31, 1967 and received the ASCE OCEA= Outstanding Civil Engineering Achievement Award of 1968. It received AISC and other awards. This Orthotropic Bridge has two side spans of 375-ft each counterbalancing the main 750-ft span. There are 14 approach spans of 292-ft or 7 on each side of the main span. Thus this bridge has the largest total Orthotropic deck area of all California bridges. The bridge has a width of 85.25 feet, and length of 5,500 feet = 468,875 square feet. It carries six lanes of Route 92 traffic across the San Francisco Bay between the communities of San Mateo and Hayward[Foley 1968][Huang 2005] (Figure 4).

18 TH STREET POC PEDESTRIAN OVERCROSSING [1968]

This orthotropic structure was designed and built as one piece in a fabrication shop. The previous welded steel deck bridge across the freeway used a plate girder as the superstructure. The new steel deck Veerendiel truss superstructure was completely shop prefabricated (Figure 5). It received a James F. Lincoln Arc Welding Award.

SAN DIEGO – CORONADO BRIDGE SAN DIEGO BAY [1969]

The San Diego-Coronado Bridge was completed in June 1969 [BR. NO. 57-0857]. This California toll bridge sweeps across the harbor area of San Diego (Figure 6). The Caltrans bridge design engineers selected a single cell box girder Orthotropic steel deck (continuous length of Orthotropic portion = 573-m). A constant depth box was used for

the 182.88-m + 182.88-m + 152.40-m main spans over the shipping channel. Steel plate girders with concrete deck were used on the remaining length of 1690 m. The area is 19.182-M wide x 518.16-M long = 10,266 sq. meters of steel deck. The bridge was erected in large pieces with the "Marine Boss" barge crane. The sections were field bolted together. The bridge is painted on the inside and outside to resist corrosion and carries six lanes of traffic. It received James F. Lincoln Welding Award and other awards. (Figure 6)

FIGURE 5 18TH STREET PEDESTRIAN OC BY ALFRED R. MANGUS

FIGURE 6 SAN DIEGO CORONADO BRIDGE SUNSET PHOTO PHOTO BY ALFRED R. MANGUS

MOVABLE BRIDGES

The Meridian Cable–Stayed Swing Bridge was completed in June 1977 [Hurdle 1968]. This structure received a lot of publicity because of increasing interest at the time in the development of cable stayed bridge technology. It received a James F Lincoln Arc Welding Award and received considerable attention from the bridge industry after opening to traffic. It is a single swing symmetrical span bridge using steel plate girders and a reinforced concrete deck. The A- frame shaped tower was fabricated from welded steel members.

The Potato Slough moveable bridge across the Sacramento River was completed in 1991(Table 2). It is a single symmetrical swing span bridge using tapered steel plate girders and a reinforced concrete deck. A design model was built and the cast-in-place reinforced concrete sculpture control tower was designed and built. Key dimensions are: Length of largest span: 160.1 ft with a total length: 2,980.1 ft. Deck width: 42.7 ft.

RECOGNITION TO INDIVIDUAL BRIDGE ENGINEERS

The California legislature can rename bridges after Caltrans employees or others. Organizations such as the Western Engineers Society of Pennsylvania' IBC = International Bridge Conference have bestowed recognition upon three bridge engineers who were with the state of California for decades. Art Elliot, James E Roberts and Charles "Chuck" Seim are IBC Roebling Award Winners for a lifetime of achievement in bridge engineering [Wilson 2001]. Other engineers at Caltrans have been bridge design contest winners by various organizations. The late Ostap "Joe" Bender started his career with The California Department of Highways and was a very talented bridge design engineer [Figure 13]. Joe Bender worked on a complete range of interesting bridges

during his career as a public servant and later in private industry. Bender designed steel plate girder structures for highways and railroads, steel box girders, two orthotropic steel deck bridges and an innovative suspension bridge. His concrete bridges include concrete box girders, cast in place concrete boxes and the cast-in-place concrete Pine Valley Bridge. Bridges that he felt that were important for his oral history are: 1957- 5th Street Southbound On-Ramp Overcrossing On Rte 165 In LA County; 1958- Lacy Street Underpass BR#53-1405; 1959- Eagle Point Viaduct BR#4-72 on US 101; 1963- Banner Ridge Overcrossing BR#17-77 On Rte 49 in Nevada County; 1964- Rte 580/680 Separation BR #33-371R/L; 680 / 580 Orthotropic Test Bridge; 1965-Santa Margarita River Bridge, BR#57-07L; 1965- Willow Creek Bridge BR #4-135; 1965 - Cocklebur Overcrossing BR#57-584 on RTE 5; 1965- Klamath River Suspension Bridge At Orleans on Rte 96 BR # 4-69; 1966 - Sacramento River Bridge and Overhead at Brytes Bend BR# 22-26R/L aka Caltrans Worker Memorial Bridge (Figure 12).; 1971-Pine Valley Creek Bridge BR#57-692R/L on Rte 8 (Figure 9).

Bender wrote in a letter in 2001. *"My approach to bridge design is based on several ideas that I have tried to incorporate in my bridges. The selected structure type should first of all:*

1. *Fit the constrains of the site*
2. *Be reasonably economical from the available choices*

Of Secondary concern are (although they may govern the selection):

1. *Appearance*
2. *Local preference*
3. *Research needs*
4. *Advancement of the art of bridge building"*

CONCRETE BRIDGES

Caltrans engineers have designed a wide range of concrete bridges. The award winning lightweight concrete bridge at Napa River has been durable [PCA 1977]. The column heights vary and are flared (Figure 7). The superstructure is variable in depth (Figure 8).

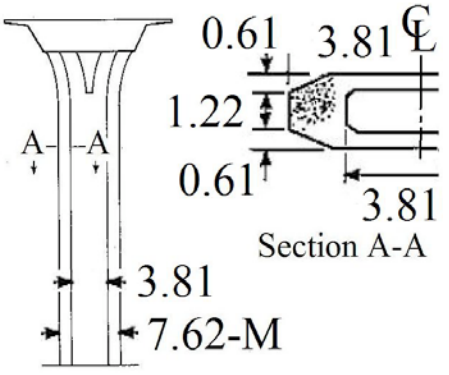

FIGURE 7 NAPA RIVER BRIDGE COLUMN
DRAWING BY ALFRED R. MANGUS

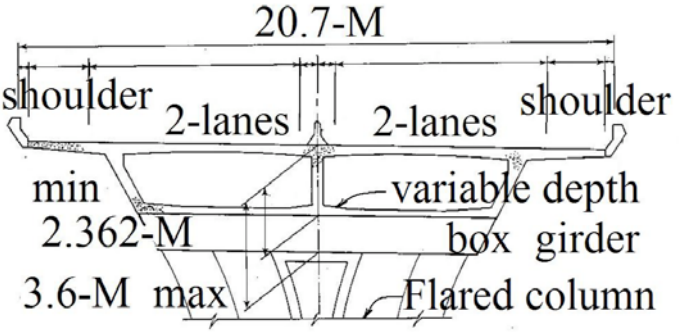

FIGURE 8 NAPA RIVER BRIDGE
DRAWING BY ALFRED R. MANGUS

The Pine Valley Bridge renamed the Nello Greer Memorial Bridge was the first Segmental concrete bridge of either precast or cast-in-place concrete designed and constructed in the USA. Documentaries produced by Caltrans to memorialize the construction of this innovative structure include the "*The Bridge*" which follows the phases of construction of the first segmental concrete bridge in the USA. The 16 minutes of civil engineering content was created by Caltrans Graphic Services with time lapse construction sequences developed by Caltrans Photo Lab.

FIGURE. 9 PINE VALLEY SEGMENTAL PHOTO BY OSTAP "JOE" BENDER

FIGURE 10 DEVILS SLIDE UNOPENED TO TRAFFIC [2011] PHOTO BY KEVIN HARPER

The Director was Richard Jones, cinematographer was John McCue, Audio was by Robert Souza, Art Direction was by David Douglas and Phil Walusek of the Portland Cement Association and "*The Bridge*" features interviews or narration by Caltrans Division of Structures staff, with short discussions on the topic of bridge design by Bert Bezzonne and Ostap "Joe" Bender. Bridge architecture is discussed by Bill Wells and bridge construction by Caltrans Resident Engineer Ralph Sommariva. Film credits recognize Lead Highway Designers Norm Larsen, Nello Greer and Highway Resident Engineer Tom Drake of Caltrans. The General Contractor was SJ Groves of New York City. The prestressing contractor was Dyckerhof and Widmann, Inc., Munich, Germany [ENR 1971].

FIGURE. 11 COCKLEBUR BRIDGE[FOR TANKS] OVER I-5 PHOTO BY OSTAP "JOE" BENDER

FIGURE 12 BRYTES BEND – STEEL TUB PHOTO BY OSTAP "JOE" BENDER

Caltrans bridge design engineers with assistance from the Office of Bridge Architect and Aesthetics staff continue to create beautiful bridges a great recent example is the Devils Slide Bridge on Rte 1 in San Mateo county which will open to traffic in 2011. (Figure 10)

The Cocklebur overcrossing over Interstate 5 is a reinforced concrete box girder with spans of 114`-128`-112` and depth of 10-feet, designed by Ostap Bender. Its unusual depth and non-standard typical section are due to the unusual live loads to support military armored vehicles or the M48A3 Patton Tank. Interstate 5 divides Camp Pendleton Marine Base. This grade separation bridge allows the marines to cross back and forth as needed to complete military exercises. The concrete bridge rails for this structure were unique as they were designed to prevent tanks from accidentally falling onto I-5 traffic (Figure 11).

STEEL BRIDGES

Caltrans engineers have designed a wide range of steel bridges. This includes many normal strength steel plate girder bridges. Caltrans engineers have also designed more complex steel bridges such as curved plate girders, steel arch bridges, steel truss bridges, tub girder bridges, suspension bridges and orthotropic bridges. Brytes Bend Bridge is a steel tub girder twin box superstructure which was fabricated from high strength steel. The steel failed during erection. The general contractor and Caltrans successfully sued the plate steel manufacturer for damages. Although heavily cracked the bridge has been retrofitted and remains in service. In spite of material setbacks the bridge as retrofit to accommodate traffic received AISC and James F. Lincoln Arc Welding Awards. Ostap Joe Bender was lead designer (Figure 12). Caltrans renamed the bridge to honor its maintenance workers. This structure which was renamed the Caltrans Maintenance workers memorial bridge in 2003 honors the 174 Caltrans workers who have been killed in the line of duty since 1923 and the creation of the original highway department.

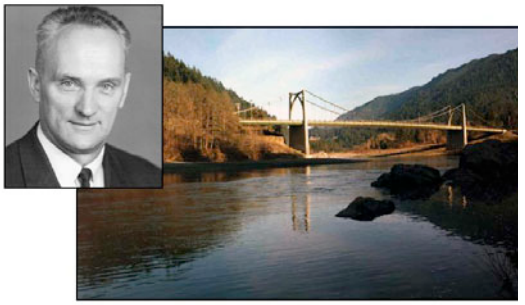

FIGURE 13 BENDER & KLAMATH RIVER SUSPENSION PHOTO BY OSTAP "JOE" BENDER

FIGURE 14 JAMES E. ROBERTS' BRIDGE PHOTO BY JOHN ADAM

SUSPENSION BRIDGES

The Klamath River Bridge at Orleans on Route 96 BR# 4-69 was designed using an aerodynamic wing cross-section shape. The superstructure configuration was influenced

by the world famous British Severn Orthotropic Box girder design (Figure 13). The previous two bridges at this site were suspension bridges built around [1915 timber] and [1940 steel] were carried away by high flood waters. The 1940 AISC Prize winning structure using the traditional stiffening truss of I-Girders, might have survived (Table 2). However large trees floating on top of the flood crest became entangled in the superstructure and facilitated the destruction of the 1940 bridge. The new bridge was completed in 1965 with a Cost: $1,420,000. Spans are 170`-430`-170` width 34-ft depth of only 5`-9". A suspension bridge is usually not the most economical type for a main span length of 430-ft. However the district highway engineers and local area residents favored replacing the 1940's bridge with another suspension span. It still may be the only multi-cell welded steel tub girder with a reinforced concrete deck. The bottom sides are sloped to have an aerodynamic wing shape. The smooth steel soffit will not catch any floating debris and the use of materials creates a very efficient stiffening system. Prefabricated cables were used rather than air spinning. Cast-in place concrete towers were used to eliminate painting. The shape of the towers was selected to match appearance of the 1940's bridge. The bridge received AISC and James F. Lincoln Awards and is featured in two books (Table 2). Designers were Ostap Joe Bender and Bert Bezzonne. PECG members' most recent award from NSBA / AISC was a merit award for the rebuilding of the Fire Damaged MacArthur Maze. Arnold Schwarzenegger's State of the State Address Tuesday, January 8, 2008. **"***In April, a fiery truck crash melted the Bay Area's 580 freeway exchange. Hundreds of thousands of Californians who depended on that interchange foresaw months of delays and stress. Yet it didn't take the expected 150 days to repair. Caltrans, working with contractors, cleared the span in 10 days and then built a new bridge and opened it up in a record 16 days later. Government can work. It can be efficient. It can lead."* – Governor Arnold Schwarzenegger. Film clips of this accelerated bridge repair may be viewed at http://www.amazingmaze.org/ .

THE TUOLUMNE BRIDGE NOW THE JAMES E. ROBERTS MEMORIAL

The Tuolumne River Bridge was selected to be named in honor of Mr. Roberts, because it was one of the first bridges that he was assigned responsibility for as a senior bridge engineer in 1968 with the California Department of Highways [Kempton 11]. Mr. Roberts laid out this Tuolumne River Bridge on a 1200-ft radius horizontal curve to meet the site requirements in December 1967(Figure 14). Computer analysis was required by the designer Mr. Dokken and the design squad because of the bridge's long spans and curved alignment [Dokken 2009]. The Bridge aesthetic unit of the California Department of Highways was called upon to provide architectural enhancements for the structures tall slender columns and sweeping curved spans. The columns were designed with triangular caps to accommodate the superstructure with insets featuring concrete dyed to match the golden California hillsides surrounding the site. Conventional concrete was used for construction of the foundations and the hexagonal columns and lightweight concrete was used for the bridge deck. The superstructure chosen was steel curved girders which were trucked into the site. The location over a future reservoir required that the superstructure be completed quickly and because of the heights above the ground the construction of a concrete superstructure would not have been practical. To accommodate future capacity in this challenging location the structure was designed

Year	Name	Type/class
1935	Sagamore Bridge, Town of Bourne, MA	Honorable Mention
1940	Klamath River Bridge, Humboldt County, CA	First Place
1950	Bridge Over Kern River, Kern County, CA	Honorable Mention
1953	Ninth and Tenth Street Connections, San Francisco, CA	N/A
1954	Indian Creek Bridge, Plumas County, CA	Honorable Mention
1955	Archibald Avenue Bridge, San Bernardino County, CA	Honorable Mention
1955	Distribution Structure Overhead Addition, Oakland, CA	Honorable Mention
1957	Trinity River Bridge, Hoopa, CA	First Honorable Mention
1958	Marsh Rd. Overcrossing, Redwood City Limits, CA	Honorable Mention
1959	Huasna River Bridge, Santa Maria, CA	II-fixed spans under 400 ft
1959	Truckee River Bridge, Truckee, CA	Honorable Mention
1959	Kern Ave. Pedestrian Overcrossing, Mac Farland, CA	Honorable Mention
1959	Grant Line Canal Bridge, Stockton and Tracy, CA	Honorable Mention
1961	Pecwan River Bridge, Weitchpec, CA	Short Span, Merit Award
1962	Elysian Viaduct Bridge, L.A., CA	Medium Span w/fixed span under 400 Ft., Merit Award
1962	Middle Fork Smith River Bridge, Crescent City, CA	Short Span w/fixed spans , Merit Award
1962	South Fork Eel River Bridge of Meyers Flat, Humbolt County, CA	Medium Span w/fixed span under 400 Ft.
1963-64	Webber Creek Bridge, 16 mil. E of Sacramento County Line, CA	Medium Span
1963-64	Vincent Thomas Bridge, San Pedro, CA	Long Span
1963-64	Devil's Canyon Bridge No. 2, 5 mil. E of San Diego County, CA	Short Span
1963-64	Cold Spring Canyon Bridge, Santa Barbara, CA	Long Span
1965	Northbound Route 280/17 Separation, San Jose, CA	Highway Grade Seperation
1965	South Fork Eel Bridge & Separation, Sylvandale, CA	Medium Span High Clearance
1965	Lebec Road Overcrossing, Bakersfield, CA	Highway Grade Separation
1966	Willow Creek Bridge, Willow Creek, CA	Short Span
1966	Route 680/580 Separation, West of San Joaquin County Line, CA	Highway Grade Separation
1967	Dry Creek Bridge, Ione, CA	Short Span
1967	Klamath River Bridge, Orleans, CA	Long Span
1967	Oak Hill Road Overcrossing, South of Victorville, CA	Highway Grade Separation
1967	Merced River Bridge, Bagby, CA	Medium Span Low Clearance
1967	Pioneer Memorial Bridge, Sacramento , CA	Medium span high Clearance
1968	San Mateo-Hayward Bridge, San Mateo and Hayward, CA	Long Span
1968	Eel River bridge and Overhead, Scotia, CA	Med. Span - Low Clearance
1968	South Fork Feather River Bridge, near Feather Falls Butte County, CA	Long Span. Merit
1968	Route 5/99 Separation, Kern county, CA	Hwy Grade Separation
1968	Valencia Blvd. Overcrossing, Valencia, CA	Hwy Grade Separation
1969	Kern River Bridge, Isabella, CA	Medium Span High Clearance
1969	McBean Parkway Overcrossing, Newhall, CA	Hwy Grade Separation
1969	Kern River Bridge, Isabella, CA	Medium Span High Clearance
1970	Sacramento River Bridge at Elkhorn, Sacramento, CA	Medium Span High Clearance, merit
1970	Eugene A. Doran Memorial Bridge (San Mateo Creek Bridge), San Mateo, CA	Medium Span High Clearance
1971	Klamath River (South Rogers Creek) Bridge, Siskiyou County, CA	Medium Span High Clearance
1972	Sacramento River Bridge at Bryte Bend, Sacramento, CA	Medium Span High Clearance
1972	Tuolumne River Bridge, near Sonora, CA	Medium Span Low Clearance
1973	West Connector Viaduct, San Jose, Ca	Elevated Hwys or Viaducts
1975	Kern River Bridge, Kern County, CA	Medium Span Low Clearance

TABLE 2 AISC / NSBA AWARD WINNING STEEL BRIDGES DESIGNED BY PECG MEMBERS

to be widened from 2-lanes of traffic to 4-lanes of traffic. The Roberts Bridge designers received awards from the steel industry an AISC Medium Span Steel Bridge award in 1972 and a James F. Lincoln Arc Welding Award. The AISC Jurors wrote "This ***gracefully sweeping bridge fits beautifully into its setting. The clean curving***

superstructure and the sculptured piers are very pleasing". Mr. Dokken, a former PECG member describes the steel design details [Dokken 2009]. Mr. Roberts was a former PECG State President and a union member for 50-years [Alden 1999] [Roberts 2001].

SEISMIC RETROFIT OF BRIDGES

A major seismic retrofit effort was lead by Mr. Roberts after the Loma Prieta and North Ridge Earthquakes. Standard solutions were developed for standard bridges [Roberts 1999]. Very unique and large bridges required a team of engineers to develop solutions or to evaluate the choices "retrofit or replace" [Roberts & Maroney 1990]. A documentary developed by PECG, The Bridge So Far: A Suspense Story" discusses issues for the replacement bridge systems selected for the East spans of the SFOBB [Copelan 2011]. The west spans of SFOBB are the 2nd most photographed bridge in California. Suspension bridges are more forgiving under seismic loadings, thus a retrofit of extra steel components and other modifications were made for it, as a cost effective solution. The new steel components were made of steel manufactured and fabricated in Brazil. SFOBB West Spans team was awarded ATC-ASCE Seismic Retrofit Project of the Decade in December 2009 at the ATC-SEI-ASCE conference. ATC-SEI- ASCE awards chair Dr Jeremy Isenberg presents five PECG members Dr Lian Duan, Dr Brian Maroney, Rodney "Rod" Simmons, John Fujimoto and Ofelia Alcantara, the lead bridge design engineers. Awards Ceremony. (Figure 15). The West Suspension Spans of the SFOBB Bridge connection San Francisco to Yerba Buena Island is the 2nd most photographed bridge in California. A large team of PECG Engineers contributed to a bridge engineering handbook which has become an industry best seller. Two of the contributing authors Alfred Mangus and Dr. Lian Duan Co-Editor on this bridge engineering handbook are very active in ASCE [Mangus 1999] (Figure 16).

FIGURE 15 PECG ENGINEERS RECEIVE AWARD [2009] COPYRIGHT PHOTO BY ATC-ASCE

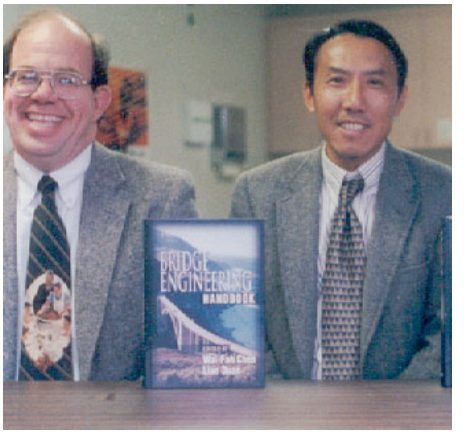

FIGURE 16 PECG ENGINEERS & HANDBOOK COPYRIGHT PHOTO BY A. MANGUS [1999]

A Caltrans Video "No was not an Answer" discusses the reconfiguration of the concrete approach spans in San Francisco for the San Francisco Oakland Bay Bridge. Interviews by District 4 [San Francisco Bay Area and District 59 [Engineering Services – Bridge Structures] Caltrans employees were filmed as a 59-minute documentary by District 4 employees of Caltrans [Copelan 2011].

ACKNOWLEDGEMENT

The authors wanted to thank all of the PECG History Committee Members and other PECG Members and leaders for their review of this paper. A second thank you to PECG for sponsoring the 2004 and 2008 ASCE www.orthotropic-bridge.org and other ASCE venues with the goal of sharing a great deal of very useful information. We also want to thank Mrs. Rita Bender permission to use photo of her late husband, Ostap Joe Bender. We also thank her of copyright release of his bridge photos to ASCE. For more info on Mr. Bender and images please contact her rifibend@comcast.net Mr. John Adam is a licensed Land Surveyor in California and active PECG Member. John's photos have appeared in engineering publications. Alfred R. Mangus was trained as a feature photographer at the Penn State Daily Collegian Newspaper and he has won a national honorable mention in student photo contest by Nikon Corporation with Nutshell Magazine. In closing the authors would like to thank the members of PECG who through their valuable public service provide safe and cost effective transportation on bridges, roads and related infrastructure across the state of California.

INTRODUCTION

This paper will discuss four award-winning documentaries developed by Professional Engineers in California Government (PECG). These films are entertaining case histories of four major Caltrans construction projects that featured ABC = Accelerated Bridge Construction elements and show how entertaining and informative communication can inform the general public about major construction projects in their community and win the communities support. The organization PECG = Professional Engineers in California Government is union which represents 13, 000 + engineers and related classes of workers employed by the State of California, for more information see the orgainizations web site at www.PECG.org. The organization was formed in 1962 as a professional association in response to member's wishes to promote a positive image for public employees engaged in transportation engineering. The organization produced or provided technical support for each of the documentaries discussed in this paper as a part of that same mission.

THE BRIDGE SO FAR - A SUSPENSE STORY

—The Bridge So Far – A Suspense Story ‖ was the first of a series of documentaries developed by the union, Professional Engineers in California Government. The documentary in addition to discussing the technical issues that surround a major bridge project examines the interplay involved in the development of a transportation mega project within the heart of the busy metropolitan San Francisco Bay area. With a historical perspective that sweeps from the inception of the San Francisco Oakland Bay Bridge in the 1930's to the Loma Prieta earthquake in 1989 when a portion of the bridge collapsed, up to early 2006 and the beginning of bridge construction the documentary provides a rare insight into the workings behind the scenes of a major transportation structural engineering project. The documentary through the use of a humorous and interesting story line provides a

powerful and compelling look at how major engineering projects not only change the places we live but change the way we think about where we live and ourselves. With a scope that includes the collision of politics, community activism, and conflicts between local, state and the Federal governments the film provides entertainment value and a thought provoking message about the staccato steps in the journey a community follows in the development of a new, safe bridge that provides greater mobility for all modes of travel across the Bay between the cities of San Francisco and Oakland. Award winning filmmaker David Brown filmed and produced the entertaining story with all the drama, comedy, optimism, dashed hopes, and plot reversals that can only happen in real life. The 3-D animation was by Rick Pepper and cartoon animation by Charlie Canfield. Movie stills can be viewed at www.thebridgesofar.com/

AMAZING: THE REBUILDING OF THE MACARTHUR MAZE

This documentary is destined to be a classic example of ABC Accelerated Bridge Construction. A success story if only for it's for its opening sequence which features the fiery collapse of a major freeway connector in downtown Oakland and then recreates the moments that led up to this conflagration with gripping animated sequences. The Interstate 80/580 connector at the MacArthur Maze links Oakland and San Francisco, on April 29, 2007, a tanker truck carrying fuel overturned, causing a fire to erupt. The heat from the flames caused a 160-foot-long, 45- feet-wide span of the ramp to collapse. With the sudden loss of a structure that serves as a key component in the regional transportation network the documentary begins to tally up the impacts that the loss of a busy thoroughfare which serves in excess of 100,000 vehicles per day and is a primary access point to the San Francisco Oakland Bay Bridge can have upon a city or a region. The cumulative costs in loss of mobility alone can be enormous and in turn justify the use of accelerated construction and emergency contracts with hefty contractor incentives for early completion of a state designed replacement structure to restore what is in essence a lifeline for the movement of goods, services and commute traffic across the San Francisco Bay. Within hours of the conflagration and bridge collapse, state staff met to set priorities, and within nine days of the incident, Caltrans opened the project for bids advertising the project with a $200,000 incentive for each day of completion ahead of schedule. The project had another clause stating that the contractor would be fined $200,000 a day for every 10-minute delay in opening each lane closure. These clauses had a cap of $5 million. The contractor, C.C. Myers, completed the project on May 24, 2009—within an amazing 25 days, earning Myers the full $5 million incentive. The film references previous successful accelerated construction efforts orchestrated by Caltrans after the Northridge earthquake in Los Angeles to quickly replace a major collapsed freeway connector where due to a state of emergency environmental requirements were temporarily put on hold and a contractor was provided with incentives to build a replacement structure designed by the state as quickly as possible with strict oversight provided by state engineering staff to ensure that the final product was built as designed, and would provide the taxpayers with a serviceable and safe replacement structure. This film communicates well the sense of urgency felt by all involved to restore this damaged link in the transportation network quickly and details how incentives are used to provide a contractor with encouragement to complete the job of bridge repair and replacement on an expedited schedule. The contractor Mr. C. C. Myers is featured to good effect throughout the video as he takes an active role in procuring materials, arranging for shipment from locations across the US and works with Caltrans to overcome barriers encountered. The film also does a good job of relaying the sincerity and dedication of the public servants at work in a tense situation.

An enduring testimonial to the value of accelerated construction which features incentives for contractors speeds the contracting process and provides strong engineering oversight by capable state engineering staff was provided in Governor Arnold Schwarzenegger's State of the State Address Tuesday, January 8, 2008.

In April, a fiery truck crash melted the Bay Area's 580 freeway exchange. Hundreds of thousands of Californians who depended on that interchange foresaw months of delays and stress. Yet it didn't take the normal 150 days to repair. Caltrans, working with contractors, cleared the span in 10 days and then built a new bridge and opened it up in a record 16 days later. Government can work. It can be efficient. It can lead."

Movie clips may be viewed at http://www.amazingmaze.org/

prefabricated replacement span. The planning and timing of this work was critical with all construction scheduled to start and complete within Labor Day weekend 2007 with the structure scheduled to reopen for morning commute traffic. The story is told from the perspectives of the contractor the legendary Bay Area figure C. C. Myers, dedicated Caltrans engineers and designers, as well as by reporters who covered the story. The technical details are instructive in this documentary and there is a time lapse sequence that should be a part of any college course that discusses the use of accelerated construction. The project moves smoothly and completes 11 hours ahead of schedule, the documentary makes this a captivating experience that illustrates how all involved must work together to make ABC = Accelerated Bridge Construction work. REBUILDING THE BOAT: FIXING I-5 IN SACRAMENTO REBUILDING THE BOAT: FIXING I-5 IN SACRAMENTO

This documentary follows a construction rehabilitation project located on a busy urban section of I-5 Freeway which follows a depressed alignment through downtown Sacramento California blocks from the State Capitol. Originally conceived as a conventional construction project with lane closures planned for

extended periods, accelerated construction is considered and utilized to reduce construction times and delays for traffic on this key arterial which carries 190,000 vehicles per day. Repair plans were placed out to competitive bidding. General Contractor C. C. Myers was the low bidder and proposed an AC = Accelerated Construction solution as a cost savings under the contract provisions. Myers' revised ABC plan was to reduce construction time from the maximum allowed of 305 days to 34 days total. Caltrans agreed to Myer's ABC Plan and put in place efforts to alert the public about freeway closures and the rerouting of traffic necessary to successfully complete the project. Movie clips may be viewed at http://www.kvie.org/programs/kvie/viewfinder/rebuildingtheboat/

THE NEXT FRONTIER: ENGINEERING THE GOLDEN AGE OF GREEN

The Next Frontier: *Engineering the Golden Age of Green* a documentary that focuses on proven renewable, clean civil engineering energy technologies that can improve our future and create a healthier place to life. This film, 56:46 long, is an

entertaining documentary which takes the viewer around the world in search of technologies and policies that will address the serious problem of excessive carbon dioxide emissions and our dangerous dependence on fossil fuels. Successful solutions for Geothermal, Solar, Tidal, and Wind were featured with operators/ users of the technology interviewed by ABC's Good Morning America's Becky Worley. Without the general public's support these technologies will not continue to be expanded, design and built. The documentary informs and simultaneously entertains with film of construction, interviews of key individuals, satirical cartoons and animated graphic of principals and techniques. A successful Tidal power generation in Ireland is featured is movie. The owners' representative and fisherman are interviewed and are pleased with this green coastal energy solution. Wind and solar examples shown are applicable to coastal sites and communities in California or elsewhere. These buildings and alternative energy support facilities require structural engineering design, plus other civil engineering professionals. Movie clips may be viewed at www.thenextfrontiermovie.com/

CALTRANS PRODUCED VIDEOS

Caltrans produced documentaries include the —*The Bridge* a construction account of the award winning Pine Valley Bridge. Another Caltrans produced Documentary with companion book Caltrans (2004), —Spanning the Carquinez Strait - The Alfred Zampa Memorial Bridge ‖ , California Department of Transportation Sacramento, CA, 2003 [35 minutes] documents the Alfred Zampa Memorial Orthotropic Suspension Bridge in Crockett-Vallejo California on west bound interstate I-80 [Figure 6]. This was the first aerodynamic orthotropic wing shaped suspension bridge completed in 2003. Contact www.dot.ca.gov/hq/esc/CHPC/historylinks.html the CHPC Caltrans History and Preservation Committee for copies of the booklet and CD-ROM.

A third Caltrans Video —No was not an Answer ‖ discusses the reconfiguration of the approach spans in San Francisco for the San Francisco Oakland Bay Bridge. Interviews by District 4 [San Francisco Bay Area and District 59 [Engineering Services – Bridge Structures] Caltrans employees were filmed as a 59-minute documentary by District 4 employees of Caltrans. A world class bridge crossing in San Francisco Bay for the new East Span portion. Streaming video clips narrated by Caltrans spokesman Bart Ney are available at www.baybridgeinfo.org/ A unique SAS = Self Anchoring Suspension Bridge with an orthotropic superstructure is featured.

CONCLUSIONS

The use of documentaries developed by the Union or Bargaining Unit # 9 Professional Engineers in California Government to highlight the excellent and cost effective Civil Engineering Design and oversight provided by public servants working in the taxpayers interest has been very effective. A successful public education effort by any measure with each of the documentaries receiving broad critical acclaim and distribution through the Public Broadcasting System, of particular note is the documentary ***A Span in Time*** which was recognized with two Emmy Awards.

ACKNOWLEDGEMENT

The authors wanted to thank the leadership of PECG, PBS Channel KVIE of Sacramento and the participants of these projects who shared a great deal of very useful information in and about the documentaries described in this paper. We also want to thank PECG for being a sponsor and the ASCE Structural Engineering Institute of the 2004 and 2008 conferences www.orthotropic-bridge.org/ We would also want like to thank Caltrans for granting reasonable access of Caltrans Copyrighted documents to PECG.

The Effects of Deteriorating Bridges on Bridges on the Bridge Network Connectivity

Evaluation of the seismic reliability of aging transportation networks traditionally ignores the deteriorating state of highway bridges. In this study, the present day seismic reliability of bridges in an existing highway network has been evaluated through a time-dependent seismic fragility analysis. An efficient Monte Carlo based algorithm is used to evaluate the network-level reliability of the aging highway bridges without the need to simplify the network layout or change its topology. The criticality of aging bridges is then assessed through different ranking strategies proposed in this study to arrive at an optimized seismic retrofit schedule. The methodology is implemented in a case in the state of South Carolina under a seismic scenario and the proposed ranking strategies are compared to the state of practice methods.

INTRODUCTION

At present more than 26% of highway bridges in the US are either labelled as structurally deficient or functionally obsolete (ASCE 2009) and also a significant percentage of highway bridges are located in regions of moderate to high seismicity (FHWA 2009). Such deteriorating and seismically vulnerable bridges are also a threat to the performance of the transportation network and hence there is an increasing need to quantify such risks to assess network level performance. However, latest studies for aging bridge reliability estimates only considers seismic threats to individual structures without any proper means to integrate into a network level reliability framework to assess the vulnerability of aging transportation networks. Few methodologies exist in literature for reliability assessment of complex transportation networks although they do not take into consideration the effects of aging and deterioration of highway bridges (Liu & Frangopol 2006; Kiremidjian et al. 2007; Ching & Hsu 2007; Fan et al. 2010; Todinov 2007). More recently, (Lee et al. 2010) estimated bridge network reliability by accounting for deteriorated bridge performances of a few structurally similar bridges with corroding bridge columns. In reality, however, transportation networks consist of large number of structurally and geometrically dissimilar aging

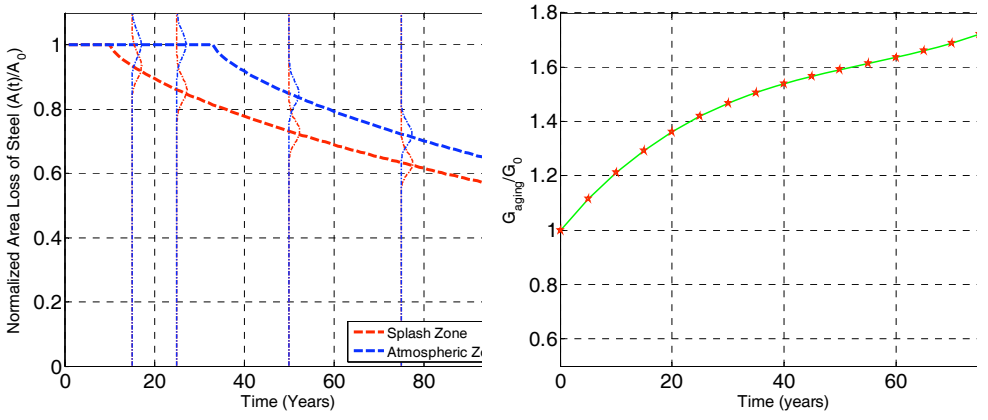
bridges with multiple aging components under different exposure conditions (Silano & Brinckerhoff 1993; Hoeke et al. 2009).

The primary objective of network level reliability assessment of transportation systems is to evaluate the probability that the system maintains its functionality over a certain time span. The adapted criterion to assess the functionality in this paper is reachability; i.e. the ability to reach a set of destination nodes in the network starting from the set of origin nodes. There are a few methodologies in the literature to approach such O-D connectivity reliability problem (e.g. [1](; Ching & Hsu 2007; Todinov 2007). A methodology based on crude Monte Carlo simulations (Todinov 2007) has been adapted in this research for network reliability framework for its simplicity and efficiency in applying to large transportation networks. The multiple component deterioration of different bridge categories in a transportation network may readily be integrated into this network reliability approach to evaluate the network level reliability of the transportation system. The fragility of non-bridge segments of a transportation system (highways) may also be considered in the presented network reliability framework; however, such fragilities are negligible compared to the bridge fragilities under seismic events and are therefore not evaluated in this research. The reliability assessment of aging transportation networks is aimed at identifying the most critical bridges in the network and proposing an optimized seismic retrofit schedule. State of the practice to rank bridges following the Seismic Retrofit Manual (Buckle et al. 2006) falls short of taking the topology and system-level reliability of the network into consideration. To address those shortcomings, four other bridge ranking strategies are introduced in this research. The network reliability framework is illustrated in a case study on the bridge network of Charleston, South Carolina, and the performance of the proposed bridge ranking strategies are compared to the current state of the practice.

BRIDGE DETERIORATION MECHANISMS

Aging mechanisms of bridges are highly dependent on the bridge type and proximity and severity to the source of deterioration. Based on proximity to the sea coast, two distinct cases of marine corrosion exposure are considered in the case study: atmospheric and splash. Additionally, the aging mechanisms considered in this study include deteriorations of critical bridge components such as reinforced concrete (RC) columns and bridge bearings. A primary form of deterioration to steel components exposed to the atmosphere is sectional area loss due to corrosion and is found to affect the reinforcing steel in RC columns and anchor bolts and dowel bars in bridge bearings. A vast amount of literature exists on the corrosion deterioration of steel embedded in concrete and regarded as a typical diffusion problem in which the time to initiate corrosion under marine chloride exposure can be expressed as (Bertolini et al. 2004):

$$T_i = \left[\frac{x^{d^2}.R_{cl,0}}{4.k_c k_e.(t_0)^{cl}} \left\{ \text{erf}^{-1}\left(1 - \frac{c_{cr}^d}{c_{s,cl}^d}\right) \right\}^{-2} \right]^{\frac{1}{(1-n_{cl})}} \quad (1)$$



where, x^{d^2} is the design value of cover thickness, $R_{cl,0}$ is the chloride penetration resistance (inverse of diffusion coefficient) determined from compliance tests, k_c is the curing factor, k_e is the environmental factor, t_0 is the

age of concrete when the compliance test is performed, n_{cl} is the age exponent that incorporates the densification of cement paste due to further hydration, c_{cr}^{d} is the design value of surface chloride content, $c_{s,cr}^{d}$ is the critical chloride content beyond which corrosion initiates and erf is the Gaussian error function. Following the corrosion initiation, a time dependent corrosion rate can be assumed following the suggestions by Vu and Stewart (2000) as:

$$i_{corr}(t) = 0.85 i_{corr,0}(t - T_i)^{-0.29} \quad (2)$$

where $i_{corr,0}$ is the corrosion rate at time $t = 0$ years that can be calculated from the water cement ratio in concrete and the reinforcement cover depth (Bertolini et al. 2004; Vu et al. 2005). The impact of severity of exposure condition as mentioned earlier on the deterioration process is shown in figure 1a which depicts the normalized area loss of steel along the service life of the bridge.

While equations 1 and 2 as given above helps to predict the area loss of steel in steel members, often the build up of corrosion debris hinders the free movement of steel bearings leading to potentially 'frozen' bearings with a reduced performance to resist lateral loads during earthquakes. This increase in friction due debris accumulation is assumed to increase from 0.04 to 0.12 at the end of the 75 year bridge service life based on the suggestions of Mander et al. (1996). Additional deterioration mechanisms considered include the increase in shear modulus of elastomeric bearing pads following the model proposed by Itoh and Gu (2009) as shown in figure 1b.

(a) (b)

Figure 1: a) Normalized mean and variance of area reduction of steel reinforcement under different marine exposure conditions and b) Increase in shear modulus of elastomeric bearing pads with aging sue to thermal oxidation.

RELIABILITY ASSESSMENT OF BRIDGE NETWORK

The network level reliability of a transportation system is the probability that the system maintains its functionality under a given seismic event. The functionality in the context of this research is defined as the ability to reach a set of destinations from a set of origins in the network. The connectivity between origin and destination nodes may be lost if enough bridges reach a damage state that involves structural failure or requires temporary closure for inspection/repair to lose all the existing routes from origin to destination nodes.

Some studies have used conventional reliability methods that applicable to sets of parallel and series sub-systems to investigate the reliability problem in transportation systems. Although those methods provide a quick estimate of the network reliability, they may not be realistic enough in large complex networks in which their application requires a lot of simplifications to the topology of the network. A number of Naive Monte Carlo simulation (MC) methods are applicable to solve the described connectivity reliability problem in complex networks without the need for any simplification in the network topology. Another advantage of MC based methods is their capability in considering multiple (O, D) pairs (Ching & Hsu 2007). Since there is often more than one (O, D) pair in real transportation networks, having this capacity is of paramount importance in the network reliability assessment.

The probability of failure of network components is provided as input in any network reliability analysis. MC based methods may incorporate both node (bridge) and link (non-bridge segment of highways) failures in network reliability assessment. In this research, however, the probability of failure of non-bridge components are considered negligible compared to that of the bridges in a seismic event. Therefore, only bridges are assigned a probability of failure in the network. Moreover, only the probability of reaching a certain structural damage state is considered as a failure criterion in bridges. Failure of the network components due to traffic overflow may also be integrated in the model, but such integration involves solving a dynamic traffic assignment problem at each Monte Carlo simulation step which adds significant computational complexity to the network reliability problem. Considering failure due to traffic congestion is on the agenda for future development of this research.

Figure 2 depicts a portion of the bridge network in the county of Berkeley, SC with the identified bridges in the network shown on the map. In network theory, the order of the network is defined as the number of the nodes in the network and is often denoted by n; while the number of the links among the nodes is referred to as the order of the network (m). The depicted bridge network is comprised of 18 bridges with nodes 8 and 6 serving as Origin and Destination nodes, respectively. There are more links connecting the bridges in the network than the minimum number required to maintain the (O, D) connectivity. The existing redundancy in the network provides higher level of reliability since the network may sustain its connectivity in case some of its components lose functionality.

Since the topology of the network cannot be reduced into series and parallel subsets, the conventional network reliability methods for series-parallel systems are not applicable. Nevertheless, combining the components in series or parallel subsets helps to reduce the ultimate computational demand in solving the network reliability problem using Monte Carlo simulations based methods. The naïve Monte Carlo simulation method, referred to as MC hereafter, is illustrated in this section. This approach requires finding the shortest path between Origin and Destination nodes at each round of Monte Carlo simulation based on algorithms such as Dijkstra (Dijkstra 1959). For a single (O, D) pair, each round of Monte Carlo simulation involves a computational complexity of $O(m2.n2.\log(n))$ in this method.

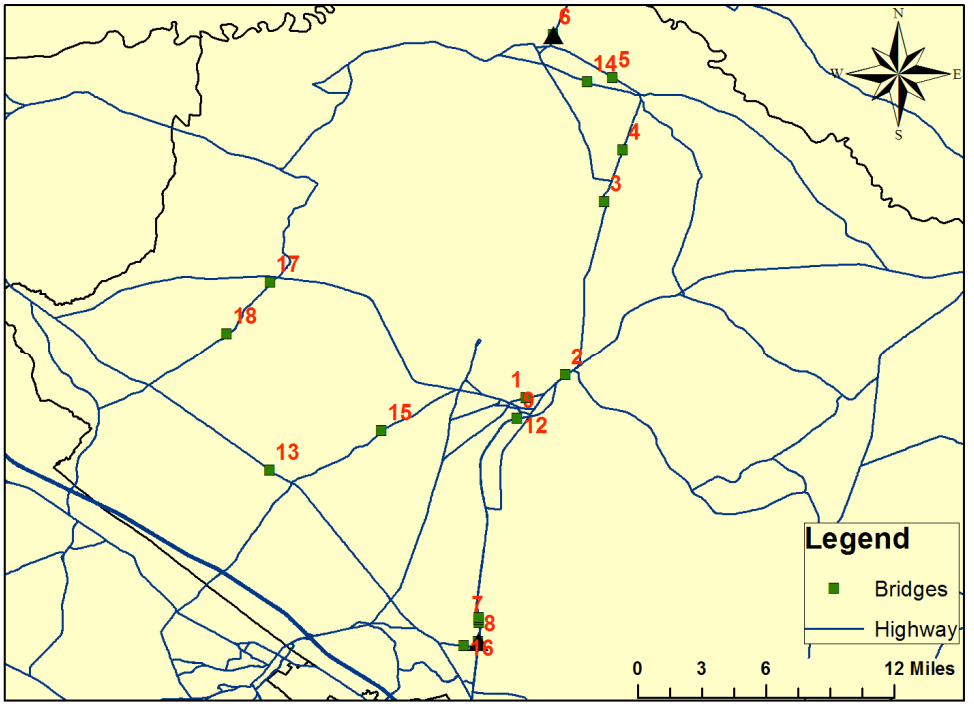


Figure 2: Portion of the bridge network in Berkeley county, SC. The nodes define the location of the identified bridges in the network. Nodes 32 and 27 denote the Origin and Destination nodes, respectively and are shown by dark triangle marks in the figure.

The pseudo-algorithm for MC is brought in Table 2. The bridge reliabilities (one minus probability of reaching the moderate damage state) are stored in a vector (b). At each round of Monte Carlo simulation, a vector of the same size as b (named z) is generated comprising uniformly distributed random numbers in [0, 1]. The values in vectors b and z are compared for each node, and the bridge is assumed to fail in case zi > bi, i being the bridge index. A search for shortest path between Origin and Destination nodes is then performed based on Dijkstra algorithm. An indicator function I[·] stores the cases in which the connectivity is lost in the network. Averaging the indicator function over the number of Monte Carlo simulations (NMC) results in the reliability of the network for the specified (O, D) pair (Todinov 2007).

Table 1: Pseudo-Algorithm for MC reliability method

Procedure MC

Store bridge reliabilities in $\boldsymbol{b}_{n\times 1}$

for $i = 1: N_{MC}$

Generate $\boldsymbol{z}_{n\times 1}$ such that $z_i \in [0\ ,1]$ (Uniformly distributed random number)

Bridge Index(i) = max{0, 1-$\boldsymbol{z}_i/\boldsymbol{b}_i$}

Mark Bridge *i* as failed if *Bridge Index(i) = 0*

Run *Dijkstra (O, D)* to find the shortest path between Origin and Destination nodes

I[·] = 1 if the shortest path is infinite; 0 otherwise

end

$$P_{OD} = \frac{1}{N_{MC}} \sum_{i=1}^{N_{MC}} \mathrm{I}[\cdot]$$

BRIDGE RETROFIT SCHEDULE AND RANKING STRATEGIES

Bridge ranking strategies help to identify the most critical bridges in the chosen network. Traditionally, ranking strategies of bridges are based on the state-of-the-practice methodologies, such as the strategies outlined in the Seismic Retrofitting Manual for Highway Structures (Buckle et al. 2006). In this study, in contrast to state-of-the-practice methodologies, new ranking strategies are proposed that account for topological aspects of the network. These are elaborated in the following sections.

State of the practice methods based on the Seismic Retrofitting Manual for Highway Structures (Buckle et al. 2006)

The state-of-the-practise methodologies can be categorized into two different methods in the increasing order of complexity: Indices Method and the Expected Damage Method. The Indices Method assigns a rank between 0 to 100 to each bridge following an assessment of structural properties of the bridge, seismicity of the region and other socio-economic factors. The Expected Damage Method is mostly based on the cost of repairing the bridge following seismic damage and incorporates the concepts of fragility curves. These reliability curves were however developed for general bridge classes using nonlinear static analysis and without considering the effects of deterioration.

Rankings Based on Network Topology

The seismic retrofit manual emphasizes the significance of network topology in ranking bridges in transportation systems. However, it falls short of providing an explicit approach to account for the topology of network. Two topological metrics are used in this study to incorporate the topology to rank the bridges in a network. *Betweenness Centrality* (*BC*) has been extensively used in the literature since it is considered as a proxy to simulate flow (traffic in case of transportation systems) in complex networks. The *BC* of a given node in the network is defined as the number of geodesic paths passing through that node:

$$BC(i) = \sum_{s,t} n_{st}^{i} \quad (9),$$

where *s* and *t* are pairs of origins and destinations in the network and n_{st}^{i} is an indicator function assuming the value of 1 if node *i* is on the geodesic path from *s* to *t* and zero otherwise. Geodesic path is defined as the shortest path between two nodes in terms of the number of links. Calculating *BC* in a network involves identifying the geodesic paths between all *(O, D)* pairs.

Eigenvalue Centrality (EC) is giving importance to nodes in a network based on the number of their connections and their neighboring nodes. Therefore, nodes directly connected to important nodes are considered more important in this method. The EC vector (X) which includes the value for all the nodes in a network is derived from Equation 10:

$$X = \lambda^{-1} \cdot A \cdot X \quad (10),$$

Where *A* denotes the Adjacency Matrix representing the topology of the network and λ represents the largest eigenvalue of the Adjacency Matrix. Vector *X* from Equation 10 can be computed recursively.

Betweenness Centrality and Eigenvalue Centrality are purely defined based on the network topology and do not take the vulnerability of bridges into account. Therefore, they are not as comprehensive as ranking based on the network reliability method which incorporates both aspects.

Ranking Based on Network Reliability

The MC approach for network reliability evaluation leads to a ranking based on the correlation of failure of individual bridges in the network with the failure in network connectivity. A bridge is deemed more important if its failure is more likely to result in the network connectivity failure. The importance index r, therefore, is defined to account for this conditional probability:

$$r = P(F_{OD}|f_i) \quad (11)$$

where F_{OD} is the event that the connectivity between the *(O, D)* pairs is lost, and f_i is the event that bridge *i* fails (reaches moderate damage state). Obviously, *r* is a probability and therefore varies in *[0, 1]*. Larger *r* values denote more critical nodes.

Ranking based on network reliability takes both network topology and bridge vulnerabilities into account which makes it computationally more expensive. However, its computational complexity is still polynomial in the form of $O(N_{MC}.m^2.n^2.log(n))$.

The described ranking strategies are applied to the bridge network of South Carolina and the rankings are compared next.

Application to the Case Study Network

The proposed time-dependent fragility analysis of aging bridge classes and the network reliability method are applied to the case study network in Figure 2. The described ranking strategies are then applied to identify the location of most critical bridges in the network.

The development of the time-dependent fragility curves and subsequent network reliability analysis requires defining a seismic scenario for the study. The historical seismic events in the region show a pattern of large far in between earthquakes (Padgett et al. 2010). The seismic event with 10% probability of occurrence in 50 years has been adapted for this study based on the seismic deaggregation map of the region, which refers to a magnitude $M_w = 7.3$ event. The historical seismology of the region also suggests a depth of 18 km for the identified seismic event (USGS 2010). Figure 3 shows the PGA contours for the defined scenario event obtained from HAZUZ-MH using western US shallow crustal event for attenuation model. The mean value within each contour is used as the base PGA level to develop the non-linear bridge fragility curves. The bridges in the network are classified by material and construction type using the described strategy. Data from National Bridge Inventory (NBI) has been used to identify bridge characteristics such as the year of construction (to aid in determining the deteriorated present day fragility curves), skew angle, and number of spans for each bridge in the network. The fragility curves

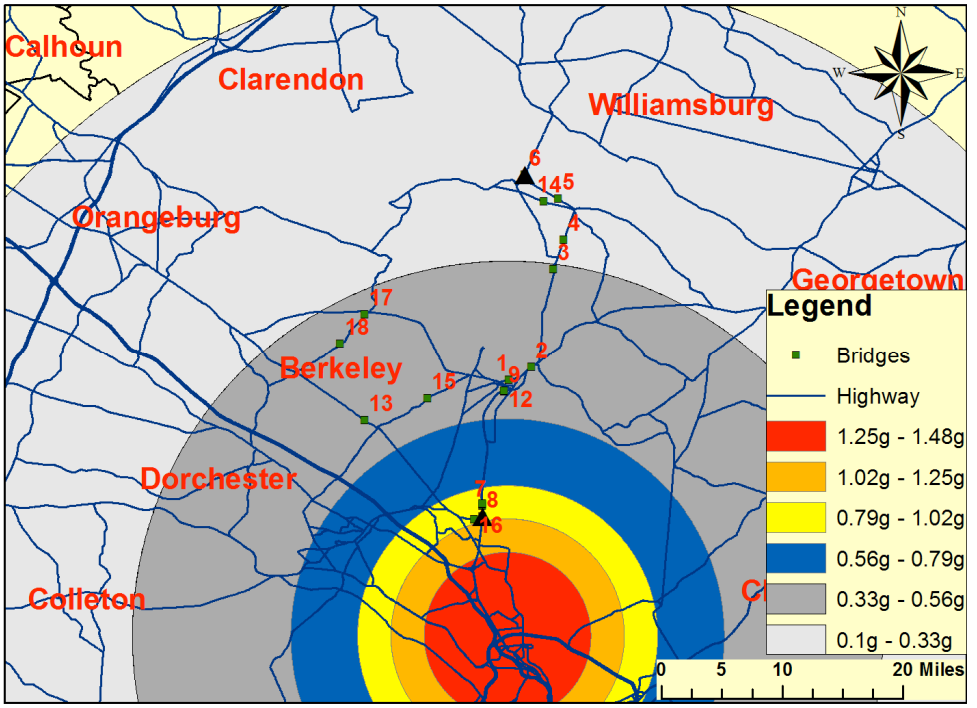

Figure 3: The PGA level contours for the defined seismic scenario

Time dependent fragility curves for aging bridges

An efficient way to quantify the effects of deterioration on the seismic vulnerability of an aging bridge is to evaluate the time dependent vulnerability following the methodology outlined in (Ghosh and Padgett 2010). The general expression representing the time dependent fragility of bridges can be represented as:

$$P[LS(t)|IM] = \Phi\left[\frac{\ln(IM) - \ln\left(med\,(t)\right)}{disp(t)}\right] \quad (3)$$

where, P[LS(t)|IM], is the probability of exceeding limit state LS, conditioned upon a given intensity of ground motion (IM), $\Phi(\cdot)$ is the standard normal cumulative distribution function, and med(t) and disp(t) are the median value and logarithmic standard deviation of the fragility function at time t in the service life of the bridge system. The time dependent fragility parameters, $med(t)$ and $disp(t)$, can be obtained following nonlinear dynamic analysis of the finite element model of the bridge at different times in the service life of the bridge.

For the network under consideration, Table XX shows the type of each bridge, their respective years of construction and the comparison of bridge fragility parameters of the present day bridge to its initial pristine state.

Bridge No.	Bridge Type	Year of Construction	Fragility Parameters (Pristine Bridge)		Fragility Parameter (Present Day Bridge)	
			$med(t)$	$disp(t)$	$med(t)$	$disp(t)$
1	MSSS Concrete Girder	1936	0.42	0.63	0.34	0.56
2	MSC Steel Girder	1944	0.26	0.62	0.25	0.55
3	MSSS Steel Girder	1996	0.30	0.49	0.29	0.48
4	MSC Slab	1997	0.73	0.86	0.73	0.86
5	MSSS Concrete Girder	1983	0.37	0.62	0.36	0.62
6	MSSS Slab	1999	0.56	0.71	0.57	0.71
7	MSSS Concrete Girder	1922	0.63	0.62	0.57	0.62
8	MSSS Concrete Girder	1922	0.63	0.62	0.57	0.62
9	MSSS Concrete Girder	1971	0.51	0.63	0.49	0.58
10	MSSS Slab	1971	0.60	0.71	0.62	0.70
11	MSSS Slab	1971	0.60	0.71	0.62	0.70
12	MSSS Concrete Girder	1971	0.51	0.63	0.49	0.58
13	MSSS Concrete Girder	1938	0.53	0.62	0.48	0.62
14	MSSS Concrete Girder	1983	0.37	0.64	0.36	0.62
15	SS Concrete	2001	2.41	1.00	3.07	1.04
16	MSSS Slab	1966	2.04	0.98	2.05	0.97
17	SS Concrete	1999	2.41	1.00	3.17	1.05
18	SS Concrete	1999	2.41	1.00	3.17	1.05

MSC = Multi-span continuous, MSSS = Multi-span simply supported, SS = Simply Supported

A close observation shows that the most fragile bridges whether in the pristine or aging condition of the network are the MSC Steel and MSSS Steel bridge with the two lowest median value as compared to all bridges in the network. From the

change in their median values however, it can be seen that these two bridges are however not the ones most affected by the effects of deterioration. Aging effects are found to be most predominant for the MSSS Concrete bridges which show the highest percentage changes in median values and hence an increase in the bridge probabilities of failure. For instance bridge numbers 1, 7, 8 and 13 shows a 19%, 11%, 11% and 9% change in bridge failures. A comparison of the time dependent fragility curves for the MSSS Concrete bridge number 1 is shown in figure XX for the pristine bridge at year 1936 and the present day bridge. The multi-span bridges that are least vulnerable to seismic events are the MSSS Slab bridges. It is also seen that the median value of this bridge type (bridge number 16) also increases with age. The same is observed in case of the simply supported bridges. The reason behind this phenomenon is that for certain type of concrete bridges, thermal oxidation of the elastomeric bearing pad increases the lateral stiffness of the bearing and consequently reduces the seismic vulnerability of the bridge. However the increase in median value for the multispan slab bridge is not as dramatic as the single span bridges because of the influence of degrading bridge columns.

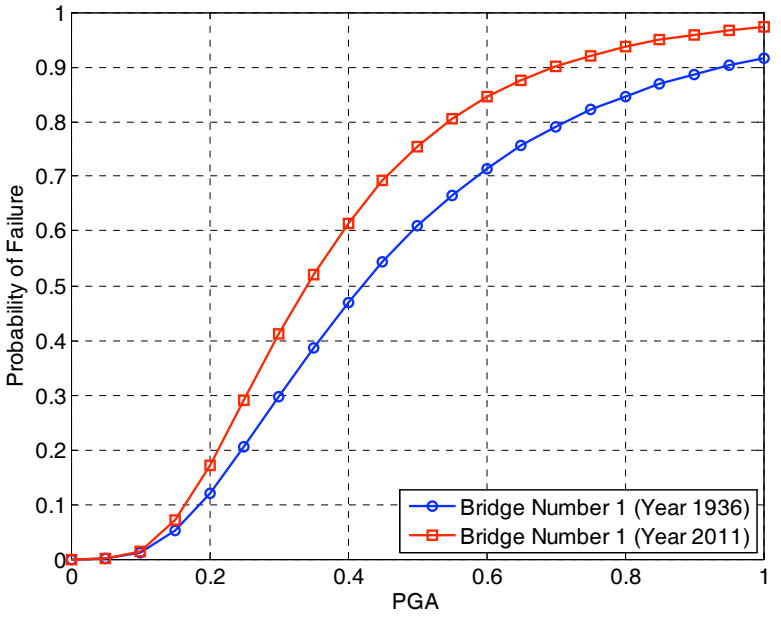

Figure XX: Pristine and deteriorated fragility curves for aging MSSS Concrete girder bridge number 1.

Bridge Network Reliability

The defined seismic scenario and the developed time-dependent fragility curves are employed to evaluate the connectivity reliability of the network depicted in Figure 2. The probabilities of reaching the moderate damage state is used as the failure criteria for the bridges in the network and serve as input to MC reliability method (Table 4).

Table 4: Probabilities of Failure for the Bridges in Figure 2

Bridge ID	Probability of Failure
1	0.679

2	0.859
3	0.802
4	0.077
5	0.207
6	0.086
7	0.777
8	0.777
9	0.440
10	0.705
11	0.705
12	0.440
13	0.450
14	0.209
15	0.032
16	0.201
17	0.030
18	0.030

Following the MC procedure results in a probability of failure of 0.909 (N_{MC} = 1,000,000) for the specified Origin and Destination nodes in Figure 2. The high probability of network failure is associated with the high number of bridges that lie in between nodes 8 and 6. The calculated high probability of network failure is consistent with the fact that most bridges in the network have a relatively high probability of failure and taking into account the number of bridges that lie in between nodes 8 and 6.

Bridge Ranking Strategies

The described different ranking strategies have been employed to identify the critical bridges in the understudy network. Table 5 compares the top five ranked bridges from different strategies. It is clear that while the two state of the practice methodologies result in generally consistent rankings, their results differ from the developed ranking methodologies. The location of critical bridges are also identified on the map of region in Figure 7.

Table 5: Top five ranked bridges in the case study network. Numbers indicate the Bridge ID within the network.

Rank	State of the practice methodologies		Developed Methodologies		
	Indices Method	*Expected Damage Method*	*Eigenvalue Centrality*	*Betweenness Centrality*	*Network Reliability Method*
1	5	5	2	2	6
2	2	14	14	1	8
3	1	2	5	16	16
4	9	1	4	17	17
5	12	9	12	12	13

Both the indices method and the expected damage method adopted from the state of the practice are highly qualitative methods. Based on discrete values of vulnerability ratings for the different bridge components, the top five bridges tied at maximum R = 48.7. The expected damage method depends on the replacement cost of the bridge and hence the number of units in the main span of the bridge. Accordingly, the top bridges as per this strategy are characterized by large number of spans (for example, bridges 5 and 14 have 10 and 11 spans, respectively).

The two topological ranking strategies share two bridges in the top five ranking despite using different concepts. The location of those two nodes, therefore, is critical in the network topology.

The network reliability method is the most comprehensive of the three developed ranking strategies since it takes into account the topological formation of the network as well as individual bridge vulnerabilities. Bridges 6 and 8 are the most critical nodes in network reliability method since survival of Origin and Destination nodes are essential for maintaining connectivity in the network. The other critical bridges are located on the perimeter of the network since the path directly connecting Origin and Destination nodes requires passing through more bridges that are also exposed to higher PGA levels. Therefore, it is likely over each step of Monte Carlo simulations that the connectivity on the direct path is lost while the indirect path maintains connectivity. As the result, the importance index *r* (Equation 10) tends to give higher values to the bridges on the indirect path.

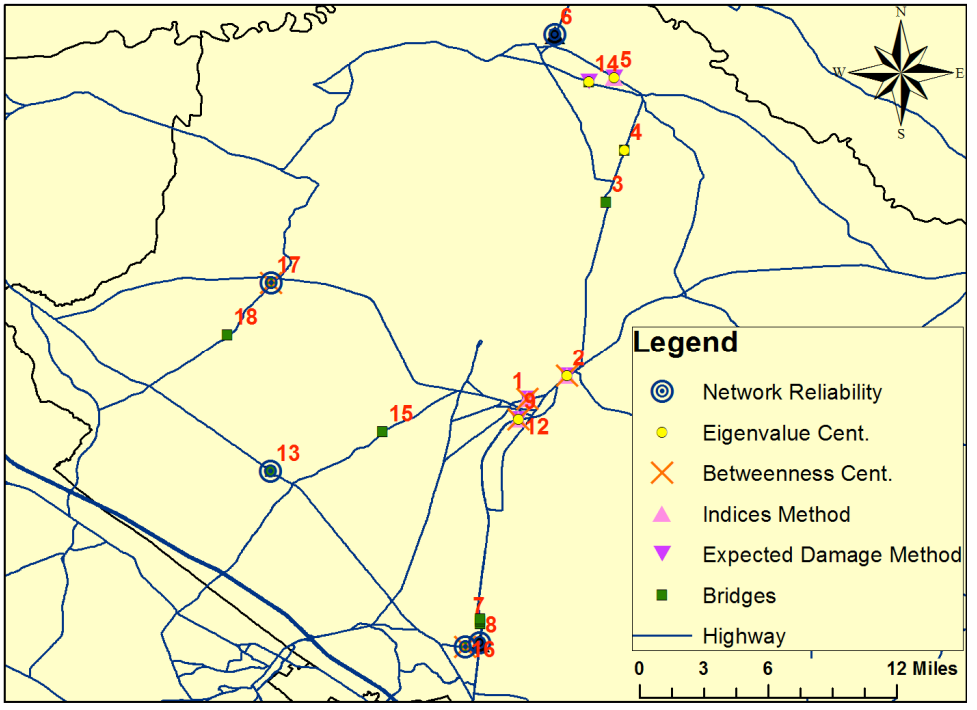

Figure 7: Top five ranked bridges in the network as per the different ranking strategies

Conclusions

Development of time-dependent fragility curves for the bridges in the network enables determining the present day probabilities of failure of deteriorating bridges

in a bridge network. The individual bridge vulnerabilities acquired this way are used to evaluate the network level reliability between a defined set of Origin and Destination pairs. The bridge ranking obtained from the presented MC network reliability approach using time-dependent fragility curves are found to be strikingly different from the qualitative rankings based on the state of the practice methodologies in the seismic retrofit manual.

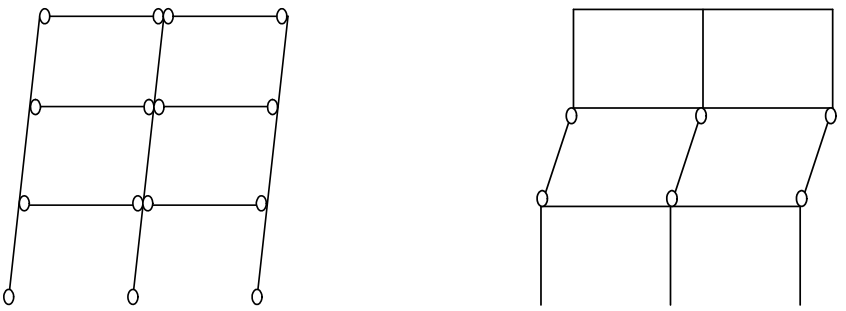
Abstract

This paper presents the minimum column-to-beam moment ratio of steel moment resisting frame (SMRF) with various connection models using the non-dominated sorting genetic algorithm-II (NSGA-II). We evaluate the minimum column-to-beam moment ratio of SMRF required to ensure the beam-sway mechanism by the pushover analysis. We investigate the influence of the connections on the minimum column-to-beam moment ratio. We consider WUF-W and RBS as the connection models. The optimal algorithm used in this paper is to minimize the structural weight and the column-to-beam moment ratios through the objective functions and to induce the beam-hinge mechanism through the constraint which is to prevent the formation of plastic hinge at the column part consisting of joints. Using the 3-story example, we compare the minimum column-to-beam moment ratio of SMRF required to ensure the beam-sway mechanism according to the connection models.



INTRODUCTION

ANSI/AISC 341-05 represents the strong column-weak beam concept to induce the collapse mechanism such as Figure 1(a). The purpose of that is to form plastic hinge at the beam earlier by designing the column moment ratio larger than beam moment ratio like Eq. (1). If the plastic hinge occurs at the column earlier, the plastic deformation concentrates at the certain story owing to the formation of the weak story. The possibility of abrupt collapse of the whole structure also increases by the collapse of column.

$$\sum \frac{M_{pc}^{*}}{M_{pb}^{*}} > 1.0 \tag{1}$$

where,
M_{pc}^{*} is the plastic column moment ratio consists of the relevant connection

M_{pb}^{*} is the plastic beam moment ratio consists of the relevant connection

(a) beam-hinge collapse mechanism (b) column-hinge collapse mechanism

Figure 1. Collapse mechanism types by plastic hinge of moment frame

When performing the dynamic analysis and inelastic analysis, it is known that the brittle fracture can be induced by forming the plastic hinge at column earlier even if satisfying the strong column-weak beam condition because that condition represented by the seismic criteria was set based on the static elastic analysis (Park and Paulay, 1975; Kuntz and Brouning, 2003).

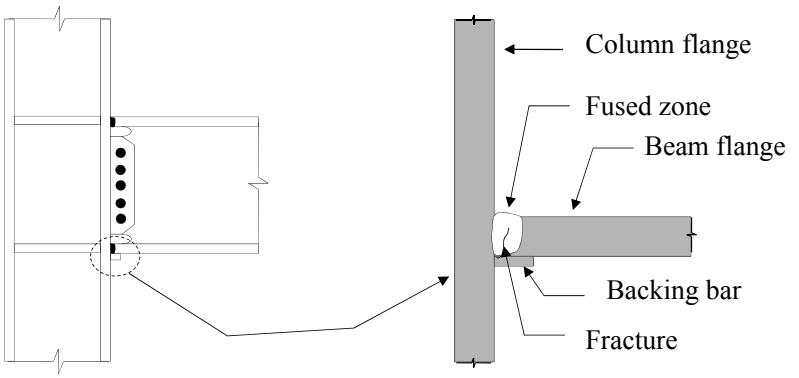
Many research have been studied to solve the strong column-weak beam condition problems (Lee, 1996; Nakashima and Sawaizumi, 2000; Dooley and Bracci, 2001; Kuntz and Brouning, 2003; Medina and Krawinkler, 2005). However, the proposed methods have been induced based on the examples designed by the engineer's experiences, the required minimum moment ratio for inducing the beam-hinge collapse mode has not been defined yet. All the existing researches which were based on linear center-line mode have not considered the effect of the connection which has a major influence on the behavior of moment frame.

Therefore, by using the optimization method, this paper evaluates the required minimum moment ratio inducing the beam-hinge collapse mode of the steel moment frame considering connection. The effects of the minimum moment ratio with different connections are compared through each difference connection modeling. In this paper, WUF-W and RBS are considered as target connection types. The objective functions are defined as the minimization of the structural weights and the minimization of the moment ratio. This paper do not consider the strength condition but the inter-story drift condition because the seismic design for moment frame is determined by inter-story drift condition (Foutch and Yun, 2002; Liu et al., 2005). The constraint condition for the plastic hinge formation of the column is also used to induce the beam-hinge collapse mode of the structure. Finally, the cross-sectional areas of continuous columns are used for the constraint condition to consider the construction of the structures. It is applied to the example of three story steel moment frames with WUF-W and RBS connection respectively, the minimum moment ratio by connections is evaluated.

SEISMIC CONNECTION

The cause of damage by the Northridge earthquake for the steel moment frame was

mainly the brittle fracture of connection such as Figure 2. It was caused by the connection details used in the field.



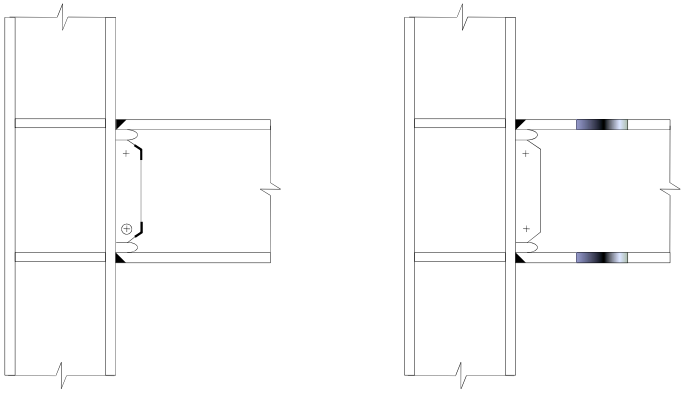


Figure 2. Connection fracture discovered in the Northridge earthquake (FEMA 355d)

Through the SAC project, the solutions for this problem have been researched, as a result, a variety of connection details were represented. According to FEMA 350, WUF-W, RBS, and WFP are suggested as certification connections which can be applied SMF. In this paper, WUF-W and RBS were studied such as Figure 3.

(a) WUF-W (b) RBS

Figure 3. Connection details suggested in FEMA 350

The WUF-W is similar to the existing connection type, but the use of weld metal which has large toughness and the removal of back up bar apply to the WUF-W, so the considerable plastic deformation can be expected at the beam ends. The structural design is performed with the assumption that plastic hinge occurs at the inside of beam near the connection due to the characteristic of good plastic behavior of WUF-W (Kim and Kim, 2009).

The RBS cuts the part of beam flange near the column flange and properly weakens the beam, thereby the RBS induces the location of plastic hinge formation to the inside of beam. The purpose of this is to prevent the brittle fracture of the columns. In the RBS, the type of cutting shape of beam flange is the taper-cut or constant-cut RBS. However, that type has the stress concentration problem, so the radius-cut RBS is the most widely used. The radius-cut RBS is so difficult to express

in the procedure of the structural analysis due to the characteristic of the shape. For this reason, Lee and Chung (2006) proposed the RBS analysis method using the RBS that has the same performance and uniform effective width of the radius-cut RBS, as in Figure 4. The equivalent effective width can be calculated through the Eq. (2)-(4). Please refer to Lee and Chung (2006) for more detail matter.

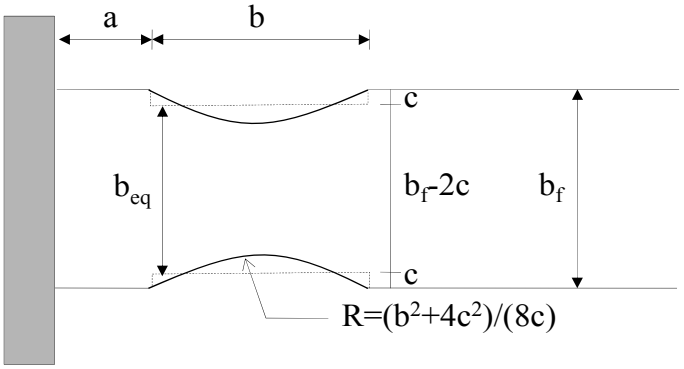

Figure 4. Equivalent effective width of radius-cut RBS proposed by Lee and Chung (2006)

$$X1 = b(\frac{L_b}{2} - (a + /2)) \tag{2}$$

$$X2 = \frac{(L_b - 2a - b)}{\sqrt{\frac{b_f - 2c}{R}}} \tan^{-1}(\frac{b}{2R\sqrt{\frac{b_f - 2c}{R}}}) \tag{3}$$

$$b_{eq} = \frac{X1}{X2} \tag{4}$$

where,
L_b is the effective length of a beam

FEMA 350 represents parameter a, b, and c for determining the shape of RBS such as Eq. (5)-(7).

$$a \cong (0.5 \; to \; 0.75)b_f \tag{5}$$

$$b \cong (0.65 \; to \; 0.85)d_b \tag{6}$$

$$assume \; c = 0.20b_f \tag{7}$$

where,
b_f and d_b are the beam flange width and depth respectively

FORMULATION

Objective functions

This paper uses two objective functions. Because the moment ratio with respect to realistic design must be evaluate to obtain rational conclusion, the first objective function is to minimize the weight of structure as in Eq. (8). By the way, because the purpose of this paper is to evaluate the required minimum column-beam moment ratio inducing beam-hinge collapse mode with difference types of connection, the second objective function is defined as the minimization of the maximum moment ratio among column-beam moment ratio for the design as in Eq. (9). It is used NSGA-II (Deb et al., 2002) which is able to perform multi-objective optimization in order to evaluate two objective functions simultaneously.

$$\min \sum_{i=1}^{m} \rho_i A_i l_i \tag{8}$$

$$\min \alpha_{\max} \tag{9}$$

where,

ρ_i is the density of the i-th element

A_i is the cross-sectional area of the i-th element

l_i is the length of the i-th element

m is the number of elements consisting of the structure

$\alpha_{\max}$ is the maximum plastic moment strength ratio among joints of the structure

ANSI/AISC 341-05 excludes roof joint when examining the moment ratio. This paper also exclude roof joint in the evaluation of moment ratio. To evaluate moment ratio of joint, Eq. (10) is used.

$$\alpha = \sum \frac{(F_y Z)_{column}}{(F_y Z)_{beam}} \tag{10}$$

where,

F_y and Z are the yield stress and plastic section modulus

Constraints

This paper uses three constraints. The first condition constraints on inter-story drift as in Eq. (11). The second condition prevents the plastic hinge from forming at the column ends consist of all joints except the roof joint as in Eq. (12). To consider construction, the third condition is that the cross-sectional areas of lower columns must be greater than or equal to that of upper columns in continuous columns as in Eq. (13).

$$\frac{\Delta}{\Delta_a} \leq 1.0 \tag{11}$$

$$N_{pc} = 0 \tag{12}$$

$$\frac{A^c_{i+1,j}}{A^c_{i,j}} \le 1.0 \tag{13}$$

where,

Δ and Δ_a are the maximum and allowable inter-story drift respectively

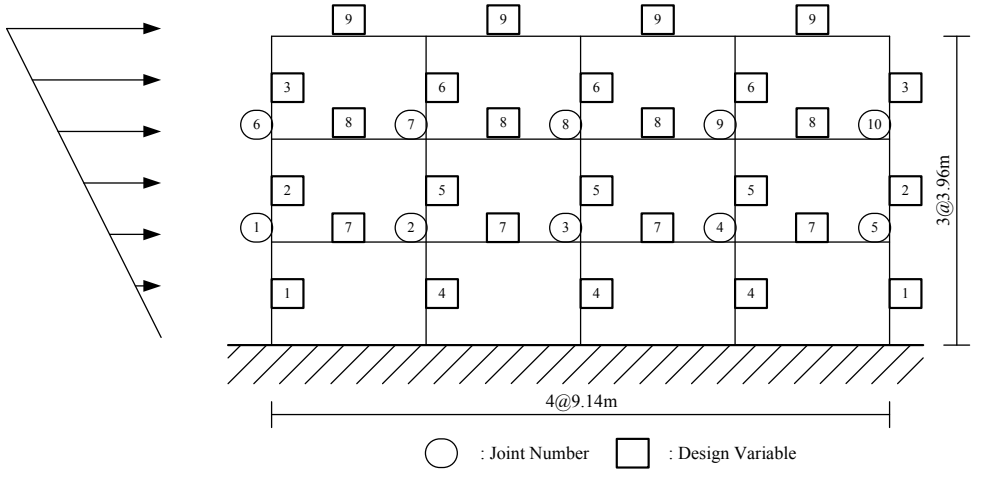
N_{pc} is the number of plastic hinges developed on the column part of joints

$A^c_{i,j}$ is the cross-sectional area of the ith floor and jth column

EXAMPLE

This paper uses three story four bay steel moment frame example and evaluates the required minimum moment ratio inducing beam-hinge collapse mode. Please refer to Hasan et al. (2002), Xu et al. (2006) and Gupta and Krawinkler (1999) for details with regard to the condition of the structural design of this example.

The nine design variables(six for columns and three for beams) for the structural optimization are used as in Figure 5. The number of cross-sectional data base whom the design variables of the columns and the beams can randomly select is 16 for the columns and beams respectively. By using ASCE 7-05, the inter-story drift constraint is evaluated.



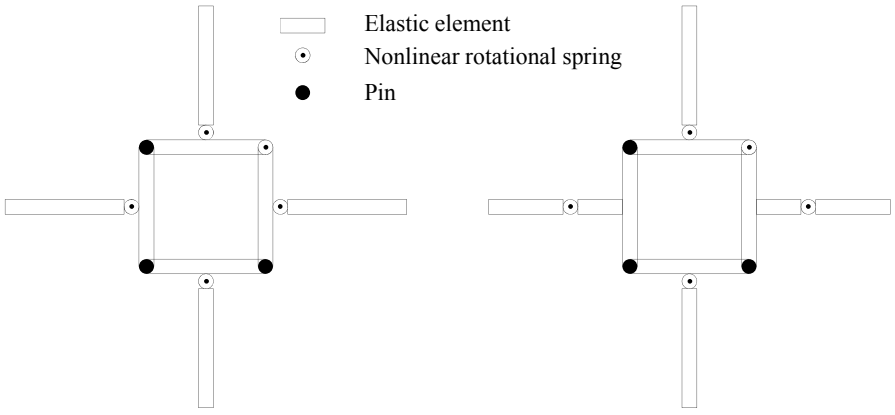


Figure 5. The elevation diagram of the example

The purpose of this paper is to evaluate the required minimum moment ratio inducing beam-hinge collapse mode of the steel moment frame with different types of connection. For this, the connection types for this paper are limited to WUF-W and RBS. By referring FEMA 355f, the analysis modeling for those connections is presented in Figure 6. The parameter a, b, and c determining the shape of RBS as in Eq. (5)-(7) are set to 0.5, 0.85, and 0.2 respectively.

To identify inter-story drift and whether the plastic hinge at the column form or not, linear static analysis and non-linear static analysis are performed respectively, by using OpenSees (2006). For the lateral loads used in non-linear static analysis, the

inverted triangle pattern is used. The target drift is set to be 5% of overall structural height, referring to the maximum inter-story drift ratio, the collapse prevention level, as suggested in FEMA 356.

(a) WUF-W (b) RBS

Figure 6. Analytic modeling of WUF-W and RBS including the panel zone

Through the structural optimization algorithm performance, total 17 feasible solutions(6 solutions for WUF-W and 11 solutions for RBS) are obtained as in Figure 7. As represented in the Table 1., as a result of conforming the constraint ratio of the feasible solution, the constraint ratio of 90% can be verified except each case 1. Each case 1 presents the constraint ratio of 80% levels in the construction constraint condition. This proves the relevance of the constraint conditions.

Both cases represent that the required minimum moment ratio inducing beam-hinge collapse mode decreases as the structural weight increases. However, it is represented that the steel moment frame with RBS requires less moment ratio than the steel moment frame with WUF-W.

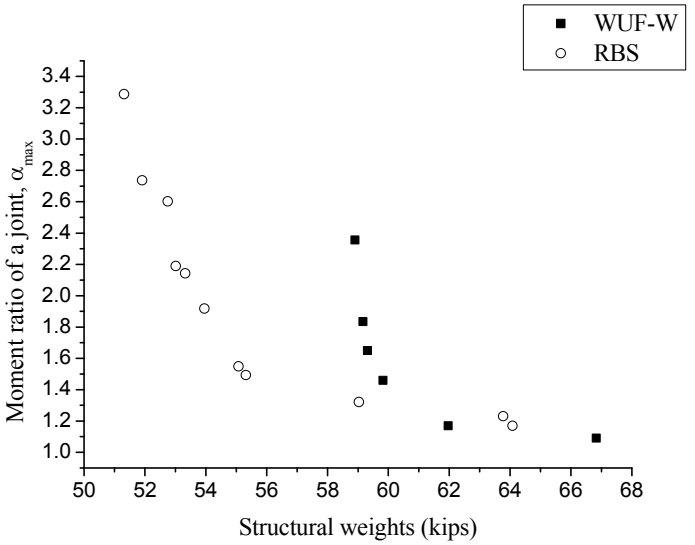

Figure 7. Comparison of the feasible solutions of WUF-W and RBS

CONCLUSION

According to existing researches, it is known that the ductile behavior of structure can be weakened when the plastic hinge forms in the columns earlier although the strong column-weak beam condition proposed in the criteria is satisfied. A variety of associated researches have limitation that linear center-line model ignoring the effects with respect to panel zone and connection is used. Therefore, this paper evaluates the required minimum moment ratio inducing beam-hinge collapse mode of the steel moment frame by using the optimization algorithm. The analysis modeling of the steel moment frame considers the WFF-W and RBS connections modeling including panel zone.

The proposed method was applied to three story four bay example for verification. Consequently, as the structural weight increases, the required moment ratio deceases. It is also represented that the design with RBS connection has less moment ratio than the design with WUF-W connection under similar structural weight. So, it is judged that the strong column-weak beam condition must be changed according to the connection type.

This research is limited to three story example, and doesn't consider non-linear dynamic behavior. Because it has limitation that doesn't include the analysis of the effects for parameter determining the shape of RBS, it is necessary to conduct the additional study of this.

ABSTRACT

Steel plate shear walls (SPSWs) consist of thin infill steel plates attached to beams, called horizontal boundary elements (HBEs), and columns called vertical boundary elements (VBEs) in building structural frames. Overall capacity of this system is provided primarily by the diagonal tension fields distributed along the entire length of the boundary frame elements due to the yielding of infill steel plates. Capacity design of the boundary frame, as currently designed, may result in very large demand on boundary frame members in some cases. In this investigation, tension field formation was controlled by discontinuous infill-to-boundary frame connections in order to reduce the demand on boundary elements. Finite element (FE) models of this system were developed and analyzed in ABAQUS. Behaviors of such a system (including overall capacity, initial stiffness and demand on boundary frames) were compared with those of the conventional SPSWs. Moreover, analytical models for estimating the plastic strength of SPSWs with discontinuous infill-to-boundary frame connections were presented.

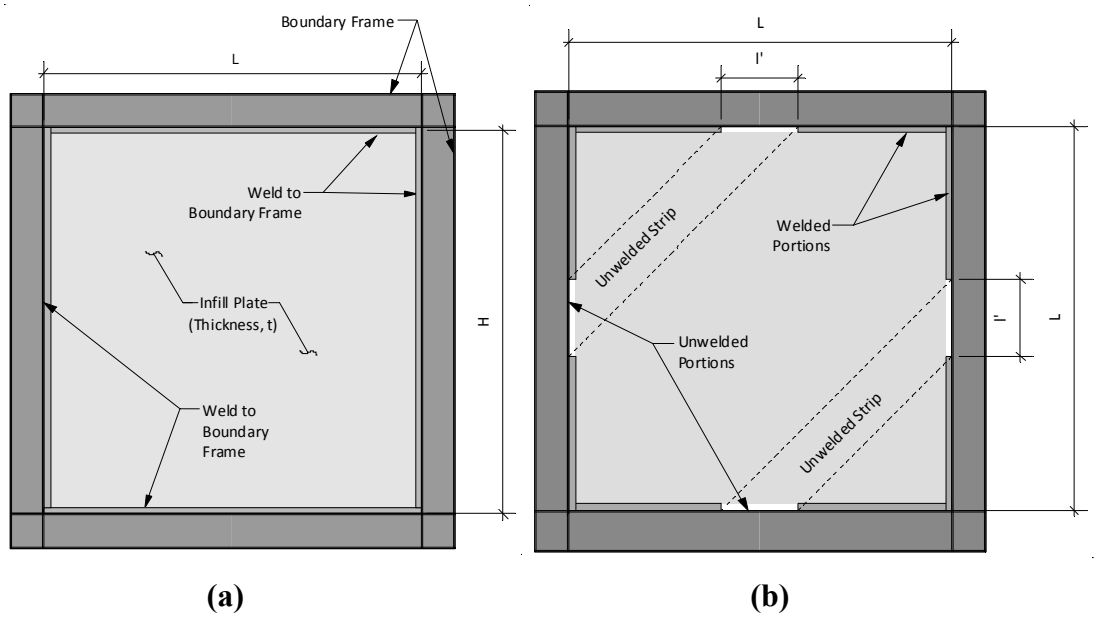
INTRODUCTION

Steel plate shear walls (SPSWs) consist of thin infill steel plates attached to beams, called horizontal boundary elements (HBEs), and columns called vertical boundary elements (VBEs) in building structural frames. As SPSWs deflect horizontally due to the lateral loads, the infill panels buckle followed by the development of plate diagonal tension field actions in the structural frame which provide the lateral resistance to horizontal shear (Thornburn, et al. 1983). SPSWs have been recently used as primary lateral force resisting systems in new and existing building construction (Sabelli and Bruneau 2006). Multiple studies have been performed validating the use of finite element analysis (FEA) as a reasonable tool in determining the overall capacity, stiffness, hysteric behavior, and failure mode of SPSWs.

Design procedures for new SPSWs are now available in the AISC Seismic Provision for Structural Steel Buildings (AISC 2005). This standard, as well as the Canadian code (CSA 2009), indicate that capacity design of the VBEs and HBEs be

used to ensure formation of the infill plate tension field actions and desirable seismic behavior of boundary frames (Elgaaly and Liu 1997; Berman and Bruneau 2008; Qu and Bruneau 2008; Qu and Bruneau 2010a; Qu and Bruneau 2010b).

Moreover, studies on seismic retrofit applications of SPSWs have been performed (Bruneau and Bhagwager 2002; Qu and Bruneau 2008). One important issue recognized from these investigations is that the demand on existing frames, due to the installed infill plates, may exceed their available strength, incurring additional costs for the strengthening work to avoid the premature failure of boundary frame. Also, in some new construction when plate thicknesses greater than required have to be used, due to the unavailability of construction materials, the demand on boundary elements can be of significant magnitude. This is especially problematic in multi-story applications where the bottom-story VBEs accumulate the tension field forces from the upper stories.



This paper attempts to address these difficulties by limiting the formation of tension fields within the plate by using discontinuous welds to connect the infill plate to the boundary elements. This paper discusses the development of an analytical model to estimate the overall strength and the validation of this model through finite element (FE) models. The overall strength, initial stiffness, and demand on boundary elements are compared between the new SPSWs and traditionally designed SPSWs. The results are used to make recommendations regarding the feasibility of implementing this method of design in common practice.

PROPOSED SYSTEM AND CONVENTIONAL SPSWS

Traditional SPSWs and SPSWs with controlled tension fields are illustrated in Figure 1. As shown, the SPSW with controlled tension fields has discontinuous plate-to-boundary frame connections. Both of these types of SPSWs were studied in this paper. For analysis purposes, the example SPSWs are identical except different plate thickness and plate-to-boundary frame connections. All example walls were modeled and analyzed in Abaqus CAE. Detailed information about the development of these models is presented in the next section.

Initial models consisted of a 3048 mm long, 2.54 mm plate bounded by four pin-ended boundary frame members of equal dimensions. The boundary frame members were specified as W48x355 A572 Grade 50, and the infill plate was ASTM A36 steel. The beams were modeled as 2 discrete beam elements 3048 mm each and the columns as 2 beam elements 3073 mm each. The extra length allowed the columns to be pinned at the base while allowing the bottom beam to freely deflect. The columns, as noted, were pinned at the base to minimize any contribution of the frame to the base shear. The plate was attached to the center-line of the beam elements, and the out-of-plane rotational degree of freedom was fixed at the connection. Since this study focused on the behavior of the plate alone, the boundary

frame members were sized to remain elastic and beam-to-column connections were assumed to be pinned. In addition, strain hardening was not considered. A view of the FEM model is shown in Figure 2.

DEVELOPMENT OF FE MODELS

Before the pushover analysis, we performed an initial eigenvalue analysis with a single lateral load applied in-plane at the top of the wall to the boundary frame. The lowest 15 eigenvalues and their graphical representation were recorded, and the coordinates of the lowest 6 eigenvalues that contributed to the known failure state of the model were superimposed onto a new, identical model. The out-of-plane coordinate was slightly displaced according to the eigenvalue shape with a greater emphasis on the lower values. This initial seeding was loaded as an initial condition onto the new model. This was intended to ensure that during pushover the plate failed at it's lowest natural frequencies.

We performed pushover analysis on traditional (fully welded) models by applying a monotonically increasing drift along the top boundary frame beam to a target level at which the wall was fully yielded. The overall base shear was recorded along with the lateral displacement at the upper left corner. The overall base shear was compared to the expected maximum capacity calculated according to Eq. 1. This was intended to calibrate the model and ensure that the control model was producing results in accordance with those predicted by accepted analytical models and previous research (Berman and Bruneau 2003). During analysis, the system reached the yield stress in the plate and remained below the yield stress in the frame. The plate buckled and deformed according to the lower eigenvalues, and all the plate reached the elastic capacity of 36 ksi (248 MPa). The pushover below shows the traditional test model with the maximum calculated shear.

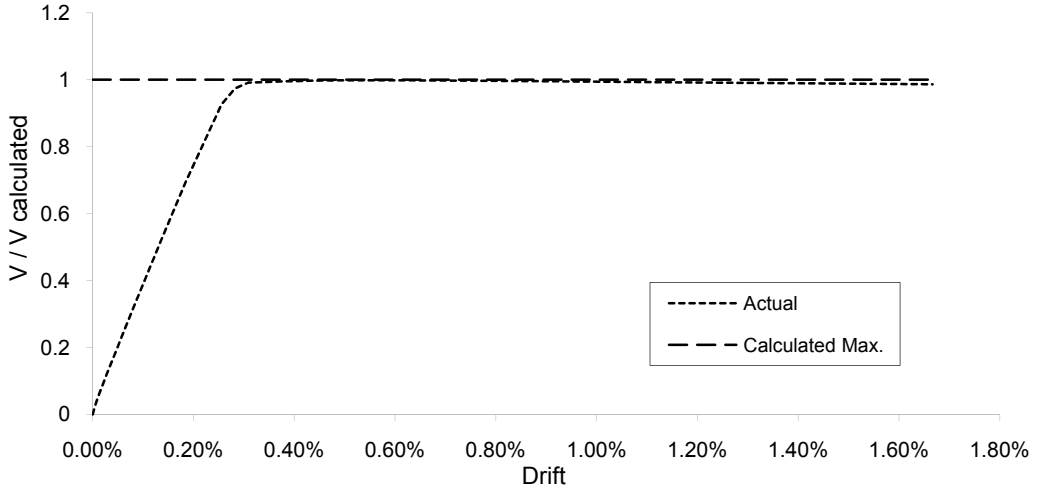

Figure 3. Traditional (fully welded) SPSW pushover curve

This process of modeling the traditional shear walls was performed for various aspect ratios between 0.8 and 2.5 as well as for different plate thicknesses between 3.18 mm and 12.70 mm. Once the models were shown to accurately predict

expected behavior, they were modified to reflect the controlled infill tension assembly.

The controlled infill tension models were formed in the same manner as the traditional walls; however, the constraint connecting the infill plate to the boundary frame was modeled as discontinuous at a ratio equal to the selected weld ratio. The model evaluated here was a 3048 mm x 3048 mm x 2.54 mm infill plate. It was bounded by W48x355 beams and columns as boundary frames, exactly as in the traditional shear wall. A weld ratio of 0.8 was evaluated, so 610 mm at the center of each edge was left unwelded. This configuration also allows the unwelded portions to the beam and column to occur 45 degrees apart corresponding to the tension field angles in typical SPSWs.

SEISMIC PERFORMANCE COMPARISIONS

During the pushover analysis of the tension-controlled system, the frame remained entirely elastic. The plate outside the area bounded by the unwelded portions reached the elastic capacity of 36 ksi (248 MPa), while the areas bounded by unwelded portions reached approximately 50% of elastic capacity, 18 ksi (124 MPa). The edges of those areas reached a higher stress than the center. The model below shows the stress distribution at the final point of the pushover, when maximum capacity has been reached.

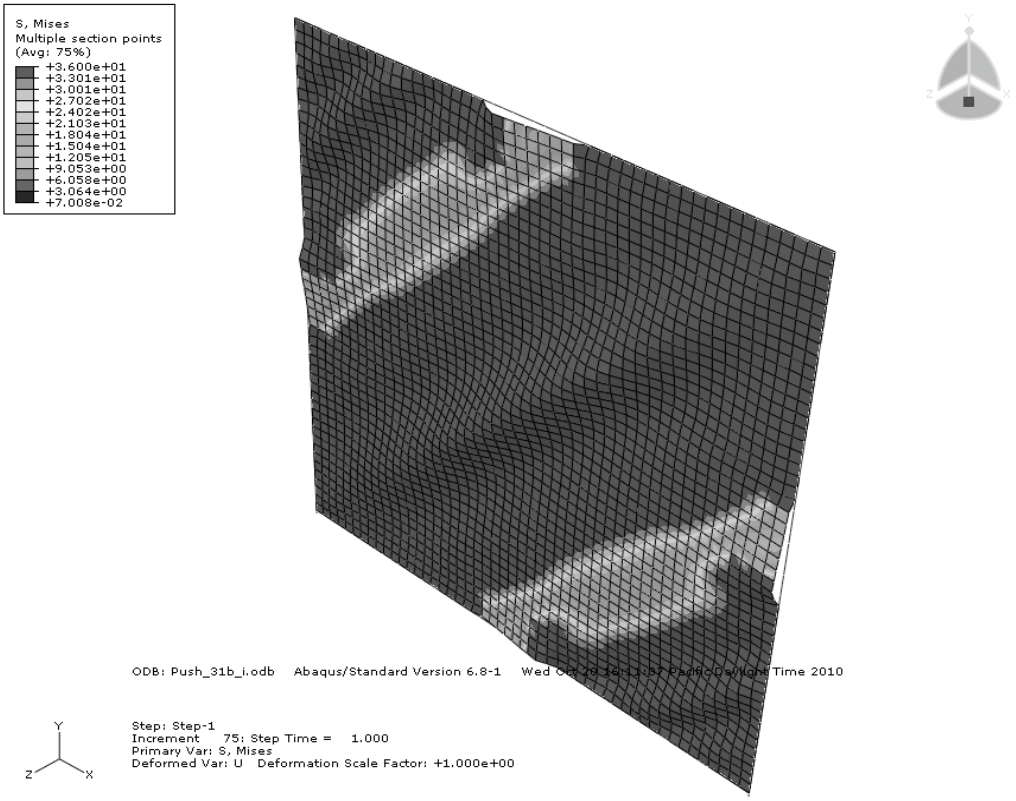

Figure 4. Stress distribution of the SPSWs with controlled tension field actions

The pushover results showed the areas of partial stress add an amount of resistance to the overall base shear, although there is no tension field formed in this area. The contribution of this area is attributed to compressional effects that develop in the plate and vary with plate thickness, length of the diagonal strip of area, and the length of the unwelded portion. These effects are accounted for in the compression effects factor shown in Eq. 4. Multiple plate thicknesses, aspect ratios, and weld configurations were modeled; however, the results here are limited to the test case described above. The traditional shear walls were compared to the plastic capacity model in Eq. 1 while the tension-controlled shear walls were compared to the tension controlled plastic capacity model in Eq. 3.

For the test case presented, the analytical model was found to closely predict the total overall base shear resisted in the FE model (see Figure 5). The first part of the analytical equation, shown in Eq. 2, accurately modeled the tension field contribution of the infill plate by accounting only for tension field formation in the welded areas. The second part of the equation, the compression effect factor, closely modeled the compressive resistance provided by the plate, perpendicular to the direction of tension field formation, by modeling that area as a wide, thin column.

For the model of a 3048 mm x 2.54 mm, 36 ksi (248 MPa) plate with a weld ratio of 0.8, the analytical model predicted the total base shear within 0.10% of the FE results. The analytical equation calculated a shear value of 826.26 kN while the FEM produced a base shear of 827.10 kN. The error increased modestly with thicker plates up to 3.25% for the plates considered in this study. This increase in error with the thicker plate is likely due to the compression effects that occur in the plate in the welded areas that act in addition to the tension fields, as noted by other researchers. (Shishkin et al. 2009). This error value remained small and consistent with error values found in how the fully welded (traditional) SPSWs compare with the plastic capacity model.

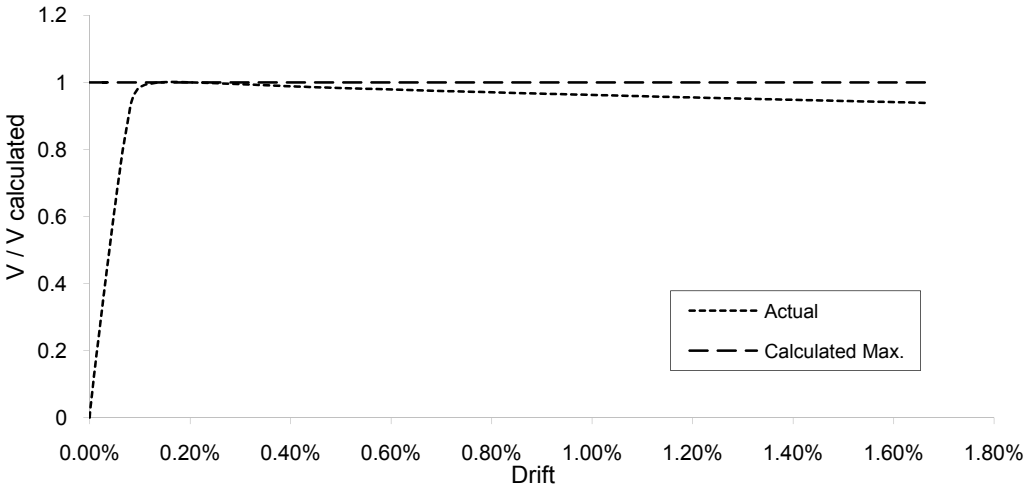

Figure 5. Pushover curve of SPSWs with controlled tension field action

Along with the overall capacity being reduced, the demand on the boundary elements was also reduced. Considering the top beam, since shear demand on the beam is generated by the tension field action, the demand is reduced proportional to how much weld area is reduced, the weld ratio. The moment demand is more dependent on the weld orientation. If load is reduced on the center of the beam, more moment reduction is observed than if the load was reduced on the edges. For the considered SPSW, where the 20% reduction in weld area was at the center of the beam, the moment demand was reduced approximately 25%.

When the tension-controlled system is considered as a method to reduce demand on boundary frames due to oversized infill plates, the overall design characteristics were found to be similar to those of the thinner infill plate. The following figure shows the moment diagram for the top beam in a SPSW where a 6.35 mm plate with a weld ratio of 0.8 was used in lieu of a 5.08 mm plate with a weld ratio of 1.0. For comparison purposes, the full demand of the 6.35 mm plate with a weld ratio of 1.0 is included to show the overall reduction experienced.

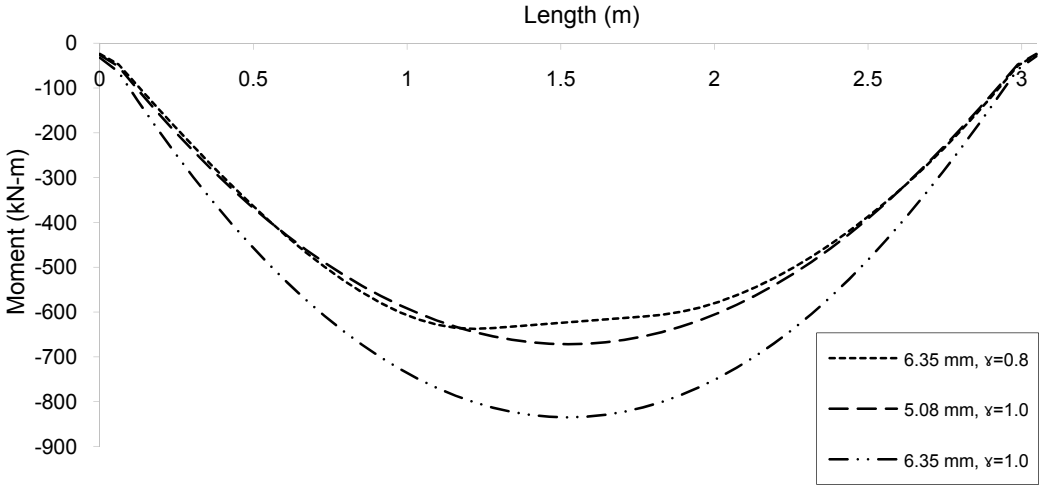

Figure 6. Moment diagrams for top beam

A similar observation was obtained from the demand on VBEs. As shown in Figure 7, bending moment and axial load in the VBEs of the SPSWs with controlled tension field actions closely resembled those of the conventional SPSWs with thinner plate, fully welded. The moment diagram and axial load diagram for the VBEs are shown in Figure 7.

When compared to the traditional SPSWs with both the oversize and normal sized plate, the stiffness of the SPSWs with controlled tension field actions is noticeably less as shown in Figure 8. This difference in stiffness would require the designers to recalculate lateral loads on SPSWs, and such difference would be reduced when the frame moment resisting action provides some stiffness to the overall system.

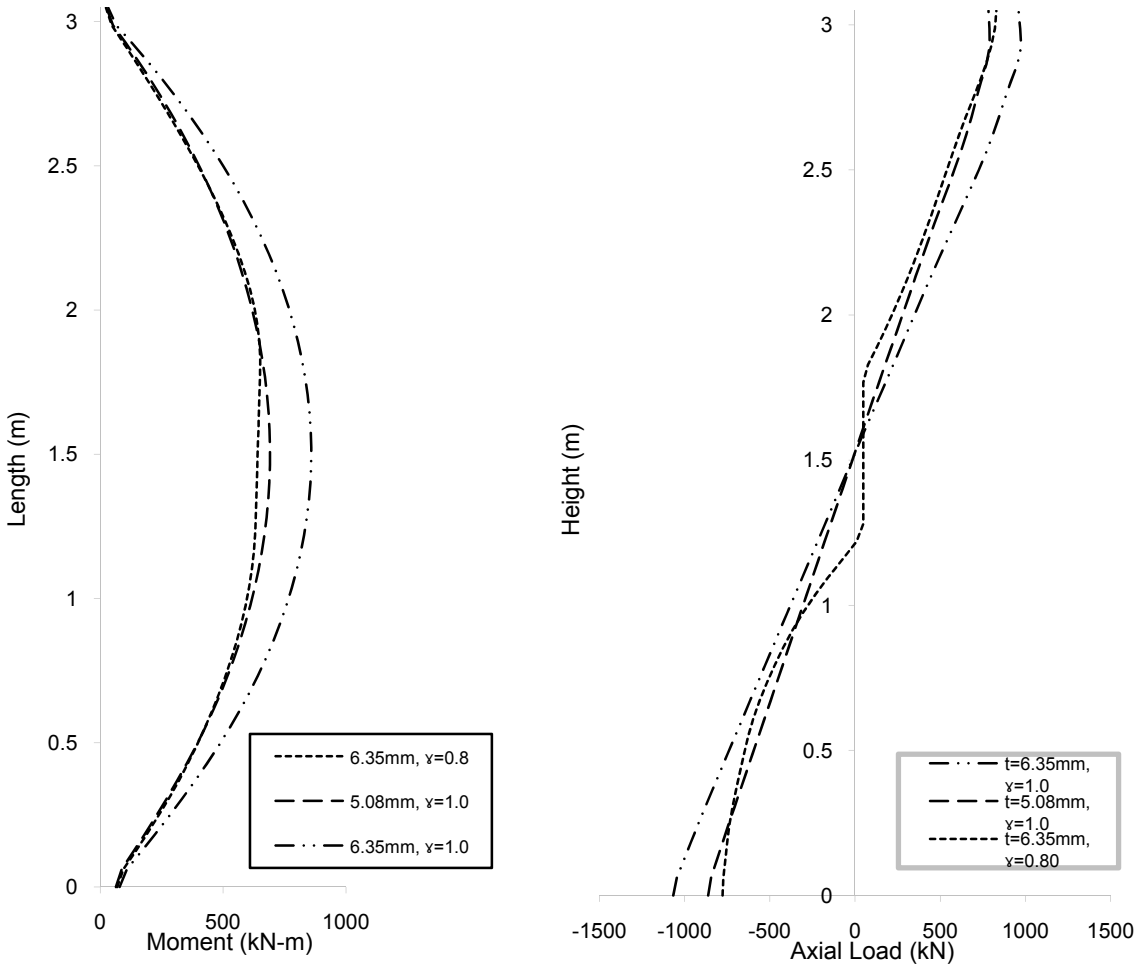

Figure 7. Column demand

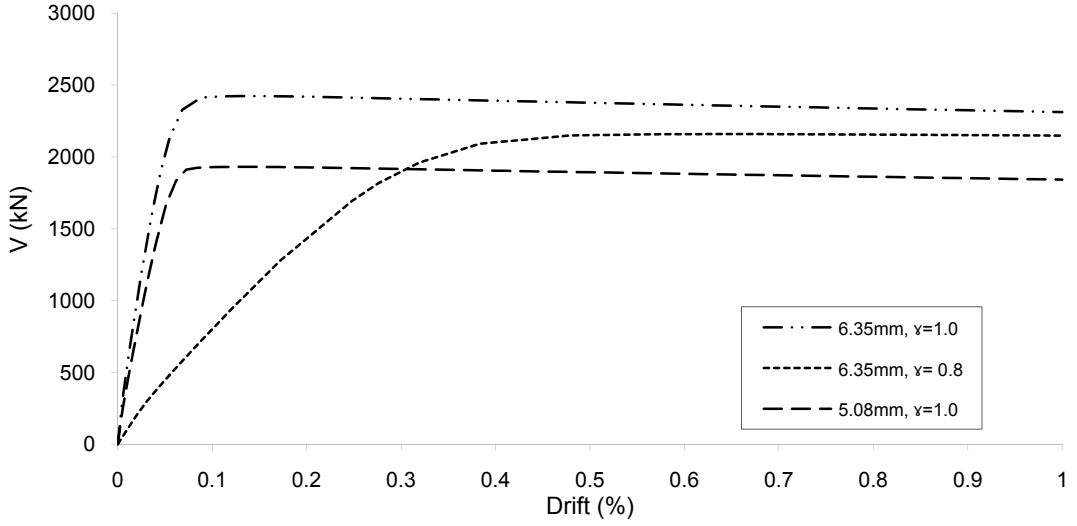

Figure 8. Pushover curves

ANALYTICAL MODELS FOR SHEAR STRENGTH ESTIMATE

Analytical models for calculating plastic strength of conventional SPSWs have been derived and validated by Berman and Bruneau (2003). According to their model, plastic strength of a single story conventional SPSW with pinned beam-to-column and column-to-base connections can be calculated by the following equation.

$$V = \frac{1}{2} F_y t L sin2\alpha \tag{1}$$

where:

V = plastic shear strength
F_y = plate yield strength
t = plate thickness
L = width of the wall
α = tension field angle

Here, the analytical plastic analysis procedure proposed by Berman and Bruneau. (2003) are repeated for the SPSWs with a non-continuous weld, or stitch-weld, connecting the infill plate to the fish-plate and the steel boundary elements. As a result, the ultimate plastic strength of the system, due to tension field action alone, is directly proportional to the weld ratio of the system.

$$V = \frac{\gamma}{2} F_y t L \sin 2\alpha \tag{2}$$

where γ = weld ratio along boundary elements (welded length / total length).

Since the weld ratio is always less than 1.0, the resistance of the wall with discontinuous plate-to-boundary frame connections is lower than that of the same wall with continuous plate-to-boundary frame connections. In addition, it is recognized that Eq. 2 only takes into account the lateral force resistance due to the tension field action. The compressional effects in the infill plate as shown in Figure 4 were not considered. The behavior of the compressional plate zone is similar to a column (i.e. buckle under an increased axial compression). As such, their strength may be considered by the AISC column design equation. As a result, equation for the plastic strength was modified as below

$$V = \frac{\gamma}{2} F_y t L \sin 2a + \Psi \tag{3}$$

where: ψ = compression effect factor,

$$\Psi = F_{CR}\ l'\ t \cos(\alpha) \tag{4}$$

Where: F_{CR} = Compressive stress in the unwelded strip

$$\text{For, } \frac{kL}{r} \le 4.71\sqrt{\frac{E}{F_y}},\ F_{CR} = \left[0.658^{\frac{F_y}{F_e}}\right] F_y \tag{5}$$

$$\text{For, } \frac{kL}{r} > 4.71\sqrt{\frac{E}{F_y}},\ F_{CR} = 0.877 F_e \tag{6}$$

$$\text{Where: } F_e = \frac{\pi^2 E}{\left(\frac{kL}{r}\right)^2} \tag{7}$$

E = elastic modulus of the plate
l' = unwelded length in the top beam
k = slenderness factor = 0.55-0.60
r = radius of gyration

Moreover, the contribution due to the compressional zone should not exceed that of the corresponding tension field action, which means the following equation should be checked.

$$\Psi \le \frac{1}{2} F_y t L (1-\gamma)\cos(\alpha)\sin(2\alpha) \tag{8}$$

The analytical model presented above has been validated by FE results. An example result comparison is given in Figure 5. As shown, reasonable agreements were observed.

CONCLUSION

Behavior of the SPSWs with discontinuous plate-to-boundary frame connections was investigated. Compared with conventional SPSWs, this system exhibits reduced stiffness and reduced demands on boundary frame members. Analytical models developed for calculating the plastic strength of such systems agree reasonable well with the results from FE models.

ABSTRACT

As part of the expansion of the athletic program at the University of Pennsylvania in Philadelphia, the space underneath the bleacher area of Franklin Field was recaptured by excavating and then converting the area under the concourse slabs and ramps to a weight training facility. The augmentation has earned the project a LEED Silver Certification.

THE HISTORY OF FRANKLIN FIELD

Franklin Field is the oldest open stadium in the United States. It originally opened in 1903 with wooden bleachers seating 30,000 spectators. In 1922 the stadium was replaced with a concrete structure with a capacity of 50,000 seats. Only 3 years after the rebuilding of the stadium, it was expanded by adding an upper tier with 25,000 more seats. This addition is a independent steel structure, laterally braced by the original concrete frame. In 1983 expansion joints were introduced into the structure.

The stadium is an open-air horseshoe shaped structure and was built on a defunct industrial landfill. The entire stadium, including the "slab on grade", are supported by concrete piles to mitigate possible settlements due to the poor soil condition. Piles are friction piles that penetrate the fill and bear in the underlying glacial till.

The façade of the stadium consists of brick clad columns forming an arcade and supporting the upper concrete rakers. The brick enclosure for these columns terminate in brick arches under the raker beams

THE PROGRAM

In 2007 the Physical Education Department at the University of Pennsylvania in Philadelphia contemplated the expansion of their training facility. One of the possible sites for this expansion was a space under the Franklin Field Football Stadium that had been filled with cinders and debris. The new excavation and enclosing of this area would yield 30,000 sf of usable space. In addition, the expansion of the concourse and upper concourse would be extended from the interior columns to the exterior "arch columns", filling in two floors in the arcade space and adding an additional 20,000 sf of usable space. This scheme enabled a significant increase of usable space while maintaining the historic appearance of the façade.

THE CHALLANGE

The Franklin Field renovation posed several challenges in that new floors were added, column bracing was removed, and the existing façade was uncovered after seven decades. To utilize the new space after excavation, existing piles and pile caps needed to be lowered and existing concrete columns extended. An innovative approach involving a temporary prestressed transfer steel frame was used to support the concrete columns during this phase of work. This approach assured minimum disturbance to and elimination of cracking of the existing concrete structure. No temporary foundation system was required for the temporary support. The frames were designed to be reused for multiple alterations. A soil anchor pinning system was installed to form the new interior retaining wall with no temporary bracing.

DESIGN APPROACH

The University archives contained copies of drawings dating back to the 1923 renovation and subsequent alterations and additions. Unfortunately, some of these drawings were in very poor condition and illegible. The majority of the drawings were architectural details with the most complete and structurally informative documents being the construction drawings of 1983 for the addition of the expansion joints. However, these were only partially accurate because they had been based on assumptions of structural configurations that did not directly affect the construction of the expansion joints. The elevations of the pile caps for the interior columns, for example, varied significantly from the 1983 or original architectural drawings.

The Implementation

The renovation program consisted of several tasks, outlined below.

1. Addition of a new foundation retaining wall ioutside of the exterior brick colonnade to form the exterior wall for the newly excavated area.
To gain as much space as possible for the lower level, the new retaining wall was placed 2 feet in front of the existing masonry arcade columns. The foundation wall is 16 feet high and 16 inch thick. It is laterally braced by the new slab on grade as well as the new concourse framing. The wall is supported by 8"ø steel cased mini piles with a 40 ton capacity.

2. Excavation of the infilled area and placement of a new floor slab; installation of a new retaining wall on the interior side of the new space.
The excavation of the fill underneath the old concourse ramps presented several challenges. The soil in itself was not stable enough for the required vertical cut. Soil nails were installed as the excavation progressed. The cut was periodically sprayed with water to maintain the soil cohesion. After the excavation reached the final vertical elevation, a gunite wall was installed in front of the cut. The wall was cocealed with a CMU wall in front of the gunite wall. A drain gutter was provided between the two walls at the ground floor level to collect any water that might penetrate through the stadia into the soil behind the new gunite wall.

3. Lowering several pile caps and consequently extending their supported columns in the new space.

Four of the existing pile caps extended up to seven feet above the desired elevation for the new lower level floor. They thus interfered with the space to be used for exercise equipment. These pile caps support the concrete columns of the original concrete frame. In order to lower a pile cap, the column above carrying a load of 36 tons, the deal load of the structure, needed to be temporarily supported by other means. Driving new piles next to the existing ones was not feasible due to the site restraints.

A frame was devised that transferred the column load to the pile caps of adjacent columns which were 19'-2 ½" away. The frame was shaped like an "A" and consisted of two HSS 8x8 tubes that formed the A's legs. The top of the "A" lined up with the 16" square column that needed to be suspended and was connected to it through a hanger arrangement. Initially the connection to the concrete column was envisioned to be through a plate welded to the column reinforcement. Tests of sample welds to the reinforcement showed, however, that the welds were too brittle due to the reinforcement's high carbon content. The connection of the hanger to the concrete column was then designed with the use of 16- 1"ø x 8" adhesive fasteners. The base of each HSS 8x8 leg rested next to the adjacent column.

The transfer frame was installed at the concourse level, one story above the pile cap, so that there would be enough room for the demolition of the pile cap and shortening of the piles. The bases of the "A" frame legs were connected to each other by a C10x15.5 tie to resist the spreading force. The center of the tie was spliced by threaded rods tensioned to match the force that would arise when the frame carried the concrete column's calculated dead load. Teflon sheets underneath the bases of the "A" frame legs meant that only small friction forces would resist the prestressing of the tie. The pre-stress forces were monitored by strain gages. The pre-stress in the "A" frame assured that there would be no movement once the column was cut loose from the pile.

The concourse level concrete beams framing into the columns that would support the loaded "A" frame did not have sufficient shear capacity to transfer the load. Shoring underneath the concourse transferred the load directly to the pile caps of these columns. The "A" frame extended from the concourse level to the underside of the concrete raker beam 20 feet above, where it was fastened to provide lateral stability.

4. Removal of the ramp connecting the concourse to the lower level (field level) and replacement of it with a framed floor.
Some of the concrete columns were braced by the ramp and required another means of lateral support for this work phase. Temporary bracing was installed during removal of the ramp and remained until after placement of the new concourse floor.

5. Addition of a new floor to the upper tier between the exterior columns and the extension to upper concourse.
The exterior free standing colonnade consists of masonry encased concrete columns that extend from the foundation to the underside of the raker beams. The masonry encasement at the upper portion forms arches that give the building appearance its special his.toric look Transverse arches connect these columns to the ones that are incorporated into the wall and that support the concourse and upper concourse. new floors were built between these

columns extending the concourse and upper concourse floors into the colonade space. The framing for these floors is steel beams and metal deck with concrete fill. The clearance of the bracing arches and the new upper concourse floor was only three feet. Thus they were removed after the floor framing was installed. This sequence of construction assured continuous bracing of the colonnade columns.

6. Repair of corroded reinforcing and structural steel.
As part of the renovation, the existing structure was evaluated. Parts of the new framed slabs were to be supported from the existing concrete beams. It was observed that many beams had spalled concrete due to reinforcing corrosion. Even some of the steel columns that had been added to support the upper tier showed significant spalling of their concrete enclosures. This was surprising since the beams and columns were previously fitted with a cathodic protection. Once an evaluation of the steel showed that it was sound enough for its structural purpose, the concrete surfaces of the damaged beams and columns were treated with a corrosion inhibiting penetration liquid to slow if not halt further deterioration.

CONCLUSION

The renovation and expansion of the Franklin field to create the George A. Weiss Pavillion presented several design and construction challenges. The successful completion of the work gave the university community a significant and unique usable space for their athletic program without compromising the appearance of one of their historic structures.

Comparison of Hybrid and Emulative Precast Concrete Shear Walls for Seismic Regions

B. J. Smith[1], Y. C. Kurama[2] and M. J. McGinnis[3]

ABSTRACT

This paper compares the measured lateral load behavior of a 0.4-scale "hybrid" precast concrete wall test specimen with the behavior of a second precast specimen designed to emulate monolithic cast-in-place reinforced concrete shear walls. Both walls have the same overall geometry and are constructed by placing rectangular wall panels across horizontal joints. The lateral resistance at the joints of the "emulative" system is provided by mild [i.e., Grade 400 (U.S. Grade 60)] steel bars, whereas the hybrid wall features a combination of mild steel bars and high-strength unbonded post-tensioning (PT) strands. The mild steel reinforcement at the base of both systems is designed to yield and provide energy dissipation, while the unbonded PT steel in the hybrid system also provides self-centering capability to reduce the residual lateral displacements of the structure after a large earthquake. The comparisons between the two walls focus on the applied lateral load versus displacement behavior, energy dissipation, behavior of the steel reinforcement, and behavior along the critical horizontal base-panel-to-foundation joint. Due to the lack of PT steel, the emulative specimen developed a residual uplift along the entire base-panel-to-foundation joint, resulting in excessive horizontal slip, large strength and stiffness degradation, and significant residual lateral displacements. In contrast, the hybrid specimen showed significantly smaller residual uplift, horizontal slip, and strength and stiffness degradation, resulting in excellent re-centering and energy dissipation with ductile behavior over much larger lateral deformations.

INTRODUCTION AND BACKGROUND

As described in detail in Smith et al. (2011), the hybrid precast wall system investigated in this research utilizes a combination of mild [i.e., Grade 400 (U.S. Grade 60)] steel bars and high-strength unbonded post-tensioning (PT) strands for lateral resistance across horizontal joints. The general test configuration for the hybrid specimen is shown in Figure 1a. Under the application of lateral loads into the nonlinear range, the primary mode of displacement in these walls occurs through gap opening at the base joint. The PT steel is provided by multi-strand tendons placed

inside un-grouted ducts to prevent bond between the steel and concrete. Thus, the tendons are connected to the structure only at end anchorages. The emulative wall configuration (Figure 1b) uses only mild steel reinforcement with no PT steel.

In both systems, the mild steel bars crossing the horizontal joint at the base are designed to yield and provide energy dissipation through the nonlinear lateral displacements of the structure. A pre-determined length of these bars is unbonded at the bottom of the base panel (by wrapping the bars with plastic sleeves) to prevent low-cycle fatigue fracture. In the case of the hybrid wall, both the PT steel and mild steel contribute to the lateral strength of the structure. Upon unloading, the PT steel provides a restoring force to close the gaps and reduce the residual (i.e., permanent) lateral displacements of the wall after a large earthquake. The use of unbonded PT tendons (as compared to bonded tendons) delays the yielding of the strands and reduces the tensile stresses transferred to the concrete (i.e., reduced cracking) as the tendons elongate under lateral loading.

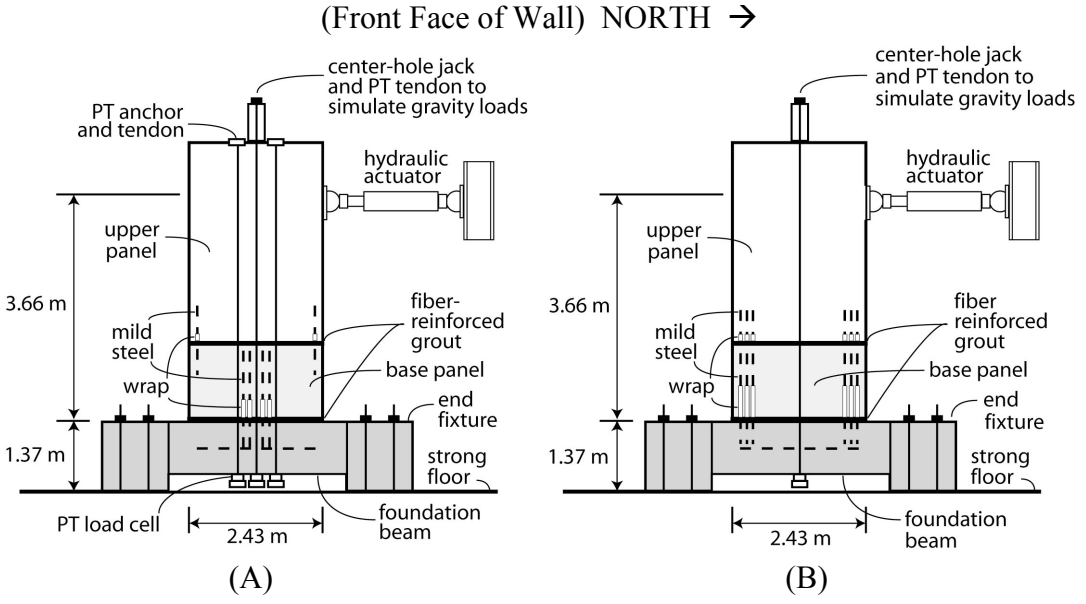

Figure 1. Test configuration: (a) hybrid wall; (b) emulative wall.

According to Chapter 21 of ACI 318 (2008), "a reinforced concrete structural system not satisfying the requirements of this chapter shall be permitted if it is demonstrated by experimental evidence and analysis that the proposed system will have strength and toughness equal to or exceeding those provided by a comparable monolithic reinforced concrete structure satisfying this chapter." The hybrid precast wall system investigated in this research falls within this category of structures that require experimental validation and analysis prior to their use in practice as a primary lateral load resisting system. The roadmap for the seismic performance assessment of hybrid walls is provided by ACI ITG-5.1 (2007), which lays out the minimum experimental evidence needed for the classification of these walls as special reinforced concrete shear walls based on ACI 318. The emulative system in Figure 1b is also not directly permitted by ACI 318, since unlike the requirements for a monolithic cast-in-place reinforced concrete structure, the longitudinal mild steel reinforcement is lumped near the ends of the wall (i.e., there is no distributed steel crossing the horizontal

joints). As compared with a distributed bar arrangement, the lumped reinforcement detail in Figure 1b provides ease of placement during the field erection process.

This paper provides a comparative experimental evaluation of these two precast concrete wall systems under reversed-cyclic lateral loading. Ultimately, the goal of this comparison is to investigate the code approval and validation of the walls according to the guidelines, prerequisites, and requirements in ACI ITG-5.1 and ACI 318.

TEST SET-UP AND SPECIMEN PROPERTIES

The tests conformed to the requirements of ACI ITG-5.1. Schematic drawings of the test setup and specimen details are shown in Figures 1 and 2, respectively. The hybrid specimen was designed as a special reinforced concrete shear wall [within an ASCE 7 (2005) "building frame system"] for a 4-story prototype parking garage with an approximate footprint of 3,770 m^2 (40,600 ft^2) in Los Angeles, CA. Both the hybrid wall and emulative wall tests were conducted at 0.40-scale, which satisfies the minimum scaling limit of ACI ITG-5.1. The specimens featured two panels: the base panel representing the 1st story of the structure and the upper panel representing the 2nd through 4th stories, thereby satisfying the ACI ITG-5.1 requirement for testing multi-panel walls (such that an upper panel-to-panel joint as well as the base-panel-to-foundation joint are evaluated). The 0.40-scale wall length, l_w, was 243 cm (96 in.), base panel height, h_{pb}, was 145 cm (57.5 in.), and wall thickness, t_w, was 15.9 cm (6.25 in.). It was possible to test the upper story panels of the 4-story prototype wall as a single panel since the joints between these upper panels were designed to have no nonlinear behavior and no gap opening. The lateral load was applied 3.66 m (12

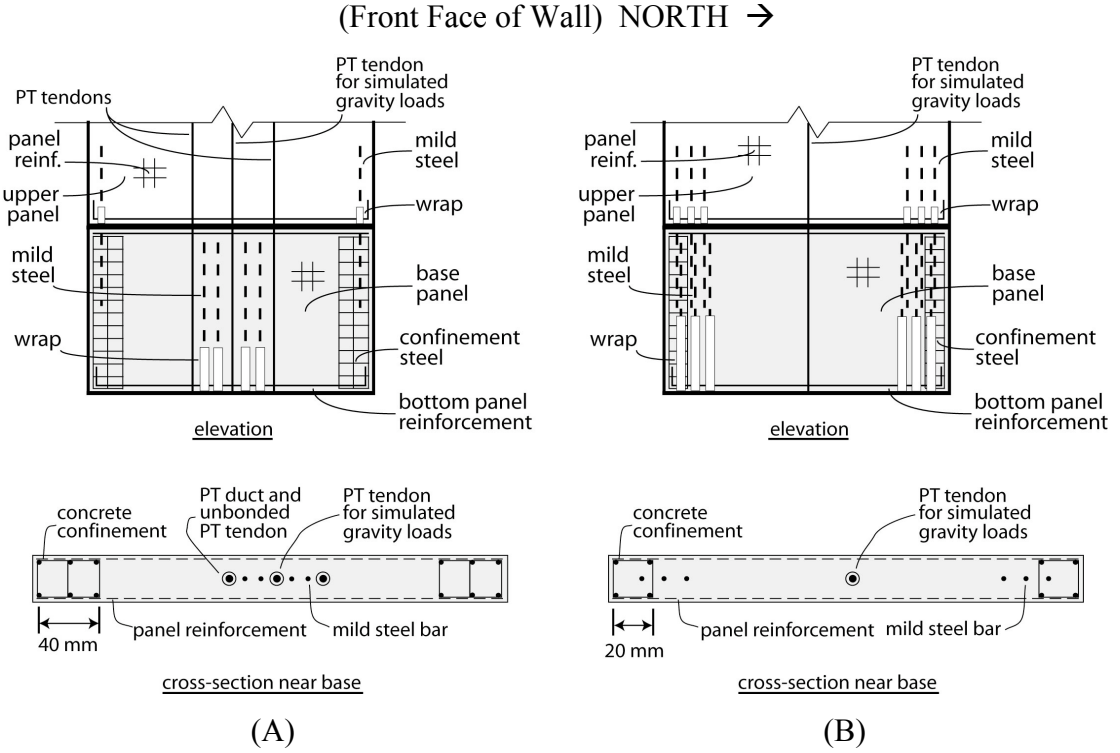

Figure 2. Test specimen details: (a) hybrid wall; (b) emulative wall.

ft) from the wall base (near the resultant location of the 1st mode inertial forces), resulting in a wall base moment to shear ratio of M_b/V_b=1.5l_w. An external downward axial load of about 325 kN (73 kips) was applied at the center of the top of each specimen to simulate the service-level tributary gravity loads acting on the prototype structure.

The hybrid wall specimen was designed using the requirements and guidelines of ACI ITG-5.2 (2009), ACI-318, and ASCE 7 (2005). More information on the design of this wall as well as the results from a pre-test analytical study can be found in Smith and Kurama (2009) and Smith et al. (2011). The structure was designed for a full-scale base moment strength of 24,400 kN-m (18,000 kip-ft) and a "validation-level" wall drift prescribed by ACI ITG-5.1 (2007) as:

$$\Delta_{wm} = 0.9\% \le \left(h_w/l_w\right)0.8\% + 0.5\% \le 3.0\% \quad (1)$$

where, h_w=height to the top of the wall; and l_w=length of the wall. The wall drift, Δ_w is defined as the lateral displacement at the top of the wall divided by the wall height. For the given wall dimensions, the resulting validation-level drift is Δ_{wm}=2.30%.

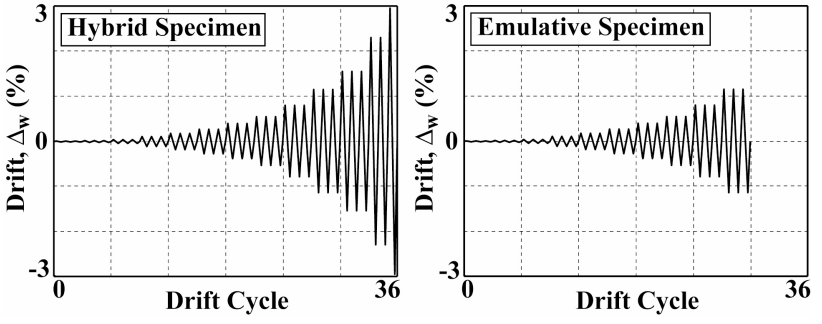
The design of the emulative wall was conducted for the same lateral force and displacement requirements as the hybrid wall according to ACI 318. Both specimens were designed with minimal overstrength in order to test the limits of the design requirements and procedures. Most of the design parameters remained consistent between the two specimens, with the primary exception of the reinforcement details.

In the hybrid system (Figure 2a), the PT steel consisted of two tendons located 27.9 cm (11 in.) north and south from the wall centerline. The tendons were placed near the wall centerline to reduce the strand strains and also keep the PT ducts away from the critical confined toe regions of the wall. Each tendon contained three 1.3-cm diameter (0.5-in.) strands [design ultimate strength, f_{pu}=1862 MPa (270 ksi)] with an unbonded length from the top of the wall to the bottom of the foundation beam of about 5.48 m (18 ft). The average initial tendon stress, calculated from the measured individual strand forces prior to the application of the lateral load, was f_{pi}=0.54f_{pu}. The mild steel crossing the base joint in the hybrid specimen (i.e., energy dissipating steel) consisted of four 19-mm diameter (U.S. No. 6) bars [measured yield strength, f_{sy}=448 MPa (65 ksi), and yield strain, ε_{sy}=0.0023 cm/cm], with one pair of bars placed 19.0 cm (7.5 in.) north and south from the wall centerline and the other pair 8.9 cm (3.5 in.) north and south from the centerline. The energy dissipating bars were unbonded over a length of 38.1 cm (15 in.) at the bottom of the base panel. Across the upper panel-to-panel joint, only two 19-mm diameter bars were used, with one bar 10.2 cm (4 in.) from each end of the wall. This reinforcement was designed not to yield so as to limit any gap opening along the panel-to-panel joint. To prevent strain concentrations in the panel-to-panel joint reinforcement, a short 7.6-cm length (3-in.) of the bars was unbonded at the bottom of the upper panel. The design unconfined concrete strength for the wall was 41 MPa (6.0 ksi) and the design confined concrete strength (at the toes of the base panel) was 62 MPa (9.0 ksi). The measured unconfined concrete strength for the base panel was 55 MPa (8.0 ksi) on the day that the wall was tested. At the base and panel-to-panel joints, fiber-reinforced grout (with polypropylene microfilament fibers at 0.065% by volume) was used. The test-day strength of the grout at the base joint was 58 MPa (8.4 ksi).

The steel reinforcement crossing the base joint in the emulative specimen (Figure 2b) consisted of six 22-mm diameter (U.S. No. 7) bars [measured yield strength, f_{sy}=427 MPa (62 ksi), and yield strain, ε_{sy}=0.0035 cm/cm], with three bars placed at each end of the wall [located 17.8 cm (7 in.), 30.5 cm (12 in.), and 43.2 cm (17 in.), respectively, from the wall end]. The bars were unbonded over a length of 55.9 cm (22 in.) at the bottom of the base panel. Across the upper panel-to-panel joint, six 22-mm diameter bars were used, with three bars at each end of the wall [located 12.7 cm (5 in.), 25.4 cm (10 in.), and 38.1 cm (15 in.) from the ends of the wall]. As in the case of the hybrid specimen, this reinforcement was designed not to yield so as to limit any gap opening or slip along the panel-to-panel joint. A 7.6-cm length (3-in.) of the bars was unbonded at the bottom of the upper panel to prevent strain concentrations in the joint reinforcement. Similar to the hybrid wall, the design unconfined concrete strength for the emulative wall was 41 MPa (6.0 ksi) and the design confined concrete strength (at the toes of the base panel) was 63 MPa (9.1 ksi). The measured unconfined concrete strength for the base panel of the emulative wall was 45 MPa (6.6 ksi) on the day that the wall was tested, which is smaller than the measured concrete strength for the hybrid wall. The test-day strength of the fiber-reinforced grout at the base joint of the emulative wall was 39 MPa (5.6 ksi).

MEASURED BEHAVIOR OF SPECIMENS

Figure 3 shows the reversed-cyclic lateral displacement history used in the testing of each specimen. The wall drift, Δ_w (positive with the wall displaced southward), was measured as the relative lateral displacement of the wall between the lateral load location and the foundation divided by the height to the lateral load. The hybrid specimen was able to sustain two fully-reversed drift cycles at Δ_w=±2.30% (i.e., the validation-level drift) followed by a greater drift cycle of =±2.95%. In comparison, the emulative wall failed after three fully-reversed drift cycles to Δ_w=±1.15%.



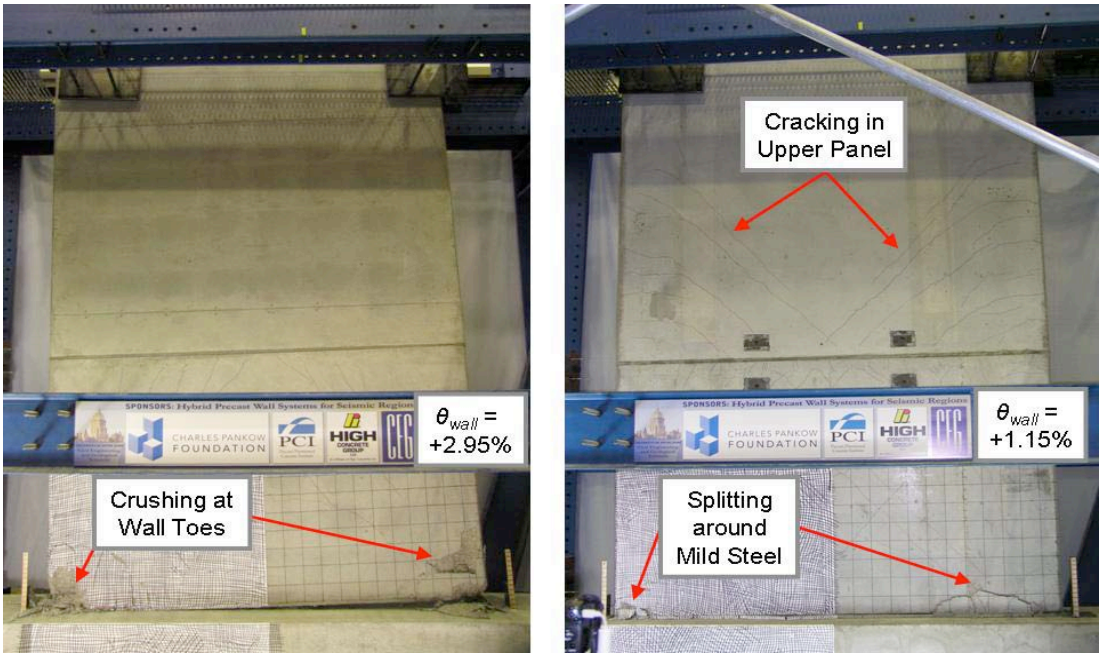


Figure 3. Drift history: (a) hybrid wall; (b) emulative wall.

Figure 4a shows the hybrid specimen at Δ_w=+2.95% (note the gap opening along the base joint at the north end). While crushing of the confined concrete was observed at the wall toes, the total strength loss at the completion of the drift history in Figure 3a was less than 20%, thus satisfying the ACI ITG-5.1 requirement for validation. Additional loading of the wall beyond the required displacement history resulted in further strength loss and subsequent failure of the specimen (defined by ACI ITG-5.1 as the drift at which the total strength loss exceeds 20%). The damage to the wall was limited to the base panel, with no concrete cracking or crushing in the upper panel and no significant gap opening or slip in the upper panel-to-panel joint.

Similarly, Figure 4b shows the emulative wall at the third cycle to Δ_w=+1.15%. While the crack widths generally remained small, the cracking was considerably more extensive than in the hybrid wall and extended high into the upper panel. Failure of the emulative specimen occurred relatively early due to the uplift of the wall from the foundation (i.e., a gap formed along the entire base joint when the wall was returned to Δ_w=0%), which resulted in excessive horizontal slip at the base together with large strength and stiffness degradation. Under load reversal with increasing slip, the concrete around the mild steel bars crossing the base joint began to deteriorate due to the shear force transfer from the bars to the surrounding concrete, eventually resulting in localized splitting of the wall panel around the bars. No significant slip or gap opening was observed in the upper panel-to-panel joint.

Figure 4. Observed damage: (a) hybrid wall at Δ_w=+2.95%; (b) emulative wall at Δ_w=+1.15%.

Lateral Load Versus Displacement Behavior. Figure 5 compares the measured base shear force, V_b versus wall drift, Δ_w behaviors for the hybrid and emulative walls. The maximum base shear resistance of the hybrid wall was 551 kN (124 kips) reached at Δ_w=+1.55%, the resistance at the validation drift (Δ_{wm} = +2.30%) was 507 kN (114 kips), and the resistance at Δ_w=+2.95% was 443 kN (99.5 kips). The specimen behaved in a reasonably symmetrical manner in the positive and negative directions, while also exhibiting excellent re-centering capability and energy dissipation. The total strength loss from the maximum base shear resistance to the peak resistance during the final drift cycle to ±2.95% was approximately 19.9% and 13.8% in the positive and negative directions, respectively, which are both within the 20% strength loss limit prescribed by ACI ITG-5.1.

The maximum base shear resistance of the emulative wall was 534 kN (120 kips) reached at Δ_w=+1.15%. Until the yielding of the mild steel bars crossing the base joint, the emulative and hybrid wall behaviors were similar (with the exception of more widespread hairline cracking in the emulative system). However, upon unloading from significant tensile yielding of the mild steel bars, the re-centering capability of the emulative wall was limited. Without the PT force, the restoring effect of the 325-kN (73-kip) tributary gravity load applied at the top of the wall and the 40-kN (9-kip) self-weight of the specimen [total 365-kN (82-kip) gravity load] was not sufficient to fully yield the bars back in compression (i.e. return to essentially zero elongation of the bars) and close the gap at the base joint. Upon reloading, the nonlinear behavior and failure of the wall was dominated by excessive horizontal slip at the base joint, with relatively small gap opening as compared to the hybrid specimen. The behavior of the emulative wall in the positive and negative directions was somewhat unsymmetrical (e.g., the maximum base shear resistance in the negative direction was only 467 kN (105 kips)], which occurred due to different amounts of slip in the two directions. The specimen failed during the third cycle to Δ_w=+1.15%, as the total strength loss from the maximum base shear resistance to the peak resistance was 32.5% in the positive direction (a smaller 11.1% total strength loss occurred in the negative direction).

(A) (B)

Figure 5. Base shear force versus wall drift history: (a) hybrid wall; (b) emulative wall.

Energy Dissipation. The primary source of energy dissipation in both wall systems is the yielding of the mild steel reinforcement over the unbonded length of the bars at the bottom joint. To quantify the energy dissipation of the structure, ACI ITG-5.1 uses the energy dissipation ratio, β, which is defined as "the ratio of the measured energy dissipated by the test module during reversing cyclic displacements between given measured drift angles to the maximum theoretical energy that can be dissipated for the same drift angles." ACI ITG-5.1 requires that β be not less than 0.125 at the validation-level drift.

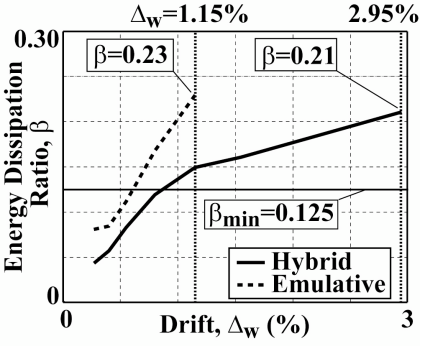

Figure 6. Energy dissipation ratio.

The solid and dashed lines in Figure 6 show the measured energy dissipation ratio, β of the hybrid and emulative walls, respectively, plotted against the wall drift. The last cycle for each drift level was used to calculate β. It can be seen that both

specimens satisfied the ACI ITG-5.1 minimum β requirement at moderate drift levels and continued to exceed the minimum requirement until the end of the test. As expected, the emulative wall demonstrated larger energy dissipation than the hybrid wall since about 41% of the base moment strength of the hybrid wall was provided by unbonded PT steel, which remained linear-elastic during most of the test.

Energy Dissipating Mild Steel Strains. Since the mild steel bars crossing the base-panel-to-foundation joint serve as the main energy dissipater for the wall system, it is essential for these bars to yield significantly but not fracture during the loading history up through the validation drift. Figure 7a shows the four mild steel bars at the base of the hybrid specimen prior to the placement of the concrete. The 38.1-cm (15-in.) long plastic-wrapped unbonded length of the bars can be seen in the photograph. The wrapping was done to reduce the steel strains and thus, prevent low-cycle fatigue fracture as the wall was displaced. Similarly, Figure 7b shows the mild steel bars at the south end of the emulative base panel. Since the reinforcement in the emulative wall was placed at the ends of the panel rather than near the centerline, larger bar elongations were expected. Therefore, a longer 55.9-cm (22-in.) unbonded length was used in the emulative wall.

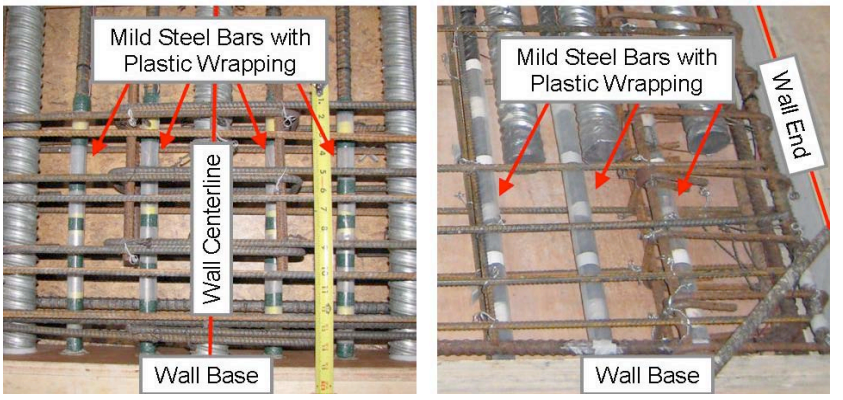

Figure 7. Mild steel bars crossing base joint: (a) hybrid wall; (b) south end of emulative wall.

Figure 8a shows the measured (using strain gauges placed within the unbonded length) and predicted [using the pre-test design procedure described in Smith et al. (2011)] strains for the south intermediate energy dissipating bar in the hybrid specimen [located 8.9 cm (3.5 in.) from the wall centerline]. For clarity, the measured bar strains are shown at the third cycle of each wall drift increment instead of the full cyclic strain history. In general, the measured and predicted strains compare favorably. Note that due to gauge failure,

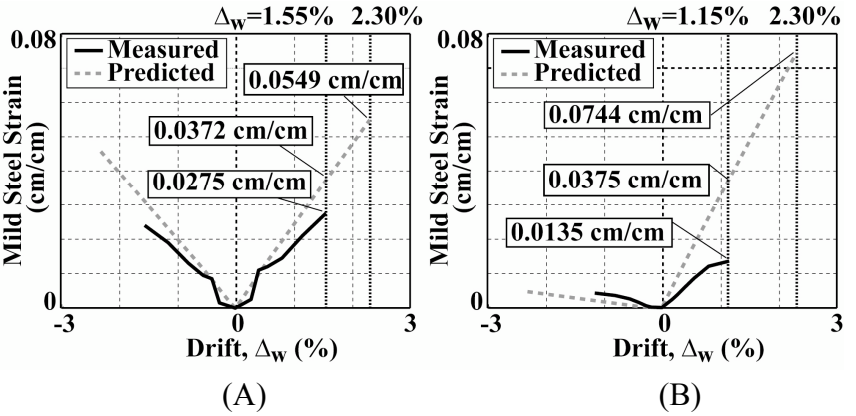

Figure 8. Mild steel strains: (a) hybrid; (b) emulative wall.

measurements could only be taken up to a maximum strain of 0.0275 cm/cm at Δ_w=+1.55%. As designed, the bars yielded (measured yield strain, ε_{sy}=0.0023 cm/cm) relatively early in the loading history and the test was completed with no undesirable behavior of the steel (i.e., no bar fracture, observable slip, or buckling).

Similarly, Figure 8b shows the mild steel strains for the south intermediate bar in the emulative wall [located 30.5 cm (12 in.) from the wall end]. Again, the bars were designed to yield relatively early in the test; however, due to the small gap opening displacements at the base of the wall, the actual axial bar strains remained relatively small. The pre-test design calculations were also based on the axial strains of the bars due to gap opening; and thus, the predictions significantly overestimated the measured strains (e.g., at the maximum drift of Δ_w=+1.15%, the measured and predicted steel strains were 0.0135 cm/cm and 0.0375 cm/cm, respectively).

PT Steel Behavior. The PT steel provides the main restoring force for the hybrid system, ensuring that the gap at the wall base is fully closed upon unloading (which requires that the mild steel bars yield back in compression) and allowing the structure to return to its initial undisplaced position after being subjected to significant lateral loading. Figure 9 depicts this restoring force by plotting the normalized average stress in each of the north and south tendons [calculated as the sum of the measured strand forces divided by $A_p f_{pu}$, where A_p is the total area of the three 1.3-cm diameter (0.5-in.) strands in each tendon and f_{pu}=1862 MPa (270 ksi) is the design strength of the strands]. The differences in the north and south tendon stresses are due to the different elongations of the two tendons as the wall was displaced laterally. Consistent with the design expectations, the PT tendons remained essentially linear-elastic until Δ_w=1.55%, which was possible since the strands were unbonded over their length. The average stresses for the north and south tendons were 0.85 and 0.65f_{pu}, respectively, at the validation-level drift of Δ_{wm}=+2.30%. Considerable stress losses can be seen in the tendons upon unloading from the Δ_w=±2.95% cycle; however, despite this loss, the residual drift of the wall at the end of the test was negligible (see Figure 5a).

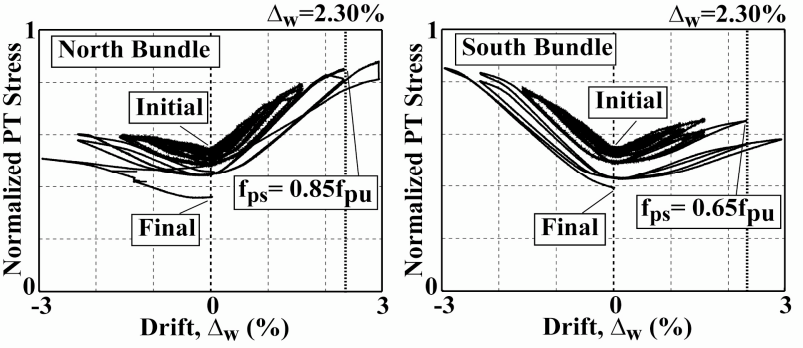

Figure 9. Average PT strand stresses: (a) north tendons; (b) south tendons.

Wall Uplift. The vertical displacement at the top of the wall, which is related to the gap opening along the horizontal joints, can be used to estimate the uplift (or axial elongation) of the test specimens. For this purpose, Figure 10 shows the residual axial elongation measured at the centerline of each wall at the location of the applied lateral load after the completion of each drift series (i.e., after unloading from the last cycle in each drift increment). The accumulation of this residual elongation (upwards

positive) represents a reduction or loss of self-centering. In the hybrid specimen, the axial elongation did not start to accumulate until the Δ_w=±1.55% drift cycles, with a maximum residual elongation of 0.25 cm (0.10 in.) upon unloading from Δ_w=±2.95%. This small amount of uplift did not affect the performance of the wall in any undesirable way. In contrast, the emulative wall accumulated significantly greater axial elongations beginning from the Δ_w=±0.27% cycles, with a maximum uplift of 0.61 cm (0.24 in.) after the last cycle to Δ_w=±1.15%.

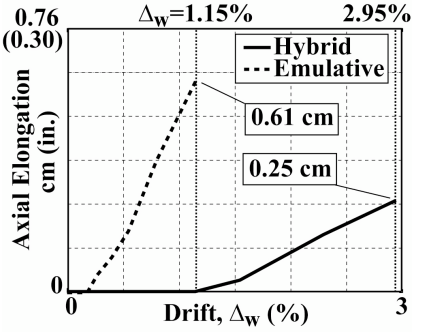

Figure 10. Wall uplift.

The large differences between the axial elongations of the two walls are related to the PT steel. In both specimens, the tensile yielding of the energy dissipating mild steel reinforcement across the base joint resulted in the plastic elongation of the bars during the loading of the wall. Upon unloading of the hybrid specimen, the restoring force provided by the PT steel and the total gravity load [365 kN (82 kips)] caused the mild steel to yield in compression and return to essentially zero elongation, thus fully closing the gap at the base joint. The accumulation of residual axial elongations, which did not start until the Δ_w=±1.55% cycles, coincided with the accumulation of PT stress losses (see Figure 9). In the case of the emulative specimen, once the mild steel bars yielded in tension, the gravity load alone was not large enough to return the bars to the zero elongation state. Over successive loading/unloading cycles with increasing wall drift, the residual tensile deformations in the bars resulted in the complete uplift of the wall (i.e., gap over the entire length of the base joint), overcoming the downward force from the gravity load. As shown in Figure 10, the axial elongation of the emulative specimen accumulated rapidly, ultimately leading to the failure of the structure due to excessive horizontal slip with large strength and stiffness degradation.

Horizontal Slip at Wall Base. By measuring the relative horizontal displacements between adjacent points on either side of the base-panel-to-foundation joint, the horizontal slip at the wall base was determined. The solid lines in Figure 11 show the measured horizontal slip at the centerline of the hybrid wall for loading in the positive and negative directions during the third cycle in each drift series [except for the final drift series where the first cycle (Δ_w=±2.30%) and the third cycle (Δ_w=±2.95%) slips are plotted]. The slip at the base was small [with a maximum slip of about 0.31 cm (0.12 in.) at Δ_w=–2.95%] and did not negatively affect the performance of the wall. Moreover, the crushing of the concrete at the wall toes did not result in a disproportionate accumulation of slip. No slip was observed at the upper panel-to-panel joint of the wall.

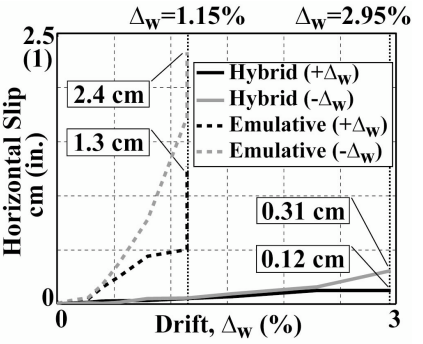

Figure 11. Shear slip at base.

For the emulative specimen (dashed lines in Figure 11), the measured slip at the base joint was much larger, with a maximum value of 2.4 cm (0.93 in.) at the

third cycle of Δ_w=–1.15% [again, the plot shows slip measurements for the third cycle in each drift series, except for the last drift series (Δ_w=±1.15%) where the first and third cycle slips are plotted]. The amount of slip was considerably greater in the negative loading direction. The slip displacements accumulated rapidly beginning from the Δ_w=±0.27% cycles when, as shown in Figure 10, the accumulation of wall uplift also initiated. Upon reloading from a configuration with complete uplift at the base, the mild steel bars were the only components transferring shear forces from the wall into the foundation until the lateral displacement was large enough to close the gap at the compression toe of the wall. The concrete around the mild steel bars began to deteriorate due to this shear force transfer, eventually resulting in the localized splitting of the base panel around the bars (see Figure 4).

At the point when slip at the base joint started to rapidly accumulate in the emulative specimen (i.e., at the first loading of the wall to Δ_w=+0.27%), an estimate of the coefficient of shear friction can be made by dividing the measured base shear force [374 kN (84 kips)] with the compression force transferred through the contact region [comprised of the measured total gravity load, 365 kN (82 kips) and the total force in the tensile mild steel bars, 552 kN (124 kips), where the mild steel stresses were determined using the measured strains and the measured monotonic stress-strain relationship for the bars]. The resulting coefficient of shear friction is equal to 0.41, which is considerably smaller than the value of 0.50 recommended by ACI ITG-5.2 for the base-panel-to-foundation joint. Note that ACI ITG-5.2 also recommends a friction coefficient of 0.60 for the upper panel-to-panel joint; however, an estimate for this coefficient could not be made from the tests since no significant slip was observed at the upper joint of the walls.

SUMMARY AND CONCLUSIONS

This paper compares the measured lateral load behavior of a 0.4-scale hybrid precast concrete shear wall specimen with the behavior of an emulative precast wall. The results demonstrate the tremendous potential for the use of the hybrid wall system as special reinforced concrete shear walls in high seismic regions, while also revealing the potential limitations of the emulative system tested in this research. Based on the measured and observed results, the following conclusions were made:

- The hybrid wall specimen demonstrated full re-centering capability while also providing large energy dissipation due to the combination of unbonded post-tensioning steel with yielding mild steel reinforcement across the base-panel-to-foundation joint.
- The behavior of the hybrid wall was consistent with the design predictions.
- The damage in the hybrid specimen was limited to the base panel.
- The hybrid specimen sustained three fully-reversed drift cycles of magnitude equal to or greater than the validation-level drift prescribed by ACI ITG-5.1.
- While the emulative wall specimen demonstrated excellent energy dissipation from the yielding of the mild steel reinforcement across the base joint, the lack of post-tensioning steel resulted in unsatisfactory re-centering capability.

- Insufficient restoring force allowed the emulative specimen to develop a residual gap along the entire length of the base joint, causing excessive horizontal slip at the base.
- The excessive horizontal slip caused large strength and stiffness degradation of the emulative wall, and ultimately led to the failure of the specimen at a relatively small drift.

ABSTRACT

Ground motion selection and scaling comprises undoubtedly the most important component of any seismic risk assessment study that involves time-history analysis. Ironically, this is also the single parameter with the least guidance provided in current building codes, resulting in the use of mostly subjective choices in design. The relevant research to date has been primarily on single-degree-of-freedom systems, with only a few studies using multi-degree-of-freedom systems. Furthermore, the previous research is based solely on numerical simulations with no experimental data available for the validation of the results. By contrast, the research effort described in this paper focuses on an experimental evaluation of selected ground motion scaling methods based on small-scale shake-table experiments of re-configurable linear-elastic and nonlinear multi-story building frame structure models. Ultimately, the experimental results will lead to the development of guidelines and procedures to achieve reliable demand estimates from nonlinear response history analysis in seismic design. In this paper, an overview of this research effort is discussed and preliminary results based on linear-elastic dynamic response are presented.

INTRODUCTION

As performance-based considerations become pre-requisite in the seismic design and evaluation of building structures, the use of nonlinear response history analysis (RHA) has gained utmost importance (e.g., for tall or irregular structures, structures with innovative structural systems and materials, and/or structures on soft soil). This rigorous analysis method requires, as input, a suite of ground motion records that have been selected and modified (i.e., scaled) appropriately to make them compatible with the site-specific hazard level(s) considered [e.g., Maximum Considered Earthquake (MCE) level, Design Basis Earthquake (DBE) level]. Ground motion selection and scaling has a large impact on the nonlinear RHA results. In fact, the ground motion record itself is undeniably the most important variable for nonlinear RHA (more than the analytical model parameters) governing the outcome and amount of uncertainty from seismic design.

Ironically, this is also the single parameter with the least guidance provided in current building codes and provisions, resulting in the use of mostly subjective choices in the selection of ground motions for nonlinear RHA.

Most of the research to date on ground motion scaling has been on single-degree-of-freedom systems (Chopra and Chinatanapakdee 2004; Martinez-Rueda 1998) with only a few studies on multi-degree-of-freedom systems (Kalkan and Chopra 2010, 2011; Kalkan and Kwong 2011; Alavi and Krawinkler 2000; Kurama and Farrow 2003; Shome and Cornell 1998). Furthermore, the previous research is based solely on numerical simulations, with no experimental data available for the validation of the results. Consequently, there is currently no consensus on which scaling methods would be best suited to achieve reliable median demand estimates over a wide range of structural properties, seismic hazard conditions, and hazard levels. Considering these issues, the research effort described in this paper is conducting a large number of small-scale shake-table experiments of re-configurable linear-elastic and nonlinear multi-story building frame structures using an exhaustive set of ground motion records. These shake-table tests will form the first experimental study on dynamic response considering a wide range of building properties, lateral strengths, and ground motion records. Ultimately, the results will not only provide the experimental evidence needed to evaluate different ground motion scaling methods, but will also investigate how different site parameters and structure characteristics affect the accuracy and efficiency of the scaling methods. After briefly discussing the current practices and challenges related to ground motion scaling, this paper summarizes the ongoing experimental research effort. Preliminary evaluation results for ground motion scaling are presented based on a linear-elastic test structure.

CURRENT PRACTICE AND CHALLENGES

Procedures for selecting and scaling ground motion records for a site-specific seismic hazard are broadly described in building codes and have been the subject of considerable research in recent years. The ground motion selection and scaling procedures in IBC (ICBO 2006) and CBC (ICBO 2007) are based on ASCE 7-05 (ASCE 2006). According to ASCE 7-05, the average 5%-damped linear-elastic acceleration response spectrum for a set of scaled records should not be less than the design spectrum over the period range from $0.2T_1$ to $1.5T_1$, where T_1 is the fundamental vibration period of the structure being designed. The design value of an engineering demand parameter (EDP) — member deformations, lateral drifts, floor accelerations, etc. — is taken as the average value of the EDP if seven or more records are used in the analysis, or its maximum value over all ground motions if the structure is analyzed for less than seven records (ASCE 7-05 requires a minimum of 3 records). These requirements for ground motion scaling are the same as those in the recently released ASCE 7-10 (ASCE 2010).

To demonstrate the challenges for the reliable use of nonlinear RHA in current practice, Figure 1 shows the estimated peak inter-story drift demands (Morgen and Kurama 2008) for a six-story reinforced concrete frame structure subjected to 10 pairs of "far-fault" MCE ground motion records satisfying the ASCE 7-05 scaling requirement. The drift demands from the 10 pairs of records range from a minimum of slightly less than 1% to a maximum of almost 5%. It is clear that if

only the peak demand from 3 records were used in design, as allowed by ASCE 7-05, then the design outcome (i.e., over-design, under-design, satisfactory) can be drastically altered depending on the records selected. Note that the demands in Figure 1 seem to be highly correlated with the ground motion maximum incremental velocity, MIV (Kurama and Farrow 2003), plotted on the x-axis.

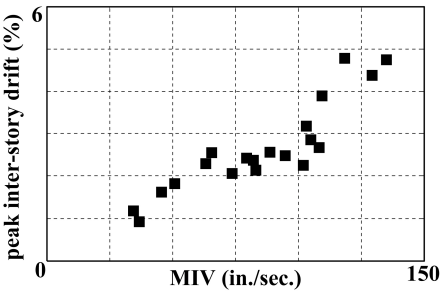

Figure 1. Peak drift demands.

GROUND MOTION SELECTION

Due to lack of specific guidelines, practitioners often select ground motion records based solely on distance, site conditions, and magnitude of the characteristic event expected to dominate the seismic hazard. However, many other factors, such as directivity of the rupture and/or basin effects contribute to the intensity and frequency content of a ground motion at a site. For example, as described in Kalkan and Kunnath (2006, 2008), "forward directivity" (with double-sided pulse) and "fling-step" (with single-sided pulse) motions with long-period, large-amplitude pulses may impose large displacement demands that require the structure to dissipate considerable energy in a single or relatively few cycles.

For the selection of the ground motions in this study, a set of criteria and identification algorithms were set to distinguish earthquake records based on their characteristic attributes associated with source, directivity, site, and/or basin effects (e.g., cyclic versus impulsive records; records with high, mid, or low frequency content; short or long duration records). Basin, duration, and pulse attributes of the records were investigated by frequency domain analyses; whereas, directivity and fling attributes were identified from the orientation of accelerometers relative to the rupture propagation plane. These attributes were then used to categorize a large library of records (PEER Next Generation Attenuation Project Ground Motions database) to facilitate the selection of the most suitable ground motions for different site-specific hazard conditions. Based on this refinement and pre-selection process, a suite of 38 representative near-fault motions (recorded within 20 km of the fault rupture) from a variety of tectonic environments were compiled for the purposes of this research as shown in Table 1.

EXPERIMENTAL STRUCTURE CONFIGURATION

The frame structure selected for the experimental investigation corresponds to a six-story building. As shown in Figure 2(a), the test frame consists of a single bay with center-to-center span length of 30 in. and story height of 17 in. These dimensions, determined based on the size limitations of the shake table, correspond to a building length-scale of, approximately, S_L=1/10. The chosen time scale is S_T=1/3. Two steel plates with total weight of 92.6 lb were securely attached to the midspan of each floor beam, and one plate with weight of 46.3 lb was attached to the midspan of the roof beam.

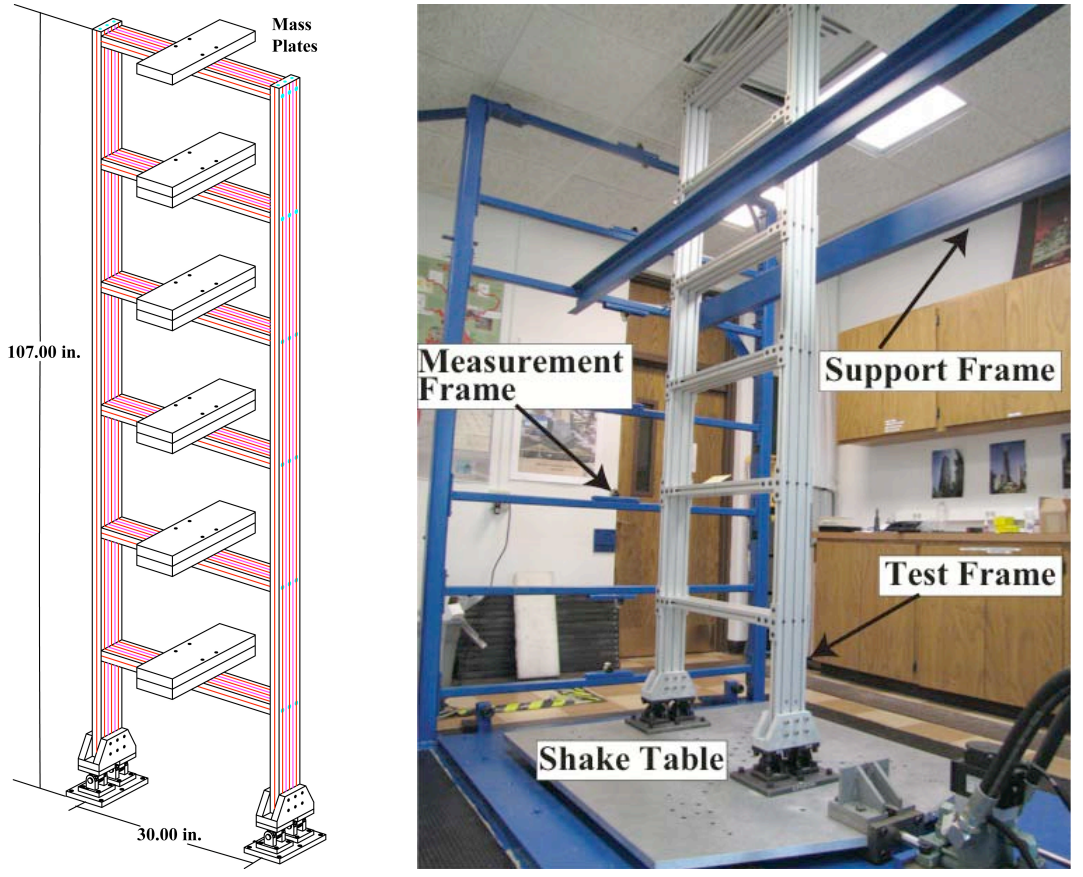
The tests were conducted on a medium-size uniaxial earthquake simulator at the University of Notre Dame that consists of a hydraulic actuator/servo-valve assembly and a hydraulic power supply that drive a 4 ft by 4 ft slip table. Figure 2(b) depicts the test frame placed on the shake table, together with the measurement and out-of-plane bracing frames mounted onto the laboratory floor. The test frame was fabricated from extruded aluminum 6105-T5 alloy with a yield strength of 35 ksi. The beam and column member cross-sections were determined to result in strength and

stiffness appropriate with the scale model. The extruded aluminum cross-section in Figure 3(a), oriented in the weak direction (with moment of inertia, I=0.7097 in.^{4} and area, A=3.00 in^2) was used for all beam and column members.



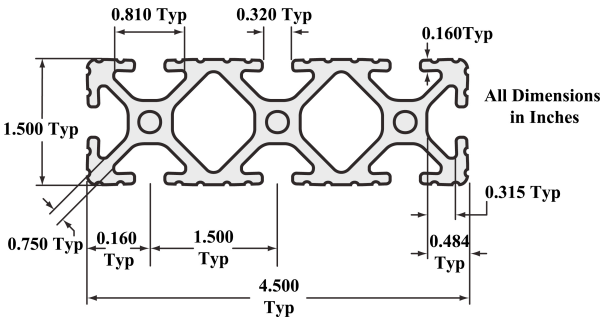


Figure 2. Six-story test frame: (a) schematic; (b) test setup.

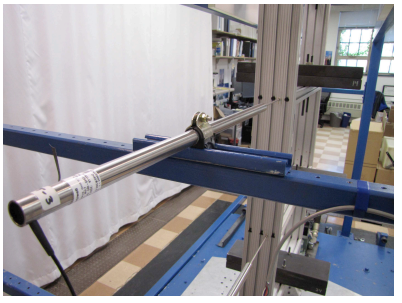
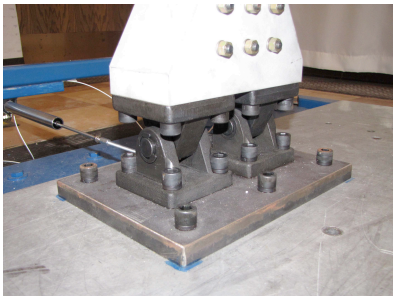


The shake table used in the experimental program can achieve a maximum acceleration of ±4 g with a 1000 lb test load at a nominal operational frequency range of 0-50 Hz. The data acquisition system is capable of recording the table displacements as well as the displacements and accelerations at each floor and roof level of the specimen. The data was collected at a high sampling rate, resulting in close-to-simultaneous excitation and response measurements. The displacements of the structure were measured using seven free unguided LVDTs (six at the floor and roof levels and one at the base) anchored between the test frame and an isolated measurement frame. An example of a mounted LVDT can be seen in Figure 3(b). The clamps used to attach the LVDTs to the measurement frame were engineered to mitigate vibrations.

The column bases were designed and constructed with pinned connections to increase the flexibility of the structure. Figure 3(c) depicts a close-up view of the pinned base connection. Each connection consists of a steel plate bolted to the shake table top, two steel clevises bolted to the plate, and two steel eye brackets inserted into the clevises and bolted to an aluminum fixture at the column base. A tight



tolerance greased steel pin was used through the eye bracket-to-clevis connection to reduce friction while eliminating backlash effects. To achieve a modular structure, each beam-column connection was constructed using three high-strength bolts passing through the column and screwing into holes tapped into the beam cross section at each end.

(b)

(c)

Figure 3. Test details: (a) extrusion profile for beam and column members (courtesy 80/20® Inc.); (b) LVDT mounted to frame; (c) pinned connection at column base.

A nonlinear beam-to-column connection is also being constructed as part of this project to allow for the future testing of nonlinear structures with different levels of lateral strength (corresponding to different response modification factors, *R*). As an important feature, the nonlinear connection will also be reconfigurable and reusable, so as to allow for the repeated testing of structures with different lateral strengths under a series of ground motion records. The design of the connection incorporates a friction-fuse concept previously investigated at the University of Notre Dame (Morgen and Kurama 2004). As shown in Figure 4, each beam-to-column connection consists of two components creating 10 rotational friction interfaces in between.

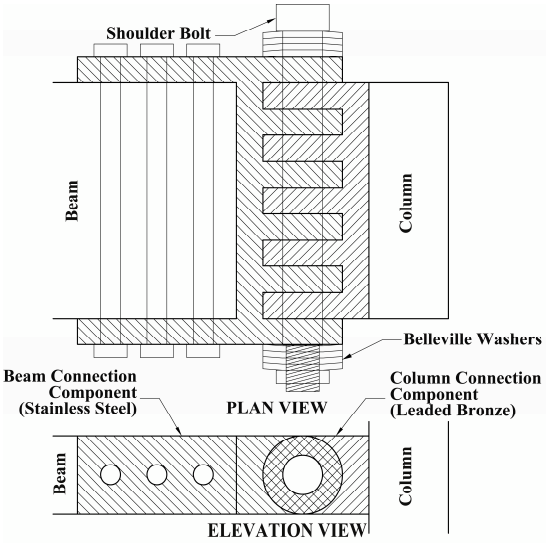

Figure 4. Nonlinear connection.

The nonlinear beam-to-column connection component bolted to the beam end will be fabricated out of stainless steel and the component bolted to the column will be lead-bronze (brass). The use of this alloy at the friction interfaces is desirable because the material continually "self-lubricates" when rubbing against an adjacent metal surface, which helps to reduce the phenomenon of stick-slip and results in a consistent value for the coefficient of friction that is relatively independent of velocity (a desirable characteristic for design and performance). The

friction force can be controlled by the normal force, F_n applied on the interfaces. In the nonlinear beam-to-column connection, this will be achieved using a single high-strength shoulder bolt (see Figure 4) running through the 10 friction interfaces. The prototype connection was designed to produce a total maximum slip moment of about 35 kip-in. at the maximum normal force level. This slip moment was designed to be greater than the yield moment of the aluminum beam cross-section, and thus, it will be used to simulate a linear-elastic structure (R=1). As the normal force is decreased, the connection is allowed to slip at a smaller moment, simulating structures with lower lateral strengths (i.e., R>1) and nonlinear hysteretic response. Belleville washers will be used to maintain a consistent level of normal force across the friction interfaces during each test. After each test, the bolt through each connection will be loosened, the structure will be brought back to plumb, and the connection bolts will be re-tightened to the desired level. A combination of steel shims and Belleville washers will be used to consistently achieve the desired bolt force in each test. Prior to the use of the connections in multi-story frame testing, isolated beam-column subassemblies will be subjected to static and dynamic loads to characterize the nonlinear connection and calibrate the bolt tightening operation as well as the number/arrangement of the shims and Belleville washers to result in the target slip moment levels. This will ensure that the desired connection performance can be achieved with relative certainty and repeatability during the multi-story frame tests.

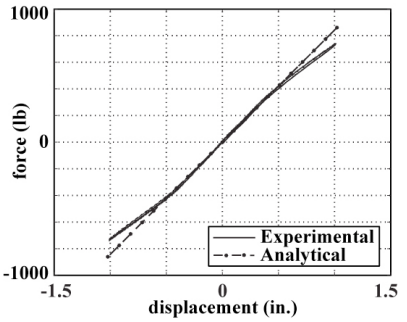
STATIC BEHAVIOR OF LINEAR-ELASTIC STRUCTURE

To investigate the stiffness characteristics of the linear test structure, monotonic and cyclic pushover experiments were conducted by holding the 4th floor of the frame stationary while displacing the base laterally using the shake table. At the 4th floor level, a steel rod with pin-ended connections (Figure 5) was placed between the test frame and a relatively stiff steel loading frame. As the base of the structure was displaced, the resulting 4th floor force in the pin-ended rod was measured using an intermediary load cell. Two string pot transducers were used to measure the absolute lateral displacements at the base and 4th floor level of the structure (note that the 4th floor displacements were very small but not zero due to the deformations of the loading frame).

Figure 5. Pin-ended rod and load cell assembly.

The 4th floor lateral force versus relative (with respect to base) 4th floor displacement results for the frame during two cycles of loading are shown using the thin black lines in Figure 6. The structure exhibited consistent and repeatable behavior in both the positive and negative loading directions; however, the onset of nonlinear behavior was observed at a relatively small load (about 500 lbs). It was found that the nonlinear behavior occurred as the beam ends lost full contact with the columns due to the stretching of the beam-column connection bolts. The flexibility of the connection bolts also reduced the initial lateral stiffness of the frame (i.e., the beam-to-column connections were not rigid as originally assumed).

Analytical models of the linear-elastic test structure were developed using the OpenSees and DRAIN-2DX programs. The flexibility of the beam-column connections (due to the flexibility of the connection bolts) was modeled by placing linear-elastic zero-length rotational springs at the beam ends. The stiffness of the rotational springs was determined by calibrating the model results (thick gray line) with the linear-elastic range of the measured behavior as shown in Figure 6.



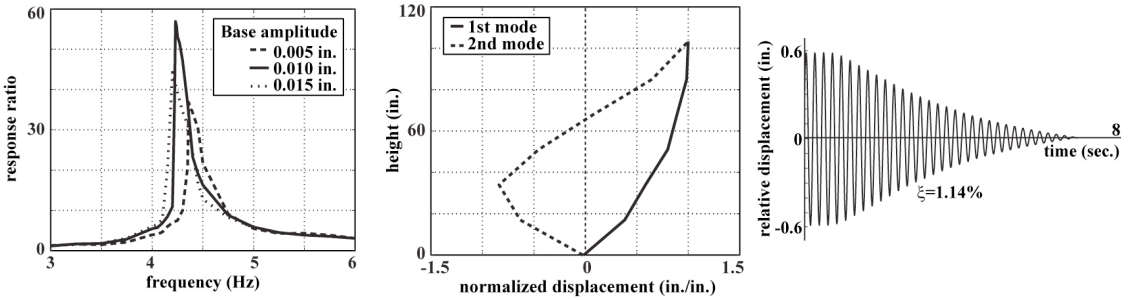


Figure 6. Measured and analytical static behaviors.

Once the nonlinear connection in Figure 4 is constructed and characterized, the hysteretic behavior of frames utilizing these connections will be determined. The analytical modeling of these frames will also utilize zero-length spring elements at the beam ends, but, unlike the linear-elastic frame, these spring elements will have nonlinear hysteretic behavior. The properties of the springs will be determined by calibrating the analytical results with the measured cyclic behavior of the frame, thus providing a full range of prediction tools.

DYNAMIC BEHAVIOR AND IDENTIFICATION

The dynamic characteristics of the linear-elastic structure were investigated by subjecting the frame to a series of sine sweep experiments. The results from three series of sine sweep tests with base excitation amplitudes ranging from 0.005 in. to 0.015 in. can be seen in Figure 7(a), where the y-axis shows the ratio of the relative roof displacement amplitude to the base excitation amplitude and the x-axis shows the frequency of the sine wave exciting the structure. While there is some amplitude dependency, it can be seen that the fundamental frequency of the structure is around f_1=4.35 Hz, (corresponding to a period of T_1=0.23 s), which was found to match very well with the analytical prediction. With the selected time scale of S_T=1/3, the test specimen corresponds to a full-scale structure with a fundamental period of about T_1=0.69 s. The second mode of vibration of the structure was measured to occur at around f_2=16.1 Hz, also with an excellent match with the analytical prediction. The measured mode shapes for the first two modes of vibration can be seen in Figure 7(b). Using the log decrement method on the decay of the measured displacement response at the roof, the damping ratio of the frame was determined as ξ=1.14%. The time-history of the roof displacement used in this calculation can be seen in Figure 7(c).

(a) **(b)** **(c)**

Figure 7. Dynamic behavior: (a) resonance peaks; (b) first and second mode shapes; (c) decay of roof displacement response.

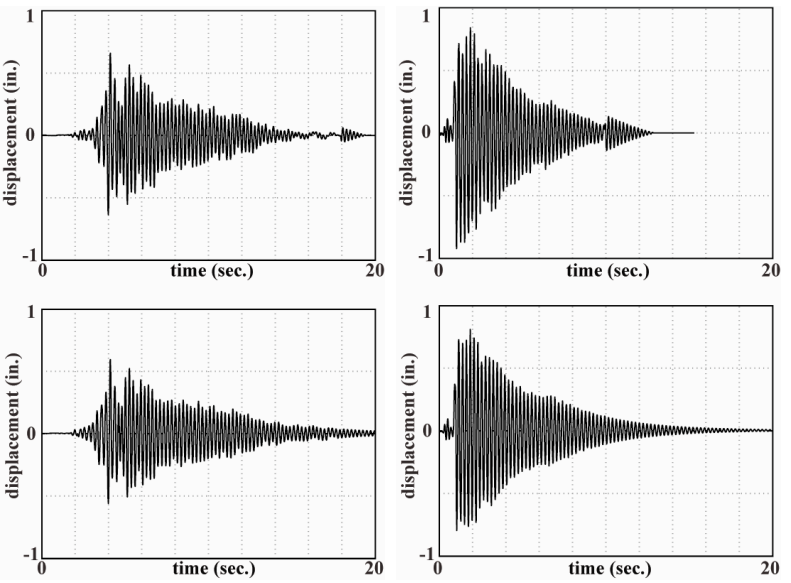

Figure 8. Measured (top) and estimated (bottom) roof displacement responses: (a) AMA090; (b) CPM000.

A subset of earthquake ground motion records was selected and the measured dynamic response of the structure was compared with the estimated response from the OpenSees analytical model as another method of model calibration. Estimated versus measured roof displacement response comparisons from the AMA090 and CPM000 ground motion records can be seen in Figures 8(a) and Figure 8(b), respectively. Once the accuracy of the model was improved and deemed sufficient, the analytical model was subjected to the full suite of 38 ground motion records from Table 1 to guide the shake table tests described in the next section.

GROUND MOTION SCALING FOR LINEAR-ELASTIC RESPONSE

With the characteristics of the linear-elastic structure fully understood and the expected displacement demands from each ground motion estimated by the calibrated analytical model, the test specimen was subjected to five series of shake table tests using 37 ground motions from Table 1 (KJM000 was not used in the experiments due to excessive displacement demands indicated from the pre-test analysis of the structure under this record). The first series of tests subjected the specimen to the unscaled ground motions at full intensity. The second series was conducted with the ground motions scaled to the median linear-elastic single-degree-of-freedom spectral acceleration at the fundamental period of the structure [$\widehat{S_a}(T_1)$]. The effects of uncertainties in structural period estimation (i.e., inaccuracies in period estimation that could be expected in typical design practice) were investigated in the third and fourth test series. For this collection of tests, the ground motion suites were scaled to the median spectral acceleration at $1.3T_1$ and $0.7T_1$ [i.e., $\widehat{S_a}(1.3T_1)$] and $\widehat{S_a}(0.7T_1)$, respectively], representing a 30% error in period estimation. Finally, the fifth series of tests subjected the structure to ground motions scaled to the median maximum incremental velocity ($\widehat{MIV}$) of the suite.

The peak roof displacement demands from the five series of experiments are plotted in Figure 9 and listed in Table 2. It can be seen that the unscaled peak displacement demands are not as strongly correlated to MIV as compared to the correlation with $S_a(T_1)$. As can be expected for a linear-elastic structure, the $\widehat{S_a}(T_1)$

scaling method produced the smallest dispersion in the peak roof displacements. However, the dispersion more than doubled with a 30% error in period estimation, with values similar to the dispersion from the MIV-scaled suite. These results are important in showing that inaccuracies in the estimation of a structure's anticipated period can lead to a much larger dispersion in the seismic demand estimates when compared with the dispersion achieved with the records scaled based on the "exact" period. The remainder of this project will investigate the effects of nonlinear structural response on these findings, including additional scaling methods in the investigation as well.

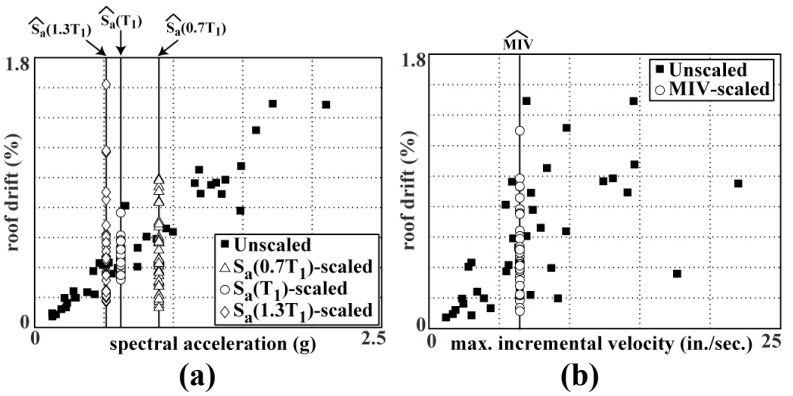

Figure 9. Peak roof displacement demands: (a) plotted against $S_a(T_1)$; (b) plotted against MIV.

SUMMARY AND CONCLUSIONS

This paper describes an ongoing research effort for a novel experimental evaluation of ground motion scaling methodologies for use in nonlinear response history analysis of building structures. The general experimental setup and the features of a 1/10-scale six-storey linear-elastic test frame structure are presented, along with identification results for the static and dynamic properties of the structure. Current efforts for extending the test structure to simulate nonlinear response, reconfigurable to different response modification factors, are also discussed. The test results from the linear-elastic structure stress the potential vulnerabilities of scaling methods that are based on knowledge of the exact properties of the structure. The future extension of this investigation to nonlinear dynamic response, considering a wide range of building properties, lateral strengths, and ground motion records, will ultimately provide guidelines and procedures for appropriate selection and scaling of ground motions for structural engineering practice.

Abstract

Steel concentric braced frames (CBFs) are widely used as systems to resist lateral loads induced from wind and seismic loading. Recent research on full-scale CBF subassemblages has shown that current design provisions fall short of the design intent. Additionally, the effect of imposed out-of-plane deformation on the system has never been evaluated experimentally in this manner. This paper describes the design, test setup and experimental results of two tests performed on a two-story, one-bay by one-bay CBFs, an HSS buckling-brace system in a single-story X-configuration, and a buckling-restrained braced frame (BRBF) in a single-diagonal configuration. The design of the gusset plates for the HSS braces followed a balanced design procedure with an elliptical clearance to permit out-of-plane rotation due to brace buckling. The HSS braces fractured at 2% story drift. The BRBF gusset plate design followed current design standards with the BRB cores fracturing at 3.5% story drift prior to any instabilities.

Introduction

Concentric braced frames (CBFs) are widely used as systems to resist lateral loads induced from seismic loading. In high seismic regions, special concentric braced frames (SCBFs) are used. Recent research on full-scale CBF subassemblages has shown that current design provisions fall short of the design intent (Chen et al. 2004, Mahin et al. 2004). Subsequent research has evaluated improvements to the connection design (Yoo et al. 2008). The results have been used to develop a design methodology to balance the multiple yield mechanisms of the frame, most importantly the brace and the gusset plate, to maximize the drift capacity. The process further evaluates all potential failure modes to ensure the desired mechanism occurs and all others are suppressed. This research has resulted in more rational design and detailing rules for SCBFs.

Prior tests performed on braced frames were planar, single and multi-story specimens. The current paper focuses on the full, three-dimensional response of a two-story, one-

bay by one-bay large-scale CBF structure that was tested using the MAST laboratory at the University of Minnesota as part of the NSF-funded project entitled "International Hybrid Simulation of Tomorrow's Braced Frame Systems" through the NEES research program. The test specimen simulated the corner bay of a two-story building system braced in two orthogonal directions. The first test used conventional HSS diagonal braces in a single-story X-configuration in each story. The second test used buckling restrained braces (BRBs) in a single diagonal configuration.

The objectives of the test were: (1) to examine the large-displacement, bi-directional behavior of CBFs and BRBFs, (2) to examine the applicability of the latest design and detailing rules for these systems, (3) to examine the behavior of columns shared by two orthogonal braces, (4) to examine the effect of gusset plates framing into the column web, and (5) to examine the effect of composite concrete slabs on the behavior of CBFs and BRBFs.

Experimental Program

Specimen Description

Two specimens were tested in this research program. Both were nearly full-scale, one-bay by one-bay, two-story frames with braces in two orthogonal bays and framing into a "shared" column. Buckling HSS braces were used in the first test while the second test used BRBs. Fig. 1(a) and 1(b) show the second and third floor plan, respectively, of both test specimens. The braced frames occur along grid lines A and 1 as indicated by the dashed lines near the girders. Note that column A-1 is the "shared" column as the two orthogonal braced bents frame into this column. The second floor deck consists of 2 in. ribbed metal deck topped by 3.25 in. of normal weight concrete for a total depth of 5.25 inches as in typical steel buildings. The third floor slab will be used to transfer the load from the loading beam into the test specimen and as such, required a 10 in. concrete slab.

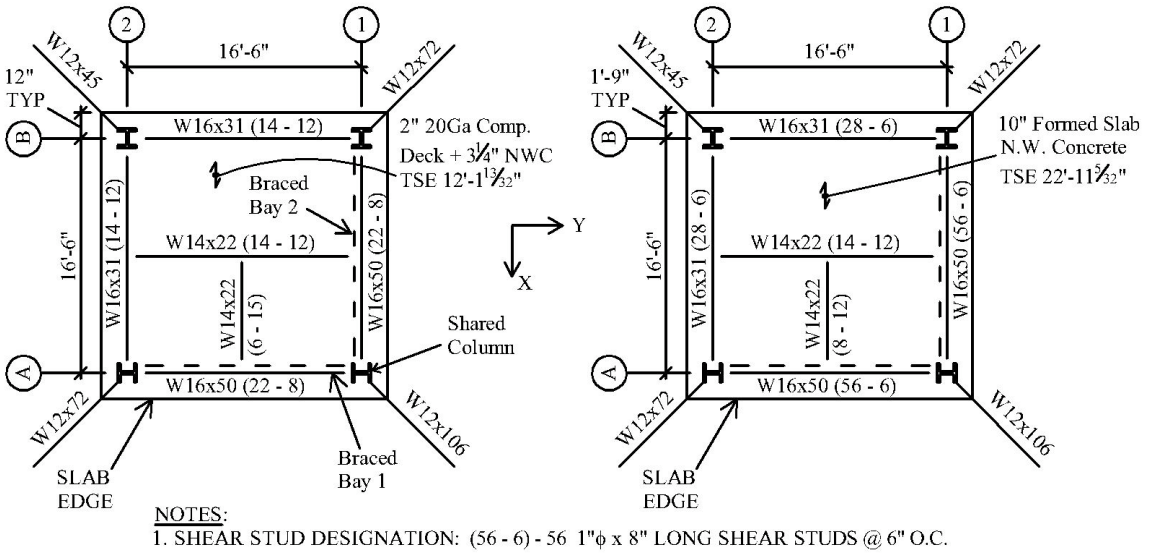

Figure 1. Test specimen floor plans: (a) second floor; (b) third floor plan

The braced frame elevations for the buckling brace frame and the BRBF are shown in Fig. 2(a) and 2(b), respectively. The beam connections in each braced bay are welded flange – welded web (WFWW) connections with demand-critical welds, while those in the other two bays are simple shear connections. The buckling braces were A500B HSS3x3x1/4 while the BRB cores were 46 ksi steel with a design maximum adjusted brace force of 220 kips at 3% story drift. A photo of the test setup showing the strongwalls, crosshead and the first specimen is shown in Fig. 3.

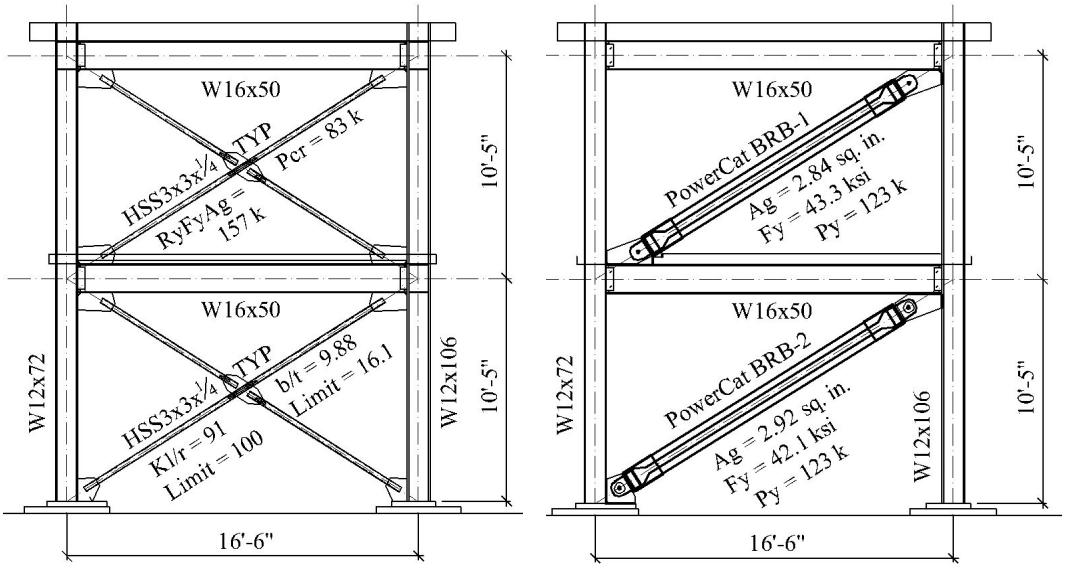

Figure 2. Braced Frame Elevations (a) HSS buckling brace frame; (b) BRBF

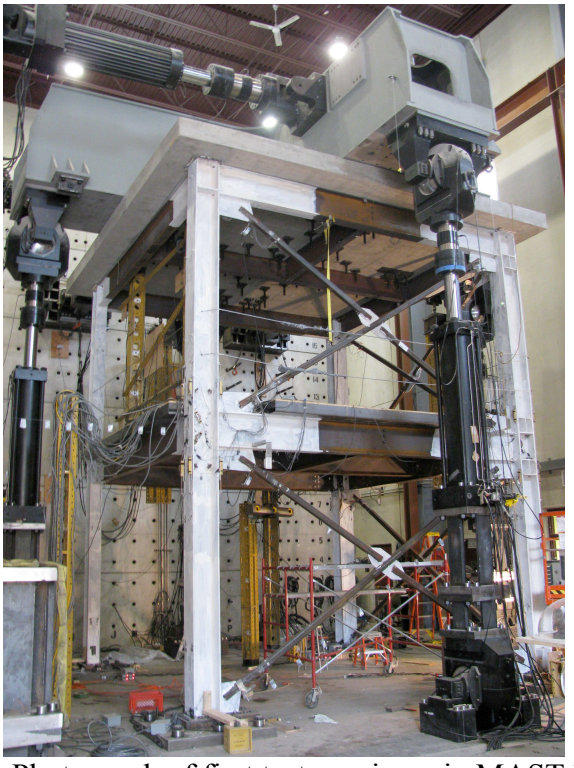

Figure 3. Photograph of first test specimen in MAST lab setup

Specimen Design

The sizes of the HSS buckling braces and BRBs in the test specimen were determined based on the capacity of the MAST lab strongfloor and force actuator system while ensuring that sizes which are typical of current construction could be used. The size of the braces chosen is typical of the upper stories in a mid to high-rise building or the lower stories of a low-rise building. The design of the test frame members followed current design practice based on the AISC Seismic Provisions (AISC 2005b), ASCE 7 (ASCE 2005), and a procedure shown by Lopez and Sabelli (2004). The beams and columns were designed to resist the maximum expected BRB force at $2.0\Delta_{bm}$, where Δ_{bm} is the brace axial deformation corresponding to the design story drift, in combination with the gravity load using the applicable load combinations. The frame beams and columns conform to the strong-column weak-beam philosophy. The demand on the shared column was found assuming 100% of the brace and beam capacities were realized in one direction while 30% of the capacities of these elements were realized in the orthogonal direction.

Gusset Plate Design

HSS Buckling Brace Test Specimen

Current seismic design rules (AISC 2005) require the bracing connection to develop the strength of the brace while accommodating the rotation associated with out-of-plane brace buckling. As shown in Fig. 4(a), accommodation of the rotational capacity is generally accomplished through a linear clearance model, whereby the brace is terminated a distance $2t_p$ before the line of restraint, where t_p is the thickness of the gusset plate. This requirement can result in large buckling lengths of the gusset plate, and consequently, lead to heavy and overly stiff connections that have a detrimental effect on the behavior of the system (Roeder and Lehman 2009).

Based on tests at the University of Washington (UW) of over 30 one-bay, one-story planar CBFs, a new clearance model has been developed that when combined with the proposed balanced design procedure (Roeder et. al. 2005), results in thinner and smaller gusset plates. These thinner gusset plates have been shown to reliably accommodate large out-of-plane gusset rotations at the brace ends and sustain the tensile strength of the brace. This clearance model, called the elliptical clearance model, is shown in Fig. 4(b). A clearance of $8t_p$ has been shown to be the most efficient.

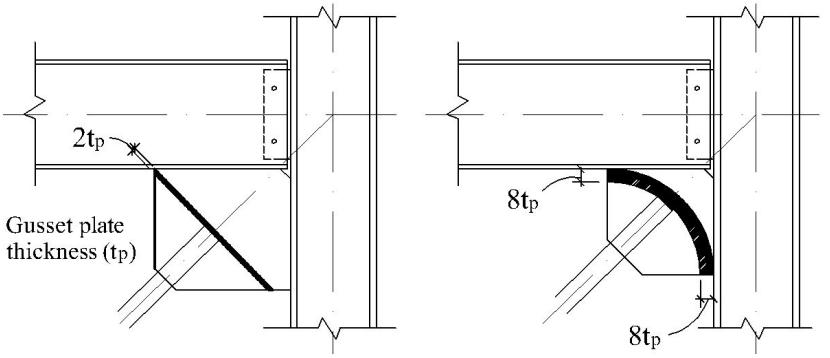

Figure 4. Current and proposed clearance models: (a) AISC $2t_p$ clearance and (b) $8t_p$ elliptical clearance model

The balance factors in the balanced design method are used in a similar manner to the AISC resistance factors except that they are used to achieve ductility and inelastic deformation capacity rather than strength. Smaller balance factors indicate that the exceedance of the considered limit state would cause significant deterioration of strength, stiffness and ductility, and/or that the capacity prediction is less reliable.

Note that the welds connecting the gusset plate to the beams and columns are sized to resist the strength of the gusset plate and not the forces that result from application of the Uniform Force Method (UFM). The buckling lengths of the gusset plates were computed as the average centroidal length and the two lengths at the extreme points of the Whitmore width. An effective length factor, *K*, of 0.65 was used.

Buckling-Restrained Braced Frame

Because BRBs are generally not expected to deform out-of-plane, the clearance model for CBFs does not apply to BRBFs. Given that much less research has been performed on gusset plates for this system, it was decided that the gusset plates in the BRBF specimen would be designed according to the current standards using the uniform force method and the limit states outlined in AISC (2005a) instead of the balanced design approach.

Loading Protocol

Cyclic displacements were applied in each horizontal direction at the top floor while rotation of the crosshead about the vertical axis was maintained at zero to prevent torsional deformation from occurring. Free rotation about both horizontal axes was permitted. To limit the differences between the uni-directional tests performed at UW and those performed here, the same uni-directional displacement histories was used in the current tests that were used in the tests at UW.

The determination of the bi-directional qualities of the bi-directional loading protocol was facilitated by nonlinear time-history analyses of prototype braced frame buildings. Three and 6-story single diagonal BRBF buildings were designed and simultaneously subjected to the X and Y-component of 10 ground motions from the SAC program.

Using rainflow cycle counting, the ratio of the frame damage (cumulative plastic deformation) in X and Y was found for each case and a ratio of 1.5 was chosen. The final displacement-controlled protocol is shown in Figure 5.

Experimental Results

Buckling Brace Test

As discussed earlier, the test specimen was loaded according to Figure 5, where the Y-direction corresponds to that shown in the floor plans in Figure 1. Figure 6 shows the story shear – story drift ratio response for the second floor of each orthogonal braced bent. The top discontinuous brace at the 2nd story fractured during the first negative drift excursion at approximately 2% story drift following the first positive excursion. This drift ratio at fracture is consistent with that observed in two previous tests of a similar single-story X-configuration at UW and those tested by Tremblay et

al (2003). After fracture, the test specimen was unloaded in this frame's direction and uni-directional loading was applied to the specimen in the other direction continuing from the drift at which fracture occurred. The test proceeded until the top discontinuous brace in Braced Bay 2 was deemed close to fracture at approximately 1.7% story drift. The test was stopped prior to brace fracture in this bent to prevent damage to the frame as this frame was to be used again for the BRBF test.

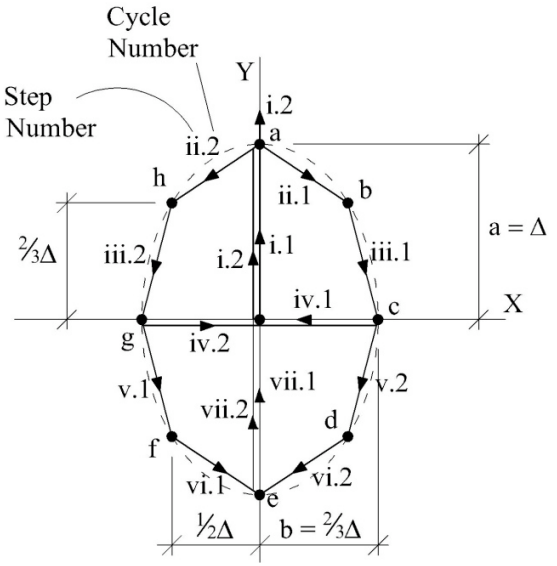

Figure 5. Bi-directional loading protocol "cloverleaf"

Based on brace strain gauge data, and global and local force-deformation curves, brace buckling occurred simultaneously in the discontinuous braces in the 1st and 2nd story of Braced Bay 1 at 0.25% story drift. Yielding of the braces occurred at 0.37% story drift. In the orthogonal direction, brace buckling occurred at 0.22% story drift and yielding at 0.36% story drift. Due to a number of factors including brace end connection stiffness and initial imperfections, brace buckling and subsequent brace damage occurred in only one half of the discontinuous brace while the continuous brace buckled in reverse curvature with the tension brace acting as a lateral support.

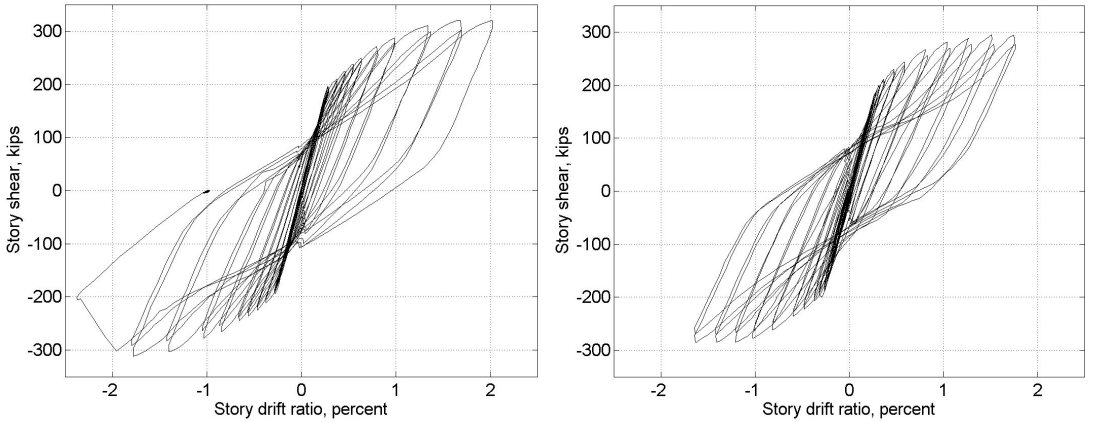

Figure 6. HSS Buckling-brace test 2nd story hysteretic curves: (a) Braced Bay 1 (Y-Direction), (b) Braced Bay 2 (X-Direction)

Prior to brace fracture there was extensive yielding in the gusset plates due to brace axial force and gusset plate bending due to brace buckling. This type of behavior was intended as part of the balanced design philosophy of maximizing energy dissipation and encouraging other yielding mechanisms beyond brace yielding. Slight gusset plate yielding was visually observed (flaking of whitewash) at approximately 0.23% story drift in the corner gussets just prior to brace buckling. Figure 7(a) shows a typical gusset yielding pattern in the corner gusset plates at 2% story drift. This pattern was typical of these joints. Additionally, frame action (opening and closing of the joint) cause additional yielding and deformation in the gusset as seen in the diagonal yield pattern originating at the intersection of the bottom beam flange and column flange shown in Figure 7(a).

Figure 7. HSS buckling-brace test, 2% story drift: (a) Gusset plate yielding, 2nd story corner gusset; (b) Column and gusset plate yielding, base

Column yielding initiated at the base of the three braced frame columns at approximately 0.46% story drift and continued to spread at the bases as the story drift increased. Figure 7(b) shows the yielding at the base of the column in Braced Bay 1 at 2% story drift. Additionally, the web of the beam on the second floor of Braced Bay 1 at the shared column side yielded and deformed at the instant of brace fracture. Up to that point, only limited yielding was observed at this location.

Buckling-Restrained Braced Frame

The BRBF followed the same loading protocol as the first test with the exception of the principal loading direction. Based on the beam web damage described previously, it was decided to make Braced Bay 2 the principal loading direction. Additionally, a web doubler plate with the same thickness as the beam web was attached to the damaged beam web to ensure that would not be the weak link in the BRBF test. It should also be noted that there were initial lateral frame deformations of XX in the Y direction and XX inches in the X direction due to the permanent frame deformation from the first test.

Figure 8 shows the story shear – story drift ratio response for the second floor of each orthogonal braced bent. Yielding of the BRB cores occurred at approximately 0.33% story drift ration in each direction. In the Y-direction, the BRB core fractured at approximately 3.5% average roof drift ratio (RDR) while in the X-direction, the BRB

core fractured at 4.1% RDR. The BRBs in the first story did not fracture as the first story columns resisted a larger amount of the story shear than the second story columns due to the base fixity. After core fracture, the load resisted by each frame was reduced by approximately 40%. The test was continued after core fracture and the frame stiffness remained the same due to the stiffness of the moment frame and the fact that the stiffness of the BRBs at this point was practically zero due to yielding of the BRB core.

At -3.2% RDR, the bottom flange in the second floor beam attached to the shared column in Braced Bay 2 (X-direction) fractured suddenly just outside of the CJP. This occurred after the web at this location exhibited ductile tearing that extended through more than half of the beam web. This tearing was initiated at the erection bolt holes at the beam splice three feet away from the centerline of the column.

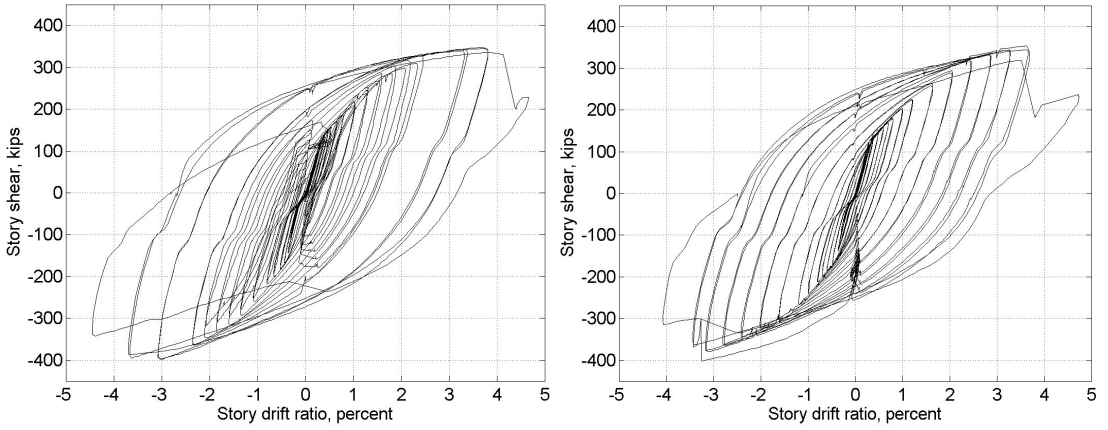

Figure 8. BRBF test 2nd story hysteretic curves: (a) Braced Bay 1, (b) Braced Bay 2

The web and bottom flange of the third floor beam at the shared column side in Braced Bay 1 also exhibited considerable yielding, local buckling and ductile tearing. The tear occurred at the edge of the gusset plate and extended completely through the bottom flange up to approximately ¾ of the beam depth. The braced frame columns yielded considerably at the base and above and below the second and third floor joints. Additionally, local buckling occurred at the base of the two frame columns that the BRBs framed into. This occurred on the side opposite of the gusset plates as shown in Figure 9(b). Column flange and web yielding can also be seen in this photo.

Limited gusset plate yielding was observed and was confined to a localized area approximately one inch square near the gusset-column reentrant corner. Weld tearing occurred in the second and third floor gusset plates at the gusset-column weld. These tears propagated through the total length of the weld and were due to frame action as they initiated when the brace was in compression and the joint was opening. Preliminary analysis indicates that this tearing had limited effect on the overall frame behavior but further analysis is required to fully quantify this.

The BRBs were connected to the gusset plates with pins which limited the amount of moment transferred between these two elements. As a result of fabrication and fit-up

tolerances, which require the hole to be slightly larger than the pin, and yielding of the pin and steel in the vicinity of the pinhole, there was a reduction in frame stiffness as the BRBs underwent a change in the sign of the axial force. This can be seen clearly in the hysteretic curves shown in Figure 8. Additional damage occurring in the frame included panel zone yielding in the columns, tearing at the bolt holes that connected the gravity beams to the braced frame columns, and beam web yielding near the end of the gusset plates. Second floor composite slab damage was limited to hairline cracks around the braced frame columns but were more indicative of shrinkage cracks than flexural cracks.

Figure 9. BRBF test photos: (a) Gusset weld tear, 3.2% story drift; (b) Column local buckling and yielding, 3.2% story drift

Conclusions and Future Work

The out-of-plane loading appeared to have negligible effect on the frame behavior. The HSS braces fractured at 2% story drift which is consistent with previous tests performed on a similar frame loaded uni-directionally at UW. There was considerable gusset plate yielding in the first test which was expected as gusset plate yielding was specifically designed for and deemed a desirable secondary yielding mechanism. Additionally, the elliptical clearance method provided adequate rotation capability of the gusset plates while providing a much more compact design than the $2t_g$ linear offset method most commonly used in practice today.

Similar to the first test, the out-of-plane deformation appeared to have minimal effect on the BRBF behavior. The BRB cores fractured at 3.5 and 4% story drift and no instabilities occurred in the BRB prior to fracture. As BRBs are proprietary and are detailed differently, especially at the ends, this type of behavior may not be typical of all BRBs. Indeed, instabilities have been shown to occur at the end of the BRBs in previous tests that have not been subjected to out-of-plane deformation (Mahin et al. 2004). Frame action, as opposed to brace action, had a dominating effect on the

demands on the gusset-frame welds. The majority of the gusset to column welds tore completely through along their lengths as a result of the joint opening.

Work is ongoing to further analyze the test results with the goals of better quantification of the effect of out-of-plane deformation on the system, the effect of the concrete floor slab, and the demands on the shared column due to bi-directional effects. To aid in this work, 3D finite element models will be developed and calibrated to the test results and parametric studies shall be performed.

ABSTRACT

This paper investigates the design of normal strength concrete mixtures that use recycled concrete aggregates as replacement for virgin natural aggregates. Three mix design methods utilizing direct weight replacement, equivalent mortar replacement, and direct volume replacement are compared based on concrete workability, compressive strength, and elastic modulus. A total of 42 mixes were made with different aggregate replacement amounts. It was determined that the concrete workability changes significantly depending on the replacement method used, with the direct volume and equivalent mortar methods resulting in the best and worst workability, respectively. The compressive strength and elastic modulus of the mixes with recycled concrete aggregates showed little variation from concrete with natural aggregates.

INTRODUCTION

Vast amounts of natural aggregates (e.g., crushed stone, gravel) are used for the construction and maintenance of our civil infrastructure. The mining, processing and transportation of these materials consume large amounts of energy and adversely affect the ecology of forested areas and riverbeds. At the same time, about half of the construction and demolition waste in the U.S. consists of old concrete rubble. By recycling the concrete from our existing infrastructure as replacement for virgin coarse aggregates in new construction, it would be possible to substantially reduce the demand for new aggregates.

Recycled concrete aggregates (RCA) can readily pass the prescriptive requirements for coarse aggregates in structural concrete (ASTM 2009); however, the use of recycled concrete as aggregate has been mostly limited to non-structural applications such as sidewalks and sub-base for roadways (FHWA 2008). In particular, almost all of the existing research on RCA concrete (e.g., Buck 1977; Corinaldesi 2010; Dhir et al. 1999; Domingo-Cabo et al. 2009; Etxeberria et al. 2007; Frondistou-Yannas 1977; Hansen 1986; Nishibayashi et al. 1984; Limbachiya et al. 2000; Olorunsogo et al. 2002; Poon et al. 2004; Rahal 2007; Ryu 2002; Sanchez de Juan et al. 2009; Tam et al. 2005; Tavakoli et al. 1996; Topcu and Sengel 2004; Uche 2008; Xiao et al. 2005, 2006) was conducted outside the U.S., limiting the application

of the findings domestically because of variations in materials and quality control. Most of this previous research used simple weight replacement of virgin natural aggregate (NA) with coarse RCA. More recently, a new method dubbed the "equivalent mortar replacement method" was proposed to result in concrete mixes with comparable fresh and hardened properties as concrete made using natural aggregates (Fathifazl et al. 2009). This method accounts for the volume of residual mortar (i.e., mortar left attached to the original aggregate in RCA) so that the resulting concrete mix has the same volume of total mortar (i.e., residual mortar plus fresh mortar) as concrete made with natural aggregates.

Currently, no accepted engineering standard exists for the design of reinforced concrete mixes with significant levels of RCA to result in comparable properties as concrete made using virgin natural aggregates. In the years to come, the renovation of our nation's aging infrastructure will result in both an increase in the supply of recycled concrete and the demand for new concrete. In many cases, the demolished structure may be near the new construction, thus allowing better quality control and reducing transportation costs. To advance the use of RCA in structural concrete, it is essential to develop a mix design methodology that consistently provides desirable fresh and hardened concrete properties using a straightforward proportioning approach. With this objective in mind, this paper provides an experimental evaluation of three aggregate replacement methods: (1) direct weight replacement; (2) equivalent mortar replacement; and (3) direct volume replacement.

AGGREGATE REPLACEMENT METHODS

The three aggregate replacement methods evaluated in this paper are described below.

Direct Weight Replacement (DWR) Method. The direct weight replacement (DWR) method, or some minor variation, has been used almost exclusively throughout the literature, most likely due to its simplicity. In this method, the weight of the total coarse material (i.e., virgin natural aggregate plus RCA) is kept constant for any percentage of aggregate replacement. The corresponding cement content and water content are also kept constant; however, to produce the same volumetric yield, the amount of fine aggregate may be decreased since similar weights of natural aggregate (NA) and RCA may occupy different volumes (depending on the specific gravity). In some variations of the DWR method, the amounts of the both the total coarse aggregate and fine aggregate are adjusted to maintain similar volumetric yields.

Equivalent Mortar Replacement (EMR) Method. The equivalent mortar replacement (EMR) method proposed by Fathifazl et al. (2009) treats RCA as a two-phase material made of residual mortar (RM) and recycled natural aggregate (RNA) rather than as a singular coarse material. The volume of the residual mortar is accounted for so that the resulting concrete mix has the same total mortar volume (i.e., residual mortar plus fresh mortar) as concrete made with virgin natural aggregates. The resulting design relationships between a target natural aggregate concrete (NAC) mix and an EMR mix are given as:

$$V_{RM}^{EMR} + V_{FM}^{EMR} = V_{FM}^{NAC} \quad (1)$$

$$V_{RNA}^{EMR} + V_{NA}^{EMR} = V_{NA}^{NAC} \quad (2)$$

where, V_{RM}^{EMR} = volume of residual mortar (RM) in EMR mix; V_{FM}^{EMR} = volume of fresh mortar (FM) in EMR mix; V_{FM}^{NAC} = volume of FM in NAC mix; V_{RNA}^{EMR} = volume of recycled natural aggregate (RNA) in EMR mix; V_{NA}^{EMR} = volume of virgin natural aggregate (NA) in EMR mix; and V_{NA}^{NAC} = volume of NA in NAC mix.

Equations 1 and 2 dictate that as the volume of RCA is increased in a given volume of concrete, the amount of fresh mortar is decreased while keeping the relative proportions of cement, water, and fine aggregate constant. Because a reduction in fresh mortar causes a reduction in the workability and place-ability of concrete, there is a limit to the maximum amount of aggregate replacement that can be utilized in EMR mixes. As a result, the EMR mixes tested by Fathifazl et al. (2009) used significant amounts of water-reducing admixtures. It was concluded that at similar water and cement contents, EMR mixes had better workability than their NAC counterparts; however, the NAC mixes used in these comparisons did not have any water reducer. Furthermore, while both EMR and DWR methods were evaluated by Fathifazl et al. (2009), the mixes used did not have similar aggregate replacement percentages, thus making direct comparisons very difficult.

Direct Volume Replacement (DVR) Method. The ACI 211 (1991) *Standard Practice for Selecting Proportions for Normal, Heavyweight and Mass Concrete* provides a common method for the proportioning of virgin natural aggregate concrete mixtures based on the absolute volume of each constituent. However, direct volume replacement has not been used in the literature as a method for the design of RCA mixes, and is proposed here as a simple method consistent with standard practice for natural aggregate mix designs. The direct volume replacement (DVR) method treats RCA as a single-phase coarse aggregate where a given volume of NA is replaced by an equal volume of RCA. Since, the resulting volumetric proportions of total coarse aggregate (RCA plus NA), fine aggregate, cement, and water remain constant, there should not be a loss in workability with an increase in the proportion of RCA as long as the inherently greater absorption of RCA (as compared with the absorption of NA) is incorporated into the design.

EXPERIMENTAL PROGRAM

An experimental program was conducted to evaluate the DWR, EMR, and DVR mix design methods on the fresh and hardened properties of concrete with varying amounts of aggregate replacement. The three properties examined are: (1) concrete slump; (2) compressive strength; and (3) modulus of elasticity. A total of 42 mixtures were designed and tested utilizing normal strength concrete.

Aggregates. One type of fine natural aggregate (FA), one type of coarse natural aggregate (NA), and two types of recycled concrete aggregates (RCA) were used in the experimental program. INDOT No. 23 concrete sand was used as the fine aggregate. For coarse natural aggregate, moraine pea gravel (NA-PG) from a local

ready-mix concrete plant was used. These fine and coarse natural aggregates are typical in ready-mix concrete construction.

The first source for recycled concrete aggregate (RCA-ND) was a precast concrete shear wall laboratory specimen previously tested to failure under reversed-cyclic lateral loading at the University of Notre Dame (Smith et al. 2010). The reason for using this test specimen as an RCA source was the availability of detailed information on the mix design as well as the fresh and hardened properties of the source concrete. After the testing of the wall, the precast panels were taken to a recycling facility, where they were crushed to a nominal maximum size of about 5-6 in. The larger pieces were removed by hand and the smaller size fractions were sieved and then combined to produce the desired RCA grading.

The second source for recycled concrete aggregate (RCA-SB) came from a construction recycling yard in South Bend, Indiana. Since this facility takes debris from many sources (e.g., sidewalks, buildings, bridges), the properties of the source concrete are not known. Furthermore, RCA-SB contained approximately 4.0% (by weight) deleterious substances (e.g., brick, asphalt, wood), some of which was manually removed during the sieving, washing, and drying process. It is likely that not all of this material was removed or taken into account when determining the percentage of deleterious material in the RCA.

Table 1 shows the specific gravity [bulk dry, saturated surface dry (SSD), and apparent], absorption, residual mortar content (RMC), and fineness modulus for the aggregates used. The specific gravity and absorption were determined using ASTM C 127 (ASTM 2009b) and ASTM C 128 (ASTM 2009b) for coarse and fine aggregates, respectively, and the fineness modulus of the fine aggregate was determined according to ASTM C 136 (ASTM 2009b). The residual mortar content, which is a measure of the percent (by weight) of residual mortar in the RCA, was determined as described in Abbas et al. (2008). Due to the residual mortar, the specific gravity for RCA is lower than that for NA while the absorption of RCA is greater than that of NA.

Table 1. Natural coarse, recycled, and fine aggregates.

Aggregate	Specific gravity			Absorption (%)	RMC (%)	Fineness Modulus
	Bulk dry	SSD	Apparent			
NA-PG	2.47	2.55	2.70	3.48	-	-
RCA-ND	2.28	2.41	2.63	5.69	60.5	-
RCA-SB	2.13	2.28	2.49	6.73	51.5	-
Sand	2.59	2.63	2.69	1.39	-	2.54

The coarse aggregate gradations used in the research are shown in Figure 1. Since significant variations in aggregate size can produce different fresh and hardened concrete properties (e.g., workability, strength) (Kosmatka et al. 2002), it was necessary to use aggregates with consistent gradation. The source concrete mix design for RCA-ND (Smith et al. 2010), which used ASTM C 33 (ASTM 2009b) No. 8 coarse aggregate [3/8-in. (9.5 mm) nominal maximum aggregate size], was selected as the basis for the aggregate gradation. NA-PG

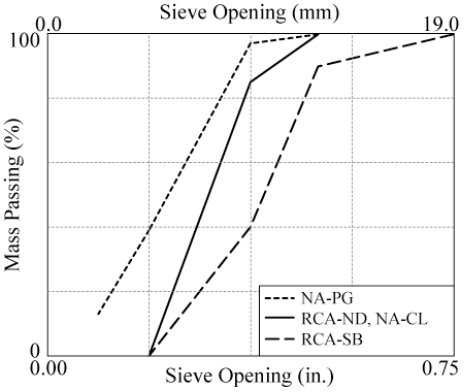

Figure 1. Aggregate gradations.

as acquired from the ready-mix concrete plant followed ASTM No. 8 requirements with no additional gradation necessary; however, RCA-ND was sieved into individual size fractions and recombined to produce gradations similar to ASTM No. 8. RCA-SB was deficient in the No. 4 aggregate size; and thus, a slightly larger gradation following ASTM C 33 No. 7 aggregate was used.

NA Concrete Mix Design. Table 2 lists the dry weight proportions for the target natural aggregate concrete (NAC) mix design that formed the basis for the RCA mixes in this research. The source concrete design for RCA-ND was used as the target NAC mix with NA-PG as the coarse natural aggregate. This mix was originally designed with a water-to-cement (*w/c*) ratio of 0.44 for a target 28-day strength of 6.0 ksi (41.4 MPa), slump of 5±1 in. (127±25 mm), and air content of 5±1.5%. From previous data (Smith et al. 2010), the average measured 28-day strength of the concrete was 6.4 ksi (44.1 MPa). Because the original mix was designed for precast concrete construction, which requires high early concrete strength for removal of formwork, ASTM C 150 Type III (ASTM 2009a) portland cement was used. The concrete also contained Sika® AEA-14 and Sikament® 686 as air-entraining agent (AEA) and high range water reducer (HRWR), respectively.

RCA Concrete Mix Designs. Table 2 also lists the RCA concrete mix designs used in this research by replacing the NA in the target mix design above. The aggregate replacement ratio, R refers to the amount of NA replaced by RCA as given by Equations 3, 4 and 5 for the DWR, EMR, and DVR methods, respectively.

$$R = 1 - W_{NA}^{DWR}/W_{NA}^{NAC} \quad (3)$$

$$R = 1 - V_{NA}^{EMR}/V_{NA}^{NAC} \quad (4)$$

$$R = 1 - V_{NA}^{DVR}/V_{NA}^{NAC} \quad (5)$$

where, W_{NA}^{DWR} = weight of NA in DWR mix; W_{NA}^{NAC} = weight of NA in NAC mix; V_{NA}^{EMR} = volume of NA in EMR mix; V_{NA}^{DVR} = volume of NA in DVR mix; and V_{NA}^{NAC} = volume of NA in NAC mix. Note that the water reducer in each mix was batched proportionally to the amount of cement (per manufacturer's specifications) so as to maintain a consistent composition for the fresh mortar. For the EMR mixes, this resulted in a decrease in the amount of water reducer as R increased (since an increase in R resulted in a decrease in the amount of cement).

Aggregate Preparation. Following dry sieving, the recycled and natural coarse aggregates were washed with water over a No. 8 (2.36 mm) sieve to further remove excess fines. All coarse and fine aggregates were then dried in an oven at 230 °F (110 °C) for at least 24 hours. To ensure that the aggregates did not absorb mix water (in turn pulling water from the cement paste and leading to decreased workability and cement hydration), the aggregates were removed from the oven, batched according to the dry weights in Table 2, blended (if necessary) according to the gradations in Figure 1, and then soaked in water for a period of 18 to 24 hours. After soaking, the excess water was decanted from the aggregates, which were then weighed to determine the amounts of absorbed and residual water on the aggregates. Using the

absorption values from Table 1, the amount of residual water on the aggregates beyond the saturated surface dry (SSD) condition was determined and subtracted from the required mix water for each concrete batch.

Concrete Slump. Each concrete batch was mixed in a rotating drum mixer according to ASTM C 192 (ASTM 2009b). To determine the workability of each mix, a variation of the ASTM C 143 (ASTM 2009b) slump test was conducted. The ASTM test requires a slump cone with a concrete volume of 0.20 ft^3 (5663 cm^3). However, because of the relatively small amount of RCA available for this project, the batch volume for each mix was limited to 0.12 ft^3 (3398 cm^3) to make four 3 x 6 in. (7.6 x 15.2 cm) cylinders. To allow for the slump measurement of these batches, the dimensions of the ASTM slump cone were scaled by half, thus reducing the required concrete volume to 0.03 ft^3 (721 cm^3). The correlation between the full slump cone and the scaled "mini slump" cone was determined based on two trial batches, one using pea gravel (NA-PG) and the other using crushed limestone (referred to as NA-CL) from a local ready-mix concrete plant. The gradation of NA-CL (Figure 1) was similar to the ASTM No. 8 gradation of NA-PG. The use of these two materials provided slump measurements of concrete with rounded aggregates (pea gravel) as well as angular aggregates (crushed limestone). The concrete batches were based on the target NAC mix design in Table 2 but the amount of water was varied so as to result in varying *w/c* ratios ranging from 0.3 to 0.5. Three mini slump measurements and three standard slump measurements were taken for each mix. The results from the standard and mini slump tests (Figure 2) were compared and linear regression analysis showed that the mini slump test could be used to predict the standard slump test according to Equation 6, with a coefficient of determination of 0.93.

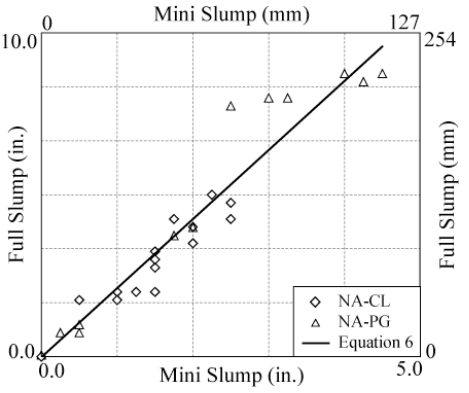

Figure 2. Standard full slump versus mini slump.

$$Full\ Slump = 2.13 * (Mini\ Slump) \quad (6)$$

Note that this regression equation is constrained so that the y-intercept is zero, which does not give the best possible fit but is done to provide a practical relationship without significantly affecting the coefficient of determination.

Curing. Following slump testing, four 3 x 6 in. (7.6 x 15.2 cm) concrete cylinders were made from each batch. Three cylinders were used to determine the compressive strength and stiffness of the concrete, while the fourth cylinder was left unbroken for future reference and microscopic structural analysis and petrography. The cylinders were made using plastic disposable molds, which were capped and stored at room temperature and humidity for approximately one day. The day after casting, the cylinders were removed from the molds and were cured for 27 days in water at room temperature, bringing the total curing duration to 28 days. In accordance with ASTM C 511 (ASTM 2009b), high-calcium hydrated lime (calcium hydroxide) was added to the curing water to prevent the leaching of lime from the concrete cylinders.

Testing. Following the 28-day curing period, the specimens were removed from the curing tank, hand dried using paper towels, and tested in a moist state according to ASTM C 39 (ASTM 2009b). Each cylinder was capped using unbonded steel caps and rubber bearing pads to help maintain an even load distribution during testing. The

testing machine was a Satec© 5590-HVL Universal Testing Machine with a 67 kip (300 kN) axial load capacity. The loading stress rate was held constant at 35 psi/s (241 kPa/s). An Epsilon© 3542RA rock averaging extensometer with 2 in. (5.1 cm) gauge length was used to measure the concrete axial strain. The concrete compressive strength was determined from the peak stress, f_{cm} reached in each test and the secant modulus, E_{sec} was determined as:

$$E_{\text{sec}} = (f_{c2} - f_{c1})/(\epsilon_{c2} - \epsilon_{c1}) \quad (7)$$

where, $f_{c2} = 0.40 f_{cm}$; f_{c1} = stress at ϵ_{c1}; ϵ_{c2} = strain at f_{c2}; and $\epsilon_{c1} = 0.00005$.

RESULTS

The slump, compressive strength, and secant modulus results for the 42 concrete mixes in Table 2 are discussed below. The results are presented as individual data (i.e., not averages) from all of the tests conducted.

Slump. Due to variations in mixture proportions for a given aggregate replacement ratio, *R*, each replacement method may be expected to provide different results for concrete workability. It can be argued that as the ratio of fresh mortar to total coarse material decreases, so too does the concrete workability. As such, the DVR method should not result in a significant decrease in workability provided that similar aggregate gradations are used in the recycled and natural aggregate mix designs and the absorption of the aggregates is accounted for. Conversely, since the DWR and EMR methods decrease the fresh mortar to coarse material ratio, the workability of these mixes is expected to decrease proportionally.

Figure 3 shows the mini slump test results for each of the mix designs. The results show that at the maximum possible replacement ratio of *R*=100%, the DVR method provided similar workability to the target mix design (cases with *R*=0%). The mixes with RCA-SB had slightly smaller slump than the mixes with RCA-ND. This may be attributed to the difference in aggregate gradation (Figure 1), with the nominal maximum aggregate sizes being 1/2 in. (12.5 mm) for RCA-SB and 3/8 in. (9.5 mm) for RCA-ND. In comparison with the DVR method, the DWR method resulted in mini slump values about 0.75 in. (19 mm) less than the target mix design at *R*=100%. The EMR mixes performed the worst and became unworkable at small amounts of replacement, with the mini slump reaching 0 by *R*=20%. Note that as investigated by Fathifazl et al. (2009), it may be possible to reach larger *R* values in EMR mixes by using large amounts of water reducer; however, this was not done in the current research.

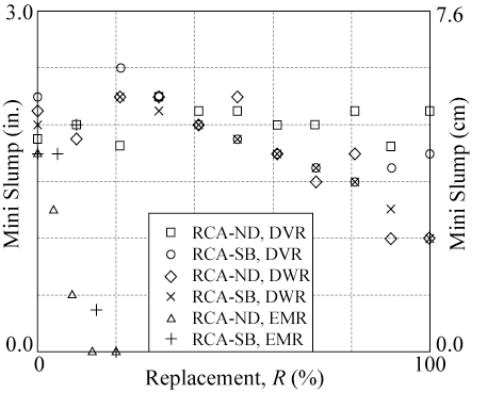

Figure 3. Mini slump.

Compressive Strength. Figures 4a and 4b show the 28-day compressive strength, f_{cm}, results for the mixes with RCA-ND and RCA-SB, respectively. At each replacement ratio, *R*, a minimum of three cylinders were tested for each RCA type and design

method. To ensure repeatability, additional batches of some of the DVR mixes with RCA-ND were made several months after the first batches. Little difference was found in the results from the original and repeated mixes.

From Figure 4, a distinction cannot be made between the compressive strengths of the RCA mixes designed using the DWR, DVR, and EMR methods. In general, each of these design methods was capable of producing RCA concrete (cases with R>0%) with comparable strength as NA concrete (cases with R=0%). No significant trend can be seen as R is increased; however, it is interesting to note that at R=100%, both RCA-ND and RCA-SB concrete were stronger than NA concrete. Furthermore, RCA-SB concrete was only slightly weaker than RCA-ND concrete despite the questionable quality of RCA-SB.

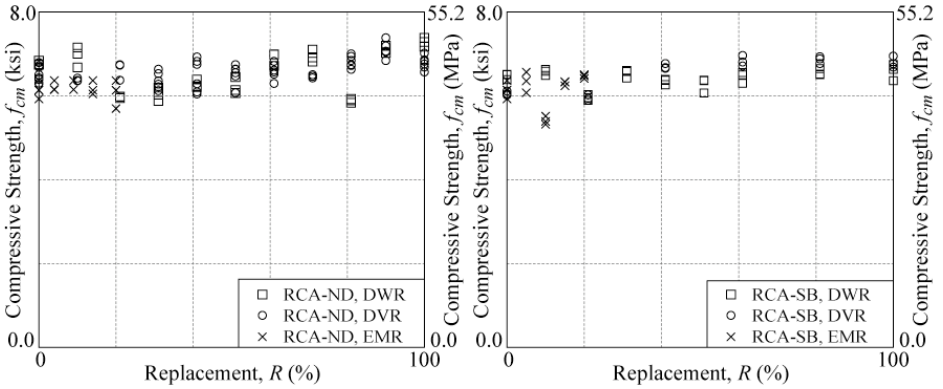

Figure 4. Compressive strength of concrete using: (a) RCA-ND; and (b) RCA-SB.

The slightly higher strengths of RCA concrete as compared with NA concrete could be because of the use of pea gravel (NA-PG) as the coarse natural aggregate in the target mix design. It is also possible that the differences between the aggregate types become more significant for higher concrete strengths. While further research should certainly be conducted on the variability of these results with additional sources of RCA and NA as well as for high strength concrete mixes, it is concluded that compressive strength may not be a limiting factor on the use of RCA in structural normal strength concrete applications.

Modulus of Elasticity. Figure 5 shows the secant modulus, E_{sec} results corresponding to the compressive strength data in Figure 4 (with the exception of the EMR mixes, for which the elastic modulus was not measured). In general, the elastic modulus findings were consistent with those for compressive strength that the replacement ratio and design method did not have a significant effect on the results. Further research is needed on the variability of these results with additional sources of RCA and NA.

For natural aggregate concrete, the elastic modulus is typically considered to vary with compressive strength. Figure 6 shows the variation of elastic modulus with respect to the square root of the compressive strength data from Figures 4 and 5. It can be seen that while the RCA mixes had consistent trends in elastic modulus as the NA concrete and no distinction could be made with respect to the aggregate used, all

of the RCA and NA mixes had elastic modulus values lower than the ACI 318 (2008) modulus (solid line).

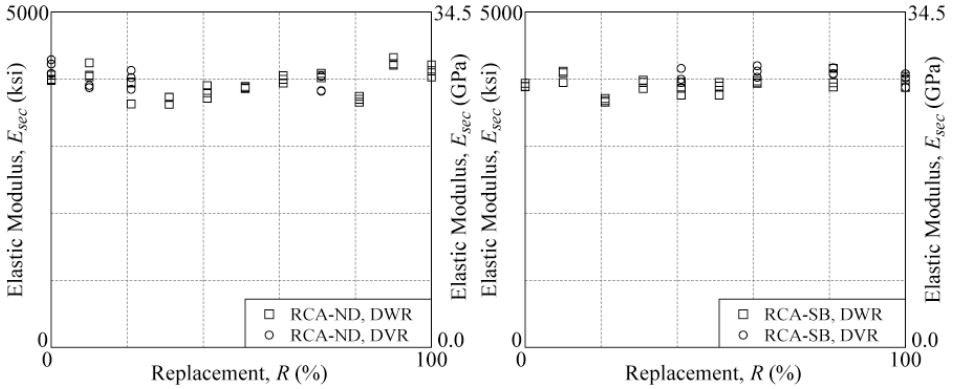

Figure 5. Elastic modulus of concrete using: (a) RCA-ND; and (b) RCA-SB.

SUMMARY AND CONCLUSIONS

This paper investigates the design of normal strength concrete mixtures that use recycled concrete aggregates as replacement for coarse virgin natural aggregates. Three mix design methods utilizing direct weight replacement (DWR), equivalent mortar replacement (EMR), and direct volume replacement (DVR) are compared based on concrete workability, compressive strength, and elastic modulus. The important conclusions from the study are given below. In interpreting these conclusions, it should be emphasized that the results are limited to the materials and mix proportions tested. Ultimately, further research should be conducted on the variability of the results with additional sources of recycled concrete and natural aggregates, as well as for high strength concrete mixes.

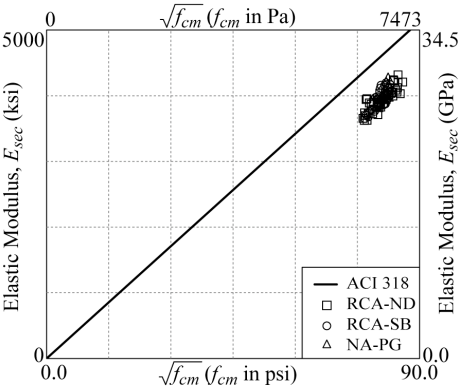

Figure 6. Elastic modulus and compressive strength.

1. The workability of fresh concrete is affected by the aggregate replacement method. The DVR method produced concrete with equivalent workability to the target natural aggregate concrete. While the DWR mixes had somewhat decreased workability than the DVR mixes, the concrete was still easily placed and finished in the cylinder molds. In comparison, the decreased amount of fresh mortar in the EMR method resulted in significantly reduced workability such that aggregate replacement ratios greater than R=20% were not possible without changing the mix proportions or increasing the amount of water reducer.
2. The different natural and recycled concrete aggregates used in this research had a relatively small effect on the compressive strength of the concrete mixes

tested, even at a 100% aggregate replacement ratio. It is concluded that compressive strength may not be a limiting factor on the use of recycled concrete aggregate in structural normal strength concrete applications.

3. For the materials tested, the aggregate replacement mix design method had no distinguishable effect on the compressive strength of concrete.
4. Similar to the compressive strength results, the aggregate type, replacement design method, or replacement amount did not have a significant effect on the elastic modulus of the concrete mixes tested.
5. While the recycled concrete aggregate mixes had consistent trends in elastic modulus as the natural aggregate concrete mixes, all of the specimens tested had elastic modulus values lower than that given by ACI 318 (2008).

ABSTRACT

Shell elements are commonly used over continuum 3D elements to model structural components for computational efficiency when information regarding behavior across the material thickness is not needed. Shell elements are widely believed to effectively capture the global hysteretic behavior of thin walled structural components. The objective of this research was to compare the hysteretic behavior of numerical models of links, such as those used in eccentrically braced frames that consisted entirely of shell and of continuum elements. The geometry, material properties, and loading protocol were consistent in the shell and 3D continuum analyses.

The results captured by the shell-based models exhibited significantly more severe global degradation of the force deformation hysteresis at large inelastic deformations then the 3D continuum elements. This discrepancy was recorded for models of entire links as well as more simplified models. The results of this investigation have brought into question the reliability of shell elements in accurately capturing the buckling behavior of thin walled structural components subjected to extreme cyclic loading.

INTRODUCTION

Shell elements are commonly used in finite element analysis (FEA) to model structures in which the dimension across the thickness is much less than other dimensions in the structure (Simulia, 2010). These elements are formed by combining plate bending and plane stress element formulations to create an element with bending and plane stress degrees of freedom. Shell elements typically used in finite element analysis include 6 degrees of freedom; 3 plate bending, 2 plane stress, and 1 allowing for rotation about the z-axis (Cook, 2002). Shell elements are used in place of full three dimensional elements to increase computational efficiency by decreasing the number of nodes within a model. Thick and thin shell element formulations are available which respectively take into account and ignore transverse shear deformation.

Shell elements are widely believed to effectively capture the global hysteretic behavior of thin walled structural components made from metals. The dimensions across the thicknesses of the plates which make up these components are generally very small relative to the global dimensions of the component. This paper focuses on the uses of this modeling technique for short beam links, such as those used in eccentrically braced frames. Additionally, the performance of such links is generally

assessed based on global hysteretic behavior as opposed to local material behavior and such the performance can be assessed without gathering material information across plate thicknesses. Numerous numerical studies have utilized shell elements to assess the performance of links and stiffened shear panels subjected to cyclic loading including; Berman et al. (2009), Dusicka and Lewis (2007), Alinia and Dastfan (2006), Richards and Uang (2005), Itani et al. (2003), Lee and Yoo (1998).

Due to the widespread use of shell elements to assess the performance of shear links and shear panels, the objective of this study was to assess the cyclic buckling behaviors of structural components modeled using these elements. In this study, the hysteretic responses of a shear link modeled using shell elements and 3D continuum elements were compared. The numerical hysteretic responses were additionally compared to experimental results to assess the validity of modeling shear links using shell and 3D element formulations.

NUMERICAL MODEL

A W12x22 link designed in accordance with the specifications provided in the Seismic Provisions (AISC, 2005) for links in eccentrically braced frames was used for the purpose of this analysis. This link was chosen due to the availability of experimental data while satisfying the compactness requirements in both the flange and the web. The link was classified as long, or flexure dominated, as defined by the requirements specified in the seismic provisions. Specifically, the link length, $e > 2.6M_p/V_p$ where M_p is the plastic moment strength and V_p is the plastic shear strength. The sectional properties of the link were consistent with the dimensions provided for a W12x22 rolled section in the AISC Steel Construction Manual. These properties were used to calculate the plastic shear and moment strengths of the link assuming a nominal yield strength f_y = 50ksi and link length e = 53in. The section properties and calculated nominal strength values are summarized in Table 1. Intermediate stiffeners spaced at 5.9 in were included on one side of the link to provide web stability. End stiffeners were additionally included to shift plastic strain away from the connection zone of the link (Dusicka, 2009). The geometric properties of the stiffeners are summarized in Table 2.

Table 1: Nominal Link Properties.

Beam	Length	Web		Flanges		Nominal Strengths		
	e (in)	h_w (in)	t_w (in)	b (in)	t_f (in)	V_p (kip)	M_p (kip in)	$\frac{2.6M_p}{V_p}$
W12X22	53	11.45	0.26	4.03	0.425	89	1458	42.6

Table 2: Nominal Stiffener Properties.

Stiffener Type	b_s (in)	h_s (in)	t_s (in)	Spacing (in)
Intermediate	1.5	11.45	0.375	5.89
End	5	11.45	0.375	NA

The commercially available FEA program ABAQUS v6.9 (Simulia, 2010) was used to numerically investigate the cyclic behavior of a the link using shell and 3D continuum elements. Three dimensional models were developed, and material as well as geometric non-linearities were incorporated. Model geometry included transverse stiffeners along the effective length of the link, the end stiffeners, and the end plate connection. A model overview for the shell and 3D continuum models is illustrated in Figure 1.

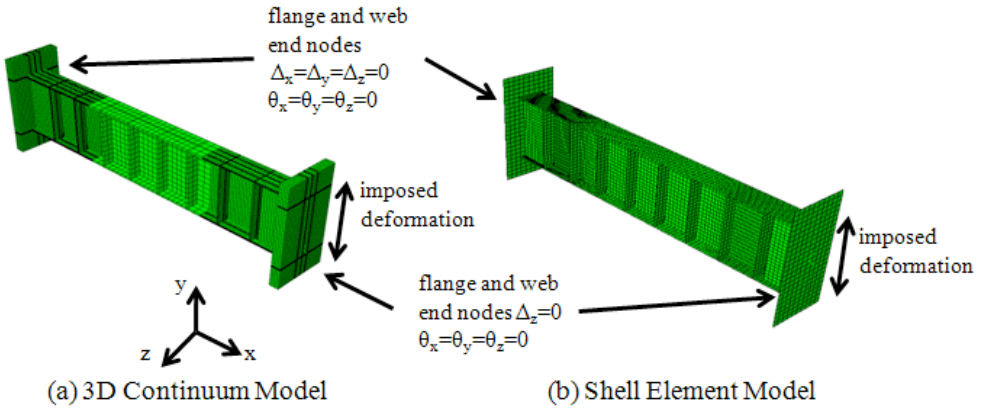

Figure 1: Link Model Overview

To model the cyclic non-linear behavior of steel material in the link, the combined Isotropic/Kinematic hardening formulation was used. The hardening parameters were calibrated using monotonic stress strain data obtained from ASTM tests on the web and flanges of available beam section. As the combined hardening formulation in ABAQUS requires cyclic stress strain data, the cyclic behavior of the steel was approximated by developing a relationship between the monotonic and cyclic behavior of A572 steel using the experimental results from Kaufmann et al. (2001). Modeling material failure was outside the scope of this study, and thereby the material failure characteristics related to fatigue and ductility limits were not included.

The boundary conditions in the models consisted of a fixed-roller system as shown in Figure 1. The nodes at one end of the link were restrained in all degrees of freedom. All rotation and transverse displacement was restrained at the other end of the link, allowing for longitudinal displacement. This ensured that artificially induced internal axial forces were not introduced to the link during loading. Shear was applied by assigning end displacements Δ_y along the y-axis as shown in Figure 1.

To overcome the geometric perfection inherent in numeric modeling, buckling mode shapes were superimposed to introduce imperfections to the model geometry. Elastic Eigen value analyses were conducted to develop the mode shapes of the link. A fraction of the displacements from the first two mode shapes were applied to the link geometry prior to running the non-linear analyses.

Different geometric assumptions and element formulations were used in the shell and 3D continuum models. The shell model was assembled using shell elements located at the center of the plate thickness. Thus in building the model, the effective height of the web, $h_{weff,}$ and stiffeners h_{seff} became $h_{weff} = h_w + t_f$ and $h_{seff} = h_s + t_f$

respectively to maintain the correct web height to thickness aspect ratios; resulting in a 4% height increase in the web and stiffeners. ABAQUS shell element formulations S4, S4R, and S8R were used in the shell model. These elements respectively utilize a linear element formulation with 4-nodes, a linear element formulation with 4-nodes, reduced integration, and hourglass control, and a quadratic element formulation with 8-nodes, reduced integration, and hourglass control. All element formulations included 6 degrees of freedom per node resulting in shell elements with bending, plane strain, and z-axis rotation degrees of freedom (Simulia, 2010). Both Simpson and Gauss integration were used in the shell analysis with 3, 7, and 9 integration points across the shell thicknesses. The continuum model conversely was assembled using ABAQUS 3D continuum elements C3D8. In building the model, the components of the shear link were defined to the geometry provided for a W12X22. C3D8 elements utilize a linear element formulation with 8-nodes and allow for 6 degrees of freedom per node. The components of the W12X22 shear link including the web, flanges, and stiffeners were assembled using ABAQUS tie constraints in both the shell and 3D continuum models (Simulia, 2010).

Global mesh convergence was conducted by analyzing strain values along the flange of the link for both the shell and 3D continuum models. In the shell model, the mesh was refined across the entire length of the link, while in the continuum model the mesh was refined only near the ends of the link where flange buckling was expected to occur. Selective convergence was used in the 3D continuum model for computational efficiency. Final mesh convergence in the 3D continuum model yielded three elements across the web and transverse stiffeners, and four elements across the thickness of the flange.

MONOTONIC BEHAVIOR

Monotonic analyses were conducted on the shell and 3D continuum models to a maximum elastic rotation angle $\gamma = 0.055$rad. The deformation was imposed at one end of the link, and the linear y-axis deformations were translated to elastic rotation angles γ. The monotonic force deformation behaviors observed in the shell and 3D continuum models can be seen in Figure 2, and the yield and ultimate strengths are displayed in Table 3. Changing the integration parameters did not have a noticeable effect on the monotonic behavior of the shell models, and thus only results obtained using Simpson integration with 3 integration points across the shell thickness are shown. Additionally, the monotonic results obtained using the ABAQUS shell elements S4 and S4R were identical, so results obtained using the S4R element have been excluded.

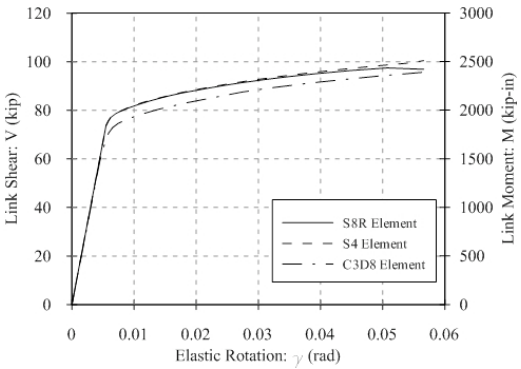

Figure 2: Monotonic Force Deformation Behavior W12x22 Model

The shell and 3D continuum models showed similar monotonic force deformation responses, however minor discrepancies existed in the results. An elastic link stiffness of 13397kip/rad was predicted by all models. The yield strength predicted in both shell models was 11% higher than the yield strength predicted in the 3D continuum model. The discrepancy in yield strength is most likely due to the 4% web height increase in the shell models. Additionally, the model which utilized S8R exhibited signs of strength degradation starting at an elastic deformation angle γ = 0.05rad. While there is no visual indication as to the cause of the strength degradation, it is possibly a result of the fact the quadratic element formulation reduces spurious shear effects by introducing additional nodes to the element. Despite these minor discrepancies, the shell and 3D continuum models predicted similar monotonic global force deformation behaviors for the link.

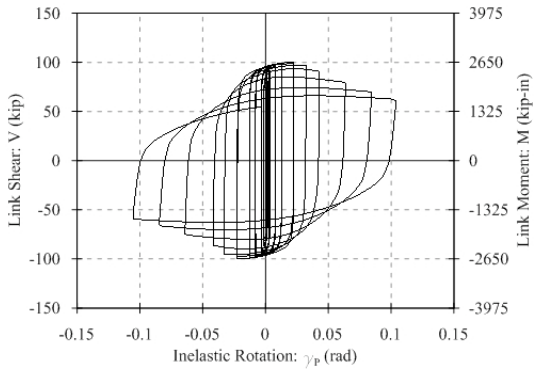

Table 3: Monotonic Yield and Ultimate Strengths W12x22 Model.

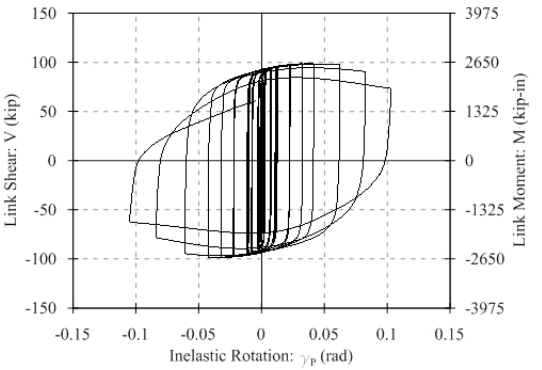
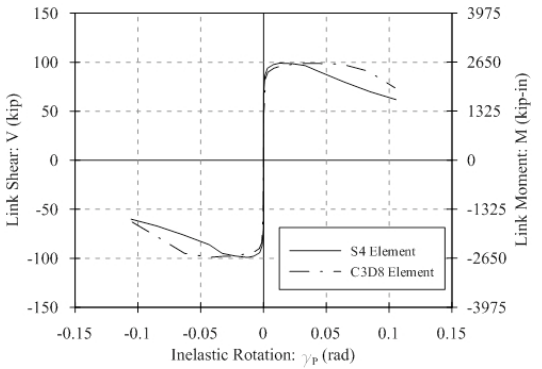
	S4 Elements	S8R Elements	C3D8 Elements	% Difference S4/S8R
f_y (kips)	75	75	73	3/3
f_u (kips)	100	97	96	4/1



CYCLIC BEHAVIOR

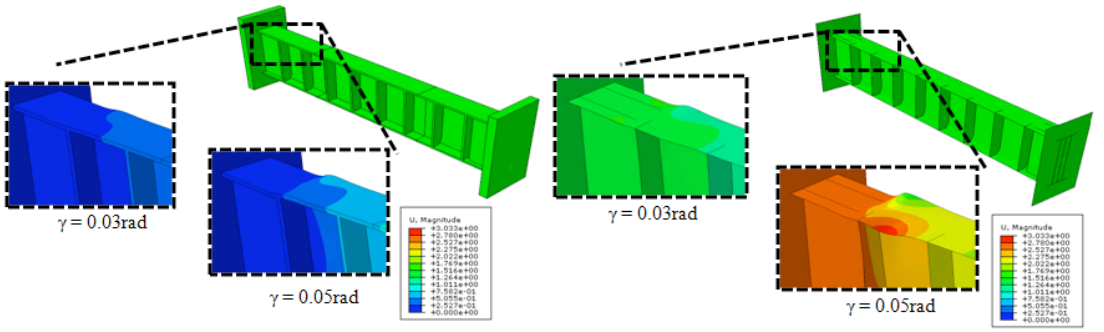
Cyclic analyses were conducted on the shell and 3D continuum models up to a total rotation angle of γ = 0.11rad. Similar to the monotonic analyses, deformations were imposed on one end of the link, and the linear y-axis deformations were translated to elastic rotation angles γ. The imposed displacement history was reversed cyclic in accordance with the specifications provided in the Seismic Provisions (AISC, 2005) for links in eccentrically braced frames. The cyclic force deformation behaviors and back bone curves for the shell and 3D continuum models are shown in Figure 3, and the maximum loads achieved at target deformations are compared in Table 4. In these plots, the elastic deformation contribution has been post-processed, resulting in only the inelastic rotation being shown. Figure 4 shows deformed link shapes at pre and post flange buckling deformation angles for the shell and 3D continuum models. Consistent with the monotonic analysis, all shell models utilized Simpson integration with 3 integration points across the shell thickness, and the results obtained using the



S4R element have been excluded. The cyclic behaviors of the S4 and S8R elements were nearly identical, so results obtained using S8R elements have subsequently been excluded for clarity.

(a) Shell Model

(b) 3D Continuum Model



(c) Back Bone Curves

Figure 3: Hysteretic Behaviors and Back Bone Curve Comparison W12x22 Model

Significant differences were observed in the hysteretic behaviors of the shell and 3D continuum models when subjected to cyclic deformations. Similar behaviors were seen at inelastic deformations lower then $\gamma_p = 0.025$rad, however the shell model exhibited large strength degradation at higher rotation angles due to the onset of flange buckling. A stable hysteretic behavior was observed in the shell model through an inelastic rotation $\gamma_p = 0.025$rad before experiencing strength degradation due to flange buckling. The shear capacity continued to decrease through $\gamma_p = 0.105$rad, at which point an overall strength degradation of 38% was observed. The continuum model, on the other hand, exhibited a more stable hysteretic behavior through an inelastic rotation $\gamma_p = 0.065$rad before strength degradation occurred due to the onset of flange buckling. An overall strength degradation of 38% was observed at an inelastic rotation angle $\gamma_p = 0.105$rad, however a majority of this degradation occurred on the last half cycle at $\gamma_p = 0.085$rad. The flange deformations shown in Figure 4 additionally showed discrepancies between the models at common rotation angles. The severity of out of plane flange deformations observed in the shell model were higher than those in the 3D continuum model.

Table 4: Post Buckle Load Difference at Selected Reversals W12x22 Model

γ_p (rad)	S4 Shear (kips)	C3D8 Shear (kips)	% Difference
0.025	100	97	3
0.047	91	99	9
0.075	70	91	23
0.10	63	74	16

(a) 3D Continuum Model (b) Shell Element Model

Figure 4: Deformed Flange Shape Comparison

STRAIN COMPARISON

Although the global behavior was of main interest, the strains in the flanges of the shell and 3D continuum models were also assessed at pre and post buckling rotation angles γ to further quantify differences in post buckling behavior. The ABAQUS cumulative plastic strain variable PEEQ was used for this comparison (Simulia, 2010). Strains were recorded in the top flange half way between the flange edge and web at the termination of the end stiffeners at cyclic reversal points. At this point, out of plane flange deformations were observed. The PEEQ strain in the shell and 3D continuum models is compared in Figure 5.

Flange strains in the shell model were higher than those in the 3D continuum model. The rate of flange strain growth in the shell model increased at a larger rate than the 3D continuum model due to the early onset and severity of flange buckling. The largest strain growth rate difference between the two models was observed after the initiation of flange buckling in the shell model for rotation angles $\gamma > 0.04$rad.

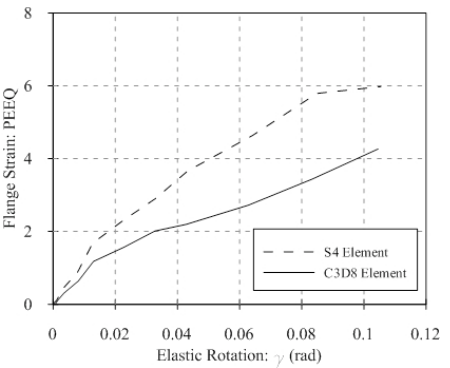


Figure 5: Flange Strain at Reversal Points

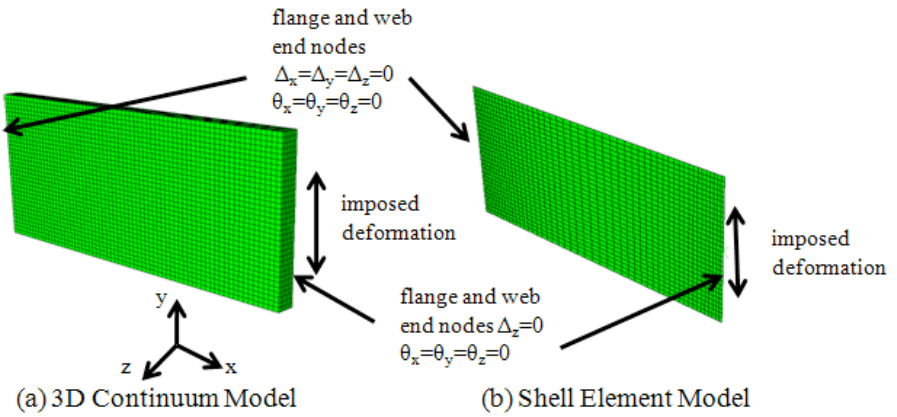
SIMPLIFIED MODEL

In an attempt to isolate the causes of the strength degradation observed in the W12x22 link model, simplified shell and 3D continuum models were created. The models consisted of a 10x5x0.5in cantilever plate subjected to displacement controlled cyclic loading. Three dimensional modeling and material and geometric non-linear behaviors were incorporated. The nodes at one end of the beam were restrained in all directions, while all rotation and transverse displacement was restrained at the other end of the link allowing for longitudinal displacement. Material properties for 316 steel provided in ABAQUS example problem 1.1.8 were used in both models. These properties accounted for both the kinematic and isotropic hardening behaviors of steel (Simulia, 2010). S4 elements were used in the shell model, while C3D8 elements were used in the 3D continuum model. The model overview is illustrated in Figure 6.

Global mesh convergence was conducted by analyzing strain values at selected locations on the beam for both the shell and 3D continuum models. Final mesh convergence in the 3D continuum model yielded three elements across the thickness of the beam. Based on the relative simplicity of the models, the mesh distributions used were much finer than the distributions required by the convergence to ensure accurate results were obtained.



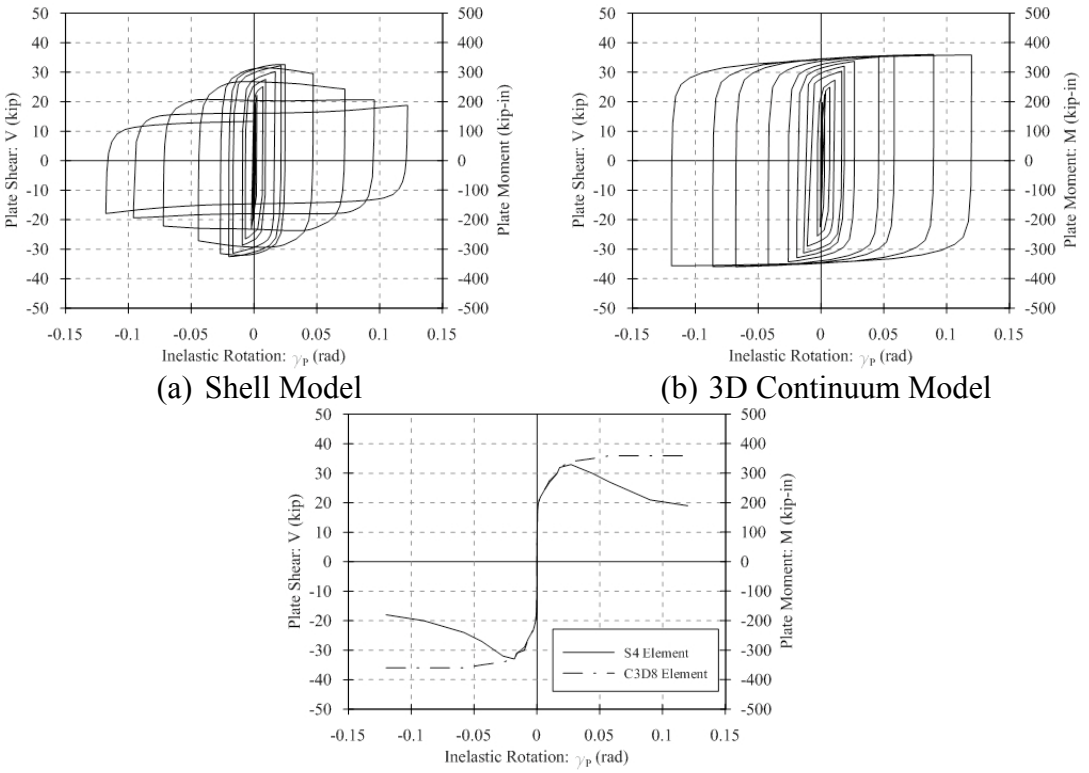


Figure 6: Simplified Model Overview

Cyclic analyses were conducted on the shell and 3D continuum models up to an elastic rotation angle of $\gamma = 0.11$rad. Deformations were imposed on one end of the link, and the linear y-axis deformations were translated to elastic rotation angles γ. The imposed displacement history was reversed cyclic in accordance with the specifications provided in the seismic provisions (AISC, 2005) for links in eccentrically braced frames similar to link models. The cyclic force deformation behaviors and back bone curves for the shell and 3D continuum models are shown in Figure 7, and the maximum loads achieved at target deformations are compared in Table 5.

(a) Shell Model (b) 3D Continuum Model

(c) Back Bone Curves

Figure 7: Hysteretic Behaviors and Back Bone Curve Comparison Simplified Model

Consistent with the results obtained in the full link models, large differences were observed in the hysteretic behaviors of the shell and 3D continuum models. Similar behaviors were recorded for inelastic deformations lower then $\gamma_p = 0.020$rad; however the shell model exhibited large strength degradation and element distortion at higher rotation angles. A stable hysteresis was observed in the shell model through an inelastic rotation angle $\gamma_p = 0.025$rad before strength degradation occurred. An overall strength degradation of 45% was observed at an inelastic rotation $\gamma_p = 0.125$rad. Strength degradation did not occur in the 3D continuum model. The recorded shear capacity of the link continued to increase through an inelastic rotation $\gamma_p = 0.125$rad due to Kinematic and Isotropic hardening effects.

Table 5: Post Buckle Load Difference at Selected Reversals Simplified Model.

γ_p (rad)	S4 Shear (kips)	C3D8 Shear (kips)	Percent Difference
0.025	32	34	5
0.047	30	35	16
0.075	24	36	31
0.098	21	36	43
0.13	19	36	48

EXPERIMENTAL COMPARISON

Experimental data was used to assess the validity of the hysteretic behaviors predicted by the shell and 3D continuum models. An experimental study was conducted by Lewis (2010) to investigate the cyclic performance of W12x22 flexure dominated shear links with intermediate and end stiffeners. The geometry and material properties of the experimental specimen were consistent with the properties used in the shell and 3D continuum models. The link was loaded to failure according the specifications provided in the seismic provisions (AISC, 2005) for links in eccentrically braced frames.

The experimental hysteretic performance of the link was under predicted by the shell model and slightly over predicted by the 3D continuum model. The experimental hysteretic behavior of the link can be seen in Figure 8, and the maximum loads achieved at target deformations are compared in Table 6. Both models accurately predicted the behavior of the shear link in pre buckling deformations through an inelastic rotation angle $\gamma_p = 0.04$rad. The experimental specimen experienced strength degradation for inelastic rotations $\gamma_p > 0.04$rad due to out of plane flange deformation, and an overall strength degradation of 18% was observed before fracture occurred at $\gamma_p = 0.055$rad. For each post flange buckling cycle, the shell and 3D continuum models respectively showed lower and higher shear capacities than were observed in the experimental data. The 3D continuum model, however, more closely predicted the post buckling shear behavior of the link, as the percent difference between the maximum predicted and experimental shear capacities at an inelastic rotation angle $\gamma_p = 0.070$rad were 22% and 2% for the shell and 3D continuum models respectively.

Table 6: Experimental Post Buckling Load Difference at Selected Reversals.

γ_p (rad)	Experimental Shear (kips)	% Difference Shell	% Difference 3D Continuum
0.025	96	5	2
0.047	93	3	6
0.070	89	22	2

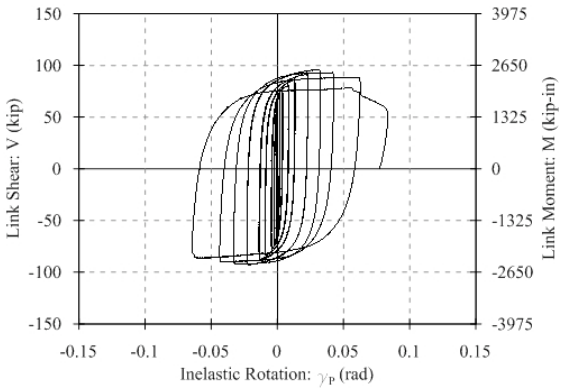

Figure 8: Experimental Hysteretic Behavior of W12x22

CONCLUSIONS

This study presented a comparison between the behavior of a link modeled using shell and 3D continuum elements. The FEA program ABAQUS was used to create shell and 3D continuum models of a W12x22 flexure dominated link with intermediate and end stiffeners. The models were subjected to monotonic and reversed cyclic loading protocols, and the force deformation behaviors were compared. Simplified cantilever beam models were additionally created in an attempt to isolate differences in hysteretic behavior between the shell and 3D continuum models.

The shell and 3D continuum models predicted the same initial link stiffness, but exhibited 11% difference in yield strength when subjected to monotonic and cyclic loading. Similar behaviors were observed between the two models at inelastic deformation angles lower then $\gamma_p = 0.025$rad, however flange buckling developed at lower link deformations in the shell model, and out of plane flange deformations were more severe throughout the cyclic loading protocol. Larger flange strains and strain growth rates were recorded in the shell model due to the relative severity of the flange buckling. Strength degradations were also observed in the simplified shell models. Both the 3D continuum and shell models accurately predicted the experimental hysteretic behavior of the link at low link deformations; however the 3D continuum model more accurately captured the post buckling behavior at large inelastic deformations.

ABSTRACT

Seismic evaluation of one of the most critical bridges in Clark County was performed in this study. The evaluation focused on the performance of the bridge columns under seismic loads in both the transverse and longitudinal directions. The method used for the bridge analysis in this study was the nonlinear static procedure (NSP) introduced by FEMA-356 for the evaluation of buildings. This method was modified to apply on bridges. The acceptance criteria set for the evaluation was the Immediate Occupancy (IO) performance level. Using such performance level was due to the high importance of the bridge and accordingly it is expected to be fully operational after major earthquake events. It was found that deficiencies in bridge performance are attributed to the fact that it was designed and detailed according to older code provisions.

INTRODUCTION

In transportation systems, bridges are vital connective elements. Compared to other highway components, bridges are the most critical components that can be affected by earthquake events. Their damage can severely disrupt the traffic. The resultant disruption from bridge damage by earthquake loads may have a great impact on the economy of the region as well as the post-earthquake emergency response, repair, and reconstruction operations. A large number of bridges were designed and constructed in accordance to older codes. These codes had either no or insufficient seismic design and detailing provisions. In recent earthquakes, a number of bridges did not perform adequately under seismic loads. Despite the fact that they were designed for earthquake resistance, some of them suffered severe damage due to lack of ductility or poor detailing (Priestly *et al.*, 1996).

ANALYSIS PROCEDURES

A pushover analysis is used in this study, the bridge is pushed, using a specific

load pattern, in the direction under consideration until the control node reaches the target displacement. The control node is defined as the node in which its displacement vs. the total base shear creates the pushover curve. The target displacement represents the maximum displacement likely to be experienced by the bridge under the considered earthquake intensity. FEMA-356 (2000) introduced the following equation to calculate the target displacement (δ_t)

$$\delta_t = C_0 C_1 C_2 C_3 S_a \frac{T_e^2}{4\pi^2} g$$

where C_0, C_1, C_2, and C_3 are modification factors to account for different parameters that affect the control node. S_a is the spectral acceleration in (g) corresponding to the effective time period of the bridge (T_e) from the spectral curve.

BRIDGE DESCRIPTION

Bridge G-947 is located at the intersection of the U.S. 95/93 highway (overpass) and both North Main St. and North Casino Center Blvd (underpass). In this study, a segment of the bridge is evaluated. The total length of the studied segment is 255.906 ft, divided into three spans of 79.953 ft, 95.953 ft, and 80 ft long. Figure 1 shows the layout of the whole bridge and the location of the studied part.

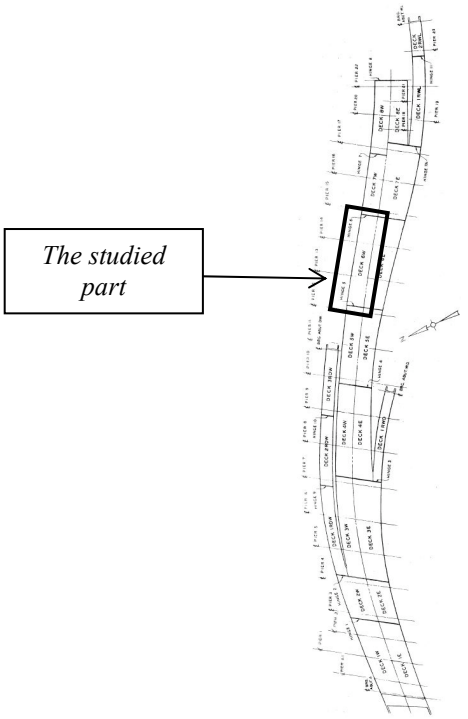

Figure 1 Bridge layout and the location of the studied part

The superstructure of the bridge is a cast-in-place box girder concrete deck that contains five intermediate webs, with a total depth of 5 ft. Each of the bridge

bents in this part of the bridge consists of two columns with integral cap beam in the bridge deck. The cap beam widths are 4.25 ft for pier-13 and 4.50 ft for pier-14.

BRIDGE MODEL

Figure 2 shows the structural model used in the evaluation. A spine model, using frame elements, was developed using SAP2000 with the bridge module. The superstructure was modeled as one element located at the centroid of the deck. Its sectional area is 66.73 ft^2 and the moment of inertias about the Y and Z axes are 259.77 and 11489.19 ft^4, respectively. Where the Y-axis is along the transverse direction and the Z- axis is the vertical axis.

An additional load of 2.067 kip/ft was added to account for the dead load from concrete barriers, pedestrian rails and wearing surfaces overlay. In addition to that, a load of 2.56 kip/ft was added to represent a portion of the live load over the four lanes of the bridge. This portion was chosen to be 25% of the design lane load in the AASHTO (2007) specifications, which is equal to 0.64 kip/ft/lane. All masses were lumped to the nodes. These masses represent the structural components in addition to the aforementioned added loads.

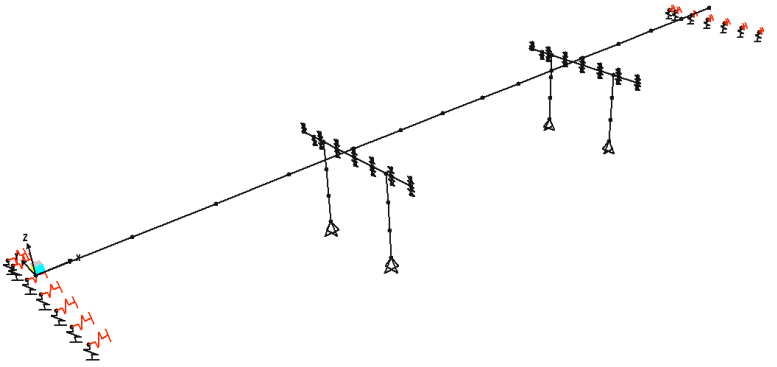

Figure 2 Structural Model using SAP2000

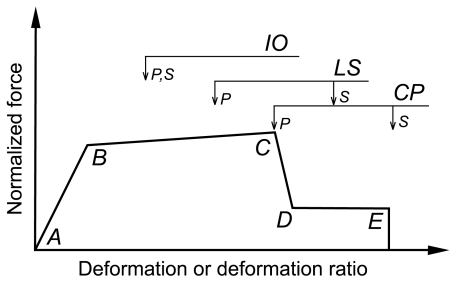
The nonlinearity is represented by the definition of the plastic hinges at the top part of the columns. According to Figure 3, FEMA-356 (2000) specifies the definition of the plastic hinges and the acceptance criteria in different structural members using a generalized load-deformation relationship. This relationship describes the general sequence of stiffness loss of an element. A linear response from "A" to an effective yield at "B" is followed by a linear response at reduced stiffness from "B" to "C", then a sudden reduction in the lateral load resistance to point "D", then response at reduced resistance to "E", and final loss of resistance thereafter (FEMA-356, 2000).



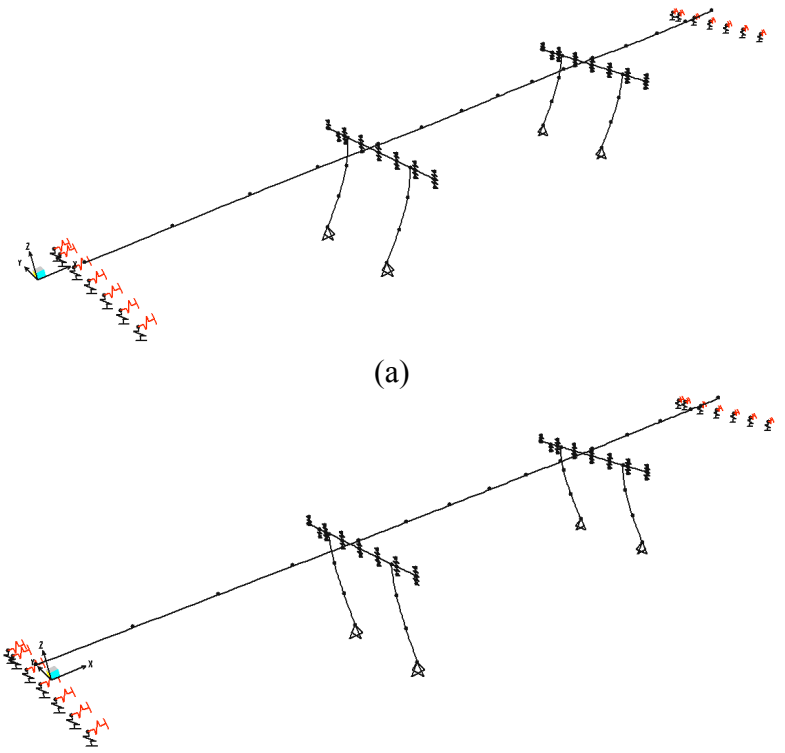


Figure 3. Generalized force-deformation relationship for plastic hinges as defined in FEMA-356 (2000).

MODAL ANALYSIS

Table 1 presents the modal participating mass ratios resulting from the modal analysis of the bridge. It shows that the fundamental modes in the longitudinal and transverse directions are mode-1 and mode-3, respectively. The two mode shapes are illustrated in Figure 4 (a) and (b). The modal participation factors along with the displacements of the control node are used in the calculation of the modification factor "C_0", using the following equation:

$$C_0 = PF \times \phi_{CN}$$

(a)

(b)

Figure 4 The fundamental mode shapes in (a) the longitudinal direction, and (b) the transverse direction of the bridge

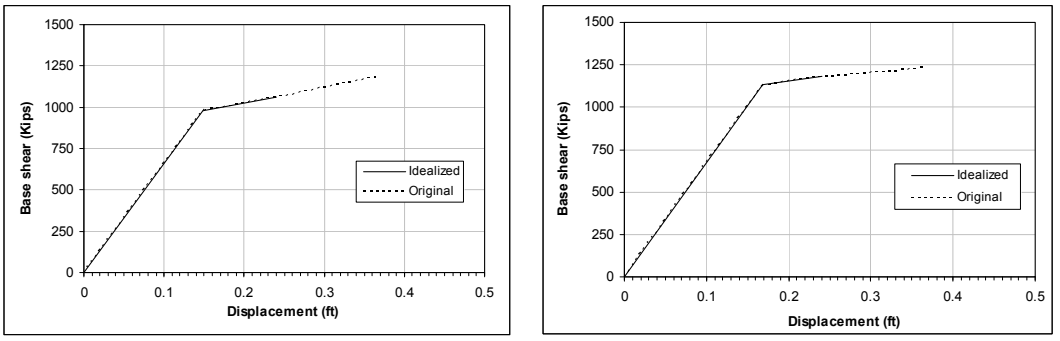

Table 1. Modal participating mass ratios for different modes

Mode	Period (sec)	UX (%)	UY (%)	UZ (%)	Sum UX (%)	Sum UY (%)	Sum UZ (%)
1	1.319	**99.88**	0.00	0.00	99.88	0.00	0.00

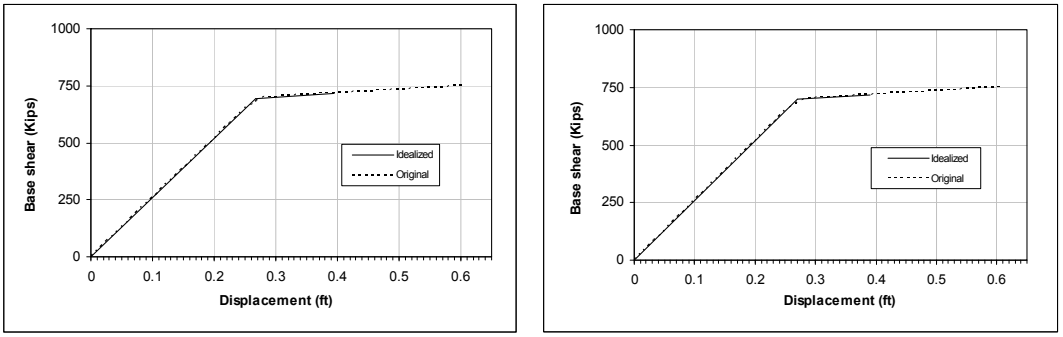
5	0.203	0.00	0.12	0.00	99.94	99.98	0.00
6	0.203	0.06	0.01	0.00	99.99	99.99	0.00

PUSHOVER ANALYSIS



Two load patterns were used in the analysis of the bridge in each of the two principle directions. These load patterns are the "uniform load pattern" and the "modal pattern". The uniform load pattern can be described as a uniform distribution of lateral forces proportional to the distribution of the bridge masses. The modal pattern is a distribution proportional to the deflected shape of the fundamental mode in the direction under consideration. In this case, mode-1 and mode-3 (resulting from the modal analysis) will be used in defining the modal pattern for the longitudinal and the transverse directions, respectively.

Pushover curves were developed based on the four analysis cases and are presented in Figures 5 and 6. The presented pushover curves show that, in all cases, the bridge exceeded the elastic range and plastic hinges were formed.

(a) Uniform load pattern (b) Modal pattern

Figure 5 Pushover curves in the transverse direction using the two load patterns

(a) Uniform load pattern (b) Modal pattern

Figure 6 Pushover curves in the longitudinal direction using the two load patterns

ACCEPTANCE CRITERIA

The acceptance criteria for the plastic hinge rotation values were used. Their values as presented in Table 2. Due to the high importance of the bridge, the acceptance criteria set for the bridge in this study was the immediate occupancy (IO) level. This performance level requires full access to normal traffic immediately following earthquake events.

Table 2 Acceptance criteria for plastic hinge rotations FEMA-356 (2000)

Acceptance Criteria (Performance levels)	Plastic Rotation (radians)
Immediate Occupancy (IO)	0.005
Life Safety (LS)	0.005
Collapse Prevention (CP)	0.01

RESULTS

Plastic hinge rotation values at the target displacements due to different load patterns in the two principle directions were extracted from the analysis results file. When these values are compared with the acceptance criteria for evaluation, about 75% of the plastic hinges violated the acceptance criteria. In the transverse direction, two plastic hinges violated the acceptance criteria in each one of the load patterns. While in the longitudinal direction, all of the plastic hinge rotations in the two load patterns violated the acceptance criteria.

On the other hand, shear force values (demand) on the columns at the target displacements (in all analysis cases) were within the shear capacities of the columns. Accordingly, the design of this bridge is governed by the inadequate development lengths of columns longitudinal reinforcement into the cap beams, and the bridge is at risk of bond slippage at this location under that level of earthquake.

CONCLUSIONS

Evaluation of Bridge G-947 in Clark County, Nevada estimates that the bridge detailing is insufficient to keep it fully operational after a major earthquake event. Using different load patterns in the evaluation process resulted in different values of plastic hinge rotations. Accordingly, it was important to use different load patterns to account for such uncertainty in the behavior of the bridge under lateral loads.

ABSTRACT

Light-gauge steel (LGS) construction is widely used for commercial and industrial buildings. In such construction the wall framing is usually an assembly of cold-formed steel (CFS) studs held between CFS tracks while the floors are normally composite concrete/LGS decks on steel bar joists spanning between load-bearing CFS walls. Heavy hot rolled steel angles or HSS tubes are welded to the top of the CFS load-bearing walls to function as load distribution members (LDM) over the wall studs and as headers over wall openings. The use of hot rolled steel elements results in significant increase in construction cost and time. Such heavy steel elements would be unnecessary if the concrete thickening on top of the CFS wall can be made to act compositely with the CFS track. The resulting concrete/CFS composite beam would be a reinforced concrete beam where the CFS track serves as the tension reinforcement. The continuity at the interface would be provided by stand-off screws that are normally used in the construction of the composite deck.

This research involved experimental and analytical studies to assess the structural performance and failure modes of concrete/CFS track composite beams and to develop optimum beam configurations for use in LGS construction. The parameters included the CFS track thickness, stand-off screw spacing, and stand-off screw configuration. Twenty-seven full-scale specimens were constructed, instrumented, and tested to failure. The flexural and shear strengths, flexural stiffness, and interface shear transfer were investigated. However, only the flexural strength and stiffness are reported in this paper. The results show that concrete/CFS track composite beams can be designed for ductile flexural failure and that the degree of composite action is dependent upon the stand-off screws intensity rather than configuration. Equations for the effective moment of inertia at service loads were derived.

BACKGROUND

Light-gauge steel (LGS) construction is widely used for commercial and industrial buildings. In such construction the wall framing is usually an assembly of cold-formed steel (CFS) studs held between CFS tracks while the floors are normally composite concrete/LGS decks on steel bar joists spanning between load-bearing CFS walls. Heavy hot rolled steel angles or HSS tubes are welded to the top of the CFS load-bearing walls to function as load distribution members (LDM) over the wall studs and as headers over wall openings. Figure 1 shows LGS framing with an HSS tube LDM and header at the top of the CFS wall.

Figure 1. Light-gauge steel framing

The use of hot rolled steel elements results in significant increase in construction cost and time. Such heavy steel elements would be unnecessary if the concrete thickening on top of the CFS wall can be made to act compositely with the CFS track. The resulting concrete/CFS composite beam would be a reinforced concrete beam where the CFS track serves as the tension reinforcement and the track flanges provide resistance to shear. Figure 2 shows the proposed composite beam. The continuity at the interface would be provided by stand-off screws that are normally used in the construction of the composite deck. Figure 3 shows a 2½" long stand-off screw. To the best knowledge of the authors, concrete/CFS composite beams have not been investigated prior to this study.

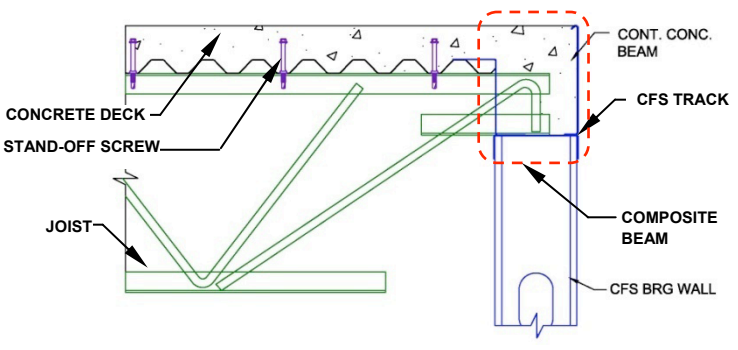

Figure 2. Proposed composite beam

Figure 3. Stand-off Screw

OBJECTIVES AND SCOPE

The main objectives of this study were to assess strength and serviceability of concrete/CFS track composite beams and to develop optimum composite beam configurations for use in LGS construction.

The study comprised both experimental and analytical investigations. Twenty-seven full-scale beam specimens were constructed, instrumented, and tested to failure. The parameters included the CFS track thickness, stand-off screw spacing, stand-off screw configuration, and pour stop engagement. The flexural and shear strengths, flexural stiffness, and interface shear transfer were investigated. However, only the flexural strength and stiffness are reported in this paper.

EXPERIMENTAL WORK

Test Specimens

Five groups of test specimens representing nine different parametric combinations of CFS track thickness, stand-off screw configuration, and engagement of one CFS pour stop were tested. Three identical specimens of each combination were constructed for a total of 27 specimens. The different cross sectional details of the test specimens are shown in Figure 4.

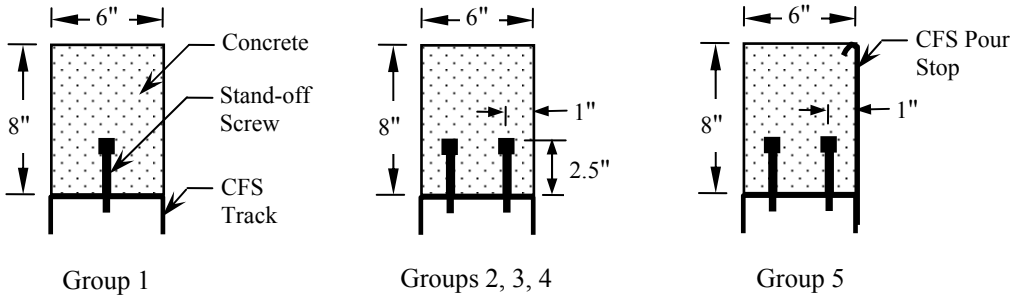

Figure 4. Cross sectional details of the test specimens

Each specimen was 9.75' long and consisted of a 6" wide by 8" deep concrete beam on top of a CFS track. The track web was 6" deep and the track flanges were 2" wide. The concrete section represented the slab thickening on top of a CFS track of a stud wall. Composite action between the CFS track and the concrete was achieved through the use of 2 ½" long by $^{5}/_{16}$" diameter stand-off screw connectors.

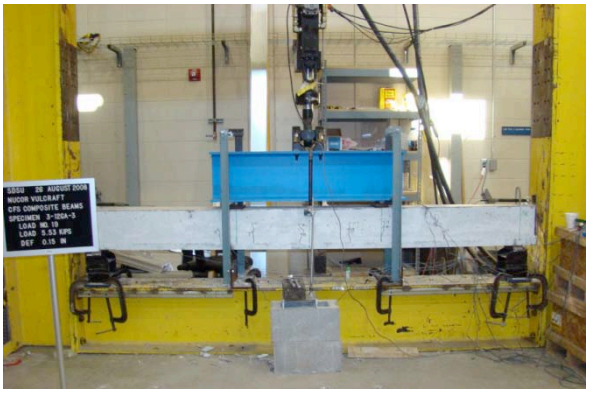
Three track thicknesses, 16-gauge, 14 gauge, and 12-gauge, were selected for this study. According to the Steel Stud Manufacturers Association section designation (SSMA, 2010), the track thicknesses used in this study corresponded to CFS sections 600T200-54, 600T200-68, and 600T200-97, respectively. Specimens in Groups 1 and 2 incorporated all three track sections, while specimens in Groups 3, 4, and 5 incorporated only the 600T200-97 track. The track represented the tension reinforcement in the composite beam section. Considering the given track cross sectional areas and an effective tension reinforcement depth, d, measured to the centroid of the track (d = 8.43"), the tension steel ratio was 0.0112, 0.0141, and 0.0201 for specimens with 16-gauge, 14-gauge, and 12-gauge tracks, respectively. For a concrete strength of 3000 psi and steel yield stress of 50 ksi, the maximum and

minimum steel ratios allowed by the ACI code (ACI, 2008) would be 0.0220 and 0.004, respectively.

The stand-off screws were placed in one row for the specimens in Group 1 and in two rows for the specimens in the other groups. The center-to-center screw spacing along the beam's longitudinal axis was 6" for the specimens in Group 1 and Group 2, 4" for the specimens in Group 3, and 12" for the specimens in Group 4 and Group 5. The CFS pour stops were 14-gauge and were used for specimens of Group 5 only. Table 1 shows a matrix of the test specimens. The specimen identification reflects the group number, track thickness, and specimen number within a parametric combination.

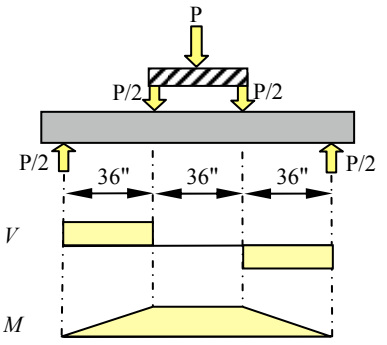
Table 1. Matrix of test specimens

Group	Specimens ID	Track Gauge	Track Thickness (1/1000")	Tension Steel Ratio	Screw Placement	Screw Spacing	Pour Stop
1	1-16GA-1, 2, or 3	16	54	0.0112	1 row	6"	No
	1-14GA-1, 2, or 3	14	68	0.0141			
	1-12GA-1, 2, or 3	12	97	0.0201			
2	2-16GA-1, 2, or 3	16	54	0.0112	2 rows	6"	No
	2-14GA-1, 2, or 3	14	68	0.0141			
	2-12GA-1, 2, or 3	12	97	0.0201			
3	3-12GA-1, 2, or 3	12	97	0.0201	2 rows	4"	No
4	4-12GA-1, 2, or 3	12	97	0.0201	2 rows	12"	No
5	5-12GA-1, 2, or 3	12	97	0.0201	2 rows	12"	Yes



Material Properties

The specified concrete compressive strength was 3000 psi. On the day of testing, the measured compressive strength values varied between 3210 psi and 5100 psi. The measured results are reported in Table 2. The specified yield stresses for the CFS tracks were 42.7 ksi, 47.9 ksi, and 52 ksi for the 12-gauge, 14-gauge, and 16-gauge tracks, respectively. However, coupon testing that was conducted following the completion of the beam specimen testing revealed that the yield stresses of the 12-gauge and the 14-gauge tracks were only 19 ksi and 45 ksi, respectively. The 16-gauge track yield stress was not measured due to lack of coupons from the same heat used to fabricate the tracks. The stand-off screws specified yield stress was 150 ksi.



Instrumentation and Test Setup

Strain in the track was measured using surface mounted strain gauges. The gauges were attached to the track at several locations along all three spans. Strain in the concrete was measured using embedded strain gages placed at 1.5" from the top of the section. The mid-span deflection under the applied load was measured by means of a pair of linear variable differential transducers (LVDT). The slip of the concrete relative to the track was measured at both ends of the specimen by means of LVDTs. More details on the instrumentation are provided by Wehbe (2008).

The beam specimen was simply supported at a span of 9.0'. Two equal point loads were applied at the one-third points by means of a 22-Kip hydraulic actuator and a steel spreader beam. The loading was applied in a displacement-controlled mode until failure. Figure 5 shows the test setup.

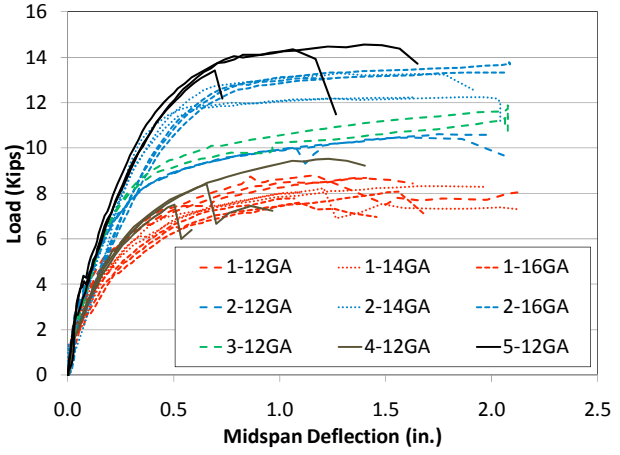
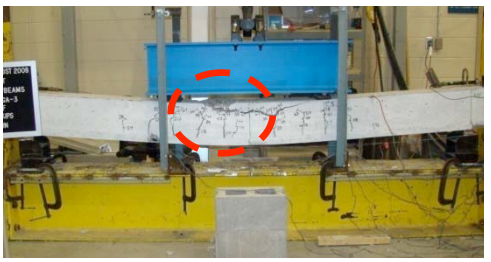
(b) Schematic of the Test Setup

Figure 5. Test Setup

Experimental Results

Overall, the specimens exhibited the same general cracking patterns beginning with initial cracking in the form of pure flexural cracks in the middle span followed by flexural-shear cracks just outside of the middle span. In general, the cracks initiated at locations of stand-off screws. Due to operator error, the loading of Specimen 3-12GA-1 was applied at a high loading rate and the specimen failed immediately after the loading was initiated. Therefore, no data was captured for Specimen 3-12GA-1, but the failure mode was noted. The measured load-deflection relationships are shown in Figure 6.





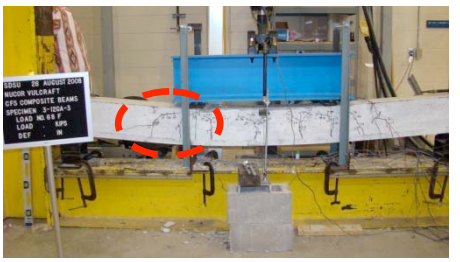


Figure 6. Measured Load-Deflection relationships

The observed failure modes included flexural, shear, and flexural-shear in the concrete section. Specimen 5-12GA-3 failed in a brittle torsional-shear mode as a consequence of the non-symmetric cross sectional stiffness and uneven seating. The observed failure modes are shown in Figure 7. All specimens experienced yielding in the flanges of the track. The yielding extended to the web except in five specimens. In general, the specimens exhibited ductile behavior except for specimens 4-12GA-2, 4-12GA-3, and 5-12GA-3, which failed in shear or torsion. Table 2 shows selected measured results for the tested specimens.

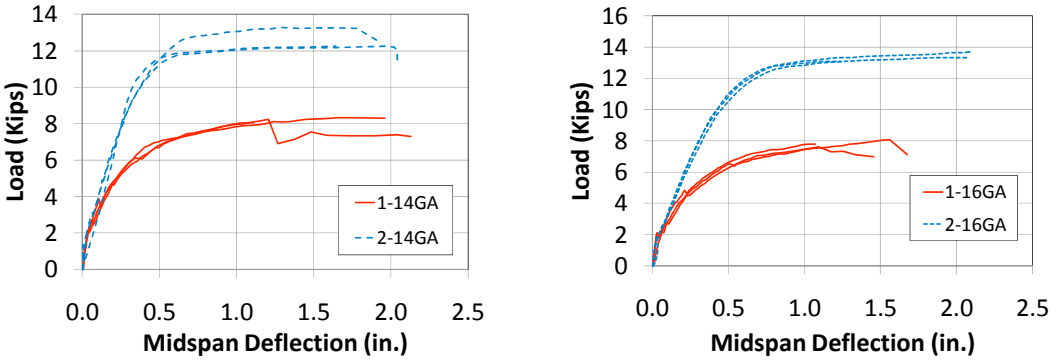
5-12GA-3	4.89	Flexural	3.80	-	13.41	Torsional-Shear

ANALYSIS OF RESULTS

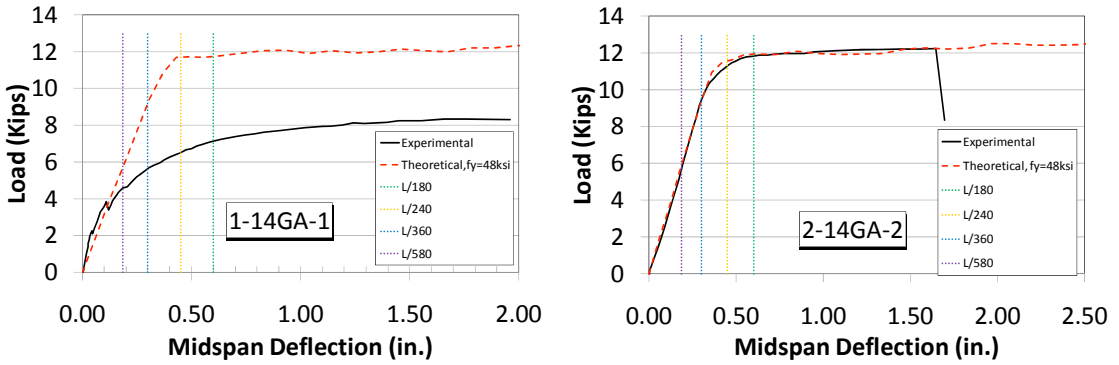


Effect of Stand-Off Screw Density

Relative slip between the concrete and the CFS track was monitored during the test. Table 3 presents the average loads at which the first slip was detected in the specimens of Groups 1 and 2. The results show substantial improvement in composite action when the stand-off screw quantity is increased from 1 screw at 6" to 2 screws at 6".

Table 3. Average load at first relative slip

Track Gauge	Average Load @ 1st Slip (Kips)		Slip Load Ratio (Group 2/Group 1)
	Group 1 (1 screw @ 6")	Group 2 (2 screws @ 6")	
12-Gauge	3.77	5.71	1.37
14-Gauge	3.80	9.50	2.50
16-Gauge	3.33	5.50	1.65



Increasing the stand-off screw density from 1 screw at 6" to 2 screws at 6" also resulted in significant improvement in strength and post-initial cracking stiffness. Figures 7 (a) and 7(b) show measured load-deflection relationships for the 14-gauge and the 16-gauge specimens, respectively. The average strength increased by 53.8% and 72.4% for the 14-gauge and 16-gauge specimens, respectively, and the average effective stiffness, taken at an applied load of 6 Kips, increased by 81.8% and 92.3% for the 14-gauge and 16-gauge specimens, respectively.

(a) 14-gauge, Groups 1 & 2 specimens (b) 16-gauge, Groups 1 & 2 specimens

Figure 7. Comparison of experimental Load-Deflection relationships

Theoretical moment-curvature relationships were used to derive theoretical load-deflection curves. The theoretical moment-curvature relationships were developed using the computer software XTRACT (Imbsen, 2002) and assuming fully composite action. Figure 8 shows theoretical and measured load-deflection relationships for 14-gauge specimens in Groups 1 and 2. Also shown are deflection limits in terms of the span length, L. The results indicate that when the stand-off screw density was 2 screws at 6" (Group 2) or better, slippage was insignificant, the flexural strength was attained, and the theoretical and measured load-deflection relationships were in excellent agreement (Figure 8-b). However, for a stand-off screw density of 1 screw at 6" (Figure 8-a), significant slippage took place and the specimen failed at approximately 33% lower than its theoretical flexural strength.

(a) 14-gauge, Group 1 specimen (b) 14-gauge, Group 2 specimen

Figure 8. Theoretical and experimental load-deflection relationships

Increasing the stand-off screw density from 2 screws at 6" to 2 screws at 4" resulted in nominal increase in strength and stiffness. The average measured strength of Group 3 specimens (2 screws at 4") was approximately 11.7% higher than that of Group 2 specimens (2 screws at 6"). The average effective stiffness, at a load of 6 Kips, of Group 3 specimens was only 3.1% higher than that of Group 2 specimens.

Effect of Stand-Off Screw Configuration

The effect of the stand-off screw configuration was determined by comparing the results of the 12-gauge specimens in Groups 1 and 4. It was found that changing the configuration from one to two rows of screws while maintaining the screw density at 1 screw per foot length had no significant effect on the stiffness of the specimens. The average measured effective stiffness at an applied load of 6 Kips was 21.7 Kip/in and 22.0 Kip/in for the specimens in Groups 1 and 4, respectively.

When 12" screw spacing was used, however, brittle shear failure was observed in two of the three specimens. The shear failure crack in each of the two specimens initiated as a flexure-shear crack that started in an exterior span at the first stand-off screw from the point load. The crack extended vertically along the screw shank, then propagated upward at an inclination towards the point load. Shear failure occurred when the flexural shear crack at the top of the screw suddenly extended in the other direction towards the bottom of concrete as shown in Figure 7(c).

Effect of Track Thickness

Contrary to what was expected, specimens with 12-gauge tracks exhibited lower strength than similar specimens but with 14-gauge and 16-gauge tracks. This was due to the unexpected low yield strength of the 12-gauge tracks. Therefore, no conclusions were made regarding the effect of the track thickness on strength. However, prior to initiation of relative slip, the specimen stiffness would be dependent on the elastic modulus and the cross sectional area of the track. For the same elastic modulus, increasing the track area would cause an increase in stiffness. A comparison among the effective stiffness values at an applied load of 6 Kips is presented in Table 4. The comparison is limited to specimens in Group 2 since the relative slip for that group was negligible at a load of 6 Kips. The results show that

the effective stiffness of the 14-gauge and 16-gauge specimens was 18.8% and 21.5%, respectively, higher than that of the 16-gauge specimens.

Table 4. Average effective stiffness of specimens in Group 2

Track Thickness	Avg. Eff. Stiffness @ Applied Load = 6 Kips (Kip/in)	Stiffness Increase (%)
16-Gauge	27.7	-
14-Gauge	32.9	18.8
12-Gauge	35.3	21.5

Effect of Pour Stop Engagement

The effect of engaging the pour stop was determined by comparing the results of the 12-gauge specimens in Groups 4 and 5. It was found that by engaging the pour stop, the average strength of the test specimens increased by 22.5% while the average effective stiffness at an applied load of 6 Kips increased by 78.9%.

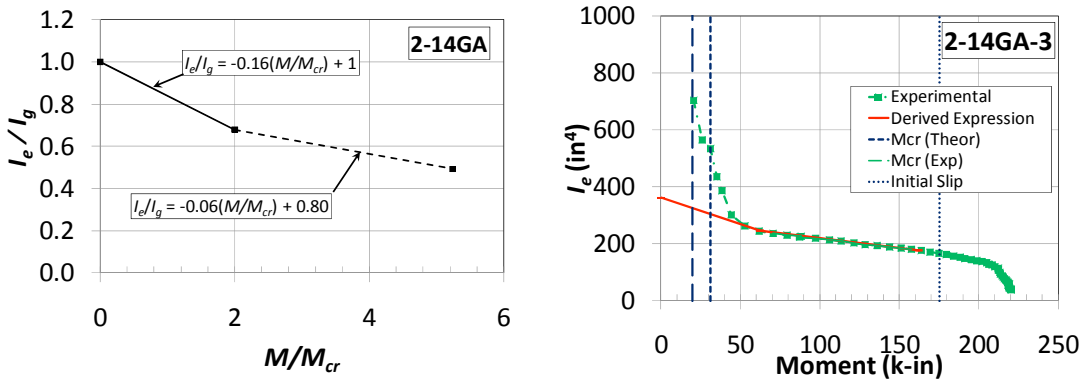
Development of Expressions for the Effective Moment of Inertia

The American Concrete Institute's building code (ACI, 2008) provides an expression (ACI equation 9-8) for determining the effective moment of inertia, I_e, of reinforced concrete members with embedded reinforcement as a function of the applied service load moment. In this study, expressions similar to that of ACI were derived for the composite beams.

The experimental load-deflection results were used to back calculate values for I_e at different applied loads. The elastic modulus of the composite section was assumed to be equal to that of the concrete, E_c, as given by the following ACI expression (ACI, 2008):

$$E_c = 33 w^{1.5} \sqrt{f'_c}$$

where E_c is in psi units, w is the unit weight of concrete in lb/ft^3, and f'_c is the concrete strength in psi. The unit weight of concrete was taken as 145 lb/ft^3.



The data set included in the analysis was limited to the range of data points that were deemed to represent service load levels. The upper limit for the service load was considered to correspond to the measured flexural strength divided by a factor of 1.4. The lower limit for the data set was considered to correspond to twice the theoretical cracking moment, M_{cr}, of the composite section. Cracking of concrete in tension was assumed to correspond to a tensile stress equal to the modulus of rupture, f_r, as given by (ACI, 2008):

$$f_r = 7.5 \sqrt{f'_c}$$

where f_r and f'_c are in psi units.

For applied moments less than $2M_{cr}$, the effective moment of inertia was assumed to vary linearly between an upper value equal to the gross moment of inertia, I_g of the composite section at zero moment and a lower value equal to I_e at $2M_{cr}$. For deflection calculations, the effective moment of inertia at mid-span was adopted for the entire beam length as is permitted by ACI (2008). An averaged best-fit line was derived for the calculated I_e for each group of specimens of identical parameters. Figure 9(a) shows the derived expressions for I_e plotted against the

applied moment, M, for the 14-gauge track specimens in Group 2. In the derived expression, I_e is normalized with respect to I_g, and M is normalized with respect to M_{cr}. The derived expressions for I_e for specimen 2-14GA-3 are compared to the experimental data in Figure 9(b).

(a) Derived expressions for I_e (b) Derived and experimental I_e

Figure 9. Derived expression for I_e for specimens 2-14GA

The derived expressions for I_e for specimens with identical parameters are presented in Table 5. Since the expressions were derived for specific specimen configuration, the applicability of each expression is limited. Therefore, additional analytical work is needed to derive a comprehensive and universal expression to replace all the case-specific expressions shown in Table 5.

Table 5. Derived expressions for I_e

Specimen Configuration	Derived Expressions	
	For $0 \le M \le 2M_{cr}$	For $M > 2M_{cr}$
1-16GA	$\left[-0.24\left(M/M_{cr}\right)+1\right] I_g$	$\left[-0.10\left(M/M_{cr}\right)+0.72\right] I_g$
1-14GA	$\left[-0.25\left(M/M_{cr}\right)+1\right] I_g$	$\left[-0.11\left(M/M_{cr}\right)+0.72\right] I_g$
1-12GA	$\left[-0.20\left(M/M_{cr}\right)+1\right] I_g$	$\left[-0.17\left(M/M_{cr}\right)+0.94\right] I_g$
2-16GA	$\left[-0.24\left(M/M_{cr}\right)+1\right] I_g$	$\left[-0.03\left(M/M_{cr}\right)+0.58\right] I_g$
2-14GA	$\left[-0.16\left(M/M_{cr}\right)+1\right] I_g$	$\left[-0.06\left(M/M_{cr}\right)+0.80\right] I_g$
2-12GA	$\left[-0.12\left(M/M_{cr}\right)+1\right] I_g$	$\left[-0.15\left(M/M_{cr}\right)+1.06\right] I_g$
3-12GA	$\left[-0.25\left(M/M_{cr}\right)+1\right] I_g$	$\left[-0.11\left(M/M_{cr}\right)+0.72\right] I_g$
4-12GA	$\left[-0.27\left(M/M_{cr}\right)+1\right] I_g$	$\left[-0.09\left(M/M_{cr}\right)+0.64\right] I_g$
5-12GA	$\left[-0.09\left(M/M_{cr}\right)+1\right] I_g$	$\left[-0.10\left(M/M_{cr}\right)+1.02\right] I_g$

CONCLUSIONS

Based on the results obtained from this study, the following conclusions are made.

1. Concrete/CFS composite beams can be designed for ductile flexural failure.
2. A stand-off screw density of 1 screw at 6" is not adequate for providing full composite action. Early slip was observed in specimens having 1 screw at 6".
3. An increase in the stand-off screw density from 1 screw at 6" to 2 screws at 6" resulted in significant increase in strength and post-initial cracking stiffness. Good composite action was attained when a density of 2 screws at 6" was used.
4. An increase in the stand-off screw density from 2 screws at 6" to 2 screws at 4" resulted in marginal increase in strength and post-initial cracking stiffness.
5. When premature relative slip is prevented, the flexural response of concrete/CFS composite beams can be predicted with good accuracy.
6. For the same stand-off screw density of 2 screws/foot, the flexural stiffness was practically unchanged when the stand-off screw arrangement was changed from 1 screw at 6" to 2 screws at 12". However, using a stand-off screw spacing of 12" may result in brittle shear failure in the concrete.
7. An increase in the track thickness resulted in an increase in stiffness.
8. Engaging the pour stop in the concrete resulted in significant increase in stiffness and strength.
9. Expressions for the effective moment of inertia of the composite beams at service loads were derived. Additional analytical work is needed to derive a universal expression to replace the case-specific expressions.

ABSTRACT

The use of fibre-reinforced polymer (FRP) composites in civil infrastructure for strengthening and repair applications is becoming more and more widespread. The use of FRP composites for structural members is also gaining popularity. The performance of FRP materials under elevated temperatures is, however, a very real design issue. An accurate understanding of the material properties and behaviour of FRP at such high temperatures are crucial and necessary pieces of information that are surprisingly scarce in the literature. This paper therefore presents the mechanical properties of pultruded carbon fibre-reinforced polymer (CFRP) plates at elevated temperatures. More specifically, CFRP pultruded plate coupons were tested at steady state for temperatures ranging from approximately 20 to 700℃. The tests showed the tensile strength of pultruded CFRP plate to decrease for temperature ranges of 20 to 150℃ and 450 to 706℃. Between these temperature ranges, the tensile strength decreased by a small amount while at 300℃ the ultimate strength was approximately 50 % of the room temperature strength. At the peak temperature of about 700℃, the tensile strength of the FRP plate was as low as 7 % of the room temperature tensile strength.

NOMENCLATURE

E_{normal}= elastic modulus at normal room temperature
T = the temperature of surface of specimen
T_g = the glass transition temperature
$f_{u,T}$=ultimate stress at temperature T℃
$f_{u,normal}$=ultimate stress at normal room temperature (i.e. 22℃)
$\varepsilon_{u,normal}$=strain corresponding to ultimate strength at normal room temperature

INTRODUCTION

Reinforced concrete (RC) infrastructure can be effectively strengthened and repaired with externally bonded fibre-reinforced polymer (FRP) composites or externally mounted post-tensioned FRP tendons and plates. There is an abundance of research related to the experimental validation of these strengthening technologies to RC structural members at room temperature or common operating conditions (e.g. Bank 2006; Hollaway and Teng 2008). There is, however, a distinct lack of research

on the characterisation of FRP construction materials as well as the strengthening of RC structures strengthened with FRP composites at elevated temperatures and fire conditions.

FRP composites consist of fibres embedded in a resin matrix (Hollaway and Teng 2008) and the commonly used carbon and glass fibres can withstand very high temperatures. In the case of carbon fibres this temperature can exceed 2000℃ (Hollaway and Teng 2008). The epoxy used in the resin matrix and also the epoxy used to bond the FRP composite to concrete surfaces can mechanically degrade with increased temperature. Such degradation commences before the glass transition temperature, T_g, is reached and can compromise the ability of the resin matrix to transfer forces amongst the fibres. Another consequence of loss of epoxy integrity is the ability to transfer forces between externally bonded FRP strengthening to the adjacent concrete substrate (Leone et al. 2008). Typically, the T_g can lie in the range of 50 to 90℃ for commercially available products used in civil infrastructure applications (Foster and Bisby 2008). Research on the ability of insulation systems to keep the temperature in the epoxy below critical temperatures for a certain period of time is becoming an active research field (e.g. Kodur et al. 2005; Stratford 2009; Bisby 2003; Hawileh et al. 2009), however, such research is outside the scope of this paper.

Of the limited testing conducted to date on FRP-strengthened RC structural elements such as beams, slabs and columns conducted under elevated temperatures, design guidance has been formulated (Kodur et al. 2007). Such testing (Stratford et al. 2009; Bisby et al. 2005; Gao and Hu 2008; Williams et al. 2008) has considered the behaviour of the entire strengthened member and not the individual materials and components. In addition, such tests were conducted in a transient state manner in which the member was initially loaded and then a fire curve (e.g. Eurocode Part1.2 2002) applied. More recent research (Foster and Bisby 2008) have identified a lack of research and understanding of the mechanical properties of FRP strengthening systems in isolation that are available to the construction industry. This research has also identified a lack of research on the bond between the FRP and the concrete substrate. The work presented in Foster and Bisby (2008) therefore was directed towards enhancing the limited research on the mechanical properties of commercially available FRP materials under elevated temperatures. In their experimental study, they investigated the mechanical properties of FRP bar and plate products under elevated temperatures. To be more precise, Foster and Bisby (2008) conducted tensile coupon tests, single-lap FRP-to-FRP bond tests, direct tension (pull-off) FRP-to-concrete bond tests, and FRP-to-concrete double-lap shear bond tests after exposure to temperatures of up to 400℃. In all tests, the strengths were found to decrease at various rates as the temperatures were increased. While the tests conducted by Foster and Bisby (2008) were focused on post fire behaviour, other researchers such as Eedson et al. (2009) and Chowdhury et al. (2009) have also investigated the behaviour of FRP composite materials for temperatures up to 200℃. Furthermore, Cao et al. (2009) investigated experimentally the tensile properties of CFRP and hybrid FRP sheets at elevated temperatures ranging from 16 to 200℃. They found the strength at elevated temperature to reduce by up to 40 % compared to ambient temperatures. In conclusion, information on the high temperature properties of FRP composites used in civil applications is still quite scarce, especially for the pultruded FRP products which are widely used in civil infrastructure applications.

This paper reports a study on the measurement of the mechanical properties of

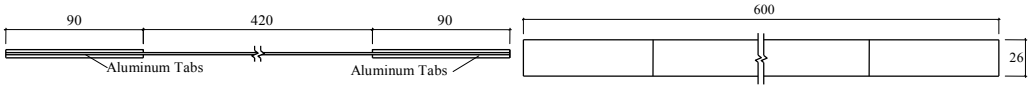
CFRP (herein FRP) pultruded plates at temperatures ranging from room temperature (approximately 22℃) up to high temperatures which may be expected in a fire (i.e. 700℃). Flat coupon specimens were prepared from commercially available pultruded FRP plate and then tested to failure in tension in a universal testing machine. The tests were undertaken in a steady state test mode in which the test specimens were heated to a specified temperature and then tested to failure in tension.

EXPERIMENTAL INVESTIGATION

The tensile tests were conducted in a an MTS 810 universal testing machine of 250 kN capacity and the temperature was applied by a high temperature MTS 653 furnace which was controlled by an MTS 409.83 temperature controller. Figure 1 shows the mounted furnace and furnace controller, as well as the grips of the universal testing machine and an FRP test specimen are shown in Figure 1. The furnace, which was capable of reaching a maximum temperature of 1400℃, gained its heat from six pairs of silicon carbide heating elements arranged in three zones. Three external thermocouples were used to measure the surface temperature of the specimens. In addition, the temperature measured from these thermocouples was considered as the real temperature of the specimens in this paper.

Figure 1. Test setup

In all elevated temperature tests, the specimens were heated to a specified temperature then loaded until failure while the target temperature was maintained. After reaching the desired temperature, times of either 5 or 30 minutes were maintained before loading which allowed the epoxy to undergo physical and chemical changes. After such time, tensile load was then applied to the specimens until failure. During the heating up and holding stages the test specimens were unrestrained (i.e. gripped at one end only) in order to enable thermal expansion. After the holding time had been reached, the grips at the originally ungripped end of the specimen were closed and then the specimens tested (while still under the influence of temperature) to failure. The heating rate of the furnace was 50℃ /min. In addition, the tests were undertaken in a ram displacement control mode at a constant rate of 2 mm/min.



The details of the Sika CarboDur 1214 Pultruded plates used in this study (Sika 2004) are included in Table 1. Tensile coupons were cut to size in the laboratory in accordance with ACI 440.3R-04 (2004) of which the dimensions are shown in Figure 2. An important consideration when testing pultruded FRP plates was to ensure

that rupture failure occurred in the body of the test specimen and away from the grips. For this reason, special attention was given to the design of the grips. Surface roughened aluminium tabs, which provided high contact friction, proved to offer the best gripping due to the ability to prevent crushing of the FRP in the grip region as well as the ability to prevent slippage. The actual cross-sectional dimensions of the test specimens within the centre gauge length region were measured using a micrometer. The measured dimensions were then used to determine the cross sectional-area of each coupon for eventual use in calculating the stress levels.

A total of 31 test coupon specimens were prepared and tested to failure as reported in this paper. The specimens were divided into 2 groups (G1 and G2) as shown in Tables 2 and 3. Group G2 was identical to G1, except for a longer holding time of 30 minutes as compared to 5 minutes for the former.

Table 1. Properties of Sika® CarboDur® Plates 1214 at room temperature (Sika 2004)

[1] SS-50-5-1: SS = Steady State, 50 = target temperature of specimen at failure, 5 = holding time at target tepperature,1 = first specimen in sub-series.

[2] Failure modes described in text

Time effect. The results of Group G2 tests show that the ultimate strength and failure modes for the specimens were almost the same as compared to the corresponding specimens in Group G1. Such results are shown in Figure 3, as well as Tables 2 and 3. The reason for this behaviour was because there was only a small amount of the

epoxy resin matrix in the specimen. It can therefore be concluded that the holding time of 5 minutes was sufficient, and that the prolonged holding time did not affect the tensile strength of the FRP coupons.

Stress-displacement relationships and failure modes. The tensile stress-displacement curves of G1 exhibit temperature dependent features as observed in Figure 4. It is evident that the ultimate strength deteriorated when exposed to elevated temperature. The stress-displacement relationship is essentially linear from room temperature to temperatures as high as 520℃ right up to rupture failure. In addition, for temperatures ranging from 625℃ to the maximum temperature of 706℃, the stress-displacement relationships become non-linear at high stress levels due to loss of fibres from oxidation.

(a) G1-Temperature series, holding time=5 minutes

(b) G2- Time series, holding time=30 min minutes

Figure 3. Typical failure modes of FRP plates

A brief description of all failure modes encountered in all tests is provided in this section. For Groups G1 and G2, the failure photographs are shown in Figures. 3(a) and (b), respectively, while the types of failure modes are listed Tables 2 and 3. Based on the group G1 test specimens shown in Figure 3(a) for increasing temperature, four different failure modes can be defined which are herein referred to as Modes I, II, III and IV. Each of the failure modes are defined in terms of the temperature ranges extracted directly from the test data provided in Tables 2 and 3.

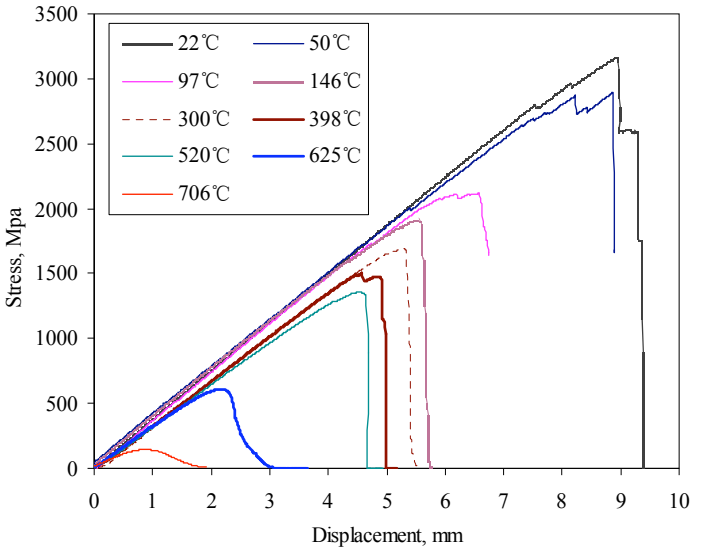

Figure 4. Stress-displacement relationship of G1

Mode I. The temperature of Mode I was relatively low and within the range of 22℃ to 50℃. The specimens failed essentially in a brittle fibre rupture fashion and also simultaneously at different positions along the length of the specimens. The temperature appears to have had little to no effect on the failure mode of these test specimens.

Mode II. For Mode II failing specimens, the rupture position was always within the furnace region. This failure mode occurred between the tested temperature ranges of 97℃ to 308℃. The primary phenomenon for Mode II was softening and gasification of the epoxy resin matrix followed by fibre rupture. Figure 5(a) shows a typical specimen which has failed in a Mode II manner. In this case, part of the epoxy has been lost.

Mode III. From 395℃ to 625℃, the specimens failed in a Mode III manner. In this case, there was no epoxy left on the pultruded FRP plate inside the furnace since the epoxy had self-ignited at about 350℃. Figure 5(b) shows a typical Mode III failed specimen. In this case, the specimen bent freely after the test as all the epoxy had been lost.

(a) Mode II (97℃ to 308℃) (b) Mode III (395℃ to 625℃)

Figure 5. Physical characteristics of the failure mode of types II and III

Mode IV. Mode IV failing specimens endured temperatures from 698 up to 706℃. For such specimens, the epoxy was completely burned and about half of the carbon fibres had oxidised.

Ultimate strength. The reduction factor of the ultimate strength at temperature T to the ultimate strength at room temperature ($f_{u,T}/f_{u,normal}$) at different temperatures is listed in Table 3, and plotted in Figure 6. The vertical axis of Figure 6 represents the strength reduction ratio $f_{u,T}/f_{u,normal}$ and the horizontal axis represents the temperature in degrees Celsius. This figure shows that two large reductions of the failure strength of the test specimens occurred at temperature ranges of 22℃ to 150℃ and 450℃ to 706℃. In addition, there was a gradual reduction in strength and at 300℃ and the ultimate strength of the test specimens reduced to approximately 50% to that of the room temperature strengths. When the temperature rose to around 706℃, the test specimens experienced a significant drop in strength compared with the room temperature strength.

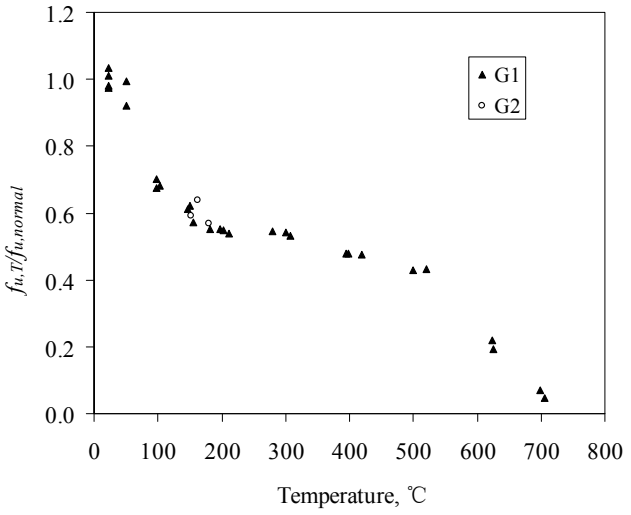

Figure 6. Ultimate plate strength

CONCLUSIONS

This paper has presented the details and results of an experimental investigation on the mechanical properties of pultruded CFRP plates at elevated temperatures ranging from 20 to 700℃ under steady state test conditions. It is important to note here that the results are specific to the type of resin and fibre as well as the fibre volume fraction of the plate tested. The failure modes and ultimate strengths have been discussed in the paper while the stress-displacement relationships have been plotted. The FRP plate was found to ignite when the temperature reached around 350℃ and 600℃. These two self-ignitions were caused by the epoxy matrix transforming into a gaseous state and then by oxidization of the carbon fibres, respectively. Generally, the stress-displacement relation was essentially linear from room temperature to temperatures as high as 520℃. Four different failure modes were

then identified and described, namely (i) rupture of the FRP plate (Mode I), (ii) partial loss of epoxy matrix followed by plate rupture (Mode II), (iii) complete loss of epoxy matrix (Mode III), and (iv) complete loss of epoxy matrix as well as considerable oxidation of the carbon fibres (Mode IV). At a temperature of 300℃, the ultimate strength of the plates reduced to approximately 50% to that of room temperature. In addition, when the temperature rose to around 700℃, the test specimens experienced a significant drop in strength compared to the room temperature strengths.

Inverse Identification of Micromechanics and Fracture Mechanics-Based Damage Evolution Law of Brittle Composites

Shen Shang[1] and Gun Jin Yun[1]

[1]Department of Civil Engineering, The University of Akron, Akron, OH, 44325, USA; ss164@uakron.edu ; gy3@uakron.edu

ABSTRACT

This paper demonstrates identification of parameters associated with damage evolution laws defined in a micromechanics and fracture mechanics-based constitutive model for damage-tolerant brittle composites. A recently developed inverse analysis methodology, called Self-Optimizing Inverse Method (Self-OPTIM), has been extended to the identification of the physics-based damage evolution laws, which has not been achievable. The Self-OPTIM can automatically self-correct the Damage Parameter Set (DPS) based on global in-situ measurements. The material response is obtained from force-driven and displacement-driven nonlinear finite element (FE) simulations. The adopted micromechanics and fracture mechanics-based damage constitutive model can reasonably simulate nucleation and subsequent growth of microcracks within brittle composite materials. It has been implemented within the Self-OPTIM software framework. Numerically simulated synthetic data from an impact tension test are utilized to show successful performance of the proposed damage identification method.

INTRODUCTION

Damage parameter identification techniques and methodologies have received significant attentions in the field of computational damage modeling (Bahloul, 2010; Broggiato and Campana *et al.*, 2007; Celentano and Chaboche, 2007; Cuesta and Alegre *et al.*, 2010; Franulovic and Basan *et al.*, 2010; Hambli, 2002; Munoz-Rojas and Cardoso *et al.*, 2010; Perie and Leclerc *et al.*, 2009). Objectives of the identification of physical damage parameters of materials are two-fold: 1) accessing current damage state of the material to determine the damage initiation; 2) predicting evolutionary behavior of the damage to provide critical information for design of materials.

A strain-rate dependent, micromechanics and fracture mechanics based damage model for brittle materials is adopted in this paper; the model is originated from a micromechanical material model called Statistical CRAck Mechanics (SCRAM) which accounts for opening, shear, growth, and coalescence of an ensemble of cracks (Dienes, 1983). Addessio and Johnson proposed an isotropic constitutive model (ISO-SCRAM) for the inelastic behavior of brittle materials based on the SCRAM (Addessio and Johnson, 1990). Their model is a simplification of SCRAM suitable for predicting the dynamic response of brittle materials under nearly isotropic microcrack distribution. Two different isotropic damage surfaces were used to determine the critical mean crack size for tension and compression cases. In their modeling, the microcrack nucleation rate was expressed as an exponential function of the mean stress as in Reference (Seaman and Curran *et al.*, 1976). Later, a two-step sequential damage model including crack nucleation and crack growth is developed to simulate the crushing behavior of damage-tolerant brittle composite (Lee and Shin, 2003). The constitutive relation and damage evolution law introduced in Reference (Lee and Shin, 2003) is adopted in this paper.

As the damage model is derived in the microscale, identifications of the damage parameters by direct observations need expensive measuring apparatus and complex measurement techniques which challenge the role of numerical simulation (Lauro and Bennani *et al.*, 2001). Most of existing inverse parameter estimation methods has applied optimization techniques which minimize objective functions expressed as differences between the responses from finite element (FE) simulations and measured experimental test data. The objective functions are expressed in terms of the local stress and strain information which only represents the material characteristic on a certain small region of the specimen due to the experiment technique (Celentano and Chaboche, 2007; Franulovic and Basan *et al.*, 2010; Hambli, 2002). Later, the

difference of global displacements (Lauro and Bennani *et al.*, 2001; Xiang and Swoboda *et al.*, 2002), both global displacement and force (Abendroth and Kuna, 2006), and modal characteristics i.e. natural frequencies and/or mode shapes (Friswell, 2007; Singh, 2009) were also implemented into the objective function. In order to improve the performance of the inverse identification technique, micro-scale experimental data (local crack behavior) was applied (Corigliano and Mariani, 2001; Iacono and Sluys *et al.*, 2006). Recently emerging techniques using optical full-field displacement measurements have greatly enhanced performance of the inverse parameters identifications by providing enriched information on deformational characteristics (Grediac and Pierron, 2006; Latourte and Chrysochoos *et al.*, 2008). Furthermore, the displacement fields extracted from the 2D planar based on Digital Image Correlation (DIC) technique were used to the identification of the damage law (Perie and Leclerc *et al.*, 2009). For facilitating use of artificial neural network (ANN)-based material constitutive models, an innovative on-line training methodology, called autoprogressive training, was developed by Ghaboussi, et al. (Ghaboussi and Pecknold *et al.*, 1998). Using their method, ANN material models could be trained by applying only in-site measured global forces and displacements.

In this paper, significant technology advancement in the field of inverse nonlinear constitutive and damage parameter identification has been made by applying the newly developed Self-Optimizing Inverse Method (Self-OPTIM). Unlike other existing inverse parameter identification methods, Self-OPTIM does not need premeasured local reference (i.e. true) stresses and strains in the objective function. Instead, only global boundary force and displacement responses that can readily be measured using conventional sensing techniques are required. It was successfully applied to estimate the cyclic elasto-plastic constitutive model parameters (Yun and Shang, 2010). In the following sections, brief descriptions about the theoretical formulation of the damage model for brittle composite and Self-OPTIM will be recapitulated. In addition, the verification with synthetic data will be carried out to investigate the capacity of the Self-OPTIM method for inverse identification of damage evolution laws of damage-tolerant brittle materials.

RECAPITULATION OF A DAMAGE MODEL FOR BRITTLE COMPOSITE

The composite material used in this paper is assumed to be brittle with isotropic distribution of microcracks. The micromechanics and fracture mechanics-based damage model considers two sequential damage processes: 1) the nucleation of microcracks and 2) the crack growth. The damaged state ω is described as a function

of the physical parameters, that is, the number of microcracks per unit volume (N) and the average size of microcracks $\bar{c}$ as follows (Krajcinovic, 1996)

$$\omega = N\bar{c}^3 \tag{1}$$

Nucleation of Microcracks. When the material reaches an initial damage stage, the crack nucleation will happen. The microcrack nucleation model following the exponential rate equation is presented as (Seaman and Curran et al., 1976)

$$\dot{N} = \begin{cases} \dot{N}_0 \exp\left[\dfrac{(P_s - P_{n0})}{P_1}\right], & P_s > P_{n0} \\ 0, & P_s \le P_{n0} \end{cases} \tag{2}$$

where $\dot{N}_0$ and P_1 are experimentally determined material parameters; P_{n0} designates a threshold stress for the nucleation of microcracks; and P_s is the hydrostatic pressure in the solid material and can be calculated as $P_s = \sigma_{kk}/3$ (Seaman and Curran *et al.*, 1976). An incremental form for a numerical approximation of Eq. (2) by the backward Euler integration scheme can be written as (Lee and Shin, 2003)

$$N_{n+1} = N_n + \Delta t_{n+1}\dot{N}_0 \cdot \exp\left[\frac{(P_s)_{n+1} - P_{n0}}{P_1}\right] \tag{3}$$

Crack Growth Criteria. After further nucleation of microcracks stops, microcracks start to grow. The rate of crack growth is assumed to be a function of overstress, i.e., the distance in the stress space between the current stress and the damage surface. For a stress state that exceeds the current damage threshold, microcracks grow. Two different damage surfaces based on the energy balance of isolated cracks are defined for tension and compression (Addessio and Johnson, 1990). The damage surface for tension case (p~~p~~<0) is expressed as (Addessio and Johnson, 1990)

$$F^n(S_{ij}, p, \bar{c}) = \frac{3}{2}S_{ij}S_{ij} + \frac{45}{4(5-\nu_0)}\left[(2-\nu_0)p^2 - \frac{2K}{\bar{c}}\right] = 0 \tag{4}$$

The damage surface for compression case (p>0) is expressed as (Addessio and Johnson, 1990)

$$F^n(S_{ij}, p, \bar{c}) = \frac{3}{2}S_{ij}S_{ij} - \frac{45}{2(3-2\nu_0^2)}\left[\left(\mu_{fr}p + \sigma_0\right)\left(\mu_{fr}p + \sigma_0 + \sqrt{\frac{\pi K}{\bar{c}}}\right) + \frac{K}{\bar{c}}\right] = 0 \tag{5}$$

where p=-σ_{kk} /3, S_{ij} is the deviatoric stress, σ_0 is the cohesive stress, $_{rf}$ is the coefficient of friction, and K is defined as (Addessio and Johnson, 1990)

$$K = \frac{\pi}{2}\left(\frac{2-\nu_0}{1-\nu_0}\right)K_{IC}G_0 \tag{6}$$

where ν_0 and G_0 are the Possion's ratio and shear modulus of the brittle solids. In addition, K_{IC} is the plane strain fracture toughness.

Rate of Crack Growth. If the state of stress is within the damage surface, the deformation is elastic and no change is made in the mean crack size. If, however, the state of stress is outside the damage surface, then the mean crack size will increase and be determined by integration of the rate of crack growth (Addessio and Johnson, 1990)

$$\dot{\bar{c}} = \beta \dot{c}_{\max} \tanh(d_s) \tag{7}$$

where $\dot{c}_{\max}$ is the shear wave speed ($\dot{c}_{\max} = \sqrt{E^*/\rho^*}$), E* and ρ* are the overall Young's modulus and the density, respectively. β is the scaling factor for crack speed and assumed to be an independent constant, d_s is the measure of the distance the amount by which the state of stress exceeds the damage surface (Addessio and Johnson, 1990)

$$d_s = \frac{3}{2}S_{ij}S_{ij} - F_d \tag{8}$$

in which

$$F_d = \begin{cases} -\dfrac{45}{4(5-\nu_0)}\left[(2-\nu_0)p^2 - \dfrac{2K}{\bar{c}}\right], & p < 0 \\ \dfrac{45}{2(3-2\nu_0^2)}\left[\left(\mu_{fr}p + \sigma_0\right)\left(\mu_{fr}p + \sigma_0 + \sqrt{\dfrac{\pi K}{\bar{c}}}\right) + \dfrac{K}{\bar{c}}\right], & p > 0 \end{cases} \tag{9}$$

The rate equation can be expressed in an incremental form as (Lee and Shin, 2003)

$$\bar{c}_{n+1} = \bar{c}_n + \beta \Delta t_{n+1}\sqrt{\frac{(E^*)_{n+1}}{(\rho^*)_{n+1}}}\tanh(d_s) \tag{10}$$

The effective modulus which is a function of the damage state ω is formulated by using the self-consistent method and differential scheme (Lee and Simunovic, 2006). This micromechanics and fracture mechanics-based damage model was implemented

into the ABAQUS user defined material (UMAT) which accounts for the two-dimensional plane-stress state. The detail formulation can be found in the series research work (Lee and Shin, 2004; Lee and Simunovic, 2006; Lee and Simunovic *et al.*, 2004).

SELF-OPTIMIZING INVERSE METHOD (Self-OPTIM)

A unique capability of the proposed Self-OPTIM method is that it can identify damage related parameters only from global forces and displacements on a partial boundary of tested specimens measured during experimental testing. Details on theoretical fundamentals of the Self-OPTIM methodology can be referred to Reference (Yun and Shang, 2010).

Figure 1 shows a schematic diagram of computational procedures of the proposed Self-OPTIM method.

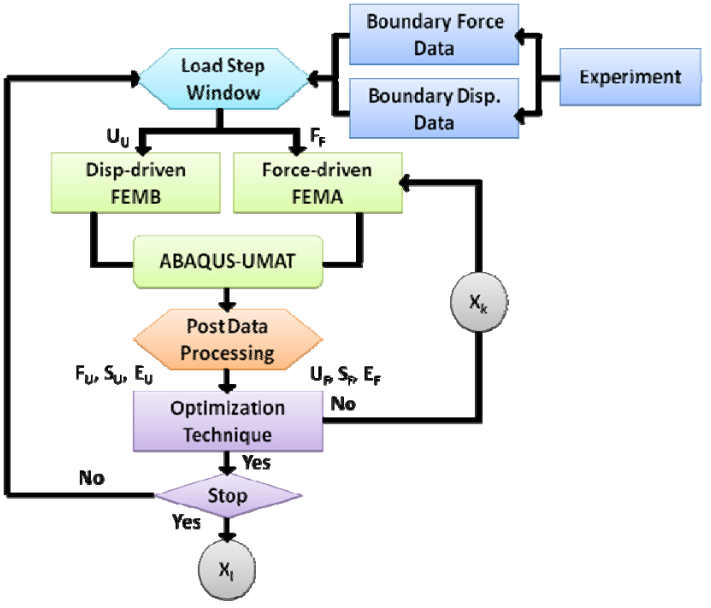

Figure 1 Flowchart of Self-OPTIM Inverse Analysis Method

At the first step, global force and displacement data on the partial boundary are measured from experimental testing. At the second step, an equilibrium path is selected in order to determine the number of load steps and boundary control data used in the identification algorithm. As the third step, these boundary force and displacement data are imposed to the force-controlled nonlinear finite element analysis (FEMA) and the displacement-controlled nonlinear finite element analysis (FEMB), respectively. The two different nonlinear FE simulations are conducted using the UMAT with the updated parameter set under the boundary control data

generated at the second step. At the fourth step, a post processing of FE analyses results automatically extracts two sets of stress and strain data ($\boldsymbol{S}_U$, $\boldsymbol{E}_U$, $\boldsymbol{S}_F$, $\boldsymbol{E}_F$,) at Gauss integration points within the specified elements and two sets of displacement and force data ($\boldsymbol{U}_U$, $\boldsymbol{F}_U$, $\boldsymbol{U}_F$, $\boldsymbol{F}_F$,) of the boundary nodal points from the *.fil* file by using the ABAQUS utility routine *posfil.for*. These steps ranging from Step 1 to Step 4 are repeated under the steady-state genetic algorithm (SSGA). At each generation, the better Damage Parameter Set (DPS) are sought following the SSGA global searching algorithm.

The proposed Self-OPTIM method uses an implicit-explicit objective function defined as a function of the two sets of stresses ($\boldsymbol{S}_{\mathrm{U}}$ and $\boldsymbol{S}_{\mathrm{F}}$), strains ($\boldsymbol{E}_{\mathrm{U}}$ and $\boldsymbol{E}_{\mathrm{F}}$), displacements($\boldsymbol{U}_{\mathrm{U}}$ and $\boldsymbol{U}_{\mathrm{F}}$), and forces ($\boldsymbol{F}_{\mathrm{U}}$ and $\boldsymbol{F}_{\mathrm{F}}$).

$$
\begin{aligned}
OF_{implicit-\exp licit} = {} & W_1 \cdot \sum_{k=1}^{LS}\left[1-\frac{\left\|\sum_{i=1}^{GP}\mathbf{S}_{iU}^{k}\right\|}{\left\|\sum_{i=1}^{GP}\mathbf{S}_{iF}^{k}\right\|}\right]^2 + W_2 \cdot \sum_{k=1}^{LS}\left[1-\frac{\left\|\sum_{i=1}^{GP}\mathbf{E}_{iF}^{k}\right\|}{\left\|\sum_{i=1}^{GP}\mathbf{E}_{iU}^{k}\right\|}\right]^2 \\
& + W_3 \cdot \sum_{k=1}^{LS}\left[1-\frac{\left\|\sum_{i=1}^{NP}\mathbf{U}_{iF}^{k}\right\|}{\left\|\sum_{i=1}^{NP}\mathbf{U}_{iU}^{k}\right\|}\right]^2 + W_4 \cdot \sum_{k=1}^{LS}\left[1-\frac{\left\|\sum_{i=1}^{NP}\mathbf{F}_{iU}^{k}\right\|}{\left\|\sum_{i=1}^{NP}\mathbf{F}_{iF}^{k}\right\|}\right]^2
\end{aligned}
\tag{11}
$$

where W_1, W_2, W_3, and W_4 are weight factors whose values indicate the relative importance of one term compared to the others (Rao, 2009); $\|\cdot\|$ indicates the Euclidean norm; *LS* indicates the number of load steps in current load step window; *GP* indicates the total number of Gauss points in current finite element mesh; *NP* indicates the total number of boundary nodal points. The objective function in Eq. (11) contains implicit full-field stress/strain data and explicit force/displacement data. Fundamentally, the proposed implicit-explicit objective function and updating approach is different from existing model updating techniques which mostly employ explicit data from in-situ measurements or laboratory testing observations. The capacity of the Self-OPTIM method will be verified numerically in the following section.

VERIFICATION WITH SYNTHETIC DATA

A finite element model for a specimen from an impact tension test (Xia and Wang, 1996) is used in this verification test. Using symmetry boundary conditions, only

quarter part of the specimen (6 mm × 4 mm) was modeled by 3mm × 2mm coupon. Both the left and the bottom boundary are constrained on their normal direction. The density, bulk, and shear moduli of the material are used to be known, that is, density ρ=1403 kg/m^3, bulk modulus K=14.02 GPa, and shear modulus =6.28 GPa. The boundary displacement and force data are generated from a displacement-driven simulation with the reference DPS $\boldsymbol{x}_T$=[$\bar{c}_0$ =0.014cm, N_0=1x10^5/cm^3, γ=10 Pa·m, β=1.0x10^{-5}, $\dot{N}_0$ =1x10^5/s/cm^3, P_{n0}=5 MPa, P_1=10 MPa]. Although static analysis is conducted, the rate effect is considered within UMAT by setting the constant time increment Δt in each load step. Thus, the strain rate can be calculated as $\dot{\varepsilon} = \Delta\varepsilon / \Delta t$. The total strain, 0.1, is caused by 200 load steps deformation with the time increment Δt=0.005 s. Therefore, $\dot{\varepsilon}$ =$\Delta\varepsilon/\Delta t$=($\varepsilon^{tol}$/n)/$\Delta t$ =10 s^{-1}. This numerical example is utilized as a reference simulation in the following subsection.

Damage Identification by Self-OPTIM. The steady state genetic algorithm (SSGA) is employed in the Self-OPTIM inverse identification. The preset upper and lower bounds of the DPS are selected ensuring that the randomly selected DPS is permissible for the problem. Even if the SSGA evaluates the objective function only for the two best DPSs in each generation, it is known to converge substantially faster than traditional GA algorithms with comparable searching performance (Yun and Caicedo, 2010).

Table 1 Identification Results by Self-OPTIM

	$\bar{C}_0$ (cm)	N_0 (/cm^3)	γ (Pa m)	β	$\dot{N}_0$ (/s/cm^3)	P_{n0} (MPa)	P_1 (MPa)
$\boldsymbol{x}_T$	0.014	1.00x10^5	10.00	1.00x10^{-5}	1.00x10^5	5.00	10.00
$\boldsymbol{x}_U$	0.018	1.30x10^5	12.00	1.40x10^{-5}	1.30x10^5	7.00	13.00
$\boldsymbol{x}_L$	0.010	0.60x10^5	8.00	0.60x10^{-5}	0.7x10^5	4.00	8.00
$\boldsymbol{x}_I$	0.0143	1.04x10^5	9.50	0.97x10^{-5}	0.85x10^5	4.57	9.71
Initial Error	28.57	30.00	20.00	40.00	30.00	40.00	30.00
	-28.57	-40.00	-20.00	-40.00	-30.00	-20.00	-20.00
Final Error	2.14	4.00	5.32	3.00	15.00	8.60	2.90

In this example, the preset upper and lower bounds of the damage model parameters are assumed have a large initial difference from the true DPS. The algorithm is terminated at 6000th generation. In each generation of the SSGA, a 90% crossover rate and a 30% mutation rate were used. The identification results are summarized in Table 1. All damage evolution related parameters are calibrated accurately except the nucleation rate $\dot{N}_0$. The reason is for a minor role of the nucleation rate in the damage evolution. The number of the microcracks increased only in a small region at the early deformation stage and kept the same state until the end of load steps. Successful identification of the initial mean radius ($\bar{c}_0$) and initial density (N_0) of microcracks implies potential capabilities of the proposed Self-OPTIM method for initial statistical damage assessment, that is, material quality assurance.

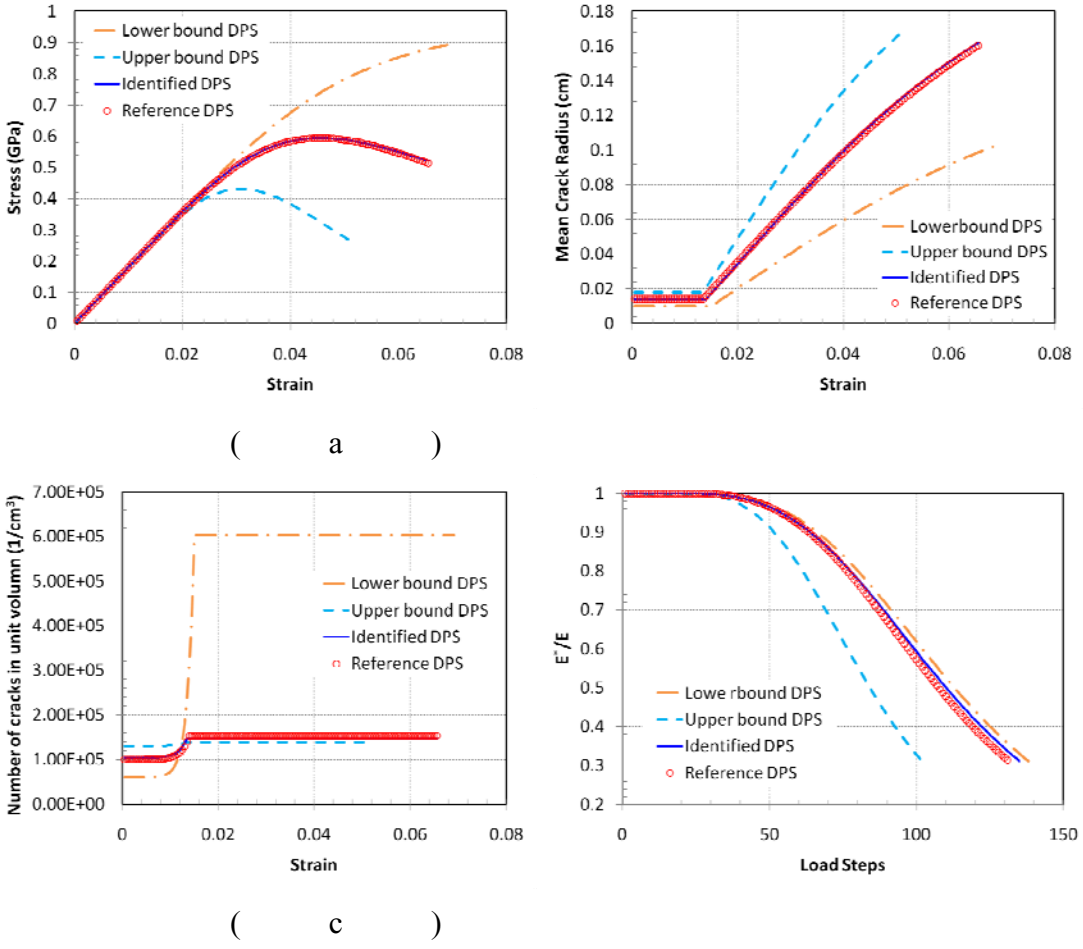

Figure 2 Comparisons of (a) the stress-strain response, (b) the mean crack radius growth and (c) the microcrack nucleation and (d) the degradation of the normalized overall Young's modulus between simulations using the upper bound DPS, lower bound DPS, identified DPS and reference DPS.

The identified response and damage behavior are compared with the result from simulations using the upper and lower bounds DPS, that is, $\boldsymbol{x}_U$, and $\boldsymbol{x}_L$. They are shown in Figure 2. Obviously, the stress-strain response is consistent with the reference. Damage evolution laws could be successfully identified by estimating its associated damage parameters.

CONCLUSIONS

In this paper, a novel method for inverse identification of damage evolution laws of damage-tolerant brittle materials has been proposed. A newly developed model-independent optimization framework, called Self-OPTIM, is combined with a damage model. In the damage model, two independent nonlinear damage modes: 1) nucleation and 2) growth of microcracks, contribute to the degradation of the stiffness. The damage model has limitations in parameter estimations due to its large number of parameters and difficulties in experimental observations. Nevertheless, the Self-OPTIM framework is still capable of finishing the inverse identification problem successfully with an acceptable DPS which reconstructs the global damage behavior consistently as the reference. The progressive damage characteristics in micro-scale are obtained even though Self-OPTIM just used the global boundary displacement and force data which can be easily acquired from the conventional material test.

ABSTRACT

Effects of beam growth in progressive collapse resistance of an actual eleven-story reinforced concrete structure are evaluated following predefined initial damage. The initial damage was caused in part by simultaneous explosion (removal) of four adjacent columns, two of which were exterior columns. In addition to the removal of these columns, two beam sections were also exploded. The structure resisted progressive collapse following such severe initial damage. An analytical model of the structure accounting for the interaction between the axial and flexural deformations is developed to study progressive collapse resisting mechanisms. The analytical results show good agreement with experimental data. The main progressive collapse resisting mechanism was the flexural-axial interaction of the second floor deep beams. The Vierendeel frame action of the floors above also contributed to collapse resistance.

INTRODUCTION

Through manmade hazards (accident or act of terrorism), or natural hazards, structures may be subject to conditions that lead to progressive collapse. Progressive collapse is defined as the spread of an initial local failure from element to element, eventually resulting in the collapse of an entire structure or a disproportionately large part of it (ASCE/SEI 7, 2010). Redistribution of loads following an imposed local damage to a structure depends on strength, continuity, redundancy, and deformation and energy dissipation capacities of the structure. From an analytical point of view, progressive collapse occurs when following loss of some structural elements, the structure has its load pattern or boundary conditions changed such that other structural elements are loaded beyond their capacity and fail (Krauthammer et al., 2003).

The Ronan Point apartment building collapse in England, 1968 generated substantial interest in general structural integrity for buildings and the prevention of progressive collapse. A second wave of interest followed the attack on the Murrah Federal building in 1995 and the terrorist attacks on the World Trade Center Towers

and the Pentagon on September 11, 2001. Progressive collapse is by nature a system-level problem where the spread of an initial local failure from element to element eventually results in the collapse of an entire structure or a disproportionately large part of it (ASCE/SEI 7, 2010).

One approach to evaluate progressive collapse of structures is to study the effects of instantaneous removal of a load-bearing element such as a column (GSA, 2003 and DOD 2010). GSA (2003) provides guidelines for progressive collapse analysis of structures based on the alternative path method and mandates instantaneous removal of one load-bearing element with different scenarios as the initiation of damage. DOD (2010) also provides two design methods: one employs the tie force method (indirect design) and the other employs the alternative path method (direct design) under initial damage scenarios in general similar to those of the GSA (2003), that is removal of one load bearing element and evaluating potential progressive collapse of the structure. The level of initial damage in many recent cases of terrorist attacks, however, was by far more significant than removal of one load bearing element. In this study, the progressive collapse resistance of a reinforced concrete structure with discontinuous columns on the floors above, subjected to a severe initial damage is studied experimentally and analytically. The initial damage was set to represent the effects of a severe explosion causing simultaneous loss of four adjacent columns and two beam segments.

BUILDING CHARACTERISTICS

This paper evaluates the progressive collapse resistance of the Crowne Plaza hotel, which was an 11-story structure above the ground located in Houston, TX. The hotel was demolished by implosion after the experiment was concluded. Figure 1 shows a view of the hotel, which had an ordinary reinforced concrete structure. The height of the first story was about 9.14 m. The height of the stories above was 3.05 m. Figure 2 shows the plan of the second floor of the structure. Crosses in the figure show the location of the exploded columns and beam segments. The second floor was a 0.15 m thick two-way slab system supported by 2.057 m deep beams running in both longitudinal and transverse directions. The width of all the longitudinal beams was 0.914 m. The width of transverse beams between axes 3 to 8 was 1.372 m. The cross section of the columns in the first floor between axes 4 to 7 was 0.914 m x 0.914 m. All the columns of floors above were sitting on the longitudinal beams in second floor. The stories above were made of 0.15 m thick two way flat slabs supported by columns. Column dimensions were 0.279 m in the longitudinal and 0.330 m to 0.406 m in the

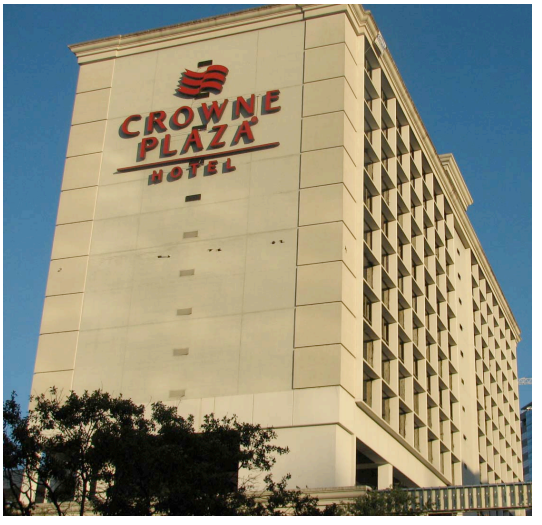

Fig. 1 - View of Crown Plaza Hotel

transverse direction of the structure. The columns on the first floor were spaced at about 9.576 m, while the columns on the floors above were spaced 3.988 m longitudinal direction. This means the columns on the floors above were not continuous to the ground and were supported by the longitudinal beams of the second floor. The structure had an elevator case at the central part of the building and two stair cases at two corners.

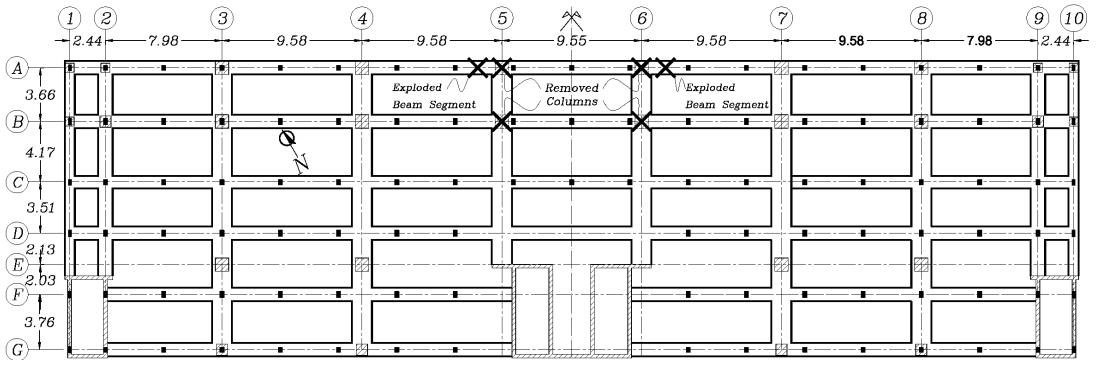

Fig. 2 - Plan of second floor

Compression and tension tests on concrete samples and tension tests on steel samples from the building were conducted. the concrete compressive strength was measured at f'_c= 26.9 MPa for a standard concrete cylinder. The modulus of rupture was determined to be about f_r= 3.4 MPa. The modulus of elasticity of concrete was estimated at 24800 MPa. The yield and ultimate stresses for beam and slab flexural reinforcement were found to be f_y= 517 MPa and f_u= 758 MPa, respectively. The modulus of elasticity of steel was set equal to 200 GPa. The steel ultimate tensile strain was measured at 0.1.

STRUCTURAL MODEL

A three-dimensional finite element model of the structure is developed, using the computer program SAP2000 version 14.1 (2009). Figure 3 shows a three-dimensional view of the second floor of the building and the location of the imposed initial damage. Bernoulli beam elements with localized plastic hinges are used to model material nonlinearity in beams, columns and slab elements. The slab elements in the vicinity of the imposed initial damage (between axes 4 and 7 and between axes A and D) undergo significant structural demand behaving nonlinearly. The slab in this region is modeled by a two-directional grid of beam elements and the slabs away from this area are modeled using elastic four-node shell elements. For the rectangular beams modeling the slabs, due to the fact that the shear flows in a continuum slab and in a two-directional grid of beams are different (MacLeod, 1990) the torsional stiffness of the cross sections were divided by two.

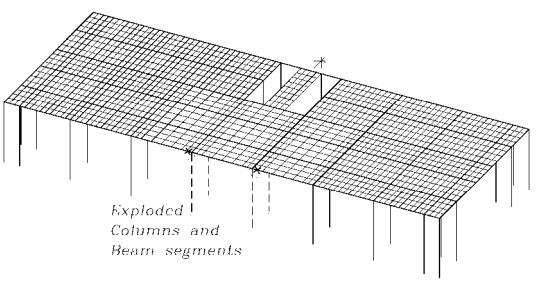

Fig. 3 - Three dimensional view of model

The beams in the second floor are modeled with T- and L-sections. The effective flange width on each side of beams is set equal to four times the slab thickness, 0.61 m (ACI 318, 2008). Geometric nonlinearity is accounted for and the equilibrium equations are written in the deformed configuration of the structure.

To account for torsional cracking an iterative procedure is used in this study. The procedure involves carrying out an analysis with an uncracked section torsional stiffness. Then, wherever the torsional moment exceeds the cracking torsional strength (ACI 318, 2008), the torsional stiffness of the section is reduced to cracked torsional stiffness (Collins and Lampert, 1973). This procedure is repeated until all cracked regions are accounted for. A mass proportional damping ratio of ξ=0.05 in the first vertical vibration mode is used.

The frame elements in the SAP2000 computer program are elastic and linear. One approach to account for plastic behavior in the program is using a localized Moment plastic hinge, which accounts only for flexural plastic deformation. The behavior of a Moment plastic hinge up to the yield point is rigid, which means the hinge has no effect on the response of the element up to the yield point. After the yield point however, the hinge provides plastic deformation to the element (in the vicinity of the hinge). So, the behavior of moment plastic hinges is called rigid-plastic.

The moment-rotation relationship for a moment plastic hinge is obtained under a constant axial force (usually zero) and the interaction of the axial force and the moment (P-M interaction) is not considered. To account for the effect of the axial force and moment interaction, the PMM (the axial force and the bending moment in two directions) plastic hinges are also available in SAP2000. In this type of plastic hinges, the P-M interaction is partially considered at the force level. Therefore, PMM plastic hinges do not include the effect of the interaction between flexural and axial deformations.

Another type of plastic hinge available in SAP2000 is a fiber plastic hinge. In fiber plastic hinges the geometry of the section and the material properties (constitutive laws) are directly used in each time step to obtain the force and deformation response of the sections, and in turn, the elements. That is, in a Fiber Plastic Hinge in addition to flexural, the axial deformation (elastic and plastic) is accounted for. Both moment and fiber plastic hinges are localized plastic hinges represent the behavior of the associated plastic hinge length.

In a localized Fiber Plastic Hinge, in addition to the plastic deformation over the assumed length of the plastic hinge, the so called “elastic” response is also included in the hinge deformation, that is, a fiber plastic hinge is not rigid-plastic. The structural model uses the elastic flexibility of the structural element. Therefore, the elastic flexibility of the region represented by the hinge is double counted. In order to resolve this issue, the solution used in this study is to change the portion of the element represented by a fiber plastic hinge (plastic hinge length) to be axially and flexurally rigid (or have relatively large stiffness to be practically rigid) which in effect diminishes the effect of the elastic flexibility of the structural element. Plastic hinges are used in the elements wherever necessary such as element ends and

longitudinal steel bar cut-off locations. Multiple plastic hinges are used over the length of an element in longitudinal beams in the second floor. In order to avoid plastic hinges with overlapping represented lengths, the lengths of the hinges in second floor beams are set equal to the distance between the hinges (less than half of the beam depth). For the slab elements, the length of all hinges is set equal to one half of the slab thickness or 0.076 m

VERTICAL DISPLACEMENT AND BENDING MOMENTS

Figure 4 shows the vertical displacements at the top of the first floor removed columns A-6 and B-6 obtained from the structural model. The permanent vertical displacements (at the end of vibration) in the second floor at the locations of removed columns A-6 and B-6 are about 66 mm and 46 mm, respectively. The vertical displacements at the top of the removed columns were measured at the site using several displacement sensors. The measured permanent vertical displacements in the second floor at the locations of removed columns A-6 and B-6 were about 56 mm and 43 mm, which are in a reasonable agreement with the analytically obtained displacements.

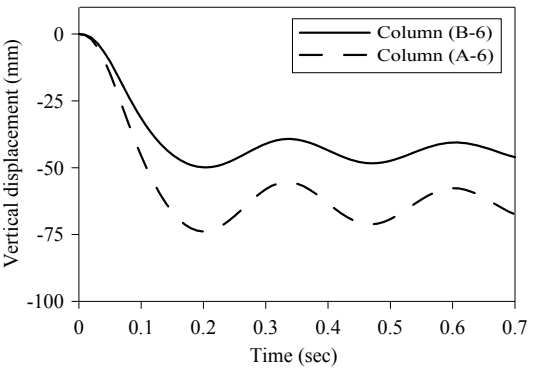

Fig. 4 - Vertical displacement versus time joints A-6 and B-6 on second floor.

Figure 5 shows the bending moment diagram of the beam in the axis B before column removal (under gravity loads) and after column removal (at the peak vertical displacement). After column removal, the central three span beams in the axis B (between axes 4 and 7) bridges over two exploded columns. The maximum negative moment at the face of the beam in axis 7 increases from 1100 kN-m before column removal to 14300 kN-m after column removal, and the maximum positive moment at the mid-span changes from 600 kN-m to 12000 kN-m. Figure 5 shows an about 13 and 20 times increase in the negative (face of the axis 7 transverse beam) and positive (mid-point of the beam) moments of the beam, respectively. The moment-curvature of the section under negative moment and subjected to zero axial load shows all the tensile rebars of the beam section yield under the action of 10700 kN-m. However, the analysis results show that the tensile rebar yielding occurs under a moment of about 13500 kN-m, which is 26% more. This large increase in the yielding moment of the section is due to the effect of an axial compressive force equal to 5100 KN on the section.

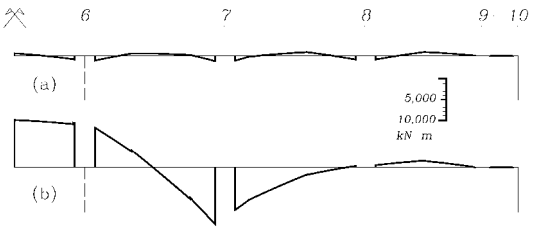

Fig. 5 - Bending moment diagram in axis B (a) before column removal; (b) after column removal at peak vertical displacement

Figures 6 and 7 show the bending moment diagrams of the beams in the axes A and C, respectively. Both figures show the bending moment diagram before column removal (under gravity loads) and after column removal (at the peak displacement of the midpoint of the beam in the axis B). After the removal of the columns and beam segments in the axis A, the left span (between axes 4 and 5) and the right span (between axes 6 and 7) of the beam, lost their connection and behave like cantilevers. The maximum negative moment of the cantilever beam at the face of the transverse beam in axis 7 is 6800 kN-m.

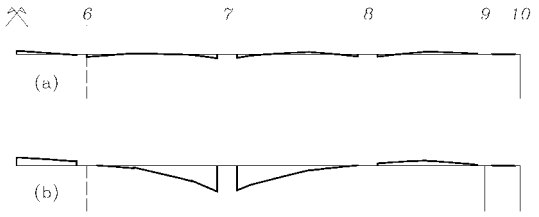

Fig. 6 - Bending moment diagram in axis A (a) before column removal; (b) after column removal at peak vertical displacement

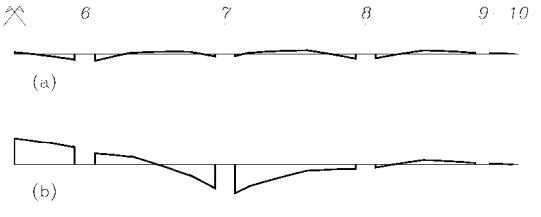

Fig. 7 - Bending moment diagram in axis C (a) before column removal; (b) after column removal at peak vertical displacement

BEAM AXIAL DEFORMATION

Figure 8 shows the axial elongation of the beam centerline of axis B (between axes 4 and 7) versus time. The longitudinal deformation (elongation) of the beam is determined as the relative horizontal displacement between the two end nodes at the intersections of the axis B with axes 4 and 7. Following the formation of cracks the mid-height of the beam section is under tensile strain. As a result, the length of the beam at its centerline increases by the sum of crack widths at the mid-height of the beam section. This phenomenon is known as beam growth (Fenwick and Megget, 1993, and Kim et al., 2004). Yielding of the rebar will influence the tensile strain of the beam centerline and increases the beam growth. In a structure however, because of the beam boundary conditions, such a growth tendency is constrained, which leads to development of compressive axial force to satisfy geometric compatibility. Such a constraint in the structure is provided primarily by the in plane action of the floor system. Analytical results show approximately two thirds of the beam axial compressive force is resisted by the in plane action of the floor system and the remaining one third by the shear forces in columns. The beam compressive force considerably increases the moment capacity of the beam through moment axial force interaction and limits the length of the cracked regions of the beam, both resulting in smaller vertical displacements. As can be seen the maximum elongation of the centerline of the beam is about 4.6 mm.

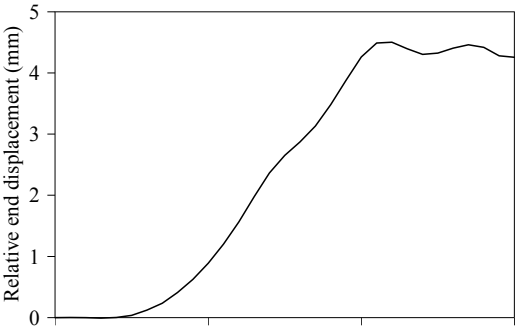

Fig. 8 - Relative horizontal displacement of line B beam between columns B-4 and B-7

Figure 9 shows the axial force of the beam in the axis B at the peak vertical displacement of the midpoint of the beam which is primarily in compression.

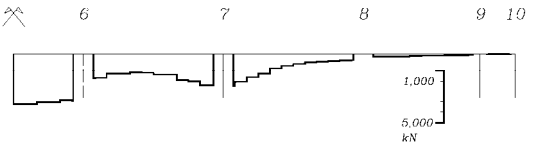

Fig. 9 – Axial compressive force in axis B beam at peak vertical displacement

AXIAL FORCE IN BEAMS

In order to investigate the development of the axial force in the beam and its effect on the system response, let us look at the central part of the structural system in the second floor as shown in Fig.10. Considering section 1-1 in the figure, the relative tendency of the beams to grow and the equilibrium of the longitudinal forces determine if a beam undergoes a tensile or compressive force. The axial tensile forces of the beam elements in axes C and D, and in the longitudinal slab elements, and the horizontal shear forces of the transverse beam and slab elements as well as the column shear forces in the second floor are in equilibrium with the sum of the axial compressive forces developed in the beams of axes A and B.

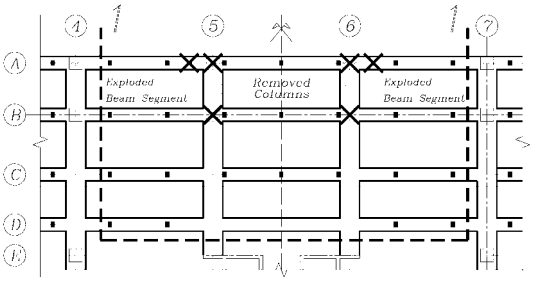

Fig. 10 – Plan of second floor in vicinity of removed columns

All the longitudinal slab elements are subjected to the axial tensile forces. Because the concrete cannot withstand the axial tensile force, it cracks and the slab rebars carry the axial tensile force. As the compressive axial force of the beam in the axes A and B increase, the axial tensile force of the slab elements closer to the axes A and B increase and the slab rebars yield, thus the axial force in the farther elements start to increase rapidly.

The columns of the second floor and the slab elements contribute taking the longitudinal forces by providing shear forces. The results of the analysis show at the peak displacement of the midpoint of the beam in the axis B, the beams in the axes C and D can take about one third of the generated axial compressive force in axes A and B, the slab elements take also about one third by providing tensile axial force. The last one third is provided by the second floor column shear forces and the slab elements satisfying longitudinal force equilibrium.

Figures 11 and 12 show the axial forces in axes A and C, respectively, at the peak vertical displacement in the mid-span of axis B beam. As can be seen, the axial force of the cantilever beam (after beam explosion) in axis A is also compressive, while the axial force in axis C is tensile (positive). The cantilever beam in the axis A, at the 2 m distance from the face of the axis 7 beam has no top rebars except the slab reinforcement. This part of the beam is subjected to a negative moment and cracks under tensile strain at the top of the section. Following the opening of these cracks, the mid height of the section elongates. But the beam is not free to expand, because it is constrained by the floor system. As discussed earlier, because of the beam boundary conditions, compressive axial force will be developed to satisfy

compatibility. The maximum axial compressive force in the cantilever part of the beam in the axis A is 2100 kN. The middle part of the beam in the axis A (between the axes 5 and 6) is subjected to tensile force with the maximum value of 300 kN.

CONCLUSIONS

Experimental data and analytical results are used to evaluate progressive collapse resistance of an actual eleven-story reinforced concrete structure following severe initial damage. The initial damage imposed on the structure was set to represent the effects of a severe explosion causing the loss of four adjacent columns and two beam segments. The analytical results show that following the imposed initial damage, the bending moments in beams increase by up to about 20 times. Such a significant increase in bending moments, results in considerable cracking of concrete and yielding of reinforcing bars in tension, which in turn leads to beam growth. That is, the tendency in a beam centerline to elongate. This growth tendency in the beams subjected to highest flexural demand, however, is constrained by the floor system, including the other floor beams as well as the slab. The frames of the structure also contribute to constraining beam growth. As a result, significant axial compression can develop in beams subjected to largest force and deformation demands. It is shown in this study that the axial force in critical beams increased the beam yield moment by about 38%. Considering the axial force developed in the critical beams and in turn the increased bending moment capacity significantly improves progressive collapse resistance of the structure.

Two primary gravity load redistribution paths are identified in this structure. One is the flexural-axial response of the second floor deep beams. The other is Vierendeel action of the flat plate structural system in floors above, which reduces the axial compressive force of the columns. The global vertical displacement of the structural model and its local deformation are in good agreement with those of the experimental data.

ABSTRACT

This paper presents an investigation into the shrinkage of concrete treated with an evaporation reducer, Confilm®, after placement. Shrinkage tests were conducted on specimens treated with the evaporation reducer both properly and improperly. In the experimental program, concrete was cured under five curing regimens: 1) concrete was dry cured to serve as a basis for comparison, 2) concrete was cured with wet towels to simulate field curing with wet burlap, 3) the evaporation reducer was used as a curing aid to reduce early-age shrinkage in concrete by applying it to the surface before the start of the test and leaving it undisturbed throughout the test, 4) the evaporation reducer was used as a finishing aid during initial finishing (troweling), and 5) the evaporation reducer was again applied just after the concrete surface was floated, but was used as a finishing aid during final finishing (three and a half hours after water was added to the concrete).

Dry curing produced the greatest early-age shrinkage. The reductions in shrinkage observed for wet curing and for the proper use of the evaporation reducer were similar. The effects of troweling the evaporation reducer produced early-age shrinkage that was approximately 75% greater than the shrinkage experienced by concrete properly treated with the evaporation reducer. However, the shrinkage of the concrete treated with Confilm® was still less than the shrinkage observed for concrete cured under wet towels. Consequently, it appears that there is little negative consequence to using Confilm® as a finishing aid. Initial finishing of the concrete treated with the evaporation reducer produced approximately 20% more early-age shrinkage than final finishing. To study the effects of the various curing regimens on tensile strength, four prism specimens were cast and cured along the sides of each shrinkage specimen. From modulus of rupture testing, no statistically significant differences were observed between the curing regimens.

INTRODUCTION AND BACKGROUND

Cracking of concrete due to shrinkage is a primary concern within the concrete industry because such cracks jeopardize the integrity of the structure (Ong and Myint-Lay 2006). The main cause for shrinkage in concrete is moisture loss. The concrete surface shrinks when water evaporates or is used by hydration at a greater rate than the rate at which moisture is replaced by external water (Kwak and Ha 2006). If external water is not available, menisci will be formed in the capillary pores of the hardened cement paste as capillary water is used for hydration or evaporates from the concrete. The surface tension forces cause tensile stress in the concrete. Shrinkage cracks occur when the tensile stresses caused by drying shrinkage are greater than the tensile strength of the young concrete. Repairing bridges that have experienced shrinkage cracking incurs substantial maintenance costs.

The current study deals with the effects of shrinkage in concrete after treating the concrete surface with an evaporation reducer and subjecting the concrete surface to initial and final finishing (troweling) because many concrete finishers like to use certain evaporation reducers as finishing aids. These results are compared with the cases of dry curing, wet curing, and concrete treated with an evaporation reducer used as a curing agent.

The objective of this research was to analyze the effectiveness of an evaporation reducer to control shrinkage on a concrete surface that was troweled (initial and final finishing) after the evaporation reducer was applied. Confilm®, an evaporation reducer produced by BASF Construction Chemicals, LLC-Building Systems was the evaporation reducer used in this work. Confilm® is often used as a finishing aid by concrete finishers. This work focused on evaluating whether or not this practice would be detrimental to concrete quality.

EXPERIMENTAL METHODS

Experiments were conducted to measure shrinkage of concrete treated with an evaporation reducer (Confilm®) over a period of seven days. This section describes the raw materials, the testing apparatus, the preparation of the shrinkage test specimens, and the sequence of operations for conducting the tests used in this research.

Raw materials. Concrete produced for this research was batched in the laboratory. The materials used for preparing concrete were procured locally in Las Cruces, New Mexico. Type I-II Featherlite brand portland cement with a specific gravity of 3.15 was used. Aggregates were obtained from CEMEX, Las Cruces. Fine aggregates were oven dried for at least 24 hours at 110 ± 5 ºC (230 ± 41 ºF) to achieve zero percent moisture. Physical properties for the coarse and fine aggregates are provided in Table 1. After oven drying, the sand was stored in plastic buckets that were tightly covered with plastic to avoid ingress of moisture.

Confilm®, an evaporation reducer, was used in this research. Confilm® is manufactured by BASF Construction Chemicals, LLC. Use of Confilm® is intended to reduce the evaporation of moisture from the surface of concrete and improve the

quality of the concrete. In accordance with manufacturer recommendations, one part Confilm® was diluted with nine parts water.

Mixture proportions. Raw materials were proportioned volumetrically, following procedures described by the Portland Cement Association, to produce concrete with a water-cement ratio of 0.5 and a slump of 76.2 to 101.6 mm (3 to 4 inches) (Kosmatka et al. 2002). Because the fine aggregate was sub-angular, the water content of the mixture was reduced by 11.86 kg/m³ (20 lb/yd³). The mixture proportions used in this study are presented in Table 2.

Mixing procedure. The volume of concrete required for each test was greater than the mixing capacity of any individual mixer available. Therefore, the required 0.099 cubic meters (3.5 cubic feet) of concrete was batched in two mixers with 53 percent of the total volume batched in the larger mixer and the remaining 47 percent mixed in the smaller one. Mixing of raw materials was conducted in accordance with ASTM C 192. As soon as the water was added to the concrete mixture, the time was noted as a reference point for all other activities. After mixing, the mixer was emptied into a wheelbarrow and slump of the concrete was measured in accordance with ASTM C 143. If the workability of the concrete was not in the acceptable range of 76 mm to 102 mm (3 to 4 inches), the concrete was discarded. Table 3 presents the measured slump values. After measuring slump, the temperature of the concrete was recorded.

Mold preparation. Molds for the experimental specimens were prepared prior to production of concrete. A 914x457x152 mm (36x18x6 inches) wooden mold was prepared for the shrinkage specimen. The mold was lined with 4 mil thick plastic sheets in two layers. Talcum powder was applied in between the plastic sheet layers to reduce friction and allow free movement of fresh and hardened concrete during shrinkage.

5	Confilm® (Final finishing)	85 (3.50)

Four steel prism molds measuring 76.2x102x406 mm (3x4x16 inches) and three steel cylinder molds measuring 102 by 203 mm (4 by 8 inches) were assembled and oil was applied to the inside surface of the molds. The prism molds were placed along the four sides of the wooden mold for the shrinkage specimen so that the prism specimens would be cured in the same environment as the shrinkage specimen.

Specimen preparation. The wooden shrinkage specimen mold was filled with concrete and vibrated using a needle vibrator to achieve uniform consolidation. The concrete was uniformly vibrated for a period of 10 seconds. The companion specimens, 102 by 203 mm (4 by 8 inches) cylinders for testing compressive strength and 76 x 102 x 406 mm (3 x 4 x 16 inches) prisms for testing flexural strength were prepared in accordance with ASTM C 192. The prism specimens were treated with evaporation reducer in the same manner as the shrinkage specimen.

Data acquisition. The system used to measure early-age shrinkage is shown schematically in Figure 1. This system was developed by Lozoya and Newtson (2004). The steel frame supporting the shrinkage measurement system was positioned over the shrinkage specimen in the longitudinal direction as shown in Figure 2. Two steel hangers that were 177.8 x 25.4 x 5mm (7 x 1 x 0.2 inches) were

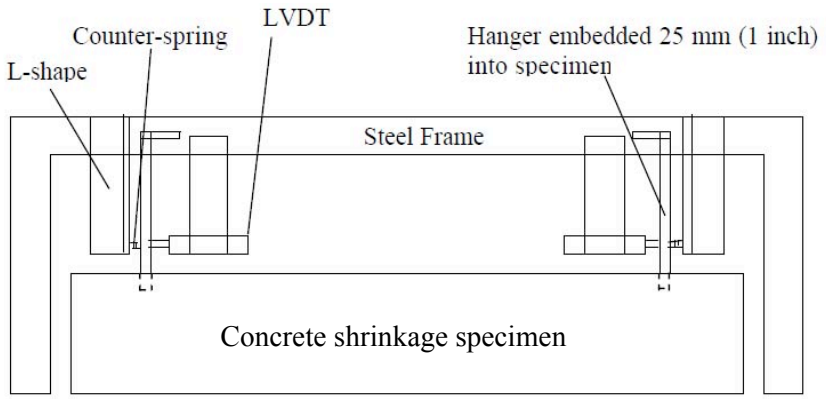

Figure 1. Experimental setup of Lozoya and Newtson (2004).

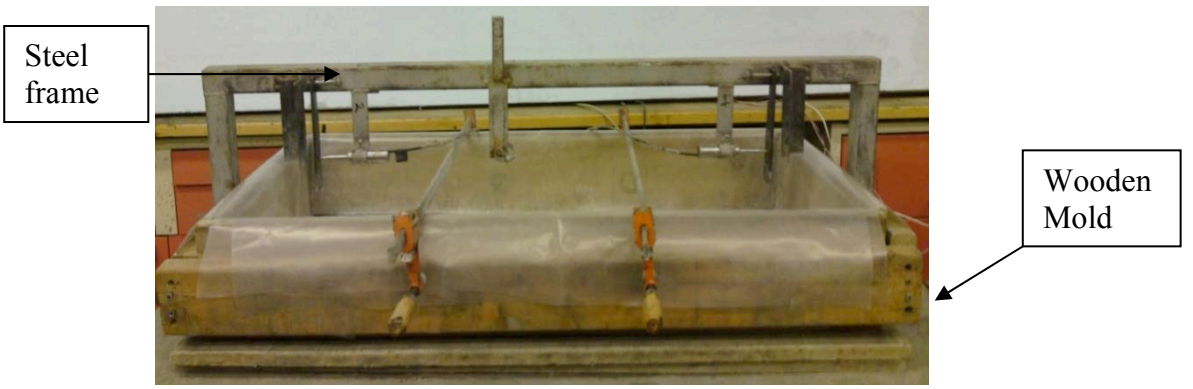

Figure 2. Shrinkage test experimental setup.

hung from metal pins attached to the steel frame and embedded 25mm (1 inch) into the freshly placed concrete. The hangers have a hole through one end that allows them to be hung from the metal pins attached to the frame. The smooth surface of the pin allows the hanger to slide freely. Near the other end, divots were made on both sides of the hangers. One divot served as a resting seat for the head of a LVDT and the divot on the opposite side of the hanger served as a seat for a counter spring. The counter spring is shown in a photograph in Figure 3. The counter springs were attached to the frame at their other ends and had a spring constant equal to that of the springs in the LVDT's. LVDT's (Sensotec model S3C) were inserted through a supporting fixture on the steel frame. The LVDT's were connected to a Superlogics 8017 electronic data acquisition module, which in turn was connected to a computer.

Temperature and relative humidity observations were performed at 15 minute intervals during the initial four hours of the test and then every day at 8:00 am and 10:00 pm local time.

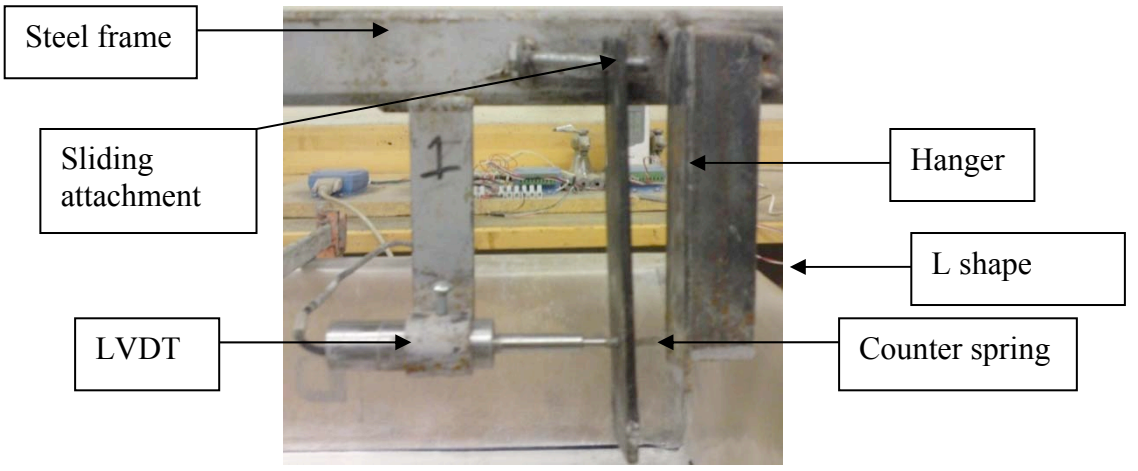

Figure 3. Close up view of hanger and LVDT.

Curing conditions. Experiments were conducted for five curing conditions intended to study the effects of the evaporation reducer (Confilm®). Three experiments were conducted for each case. The five curing conditions investigated were:

1. Concrete was dry cured to serve as a basis for comparison.
2. Concrete was cured with wet towels to simulate field curing with wet burlap.
3. The evaporation reducer was used as a curing aid to reduce early-age shrinkage in concrete. The evaporation reducer was applied to the surface before the start of the test and left undisturbed throughout the test.
4. The evaporation reducer was used as a finishing aid during initial finishing (troweling). The evaporation reducer was applied immediately after the surface was floated, and then the surface was immediately steel troweled.
5. The evaporation reducer was again used as a finishing aid and was applied just after the concrete surface was floated. In this case, the concrete was troweled during final finishing, three and a half hours after water was added to the concrete.

Strength testing. Three cylindrical specimens from each batch were moist cured and four prism specimens were cured alongside each of the shrinkage specimens. All strength specimens were tested at an age of seven days. ASTM C 39 was followed for testing the compressive strength of the cylindrical specimens. Flexural strengths for prism specimens were determined according to ASTM C 78.

RESULTS AND DISCUSSION

Concrete shrinkage was measured for a period of seven days under five different curing conditions. Three tests were performed for each curing condition. This section presents an analysis of the test results and an evaluation of the effectiveness of Confilm® as a curing agent.

Dry Curing. The first curing condition, dry curing, is used as a basis of comparison in evaluating the other test cases. In the dry curing condition, the concrete was air cured without any addition of water or external curing aid. Maximum shrinkage strains observed during the initial 24 hour period and over the seven day period were 258μ and 1208μ, respectively.

Wet towels curing. In the second curing condition, wet towels were placed on the surface of the concrete four hours after water was added to the concrete. The wet towels were rewetted every eight hours. This simulates the use of wet burlap in field curing. A peak shrinkage strain of 212μ was recorded over the seven day period and 78μ was observed during the first 24 hours. Minor expansion was observed during the first few hours of these tests. This is a reduction of 70% and 82% from the shrinkage observed for dry cured concrete at 24 hours and seven days, respectively.

Confilm® curing. The third curing condition studied the effect of Confilm® used as a curing agent on concrete shrinkage. In this case, concrete was treated with Confilm®,

an evaporation reducer, just before the start of the shrinkage tests. The concrete surface was screeded and floated. Then, the evaporation reducer was applied as a thin layer on the concrete surface. In accordance with the recommendations of the manufacturer, Confilm® was applied at a rate of 52.81 ml/m^2 (1.296 x 10^{-3} gal./ft^2). Maximum strains of 48μ and 152μ were observed for 24 hours and seven days, respectively. These shrinkage values are approximately 40% less than the values obtained by wet curing with towels.

Confilm® curing with initial finishing. In the fourth curing condition, the concrete surface was floated immediately after placement and compaction. After floating, Confilm® was applied on the concrete surface at a rate of 52.81 ml/m^2 (1.296 x 10^{-3} gal./ft^2). Then, surface finishing was performed before the start of the test. Use of Confilm® aided in easy and smooth finishing. A maximum 24 hour horizontal shrinkage strain of 93μ was observed by averaging the values from three tests. After seven days, an average horizontal shrinkage strain of 169μ was observed. These shrinkage values are 94% and 11% greater than the shrinkage observed when the Confilm® was used properly.

Confilm® curing with final finishing. In the fifth curing condition, Confilm® was applied to the floated concrete surface at a rate of 52.81 ml/m^2 (1.296 x 10^{-3} gal./ft^2). The concrete surface was finished only after the concrete was initially set. Three and a half hours after adding water to the mixture was considered as the standard time for final finishing. Use of Confilm® again aided in easy and smooth finishing. However, finishing was less smooth than in the initial finishing case since the Confilm® dried somewhat between the time when it was applied and final finishing. The average horizontal shrinkage strains observed for this case during the early-age and long term were 75μ and 167μ, respectively. Figure 10 presents the shrinkage strains versus time. These shrinkage strains are approximately 20% less than the shrinkage observed when the Confilm® was disturbed by initial finishing, and about 60% greater than the shrinkage observed when the Confilm® was used properly.

Comparison of 24 hour shrinkage. Dry curing was considered to be a basis for comparison for the other curing conditions. The maximum average values of 24 hour shrinkage strains obtained for the different tests cases are provided in Table 4. The shrinkage strain of 78μ observed for wet towel curing was 70% less than that from

Table 4. Average shrinkage strains for all curing conditions.

Case	Curing Condition	24-Hour Shrinkage Strain (με)	7-Day Shrinkage Strain (με)
1	Dry	258	1208
2	Wet towels	78	212
3	Confilm®	48	152
4	Confilm® (Initial finishing)	93	169
5	Confilm® (Final finishing)	75	167

dry curing. In the third case, concrete treated with Confilm®, the shrinkage was 82% less than the shrinkage from dry curing. A shrinkage strain reduction of 39% was observed for the Confilm® curing case when compared with wet curing.

In the fourth case, even though lower shrinkage strains were observed by 64% when compared to dry case, the shrinkage strain was greater by 18% and 94% than the shrinkage strains for Cases 2 and 3, respectively. It appears that initial finishing disrupted the evaporation barrier provided by Confilm® which allowed a moderate increase in shrinkage, lowering the evaporation. For the final case, Confilm® with final finishing, the shrinkage strain was less than the shrinkage from Cases 1, 2, and 4 by 71%, 4%, and 23%, respectively. However, it was greater than Case 3 by 58%. Noticeable differences in shrinkage strain were observed between Cases 4 and 5 (initial and final finishing respectively) only when compared with Case 2. When compared with concrete shrinkage strain from Case 2 (78μ), there was an increase in Case 4 by 18% and a decrease by 4% in Case 5. Since the shrinkage from Case 5 was comparable to the shrinkage from Case 2, it appears that using Confilm® as an aid for final finishing is a reasonable practice. The 24 hour shrinkage strains for the different cases are plotted in Figure 4.

Comparison of seven day shrinkage. The horizontal shrinkage strains observed over a period of seven days are compared in Figure 5. Figure 6 illustrates the same shrinkage strains for the different curing conditions, but excludes the dry curing condition. The maximum shrinkage strains recorded at the end of seven days are tabulated in Table 4. The shrinkage from dry curing was much greater than the other values since no curing aid was provided. In the second case, where wet towels were placed on the surface of concrete, the shrinkage strain decreased by 82% when compared to dry curing. This observation is consistent with results from Lozoya and Newtson (2004). In the third case, treatment of the concrete with Confilm® reduced

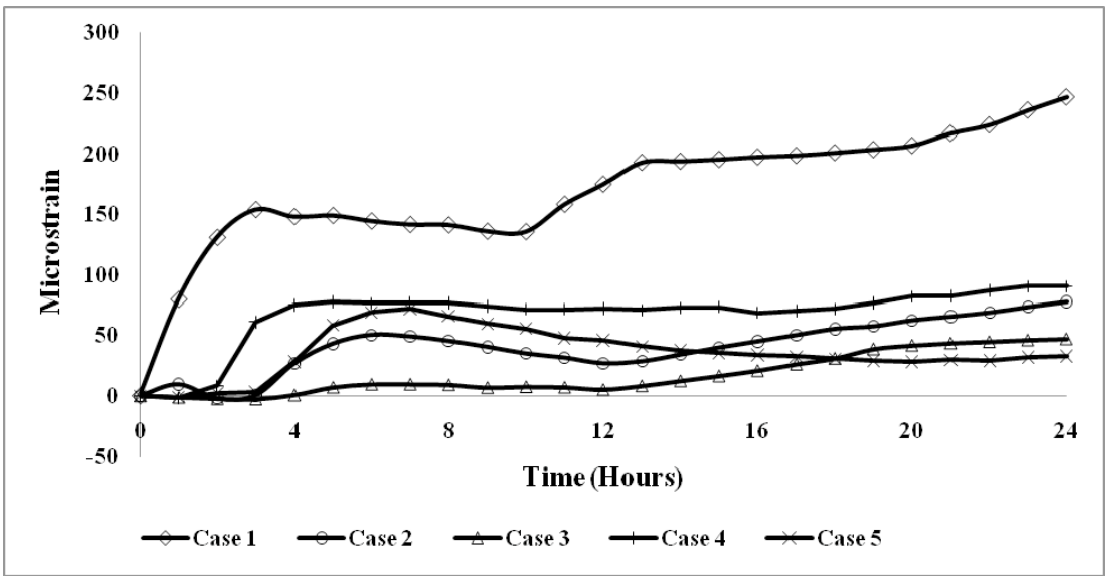

Figure 4. Average 24 hour shrinkage strains.

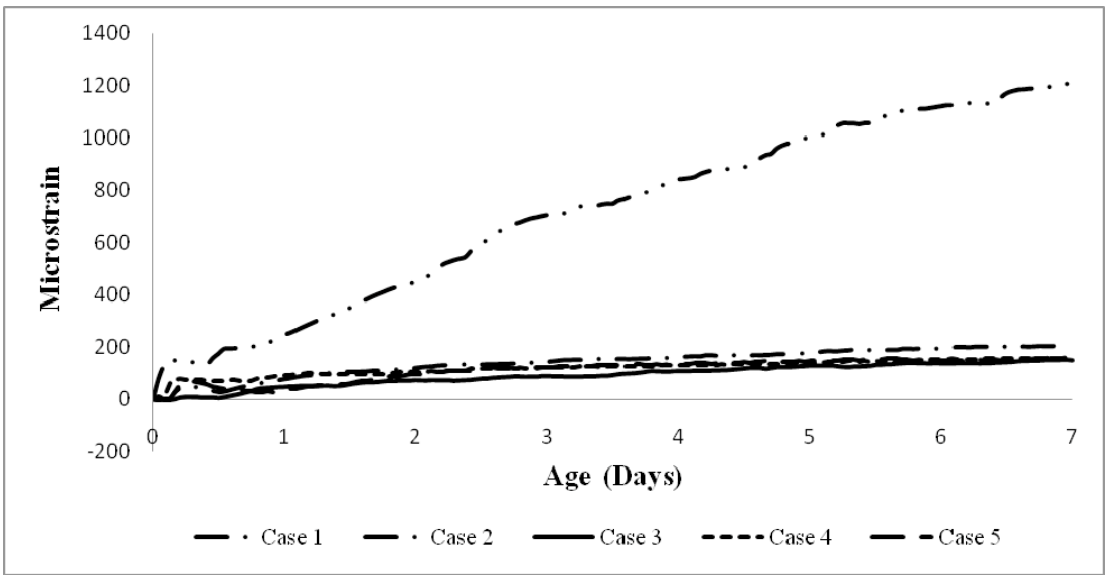

Figure 5. Average seven day shrinkage strains.

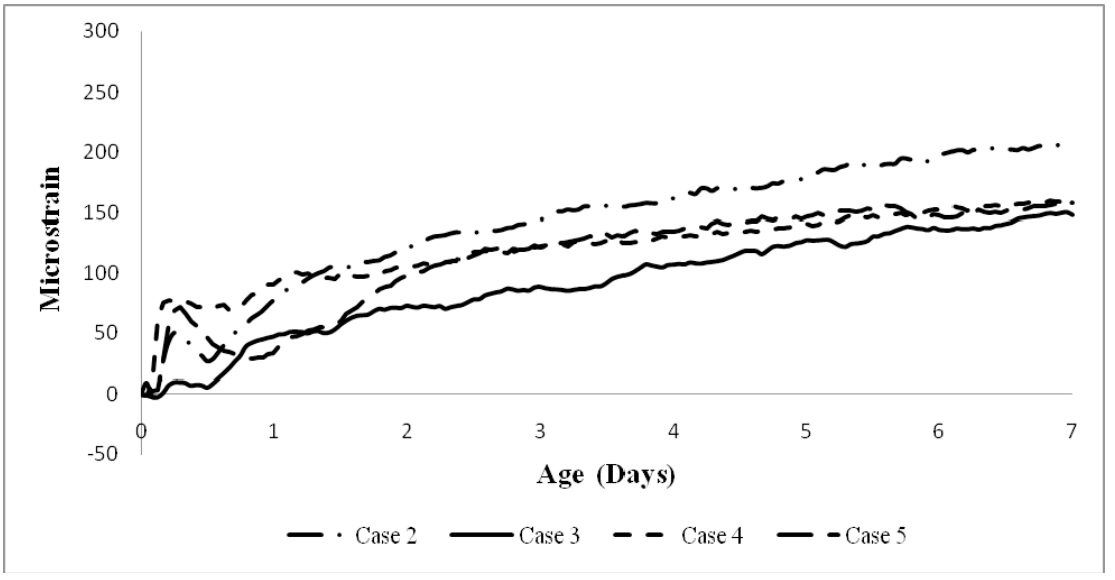

Figure 6. Average seven day shrinkage strains for Cases 2-5.

the shrinkage strain by 87% and 28% when compared with dry cured concrete and concrete cured using wet towels, respectively. The increased shrinkage observed when using wet towels may indicate that when the towels dry, water is wicked from the concrete. Alternatively, the addition of water may lower the temperature of the concrete and cause greater thermal shrinkage.

The shrinkage strain observed for Case 4 is greater than the shrinkage from Case 3, by 10%. This increase is likely due to the finishing after application of

Confilm®. This finishing might have slightly disturbed the Confilm® barrier over the concrete surface that prevents loss of moisture from the concrete.

Lower shrinkage strains were observed for Confilm® curing with initial finishing when compared to the dry curing and wet curing conditions by 86% and 20%, respectively. This reduction indicates that Confilm®, even when misused, generates a barrier over the concrete surface that prevents loss of moisture from concrete and reduces shrinkage.

The shrinkage strain experienced by concrete treated with Confilm® that was disturbed by final finishing (167μ) was similar to the shrinkage of concrete treated with Confilm® disturbed by initial finishing (169μ). Since both finishing operations on Confilm® treated surfaces resulted in less shrinkage than wet curing with towels, it appears that using Confilm® as a finishing aid has little negative consequence.

Tensile strength results. Prism specimens were placed and cured along each side of the shrinkage specimens to monitor the effect of curing in each test case except for the dry test case. They were treated in the same manner as the shrinkage specimen. At an age of seven days, these prism specimens were tested for flexural strength according to ASTM C 78. The average flexural strength values are tabulated in Table 5. These values ranged from 3.74 MPa to 4.55 MPa (542 psi to 660 psi).

The greatest flexural strength was observed for the prisms produced for the dry curing case. However, this set of prisms was moist cured (not cured beside the shrinkage specimens). Consequently, the high strength is not a reflection of the curing method for the shrinkage tests. From Table 5, the specimens treated properly with Confilm® had slightly greater flexural strength than the concrete cured with wet towels. It was also observed that finishing after treating with the evaporation reducer slightly decreased the flexural strength of concrete. However, neither of these observations appear to be statistically significant.

Compressive strength results. The same mixture proportions were used for all of the concrete produced for this research. Quality of the concrete was monitored by testing companion specimens for compressive strength. Cylindrical specimens of size 102 by 203 mm (4 by 8 inch) were used as companion specimens. After demolding, the cylindrical specimens were moist cured for seven days. Then, the specimens were tested for compressive strength according to ASTM C 39. The average compressive strength values are provided in Table 5. These values ranged from 28.6 MPa to 38.0 MPa (4150 psi to 5520 psi). The cylinders produced for the dry cured case had the

Table 5. Average strength results.

Case	Curing Condition	Modulus of Rupture MPa (psi)	Compressive Strength MPa (psi)
1	Dry	4.48 (650)	38.0 (5520)
2	Wet towels	3.93 (570)	32.9 (4780)
3	Confilm®	4.14 (600)	30.7 (4450)
4	Confilm® (Initial finishing)	3.85 (559)	32.9 (4770)
5	Confilm® (Final finishing)	3.74 (542)	28.6 (4150)

greatest strength which indicates that this mixture is a little different from the other mixtures. If this is the case, the shrinkage for the dry curing case may also be erroneously high. However, the magnitude of the expected increase would not be expected to change the conclusions drawn from the shrinkage results. If the dry case were omitted from analysis, there would be no changes to the conclusions drawn about the effectiveness of Confilm®.

CONCLUSIONS

Shrinkage cracking is a serious problem affecting the durability, serviceability and maintenance costs for concrete structures. Shrinkage cracks occur on a concrete surface when loss of moisture causes tensile stresses that exceed the tensile strength of concrete. Moisture loss is caused by environmental factors like high wind velocity, low relative humidity, and extreme differences between air and concrete temperatures. Water-to-cement ratio, cement type, cement content, aggregate properties, and degree of hydration of the cement also affect the development of shrinkage. Shrinkage in concrete can be controlled to a certain degree by wet curing the concrete and allowing uninterrupted hydration of the cement. Other methods of limiting moisture loss include the use of evaporation reducers such as Confilm®. However, concrete finishers often like to use Confilm® as a finishing aid. Disturbing the evaporation barrier with finishing operations is widely thought to harm the concrete. Consequently, this practice is generally considered to be unacceptable.

To study the effects of misusing the evaporation reducer (Confilm®) as a finishing aid on concrete shrinkage, five sets of shrinkage tests were performed by varying the curing conditions. The following conclusions were drawn from the results of the testing:

1. Wet curing with towels reduced shrinkage by 80% compared to dry curing. This observation was consistent with results from Lozoya and Newtson (2004).
2. Using Confilm® as a curing aid (no troweling) resulted in 30% less shrinkage than wet curing with towels. The difference in shrinkage between these two cases may have been partly due to external water decreasing the temperature of the wet cured concrete which would increase shrinkage.
3. Disturbing the Confilm® barrier by finishing, increased the early-age shrinkage strains by 94% compared to concrete treated with Confilm® properly.
4. Even though the shrinkage strains measured at the end of seven days were similar for both initial and final finished concrete treated with Confilm®, these values are greater than the concrete treated with Confilm® alone. This indicates that disrupting the evaporation barrier increases shrinkage. However, the shrinkage strains for the troweled Confilm® cases were less than the shrinkage from wet curing with towels. Therefore, it appears that using Confilm® as finishing aid has little negative consequence.

5. Troweling a concrete surface treated with Confilm® in a final finishing operation resulted in shrinkage that was only slightly less than the shrinkage observed for initial finishing.
6. No significant difference in flexural strength values were observed between the curing methods used in this research.

ABSTRACT

This article discusses the issues in structural design revealed by the highway I35W Bridge's collapse that occurred at August 1st, 2007, based on an analysis of the bridge's original design drawings, a series of detailed finite elements computations, and the material evidences disclosed by National Safety Transportation Safety Board (NTSB) official investigation. These issues include (i) the redundancy consideration for multi-span bridge; (ii) the reason for those undersized designs in that bridge; (iii) the effects of lateral force on gusset plates' load capacity in steel-truss structure; (iv) the criterion of gusset plate's stability and a thin-plate theory-based model for load-rating. This analysis concludes that the lessons learned from the I35W Bridge may have certain significance for the safety assessments of those similarly-structured steel bridges. A bridge's service life is 75 years or longer. According to a NTSB's document [37], there are more than hundreds this kind of aged bridges still in service [4].

1.INTRODUCTION

The past century can be remembered as the most successful period for bridge engineering, which has also brought up great challenges to bridge engineers to digest rapidly-developed ideas, new tools, and novel methodologies in related engineering sciences while to assure new designs and existing bridges' operation being safe, economic, and technologically advancing. While enjoying great success for decades, we did have suffered several significant setbacks. One example is the collapse of the Minneapolis I35W highway bridge.

August 1st of 2007, 6:05PM, the interstate I35W Bridge in the City Minneapolis, Minnesota, collapsed suddenly. The 8 traffic-lane, 1000-foot-long deck of the 1907-foot-long bridge fell into Mississippi River within seconds, resulted in 13 fatalities and 145 injuries, see Figs. 1, 2.

Designed in 1964 and opened to traffic at 1967, the I35W Bridge stretches from north to south over the Mississippi River in the City Minneapolis in Hennepin County, Minnesota. The major part of the bridge is a 1000 foot (304.8 meters) long, 108 foot (32.92 meters) wide, three-span steel deck-truss superstructure, which collapsed completely. The bridge originally had six traffic lanes. After two major rehabs in last century, it has been widened into eight lanes with two auxiliary lanes and its concrete deck has been reinforced from 6.5 inches to 8.5 inches thick. NTSB's official investigation [1,2] indicates that, at the moment of the collapse, two lanes of the bridge were occupied by piled construction materials and heavy trucks; four lanes were opened to traffic; and the other two lanes were empty.

This article summarizes an independent investigation of this disaster based on material evidences and advanced computations. The theoretical background and the analytical methodologies applied can be found, for examples, those in the references list [5-26, 30-33,43-

46,50-51]. A part of preliminary results of this analysis have been submitted to the related investigation and administrative agencies since the second week after the bridge's collapse [27,28].

This article is organized as follows: the next section introduces the structural and material's models applied in the analysis. The third section analyzes the results obtained and compares the data with materials' evidences. The following section discusses the reasons that had caused this bridge's undersized design. The fifth section explores further the underlying structural issues that triggered the collapse, from which the lessons learned do have certain significance for the procedure of gusset plates' assessment currently applied. A model based on two-dimensional plate buckling theory has been introduced. The last section summarizes the conclusions.

2. METHODOLOGY AND MODEL APPLIED

2.1 Structural Model: As depicted in Fig. 2, the steel superstructure of I35W Bridge contains three parts: (i) two main truss-frames, west and east; (ii) lateral bracings and 27 floor trusses, (iii) reinforced concrete-slab deck. Fig. 3 is a two-dimensional model of the bridge's main frame and the locations of major gusset plates, i.e. the nodes in the truss-network. Additional subscript "*E*" or "*W*" may be used in the following text to denote a node at eastern or western main frame. As illustrated in Fig. 4a, a two-level computational model has been developed, i.e. using 3D finite element to obtain force-deflection behavior of gusset plate, which is implemented into truss network of the bridge superstructure.

2.2 Materials Model: A structural failure is often started by material's failure in one or several key-structural components, which introduces extra complexities to an analysis of a structural collapse like I35W Bridge. In a new sustainable structure's design, it is generally required to keep the stress level in all components within material's yield limit. By contrast, a failure means applied stress reaches a material's strength limit while the material's strain surpasses yield strain. As explained by the example in Fig. 4b, for the defect-free plate under uniaxial tension on left-upper corner, the corresponding average stress-strain curve is the solid line that linearly increases from the origin and connects the thick dash line that ascends nonlinearly, plotted in middle. A material's failure is the result of evolution of one or many defects. When a defect in the form of crack exists in the plate, as plotted in the lower-left, the average stress-strain relations can be represented by the linearly solid line connected with these thin short-dashed lines corresponding for different crack lengths. When the material elements at crack tip fails, the crack grows, for example, from a_0 to a_2, the plate's elongation will increase continuously while applied stress decreases, as illustrated by the solid line connected through the dots. For common 30-50 grade mild structural steels at room temperature, such a crack growth is an accumulation of micro-scaled damages in the form of voids nucleation, growth and coalescence [9-13,30-33]. The "spring model" or "cohesive model", developed in [12,13], have been implemented into finite element analysis to count such a damage-induced material's failure.

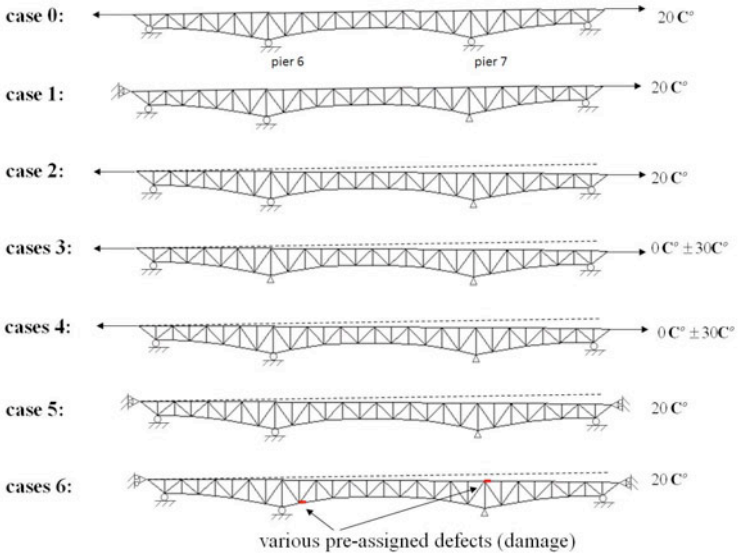

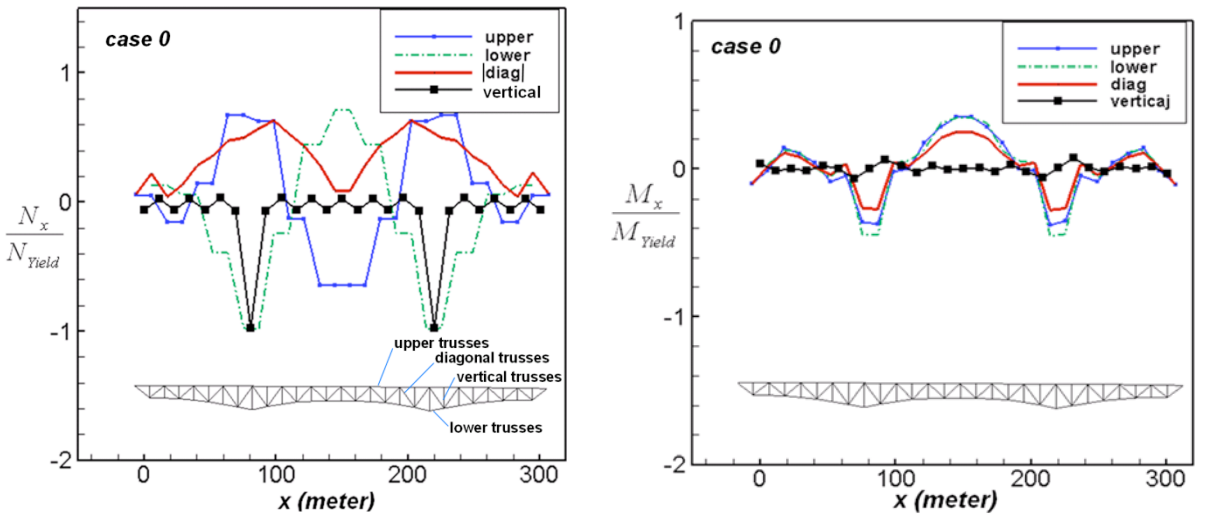

Fig. 5: Cases analyzed: Case 0: flat deck; all support bearing are rollers; **case 1**: the same as 0 but the pier 7 bearing was locked; **case 2**: design condition - the same as 1 but with deck slope; **case 3**: design condition but with locked pier 6 bearing, temperature varies; **case 4**: design condition, temperature varies; **case 5**: design condition, horizontally confined; **case 6**: design condition but with pre-existing defects at various gusset plates; see [27a]. Each case contains several respective sub-cases with different parameters.

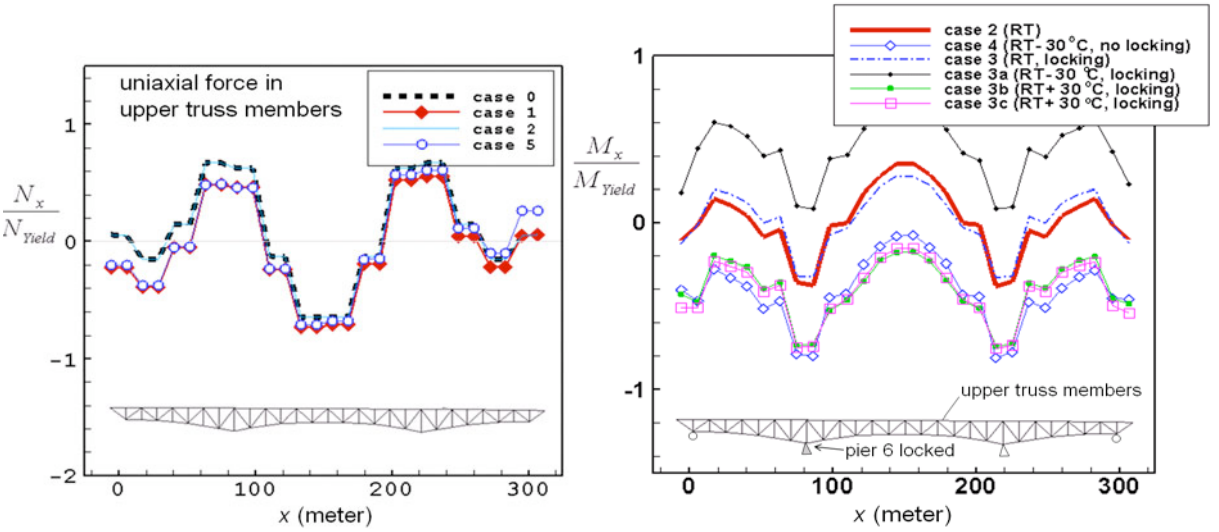
2.3 Cases Analyzed: in the first report that was finished seven weeks after the disaster [27a], a primary object was to identify the locations that might initiate the failure through computer simulations of various possible failure processes, so as to assist official investigation to identify the actual location and causes. Due to limited data and information at the time, 2D and 3D computer simulations for about 20 cases (Fig. 5) of the bridge's superstructure's failure have been performed to consider various circumstances which include (a) the effects of supporting bearing conditions to superstructure's load path and stress amplitude; (b) whether the bridge-deck's slop (about 1 degree, see Fig. 2) caused extra horizontal forces; (c) temperature's change-induced thermal stresses, which include two cases: day-night and seasonal shifts caused uniform changes and the case with non-uniform temperature distribution, for example, the upper chords (the trusses near deck) are warmer than other parts; (d) pre-existing defects at various locations.

3. RESULTS AND DISCUSSION



3.1 Forces and Bending Moments Distributions: Plotted in Fig. 6(a) are the uniaxial forces in the four groups of truss members in main frame, which are upper chords, lower chords, truss diagonals, and truss verticals. The force in upper chords, the solid line connecting small solid dots, reaches its positive maximum above the piers of center span while the negative maximum at the center. By contrast, the force in lower chords, the light dash-dot line, has a positive peak at the center and two negative maximums above the piers. The distribution of the force in truss diagonals (solid line) is characterized by the peaks around the spots where the upper chord's force decreases from positive to negative while the lower chord's force inversely uprises. As plotted in Fig. 6(b), the bending moment in truss-verticals is ignorable whereas that in other reaches positive maximum in the centre of middle span and negative maximum just above two piers. In this case the bending moment in the diagonal members is generally lower than that in upper and lower chords.

(a) (b)

Fig. 6 (a) Uniaxial force in the four groups of major truss members in main frame, where N_x is the uniaxial force and N_{Yield} is that when material yields; (b) the bending moment distributions, where M_x is in-plane moment and M_{Yield} is the moment at yield. No bearing-lock or temperature change (case 0).

Fig.7(a) shows a comparison of the upper chords' uniaxial forces for the cases 0,1,2, and 5, which indicates that the deck's slope and the horizontal constraint/forces from approaching spans do not have remarkable effects on this force's distribution. By contrast, Fig.7(b) are the bending moments in upper chords when temperature changes while supporting bearings are locked, i.e. the cases 3 and case 4 in Fig. 5, respectively; compared with the case 2 that is the normal design condition. It demonstrates a significant combined effect of temperature change and locked bearing. In practice, severe corrosion may drastically increase the friction resistance of a bridge's roller bearing; an extreme case is that a roller bearing eventually is fully locked so it becomes a pin point that does not allow horizontal movement. This induces considerable high thermal stress when temperature changes, as demonstrated by this plot.

(b)

Fig. 7: The same plots as that in Fig. 6 but considering temperature change and locked bearings, where RT refers to room temperature; (a) Uniaxial forces in upper chords and (b) the corresponding bending moment.

3.2 Scenario of the Collapse: Now we discuss the following two issues: the sequence of the bridge's superstructure's collapse and what we can learn from it. One may notice that the force and bending moment distributions in Figs.6 and 7 are nearly symmetric to the central span of the bridge. Just after the disaster, there was an argument regarding the sequence of the failure, i.e., which approach of the bridge failed first. An opinion gained many echoes was that all structural components between the two piers over the river failed almost simultaneously, i.e. a horizontal fall of the central span. To clarify this issue, Fig.8 are the photographic pictures recorded by Army Engr. Corp. from south side of the bridge, which was reported by medium (CNN). The water splashes at the moment that middle span was fallen, i.e. Fig. 8(d), reveals the collapse initiated from south side [27a]. The north approach span failed subsequently without showing any capacity to resist the collapse.

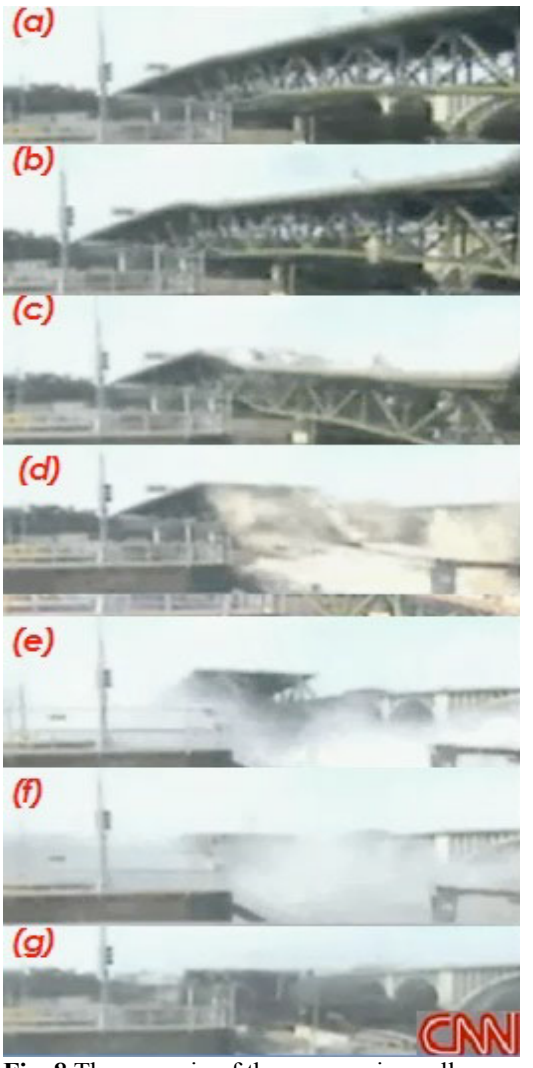


Fig. 8 The scenario of the progressive collapse presented by I35W (Army Corps' Video)

In bridges' design, the three-span like I35W is a common structure; the underlying idea is to gain long central span with minimized cost. This can be explained by the influence-line solutions in Fig. 9. By comparing the bending moments in the three cases with the same middle span length "b" and under the same distributed load "q", one can find that the maximum bending moment of the case (a) is about 80% higher than that in case (c); similarly, the moment of case (b) is about 20% higher than case (c).

However, from the viewpoint of structural integrity, the advantage of the three-span design (c) is traded-off by lower redundancy. This is because, when one of three spans is severely damaged or fails, the force distributions in other two shift back to the situation similar to the case (a). Such a scenario is illustrated in Fig. 10. This, the author believes, was a reason that caused the progressive collapse of I35W Bridge. This leads to a conclusion that states as following: to avoid a similar progressive collapse that occurred in I35W Bridge, an additional safety factor may be necessary for those key single-load path structural components in a multi-span bridge if its design of load capacity is merely based on the influence-line analysis described in Fig. 9(c).

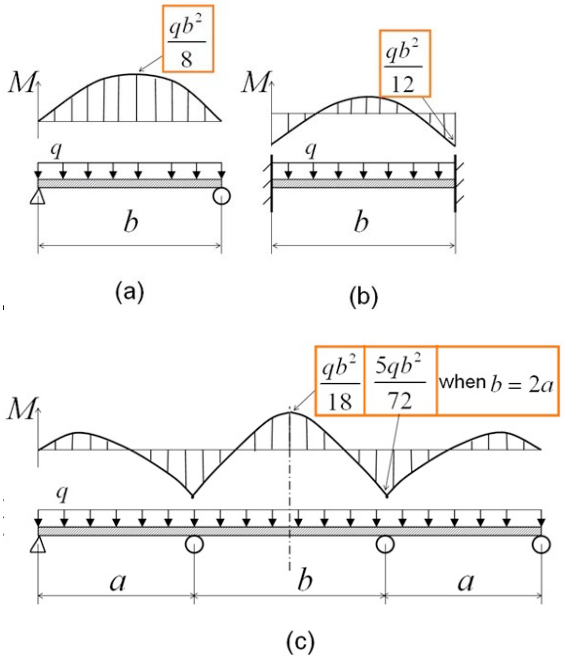

Fig. 9 The influence-line solutions explain the benefit of a three-span bridge's design like that in I35W because the peak bending moment in case (c) is much lower than that in case (a) and case (b) for the same span length "*b*" and uniformly distributed load density "*q*".

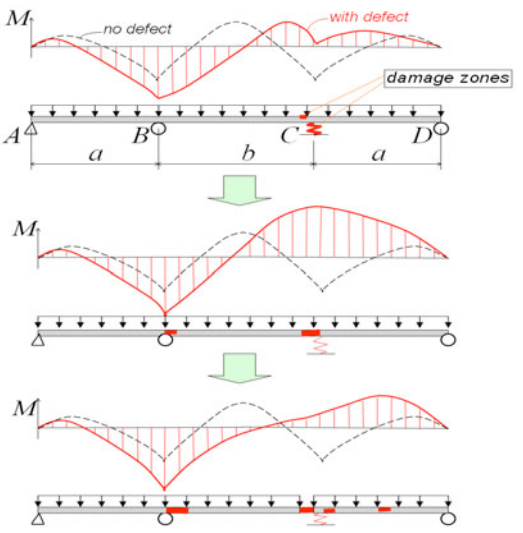

Fig. 10 A scenario that a material's failure induces a progressive structural failure in a three-span bridge, where the material's failure occurs first at the location just above the bearing support C, which results in the material's failure around the bearing support B; subsequently the beam AB becomes a simple span that is the same as the case (a) in Fig. 9.

3.3 Where the Collapse Started: The early study [27a] suggested that damage-induced material's failure caused the structural failure. Such a material's damage can be, for example, fatigue-induced cracks or significant corrosion-resulted section loss. Obviously, an undersized design has the same effect as such a damge. Three possible failure patterns were focused, see Fig. 11, and the case (c) was considered as mostly close to reality [27a]. Although this simulation was done just a couple of weeks after the collapse (submitted to NTSB at August 17th, 2007), it does demonstrate significant deflection around the node U'9 and U'10. The "undersized" gusset plate U'10 actually initiated the bridge's failure[1,2,41].

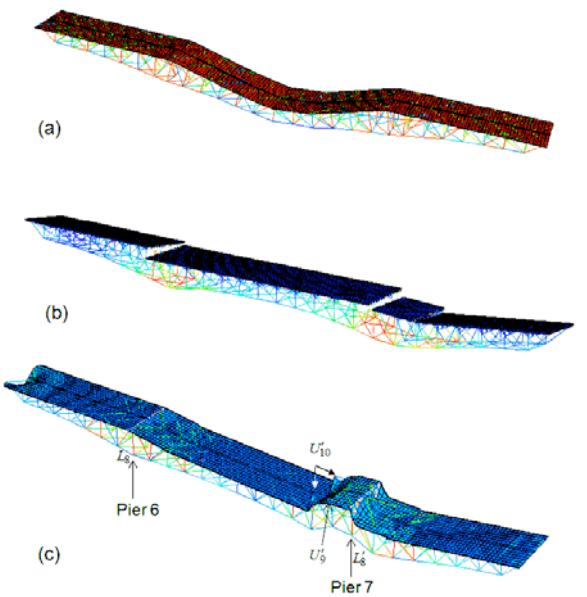

Fig. 11. Three failure patterns of the bridge

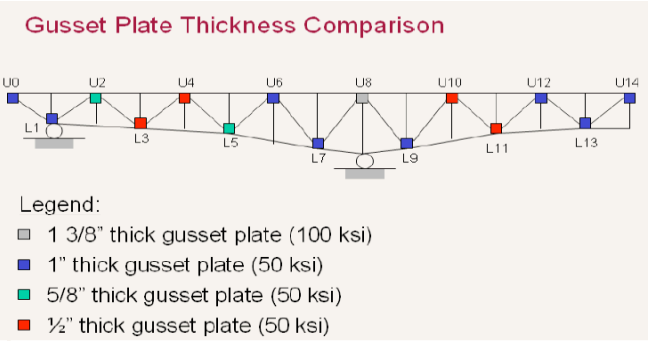
3.4 NTSB's Findings and Conclusions: after thorough examination of the wrecked pieces of the bridge, at January 15, 2008 and November of 2008, respectively, NTSB has released the results of the official investigation [1,41], which disclosed that the gusset plates at the nodes U10,U'10,L11,L'11 in main frames of central span and U4, L3,U'4,L'3 of the approach-spans are undersized, which are half inch thick.



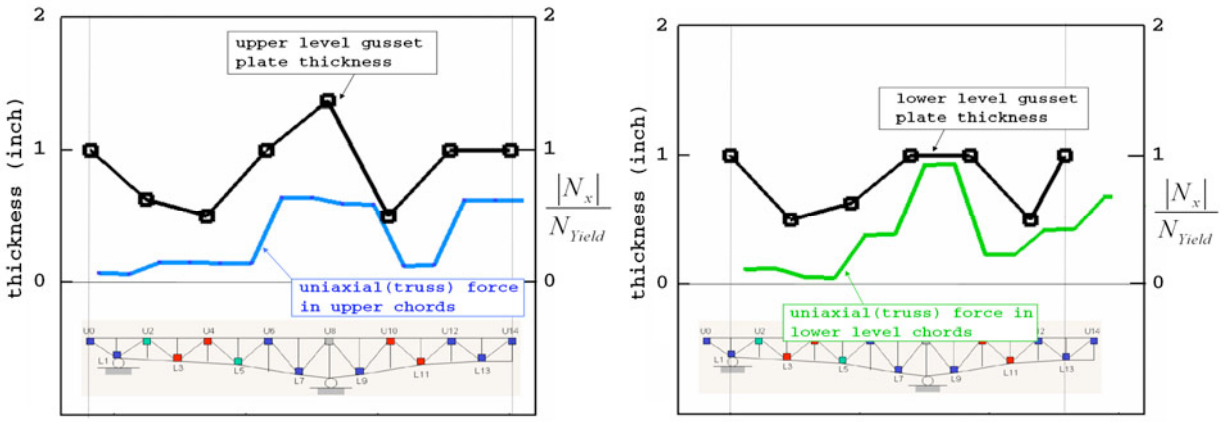


Fig. 12 Gusset Plates Thickness in I35W Bridge[1,41]

By contract, all other gusset plates in the nodes that connect four or five truss members were one inch in thickness or more, see Fig. 12. Also, the NTSB's analyses of the video recorded at the instance of the collapse indicates that the half-inched gusset plate at node U'10 failed first, which triggered the subsequent collapse of the bridge. The record of the design firm of the I35W bridge reveals the bridge designed without appropriated calculation, which resulted in the undersized gusset plates.

(a) (b)

Fig. 13 Comparisons between the gusset plate thickness and the uniaxial forces in horizontal truss members plotted in Fig. 7a: (a) upper chords; (b) lower level chords.

4. WHY THE GUSSET PLATES UNDERSIZED

Plotted in Fig.13 are the comparisons between the actual gusset thicknesses from Fig. 12 and the uniaxial forces of upper and lower-chards that were given in Fig. 6(a). An obvious coincidences between the force distributions and gusset thicknesses can be seen except near the end nodes (U_0, L_1). All half-inch gusset plates (U_4, U_{10}, L_3, L_{11}) are at or close to the locations with the lowest truss force. This fact seems implying that the plates' thicknesses were designed based on the forces in horizontal trusses.

However, by checking the results plotted in Fig. 6(a) carefully, one can find another fact: the force in diagonal member almost reaches its peak value at the location, for example, between

$U_{10}L_9$ and $U_{10}L_{11}$, where the upper and lower chords forces change signs. The reason is obvious: at this location the diagonal truss $U_{10}L_9$ transfers the deck load-induced compression force flow in middle upper chords of central span into lower chords and supporting bearings; whereas $U_{10}L_{11}$ transfers the tension force flow in middle lower chords into upper chords above the piers; whereby the gusset plates like L_9, U_{10} and L_{11} are the "pivots" for these load paths of force flows, as explained in Fig. 14.

Therefore, a statement has been given in the third paragraph, section 5 of the report [27a]: "Due to the limited computation capability in past, it seems that the original design and subsequent early investigations could only treat the 9340 bridge* as a truss-assembled structure, which led to the focus onto the forces and damage conditions in truss members….". Obviously, the truss force in upper and lower level chords had been used as the governing parameters for the gusset plate design, whereas the corresponding stress concentration in the gusset plates did not obtain sufficient consideration at the time.

Based on an examination of all original design drawings and the material evidences disclosed by NTSB's investigation, several other "undersized" structural components have also been identified in the analysis [29]. These components are the upper and lower chords attached to those undersized gusset plates in Fig. 12. It has been found that the thicknesses of upper chords' wall and gusset plates are actually proportional to the bending moment solution of the one-dimensional influence line analysis illustrated in Fig. 10c. This fact reveals that the NTSB-disclosed undersized gusset plates are the consequence of a bias toward a "one-dimensional model" in the original design, which did not give sufficient consideration to the effects of the forces from diagonal truss members input into gusset plates [29].

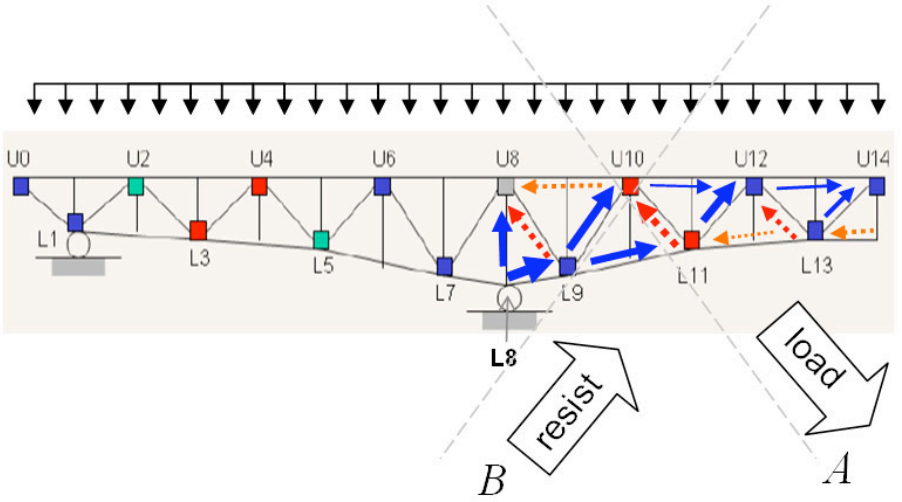

Figure 14 An illustration of the main "load path" in central span of I35W, where the blue solid-line arrows represent compression and the red dotted line arrows represent tension. The compression is mainly corresponding to the resistance from the pier and the global bending moment; whereas the tension is mainly corresponding to span's weight and deck load. The gusset plates U10, L11, U12 are the pivots to balance load and resistance forces transferred by diagonal members. The major function of vertical trusses is to provide redundancy to the truss cells except the member L8-U8.

* The I35W Bridge is numbered as 9340 in national bridge inventory.

5.“TRUSS APPROXIMATION” AND GUSSET PLATE

A practical question is: how to determine a gusset plate’s capacity in practical applications? Conventional consideration treats gusset plates as additional stiffeners that do not have significant effect to a truss network load capacity. The author of this paper had also been convinced for while that “truss-approximation”, i.e. omitting bending moment and shear in slender structural members of a truss network, was good enough for applications. Under this approximation, a gusset, which fastens connected truss-members, becomes a “hinge” that allows free rotation between adjacent members because of no bending moment exists. This approximation generally provides acceptable accuracy for long beams/trusses while significantly simplifies analysis, which has been successfully applied over centuries. However, it should be noticed that the resulted “hinge approximation” implies the ignorance of the secondary stress caused by bending moment at a gusset plate and the corresponding stress concentration. These stresses may not have significant effect to truss members but can be crucial for a gusset plate. To demonstrate this point, two simple examples are given in Fig. 15 to explain the differences.

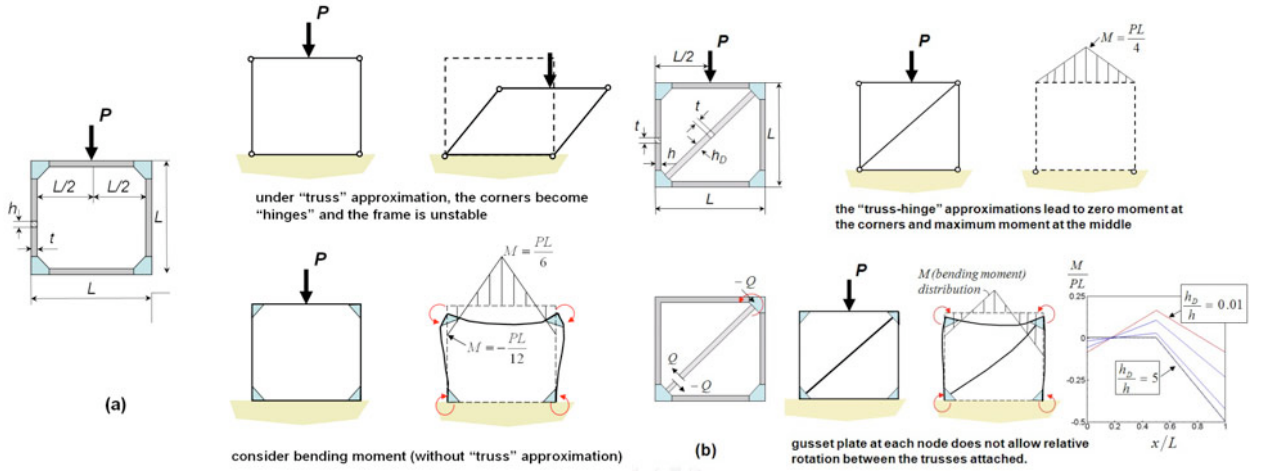

Fig. 15 (a) The truss-cell is an unstable structure when hinges are at the corner. By contrast, gusset plates keep the adjacent trusses perpendicular to each other, resulted in the bending moments at the corners; (b) An additional diagonal bracing stabilizes the frame; the bending moments become more remarkable at the upper-right node gusset and its amplitude increases when the ratio of the widths of diagonal bracing (h_D) and vertical trusses (h) increases; when this ratio is large, the upper horizontal truss is like a cantilever fixed at right end by the gusset plate.

Fig. 15(a) shows a square truss-cell that is unstable when the nodes at the corners are hinges. Adding gusset plates to keep the adjacent trusses perpendicular to each other, which makes the cell becomes a stable frame but results in bending moment at the gusset. When an additional diagonal truss is added to the cell in (a), as illustrated in Fig. 15(b), the cell becomes a stable structure despite hinges at the nodes. The corresponding bending moment in upper chord is plotted when a concentrated force is imposed. As a comparison, the lower part of this figure is an analytical solution when the nodes are stiffened by gusset plates; stronger diagonal member results in higher bending moment at the node, hence, the gusset plate.

It is no doubt that “truss approximation” can provide satisfied solution for the uniaxial forces of slender members in many cases. However, when force flows in a truss-network are not uniform, instead, varying drastically, the corresponding bending moments, particularly, at gusset

plates, can be remarkable. This may occur at least under the following three conditions: (i)concentrated load presents; (ii) inhomogeneous internal stress, for example, thermal stress; (iii) residual stresses caused by, for example, in-appropriated welding or cambering. For a structural member like a gusset plate with complicated geometry, a bending moment-induced stresses and corresponding stress concentration may have substantial effects on its load capacity and fatigue life. The effect of bending moment can be viewed directly by the numerical analysis presented in Fig.9(c), which shows significant relative rotation between adjacent trusses around those pivotal nodes such as U10, L11 when the superstructure starts to fail. This result can be verified by the bowing of the actual U'10 gusset plate observed four years before the bridge's collapse, see Fig. 16(a), which could be caused by a past deck's overload or the result of cambering during erection. In either case, such a bowing implies reduction of the gusset's load capacity and, thus, its vulnerability to this kind of loads applied later.

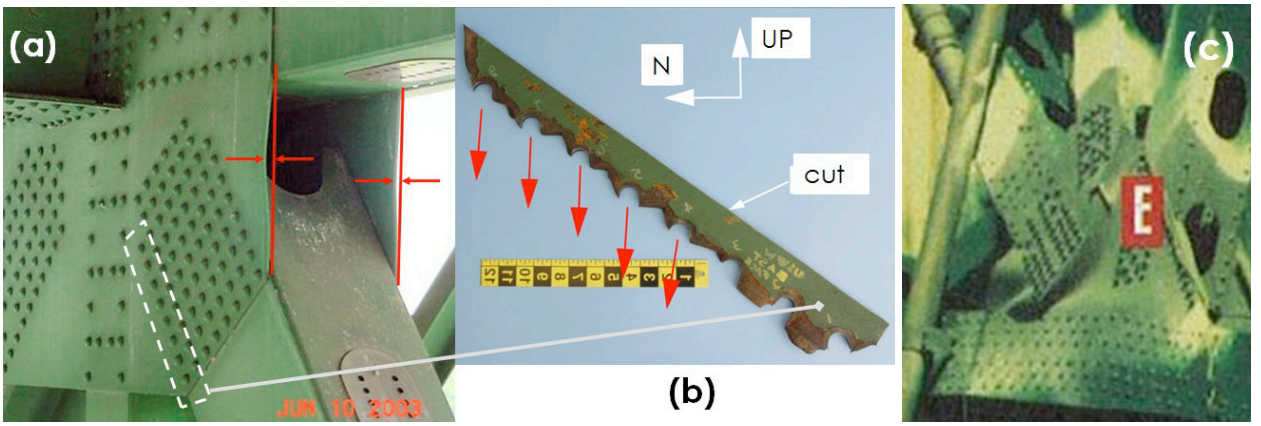

Fig. 16 Three patterns of gussets' failures:(a) bowing, I35W Bridge's gusset plate U10' [2]; (b) a cut of the U10' plate's lower part; (c) buckling due to the large ratio of unbraced length /gusset thickness, which occurred in the highway I90 Grand River Bridge, Ohio, 1997 [47];

6. GUSSET PLATES' LOAD RATING

6.1 Failure patterns of gusset plates: The gusset plates' failure in I35W Bridge is not a unique case. Fig. 16(c) shows a gusset's buckling that occurred 1997 at the Grand River Bridge that carried highway I90 of Ohio [47,48]. Therefore, it can be assure that gusset plate may fail at least by three different patterns: (i) bending and associated rotation-induced bowing, on the part of a gusset plate with free-edge between two adjacent trusses, see Fig. 16(a); (ii) tension-dominated ductile failure between the edges of two adjacent trusses, which can be a cause or the result of a bowing presented at another edge of one truss, or occurs independently; (iii) buckling in the unbraced area in the front of an attached truss, which may be accompanied by bowing nearby, as demonstrated in Fig. 16(c).

Most gusset plates in steel bridges are made of 30-70 grade mild steels. This class of steels often fails in the form of ductile fracture except under some particular circumstances such as temperature below ductile-brittle transition point or within the area near or at a welded joint. For a thin gusset plate, buckling or bowing is when compression force reaches instability limit when applied stress may be much lower than yield strength. By contrast, a tension-dominated failure is an accumulation of shear deformation along slip-planes of polycrystalline matrix at yield limit, which may present in two modes: the out-plane shear that induces necking; and the

in-plane shear that often starts at a free edge with stress concentration, for example, a rivet's hole or a crack, and then leads to a Lude's band. Both modes present in Fig. 16(b) but within different areas.

6.2 Load-rating gusset plates: The "bowing" of the U'10 gusset plate of I35W in Fig. 16a is considered as an early warning sign. That tragedy proofs a failure of such a gusset can lead to entire bridge's fall. Therefore, in a new truss-bridge's design or an aged bridge's load-rating, a practical issue is to identify its load capacity based on each structural components' capacities including all gusset plates, whereby the following two steps are essential:

1) Compute the forces and bending moments input into a gusset plate in a truss bridge, if the "truss approximation" applies, it should be aware of the corresponding deviation in result.
2) Determine the limit state for each gusset plate within engineering acceptable accuracy.

To this end, a procedure and associated computer programs have developed to investigate the failure process of I35W Bridge based on the theories and methodologies introduced in [5-26, 30-33,43-46,50-51]. A series of in-depth three-dimensional computations of I35W Bridge under the actual live loads at the instance of collapse, see Fig. 17, as well as the bridge under various design conditions, have been performed [28,29] according to original design drawings and in the light of the material evidences of NTSB's investigation[1,2] and FHWA's technical advisory [3].

In addition to the discussions of more undersized-components disclosed from original design drawings and the evidence of the one-dimensional influence line solution-biased original design, another conclusion obtained in [29] is that the nodes connecting floor trusses and main truss-frame, see Fig. 17b, was inappropriately designed. This is because it actually divides deck load to two high-amplitude force flows input into a weak gusset plate, i.e. compression on the plate's top and downward tension on its bottom edge. The particular structural features presented in this part and the implications to load capacity are to be discussed in follows because they can be useful for other gusset plates' load rating in general.

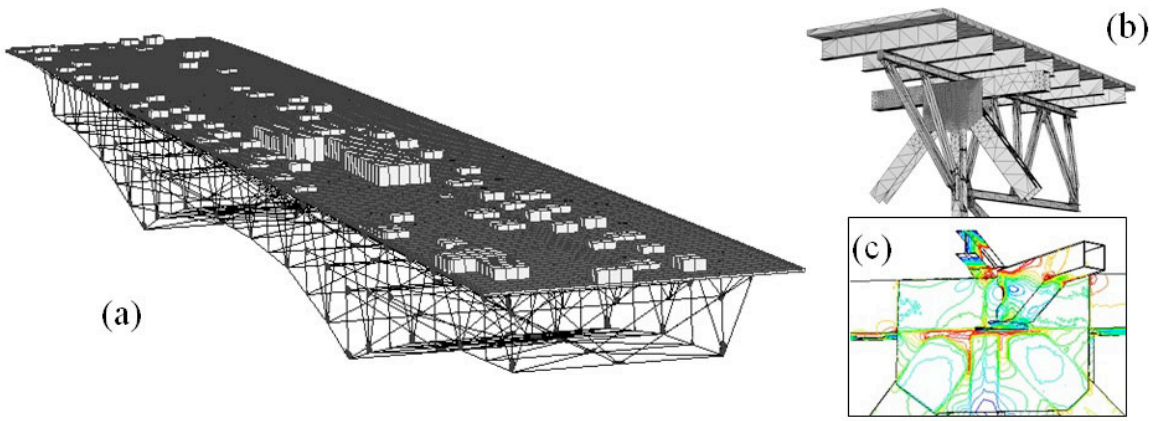

Figure 17. (a) A fully-scaled computation of I35W Bridge [29] based on design drawings and live load at the time of collapse, where the trucks, cars, and construction materials are represented by the brick elements with the densities corresponding to their weights; (b) a finite element model for the connection between floor truss and main flame at the node U10; (c) computed stress contour on an inside gusset plate[27b], which indicates the stress on the inside horizontal lateral bracing introduces lateral force that affects the deformation of the gusset plate.

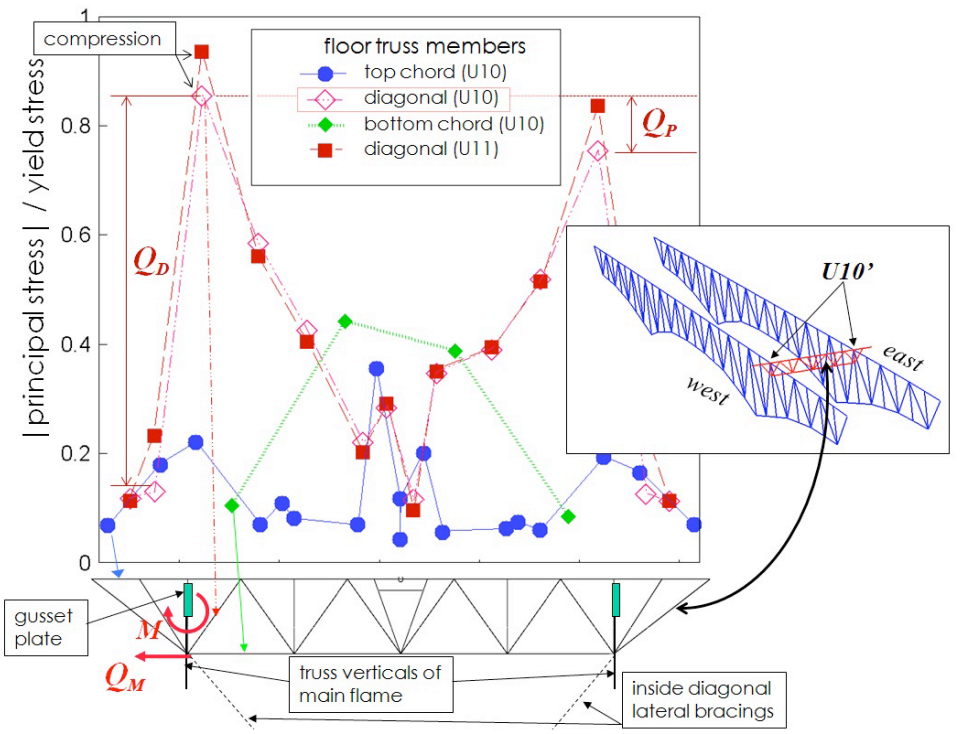
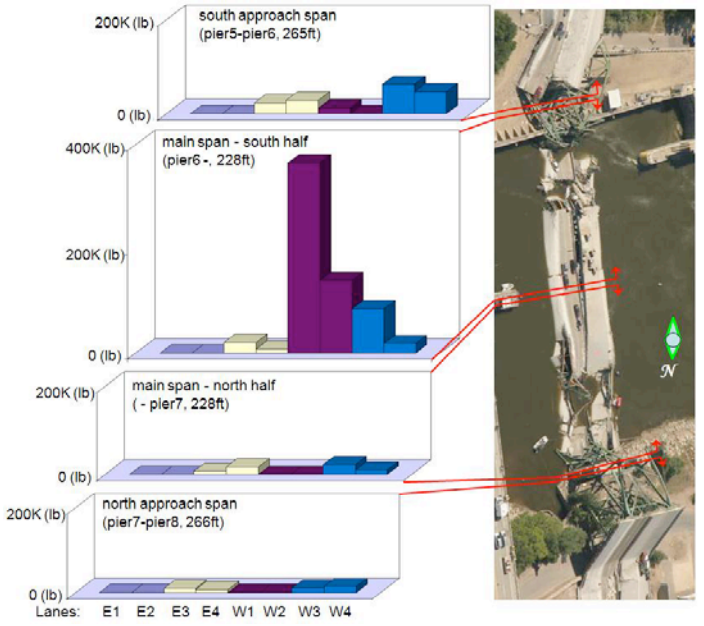
Plotted in Fig. 18 are the computed uniaxial stress in the floor trusses that connect the south U10' and U11' gusset plates of I35W. Here we focus on the stress distribution in the diagonal

members of the floor truss attached to U10', which is plotted as the empty diamonds linked by dash lines. One may notice that the two highest stress peaks occur in the diagonal members just inside the gusset plate on each side, by which the amplitude of the peak near western U10' is about 13% higher than that near the eastern U10'. This difference is denoted as *Qp* in the figure, which, obviously, is caused by the eccentric deck live load at the moment of the collapse, see Fig. 19a. Another notable phenomenon in Fig. 18 is the difference in stress level between the diagonal floor trusses member inside and outside a gusset, denoted as Q_D (on left).

In original design drawings the inside floor truss-diagonal near the gusset was made of W12x92 H-beam; the insider floor truss bottom chord was W12x85 H-beam; and the two outside floor truss-diagonals were W8x35 and W10x54, respectively. Therefore, the magnitude of Q_D implies that, at the node below the gusset plate, the outwards lateral force from the inside truss-diagonal was about 2.6 time higher than the sum of the inwards lateral forces input from the two outside diagonal members. Their resultant must be balanced by the tensions in the floor truss bottom chord, the horizontal force component in the diagonal lateral bracing, and the lateral shear in the main flame vertical truss. According to Fig. 18 there is no significant stress in the bottom chord; whereas the inside diagonal lateral bracing is a very slender beam that has very limited capacity to carry horizontal force. Therefore, the majority of the horizontal resultant is balanced by the lateral shear of the main flame's truss vertical, which is denoted as Q_M in the figure. Q_M produces a bending moment to the attached gusset plate, denoted as *M*.





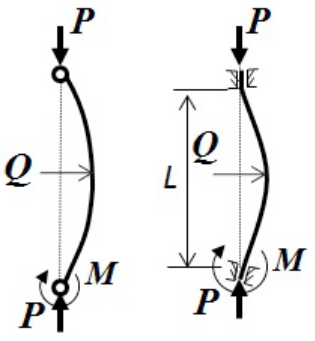


Fig. 18 Stress distribution in floor trusses connect to U10' and U11', which result in the out-of-plane force Q_M and bending moment *M* onto the gusset plate; see the discussion in the text.

On the other hand, the Q_P in Fig. 18 represents the difference of the forces that the floor truss input to eastern and western main flames, respectively. Again, because the stresses on the two

ends of the floor truss' horizontal members attached to the two main flames are almost equal, Q_P should be balanced by the lateral shear on main truss vertical and the horizontal lateral bracings between the two main flames, i.e. the one horizontally attached to the gusset plate in the computation of Fig. 17(c). Fig. 19(a) gives the deck load's distribution of the I35W Bridge when it collapsed; although the majority of the live loads was on the western side, it should be noticed that the stock-piled construction materials, which is the heaviest part of entire live-load, were on the lane W1 that is just beside the central line. This can be a reason that the difference Q_P is less than 15% of the total force in the floor truss diagonal. Obviously, there is no need to address the fact that the deck load-induced vertical force on the western gusset plate is much higher than that on the eastern side. In Fig. 19(a) the live-load on the lane W1 equals the weight of several design trucks (80 kips each). In practical application, a worst scenario could be the case that multiple presence of heavy trucks line on one side of a bridge's deck, for example, the lane W4 in Fig. 19(a). Under this situation, Q_P can be significantly higher.

(a)

(b)

Fig. 19 (a) I35W Bridge's deck live load distribution at the moment of collapse, which causes the difference Q_P in Fig. 18; (b) Eular's instability models with lateral force and bending moment under two boundary conditions; for gusset plate, the lateral force and bending moment are out-of-plan force and moment.

The forces Q_P and Q_D in Fig. 18 introduce extra out-of-plane force Q_M and bending moment M to the gusset plate, as illustrated at the left-low corner of Fig. 18. These kinds of lateral forces and moments generally may have significant impact to the gusset and the attached truss-verticals' stabilities. For an engineering evaluation, conventional procedure often simplifies a structure into a one-dimensional model, then applying Eular's instability criterion, as illustrated in Fig. 19b. This criterion is exact for long slender structures such as bars and columns. For a two-dimensional structure like a gusset plate, Eular's criterion is generally over-conservative when all external forces lie in the same plane as the plate does. However, for either a one-dimensional bar or a two-dimensional plate, when lateral force or out-of-plane bending presents, see Fig. 19b, corresponding modifications are necessary. Theoretical solutions of lateral forces have already been obtained for one-dimensional bar, for examples, see [5,6]. Theoretical

analyses in these literatures indicate that, when an out-of-plane force Q or bending moment M is proportional to in-plane compression force P, for an elastic slender structure component the following relationship holds:

$$M_{\max} \propto \frac{P^2}{1-(P/P_E)} \tag{1}$$

where $M_{\max}$ is the maximum bending moment in the component; P_E is the Eular's prediction of the load at onset of instability. This relationship implies that a lateral load does not have strong effect on the instability load. However, the maximum bending moment may increase drastically because it is proportional to the square of in-plane load. This may cause material's yielding earlier than the case without out-of-plane forces, resulted in reduction of system stiffness and subsequent loss of stability even when applied load is still lower than Eular's prediction [50, 51].

A thin-plate theory [5,6] based model has been developed, see Fig. 20, which partitions a gusset plate into several zones characterized by different failure modes and the model enables to obtain analytical or semi-analytical solution for each mode. This is because a gusset plate's un-braced area is generally one order greater than its thickness. Such a thin plate may fail through two mechanisms: tension-induced material failure or buckling under compression, as discussed early in this paper. Accordingly, the two cases in Fig. 16 demonstrate the three corresponding patterns: (i) buckling at unbraced area due to compression, Fig. 16c; (ii) compression-induced bowing of the triangle area of a gusset, Fig. 16a; (iii) tension induced necking in another triangle area of the gusset, together with shear failure around rivets, Fig. 16b. These patterns may occur concurrently or a dominant one triggers another. The challenges for design and load-rating a gusset plate are to identify the key parameters that are able to characterize geometric complexities and to compute the limit load at critical conditions considering lateral perturbation.

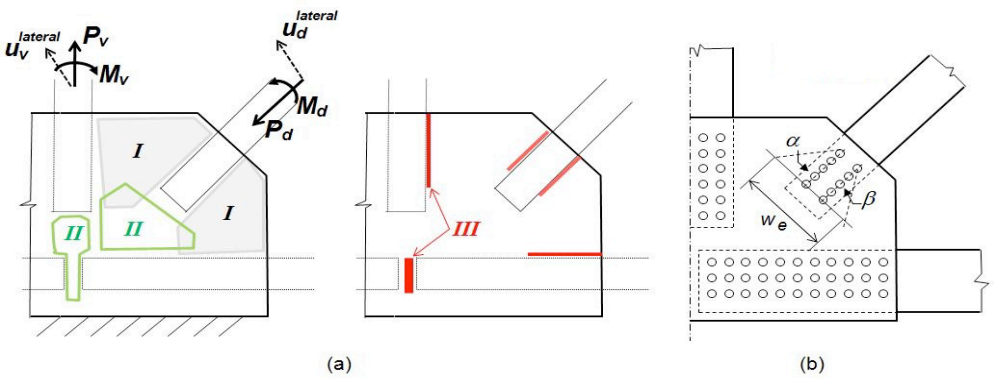

Fig. 20 A thin-plate theory based model[49a] to analyze gusset plate: (a) the gusset plate is parttioned into three characteristic zones that may be governed by different failure modes: I. bowing/necking, II. buckling, III. shear failure dominates; (b) a proposed "Modified Whitmore Model (WWH) where the angles α and β are determined by local geometries.

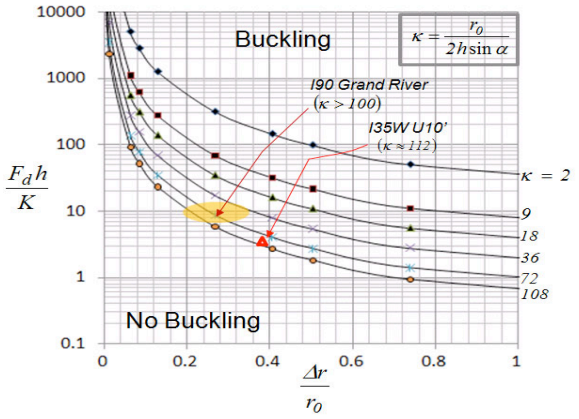

Fig. 21 A semi-analytic solution of gusset buckling based on Von Karman's thin plate instability theory[38]. For a given geometric parameter κ, each curve in this chart defines the corresponding critical load at buckling for a modified Whitmore mode [49a,b]; F_d: the critical load at buckling

For buckling, a group of semi-analytical solutions has been obtained based on Von Karman's thin plate stability theory [38] after some additional geometric modifications to the Whitemore model. Introductions of this theory and related applications can be found, for examples, in [5,6,40]. Further theoretical developments of structural stability can be found, for examples, in [43,44,50-51]. According to this theory, the stability of this fan-shaped is governed by the stationary solution of the following equilibrium condition (in polar coordinate system):

$$K\Delta\Delta w = N_{rr}\frac{\partial^2 w}{\partial r^2} + N_{\theta\theta}\left(\frac{\partial w}{r\partial r} + \frac{\partial^2 w}{r^2\partial\theta^2}\right) - 2N_{r\theta}\left(\frac{\partial w}{r^2\partial\theta} - \frac{\partial^2 w}{r\partial\theta\,\partial r}\right) \quad \text{where} \quad K = \frac{Eh^3}{12(1-v^2)} \tag{2}$$

where $N_{rr}, N_{\theta\theta}, N_{r\theta}$ denote the in-plane radial, hoop, and shear force densities, respectively; w is out-of-plane displacemen. The solved force is plotted in Fig. 21 after normalization.

Conclusions

To avoid a progressive collapse that occurred in I35W Bridge, additional safety margin, i.e., an enlarged safety factor for ASD-Allowable Stress Design (or η_R in LRFD), is necessary for all key single load-path structural members in a multi-span bridge if this bridge's design is merely based on the one-dimensional influence-line analysis explained in Fig. 9(c).

Roller bearing condition is crucial for maintaining an aged bridge's safety operation. Corrosion or other deterioration induced roller bearing lock may result in significant thermal stresses in a bridge.

Stress concentration and bending moment: bending moment and induced-stress concentration around truss-joints may have remarkable effect on bridge's load capacity and fatigue life. Due to the limited computational means in past, these effects might be treated in an *ah hoc* way, for example, large safety factor. In order to avoid over-conservative or risky designs, relatively accurate computation is necessary.

Effects of lateral forces: based on NTSB's material evidences, the results of this analysis suggest three failure modes of gusset plates, i.e. buckling, bowing, and tension-induced necking; the necking is an out-of-plane shear failure, which is essentially the same as an in-plane shear failure in ductile steels. The three failure modes may occur at different areas in a gusset, depending upon the forces and bending moments input from attached trusses. Obviously, the amplitudes of these forces are strongly depending upon deck's live load distribution, bearings' condition, and the details of superstructure's design. Both the eccentric

deck's live load and the inappropriated design of the joint between floor truss and main trusses frames in I35W caused remarkable out-of-plane (lateral) force and bending moment.

Load-rating gusset: this analysis concludes that the lateral forces involved in I35W Bridge's failure may present in other similarly-structured truss bridges, which may significantly reduce a gusset plate's capacity, especially, against buckling, because of localized nonlinear effects. To accurately capture these kinds of load paths, three-dimensional consideration and detailed computation are necessary.

Based on the theories introduced in [5,6] and Von Karman's thin plate stability formulation[38], a semi-analytical solution for a modified Whitmore model of gusset plate's stability has been developed.

ABSTRACT

The limestone composed of calcium carbonate is an important resource as the main material for the cement, which is the basis of all construction materials, and most calcium in natural environment takes the morphology of calcium carbonate. This paper presents a basic study on the development of construction materials in an eco-friendly manner by using biomineralization of effective microorganisms.

Micro-biologically induced calcite precipitation (MICP) was achieved using the effective microorganism, *Sporosarcina pasteurii* ATCC11859, an aerobic bacterium pervasive in natural soil deposits. This study searched beneficial microorganisms inhabiting on the based experimental method (16S rDNA base sequence analysis, the EDTA titration method, and X-ray diffraction analysis) of using standard cultured microorganism, *Sporosarcina pasteurii* ATCC11859, to separate and identify eight new beneficial microorganisms, *Sporosarcina soli* KNUC401, *Bacillus massiliensis* KNUC402, *Arthrobacter crystallopoietes* KNUC403, *Lysinibacillus fusiformis* KNUC404, *Halomonas aquamarina* WC-1, *Halomonas hydrothermalis* WC-2, *Bharhavaea cecembensis* JC-1, *Microoccus yunnanensis* JC-2, producing calcite (a mineral morphology of calcium carbonate), for basic research. The result of this study, bio-mineral characteristics of these microorganisms, has been researched. This research, which used eight newly identified effective microorganisms, may be premature for its application to actual situation and thus needs further consideration for advanced research in the future. The effect of the application of calcified Cell-$CaCO_3$ to mortar performance can lead to the development of a new material that will contribute to alleviation of environmental problems as well as facilitation of concrete remediation and repair work.

The results of this experiment showed formation of calcite and hardening of mortar surface. Scanning electron micrographs (SEM) verified formation with precipitated calcite forming bonds at particle-particle contacts. X-ray diffraction (XRD) analysis confirmed that the observed calcite was comprised of calcium carbonate. Additionally, the basic experiment indicated that mortar pores could be filled by calcified Cell-$CaCO_3$ with microorganisms and calcite complex structure.

INTRODUCTION

The ancient earth crust was covered with volcanic rock and meteorite materials, and microorganisms have taken an important role of various chemical process of the earth such as bioleaching of a variety of metals including steel and circulation of organic materials. The microorganisms have been involved in the interaction with control factors of the earth chemical through these bio-chemical processes [11]. Development and synthesis of nano materials by microbial biomineralization are currently in early investigation stage, and the possibility of using particles of uniform size and regularity, which are produced by microorganisms in the process of adaptation to environment and preservation of species, as functional nano materials has been examined [10]. Limestone among these rocks formed by microorganisms has built vast sedimentary basin from continental shelf to ocean floor, and a huge amount of carbon dioxide in the earth crust has been contained in the limestone through

this sedimentation of the earth chemical process. Limestone is a sedimentary rock composed of calcium carbonate, and its component, calcium, is the most abundant element after carbon and silicon [1]. The limestone composed of calcium carbonate is an important resource as the main material for the cement, which is the basis of all construction materials, and most calcium in natural environment takes the morphology of calcium carbonate. Calcium carbonate is largely classified into three types of crystallization-calcite, aragonite, and vaterite, and it is used mainly as a filler material. There chemical and organic processes of calcium carbonate production in natural environment. When these processes occur continuously and simultaneously, bio-chemical reaction accompanied by micro-chemical process takes place. This reaction is called biomineralization by microorganisms [2].

Additionally, the technique to use microbial biomineralization for the improvement of surface quality and functionality of concrete has been proven to be possible by earlier research finding of such a microbe, i.e. *Sporosarcina pasteurii* ATCC1189, which inhabits the soil to form calcite as a mineral morphology (crystallization) of calcium carbonate [3,4,5,9]. Although a lot of researches in construction material field have been conducted to eradicate harmful contagious germs and fungi, there are a few researches on the improvement of quality and functionality of concrete by using microorganisms. Previous research trend to apply these microorganisms to concrete has been carried out preliminarily with their application to mortar. Since the best pH environment for *Sporosarcina pasteurii* inhabiting the soil is around 9 but the pH of cement environment is strong alkaline with pH of 12, its long-term survival has been the research issue for many studies [6,7,8,12]. Accordingly, if microorganisms with similar characteristics of producing calcite, a mineral morphology of calcium carbonate, like *Sporosarcina pasteurii*, but having a longer life in concrete can be identified for its use in concrete, it should be very advantageous and thus a merit for this research. This study searched beneficial microorganisms inhabiting concrete structure based on the experimental method of using standard cultured microorganisms, *Sporosarcina pasteurii* (ATCC1189), to separate and identify eight new beneficial microorganisms, *Sporosarcina soli* KNUC401, *Bacillus massiliensis* KNUC402, *Arthrobacter crystallopoietes* KNUC403, *Lysinibacillus fusiformis* KNUC404, *Halomonas aquamarina* WC-1, *Halomonas hydrothermalis* WC-2, *Bharhavaea cecembensis* JC-1, *Microoccus yunnanensis* JC-2, producing calcite (a mineral morphology of calcium carbonate), for basic research. The result of this research, bio-mineral characteristics of these microorganisms, has been reported [14].

This study presents in-depth characterization of these eight newly identified microorganisms, producing calcite, in terms of their contribution to improvement of construction structure as well as the evaluation of Cell-$CaCO_3$ preparation in accordance with the calcite production performance of these microorganisms. This useful Cell-$CaCO_3$ was applied to mortar for the purpose of the improvement in the quality and performance of concrete in this study to evaluate the compressive strength property in relation to various curing conditions. Then, the mortar was forced to crack for the investigation of the crack filling ability of these microorganisms by calcite production. Finally, the direction for future research and the possibility for future development are discussed.

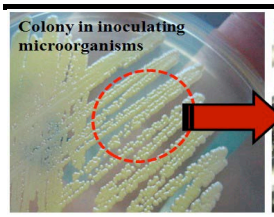
NEWLY IDENTIFIED CALCITE-FORMING EFFECTIVE MICROORANISMS

This study uses MICP (micro-biologically induced calcite precipitation) by eight newly identified microorganisms by 16S rDNA sequence analysis as shown in table 1 in addition to the typical microorganisms, *Sporosarcina pasteurii* ATCC11859, which inhabits the soil and produces calcite as previously discussed. The 16S rDNA sequence analysis among the methods for identification of microorganisms computes the similarity and evolutionary distance between cultured microorganisms based on the previously analyzed data of the microorganisms.

Table 1. List of newly identified calcite-forming effective microorganisms

No	Job Type	Isolate No.	Nearest neighbor based on 16S rRNA sequence (Accession No.)	Similarity (%)
1	**Identify**	KNUC401	*Sporosarcina soli* (GQ214000)	**98.83**
2		KNUC402	*Bacillus massiliensis* (GQ213997)	**96.60**
3		KNUC403	*Arthrobacter crystallopoietes* (GQ213998)	**99.85**
4		KNUC404	*Lysinibacillus fusiformis* (GQ213999)	**100.00**
5		WC-1	*Halomonas aquamarina* (AJ306888)	**99.56**
6		WC-2	*Halomonas hydrothermalis* (AF212218)	**98.21**
7		JC-1	*Bharhavaea cecembensis* (AM286423)	**99.58**
8		JC-2	*Microoccus yunnanensis* (FJ214355)	**99.29**

[Computational method of micro-biological evolutionary distance]



K = -(1/2)In{(1-2P-Q)(1-2Q)1/2} *K : Micro-biological evolutionary distance

*P,Q denotes the replacement ratio for each metastasis type and changeover type among rDNA replacement ratios

It analyzes rDNA sequence of 1,300～1,400bp for the identification of microorganisms. Similarity between cultured microorganisms was determined by the computational method of micro-biological evolutionary distance, and the evolutionary distance between organisms is proportional to the number of transition of DNA elements during the evolution process. There are various types of DNA element transition. Sometimes, several transitions take place in the same place of DNA sequence, and other types of transition occur. Changeover-type transition (pyrimidine from purine or the reverse transition) is known to occur easily by metastatic transition (the distance between purine and pyrimidine or the distance between pyrimidine) [13]. The equation for similarity analysis is based on this property of DNA element transition, and there are only about 4,000 species that have been identified so far according to microbiology reports. If the similarity between cultured microorganisms is below 98.5%, it is regarded as a new species. It is current situation that this type of research dealing with the use of microorganisms in construction material field does not exist, and these eight newly identified effective microorganisms resources not only suggest a basic direction for future research but also are expected to have an academic merit in consideration of their environmental benefit.

The mechanism of micro-biologically induced calcite precipitation (MICP) is very complex. As it was discussed in our previous research [15], the bio-chemical precipitation of $CaCO_3$ in natural environment is generally accompanied with biomineralization of microorganisms. These microorganisms produce $CaCO_3$ on their surface to protect themselves from outside environment. This biomineralization attracts various cations (elements like magnesium, sodium, potassium, calcium, etc.) including Ca^{2+} from the surrounding environment and combines the cations to the cell membrane of these microorganisms to contribute to the precipitation of $CaCO_3$. The precipitated $CaCO_3$ takes the form of a composite Cell・$CaCO_3$ produced by the combination of a cell and inorganic molecule ($CaCO_3$), and is crystallized with continuous activity of the microorganisms. The precipitated $CaCO_3$ is produced not by pure chemical reaction but by bio-chemical reaction. The cell membrane of calcite-forming effective microorganisms as shown in table 2 takes negative electric charge and attracts various cations including Ca^{2+} from the surrounding environment to precipitate $CaCO_3$ on its cell membrane. Our previous research found based on previous research trend that *Sporosarcina pasteurii* ATCC11859, which inhabits the frequently studied soil for the purpose of the improvement in the quality and performance of concrete and forms endospore at extremely hostile environment, produced urease by its metabolism in the urea environment and contributed to the precipitation of $CaCO_3$ on its cell membrane as grown in the Urea-$CaCl_2$ culture medium.

Table 2. Mechanism of $CaCO_3$ precipitation by calcite-forming effective microorganisms

$Ca^{2+} + Cell \rightarrow Cell \cdot Ca^{2+}$

$Cl^- + HCO_3^- + NH_3 \Leftrightarrow NH_4Cl + CO_3^{2-}$

$Cell \cdot Ca^{2+} + CO_3^{2-} \rightarrow Cell \cdot CaCO_3\downarrow$

[Composition of Urea-$CaCl_2$ culture medium]

Make up to 1L of distilled water

1) Nutrient Broth [NB] : 3g (0.3%)

2) Ammonium chloride [NH_4Cl] : 10g (1%)

3) Sodium bicarbonate [$NaHCO_3$] : 2.12g (CO_3^{2-} 25.2mM)

- Adjusting pH concentration to 6.0 with shaking
- Autoclave for 15min. at 121℃

4) Urea [$CO(NH_2)_2$] : 20g (2%)

5) Calcium chloride [$CaCl_2$] : 3.70g (Ca^{2+} 25.2mM)

The bio-chemical mechanism of $CaCO_3$ production on the surface of microorganisms grown in the Urea-$CaCl_2$ culture medium discussed in this section is an important factor of influence of urease to the $CaCO_3$ precipitation. This study prepared culture medium for continuous research and considered the interaction with microorganisms. Since the mechanism of $CaCO_3$ precipitation is very complex, it can be subjected to the influence of the concentration of microorganisms, ion strength (the total of all ions in the solution), pH of the solution, etc. before the contribution of $CaCO_3$ to the improvement in the dynamic performance of concrete. Urease is an enzyme for the hydrolysis of urea to form ammonia and carbon dioxide. This urease action increases the surrounding pH due to the ammonia generated from the hydrolysis of urea and produces carbon dioxide to create an environment conductive to the precipitation of $CaCO_3$.

EVALUATION OF CALCIUM CARBONATE CRYSTALLINITY BY CALCITE-FORMING EFFECTIVE MICROORANISMS

Cell-$CaCO_3$ precipitation reactivity. Previous research found that *Sporosarcina pasteurii* ATCC11859, which likes alkaline environment around pH 9 and forms endospore in harsh environment, produced urease from urea by its metabolism, and contributed to the production of calcite. This experiment used Urea-$CaCl_2$ culture medium to investigate the calcite production of the eight newly identified effective microorganisms in the same urea environment. The Urea-$CaCl_2$ culture medium is chemically composed of 1) 3g (0.3%) of NB (Nutrient Broth) in powder state for the growth of the microorganisms, 2) 10g (1%) of water-soluble Ammonium chloride for the reaction during Calcium carbonate precipitation, 3) 2.12g of Sodium bicarbonate (CO_3^{2-} 25.2mM), 4) 20g (2%) of urea, and 5) 3.70g of Calcium chloride (Ca^{2+} 25.2mM) in 1L distilled water. These eight newly identified useful microorganisms for this experiment were visually verified through a microscope to produce mineral crystal of $CaCO_3$ in the same environment used for the previous experiment with *Sporosarcina pasteurii* ATCC11859, i.e. solid Urea-$CaCl_2$ agar culture medium as shown in figure 1. The biomineralization of calcium carbonate in the Urea-$CaCl_2$ culture medium is initiated by chemical reaction of Ca^{2+}, ionized form of calcium chloride in aqueous solution, and bicarbonate (HCO_3^-) from sodium bicarbonate to produce calcium carbonate ($CaCO_3$) and hydrogen ion (H^+) in the solution [$Ca^{2+} + HCO_3^- \rightarrow CaCO_3 + H^+$]. Here, calcium carbonate ($CaCO_3$) and hydrogen ion (H^+) is the product of a pure chemical reaction, and carbonate ion (CO_3^{2-}) mainly remains in the form of bicarbonate (HCO_3^-) ion in the solution before the production of calcite ($CaCO_3$). The second process of making urease by microorganisms involves raising pH around the microorganisms by ammonia (NH_3) generated from hydrolysis of urea and promotes production of calcite ($CaCO_3$) by emitting carbon dioxide (CO_2). Ammonium chloride (NH_4Cl) in the Urea-$CaCl_2$ culture medium is used in the production of calcite by microorganisms by reacting with carbonate (CO_3^{2-}). The

chemical reaction leaves chloride ion (Cl^-), bicarbonate (HCO_3^-), and ammonia (NH_3) in the aqueous solution, and this reaction can be reversed so that a balanced state is reached depending on the pH of the solution [$Cl^- + HCO_3^- + NH_3 \Leftrightarrow NH_4Cl + CO_3^{2-}$]. Here, MICP, the production of calcite by microorganisms, is subjected to metabolism of the microorganisms, and it is a much more complicated process than regular chemical method.

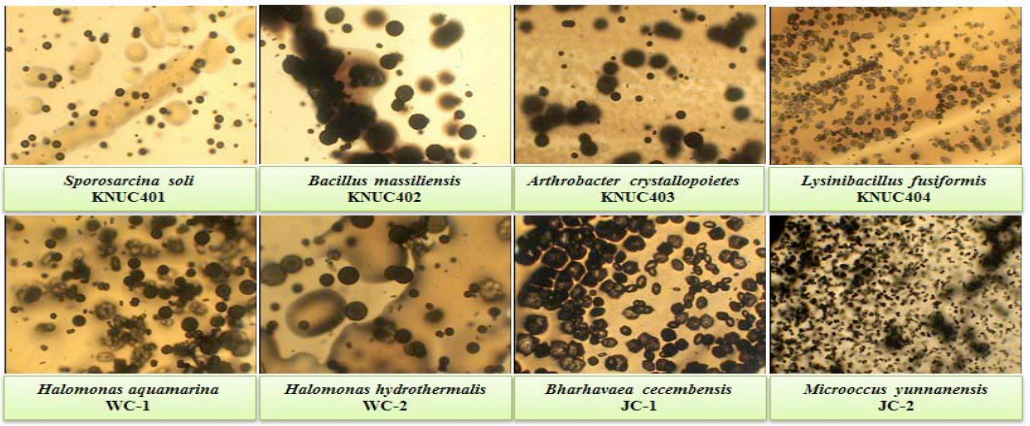


Figure 1. Micro-biologically induced calcite precipitation by effective microorganisms in the Urea-$CaCl_2$ culture medium

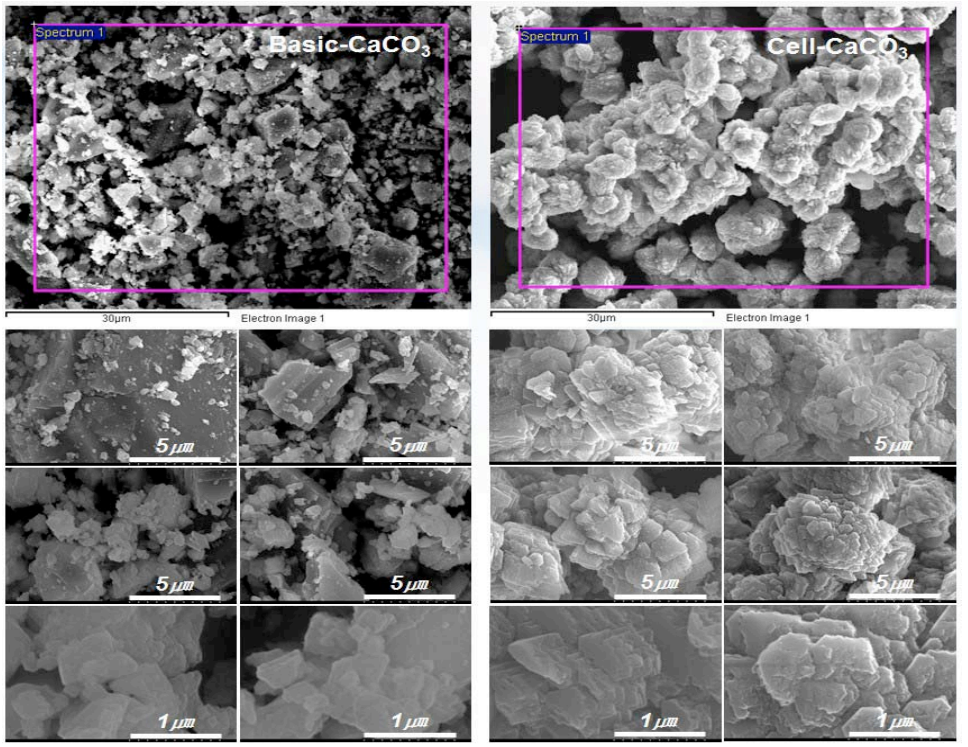

Figure 2. Comparison of scanning electron micrographs of micro-biologically induced calcite precipitation by effective microorganisms

Calcite-forming effective microorganisms in the Urea-$CaCl_2$ culture medium generate ammonia through hydrolysis of urea during the process of making urease to change the surrounding pH to alkaline of pH 9 and emit carbon dioxide to protect themselves from harsh

surrounding environment to form a crystallization of calcium carbonate (Cell-$CaCO_3$), i.e. calcite, on their cell membranes. The crystallized morphology of Cell-$CaCO_3$ formed in solid Urea-$CaCl_2$ liquid culture medium was identified as a particle, of which substituent molecules was combined by metabolism of the microorganisms, in the figure 2. Its magnified image in 1㎛ caliber shows a structure of very minute crystals formed by the microorganisms and combined with themselves.

Calcite crystallinity by effective microorganisms. This experiment is a preliminary investigation of bio-mineral production of calcite by microorganisms and evaluates the calcite crystallinity by metabolism of the microorganisms. The test method involves preparation by 500㎖ of Urea-$CaCl_2$ liquid culture medium for separate inoculation was applied in previous research, and eight newly identified effective microorganisms inhabiting and separated from natural environment, in order to determine the crystallinity of the mineral produced by microorganisms. They were cultured for 7 days in a 180rpm shaking incubator at 30℃. The culture was filtered through 0.45㎛ membrane filter, and the crystal structure of the mineral produced by the microorganisms was analyzed by X-ray diffraction (XRD) as shown in figure 3. All of the mineral crystals precipitated by eight calcite-forming effective microorganisms separated from natural environment were determined to be a mineral morphology of calcium carbonate (calcite) by XRD analysis.

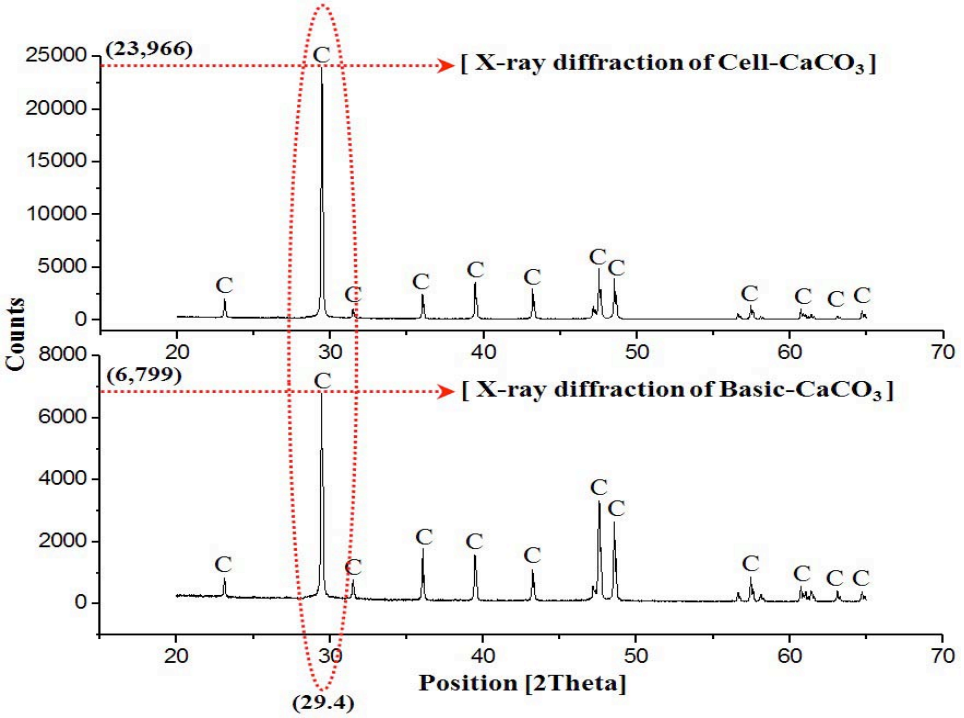

Figure 3. Comparison of X-ray diffraction analysis of micro-biologically induced calcite precipitation by effective microorganisms

The test for the evaluation of calcite crystallinity produced by microbial metabolism in the Urea-$CaCl_2$ liquid culture medium found that urease was produced from urea, and all of the previously discussed *Sporosarcina pasteurii* ATCC11859 and newly identified eight calcite-forming effective microorganisms resources, which produce a mineral morphology of calcite, exhibited the characteristics of forming calcite for the calcium carbonate crystallinity in the Urea-$CaCl_2$ liquid culture medium. Moreover, the crystal structure of the calcite with and without microorganisms differed greatly as shown in figure 3 of XRD analysis.

Thus, all of the eight calcite-forming effective microorganisms separated from natural environment, which produce urease in the Urea-$CaCl_2$ liquid culture medium and contribute to the precipitation of calcite, exhibited the characteristics of making the crystal structure of the calcite crystal structure by their metabolism. The crystal phase, morphology, and particle size of the calcite precipitated by microorganisms in the Urea-$CaCl_2$ liquid culture medium vary by the composition of the culture solution, pH, temperature, supersaturating, agitating speed, added ions, etc. The calcite synthesized in the culture solution mainly exhibited three types of crystal shape (spindle-regular quadrangular pyramid, chain, and rhombohedron). Each oxygen element of carbonate, CO_3, generally combines with two Ca elements of cation layer close to one carbon element.

However, all of the calcium carbonate and the crystal structure of mineral in the Urea-$CaCl_2$ liquid culture medium by eight calcite-forming effective microorganisms exhibited rhombohedral structure with lattice constants of a=4.99Å, c=17.06Å, and Ca and CO_3 ions alternate each other to form a layer of a little distorted shape with CO_3 in one layer combined to six oxygen elements.

EFFECT ON THE COMPRESSIVE STRENGTH OF MORTAR MIXED WITH MICROBIAL BIOCHEMICAL CALCIUM CARBONATE

Experimental methods. This experiment evaluates compressive strength of mortar to apply bio-mineral production of calcite to improvement of mortar performance. The size of the mortar specimen was 50.8×50.8×50.8mm, and the materials used for the preparation of 1 set (18 specimens each) were 1,308g of ordinary Portland cement, 3,924g of river sand passing through 1.2mm sieve, and 720㎖ of mixing solution. Distilled water only and included Basic-$CaCO_3$ and Cell-$CaCO_3$ in the Urea-$CaCl_2$ liquid culture medium were used as mixing solution depending on the experimental setting as shown in table 3. For the application of biomineralization to improvement of mortar performance, $CaCO_3$ solution in the Urea-$CaCl_2$ liquid culture medium of pH 7 was prepared of distilled water. $CaCO_3$ solution in the Urea-$CaCl_2$ liquid culture medium is used in microbial experiment. The biggest reason for using $CaCO_3$ solution in the Urea-$CaCl_2$ liquid culture medium instead of water in the application of microorganisms to mortar mix is because it can restrain or buffer the change of the environment around the microorganisms.

Table 3. Experimental composition of mortar mix

Group	Name	Mixing materials	Mortar mixing water	Specimens total
Control group	**W**	- Cement 1,308g - Sand 3,924g, - Mixing water 720 ㎖ to 18EA(1SET) of mortar specimens	Distilled Water only	**18EA (6SET)**
Experimental group	**BC**		Included Basic-$CaCO_3$ solution in the Urea-$CaCl_2$ liquid culture medium	**18EA (6SET)**
	MC		Included Cell-$CaCO_3$ solution in the Urea-$CaCl_2$ liquid culture medium	**18EA (6SET)**
Total				**54EA (18SET)**

[$CaCO_3$ solution in the Urea-$CaCl_2$ liquid culture medium]

1) 720 ㎖ of distilled water containing NB(nutrient broth) 2.16g and NH_4Cl 7.2g, $NaHCO_3$ 7.2g, $CaCl_2$ 12.6g, Urea($CO(NH_2)_2$) 14.4g
2) Make the calcite-forming microorganisms of step 1 up to 10 ㎖ with distilled water
3) Shaking incubation to adjusting pH concentration to 7.0 with calcite-forming microorganisms

This method is used to obtain the best realistic experimental result for the evaluation of compressive strength of mortar mixed with $CaCO_3$ solution in the Urea-$CaCl_2$ liquid culture medium. The mortar specimens not mixed with $CaCO_3$ were set as control group of pure distilled water and Included $CaCO_3$ solution in the Urea-$CaCl_2$ liquid culture medium. All specimens were prepared in the set of six each (for a total of 18 specimens each) to make it one group. A total of three groups were fabricated to make a total of eighteen each (for a total of 54 specimens each). All mortar specimens mixed with and without microorganisms were demolded after 24 hours and cured at constant temperature of 25℃ and humidity of 50% by a thermo-hydrostat for 28 days. They were divided into groups of two depending on the curing condition (air and water). Compressive strength of the mortar specimens was measured at 3 days, 7 days and 28 days, and the surface of the mortar specimen was kept completely dry for the compressive strength measurement

Experimental results. The mortar specimen mixed with Cell-$CaCO_3$ manifested 23.96% and 18.26% and 9.67% increase in compressive strength at 3 days and 7 days and 28 days, respectively, of air curing.

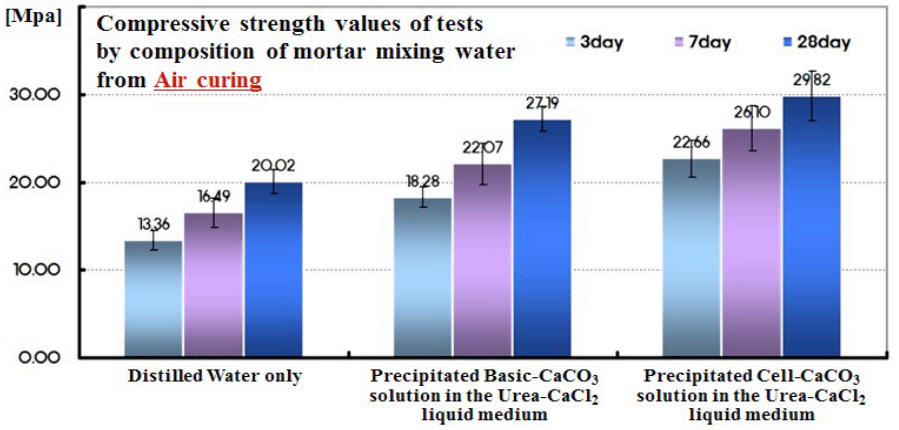

Figure 4. Compressive strength values of tests from air curing by different types of mortar mixing water

Additionally, the mortar specimen mixed with Cell-$CaCO_3$ manifested 43.48% and 13.80% and 8.05% increase in compressive strength at 3 days and 7 days and 28 days, respectively, of water curing.

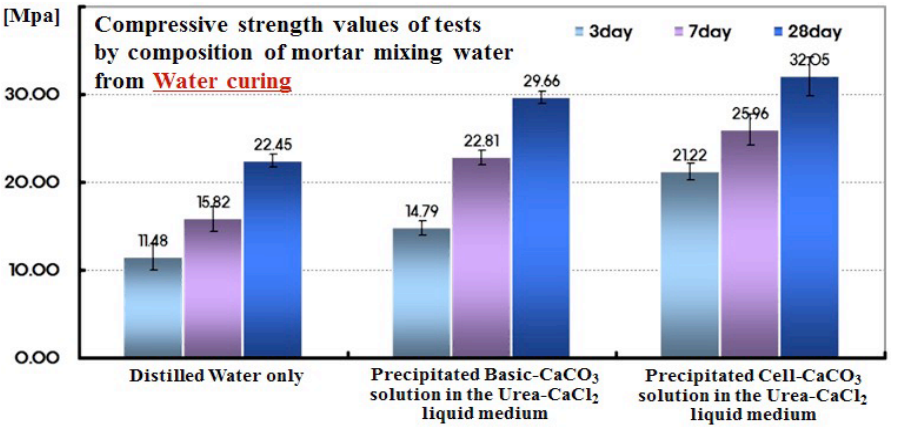

Figure 5. Compressive strength values of tests from water curing by different types of mortar mixing water

Among these specimens, the compressive strength of mortar specimens mixed with Cell-$CaCO_3$ increased by 69.61% and 58.28% and 48.95% at 3days and 7 days and 28 days, respectively, of air curing in comparison to the compressive strength of ordinary mortar specimens. Moreover, the compressive strength of mortar specimens mixed with Cell-$CaCO_3$ increased by 84.84% and 64.10% and 42.76% at 3day and 7 days and 28 days, respectively, of water curing as shown in figure 4 and 5. Of particular notice here is that the compressive strength of mortar specimens increased significantly in comparison to control group specimens not subjected to $CaCO_3$ treatment. This means that the $CaCO_3$ affects the mortar strength to a certain degree and that the overall increase in the compressive strength of mortar is caused by the presence of certain quantity of bio-organic materials.

Additionally, the use of Cell-$CaCO_3$ in the application of microorganisms to mortar in high pH environment showed more effectiveness in the growth of microorganisms in strong alkaline cement environment. Thus, it is deemed that more investigative studies are needed to understand accurately the role of interaction between microorganisms applied to mortar for the improvement of mortar compressive strength after micro-biologically induced calcite precipitation.

MORTAR CRACK REPAIRING BY MICROBIAL BIOCHEMICAL CALCIUM CARBONATE PRECIPITATION

Experimental methods. This experiment examines filling of crack artificially induced in mortar by using micro-biologically induced calcite precipitation (MICP). The specimen was prepared by mixing 30g of cement, 10g of sand, and 15g of distilled water in Petri dish of 5cm to the thickness of 0.5cm. The artificial crack was induced by drying the specimen at 60℃ right after mixing.

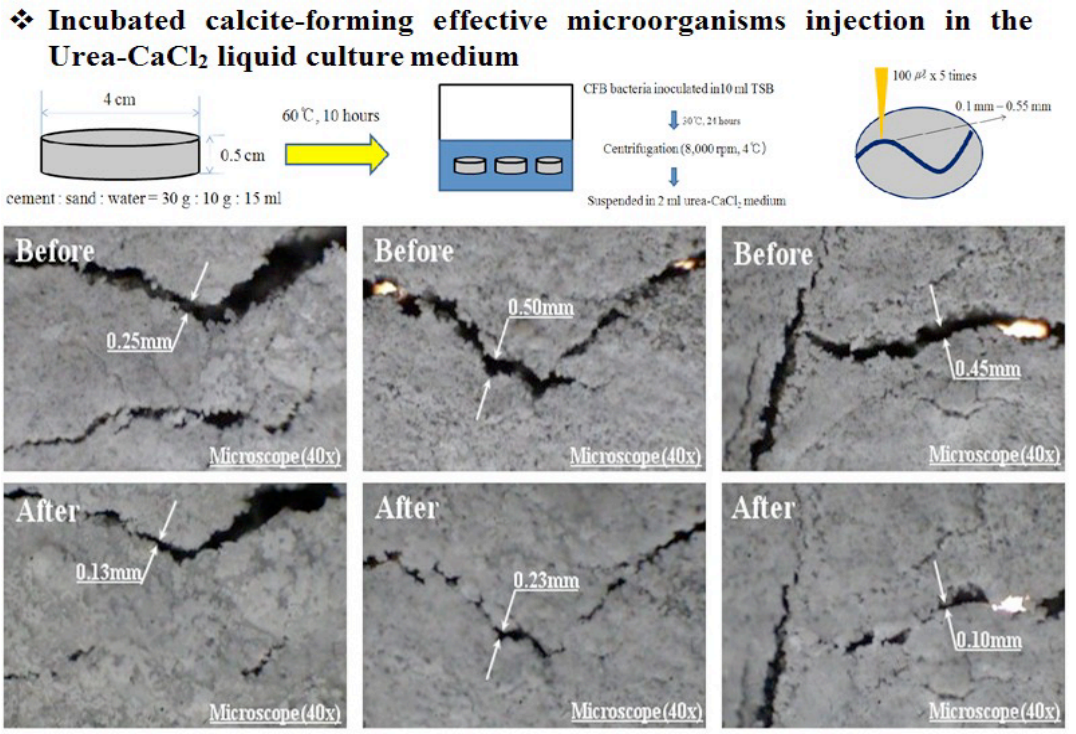

Figure 6. Repairing of crack in mortar from injection of calcite-forming effective microorganisms by micro-biologically induced calcite precipitation

This prepared specimen was cured in water for 7 days to remove unhydrated cement slurry remaining on the surface and in crack of the mortar, and the specimens to be used for the examination of crack filling capability was selected arbitrarily for the crack width between minimum hair thickness of 0.1mm and maximum thickness of 0.7mm. The selected Microorganisms inoculated and cultured in 30㎖ Urea-$CaCl_2$ liquid culture medium of pH 6.0 for calcite precipitation was injected into the crack in mortar. The injection method involved using pipet of 100㎕ capacity to dispense 100㎕ culture solution containing the selected microorganisms to the crack center five times a day for 3 days. This experimental setup was kept at constant temperature of 30℃ and humidity of 60% to examine the crack-filling capacity of the microorganisms by MICP. The evaluation was conducted by inspection with microscope of 40x magnifying power at the same place for 20 days.

Experimental results. The experimental result showed that the filling capacity of microorganisms in the Urea-$CaCl_2$ liquid culture medium and dispensed into artificially induced crack in mortar was somewhat effective in filling the mortar crack by MICP as shown in figure 6. Since crack filling capacity of microorganisms depends on the growth of the microorganisms at right humidity and oxygen supply, it was more effective in smaller and shallower crack site than in wider and deeper crack site. It was also found that the calcite precipitated in mortar crack during the growth of the microorganisms was the major material for the increase in compressive strength of mortar.

CONCLUDING REMARKS

This study investigated the application of Micro-biologically Induced Calcite Precipitation (MICP) to the development of next-generation smart concrete in consideration environmental issues. Calcite is formed by biomineralization of microorganisms in this study. The possibility of using calcite-forming microorganism, *Sporosarcina soli* KNUC401, *Bacillus massiliensis* KNUC402, *Arthrobacter crystallopoietes* KNUC403, *Lysinibacillus fusiformis* KNUC404, *Halomonas aquamarina* WC-1, *Halomonas hydrothermalis* WC-2, *Bharhavaea cecembensis* JC-1, *Micrococcus yunnanensis* JC-2, for the production and precipitation of calcite has been proposed in various studies to improve the quality and performance of concrete. This study applied this property of microorganisms to produce and precipitate calcite for the purpose of improving concrete performance and quality. In addition to previously reported *Sporosarcina pasteurii* ATCC11859, eight additional microorganisms inhabiting natural environment were identified by 16S rDNA sequence analysis. These newly identified microorganisms were found to be effective in production of calcite, and the calcium carbonate crystallinity by MICP was evaluated.

These effective microbial resources were first applied to mortar environment for the aforementioned purpose of improving the performance and quality of concrete. The compressive strength of the mortar specimens was evaluated by curing conditions, and artificial crack was induced in the mortar to examine the filling capacity of the microorganisms by MICP. The effects of the application of these useful microorganisms include not only concrete repairing function but also the development of new environment-friendly materials for improved concrete performance. This research theme will continue to be one of the most important research subjects in the future. Additional merit of this study is the use of microorganisms actually inhabiting in concrete structure and producing calcite in natural environment.

These microorganisms surviving in the natural environment for long times are not only safe environmentally but also effective as a new material of low-loading to environment. This research development of using effective microorganisms is not in the state of practical implementation, and more thorough investigations are needed in the future in order to secure

definite foundation for its use in terms of improving the quality and performance of concrete. Nonetheless, the changeover to new paradigm or idea based on such existing concepts as the theme of this study will certainly prepare the foundation for more advanced research in the future as shown in figure 7.
